Among companion animals, dogs are the most susceptible to poisoning with illicit substances though problems occasionally arise in cats, ferrets, birds, or other animals in the household. Exposure may be through voluntary ingestion or malicious poisoning and other forms of animal abuse (Kisseberth and Trammel, 1990). There are reports of adolescents entertaining themselves by intoxicating dogs, cats, and birds with second-hand marijuana smoke (Schwartz and Riddle, 1985; Buchta, 1988).

Police dogs are at particular risk for ingestion of illegal drugs. They may come into contact with large quantities of the high-purity chemicals in the line of duty (Dumonceaux and Beasley, 1990; Kisseberth and Trammel, 1990). They may ingest whole bags of drugs which must be removed surgically or via endoscopy to prevent rupture and massive exposure (Dumonceaux and Beasley, 1990). Police dogs may be at increased risk for malicious poisonings. Recently news reports document the use of dogs as "drug mules" to move bags of heroin, which were surgically implanted. Deaths in several of these dogs were attributed to secondary infections (McLaughlin, *CNN News* February 2, 2006).

Illegal drug ingestion in small animals presents a diagnostic challenge, and often an ethical challenge, to the clinician. Pet owners may not be aware of what the animal was exposed to, as in the case of animal intoxication by adolescents (Schwartz and Riddle, 1985; Buchta, 1988). Jones in 1978 reported that a dog ingested illicit substances from a neighbor's garbage can. Violence is intrinsic to the drug culture in poor neighborhoods (Johnson and Myron, 1995). It could take the form of malicious poisoning or other forms of animal abuse. Suspected malicious poisoning with illicit drugs has been reported (Bischoff *et al.*, 1998).

The pet owner who *is* aware that the animal ingested an illegal substance may be reluctant to admit it (Godbold *et al.*, 1979; Kisseberth and Trammel, 1990; Dumonceaux, 1995; Welshman, 1986; Frazier, 1998; Janczyk *et al.*, 2004; Volmer, 2005). Sadly, animals may occasionally be euthanized in part due to an incomplete history (Smith, 1988). The owner should be aware that a proper history is

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
ISBN: 978-0-12-370467-2
*Copyright © 2007, Elsevier Inc. All rights reserved.*

required if appropriate treatment is to be administered (Welshman, 1986). Diagnostic laboratories have screens available to detect the presence of many illegal drugs, but these screens take time and may be expensive (Janczyk *et al.*, 2004). Awareness of the animal's home situation, including the neighborhood or the presence or adolescent children in the household may be helpful in determining the potential for exposure to illegal substances. The astute clinician may want to ask if there was a party in the home when the pet became ill (Kisseberth and Trammel, 1990).

A veterinarian may have to balance client confidentiality with legal obligation. The client bringing the pet to a veterinary clinic is aware that it requires medical attention, but the threat of legal action may discourage them from disclosing critical information. It is prudent to be aware of the local laws concerning animal abuse, drug possession, and their responsibility toward reporting illegal activities.

Pet owners who do admit that their pet ingested illegal drugs may not be fully aware of what was ingested, or know only the street name of the drug. Drug dealers may combined drugs or make substitutions and many drugs are very similar in appearance (Kisseberth and Trammel, 1990).

## Illicit drugs and large animals

Horses may be "doped" to improve athletic performance, or to hide soundness or temperament problems. Cocaine has been detected in urine samples from horses at athletic events (Queiroz-Neto *et al.*, 2002; Kollias-Baker *et al.*, 2003). It is expected that such drugs would be given in relatively small doses, but dose miscalculations may occur. Exposure to plants grown for illicit drug manufacture may occur in herbivores. There are reports of lethal marijuana exposure in cattle fed hay and horses on pasture (Cardassis, 1951; Driemeier, 1997).

Anhydrous ammonia is an ingredient in illegal methamphetamine production. It is also used to instill nitrogen into the soil for fertilization and tanks may be stored near animal facilities. Unscrupulous manufacturers of the drug often steal anhydrous ammonia from farm tanks and may fail to close the tank valves before leaving the premises. The *Iowa State Daily* on September 7, 2004 reported 21 cattle dead from anhydrous ammonia intoxication blamed on the methamphetamine trade. The *Huron Daily Tribune* reported more than 30 cattle dead and at least 40 with severe ocular lesions in Michigan after a similar incident.

# THE VETERINARIAN AND THE DRUG ENFORCEMENT ADMINISTRATION (DEA)

Title 21 of the US Code of Federal Regulations establishes the Drug Enforcement Administration (DEA), which classifies drugs into five categories as listed in Table 24.1.

**TABLE 24.1 DEA drug schedules**

| Classification | Description | Examples |
|---|---|---|
| Schedule I | 1. High potential for abuse.<br>2. No accepted medical use in Unites States.<br>3. Lack of accepted safety for use under medical supervision. | Heroin<br>LSD<br>Marijuana<br>MDMA<br>Mescaline<br>Psilocybin |
| Schedule II | 1. High potential for abuse.<br>2. Currently accepted medical uses, may have restrictions.<br>3. Severe physical or psychological dependence potential with abuse. | Amphetamine<br>Cocaine<br>Methamphetamine<br>Morphine<br>Opium<br>Pentobarbital<br>Phencyclidine |
| Schedule III | 1. Less potential for abuse than schedule I or II drugs.<br>2. Currently accepted medical uses.<br>3. Moderate or low potential for physical or psychological dependence with abuse. | Ketamine<br>LSA<br>Thiopental |
| Schedule IV | 1. Low potential for abuse relative to schedule III.<br>2. Currently accepted medical use.<br>3. Limited physical or psychological dependence potential with abuse. | Butorphanol<br>Diazepam<br>Flunitrazepam |
| Schedule V | 1. Low potential for abuse compared to schedule IV.<br>2. Currently accepted medical use.<br>3. Limited potential for physical or psychological dependence with abuse compared to schedule IV. | Low-dose codeine preparations<br>Low-dose opium preparations |

Because some veterinary drugs, such as ketamine and phenobarbital, are coveted on the illegal drug market, failure of the veterinarian to prescribe drugs appropriately may lead to loss of license or risk of imprisonment (Gloyd, 1982). A veterinarian was fined and lost his license in the year 2000 for selling steroids illegally (*AVMA News*, October 15, 2000) and a few years later, an Internet pharmacy was fined more than $40,000 for contracting veterinarians to write prescriptions without examining animals and for dispensing drugs not approved by the Food and Drug Administration (FDA) (*AVMA News*, April 19, 2002).

## MAJOR CNS DEPRESSANTS

Substances that have a depressant effect on the central nervous system (CNS) include marijuana, barbiturates, opioids, and club drugs flunitrazepam (Rohypnol®), and GHB. Ketamine, a sedative-hypnotic, will be discussed with related compound phencyclidine under the category of hallucinogens. Depressants act at a variety of receptor sites within the CNS. Some receptors are named for the drugs that bind to them, including opioid receptors and cannabinoid receptors.

### Marijuana

*Cannabis sativa* has been used for over 4000 years for its psychotropic effects (Di Marzo and De Petrocellis, 2006). Common names include marijuana, hemp or Indian hemp, pot, ganja, dagga, hashish, and kief (Burrows and Tyrl, 2001). The crude product, usually called marijuana in the United States, is produced from dried chopped leaves and the female inflorescences (Kisseberth and Trammel, 1990; Frohne and Pfänder, 2004; Volmer, 2005). Sinsemilla, Spanish for "without seeds," accounts for approximately 85% of the US marijuana production due to the absence of seeds and the very high content of the active ingredient (Anonymous, 2005; Volmer, 2005). Hashish is a dried resin and compressed resin made from the *C. Sativa* often formed into balls, sheets, and cakes and used for smoking. Hashish oil even more concentrated and may be mixed with tobacco or marijuana and smoked.

Cannabinoids are a variety of related compounds found in *C. sativa*. More than 60 are known, the most important being $\Delta^9$-tetrahydrocannabinol (THC). THC is a lipid-soluble monoterpene present in all parts of the plant, with highest levels in the flowers and leaves (Ashton, 2001; Burrows and Tyrl, 2001). Common cultivars grown in 1974 contained approximately 1% THC, whereas recent cultivars of sinsemilla may contain more than 6% THC (Anonymous, 2005). The average marijuana cigarette ("joint" or "reefer") used today contains about 150 mg of THC, up from 10 mg in the 1960s and 1970s (Ashton, 2001). Hashish contains 5% THC on average, and hashish oil averages 15% THC and may be added to a marijuana cigarette to double the potency (Ashton, 2001; Anonymous, 2005).

There are a variety of accepted and controversial medical uses for marijuana and its active compound. Some states allow possession and use of marijuana for medical treatment under certain conditions. Though laws change frequently, states with medical marijuana laws currently include Alaska, California, Colorado, Maine, Maryland, Nevada, Oregon, Rhode Island, Vermont, and Washington. Prescription products include dronabinol (Marinol®) capsules, which contain THC in sesame oil and are currently classified as a schedule I drug by the DEA, and Nabilone (Cesamet®), a synthetic form of THC classified as schedule II. These drugs are used to treat nausea in cancer patients and may be superior to other antiemetics such as metaclopramide. They improve weight gain among patients with AIDS, cancer, or Alzheimer's disease and may have uses in the treatment of glaucoma, multiple sclerosis, chronic pain, epilepsy, and various psychiatric disorders (Di Marzo and De Petrocellis, 2006).

Illegal marijuana is most commonly used in the form of marijuana cigarettes called "joints" or "reefer." Alternately, marijuana may be rolled in a tobacco leaf and called a "blunt" or smoked using a water pipe ("bong") or other type of pipe. Marijuana may be brewed into a tea, or more commonly baked into brownies, cookies, or cakes (Ashton, 2001; Volmer, 2005). Many veterinary exposures come from the ingestion of tainted baked goods. Marijuana cigarettes are sometimes dipped in a mixture of phencyclidine, methanol, and formaldehyde. Ketamine, opium, cocaine, and heroin may be added to a marijuana cigarette or used with marijuana (Volmer, 2005). Street names for marijuana include "grass," "hemp," "Mary Jane" or "MJ," "pot," "puff," and "weed."

Dogs less than 1 year of age are the most likely companion animal to ingest marijuana (Kisseberth and Trammel, 1990; Janczyk *et al.*, 2004). Free marijuana leaves or marijuana cigarettes were recovered from 203 of 213 canine ingestions in a report by Janczyk *et al.* 2004. Baked goods, as noted, may be attractive to dogs (Jones, 1978; Godbold *et al.*, 1979; Janczyk *et al.*, 2004). Fresh plants or the refined resins may also be available to animals (Burrows and Tyrl, 2001). Intentional intoxication of small animals using second-hand smoke has been reported (Schwartz and Riddle, 1985; Buchta, 1988; Frohne and Pfänder, 2004).

Large animals have been exposed through grazing marijuana or ingesting marijuana bales as hay (Cardassis, 1951; Driemeier, 1997). Horses have been bedded on hemp fiber, which may present an impaction risk (Green, 1996; Smith and Papworth, 1996).

#### *Toxicity*

No deaths from marijuana intoxication have been reported in humans (Ashton, 2001). Few veterinary deaths have

been reported. Marijuana has a very wide safety margin in that the lethal dose is approximately 1000 times the effective dose (Volmer, 2005). No deaths were reported in dogs and monkeys ingesting 3–9 g marijuana per kg of body weight (Burrows and Tyrl, 2001). Janczyk *et al.* (2004) documented the survival of a dog that ingested 26.8 g marijuana/kg body weight. The $LD_{50}$ for oral marijuana exposure in rats is 666–1000 mg/kg (Kisseberth and Trammel, 1990; Burrows and Tyrl, 2001). Driemeier (1997) reports that four of five debilitated cattle died after the group ingested 35 kg. Horses and mules have died after ingesting large quantities of fresh marijuana of the species *Cannabis indica* (Cardassis, 1951).

### Toxicokinetics

Absorption of inhaled THC may approach 50% (Burrows and Tyrl, 2001; Janczyk *et al.*, 2004). Gastrointestinal absorption is erratic in humans and dogs. Blood levels obtained by ingestion are 25–30% those obtained by smoking in humans (Ashton, 2001). Onset of clinical signs is delayed from the 6–12 min associated with the respiratory route to 30–60 minutes or longer after ingestion (Janczyk *et al.*, 2004).

Circulating THC is up to 99% protein bound in humans (Volmer, 2005). Plasma levels peak within 2–3 h. This lipid-soluble compound is rapidly distributed to the brain and other tissues. Within the brain, THC accumulates in the neocortical, limbic, sensory, and motor areas. Distribution is blood flow dependent and peak accumulation in adipose tissue occurs in 4–5 days in humans (Ashton, 2001). The plasma half-life of THC is short due to the rapid tissue distribution (Volmer, 2005).

THC is rapidly metabolized by the mixed-function oxidase system of the liver (Burrows and Tyrl, 2001). The significant first-pass effect may account for the lower blood levels associated with ingestion versus inhalation (Ashton, 2001, Janczyk *et al.*, 2004). 11-Hydroxy-$\Delta^9$-THC is the physiologically active major metabolite of THC (Volmer, 2005). There are more than 20 other known metabolites.

Between 65% and 90% of a dose of THC is excreted as the parent compound or conjugated metabolites through the feces and there may be significant enterohepatic cycling (Kisseberth and Trammel, 1990; Ashton, 2001; Volmer, 2005). Ten to twenty-five percent of THC is excreted as the parent compound, metabolites, and conjugates in the urine. Complete elimination in humans is expected to take 30 days.

### Mechanism of action

CB1 and CB2 are the two cannabinoid receptors that have been identified in rats, guinea pigs, dogs, monkeys, pigs, and humans (Ashton, 2001). CB1 receptors are widely distributed in certain areas of the brain: in the cerebral cortex, they regulate cognitive function. The CB1 receptors in the hippocampus and amygdala are important in emotional status. Cerebellar CB1 receptors influence dopaminergic signaling, movement, and postural reflexes. CB1 receptors are also present in the basal ganglia, brain stem, and autonomic nervous system (ANS) where they regulate pain perception and cardiovascular and gastrointestinal function (Ashton, 2001; Di Marzo and De Petrocellis, 2006). CB1 receptors are located within lipid membranes of presynaptic neurons and coupled to G-proteins. They inhibit cAMP and stimulate mitogen-activated protein kinases to modulate control of ion channels, particularly voltage-activated calcium ion channels and potassium channels (Janczyk *et al.*, 2004; Ashton, 2001; Di Marzo and De Petrocellis, 2006). The end result is inhibition of release of neurotransmitters, both excitatory and inhibitory. CB1 receptors also activate phosopholipase C and PI-3-kinase. The endogenous ligands for cannabinoid receptors, known as endocannabinoids, are derived from arachidonic acids and closely related to prostaglandins.

CB2 receptors are absent in the CNS but found in the peripheral nervous system (PNS) and immune system where they play a part in inflammation and pain regulation (Volmer, 2005; Di Marzo and De Petrocellis, 2006). CB2 receptors regulate ceramide biosynthesis (Di Marzo and De Petrocellis, 2006).

### Clinical signs

Clinical signs of marijuana intoxication in dogs are similar to those in humans (Dumonceaux and Beasley, 1990; Dumonceaux, 1995). The signs attributable to the CNS include depression, ataxia, mydriasis, disorientation, behavioral disturbances, hyperesthesia, and recumbence, or less commonly stupor, tremors, or seizures. Ingestion exposures may cause mild gastrointestinal irritation and vomiting. Other signs that have been reported include hypothermia or less commonly hyperthermia, bradycardia, vocalization, and compulsive eating (Burrows and Tyrl, 2001; Janczyk *et al.*, 2004; Volmer, 2005). Severe clinical signs described in a ferret included ataxia with rapid onset of coma, muscle twitching, hypotension, and hypothermia (Smith, 1998). A case of atopic dermatitis was reported in a dog living in a home where *C. Sativa* was grown previously (Evans, 1989).

Onset of clinical signs in cattle began 20 h after ingesting dried plant material and included muscle tremors, hypersalivation, and mydriasis. Animals were reluctant to move and lacked coordination. Four of the five exposed animals died within 3 days and one recovered with no treatment. These animals were already debilitated at the time of exposure (Driemeier, 1997). Rapid onset of clinical signs was described in eight horses and seven mules ingesting fresh plant material, including dyspnea, tremors, hypothermia, hypersalivation, sweating, recumbence, and death within 30 min (Cardassis, 1951).

### *Management*

The prognosis for full recovery in small animals exposed to marijuana is excellent with proper treatment. Janczyk *et al.* (2004) reported 100% survival in 213 cases. Rate of recovery is dependent on dose and route of exposure. Most animals exposed to second-hand smoke recover within a few hours. Dogs who ingest a small dose of plant material may recover within 24 h, but those ingesting large doses may show clinical signs for several days (Kisseberth and Trammel, 1990; Dumonceaux, 1995; Burrows and Tyrl, 2001; Volmer, 2005).

Treatment for THC exposure includes decontamination, supportive, and symptomatic care. Mild intoxication may only require observation (Burrows and Tyrl, 2001). Animals ingesting relatively large quantities may require gastrointestinal decontamination to decrease THC absorption. Emesis may be initiated in the asymptomatic patient within an hour of ingestion (Dumonceaux and Beasley, 1990; Dumonceaux, 1995). Animals showing signs such as CNS depression should not be given emetics, but repeated dosing with activated charcoal and cathartics may prevent absorption and enterohepatic cycling and thus decrease the duration of clinical signs.

Observation of the patient includes monitoring heart rate and rhythm, body temperature, and respiration. Stuperous or comatose dogs may be at risk for severe respiratory suppression or hypothermia and must be treated appropriately. Central nervous stimulation that is severe or dangerous can be treated with diazepam ( Janczyk *et al.*, 2003).

There is inadequate information in the literature concerning treatment of large animals for marijuana ingestion. Treatment was not attempted in the few cases presented. The rapid onset of clinical signs in the horse case did not allowed much time for veterinary intervention. Basic treatment procedures in large animals should parallel those used in small animals. Gastrointestinal decontamination for large ingestions may involve gastric lavage or, in cattle, rumenotomy, and intragastric or intraruminal instillation of activated charcoal and cathartics. Monitoring and symptomatic and supportive care should proceed as above. Veterinary laboratories may test blood or plasma for THC using thin-layer chromatography or gas chromatography/mass spectroscopy (GC/MS). Drug testing kits may be available form pharmacies. There is a poor correlation between blood and plasma THC levels and clinical signs (Ashton, 2001).

### *Pathology*

There is little information on lesions associated with marijuana overdose in small animals because so few have died. Pulmonary edema was noted in a cow (Driemeier, 1997). Plant material was identified in the stomach of the horses as *C. indica.* There was edema and petechiation of the gastric wall and myocardial hemorrhage (Cardassis, 1951).

## Barbiturates

Barbiturates are derived from the non-sedative barbituric acid. Purified barbiturates are bitter tasting white powders. They are frequently available as a sodium salt and are weakly acidic in aqueous solution. Barbiturates have been used in anesthesia and sedation and seizures control, and though still commonly used by veterinarians are becoming more uncommon in human medicine (Kisseberth and Trammel, 1990). There are four classifications of barbiturates based on the duration of their activities. The duration of ultra-short-acting barbiturates generally is approximately 20 min and these drugs are given intravenously (IV) to effect. Examples include thiamylal sodium and thiopental sodium, both schedule III and methohexital sodium which is schedule IV. The duration of short-acting is approximately 3 h and they are given IV for anesthesia. Common examples of short-acting barbiturates are pentobarbital sodium and secobarbital sodium, both schedule II. The duration of an intermediate-acting barbiturate such as butabarbital or amobarbital, both schedule III, is 3–6 h. Effects of long-acting barbiturates may last for 12 h and these drugs have use in sedation and anticonvulsant therapy. Phenobarbital, methylphenobarbital, and barbital sodium are examples of long-acting barbiturates and are schedule IV drugs (Kisseberth and Trammel, 1990; Branson, 2001; Volmer, 2005). Barbiturates are known as downers, reds, Christmas trees, and dolls on the illegal market (Anonymous, 2005).

Barbiturate overdose may be iatrogenic or due to accidental ingestion of prescription or illicit drugs. A common problem in veterinary medicine is exposure to carcasses of animals that were euthanized with barbiturates. This problem has been reported in dogs and in wildlife (Humphreys *et al.*, 1980; Branson, 2001; *AVMA News*, 2002; Volmer, 2005). According to the *AVMA News*, at least 34 eagles have died from pentobarbital poisoning. Veterinarians and animal owners are responsible for proper carcass disposal and may be liable for wildlife poisonings.

### *Toxicity*

The $LD_{50}$ for pentobarbital in the dog is 40–60 mg/kg by the IV route or 85 mg/kg per os (PO) (Branson, 2001). The oral $LD_{50}$ for cats is 125 mg/kg (Volmer, 2005). The margin of safety for barbiturates is low, the therapeutic dose may be 50–70% the $LD_{50}$ (Kisseberth and Trammel, 1990; Branson, 2001).

### *Toxicokinetics*

Gastrointestinal absorption of barbiturates is variable, with rapid absorption of short-acting compounds and slower absorption of long-acting barbiturates (Branson, 2001). Barbiturates are rapidly distributed throughout the body and readily cross the blood–brain barrier. Short-acting

thiobarbiturates are highly lipid soluble and cross rapidly from the circulation to the brain, causing a rapid onset of CNS depression. This is followed by rapid redistribution to tissues with less perfusion and rapid recovery from the clinical effects. Longer-acting barbiturates are less lipophilic, therefore they enter and leave the brain more slowly and thus have a more gradual onset and longer duration (Branson, 2001; Volmer, 2005). Barbiturates cross the placenta and fetal concentrations equilibrate with those of the dam within minute (Branson, 2001).

There is significant variation in barbiturate metabolism and excretion based on the barbituric acid derivative, the species of animal, and the individual. Barbiturates are metabolized by microsomal P450 enzymes in the liver. Barbiturates may interfere with metabolism of other compounds either by binding to the P450 enzymes to block metabolism or, in chronic exposures, through induction of P450 enzymes to increase the rate of metabolism of substances including endogenous steroids (Volmer, 2005). Some barbiturates, in particular the short-acting thiobarbiturates, undergo significant oxidation in the tissue. Phenobarbital is metabolized very rapidly in ruminants and horses, relatively rapidly in dogs, more slowly in humans, and slower still in cats (Branson, 2001).

Barbiturates are excreted as the parent compound and metabolites in the urine. Excretion of some barbiturates is dependent on urine pH and may be increased 5–10 times in alkaline urine through ion trapping (Volmer, 2005). Ion trapping is less effective with short-acting barbiturates which are highly metabolized, highly protein bound, and have high p$K_a$s (Kisseberth and Trammel, 1990; Volmer, 2005). Barbital is excreted very slowly in birds (Branson, 2001).

### *Mechanism of action*

Barbiturates bind to the $\gamma$-aminobutyric acid (GABA) receptor complex and decrease the rate of GABA dissociation (Branson, 2001). These actions increase permeability of the postsynaptic membrane to chloride and lead to membrane hyperpolarization and reduced excitability. GABA receptors are found in motor and sensory area of the cerebral cortex, and may be present in the thalamus where barbiturates may act to control seizures and induce anesthesia. Barbiturates may also act to inhibit glutamate receptors and decrease norepinephrine (NE) release. Actions on the PNS include inhibition of depolarization of acetylcholine-sensitive nerves at postsynaptic junctions and motor end plates (Branson, 2001).

Respiratory depression is caused by suppressing chemoreceptors by barbiturates (Branson, 2001; Volmer, 2005). The effect is more severe in cats, where the reticular formation governs medullary control of respiration. Control of respiratory activity is believed to be more complex in other species (Branson, 2001). Barbiturates may cause hypotension and secondary anuria. Increased heart rate is believed to be governed by arterial pressoreceptors. The effects of barbiturates on levels of sodium, potassium, and calcium in cardiac myocytes affect cardiac contractility. Hypothermic animals are predisposed to ventricular fibrillation with barbiturates. Fibrillation is reported in 100% of hypothermic animals given pentobarbital and 50% of those given thiopental.

### *Clinical signs*

Onset of clinical signs depends on the route of expose, the barbiturate involved, and the presence or absence of food in the stomach. Animals that have ingested short-acting barbiturates may show clinical signs within 10–30 min. If long-acting barbiturates were ingested, the first effects may be not been seen for an hour (Kisseberth and Trammel, 1990). The time to onset of clinical anesthesia is doubled if phenobarbital is given to an animal with food in the stomach versus an empty stomach. Duration of effects is also variable, as alluded to previously, and dependent on the agent involved, species of animal, nutritional status, age, sex, and weight. The duration of a given barbiturate may be prolonged in greyhounds, which have less adipose tissue for the drug to partition (Branson, 2001).

The predominant signs of barbiturate intoxication are profound CNS depression and anesthesia (Humphreys *et al.*, 1980; Kisseberth and Trammel, 1990; Volmer, 2005). Animals may prevent with severe ataxia, weakness, disorientation, and loss of deep tendon reflexes. Hypothermia is common and is associated with cardiac arrhythmia in humans and dogs. The pulse is rapid and weak and severe respiratory depression may lead to cyanosis and death (Branson, 2001; Kisseberth and Trammel, 1990).

Certain preexisting conditions may enhance the effects of barbiturates such as renal failure and uremia, which may decrease plasma protein damage as well as rate of excretion. Barbiturates may accelerate liver damage in individuals with liver disease (Branson, 2001). Barbiturates are also known to cause allergic reactions.

### *Management*

Decontamination for recent exposures, monitoring, and symptomatic and supportive therapy are the basis of treatment for barbiturate overdose. Respiratory function, cardiac function, and body temperature must be monitored closely. Emetics may be given to the *asymptomatic* animal within several hours of ingestion. Intubation and gastric lavage are more appropriate in the animal with CNS depression. Repeated doses of activated charcoal function to decrease the biological half-life of barbiturates. A cathartic such as sorbitol may be added, but magnesium-containing cathartics such as magnesium sulfate (Epsom salt) should be avoided as they may enhance CNS depression. Monitoring and control of normal body temperature is essential to prevent ventricular fibrillation and decrease the duration of the clinical signs (Branson, 2001). Intubation and assisted ventilation may be required in cases of severe

respiratory depression. Fluid therapy may be needed to maintain cardiac and renal function. Alkaline diuresis has been used to increase the rate of excretion of some barbiturates but is ineffective with short-acting barbiturates (Kisseberth and Trammel, 1990; Volmer, 2005). Because tissue partitioning attenuates the effects of barbiturates, it is possible for the patient to relapse as the drug repartitions from the tissues back into plasma (Kisseberth and Trammel, 1990).

The use of certain drugs may be contraindicated in the barbiturate overdose patient. Dextrose, fructose, lactate, pyruvate, and glutamate may increase partitioning of barbiturates into the CNS. Epinephrine and isoproterenol cause reanesthetization after thiopental exposure. Sulfonamides, salicylates, and doxycycline increase bioavailability of barbiturates by displacing them on plasma proteins (Branson, 2001).

Many laboratories can analyze sample such as urine, blood products, or tissues for barbiturates. Common techniques include thin-layer chromatography and GC/MS techniques.

## Opioids

Opium is produced from *Papaver somniferum*, a poppy, and its use was recorded in the Ebers Papyrus, one of the oldest known medical texts dated around 1500 BC. The unripe seed capsule is incised after the petals have fallen. Material that exudes from the capsule is dried, collected, and dried further to produce opium. Powdered opium is 75% inert ingredients, about 10% morphine, the major active alkaloid, 0.5% codeine, and the third major alkaloids is dimethylmorphine or thebaine, which acts as a convulsant (Branson and Gross, 2001). Laudanum is deodorized tincture of opium and paregoric is camphorated tincture of opium.

Morphine sulfate is a schedule II drug commonly used medicinally for pain control and sedation. Oxymorphone is a schedule II morphine derivative approved for use in dogs and cats in the United States. Oxomorphone is approximately 10 times more potent than morphine (Branson and Gross, 2001). Other morphine derivatives include codeine and the more potent hydromorphone, both schedule II drugs. Heroin is a schedule I morphine derivative.

Synthetic opioids include methadone, propoxyphene, meperidine, pentazocine, all schedule III drugs. Butorphanol is schedule IV drug. Oxycodone and hydrocodone are common prescription synthetic opioids classified as schedule II. Fentanyl is formulated into injectable solutions, slow-dissolving sticks for oral transmucosal absorption, and patches that release doses of 25, 50, 75, or 100 μg/dl/h for transdermal absorption. Fentanyl is about 80 times more potent than morphine (Branson and Gross, 2001). Other potent synthetic opioids are alfentayl, sufentanil citrate, and etorphine HCl, which is 10,000 times as potent as morphine and used in wildlife capture. These potent drugs are classified in schedule II.

The morphine derivative heroin is the most abused of the opioids (Dumonceaux, 1995; Anonymous, 2005). A white to dark brown powder, heroin often contains additives such as sugar, starch, powdered milk, quinine, or strychnine. Heroin is usually injected but may be insufflated (snorted) or smoked. Oxycodone, sold as OxyContin®, Percocet® and in a generic form, is commonly used recreationally. Pills are time released but may be crushed and injected, or insufflated. Hydrocodone, sold under various trade names and in a formulations with acetaminophen (Vicodin®), is also commonly sold on the illegal drug market. Fentanyl may be produced in clandestine laboratories, and is used IV. Small animal exposure to opioids may be due to accidental ingestion of pharmaceutical drugs, illegal drugs, or occasionally oral or parenteral dosing with malicious intention.

### *Toxicity*

With such a wide variety of opioids, there is much variation in toxicity. The minimum lethal dose of morphine in dogs is between 110 and 210 mg/kg given parenterally (Kisseberth and Trammel, 1990; Branson, 2001; Volmer, 2005). The minimal lethal dose for subcutaneous (SC) injection of morphine in the cat is 40 mg/kg (Volmer, 2005). Heroine doses of approximately 0.20 mg/kg caused clinical signs in dogs, including sedation and respiratory depression, whereas a dose of 0.58 mg/kg caused increased duration of effects, respiratory difficulty, and aggressive behavior with clinical signs lasting up to 8 h (Garret and Gürkan, 1980). The minimum lethal dose of heroin for the dog is 25 mg/kg given SC (Volmer, 2005). The minimum oral lethal dose of heroin for the cat is 20 mg/kg (Volmer, 2005). Meperidine causes clonic convulsions in cats at a dose of 30 mg/kg (Branson and Gross, 2001).

### *Toxicokinetics*

Opioids are weakly acidic and absorption after oral dosing is predominantly in the small intestine. There is rapid absorption from the subcutis (Branson and Gross, 2001). Distribution is somewhat variable. Heroin is more lipophilic than morphine and more readily crosses the blood–brain barrier (Garrett and Gürkan, 1980). Opioids are also distributed to skeletal muscle, kidney, liver, intestine, lungs, spleen, brain, and placenta (Kisseberth and Trammel, 1990).

Opioids are readily metabolized in the liver and, when ingested, there is a significant first-pass effect (Kisseberth and Trammel, 1990; Volmer, 2005). Phase I metabolism includes hydrolysis, oxidation, and *N*-dealkylation. Approximately 50% of a morphine dose is conjugated to glucuronide in most species. A notable exception is the cat, accounting in part for the increased sensitivity of felines (Kisseberth and Trammel, 1990; Branson and Gross, 2001; Volmer, 2005). The primary conjugate is morphine-3-glucuronide, though the metabolically active morphine-6-glucuronide is also produced. Heroin is metabolized in the

liver and other tissues and is cleared more rapidly than morphine. Deacetylation produces 6-*o*-acetylmorphine and morphine, which appear in the plasma of dogs within minutes (Garrett and Gürkan, 1980).

Opioids are excreted predominantly as metabolites in the urine (Volmer, 2005). Metabolites may be detected horse urine for up to 6 days (Branson and Gross, 2001). There is some biliary excretion and enterohepatic cycling (Garrett and Gürkan, 1980; Branson and Gross, 2001; Volmer, 2005). The biological half-life of morphine in cats is about 3 h (Branson and Gross, 2001). The initial plasma half-life of heroin in dogs is 8 min, but the terminal half-life is 80 min due to repartitioning from the tissues (Garrett and Gürkan, 1980).

### *Mechanism of action*

Opioids may act as agonists or antagonists. Morphine and related drugs act as agonists, particularly at $\mu$ receptors. Naloxone is an antagonist with a high affinity for the $\mu$ receptors and a low affinity for $\delta$ receptors (Volmer, 2005). An opioid is classified as a partial agonist if it acts as an agonist at one receptor but an antagonist at another. Major opioid receptors are designated $\mu$, $\delta$, and $\kappa$ and are believed to be stimulated by endogenous endorphins. The $\mu$ receptors are activated by endogenous enkephalins. These receptors may be further differentiated into $\mu_1$ and $\mu_2$. Activation of the $\mu_1$ receptor induces supraspinal analgesia and $\mu_2$ receptor activation causes spinal analgesia, suppression of respiration, and inhibition of gastrointestinal motility. The $\delta$ receptors are more selective for enkephalins than the $\mu$ opioid receptors and are involved in spinal analgesia. Activation of $\kappa$ receptors produces spinal and supraspinal analgesia, sedation, and dysphoria (Branson and Gross, 2001). The $\sigma$ receptor, previously classified as an opioid receptor, does not appear to mediate analgesia.

Opioid receptors are found in the CNS, ANS, gastrointestinal tract, heart, kidney, pancreas, adrenal glands, vas deferens, and on the surface of lymphocytes and adipocyte (Volmer, 2005). Opioid receptors in the CNS are concentrated in the amygdala and frontal cortex in the dog, monkey, and human where stimulation is associated with CNS depression. Activation in the cat, swine, goat, sheep, horse, or ox may alter dopaminergic or noradrenergic function, leading to excitation. Activation of opioid centers in the chemoreceptor trigger zone in the fourth ventricle of the brain produces emesis. Opioid receptors are present in the brain stem, including the cough centers where they suppress the cough reflex, and the respiratory centers, though initial increases in respiration are followed by respiratory suppression due to generalized CNS depression. Stimulation of gastrointestinal opioid receptors decreased motility, leading eventually to delayed passage of ingesta, increased water absorption, and constipation.

### *Clinical signs*

The clinical effects of opioids are dependent on age (neonates may have an incomplete blood–brain barrier), species, and the compound involved. Clinical signs in dogs are similar to those described in humans. Early clinical signs in dogs exposed to narcotics may include transient excitation and rapid respiration, drowsiness and ataxia, decreased pain perception, hypersalivation, vomiting, defecation, and urination. Animals may progress to stupor or coma with hypothermia, hypotension, respiratory depression, and death (Kisseberth and Trammel, 1990; Dumonceaux, 1995; Branson and Gross, 2001; Volmer, 2005). Other signs may include decreased urination and constipation. Signs were similar in dogs given low doses of heroin and included early aggressive behavior, brief unconsciousness, and a period of weakness, hypersalivation, and respiratory difficulty that lasted up to 8 h (Garret and Gürkan, 1980). Propyoxyphine may induce tremors and convulsions in dogs.

Cats may present with excitation, aggression, insomnia, and hyperthermia as well as increased pain threshold. Cats do not vomit at doses less than 700 times the emetic dose for dogs. Horses, ruminants, and swine show similar CNS stimulation. Clinical signs in rabbits depend on the drug used, e.g. morphine induces hypothermia whereas apomorphine induces hypothermia (Branson and Gross, 2001).

### *Management*

The basis of treatment for opioid exposure is early decontamination, symptomatic and supportive care, and the judicious use of an opioid antagonist. Animals presenting immediately after ingestion of narcotics should be given emetics to induce vomiting. If large doses were ingested and contraindications against emetic use are present, enterogastric lavage on the anesthetized and intubated animal may be performed to evacuate the stomach and instill activated charcoal and cathartics. Decontamination may be effective for several hours after ingestion due to decreased gastrointestinal motility (Dumonceaux and Beasley, 1990; Kisseberth and Trammel, 1990; Dumonceaux, 1995; Volmer, 2005).

Animals must be monitored closely for respiratory dysfunction, the most common cause of death in opioid overdoses. Assisted ventilation may be necessary. Body temperature should be monitored and maintained. Seizures can be treated with diazepam. The opioid antagonist Naloxone may be used to treat severe CNS depression or respiratory depression. Naloxone is given parenterally at a dose of 0.01–0.02 mg/kg and repeated as necessary. This drug has a very short half-life. Patients that fail to respond to a 10 mg dose of Naloxone are unlikely to respond to a higher dose.

## OTHER CNS DEPRESSANTS

Other drugs may have depressant activities on the CNS. Two commonly used "club drugs" are discussed below: flunitrazepam and GHB.

### Flunitrazepam

Flunitrazepam is not sold in the United States but available in more than 60 countries, including many in Europe and Latin America, as Rohypnol®, Narcozep®, and other trade names, as a sedative. Rohypnol® has gained notoriety as the "date rape drug" and is sold as tablets imprinted "Roche 1" and "Roche 2" designating their manufacturer and mg dosage. Tablets may be crushed and insufflated, or dissolved in a drink intended for an unsuspecting victim (Smith, 2002; Anonymous, 2005). Blue coloring has been added to these pills to reduce the potential for this use (Smith *et al.*, 1996; Rimsza and Moses, 2005). Street names include "roofies" or "rophies," "Roche" or "la rocha," "Mexican valium," "forget me pills," "Rope," and "R2." Injectable forms of flunitrazepam are also available (Anonymous, 2005).

The estimated human lethal dose of flunitrazepam is 415 mg/kg, though death has been reported in an elderly patient given 28 mg PO. This drug is 85% bioavailable after ingestion with peak plasma concentrations within an hour or two. Flunitrazepam is metabolized to two active products, which are excreted with the parent compound in human urine for a few days (Smith *et al.*, 2002; Gable, 2004; Anonymous, 2005). Clinical signs of sedation and amnesia occur within 20 min of oral dosing and may persist for 12 h. Other signs include muscle relaxation, visual disturbances, and confusion. Deaths attributed to this drug are rare (Smith *et al.*, 2002; Anonymous, 2005; Rimsza and Moses, 2005).

Animals that have ingested flunitrazepam should be monitored closely for respiratory and CNS depression and changes in heart rate and body temperature. If ingestion was recent and there is no evidence of clinical signs, emetics can be given. Activated charcoal and cathartics may be given to minimize absorption. Gastric lavage may be performed on the anesthetized and intubated patient who has ingested a large dose. Human overdoses have been treated with the flunitrazepam antagonist flumazenil, but repeated dosing may be needed due to the short half-life of this drug. Flumazenil treatment has been reported to cause seizures in some people (Smith *et al.*, 2002). Analyses are available at some laboratories for flunitrazepam, but doses are often quite low and urine must be collected soon after ingestion.

## GHB

Another popular "club drug" that has been associated with date rape is GHB. This drug is a derivative of GABA and is present in the body under normal conditions. Synthetic GHB is used medicinally in Europe and produced in clandestine laboratories. It was sold as a nutritional supplement for body builders at one time, and is currently used to treat narcolepsy. Industrial solvents $\gamma$-butyrolactone (GBL) and 1,4-butanediol (BD) are metabolized to GHB. BD is available in printer ink cartridges and has been sold as a supplement at health food stores. GHB is most commonly sold as a clear liquid in small vials and added to bottled water (Smith *et al.*, 2002; Rimsza and Moses, 2005). Street names include "Liquid X" or "liquid ecstasy," "soap," or "salty water" due to the flavor of the product, "easy lay," "Georgia homeboy," "grievous bodily harm," "G," "goop," "gib," or "scoop."

GHB receptors are present in the hippocampus, cortex, and other areas of the brain (McDonough *et al.*, 2004). GHB is involved in regulation of sleep cycles, body temperature, memory, glucose metabolism, and dopamine levels (Smith *et al.*, 2002). GHB may also be converted back to GABA (McDonough *et al.*, 2004). Human death has been reported at a GHB dose of 5.4 g taken orally, but other patients have survived doses of 29 g. The $LD_{50}$ for rodents and rabbits is approximately 2 g/kg. GHB is rapidly absorbed from the gastrointestinal tract. This highly lipophilic drug readily crosses the blood–brain barrier. GHB is rapidly metabolized to carbon dioxide though 2–4% of a given dose may be excreted in the urine (Smith *et al.*, 2002; Gable, 2004). Half-life is dose dependent.

Clinical signs attributed to GHB usually occur within half an hour of ingestion and include euphoria, reduced anxiety, and drowsiness. CNS depression may progress to loss of motor control, unconsciousness, and respiratory depression (Smith *et al.*, 2002; McDonough *et al.*, 2004; Rimsza and Moses, 2005). Seizures, bradycardia, and hypothermia are noted in nearly a third of overdose patients (Smith *et al.*, 2002).

Treatment consists of decontamination with gastric lavage for large ingestion or activated charcoal, *emetics are contraindicated* due to the rapid onset of this drug, and close monitoring of the respiratory, cardiovascular, CNS, and body temperature, and supportive care as needed. Seizures have been treated with benzodiazepines. Patients who appear stable should be monitored for at least 8 h. GHB is difficult to analyze for as it is rapidly metabolized and normally present in the body (Smith *et al.*, 2002; Gable, 2004).

## STIMULANTS

The major illicit drugs classified as stimulants are cocaine and amphetamines. While the cocaine is a plant alkaloid, amphetamines are a large group of compounds, including prescription drugs such as methylphenidate, sold as Ritalin®, methamphetamine, which is frequently produced in clandestine laboratories. Stimulants in general

act on the ANS, usually on adrenergic receptors. Popular "club drug" MDMA, or ecstasy, has significant action on serotonin receptors as well.

Various legally available compounds act as stimulants through various mechanisms. These include nicotine, caffeine, and related compounds, discussed elsewhere in the text. Areca alkaloids, described below, are commonly used as stimulants across much of Asia and are available in some parts of the Unites States and Europe.

## MAJOR STIMULANTS

### Cocaine

Cocaine is the natural alkaloid of the shrubs *Erythroxylon coca* and *Erythroxylon monogynum*, originally from the Andes Mountains in South America but currently grown in Mexico, the West Indies, and Indonesia as well (Queiroz-Neto *et al.*, 2002; Anonymous, 2005; Volmer, 2005). Traditionally, *E. coca* leaves are brewed into tea by those native to the Andes Mountains, who may still share this delightful beverage with unsuspecting tourists to counter the effects of the high altitude. Cocaine is a schedule II drug used for topical anesthesia and vasoconstriction of mucous membranes (Kisseberth and Trammel, 1990; Volmer, 2005). It may be second only to marijuana in illegal consumption in the Unites States. According to surveys in the 1980s, approximately 15% of the US population had tried cocaine (Kabas *et al.*, 1990).

Cocaine is sold in the powdered white salt form, cocaine HCl, ranging in purity from 12% to more than 60%. It may be diluted with inert ingredients such as lactose, inositol, mannitol, cornstarch, or sucrose, or with active compounds including procaine, lidocaine, tetracaine, caffeine, amphetamine, or quinine (Kisseberth and Trammel, 1990). The water-soluble salt may be injected, ingested, or insufflated (Anonymous, 2005; Rimsza and Moses, 2005). Common street names for cocaine HCl include "bernies," "blow," "C" or "big c," "coke," "girl" or "white girl," "gold dust" or "star dust," "her," "lady" or "white lady," "nose candy," "snow," or "toot."

Cocaine HCl is converted to the free alkaloid by dissolving it in a basic solution which is boiled to precipitate the alkaloid. The dry precipitate is broken into "rocks" which are 75–90% pure, but may be diluted with inert ingredients or active compounds such as procaine, lidocaine, amphetamines, heroin, caffeine, phencyclidine, ergot alkaloids, or strychnine. The free base readily vaporizes with heat and the smoke is inhaled, though it may be taken orally. This form of cocaine is termed "crack" because of the sound produced when it is heated, "bedrock," "beamers," "BJ's," "bolo," "crank," "crystal," "flake," "ice," "jelly beans," "rock," "rooster," "space," "tornado" or "24/7."

Exposure to illicit cocaine is most likely to effect dogs, particularly police dogs, but athletic horses may be dosed with cocaine to improve performance (Dumonceaux and Beasley, 1990; Kisseberth and Trammel, 1990; Frazier *et al.*, 1998; Queiroz-Neto *et al.*, 2002; Kollias-Baker *et al.*, 2003; Volmer, 2005).

#### *Toxicity*

The $LD_{50}$ for cocaine in dogs is 3 mg/kg IV, and 20 mg/kg IV is the $LD_{99}$ (Kisseberth and Trammel, 1990; Volmer, 2005). Dogs can tolerate 2–4 times the above doses given PO (Kisseberth and Trammel, 1990). The minimum lethal dose in cats is approximately 7.5 mg/kg IV or 16 mg/kg SC (Volmer, 2005). Horses given 50 mg of cocaine IV showed no clinical signs, but performance was enhanced at 200 mg (Kollias-Baker *et al.*, 2003).

#### *Toxicokinetics*

Cocaine is highly lipophilic and readily absorbed from all mucosal surfaces, including those of the nose, oral cavity, gastrointestinal tract, and alveoli. Approximately 20% of an ingested dose is absorbed (Kisseberth and Trammel, 1990). Peak plasma concentrations appear between 15 min and 2 h after ingestion and cocaine readily crosses the blood–brain barrier (Volmer, 2005). The neurological effects of cocaine and crack last for 15–20 min after insufflating or 5–10 min after smoking recreational doses. Cocaine undergoes hydrolysis by plasma esterases to water-soluble metabolites benzoylecgonine, ecgonine methyl ester, and others (Queiroz-Neto *et al.*, 2002). Hepatic esterases and demethylating enzymes play a role in cocaine metabolism.

Up to 20% of a dose of cocaine may be excreted unchanged in the urine (Volmer, 2005). Benzoylecgonine and ecgonine methyl ester are the primary metabolites excreted in the urine of most mammals in both conjugated and unconjugated forms (Kollias-Baker *et al.*, 2003). Other metabolites include norcocaine, benzolynorcgonine, norecgonine, and ecgonine. Kollias-Baker *et al.* (2003) found cocaine in the urine for up to 24 h when horses are dosed sublingually with 2.5 mg. Larger doses are detectable for 2–3 days.

#### *Mechanism of action*

Cocaine increases release of catecholamines and blocks reuptake of NE, serotonin, and dopamine, leading to increased neurotransmitter concentrations at synaptic junctions (Kisseberth and Trammel, 1990; Volmer, 2005; Queiroz-Neto *et al.*, 2002). NE regulates thalamic effects on appetite, body temperature, and sleep (Queiroz-Neto *et al.*, 2002). Cardiac effects are often associated with IV dosing (Kabas *et al.*, 1990; Kisseberth and Trammel, 1990). Cocaine has direct effects on the myocardium, where it acts by blocking sodium ion channels, thus causing conduction disturbances and prolonged R waves. Cocaine increases calcium concentrations within cardiac myocytes and may promote depolarization during the diastolic interval and ventricular fibrillation. Cocaine slows conductance at the

bundle of His. Oxygen demand is increased within the myocardium and there may be constriction of the coronary vasculature, which may cause infarction.

### *Clinical signs*

Clinical signs of cocaine toxicosis are associated with CNS stimulation, sometimes followed by depression. Signs in dogs include hyperactivity, hyperesthesia, tremors and seizures, and death. Other signs are mydriasis, hypersalivation, and vomiting. Cardiac changes are consistently reported. Dogs dosed IV with cocaine had increased heart rate, cardiac output, and mean arterial pressure (Catravas and Waters, 1981). Death was attributed to hyperthermia, which could be secondary to increased muscular activity and peripheral vasoconstriction. Frazier *et al.* (1998) reported a body temperature of 105 °F (40.56°C) in one dog. Respiratory and cardiac arrest, the latter attributed to coronary vasospasm, have also been implicated as the cause of death. Lactic acidosis, hypoglycemia or hyperglycemia, and elevated creatinine phosphokinase have been reported (Kisseberth and Trammel, 1990; Volmer, 2005).

Queiroz-Neto *et al.* (2002) reported mild clinical signs in horses given low IV doses of cocaine, such as increased alertness, irritability, muscle tremors, vocalization, and stereotypical behaviors like head bobbing and pawing at the ground. Cribbing was reported in at higher doses. Most horses defecated within 10 min of dosing and recovered within 20 min.

Lesions reported in dogs include subendocardial and epicardial hemorrhage, degeneration of cardiac myofibers, coronary vasoconstriction, pericardial effusion, and pulmonary hemorrhage (Kisseberth and Trammel, 1990; Frazier *et al.*, 1998).

### *Management*

Early decontamination of dogs suspected of recently ingesting cocaine has been recommended, but may have limited effect as the drug is absorbed extremely rapidly. Emesis may initiate seizures. Gastric lavage in the patient who has ingested a large quantity of cocaine may be safer. Police dogs that have ingested bags of cocaine require cautious endoscopic or surgical retrieval to prevent rupture or obstruction. Surgically implanted bags must be removed with equal caution and secondary infection treated as necessary. Symptomatic and supportive care includes maintaining body temperature, acid–base, and electrolyte status, and monitoring cardiac and respiratory function. Body temperature may be maintained by use of a cool environment, cool fluids, cool bath, wet towels, fans, or cool water enemas (Dumonceaux, 1995; Volmer, 2005). Decreased stress is recommended to prevent hyperthermia. Physical restraint has been associated with death in humans (Pestaner and Southall, 2003).

Seizure control may also prevent hyperthermia. Diazepam has been used to decrease seizure activity, however two of six animals that had an apparent favorable response to diazepam died within 72 h (Catravas *et al.*, 1977). Barbiturates have been recommended to treat refractory seizures (Volmer, 2005). Chlorpromazine given before cocaine dosing has been effective experimentally to reduce severity of seizures, maintain blood pH, maintain body temperature, decrease heart rate and blood pressure, and prevent arrhythmias (Catravas and Waters, 1981). However, phenothiazine tranquilizers are known to lower the seizure threshold (Dumonceaux and Beasley, 1990; Volmer, 2005).

Animals may require respiratory support, including intubation and mechanical ventilation, for severe or prolonged respiratory depression. Cardiac signs such as tachycardia may be short lived. Treatment of life-threatening cardiac arrhythmia with $\beta$-blockers such as propranolol has been recommended. Pretreatment of dogs with propranolol before cocaine injection did not increase survival (Catravas and Waters, 1981).

Urine and plasma are routinely tested for cocaine at many laboratories. Thin-layer chromatography and immunoassays may be used with confirmation by GC/MS.

## Amphetamines

The term "amphetamine" refers specifically to $\alpha$-methylphenylethylamine, a schedule II drug, but the term is often used to describe various derivatives. The term "amphetamines" (plural) will be used here to describe a group of related compounds unless specified otherwise. Common amphetamines include schedule II drug methamphetamine and schedule I drugs 2,5-dimethoxy-4-methylamphetamine ("DOM," "STP"), 2,5-dimethoxy-4-bromoamphetamine ("DOB"), and methylphenidate, 4-methylaminorex (4MA), and 3,4-methylenedioxy-*N*-ethylamphetamine (MDEA). The "designer drug" MDMA ("ecstasy") has some unique characteristics which are discussed separately.

Historically, amphetamines were used by veterinarians to the stimulation of medullary respiratory centers in order to increase respiratory rate and depth in animals (Adams, 2001). These drugs are not currently used in veterinary medicine. Physicians have used amphetamines to control appetite in obese patients, to treat narcolepsy, depression, alcoholism, and, counter intuitively, to control hyperkinetic behavior in children. Most are sold as tablets or capsules, which may be sustained release.

Amphetamines on the illegal market are sold as "bennies," "dex" or "dexies", "speed," or "uppers." Prescription products may find their way to the illegal market, but many "designer" amphetamines such as methamphetamine are created in clandestine laboratories. Crystal methamphetamine, called "ice" or "glass," may be smoked, powdered methamphetamine, termed "crank," or "meth," may be dosed IV, orally, or insufflated. "Yaba" may also contain caffeine. Other "designer" amphetamines include 4MA, sold as "euphoria," "U4EUH," or occasionally "ice," MDEA,

sold as "Eve," and MDMA. Drug dealers may combine amphetamine with inert or other active ingredients, or may substitute other drugs such as heroin, cocaine, or phenylethylamine. Accidental ingestion of prescription amphetamines is the most likely exposure risk for companion animals (Volmer, 2005). Potential exists for exposure of companion animals to illegal drugs. Illegal doping may occur in horses.

### *Toxicity*

Catravas *et al.* (1977) found that 10 mg/kg IV amphetamine killed dogs within 3 h. $LD_{50}$s for orally administered amphetamine sulfate and methamphetamine in the dog are 20–27 and 9–100 mg/kg, respectively (Diniz *et al.*, 2003; Volmer, 2005).

### *Toxicokinetics*

Absorption of amphetamines through the gastrointestinal system is usually rapid, though it is slower with sustained release products. Methamphetamine absorption is more rapid by insufflation with onset of clinical in 2–5 min, whereas the onset after PO dosing is 15–20 min (Anonymous, 2005). Peak plasma concentrations of amphetamine occur 1–3 h after ingestion, unless a sustained release product was ingested. Amphetamines are highly lipid soluble and readily cross the blood–brain barrier (Volmer, 2005). Concentrations in the cerebral spinal fluid may be 80% those found in the plasma (Kisseberth and Trammel, 1990). Methamphetamine has increased partitioning to the CNS compared to other amphetamines (Rimsza and Moses, 2005). Amphetamine is also distributed to the kidneys, liver, and lungs, with negligible storage in the adipose tissue (Baggot and Davis, 1972).

There is significant hepatic metabolism of amphetamines. The two major pathways are hydroxylation and deamination. Deaminated products may be oxidized and conjugated to glycine (Baggot, 1972). Active metabolites may be produced (Volmer, 2005). Amphetamine and its metabolites are excreted primarily in the urine and minimally in the bile. About 8% of an amphetamine sulfate dose is excreted unchanged in the urine in swine and 30% in dogs. Rate of excretion is significantly increased as urine pH declines. Amphetamine is almost completely eliminated within about 6 h in dogs with an average urinary pH of 7.5, and in 3⅓ hours if the urinary pH averages around 6.0 (Volmer, 2005).

### *Mechanism of action*

Questions remain concerning the mechanism of action of amphetamines. Sympathetic central and peripheral effects are due to direct actions on $\alpha$ and $\beta$ adrenergic receptors, increased release of catecholamines, particularly NE, inhibition of monoamine oxidase (MAO), and inhibition of catecholamine reuptake (Adams, 2001; Diniz *et al.*, 2003). Amphetamines may promote serotonin and dopamine release, and act directly on dopamine receptors (Volmer, 2005).

### *Clinical signs*

Common clinical signs of amphetamine toxicosis in animals include hyperactivity, restlessness, tremors, and seizures, though occasionally ataxia and depression. Hyperthermia may be secondary to seizures and peripheral vasoconstriction. Tachycardia and ventricular premature contractions, hypertension, or occasionally hypotension can also occur. Other signs include mydriasis, hypersalivation, and vocalization. The cause of death in amphetamine overdosed dogs could be disseminated intravascular coagulation secondary to hyperthermia and respiratory failure (Davis *et al.*, 1978; Diniz *et al.*, 2003). Cerebrovascular hemorrhages due to hypertension, hypoglycemia, lactic acidosis, and cardiac failure have all been implicated as the cause of death after amphetamine overdose (Catravas *et al.*, 1977). Liver failure, possibly secondary to hyperthermia inducing heat-shock proteins and hypoxia due to reduced hepatic blood flow, has been described in humans (Diniz *et al.*, 2003).

Serum chemistry abnormalities in addition to lactic acidosis and hypoglycemia that have been reported with amphetamine overdose include hyperkalemia, hyperphosphatemia, and elevated liver enzymes such as alanine transaminase, alkaline phosphatase, and aspartate transaminase (Catravas *et al.*, 1977; Diniz *et al.*, 2003). Rhabdomyolysis may be evident based on increased creatine kinase, myoglobinuria, and evidence of renal failure. Lesions reported in experimental dogs dosed with amphetamines include subendocardial and epicardial hemorrhage and myocardial necrosis.

Low doses of amphetamine given to horses caused increases in heart rate during rest and exercise, increased blood pressure, second-degree block at the atrioventricular (AV) node, and premature ventricular contractions (Smetzer *et al.*, 1972).

### *Management*

The prognosis for animals that have ingested amphetamines depends on the dose, time between exposure and presentation, and severity of clinical signs. Gastrointestinal decontamination should be initiated in animals that present within 2 h of ingestion (Dumonceaux, 1995; Kisseberth and Trammel, 1990). Rapid onset of clinical signs may preclude the use of emetics. Gastric lavage of the sedated animal may be warranted if large doses are ingested. Activated charcoal and a cathartic may help prevent absorption. Repeat dosing may be necessary for sustained release products.

Animals should be monitored closely for neurological signs, hyperthermia, cardiac arrhythmias, or respiratory insufficiency. Baseline serum chemistries should be taken and animals monitored for hypoglycemia, electrolyte abnormalities, lactic acidosis, myoglobinuria, and liver or kidney damage, etc.

Minimal external stimulation may prevent seizure activity. Diazepam may paradoxically exacerbate the clinical signs of many amphetamines (a possible exception is MDMA, see below) and is thus contraindicated (Volmer, 2005). Chlorpromazine given at 10–18 mg/kg IV was determined by Catravas *et al.* (1977) to prevent death in experimental dogs dosed with amphetamine when given early in the progression of clinical signs. Treatment decreased hyperthermia, convulsions, hypertension, and heart rate. Normal respiration was maintained. However, chlorpromazine may lower the seizure threshold. Haloperidol at 1 mg/kg IV also decreased the clinical effects of amphetamines on body temperature, blood pressure, heart rate, respiration, and decrease convulsions in experimental dogs (Catravas *et al.*, 1977). Short-acting barbiturates have also been recommended for treatment of amphetamine-induced seizures (Dumonceaux and Beasley, 1990).

Cool IV fluids, ice packs, fans, cool water baths or cool moist towels, or gastric lavage with cool water may be used to treat hypothermia. The shivering response may increase body temperature (Smith *et al.*, 2002).

Cardiac arrhythmias in the amphetamine overdose patient may resolve with treatment of central nervous signs (Smith *et al.*, 2002; Diniz *et al.*, 2003). Propranolol has been found to decrease the heart rate and blood pressure in experimental dogs given amphetamines, but did not improve survival (Catravas *et al.*, 1977). The use of $\beta$-blockers may lead to $\alpha$-receptor-mediated vasoconstriction and spasms of the coronary artery (Diniz *et al.*, 2003). Lidocaine, procainamide, or amiodarone have been recommended to treat ventricular arrhythmias.

Urinary acidification with ascorbic acid or ammonium chloride may increase amphetamine excretion but should not be attempted in the presence of acidosis or rhabdomyolysis, or if acid–base status cannot be monitored. Treatment of acidosis and rhabdomyolysis involves fluid diuresis and alkalinization. Respiratory support may be required (Liechti *et al.*, 2005).

Urine or plasma samples may be tested for amphetamines at many diagnostic laboratories. Thin-layer chromatography is commonly used, and immunological assays are available for some compounds (Smith *et al.*, 2002). GC/MS may be used for confirmation.

## OTHER STIMULANTS

MDMA, sold as "ecstasy," is a common illegal club drug and will be discussed in some detail. Many legally available compounds are commonly used as stimulants. These include nicotine from tobacco products, the methylxanthines caffeine, theobromine, and theophyllin found in common food and drink products, and alkaloids of the areca nut, present in betel quid. The latter compounds will be addressed briefly.

## MDMA

MDMA, more frequently known as "ecstasy," is a schedule I drug. MDMA was used as an appetite suppressant and in psychotherapy (Smith *et al.*, 2002). The drug has shown some promise in the treatment of Parkinson's disease and post-traumatic stress disorder, but there are no accepted medical uses at this time (Morton, 2005). Currently, MDMA is one of the most popular club drugs in the Unites States and use increased 70% worldwide between 1995 and 2001 (Anonymous, 2005).

MDMA has been sold under numerous different names, a short list of which includes "Adam," "Batman," "bibs," "blue kisses," "blue Nile," "charity," "clarity," "Debs," "decadence," "E," "Eve," "go," "happy pill," "hug drug," "lover's speed," "M," "roll" or "rolling," "Scooby snacks," "X," and "XTC." Tablets containing 50–150 mg MDMA are often brightly colored with pressed images, often of product logos, butterflies, smiley faces, numbers, or letters. Less commonly encountered are the powdered or capsule forms. "Ecstasy" tablets tested in Europe during the 1990s only contained 50% MDMA, on average (Libiseller *et al.*, 2005). Other common ingredients included 3,4-methylenedioxyamphetamine (MDA), MDEA, caffeine, dextromethorphan, ephedra, and phenylpropanolamine.

The estimated lethal oral dose of MDMA for humans is 2 g. Based on this and the average recreational dose of 125 mg, the safety ratio (or therapeutic index) is estimated to be approximately 15 (Gable, 2004). The $LD_{50}$ of MDMA in rats is between 160 and 325 mg/kg PO. Dogs given 15 mg/kg MDMA showed severe clinical signs and one of six dogs died (Frith *et al.*, 1987). MDMA is metabolized in the liver by *N*-demethylation to the active metabolite MDA (Smith *et al.*, 2002).

MDMA is structurally similar to amphetamines and mescaline, which may explain some of the clinical effects (Lyles and Cadet, 2003). MDMA increases neurotransmitter release, including serotonin, dopamine, and NE (Smith *et al.*, 2002; Morton, 2005; Rimsza and Moses, 2005). Hallucinogenic effects have been attributed to serotonin release and inhibition of reuptake. This drug also inhibits MAO. MDMA directly binds to certain receptors, including 5-$HT_2$ receptors, $\alpha_2$-adrenergic receptors, $M_1$ muscarinic receptors, and $H_1$ histamine receptors, with less affinity for 5-$HT_1$, dopamine, $M_2$, $\alpha_1$, and $\beta$ receptors (Lyles and Cadet, 2003; Morton, 2005). Frith *et al.* (1987) described the effects of MDMA given to dogs at increasing oral doses. Clinical

signs began after about 45 min continued for 6–8 h. Dogs given low doses (3 mg/kg) most frequently showed signs of hyperactivity and mydriasis. Dogs given 9 mg/kg also became tachypneic with hypersalivation and circling behavior. One of six dogs given 15 mg/kg MDMA died after showing clinical sings that included vocalization, aggression, convulsions, and front limb paralysis.

Onset and duration of clinical signs are similar in humans, though onset is more rapid with insufflation (Smith *et al.*, 2002; Rimsza and Moses, 2005). Mydriasis, delirium confusion, agitation, bruxism, tremors, seizures, and loss of consciousness have been noted in MDMA users, as have hyperthermia and rhabdomyolysis. Cardiovascular changes may include tachycardia or less commonly bradycardia, AV block, and hypertension. A few deaths have been attributed to cardiopulmonary arrest. Liver failure has been reported to cause a few deaths after ingestion MDMA (Andreu *et al.*, 1998; Gable, 2004; Liechti *et al.*, 2005; Rimsza and Moses, 2005). Onset may occur days to weeks after exposure and the mechanism is not understood, though a hypersensitivity reaction has been suggested in some cases.

Treatment of MDMA exposure consists of appropriate gastrointestinal detoxification, as with amphetamines, and symptomatic and supportive care. Though not recommended for treatment of other amphetamine-type drugs, diazepam has been recommended to reduce agitation and anxiety in humans that have ingested MDMA (Smith *et al.*, 2002).

### Betel quid

Though not common in most areas of the Unites States, alkaloids of the areca nut are believed to be the fourth most commonly used psychoactive substances in the world after caffeine, ethanol, and nicotine. It is estimated that 10–20% of the world population use "betel quid" containing these alkaloids, mostly in South and Southeast Asia and the Asia Pacific regions (Gupta and Ray, 2004). However, these products can be purchased in the US cities with large populations of immigrants from these areas.

Palm trees of the genus *Areca* are cultivated in tropical and subtropical areas of the world to produce betel quid (Deng *et al.*, 2001). The nut of this palm tree may be ingested green, ripe and raw, baked, roasted, boiled, fermented, or processed with various sweeteners (Gupta and Ray, 2004). It is most commonly processed with leaves from the betel shrub, *Piper betle.* Calcium hydroxide is usually added (Deng *et al.*, 2001; Gupta and Ray, 2004). Tobacco and various spices may be added. The betel quid industry is worth hundreds of millions of dollars. Betel quid is produced locally or under trade names such as Supari, Mainpuri tobacco, mawa, pan masala, and Gutka. Gutka is illegal in some parts of India (Gupta and Ray, 2004). Alkaloids present in areca nut include arecoline, arecaidine, guvacine, and guvacoline. These alkaloids bind to muscarinic receptors, induce coronary vasospasms, and have weak activity on nicotinic receptors in ganglia.

Oral submucosal fibrosis is a preneoplastic disease that is common in young people who use betel quid (Gupta and Ray, 2004). Clinical signs seen in inexperienced users and overdoses are more likely to be of interest to the veterinarian and may include mucosal irritation, nausea and vomiting, bronchoconstriction, hypersalivation, lacrimation, urinary incontinence, diarrhea, hypertension or hypotension, tachycardia, acute myocardial infarction, and extrapyramidal signs (Deng *et al.*, 2001). Most patients given supportive care recover within 24 h, and atropine has not been effective as a treatment in humans.

## HALLUCINOGENS AND DISSOCIATIVE DRUGS

The clinical effect of this type of drug is relatively unpredictable and dependent very much on the individual and their environment (Nichols, 2004). Many compounds that alter consciousness have been termed "hallucinogens," though they may only induce hallucinations under specific circumstances or at very high doses, like marijuana or MDMA. "Psychomimetic," is a term used to describe drugs that cause behavioral changes mimicking psychosis, but the value of this term in veterinary medicine is questionable. "Psychedelic" is also used commonly by the media.

Lysergic acid diethylamide (LSD), a synthetic product similar to natural ergot alkaloids, is a common hallucinogen that acts on serotonin receptors. Hallucinogens with a similar mechanism of action include mescaline and *N*,*N*-dimethyltryptamine (DMT), described below. *Psilocybe* spp. and related mushroom species contain the hallucinogen psilocybin. Vomiting was reported after ingestion in a dog (Spoerke, 2005). Behavioral changes in a horse suspected of ingesting *Psilocybe* spp. included fear and extreme aggression with recovery within 48 h (Hyde, 1990). Severe toxicosis in a colt included hyperexcitability, tremors, mydriasis, and bruxism, and was eventually euthanized due to traumatic injuries and weakness (Jones, 1990). Signs of psilocybin in cats are similar to those described below with LSD (Jacobs *et al.*, 1977). DMT is produced by several plants including *Psychotria viridis*, used to produce a tea known as Ayahuasca in the traditional practices of the indigenous people of the Amazon, *Anadenanthera peregrina* seeds, called yopo by native people of the Amazon rain forest, and *Phalaris* spp. of grass which grow around the world. Leaves of the plant *Salvia divinorum* are legal to possess and are commonly used to produce hallucinogenic effects through a unique mechanism described below.

Dissociative anesthetics are so-called because they uncouple functions of the brain such as sensory and motor

activity, emotion, and consciousness, sometimes producing a cataleptic-type state (Branson, 2001). Affected individuals become disconnected from their environment and there is an absence of response to nociceptive stimuli (Branson, 2001; Volmer, 2005). The synthetic drug phencyclidine is an example of a dissociative agent. Ketamine, a familiar therapeutic drug to most veterinarians, is a dissociative anesthetic and also a popular "club drug." These drugs will be discussed at some length.

Several naturally occurring substances are used to produce hallucinogenic effects by various mechanisms. Certain species of mushrooms in the genus *Amanita*, specifically *A. muscaria and A. pantherina*, contain ibotenic acid and muscimol, which bind glutamate receptors and may be intentionally ingested. Various plants containing atropine and scopolamine, including *Datura stramonium, Atropa belladonna, Mandragora officinarum*, and *Hyoscyamus niger*, are routinely smoked or ingested (Halpern, 2004). The drug dextromethorphan is used recreationally for its dissociative effects. These substances will not be addressed further in this section.

## Lysergic acid diethylamide

LSD is the most powerful known hallucinogen (Nichols, 2004; O'Shea and Fagan, 2006). The D isomer of LSD is responsible for the molecule's effect on the CNS. The story of Albert Hoffman's synthesis and subsequent exposure to LSD is well documented. This drug was marketed under the trade name Delysid and used in psychotherapy and for experimental purposes. Though there are no current medical uses for this drug, it has shown some promise for use in the treatment of alcoholism, drug addiction, and obsessive–compulsive disorder. After becoming a popular recreational drug, LSD use was banned by the government in 1966, and it is currently a Schedule I drug (Nichols, 2004; Volmer, 2005).

LSD is a colorless, odorless, and flavorless white powder that is usually dissolved in water. It is applied to other substances such as blotter paper, microdots, tiny tablets, gelatin squares (termed "window pane" or "window glass"), stamps, and sugar cubes. Street names for LSD reflect these applications and include "acid," as in "spiked with acid," "blotter" or "blotter acid," "cubes," "dots" or "microdot," "L," "sugar" or "sugar cubes," "trip," or "wedding bells." Use of LSD is declining in the Unites States (Banken, 2004).

### *Toxicity*

The human effective dose of LSD is between 0.05 and 0.20 mg. Products sold currently usually contain 0.04–0.06 mg and carry less likelihood of an adverse reaction than the pills sold in the 1960s, which could contain up to 0.25 mg LSD. Increasing the dose may produce both quantitative and qualitative differences in the response (Nichols, 2004). The IV $LD_{50}$ for rats is 16 mg/kg. The minimal toxic dose in humans is between 0.70 and 2.80 mg/kg (Volmer, 2005). No human deaths have been attributed to the direct effects of LSD (Nichols, 2004). Some cats given intraperitoneal (IP) injections of 2.5 μg LSD/kg body weight showed mild clinical signs, and a dose of 50 μg/kg produced significant clinical signs in all cats tested (Jacobs *et al.*, 1977).

### *Toxicokinetics*

LSD is rapidly absorbed after ingestion in humans (Riordan *et al.*, 2002; Volmer, 2005). Peak plasma concentrations occur within 6 h and LSD is approximately 80% protein bound. Metabolism occurs primarily in the liver by hydroxylation and glucuronide conjugation to an inactive metabolite. Eighty percent of a dose of LSD is excreted in the feces and the elimination half-life is between 2 and 5 h (Volmer, 2005). Clinical effects may persist for 12 h (Nichols, 2004).

### *Mechanism of action*

Many "recreational" hallucinogens act primarily as antagonists at serotonin receptors (Volmer, 2005; O'Shea and Fagan, 2006). LSD is structurally similar to serotonin. Actions at the $5\text{-HT}_{2A}$ receptor are believed to be responsible for the hallucinogenic effects, though the signaling pathways involved have not been completely elucidated. Affected $5\text{-HT}_{2A}$ receptors are located in the pyramidal cells of the prefrontal cortex, the reticular nucleus of the thalamus, and possibly the locus coeruleus, where the effect is to alter sensory processing. LSD and some other hallucinogens also have a strong affinity for the $5\text{-HT}_{1A}$, $5\text{-HT}_{2C}$, and other serotonin receptors, but the significance of this is not understood (Nichols, 2004). LSD causes increased release of glutamate in the prefrontal cortex, has a high affinity for dopamine receptors $D_1$ and $D_2$, and shows some affinity for $\alpha_1$ and $\alpha_2$ adrenergic receptors.

### *Clinical signs*

Clinical signs in humans begin within an hour and a half of ingestion and usually last a few hours, though if large quantities are ingested effects may linger for up to 12 h (Anonymous, 2005). Signs in humans include euphoria, distraction, hallucinations, synesthesia, disorientation, incoordination, mydriasis, and sometimes severe anxiety. Malignant hyperthermia has also been reported in humans after LSD use (Riordan *et al.*, 2002). General signs reported in nonhuman animals include disorientation, mydriasis, depression or excitation, and vocalization. Clinical signs reported in cats given IP injections of LSD included paw flicking, head and body shaking, yawning, chops licking, bizarre sitting and standing positions, falling from their perch, leaping about, compulsive scratching at the litter,

pawing at the water, biting objects in the cage, grooming behavior including rubbing the head with paws, licking, biting and scratching, play behaviors including pawing and sniffing objects, tail chasing, and "hallucinatory behavior" which involved tracking, staring at, batting at, or pouncing on objects that were not apparent to the observer, frequent defecation, and occasionally emesis. Grooming behaviors were often not completed, the cat would lick or bite the air or stick her tongue out. Rage behavior and vocalization were not seen in these cats (Jacobs *et al.*, 1977). Based on this study, one can only imagine the presenting complaint in a companion animal after accidental exposure to LSD.

#### *Management*

Deaths have not been ascribed directly to LSD toxicosis humans, though fatal accidents have been reported due to behavioral changes and impaired judgment (Nichols, 2004). Treatment is based on close observation with supportive and symptomatic care. Because absorption of LSD is relatively rapid and effects are self-limiting, gastrointestinal decontamination is considered to have limited, if any, benefit. Clinical signs may persist for up to 12 h after ingestion of a large dose.

Animals should be kept in a quiet, dark room to minimize sensory stimulation. Minimal restraint may prevent hyperthermia (Volmer, 2005). Diazepam may be used to control severe agitation (Volmer, 2005; O'Shea and Fagan, 2006). Phenothiazine tranquilizers may lower seizure threshold. Haloperidol has been recommended to treat psychotic behavior secondary to LSD exposure in humans.

Laboratory techniques that have been employed in the detection of LSD include immunoassays, thin-layer chromatography, high-pressure liquid chromatography (HPLC), and liquid chromatography/mass spectrometry (LC/MS).

#### *Lysergic acid amide*

The seeds of *Ipomoea violacea*, the morning glory, contain lysergic acid amide (LSA), which is approximately 1/10th as potent as LSD, at a concentration of 0.02% dry matter (Halpern, 2004). Ingestion of 150–300 seeds may cause clinical effects in humans. The seed coat may be protective, thus seeds must be crushed, germinated, or soaked in water for ingestion to be effective. A word of caution to the adventurous, emetics may be added to commercial morning glory seeds. Other sources of LSA include seeds of the Hawaiian baby woodrose, *Argyreia nervosa*, at a concentration of 0.14% dry matter, and endophyte-infected sleepy grass, *Stipa robusta. S. robusta* is present in the Southwestern Unites States.

## Phencyclidine and ketamine

Phencyclidine, 1-(1-phenylcyclohexyl)piperidine, is a schedule II synthetic drug with more than 80 known analogs. One such analog, ketamine or 2((-*o*-chlorophenyl)-2-methylamino)-cyclohexanone HCl, has less than 1/10th the potency of phencyclidine and is a schedule III drug (Volmer, 2005). Phencyclidine was originally used as an anesthetic under the trade names Sernyl for human patients and later Sernylan for veterinary patients. Sernyl, given IV, was decreased response to nociceptive stimuli with insignificant respiratory and cardiac depression and no loss of corneal, papillary, or other reflexes (Branson, 2001). However, Sernyl was associated with postoperative psychosis, dysphoria, delirium, violent behavior, and hallucinations (Kisseberth and Trammel, 1990; Pestaner and Southall, 2003; Anonymous, 2005; Volmer, 2005). Sernylan was used in dogs, nonhuman primates, and was the preferred anesthetic for crocodilians (Ortega, 1967; Stunkard and Miller, 1974). Phencyclidine was last used commercially in the United States in 1978.

Phencyclidine is easily synthesized in clandestine laboratories. It is available in powdered or crystal forms which may be dissolved in liquids such as water or "embalming fluid," which contains formaldehyde and methanol, or it may be sold in tablets or capsules. Street products range from 5% to 90% purity and phencyclidine may be substituted for THC, mescaline, LSD, amphetamine, or cocaine (Kisseberth and Trammel, 1990). Phencyclidine is said to have a distinctive odor. This drug is frequently sold under the name "PCP" but other terms include "angel dust" or "angel hair," "boat" or "love boat," "dummy dust," "CJ," "hog" or "hog dust," "PeaCe Pill," "rocket fuel," "stardust," "whack," and "zombie dust." "Embalming fluid" is added to tobacco, marijuana, or other leafy material such as parsley, mint, or oregano for smoking. Names for this type of product include "supergrass." "amp," "happy sticks," "sherm," and "wet sticks."

Ketamine is not as readily produced by the amateur chemist but is used in veterinary and human medicine. Ketamine is labeled for use in cats and nonhuman primates. It may be used by physicians in pediatrics and in emergency and critical care situations where maintenance of blood pressure and respiration are crucial (Smith *et al.*, 2002; Volmer, 2005). Ketamine is a flavorless, odorless liquid which may be dried and crystallized then powdered for illicit use. Ketamine may be ingested and used to "spike" drinks, injected, insufflated, or placed into tobacco or marijuana cigarettes and smoked. Street names for ketamine include "cat valium," "green," "jet," "K," "special K," or "vitamin K," "keets," "kit-kat," "super acid," and "super C."

#### *Toxicity*

Phencyclidine given orally at doses of 2.5–10 mg/kg produces clinical effects in dogs and doses of 25 mg/kg were lethal in all of six dogs treated (Kisseberth and Trammel, 1990; Volmer, 2005). Given via intramuscular (IM) injection, 2 mg/kg caused muscular incoordination, 5 mg/kg caused immobilization and convulsions in one of five dogs, and

15 mg/kg caused convulsions in both of two dogs treated (Ortega, 1967).

Ketamine has a high therapeutic index in domestic mammals. The sedative dose in cats is 20 mg/kg IM. Doses of 5–10 mg/kg IM have produced convulsive seizures in dogs. IV injections of 2 mg/kg produce ataxia in sheep and dissociative analgesia in cattle. Doses of 5–15 mg/kg IV may cause struggling and vocalization in goats (Branson, 2001). The approximate $LD_{50}$ for ketamine in rodents is 600 mg/kg PO (Gable, 2004). Large doses of ketamine do not appear to produce analgesia in chickens or pigeons and pigeons may go into respiratory failure with doses of 0.11 mg/g; 0.05–0.1 mg/g produces anesthesia in parakeets, but 0.5 mg/g IM may be lethal (Branson, 2001).

### *Toxicokinetics*

Phencyclidine is ionized at gastric pH, thus little is absorbed in the stomach, but there is significant intestinal absorption (Kisseberth and Trammel, 1990; Volmer, 2005). Inhaled phencyclidine is well absorbed. The drug is lipophilic, with a wide tissue distribution that includes the CNS, adipose tissue, and gastric secretions. The latter leads to recycling and increases the biological half-life. Metabolism is variable between species. Approximately 68% of a given dose undergoes hepatic metabolism in the dog to a monohydroxyl form which is then conjugated for excretion. The remaining 32% is excreted unchanged in the urine. Approximately 88% of a dose of phencyclidine is excreted unchanged in the urine in cats.

Ketamine is well absorbed by parenteral routes, but little is absorbed after oral dosing in humans. There is a significant first-pass effect after ingestion of ketamine (Smith *et al.*, 2002). Peak plasma levels in cats occur 10 min after IM injection (Branson, 2001; Volmer, 2005). Ketamine is about 50% bound to plasma proteins in horses. It is distributed to the brain, adipose tissue, liver, lung, and other tissues. Ketamine undergoes hepatic metabolism via *N*-demethylation or hydroxylation and glucuronide conjugation to a water-soluble metabolite for excretion in the urine. The elimination half-life is approximately 67 min in the cat after parenteral dosing, 60 min in the calf, 42 min in the horse after IV dosing, and 2–3 h in the human.

### *Mechanism of action*

How compounds like phencyclidine and ketamine produce dissociative effects is not entirely understood. It is known that these drugs act on sites in the cerebral cortex, thalamus, and limbic system (Branson, 2001; Pal *et al.*, 2002; Volmer, 2005). The effects on behavior and cognition in humans may mimic schizophrenia. Phencyclidine and ketamine bind to *N*-methyl-D-aspartate (NMDA) receptors at a different site than glutamate, the excitatory neurotransmitter, and therefore act as noncompetitive inhibitors. Reuptake of NE, dopamine, and serotonin is decreased through inhibition of the biogenic amine reuptake complex (Smith *et al.*, 2002; Volmer, 2005). The sympathomimetic effects are associated with changes in heart rate, blood pressure, and cardiac output and increased myocardial oxygen consumption. Cardiovascular effects are more prominent with ketamine than phencyclidine. Ketamine induces stage I and stage II anesthesia but not stage III (Branson, 2001). Ketamine acts on non-NMDA glutamate receptors, dopaminergic receptors, nicotinic receptors, muscarinic receptors, and opioid receptors. Analgesic properties may be attributed to the actions of ketamine on opioid receptors. Ketamine binds dopamine receptors in dogs.

### *Clinical signs*

Dogs dosed with phencyclidine appear depressed at low doses and stimulated at high doses, with the potential for convulsive seizures (Branson, 2001). Onset of clinical effects is within 2 min of IV dosing (Ortega, 1967). Signs reported in dogs include muscular rigidity, grimacing facial expression, increased motor activity, head weaving, stereotyped sniffing behaviors, blank staring, incoordination, hypersalivation, nystagmus, and opisthotonus, ascending loss of motor function, coma, tonic–clonic convulsions, and hyperthermia. Cardiovascular effects include tachycardia, hypertension, and cardiac arrhythmia and deaths occur due to respiratory failure. Signs of phencyclidine in swine include muscle tremors and hypersalivation (Frost, 1972). Behavioral changes have been noted in neonates that were exposed during gestation (Branson, 2001).

Reported changes in clinical chemistry parameters include acidosis, hypoglycemia, electrolyte imbalances, and increased creatine phosphokinase and aspartate transaminase. Postmortem lesions associated with phencyclidine include epicardial and subendocardial hemorrhage and pulmonary congestion and hemorrhage (Kisseberth and Trammel, 1990). Clinical signs attributed to low doses of phencyclidine in humans include ataxia, slurred speech, hyperesthesia, hostility, sweating, drooling, hallucinations, incoordination, and disorientation. Overdose may cause coma, seizures, hypotension, muscle rigidity, and hyperthermia with the potential for rhabdomyolysis and renal failure. The clinical effects may last for days.

Pineal, pedal, photic, corneal, papillary, laryngeal and pharyngeal, and other reflexes are maintained during ketamine anesthesia (Branson, 2001; Volmer, 2005). There are significant species differences in the effects of ketamine. Ketamine increases muscle tone in cats, sometimes causing forelimb extensor rigidity or opisthotonus. Other signs in cats include mydriasis and fixed staring. Hypersalivation and chops licking are associated with oral dosing. Most cats can sit within 2 h and recover completely within 10 h. Ketamine causes excitation in dogs and may produce tonic–clonic seizures. Pulmonary edema was reported in a dog 2 days after anesthesia with ketamine and xylazine. Hypersalivation, apneustic breathing, and increased pulse

are reported in sheep. Goats hypersalivate, struggle, and vocalize but usually recover within 20 min of dosing. Nonhuman primates have increased heart and respiratory rates and hypertension (Branson, 2001).

Ketamine in humans has a rapid onset after ingestion or insufflation. Low doses produce analgesia and higher doses producing amnesia. Effects usually last about 45 min, but some users report hallucinations or "out of body experiences" lasting up to 1 h and full recovery may take up to 5 h (Smith *et al*., 2002; Gable, 2004; Anonymous, 2005). Other signs include mydriasis, perspiration, slurred speech, disorientation, nausea and emesis, paranoia, hypertension, and respiratory depression. Human deaths due to ketamine are quite rare and may be due to a combination of factors.

#### *Treatment*

Prognosis for an animal overdosed with phencyclidine or ketamine is generally good with early intervention, but self-induced trauma or rhabdomyolysis may complicate treatment. Cats that have undergone ketamine anesthesia usually recover rapidly and are able to sit up within about 2 h (Branson, 2001). Dogs injected with low doses of phencyclidine (1 mg/kg IM) recovered almost completely in a little over an hour, and at higher doses (5 mg/kg) were able to sit up within 2 h (Ortega, 1967).

Treatment of phencyclidine or ketamine overdose is generally symptomatic and supportive. Animals must be kept in a dark and quite room (Volmer, 2005). Use of restraint on human phencyclidine users has been associated with deaths, possibly due to catecholamine release and hypertensive crisis, or respiratory compromise (Pestaner and Southall, 2003).

Inducing emesis is of limited use due to the rapid absorption of phencyclidine, but may be attempted in very recent ingestions of large doses if no contraindications exist. Activated charcoal binds phencyclidine, prevents recycling, and is known to reduce mortality in dogs and rats. Forced diuresis with mannitol or furosemide may increase the rate of clearance. Urinary acidification enhances excretion but must be pursued with caution to prevent exacerbation of acidosis or, less commonly, myoglobinuric renal failure due to rhabdomyolysis. Electrolyte abnormalities and hypoglycemia should be corrected as necessary (Kisseberth and Trammel, 1990; Volmer, 2005).

Body temperature of the patient should be monitored. Cardiorespiratory abnormalities have been reported in some species. Muscle rigidity, hyperactivity, and seizures associated with ketamine can be successfully treated with diazepam (Branson, 2001). Severe seizures may require barbiturates or general anesthesia. Phenothiazine tranquilizers may decrease the seizure threshold, exacerbate anticholinergic effects, and produce hypotension, and therefore are contraindicated (Volmer, 2005).

## Other compounds

Mescaline, the active compound in peyote, is a well studied hallucinogen due to its significance both culturally and in the illicit drug trade. DMT is also another culturally significant compound that is familiar to some in the illegal drug trade. Salvinorin A is an agent hallucinogenic potential that is found in the legal herb *S. divinorum*.

#### *Mescaline*

Use of mescaline dates back to approximately 8500 BC (Bruhn *et al*., 2002). It is derived from several species of cactus including *Lephophora williamsii*, the peyote, *Trichocereus pachanoi*, the San Pedro cactus, and *Trichocereus peruvianus*, the Peruvian torch cactus. The latter two cacti are native to South America and are common ornamental plants. Both may be boiled into a soup for ingestion. Peyote grows in the Southwestern Unites States and Mexico, and is used legally by indigenous people. A tuberous root grows into the ground and is capped by crowns or "buttons" which are removed. The buttons may contain 1.5% mescaline on a dry matter basis. Buttons may be eaten fresh but are often dried. Dried buttons may be chewed, powdered, reconstituted, or steeped into a tea. Pickled buttons have caused botulism (Halpern, 2004). Though traditional uses are permitted, mescaline is a schedule I drug.

Mescaline is well absorbed by oral and parenteral routes in the dog with maximum plasma levels detected within an hour of ingestion. Mescaline levels detected in the brain are similar to blood levels. Renal, hepatic, and spleenic concentrations are 3–6 times blood levels. Mescaline can be detected in the urine within 30 min of exposure and remains detectable for up to 24 h. Between 28% and 46% of a given dose is excreted unchanged in the urine (Cochin, 1950). The effective dose of mescaline in humans is 0.3–0.5 g (Anonymous, 2005). The mescaline molecule is structurally similar to serotonin and acts on the 5-$HT_{2A}$ receptor (Nichols, 2004).

Clinical signs of mescaline intoxication in dogs include vomiting, mydriasis, injection of the conjunctiva, hyperreflexia, chewing motions of the jaw, and either excitation and disorientation or profound depression. Dogs are reported to recover from severe depression within 10 h. Signs in humans are fairly similar and may include emesis, especially after ingestion of *Trichocereus* spp. (Halpern, 2004). Other signs may include mydriasis, sweating, hallucinations, synesthesia, disorientation, incoordination, increased heart rate and blood pressure, and hyperthermia. People usually recover after 12 h.

#### *S. divinorum*

*S. divinorum*, known as salvia, is a perennial sage closely related to mint. The plant is native to Mexico and grows in humid, semitropical climates. It is grown in the United

States. The plant is of cultural significance to the Mazatec Indians of Oaxaca, Mexico, where it is used to treat diarrhea, headaches, rheumatism, and semi-magical diseases (Prisinzano, 2005). These indigenous Mexicans either chew the fresh leaves or extract juice. Salvia may also be smoked (Frohne and Pfänder, 2004; Prisinzano, 2005). Use of salvia is currently legal in the Unites States, though it is considered a "drug of concern" by the DEA. Salvia is a controlled substance in Denmark, Austria, and Italy.

Salvia contains various diterpenes, including salvinorums A through F and divinatorins A through C. Biological effects are attributed to salvinorin A. Similar compounds are present in plants of the genus *Coleus*. Salvinorin A is absorbed through the oral mucosa (Halpern, 2004). Little is known about the metabolism of this compound, but the elimination half-life in nonhuman primates averages 55.6 min (Prisinzano, 2005). Unlike other traditional hallucinogens, salvinorin A is an agonist at the $\kappa$ receptor and has no known effect on the $5\text{-HT}_{2A}$ receptor (Halpern, 2004; Prisinzano, 2005). No toxic effects were seen in mice given high doses of salvia (Prisinzano, 2005). Clinical signs associated with salvia use in humans are brief and self-limiting. They may include hallucinations, and at high doses loss of consciousness, and short-term memory. Most users recover within an hour. Treatment should be based on observation with symptomatic and supportive care as needed.

## CONCLUSION

Toxicoses due to ingestion of illegal substances are infrequently reported in the veterinary literature, but with the high incidence of "recreational" drug use in the United States, occasional companion animal exposures are likely. Exposure may be through accidental ingestion of the owner or neighbor's private "stash" or intentional exposure, either with lethal intent or as an attempt to get the pet "stoned." Though companion animals are far more likely to ingest "recreational" drugs, there are documented exposures of cattle and horses to illegally cultivated marijuana and illegal drugs have been used to enhance the performance of horses.

There are a large variety of drugs used for recreational purposes, and their actions vary mechanistically and produce a broad range of clinical signs. Treatment for most is through detoxification – though often severe CNS signs preclude use of emetics – and symptomatic and supportive therapy. Rarely are specific treatments available, though antagonists are available for opioid drugs. Quantity of the drug ingested and severity of clinical signs are important for determining prognosis with many drugs. Some drugs, however, such as marijuana, may cause severe CNS signs but affected animals have an excellent prognosis with early and appropriate intervention.

## INTRODUCTION

Aluminum (Al) is the third most abundant element that naturally occurs in the earth crust. As a result, it is present in water, soil, and air. Small amounts of Al are released into the environment from coal-fired power plants, incinerators, and roofing and siding materials. In addition, Al and Al-based compounds are used for a variety of purposes, from medicines to explosives. Under some circumstances exposure of animals and humans to Al is inevitable. Poisoning in animals by Al is rare, but in several incidents the outcome has been very serious or deadly. Among all Al compounds, Al phosphide is of major concern to animals, because at low stomach pH, phosphide converts to toxic phosphine gas. Al has been widely studied for its toxicological effects, especially for neurotoxicity and developmental toxicity in laboratory animals. This chapter focuses on Al toxicity in animals.

## BACKGROUND

Aluminum (Al) metal is obtained from Al-containing minerals, primarily bauxite. Al metal is silvery white in appearance and light in weight. Al is a component of beverage cans, pots and pans, siding and roofing, and foil. It is also found in the products such as antacids, astringents, buffered aspirin, and food additives. In the powdered form, Al is used in fireworks and explosives (ATSDR, 1999). Often, Al complexes with other elements and forms Al oxide, Al chlorhydrate, Al hydroxide, Al chloride, Al lactate, Al phosphate, and Al nitrate.

The implication of Al in the etiology of neurodegenerative disease like Alzheimer's disease has been controversial; its role has clearly been established in encephalopathy and amyotrophic sclerosis (Deloncle and Pages, 1997). From a toxicological perspective, Al phosphide, which is commonly used as a pesticide, has been encountered in poisoning of cows. In these cases, the majority of toxicity comes from phosphine ($PH_3$) gas which is generated from phosphide in the gastrointestinal (GI) tract. Acute toxicity of Al in animals is rare, but following subacute or chronic exposure, Al can produce a variety of toxicological effects. Since Al readily crosses the blood–brain barrier (BBB) and the placental barrier, it appears that neurotoxicity and developmental toxicity are of particular concern in relation to Al toxicity.

## TOXICOKINETICS

Aluminum (Al) is poorly absorbed following either oral or inhalation exposure, and practically none is absorbed following dermal exposure. Bioavailability of Al depends on its form. For example, Al nitrate has shown to be twice as bioavailable as Al chloride in rats (Yokel and McNamara, 1988). In Wistar rats receiving a single gavage dose of Al hydroxide, Al citrate, Al citrate with added sodium citrate, or Al maltonate, the fractional intestinal absorptions were 0.1%, 0.7%, 5.1%, and 0.1%, respectively. In rabbits, following a single oral dose of the water-soluble compounds, Al chloride (333 mg Al/kg), Al nitrate (934 mg Al/kg), Al citrate (1081 mg Al/kg), and Al lactate (2942 mg Al/kg), Al absorption was 0.57%, 1.16%, 2.18%, and 6.3%, respectively (Yokel and McNamara, 1988). It appears that the oral absorption of Al can vary 10-fold based on chemical form alone, that is less absorption for water-insoluble forms and more for water-soluble forms. Furthermore, bioavailability can be influenced by other factors, such as variable

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

amounts of essential and nonessential trace minerals, metal binding ligands, and other dietary constituents, that can enhance or inhibit Al absorption.

Evidence suggests that Al is primarily absorbed in the duodenum and jejunum. The acidic pH of the stomach may solubilize Al from insoluble species such as $Al(OH)_3$, facilitating absorption (Yokel, 1997). The main mechanism of absorption of Al is probably passive diffusion through paracellular pathways. Another proposed mechanism for absorption of Al is an energy-dependent process that involves calcium channels. Al may be taken up into mucosal cells, which may provide a barrier to its absorption. Small amounts of Al may then be slowly released into circulation (Van der Voet, 1992). Free Al ions occur in very low concentrations, because they complex with many molecules in the body, such as organic acids, amino acids, nucleotides, phosphates, carbohydrates, and macromolecules. Therefore, toxicokinetics of Al can vary depending on the nature of these complexes.

From the circulation, Al distributes to every organ, and the highest concentrations can be found in bone, brain, and lung tissues. It is well established that Al deposits in bones and from there it is slowly released. Long-term oral exposure to Al results in an increase in Al levels in the bone (Ahn *et al.*, 1995; Konishi *et al.*, 1996). Al also accumulates in the brain, kidneys, liver, lung, and in hematopoietic tissue. Slow elimination coupled with continued exposure may produce an increasing body burden of Al. Furthermore, Al levels are increased with age. Within cells, Al accumulates in the lysosome, cell nucleus, and chromatin. In the blood, about 80–90% of Al binds to plasma proteins (Wilhelm *et al.*, 1990). Evidence suggests that Al primarily binds to transferrin, and some amounts to albumin. It is important to note that binding of Al to albumin is nonspecific and much weaker than to transferrin.

In general, brain Al concentrations are lower than many other tissues. Al is known to cross the BBB and enter the brain by transferrin receptor-mediated endocytosis. Following inhalation exposure, Al can enter the brain by two mechanisms: (1) via the olfactory tract and (2) via nasal epithelium and axonal transport (Perl and Good, 1987; Zatta *et al.*, 1993). It is noteworthy that the cells that accumulate the most Al are long-lived postmitotic cells, such as neurons (Ganrot, 1986). In rabbits, increases of 4- to 10-fold and 10- to 20-fold Al concentrations in brain are associated with neurotoxicity and death, respectively. Al is actively removed from the brain by means of an energy-dependent process.

Regardless of the route of exposure, from the circulation Al primarily excretes in the urine and very little in the bile. Renal elimination of Al depends on the Al complex. For example, Al bound in a low-molecular-weight complex could be filtered at the renal glomeruli and excreted, while Al in a high-molecular-weight complex would not. Animal studies suggest that following a single exposure Al levels in urine can elevate as much as 14-fold. Al is primarily excreted in urine during the first 24 h period, and returns to normal levels 5 days post exposure (Ittel *et al.*, 1987). The rate of Al clearance is consistent with glomerular filtration rate (GFR), although proximal tubular Al reabsorption and Al excretion in the distal nephron have been suggested. Several animal studies have revealed a decrease in Al clearance and an increase in $t_{1/2}$ with increased Al concentration. This may be due to the high Al concentrations that probably formed unfilterable Al complexes, thereby reducing the plasma filterable Al fraction. Because of the limited GI tract absorption of Al, only a limited amount of Al excretes in the milk.

Following oral ingestion, unabsorbed Al excretes in the feces.

## MECHANISM OF ACTION

The central nervous system (CNS) and bone appear to be the two major target organs for Al toxicity. It has been known for a while that Al is involved in neurodegenerative diseases like Alzheimer's, encephalopathy, and amyotrophic sclerosis (Deloncle and Pages, 1997). However, the exact mechanism by which Al- induces neurotoxicity remains to be established. Al mainly deposits in the hippocampus, cortex, and amygdala, which are the areas of brain that are also rich in glutamatergic neurons as well as in transferrin receptors. Upon entering the brain, Al displaces physiological cations, such as magnesium, calcium, or iron, and modulates their metabolism. Studies suggest that Al neurotoxicity can be modulated by the levels of tissue and cytoplasmic calcium. Al, by replacing calcium in the synaptic area, perturbs neurotransmitter release and alters neurotransmitter systems. High Al levels appear to modify cholinergic neurotransmission. Al is known to associate with many epithelia and endothelia, including the BBB, and may be responsible for compromising the properties and integrity of these membranes (Wen and Wisniewski, 1985; Exley, 1996).

Al competes with magnesium in the biological system despite an oxidation state difference, and binds to transferrin and citrate in the bloodstream (Ganrot, 1986; McDonald and Martin, 1988). Al may also affect second messenger systems and calcium availability (Birchall and Chappell, 1988), and irreversibly bind to cell nucleus components (Dryssen *et al.*, 1987; Crapper-McLachlan, 1989). In addition, Al has been shown to inhibit neuronal microtubule formation.

It has been demonstrated that, in some conditions, Al can cross the BBB without altering the functional characteristics of the membrane, while in other conditions Al interacts with the BBB with subsequent effects on its barrier function (Vorbrodt *et al.*, 1994). Al-related toxicological

effects are noticed on both sides of the BBB (Deloncle and Pages, 1997). In neurons, glutamic acid in the form of a stable Al–glutamate complex is unable to detoxify cellular ammonia, which leads to neuronal death (Harris, 1992). Important events such as accumulation of Al in lysosomes (protease-rich vacuoles) and the hyperphosphorylation of neurofilaments (NFs) are involved in the molecular mechanism of Al-induced neurotoxicity (Bizzi and Gambetti, 1986; Ganrot, 1986; Delamarche, 1993).

## TOXICITY

Al is a toxic metal to animals. Although acute toxicity is rarely encountered, a high acute dose or repeated long-term exposure often leads to serious toxicological effects. Toxicity of Al depends on its form or complexes. Oral $LD_{50}$ values for Al nitrate in Sprague–Dawley rats and Swiss Webster mice are reported to be 261 and 286 mg Al/kg, respectively (Llobet *et al.*, 1987). For Al bromide, these values are 162 and 164 mg Al/kg, respectively. $LD_{50}$ values for Al chloride in Sprague–Dawley rats, Swiss Webster mice, and male Dobra Voda mice are 370, 222, and 770 mg Al/kg, respectively (Ondreicka *et al.*, 1966; Llobet *et al.*, 1987). The $LD_{50}$ values for Al sulfate in male Dobra Voda mice are reported to be 980 mg Al/kg (Ondreicka *et al.*, 1966). A single gavage exposure to 540 mg/kg as Al lactate was found to be lethal in female New Zealand rabbits (Yokel and McNamara, 1985). In subchronic and chronic studies, Al has been found to cause lethality in mice (Golub *et al.*, 1987), but not in rats (Dixon *et al.*, 1979) and dogs (Pettersen *et al.*, 1990).

Toxic effects of Al depend on the target organ. Such effects may in part be related to Al deposition and substitution of physiological elements, such as calcium, magnesium, and iron. Alterations by Al deposits can occur in: (1) the bone, interfering in heme synthesis leading to anemia, and (2) the myocardium, leading to myocardiac infarction, and (3) the brain, leading to neurotoxicity.

There is conclusive evidence that Al compounds are neurotoxic to laboratory animals following oral exposure. Marked signs of neurotoxicity, including ataxia, splaying, and dragging of hind limbs, and paralysis occurred in maternal mice that were exposed during gestation and lactation to Al with estimated doses of 184 mg Al/kg/day (Golub *et al.*, 1987) or 250 mg Al/kg/day (Golub *et al.*, 1992) as Al lactate. Adult mice that consumed 195 mg Al/kg/day as Al chloride for 5–7 weeks in a diet that also contained 3.5% sodium citrate showed neurotoxic effects (Oteiza *et al.*, 1993). The citrate is likely to have enhanced the responses of Al neurotoxicity. Changes in brain biogenic amines (decreased dopamine and 5-hydroxytryptamine, and increased norepinephrine) occurred in rats that were treated with 21.4 mg Al/kg/day as Al nitrate by gavage for 6 weeks (Flora *et al.*, 1991).

Evidence suggests that more serious disturbances occur in the brain following Al exposure. An alteration of the BBB would be necessary for Al brain transfer, but the mechanism leading to this alteration is still completely unknown, even though Al-induced peroxidation is perhaps a process involved therein. Elevated Al levels have been related to impaired motor function and to a number of cognitive deficiencies in both humans and experimental animals (Sturman and Wisniewski, 1988). Neurofibrillary degeneration has been observed in brain regions that exhibit elevated Al levels (Krishnan *et al.*, 1988).

Histopathological changes in the brain of rats, receiving 92 mg Al/kg/day as Al chloride and a high level of citrate (598 mg/kg/day) for 6 months, showed extensive vacuolization in astrocytes, swelling of astrocytic processes, neuronal vacuolization, and nuclear inclusions (Florence *et al.*, 1994). In other studies, increased Al levels and histological alterations in the brain (particularly increased numbers of abnormal and damaged neurons and reductions in cell density in areas of the hippocampus and neocortex) also occurred in rats that received an estimated 12 mg Al/kg/day as Al fluoride in drinking water and base diet for 45–52 weeks (Varner *et al.*, 1993, 1998).

There is some evidence that neurotoxic agents given prenatally induce subtle neurobehavioral impairment and delayed development of nervous system functions without any morphological malformation (Vorhees *et al.*, 1979; Adams and Buelke-Sam, 1981). The entry of Al into the developing nervous system is enhanced by the immaturity of the BBB (Thomas *et al.*, 1989), and the increased neuronal expression of transferrin receptors (Mollgard *et al.*, 1987). Al has been widely studied for reproductive/developmental/placental toxicity and teratogenecity in laboratory animals. These effects have been discussed in detail in the "Placental Toxicity" chapter of this book (chapter 15). In brief, Al crosses the placental barrier, accumulates in fetal tissues, and produces adverse/birth defects (Golub and Domingo, 1998).

It is important to mention that the acute toxicity associated with Al phosphide ingestion is primarily due to the formation of the highly toxic gas phosphine, instead of Al. There are incidences in which cows died by inhaling and ingesting grains treated with Al phosphide that was used for fumigation.

Although long-term oral exposure to Al results in an increase in Al levels in bones, there is no evidence that the accumulation of Al alters the bone structures histologically (Konishi *et al.*, 1996).

### Diagnosis

Diagnosis of Al poisoning can be based on history of Al exposure, clinical signs, and testing of Al in animal tissues.

Using atomic absorption spectrometer or inductively coupled plasma, Al can be measured in the blood, urine, feces, and hair. Only the urine measurement can indicate whether recent exposure to excess levels of Al has occurred. High concentrations in the lung usually reflect inhalation exposure and elevated levels in bone, liver, and spleen reflect sequestration (Yokel, 1977). In the diagnostic setting, liver and kidney are tested for Al and stomach/rumen content for phosphene ($PH_3$) when aluminum sulfide poisoning is suspected. Aluminum levels in the range of 6–11 ppm in the liver and 4–5 ppm in the kidney of cows and sheep are regarded as toxic levels. In dog liver, an Al level greater than 1.2 ppm is considered high (Puls, 1994). Aluminum levels greater than 1200 ppm in the diet are considered toxic to cattle and sheep.

## TREATMENT

There is no specific antidote for Al toxicity. So, treatment relies on symptomatic and supportive therapies. Use of activated charcoal and cathartics can be rewarding. In the case of Al phosphide, sodium bicarbonate (5% solution) can be administered to stop conversion of phosphide to phosphine gas.

## CONCLUSIONS

Aluminum is a commonly occurring metal in the environment, and as a result a small amount is normally present in the body. Single exposure or repeat exposure to higher levels of Al or its compounds (particularly Al phosphide) often leads to serious toxic effects or death. Since Al crosses the BBB and placental barrier, it produces neurotoxicity and developmental toxicity.

There is no specific antidote for Al toxicity. There is evidence that dietary Si can reduce GI Al absorption and increase its elimination. Dietary Si can also reduce brain Al accumulation. Avoid using desferrioxamine, as it can increase the Al concentration in the brain. Instead, use of an orally effective Al chelator, such as 3-hydroxypyridine-4-one, can be recommended.

## ACKNOWLEDGMENTS

I would like to thank Mrs. Joan Jenkins and Mrs. Denise M. Gupta for their assistance in preparation of this chapter.

# Arsenic

*Tam Garland*

## INTRODUCTION

The ubiquitous element arsenic (As) is a non-metal or metalloid in group V of the period chart. Frequently it is referred to as arsenic metal and is classified for many toxicological purposes as a metal. It exists in several forms and has a long history of various uses. It has been used in preparations from insecticides for animal to wood preservatives, herbicides and even has some medicinal uses. It is responsible for many poisonings in people and animals, both large and small.

## BACKGROUND

Arsenic is a ubiquitous element with several different forms. The form may determine the toxicity. The prevalent valences are the +3 and the +5 forms. Arsenic is found in both organic and inorganic forms with valet numbers ranging from +3 to +5. $As^{+3}$ or arsenite is more toxic than arsenate or $As^{+5}$. The toxicity of arsenic is determined by its form.

It is found as different ores and rocks being mined, then smelted resulting in elemental arsenic and arsenic trioxide. In the environment, arsenic usually exists as the pentavalent form and soil microorganisms may methylate it. Since it is a ubiquitous in many forms it is not likely that complete avoidance is possible.

Arsenic has a long and varied history of its sources and uses. A partial list is available in Table 26.1.

## PHARMACOKINETICS/ TOXICOKINETICS

Different toxic disease syndromes are caused by the different forms of arsenic. Inorganic arsenicals and trivalent organics cause a disease syndromes characterized by an effect on the gastrointestinal (GI) tract and the capillaries. In extremely low doses it is possible the body will develop a tolerance to the arsenic. Pentavalent organic arsenicals produce a neurological syndrome.

There are many factors influencing the absorption of arsenicals. Among those variables are the form of the metal, the particle size, the purity, the solubility, the species affected, and the physical condition of the animal exposed. Susceptibility to inorganic arsenicals varies among species, being highest in humans, followed by dogs, rats, and mice (Harrison *et al.*, 1958; Hays, 1982). So clearly there are many variable affecting the absorption and toxicity of this metal, which increases the difficulty of making accurate predictions of lethal amounts.

Pentavalent organic arsenicals are better absorbed than are the trivalent arsenicals, especially through the GI tract. Small amounts of either form may be absorbed via the intact skin, but it usually remains locally within the skin. However, absorption is limited by the size of the arsenical particle size. If the particle size is too large, it is not absorbed. Hence, a more toxic arsenical that is not absorbed because of large particle size may effectively be less toxic.

Once arsenicals are absorbed, the distribution is through the blood to all the organs of the body. Arsenic accumulates in the liver and is slowly distributed to the

TABLE 26.1 Sources and uses of arsenic

| Sources | Valence/form | Uses |
|---|---|---|
| Commercial uses and products | Inorganic arsenic trioxide (+3) | Insecticide, cattle dip (0.18%) |
| | Inorganic sodium arsenite (+3) | Defoliant (highly toxic) |
| | Inorganic copper acetoarsenite (+3) | Paris green – insecticide (emerald green) |
| | Inorganic arsenic trioxide (+3) | Smelters |
| | Inorganic sodium arsenate (+5) | Herbicide |
| | Inorganic chromated copper arsenate (+5) | Wood preservative |
| | Inorganic lead arsenate (+5) | Insecticide and medicinal |
| | Organic pentavalent (+5) | Monosodium methylarsenate (MSMA) and disodium methylarsenate (DSMA) (highly toxic to cattle) |
| | | Ant bait |
| | | Leaded gasoline |
| | | Ant baits |
| Natural sources | | Ores, minerals, volcanoes |
| | | Ground water and soil |
| Medicinals | Potassium arsenite (+3) | Fowler's solution tonic/conditioner |
| | Organic trivalent arsenical | Thiacetarsamide – heartworm treatment in dogs |
| | Organic pentavalent arsenical | Tryparsamide – trypanosomiasis – old |
| | Organic trivalent arsenical | Melarsoprol – trypanocidal |
| | Organic pentavalent arsenical | Arsenicals feed additives (arsanilic acid, sodium arsanilate, 3-nitro, 4-hydroxyphenylarsonic acid) |

other tissues. The spleen, kidneys, and lungs are able to accumulate large amounts of arsenic. Arsenic has been shown to cross into the placenta barrier, particularly in monkeys, hamsters, and gerbils. Chronic doses are stored in the bone, the skin, and other keratinized tissues, such as skin, hair, hooves, and nails (Agency for Toxic Substances and Disease Registry, 1990).

The biotransformation of the arsenicals is poorly understood. There is some conversion from the +5 state to the +3 state, but the redox equilibrium favors the +3.

Methylation occurs by microorganism in the soil, but inorganic arsenicals are also methylated *in vivo*. The *in vivo* process may aid in the detoxification process. The kidneys may reduce a small amount of pentavalent arsenic to the more toxic trivalent form.

Arsenicals are excreted through many processes. In most species, between 40% and 70% of the absorbed amount of pentavalent arsenicals are excreted through the urine within 48 h (Vahter, 1983). It may also be excreted in much smaller quantities through the sweat. Trivalent forms of arsenic are excreted more slowly and through the bile into the fees.

## MECHANISM OF ACTION

Arsenite (+3) react with sulfhydryl groups (—SH) of proteins and inhibits the enzymes by blocking the active groups. The arsenite inhibits alpha-keto oxidases which contain dithiol groups and are involved in oxidation of pyruvate. Lipoic acid, an essential co-enzyme for pyruvic acid oxidase and alpha-oxyglutaric acid oxidase are inhibited by the arsenite. These play an essential role in the tricarboxylic acid cycle. Actively dividing cells that have a high oxidative energy requirement are most susceptible to the effects of arsenicals.

Arsenites induce vasodilation and can cause capillary damage. The cellular integrity of the capillary is affected by an unknown mechanism. Evidence of vascular instability is seen by the presence of congestion, edema, and hemorrhage in most of the visceral organs of animal with acute poisoning. This same mechanism of action occurs with inorganic arsenicals and with organic trivalent arsenicals, and they may be considered as "vascular poisons" (Hann and McHugo, 1960; Agency for Toxic Substances and Disease Registry, 1990; Jubb and Huxtable, 1993).

Arsenates (+5) are a little different. They are uncouplers of oxidative phosphorylation. The inorganic pentavalents may substitute of phosphate in this reaction. The result is an increase in body temperature. Organic pentavalents have an unknown mechanism of action. There is some thought that they may interfere with vitamins B6 and B1, which may allow for the demyelination and subsequent axonal degeneration that occurs.

Although arsenicals have been classified as carcinogens in people, this has not been the case in animals. Experimentally there have attempts to document arsenic-related

cancer in animals but the experiments have been unsuccessful (Agency for Toxic Substances and Disease Registry, 1990; Chan and Huff, 1997).

## TOXICITY

Inorganic arsenicals are up to 10 times more toxic than pentavalent arsenicals. The order of toxicity from greatest to least follows this schematic: inorganic $As^{+3}$ (arsenite) > inorganic $As^{+5}$ (arsenate) > trivalent organics > pentavalent organics ($I\,As^{+3} > I\,As^{+5} > O\,As^{+3} > O\,As^{+5}$). In other metal toxicities, the organics are more toxic but with arsenicals the inorganics are the more toxic.

Toxicity is also influenced by many factors, including particle size. The more finely ground, the more surface area there is for reactions. Solutions, such as dips and defoliants are the most dangerous. However the causes of the poisonings are varied. Debilitated animals are more sensitive. Since arsenic is not biodegradable, the soil and the old corrals around old dipping vats are still a source for arsenic poisoning. The area around smelters are also a source of poisoning, similar to that of dipping vats. Human mistakes and carelessness are the largest contributing factors to toxic events. For example, feeding a product known as gin trash instead of cotton seed hulls has resulted in acts numerous animals being poisoned.

Clinical sings caused by either inorganic or trivalent aliphatic arsenicals are similar. Peracute toxicities often result in sudden death within minutes to a few hours, if the dose is high, of dissolved arsenic ingestion. Acute poisonings have more clinical signs: abdominal pain or colic, vomiting, a staggering gait and weakness, clear incoordination, rapid weak pulse and shock, diarrhea, followed collapse, and death. If the acute poisoning is through dermal contact, then the arsenic will also be systemic. The skin will have blisters, edema, and may be cracked and bleeding, leaving the skin susceptible for secondary infection (National Academy of Science, 1977; Evinger and Blakemaore, 1984) Those receiving a lower dose over a period of time may have subacute poisonings will likely live several days, developing depression and anorexia. Movements may be difficult, stiff, and incoordinated. Diarrhea is dark and possibly hemorrhagic and very fluid. Hematuria may be present, or the urine may contain protein and casts (National Academy of Science, 1977; Osweiler *et al*., 1985). However, those suffering chronic poisoning are easily fatigued and have dyspnea when they are moved. These animals display intense thirst and have a rough dry hair coat as well as dry, brick-red mucous membranes. Cattle are described as having enlarged joints.

Clinical signs of phenylarsenic poisoning occur within 3 days of a high dose or after chronic exposure. Most noticeable are the neurological signs. The animal is generally bright and alert but uncoordinated. The animal may or may not be blind, and these animals may have erythema in the skin. Some of the neurological damage may be reversible unless the nerves are damaged.

Lesions are often dependent upon the dose and survival times. There may be no lesions at all in animals that die from peracute poisoning. However, even these animals have some GI irritation. With the exception of peracute deaths, most of the other animals that die from some form of arsenic poisoning may have excess fluid in the GI tract. In cattle there is hyperemia of the abomasum and this may be the only finding. If there are other lesions in cattle, it is often necrosis of the rumen mucosal epithelium. Ruminants have gelatinous serosal edema in the rumen, reticulum, omasum, and abomasum. The GI tract may have indication of irritation and be hemorrhagic. Lesions are indicative of capillary damage and the liver is usually soft and yellow.

The phenylarsonics (+5) are used in feed additives and lesions would be expected to be associated with overdoses in the feed mixture. A "downer pig" may have severe abrasions with muscle atrophy. Microscopic lesions indicate there is demyelination in the optic nerve and the posterior cord.

## TREATMENT

A diagnosis of arsenic poisoning is important and is based upon clinical history and signs. If more than one animal is involved, then lesions may also be important. Diagnostic arsenic levels in the kidney and liver are usually more than 8–10 parts per million (ppm), unless several days have lapsed since exposure, in which case it would likely be 2–4 ppm. Diagnostic levels of arsenic in the urine and feces are greater between 10 and 20 ppm. Arsenic should not be found in phenylarsonic acid intoxications.

Arsenic can poison to large and small animals. If small animals are not showing clinical signs then evacuation of the stomach followed by lavage with 1% of sodium bicarbonate solution is recommended treatment. As a general rule early treatment, within 4 h of exposure is best. In carnivorous small animals, emetics followed by gastric lavage is the best treatment. The lavage may be milk and egg whites or with 1–5 g of sodium thiosulfate. In herbivores treatment within 4 h of exposure is also best. A large saline purgative is effective, demulcents, 20–30 g of sodium thiosulfate orally followed by a 10% solution 3 times a day for the next several days.

Regardless of the carnivore or herbivore if treatment is more than 4 h after exposure, then dimercaprol (British anti-Lewisite, BAL) is recommended at 1.5–5 mg/kg,

intramuscularly, 2–4 times a day for 10 days or until recovery should be administered. Additionally, sodium thiosulfate at 30–40 mg/kg administered intravenously 2–4 times daily until recovery, which if recovery occurs will be within 2–4 days.

If the diagnosis is a phenylarsenic compound, there is no effective treatment for nerve damage caused by these compounds. BAL is not effective for these intoxications.

## CONCLUSION

Determining the diagnosis early and initiating treatment early will determine the prognosis. Acutely poisoned animals have a poor prognosis without early intervention. Understanding the differentials is important to institute the appropriate treatment for the appropriate condition. Arsenic produces signs of severe gastroenteritis, similar to those of pancreatitis, viral or bacterial gastroenteritis, irritating plants, caustic agents, and zinc phosphide poisoning. Likewise, other heavy metals will produce similar clinical signs. However, poisoning with phenylarsonics, used most frequently in feed additives, have a high morbidity rate but are associated with a low mortality rate. Recovery generally requires 2–4 weeks.

CHAPTER

# 27

# Cadmium

*Stephen B. Hooser*

## INTRODUCTION

Cadmium accumulation in plants and animals is increasing from several sources of environmental exposure. The application of rock phosphate (which contains varying amounts of cadmium depending on the source) and sewage sludge fertilizers results in cadmium deposition in the soil of pastures (Piscator, 1985; ATSDR, 1999). In addition to direct ingestion of soil containing cadmium, some forage plants extract cadmium from the soil. Although cadmium accumulation in the soft tissues of livestock has been demonstrated and there is ample experimental documentation of the toxicity of cadmium in animals, under natural conditions, documented cases of direct toxic or carcinogenic effects of cadmium in livestock have been uncommon (Dorn, 1979).

## BACKGROUND

Pure cadmium is a soft, silver-white metal with an atomic number of 48 and a molecular weight of 112.41. It is a divalent transition metal with chemical properties that are similar to zinc and is usually found as a mineral in combination with other elements to form cadmium oxide, cadmium chloride, or cadmium sulfate (ATSDR, 1999). Numerous compounds are formed from cadmium and thus it is used in batteries, solders, semiconductors, solar cells, plastics stabilizers, and to plate iron and steel. All soil and rocks contain some cadmium. It can enter the environment from zinc smelting and refining, coal combustion, mine wastes, iron and steel production, and from the use of rock phosphate and sewage sludge as fertilizers (Klasing, 2005).

Cadmium accumulation in plants and animals is increasing from a variety of sources, being the most severe in the vicinity of zinc smelters. The use of cadmium-containing mineral supplements in feed (e.g. from calcium phosphate), the application on pastures and hay fields of phosphate fertilizers (which contain varying amounts of cadmium depending on the source) and sewage sludge results in cadmium deposition in the soil (Piscator, 1985). Some plants readily extract cadmium from the soil thereby making it available for consumption. For example, cadmium concentrations in clover grown in soil fertilized with high cadmium rock phosphate were significantly higher than the concentrations in clover grown in soils treated with low cadmium phosphate fertilizer (McLaughlin *et al.*, 1997). A New Zealand National Survey of soils and plants, and random testing of kidneys from grazing animals revealed that there was an approximately two-fold increase in soil cadmium while over a 3-year period, 14–20% of cattle kidneys exceeded the New Zealand maximum residue level of 1 μg Cd/g (Roberts *et al.*, 1994). In a study where cattle were allowed to graze pastures treated with anaerobically digested sewage sludge for up to 8 years, cadmium was the only metal to accumulate consistently in increased amounts in the tissues of the cattle (Fitzgerald *et al.*, 1985). It has been reported that cattle grazing on sewage sludge treated pastures consumed significantly more (up to 3 times) cadmium than cattle on control pastures (Reddy and Dorn, 1985). In addition, a Swedish study has found a direct correlation between cadmium in feed and pig kidneys (Grawe *et al.*, 1997). A recent study reporting the analysis of Wisconsin dairy feeds for heavy metals found that cadmium concentrations in complete dairy feed rations were the closest of the heavy metals to US maximum acceptable concentrations, suggesting that cadmium has the greatest potential to exceed those maximum standards if the amounts of

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

cadmium in feeds increases in the future (Li *et al.*, 2005). However, several studies have failed to demonstrate any adverse clinical manifestations related to increased cadmium concentrations in the animals examined. In one study, although cattle on pasture fertilized with sewage sludge consumed increased amounts of cadmium and had increased fecal excretion and kidney accumulation of cadmium (Reddy *et al.*, 1985), there were no adverse health effects noted in these cattle (Dorn *et al.*, 1985). Similarly, when corn silage or corn that was grown on sewage sludge fertilized fields were fed to sheep or pigs, respectively, significant increases in kidney cadmium concentrations were measured, but no other adverse treatment-related effects were noted (Lisk *et al.*, 1982; Telford *et al.*, 1982). Although cadmium is of concern in the environment, and cattle grazing on cadmium-contaminated pastures have increased tissue concentrations of cadmium, two additional studies conclude that accumulation of cadmium in the liver and kidneys of cattle may be a moderately effective screen for the entry of cadmium into the human food chain, as long as liver and especially kidneys are not consumed (Sharma and Street, 1980; Johnson *et al.*, 1981). It has been reported that regardless of the concentrations of cadmium fed to livestock, the amount in meat, milk, and eggs is always lower than that in the diet that the animal was eating. Thus, foods derived from those products decrease human exposure (Klasing, 2005). This is fortunate as chronic cadmium poisoning has been documented in humans. In these cases, it has been associated with osteoporosis, renal lesions, tissue mineral imbalances, and death. In addition, the Department of Health and Human Services has determined that cadmium and cadmium compounds may be reasonably anticipated to be carcinogens.

## PHARMACOKINETICS/ TOXICOKINETICS

In animals, cadmium exposure is primarily through oral ingestion. Compared to other divalent cations such as zinc and iron, intestinal absorption of cadmium is relatively low, ranging from approximately 1% to 5% in most species, with up to as much as 16% in cattle, dependent on the dose (Klasing, 2005). Interestingly, cadmium bound to metallothionein in foods of animal origin is absorbed less efficiently than cadmium salts and therefore, may be less available for uptake (Groten *et al.*, 1990). After absorption, cadmium is transported in the plasma bound to albumin and in lesser amounts to other serum proteins. It distributes throughout the body with the highest concentrations in the liver and kidneys, which account for approximately one-half of the total cadmium in the body. Muscle and bone do not accumulate high concentrations of cadmium. Blood cadmium concentrations are indicators of recent exposure while urine cadmium is a better indicator of the body burden. Cadmium is not transported well into milk or eggs, or across the placental barrier (Klasing, 2005). In pregnant and lactating livestock, the toxicokinetics of cadmium have been compared. In this study, the kinetics of cadmium were measured in lactating versus non-lactating ewes after a single intravenous or oral administration of cadmium chloride. The non-lactating ewes exhibited a low cadmium bioavailability (0.12–0.22%), a large steady-state volume of distribution (23.8 ± 5.41/kg), and a low blood clearance (0.20 ± 0.031/kg/day) with a mean residence time of 113 ± 28 days. The lactating ewes had a higher bioavailability (0.33–1.7%), and the mean residence time was close to that of the non-lactating ewes despite a greater blood clearance (0.46 ± 0.0131/kg/day) because the volume of distribution of cadmium in the body was larger. The cadmium clearance in milk remained low in the lactating ewes (Houpert *et al.*, 1997).

In the body, cadmium is excreted very slowly, with daily losses of approximately 0.009% of the total via the urine and approximately 0.007% in the feces via the bile. Cadmium–protein complexes are excreted in the kidneys and then resorbed from the filtrate in the proximal tubules. This area of the renal cortex accumulates cadmium and is susceptible to damage and necrosis. Depending on the species, the biological half-life of cadmium can vary from months to years, which results in cadmium accumulating in animals as they age (Klasing, 2005). For example, several studies have documented age-related increases in cadmium in the kidneys of horses (Elinder *et al.*, 1981a; Anke *et al.*, 1989).

In mammals and birds, cadmium accumulates in the liver and kidneys at concentrations of 0.1–2.0 and 1–10 mg/kg wet weight, respectively. It has been discovered that animals with long-life spans, such as horses, can accumulate large amounts of cadmium in their organs, particularly in their kidneys. In samples of renal cortex from old horses, concentrations of up to 200 mg/kg have been reported (Elinder, 1992).

## MECHANISM OF ACTION

Experimentally, acute exposure to high doses of inorganic cadmium leads to its accumulation in many organs, eliciting liver and in some cases, testicular damage (Dixit *et al.*, 1975; Habeebu *et al.*, 1998; Klasing, 2005). Once inside the cell, free cadmium binds to protein sulfhydryl groups, disrupting the cellular redox cycle, depleting glutathione, and eliciting intracellular oxidant damage. In addition, its similarity to other divalent cations such as calcium interferes with their normal functioning (Klasing, 2005). Cadmium ions can displace zinc and other divalent metals from their

binding sites on metalloproteins. For example, in the testis, cadmium can interfere with zinc-proteins, leading to widespread apoptosis and necrosis (Xu *et al.*, 1999). In the liver, acute cadmium toxicity results in widespread hepatocyte apoptosis, followed by varying degrees of necrosis depending on the dose (Habeebu *et al.*, 1998). This is related, in part, to the effects of resident liver macrophages (Kupffer cells) to potentiate and increase the initial liver damage caused by cadmium alone. This has been demonstrated in several systems in which inhibition of Kupffer cells significantly decreases liver damage caused by a toxic dose of cadmium (Sauer *et al.*, 1997a, b).

Cadmium readily binds to, and induces the production of, metallothionein, a cysteine-rich, metal-binding protein. Binding to metallothionein does not have a major effect on the uptake of cadmium, but is, in part, responsible for retention of cadmium within cells and its long half-life (greater than 10 years in humans). Metallothionein does this by decreasing cadmium elimination, especially in bile. Within hepatocytes, metallothionein binds to cadmium, decreasing its hepatotoxicity. Experimentally, rats that have greater induction of metallothionein in the liver are somewhat protected from cadmium hepatotoxicity (Kuester *et al.*, 2002). However, in the kidneys the cadmium–metallothionein complex is nephrotoxic and it has been theorized that it may play a role in chronic poisoning in humans (Klaassen and Liu, 1997).

## TOXICITY

Increased exposure to cadmium in combination with zinc, lead, and/or other metals continues to occur in the vicinity of non-ferrous metal smelters and processing facilities. These exposures have resulted in toxicoses, although it can be difficult to separate the effects of cadmium from those of lead, zinc, and other metals. In one such case in the Netherlands, kidney cadmium concentrations were found to be twice those of cattle in control areas. However, although hemoglobin, blood iron concentrations, and iron-binding capacity were lower in the cadmium-exposed cattle compared to controls, no adverse clinical effects were observed (Wentink *et al.*, 1992). In an additional study in the Netherlands, bulls fed diets containing increased concentrations of cadmium, lead, mercury, and arsenic had increased concentrations of cadmium in the kidney and liver, but did not exhibit histological lesions related to the intake of heavy metals (Vreman *et al.*, 1988). However, more recently, deaths in horses exposed to cadmium, lead, and zinc from a non-ferrous metal processing plant in Eastern Europe were attributed to ingestion of these metals in their feed. Analysis of tissues from a number of these horses revealed extremely high concentrations of cadmium (40–100 times normal) and 3–6 times the normal concentrations of lead (Bianu and Nica, 2004). Toxicoses have also been reported in sheep and horses in the vicinity of non-ferrous metal smelters in China. Analysis of the tissues from these animals revealed lead and cadmium concentrations significantly higher than those of controls (Liu, 2003).

A survey of cadmium concentrations in tissues from healthy swine, cattle, dogs, and horses in the midwestern United States was conducted in the mid-1970s. While the median cadmium concentration was low, at or below 0.6 ppm in the kidneys of cattle, swine, and dogs, the median concentration in the kidneys was 4 times greater in horses (Penumarthy *et al.*, 1980). One study has indicated that horses may be more at risk for cadmium toxicity than other species. In this Swedish study, the cadmium concentrations in the kidney cortices of 69 otherwise normal horses were measured and correlated to any histological lesions that were noted. In that study, renal cadmium concentrations ranged from 11 to 186 μg Cd/g wet wt., with an average of 60 μg Cd/g. This study found a correlation between increased chronic interstitial nephritis and increasing cadmium concentrations in the renal cortex. There was no obvious relationship between the age and the frequency of renal lesions (Elinder *et al.*, 1981a). These same authors also found that cadmium concentrations in the kidney cortices were approximately 15 times greater than those in the liver of the same animals (Elinder *et al.*, 1981b). Age-dependent increases in kidney metallothionein and cadmium have also been reported in horses (Elinder *et al.*, 1981a; Jeffrey *et al.*, 1989; Plumlee *et al.*, 1996). However, these later studies and others (Holterman *et al.*, 1984) have not reported renal lesions similar to those reported by Elinder *et al.* (1981a). One diagnostic investigation has reported lameness and swollen joints, i.e lesions of osteochondrosis, in addition to osteoporosis and nephrocalcinosis in horses near a zinc smelter in Pennsylvania. In the horses examined, kidney zinc and cadmium concentrations were elevated. It this case, it was postulated that the osteoporosis that was observed in one foal and the nephrocalcinosis seen in the foal and its dam were related to the elevated renal cadmium (Gunson *et al.*, 1982). When ponies were raised near a similar zinc smelter for periods of time up to 18.5 months, there were significant elevations in tissue zinc and cadmium concentrations. Increases in tissue cadmium concentrations were correlated with increasing age, although increases in tissue zinc concentrations were not. Generalized osteochondrosis was present in joints of the limbs and cervical vertebrae, and there was lymphoid hyperplasia. From this study, it was concluded that the development of osteochondrosis was associated with increased exposure to zinc and possibly cadmium. However, other lesions of cadmium toxicosis, such as renal damage or osteomalacia, were not present (Kowalczyk *et al.*, 1986).

In wildlife, white-tailed deer (*Odocoileus virginianius*) harvested within 20 km of zinc smelters in Pennsylvania had very high kidney concentrations of cadmium and zinc. These deer were also reported to have had joint lesions similar to zinc-poisoned horses from the same area (Sileo and Beyer, 1985).

In humans, occupational exposure to cadmium has been associated with renal dysfunction and osteomalacia with osteoporosis. One of the earliest effects of chronic cadmium exposure is renal tubular damage with proteinuria (Bernard *et al*., 1992). Other chronic effects can include liver damage, emphysema (through inhalation), osteomalacia, neurological impairment, testicular, pancreatic, adrenal damage, and anemia. Tumorigenic effects have been reported in experimental animals (Lee and White, 1980). Historically in the 1940s, high environmental exposure in one area of Japan from eating cadmium-contaminated rice resulted in itai-itai (ouch-ouch) disease. This was manifested by intense bone pains and pathological bone fractures, mainly in elderly women, with osteoporosis and renal dysfunction (Kobayashi, 1978). In addition, studies in Europe and China have demonstrated that low to moderate exposure to cadmium from zinc smelters resulted in a decrease in bone density, and an increase in fractures in women. In one of these studies, cadmium concentrations in the blood and urine were taken as biomarkers of exposure (Katzantzis, 2004). Experimental studies in animals have confirmed the adverse effects of cadmium on bones. Six mechanisms have been theorized to explain these effects: (1) interference with parathyroid hormone stimulation of vitamin D production in the kidney, (2) reduced renal vitamin D activation, (3) increased urinary excretion of calcium, (4) reduced intestinal calcium absorption, (5) interference with calcium deposition in bones, and (6) interference with bone collagen production (Kjellstrom, 1992).

## TREATMENT

In animals, cadmium toxicosis is prevented by minimizing exposure in the environment and in feedstuffs.

## CONCLUDING REMARKS/FUTURE DIRECTIONS

Although toxicoses in domestic animals are uncommon, exposure is gradually increasing especially in grazing animals. Since chronic cadmium toxicity is of concern to humans, continued close observation and analysis of cadmium in animals is indicated to provide a system for environmental cadmium surveillance.

CHAPTER

# 28

# Copper

*Larry J. Thompson*

## INTRODUCTION

Copper is a transition group metal with high electrical and thermal conductivity. The chemical abbreviation for copper is Cu, which comes from the Latin word, cuprum, which refers to the island of Cyprus, known in the ancient times for large deposits of copper ore. The Bronze Age followed the discovery that adding tin (and other metals) to copper made the resulting metal alloy much more durable. Copper has been shown to be an essential element for both animals and plants but can be toxic under certain conditions. This chapter describes the toxicity and deficiency of copper in animals.

## BACKGROUND

Toxic insults from copper occur in two main categories, acute and chronic. The acute overexposure of animals to copper can occur by both oral and parenteral routes (Galey, *et al.*, 1991) but is relatively uncommon. Sheep are very susceptible to chronic copper poisoning, where even a slight excess of copper in the diet can build up over weeks or months to cause problems. Cattle and other ruminants are less likely to suffer from chronic mild to moderate copper excesses in the diet but can be affected by relatively high levels (Gummow, 1996). Monogastric animals seem to tolerate excess dietary copper much better than ruminants and high dietary copper additions (up to 250 ppm) have been used for growth promotant effects, such as in pigs and poultry. Finally, certain breeds of dogs (e.g. Bedlington terriers) have a genetic predisposition for liver copper accumulation similar to Wilson's Disease in humans (Taboada and Thompson, 1997). Each of these may have a different clinical presentation with the main target organs for acute copper exposure generally being the gastrointestinal tract, liver and kidney with the target organs for chronic problems being the liver, red blood cells and kidney.

Dietary sources of copper include normal plant concentrations of copper, with forages and cereal grains usually containing less than 10 ppm copper on a dry matter (DM) basis. Some oilseed meals can contain up to 35 ppm copper in DM. By far the largest source of copper in the diet will be feed additives such as copper sulfate, copper chloride and copper oxide. Additional sources of copper for the animal may be chelated copper sources in the diet or the administration of boluses containing copper metal wires or other solid forms of copper that remain in the rumen/reticulum and slowly dissolve over time. Misformulation of rations or errors in the mixing of feed can result in high concentrations of copper. Problems can arise from the use of feed formulated for a copper-tolerant species when used for a copper-sensitive species such as sheep, or the use of trace mineralized salt in sheep diets. Other sources for large acute oral copper exposures would include copper sulfate foot baths and copper algaecides or fungicides. Most water sources have low copper concentrations but the use of copper piping with slightly acidic water can result in additional copper being dissolved.

## PHARMACOKINETICS

Copper is primarily absorbed in the small intestine and transported in the blood by transcuprein and albumin, which serve to reduce the oxidative effects of divalent copper. In the liver, copper can be stored in the lysosomes,

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

excreted in the bile or incorporated into ceruloplasmin for use and transport to cells in other parts of the body. Biliary excretion is the major mechanism responsible for copper homeostasis and identified genetic disorders of copper accumulation are due to impaired biliary excretion. Copper is utilized by essentially every cell in the body and there are several important copper-dependent enzymes including cytochrome C oxidase, superoxide dismutase, lysyl oxidase and dopamine beta hydroxylase.

In the ruminant, copper has a complex interrelationship with dietary molybdenum and sulfur which, when present in excess, will both decrease copper absorption and inhibit copper utilization. In the reducing environment of the rumen, excess sulfur favors the formation of sulfides which can inhibit copper absorption from the gastrointestinal tract. Additionally, the formation of tri- and tetrathiomolybdates can also inhibit the absorption of copper or, if in high amounts, can cause systemic effects by holding copper in a non-biologically available form (NRC, 2005).

## MECHANISM OF ACTION

Acute exposure to excess copper causes gastrointestinal irritation and can cause erosions of the mucosa as well as a blue-green discoloration of the contents and wall. Normally, the free copper concentration in cells is kept very low by copper-binding proteins such as metallothionein, glutathione and copper chaperone proteins. An excess of copper can overwhelm these binding proteins and allow free copper ions to exist in the cell which can directly bind proteins and nucleic acids. Additionally, the free copper can form reactive oxygen species and hydroxyl radicals, causing lipid peroxidation of membranes and damage to nucleic acids and cellular proteins (NRC, 2005).

Chronic copper toxicosis in sheep is caused by the inability of the sheep to increase the biliary excretion of copper in response to dietary increases. Copper will then accumulate in the liver but during this accumulation phase there will be little or no evidence of negative effects (Bremner, 1998). If accumulation continues, the liver can suffer direct damage from the high concentrations of copper. When damage is severe, hepatic necrosis develops and copper is released into the bloodstream. Additionally, stress to the animal can also accentuate this mobilization of copper from the liver and into the bloodstream. Increasing copper concentrations in the bloodstream will overwhelm the protective transport actions of transcuprein and albumin, which can then result in the lysis of red blood cells due to the oxidation of the red blood cell membrane by ionic copper. As copper is mobilized from the liver, it can accumulate in the kidney. The kidney can be damaged both from the accumulation of copper as well as the direct toxic effects of hemoglobin following the hemolytic event. Cattle can also be affected by chronic copper toxicosis, with a strong suspicion of breed differences (Du *et al.*, 1996) but with hemolysis occurring with less frequency than in sheep.

Chronic copper toxicosis in dogs is primarily seen in the Bedlington terrier where genetic studies have shown it to be an autosomal recessive disorder (Forman *et al.*, 2005). Other breeds including West Highland White terriers, Skye terriers and Doberman pinscher (Speeti *et al.*, 1998) have breed related hepatic copper accumulation, the origin of which is less defined. Chronic copper toxicosis in dogs will also have a period of copper accumulation without clinical signs or detectable damage to the liver. As copper concentrations increase, the animal develops a chronic active hepatitis with necrosis and inflammation. As with sheep, excess free copper damages many cellular components of the liver, including the lipid peroxidation of mitochondrial membranes. A sudden release of copper with the resulting hemolytic crisis is much less likely to occur in dogs. The disease usually appears at 2–6 years of age, with animals often showing no problems before this time.

## TOXICITY

There is a paucity of information on the amount of copper needed for acute poisoning in various species, but the general range is given as 25–50 mg/kg of body weight. Copper sulfate is most often implicated in clinical cases as the copper source. The toxic dose of copper sulfate in cattle is 200– 800 mg/kg, with sheep more sensitive at 20–100 mg/kg. Affected animals show clinical signs of salivation, gastroenteritis and abdominal pain which may rapidly develop to dehydration, shock and death. Animals that survive longer than 24–48 h develop liver and kidney damage and the animal may have an acute hemolytic crisis. Postmortem findings include gastroenteritis and a blue-green discoloration to the gastrointestinal tract and contents. Varying degrees of liver and kidney lesions are present, with milder lesions in acute deaths and more dramatic lesions developing after 48 h. Diagnostic testing of the intestinal tract contents shows a high level of copper. In acute deaths, there are normal levels of copper in the liver and kidney. If the animal survives over 24 h, elevated copper levels are found in liver and kidney.

In sheep, even normal levels of copper in feeds (10–20 ppm) can cause hepatic copper accumulation when the molybdenum level in feed is low (less than 1 ppm). As the copper-to-molybdenum ratio (Cu:Mo) increases above 6:1, the risk of copper accumulation increases, with those diets whose ratio is above 20:1 being very dangerous for sheep. At the higher Cu:Mo ratios, toxic accumulation of copper in the liver can occur over a matter of weeks. In

affected animals, there may be an acute hemolytic crisis and the animals show clinical signs of weakness, anorexia, icterus, dyspnea and pale mucous membranes. There may be hemoglobinuria and death is common amongst severely affected animals. Postmortem findings include icterus, swollen liver, enlarged spleen and the kidneys appear dark, often referred to as gunmetal blue or black kidneys. Antemortem testing of serum copper often shows an elevation above normal, but this decreases over time with a rapid decrease following fluid therapy. Postmortem diagnostic testing for copper should be performed on both liver and kidney. Mobilization of copper from the liver may reduce copper concentrations to normal levels but the mobilized copper is then accumulated in the kidney. The ration should be tested for both copper and molybdenum. The close environment of the sheep should be inspected for extraneous sources of copper.

Young dogs with genetic susceptibility to chronic copper toxicosis may develop an acute syndrome of weakness, vomiting and anorexia. Older dogs may present with a more chronic syndrome of weight loss and anorexia, which may progress to ascites and neurological signs related to a developing hepatic encephalopathy. If untreated, the animal may succumb to liver dysfunction and postmortem findings may include a cirrhotic liver. Antemortem diagnostics would include an evaluation of liver enzymes. In suspect cases, a liver biopsy should be used to confirm elevated copper content (Taboada and Thompson, 1997).

## TREATMENT

Treatment of animals acutely poisoned with copper mainly consists of supportive treatment directed at the shock, dehydration and damage to the gastrointestinal tract.

Treatment of sheep with severe clinical signs following hemolytic crisis is often unrewarding. Supportive care should include fluid therapy and the consideration of a blood transfusion. Ammonium or sodium molybdate (50–500 mg) and sodium thiosulfate (0.3–1 g) should be used daily as a drench for up to 3 weeks not only in affected animals but also in other animals that have received the same diet. Ammonium tetrathiomolybdate has been suggested as a treatment but is difficult to obtain. It can be administered IV or SQ at 1.7–3.4 mg/kg on alternate days for three treatments. Molybdenum in the diet can be increased to 5 ppm and zinc can be supplemented at 100 ppm to reduce copper absorption.

Dogs affected with chronic copper toxicosis should be fed a low copper diet, e.g. avoiding organs meats which are usually higher in copper. The use of oral chelating agents is suggested to enhance urinary excretion of copper. The use of d-penicillamine at 10–15 mg/kg PO twice daily or the use of trientine hydrochloride at 10–15 mg/kg PO twice daily have been suggested. Liver enzymes should be monitored every 6 months and consideration be given to liver biopsy to assess liver copper concentrations. The addition of elemental zinc to the diet (100–200 mg/day as the acetate) should be considered to reduce copper absorption.

## CONCLUSION

In trace amounts, copper is an essential element, but in excess it is a toxicant. In general, sheep and certain breeds of dogs are more susceptible to copper poisoning. Copper produces toxicity by multiple mechanisms. Poisoned animals are usually treated with ammonium molybdate and sodium thiosulfate. In addition, supportive care including fluid therapy and blood transfusion are beneficial.

CHAPTER

# 29

# Fluoride

*Larry J. Thompson*

## INTRODUCTION

Fluorine is a member of the halogen group on the periodic table and is rarely found in elemental form in nature but instead exists as fluoride, the monovalent anion, combined with other elements. The most common mineral containing fluoride is fluorspar, also known as fluorite ($CaF_2$), and soils generally contain calcium fluoride ($CaF_2$). Although now rare, sodium fluoride and sodium fluorosilicate ($Na_2SiF_6$) had been used as insecticides and anthelminthics. Sodium fluoroacetate (compound 1080) is another formerly used rodenticide that is rarely seen in the United States today but may be found in other parts of the world (e.g. Australia). Fluoroacetate can also be found naturally in several species of plants. (*Gastrolobium* spp., *Oxylobium* spp. and others.) Sodium fluoride, sodium fluorosilicate and fluorosilicic acid have been used in the United States for the fluoridation of drinking water for humans to prevent the development of dental caries (CDC, 2001). When the gas hydrogen fluoride (HF) is dissolved in water it forms hydrofluoric acid, a very hazardous chemical that has industrial and laboratory uses such as purifying metals, etching glass and cleaning semiconductors due to its ability to dissolve silicates and metal oxides. This chapter will stress the chronic effects of fluoride excess, also called fluorosis or fluoride toxicosis, in large animals.

## BACKGROUND

Fluoride is present at low levels in virtually all feed and water sources, thus animals will have continuing exposure throughout their lifetime. While a small amount of fluoride in the diet has been shown to improve bone and teeth development, a chronic excess of fluoride can have adverse effects on teeth, bone and other body systems. Large animals have been exposed to excess fluorides through the ingestion of high-fluoride rock phosphates used as nutritional supplements, by the ingestion of forages contaminated with excess fluorides from industrial pollutants or volcanic emissions, or through water containing excess fluorides from industrial pollution or dissolved from natural sources (Shupe and Olson, 1971, 1983). Rock phosphates destined for animal diets must be defluorinated before use or have a phosphorus to fluorine ratio (P:F) of more than 100:1 in order to avoid exposing the animal to excess fluoride (Osweiler, 2004). Following a long history of problems, industrial contamination of forages and water with excess fluoride has decreased due to recognition of the problems caused by excess fluoride and increased regulatory controls on fluoride-emitting industries. Historical point sources for fluoride emissions have included the smelting industries (e.g. aluminum, copper and steel), brick or ceramic product factories, coal-fired power plants and the phosphate-processing industries. Plant uptake of fluoride by translocation from the soil is usually not an important source of fluoride for grazing animals. Much more significant sources include airborne fluoride that settles on plant surfaces and fluoride from soil that is ingested directly or contaminates the plant (NRC, 2005). Acute fluoride poisoning in large animals is rare but can occur following exposure to fluoride containing commercial products (Bischoff *et al*., 1999) or to ash and tephra following volcanic eruptions (Shanks, 1997).

## PHARMACOKINETICS AND MECHANISM OF ACTION

Sodium fluoride is readily absorbed from the digestive tract and is several times more biologically available than fluoride compounds from feed or environmental sources. Fluoride is distributed to all parts of the body with approximately 50% of absorbed fluoride being excreted by the kidneys. The remainder will be incorporated into bone and teeth with very little accumulation in the soft tissue. Fluoride concentrations in the blood, urine and soft tissues may reflect recent ingestions but will also increase slowly over time with continuing excess fluoride exposure and accumulation in the bone. Greater than 95% of the body burden of fluoride will be contained in the bones with bone levels dependent upon the amount of fluoride ingested, duration of exposure, bioavailability, species, age and diet of the animal involved. If dietary fluoride exposure decreases, bone fluoride levels will decrease slowly over a long period of time. In cattle there appears to be a partial placental barrier to the movement of fluoride to the fetus as even high levels of fluoride in the diet of the dam did not adversely affect the health of the calves, even though higher fetal blood and bone fluoride concentrations resulted (NRC, 2005). Fluoride is excreted in the milk but this does not appear to be a significant source for the neonate.

The major adverse effects of chronic excess fluoride ingestion concern the teeth and bones of affected animals. Fluoride substitutes for hydroxyl groups in the hydroxyapatite of the bone matrix which alters the mineralization and crystal structure of the bone. Bone changes induced by excess fluoride ingestion, termed skeletal fluorosis or osteofluorosis, include the interference of the normal sequences of osteogenesis and bone remodeling with the resulting production of abnormal bone or the resorption of normal bone. The fluoride content of bone can increase over a period of time without other noticeable changes in the bone structure or function. Once lesions start to develop, they are usually bilateral and symmetric. The most consistent gross changes are abnormal bone formation on the periosteal surface with thickening of the cortex. In cattle, earliest clinical changes usually occur on the ribs and mandible as well as the medial surfaces of the metatarsal and metacarpal bones. Histologically, bones will have abnormal remodeling and mineralization with irregular collagenous fibers and excess osteoid tissues. While an excess of ingested fluorides can adversely affect the bones at any time in the animal's life, the bones in younger animals are more responsive to the excess fluoride.

Dental fluorosis develops when the period of excess fluoride intake occurs during the period of tooth development, in cattle this will generally be before 30–36 months of age. Teeth are affected during development with damage to ameloblasts and odontoblasts and the resulting abnormal matrix unable to mineralize normally (Shearer *et al.*, 1978). Both enamel and dentine are adversely affected. Affected teeth may erupt with mottling (alternating white opaque horizontal areas or striations in the enamel), hypoplasia, dysplasia (abnormal soft dull white chalky enamel or horizontal zones of constriction), erosion or pitting of enamel and affected teeth are prone to excessive abrasion and discoloration.

Acute fluoride toxicosis occurs when soluble forms of fluoride (e.g. sodium fluoride) are ingested in large doses. Absorption is rapid and clinical signs can appear within 30–60 min following ingestion. Although the exact mechanism of action is not known with certainty, fluoride concentrations in blood and soft tissues rapidly increase which leads to hypocalcemia. Sudden death from acute fluoride exposure is thought to involve the development of hyperkalemia or diminished $Na^+/K^+$-ATPas activity and the inhibition of glycolysis (NRC, 2005).

## TOXICITY

There are a number of factors that influence the amount of fluoride required to produce specific lesions and clinical signs including the amount of fluoride ingested, duration of exposure, bioavailability, species, age and diet of the animal involved. The point where fluoride ingestion becomes detrimental to the animal also varies from animal to animal. Clinical signs develop slowly and can be confused with other chronic problems. Animals often show non-specific intermittent stiffness and lameness, which appear to be associated with periosteal overgrowth leading to spurring and bridging near joints as well as ossification of ligaments, tendon sheaths and tendons. The clinical presentation may easily be confused with other conditions, such as degenerative arthritis, but the lesions associated with fluorosis are not primarily associated with articular surfaces. In severe cases, affected cattle may become progressively more lame and eventually may refuse to stand or may stand with rear legs upright and be on their knees to graze (Shupe and Olson, 1983). Lameness in cattle leads to abnormal hoof wear with elongated toes, especially in the rear legs. In long-term studies with cattle on varying levels of fluoride intake, skeletal neoplasms were not seen even in cattle with severe osteofluoritic lesions (Shupe *et al.*, 1992).

A great deal of effort has gone into the classification of dental lesions in cattle produced by excess fluoride ingestion. The incisor teeth are evaluated for enamel defects and abrasion pattern. The usual classification system ranges from a value of 0 for normal teeth to a value of 5 for severe fluoride effects (Shearer *et al.*, 1978; Shupe *et al.*,

1992). Because of the nature and complexity of the disease these dental lesion should not be the sole criterion for diagnosis. In general, severely affected teeth appear with brown or black discoloration, may have enamel defects and show increased wear including exposure of the pulp cavity, which causes pain while chewing roughage or swallowing extremely cold water. There will be a correlation between lesions on incisor teeth and those cheek teeth that form and mineralize at the same time. Cheek teeth that are abnormally worn cause improper mastication with roughage being difficult for the animal to utilize. The animal will have variable and decreased intake and the decreased production, slowed growth and general poor health associated with poor nutritional status. Animals with chronic exposure to excess fluorides have dry skin and hair coat.

Acute fluoride poisoning of cattle can result in clinical signs of depression, weakness and ataxia with postmortem findings of gastroenteritis (Bischoff *et al.*, 1999) and degenerative changes in the renal tubular epithelium.

## TREATMENT

Diagnosis of chronic fluoride toxicosis is based upon clinical signs, exposure history, dental lesions, evaluation of lameness and bony lesions and elevated urinary fluoride concentrations. Normal cattle urine contains less than 6 ppm fluoride. Animals having recent exposure or continuing release from fluorotic bone will have 15–20 ppm urinary fluoride (Osweiler, 2004). The biopsy of a rib or coccygeal vertebrae for fluoride analysis, as well as radiographic examination of teeth or bones, may also be helpful. A full postmortem examination should be performed, with attention to bone and teeth for both gross and histopathologic examination. Various bone samples should be submitted for fluoride analysis including metatarsal, metacarpal, rib, pelvis and mandible. Normal values for cattle are 400–1200 ppm fluoride on a dry, fat-free basis. Animals affected with chronic fluorosis can contain 3000–5000 ppm fluoride on a dry, fat-free basis. Analysis of feed, water or suspect material should also be included.

There is no specific antidote or treatment for chronic fluoride toxicosis. Sources of excess fluoride should be identified and removed from the diet. With reduction of dietary fluoride to background levels, mild to moderate bone changes may be reduced and normal bone laid down. Extensive bone lesions will not be remodeled to normal and teeth lesions are irreversible. Symptomatic and supportive care for animals with bone and teeth changes include providing high quality easily masticated feeds, limited grazing area and provisions to avoid cold or frozen water. For mild fluorotic changes, improving the diet and grazing may avoid excess wear on the teeth and reduce mastication problems.

# Iron

*Stephen B. Hooser*

## INTRODUCTION

Iron is an essential element necessary for animal and plant life. It works as an oxygen ($O_2$) carrier in hemoglobin/myoglobin and is involved in numerous biological oxidation–reduction reactions, including photosynthesis. Iron is present in cytochrome P450 and is crucial for the metabolism of many chemicals in the liver, kidney, and other organs. Deficiencies in iron can result in anemia. Excess iron can cause iron overload and organ damage, while oxidation of ferrous to ferric iron in hemoglobin results in methemoglobinemia and an inability of red blood cells (RBCs) to carry $O_2$. Consequently, because of its importance, the uptake, distribution, storage, and excretion of iron is very tightly regulated in animals under normal conditions. Because of its reactivity, free iron compounds are sequestered with proteins to ensure that they do not initiate intracellular oxidative damage through electron donation and the formation of reactive oxygen species (ROS) such as hydroxyl radical. In this chapter, we will deal primarily with clinical animal exposures to excess iron through ingestion, parenteral administration, or genetic iron storage abnormalities. Nutritional deficiencies or exposure to chemicals causing methemoglobin formation such as nitrates in ruminants, or nitrites and chlorates in all species are discussed elsewhere.

## BACKGROUND

Iron is very abundant in the universe and is the fourth most abundant element on earth. Its atomic number is 26 and its atomic weight is 55.847. It has been recognized to be an essential nutrient for more than 100 years and is present in all the cells of the body. The largest amount of iron is incorporated into the proteins hemoglobin and myoglobin. Within RBCs (erythrocytes), hemoglobin transports $O_2$ from the lungs to cells throughout the body, while myoglobin binds $O_2$ for use in muscle cells (Klasing, 2005). Iron present in the serum is bound to the protein transferrin, and in milk is bound to lactoferrin. Iron-containing proteins in the mitochondrial electron transport chain are essential for oxidative phosphorylation and energy production. Iron is also contained in enzymes of the Krebs cycle and in cytochromes P450 which are necessary for the metabolism of chemicals (Fairbanks, 1994).

The iron content of feedstuffs can be highly variable depending on the components. Iron in plants is subject to wide variation depending on the type of plant and the amount of iron in the soil, while many animal-based feed components are often rich in usable iron. The iron content of water can also vary greatly (Klasing, 2005). Large amounts of iron in water give the water a rusty color and a metallic taste, but upper limits of iron in drinking water for livestock and poultry have not been established since experimental data are not sufficient to make definite recommendations (NRC, 1974).

Worldwide, iron-deficiency anemias affect large numbers of people, but nutritional iron deficiencies are much less of a problem in animals. However, there are groups of animals which are vulnerable to iron deficiency including newborn piglets, veal calves, and those animals with parasitic infestations (Underwood, 1977). For instance, newborn piglets have very low concentrations of liver iron (29 mg/kg) compared to newborn rabbits whose liver iron stores average 135 mg/kg.

There is accumulating evidence that excessive iron deposits in the brain, and alterations in iron metabolism play an important role in neurodegenerative diseases (Connor *et al*., 1995; Lan and Jiang, 1997; Fredriksson *et al*., 1999;

*Veterinary Toxicology, Edited by Ramesh C. Gupta*

Dal-Pizzol *et al.*, 2001; Qian and Shen, 2001; Arosio and Levi, 2002).

## PHARMACOKINETICS/ TOXICOKINETICS

The homeostatic regulation of iron in the body is complex and involves uptake, transport, utilization, storage, and loss. Under normal conditions, iron is poorly absorbed from most diets with approximately 5–15% absorbed from the gastrointestinal (GI) tract. This uptake can double in iron deficiency. The body has a very limited ability to excrete iron, therefore iron homeostasis is maintained by adjusting iron absorption to the body's needs. The amount of dietary iron that is absorbed through the GI tract is determined by the needs of the individual animal and is inversely related to serum ferritin concentrations (Bothwell *et al.*, 1979). There are four main factors influencing iron absorption in the GI tract: 1) individual factors including the animal's age, iron status, and health, 2) conditions in the GI tract, 3) the chemical form and amount of iron ingested, and 4) other components of the diet which can enhance or reduce intestinal absorption. Iron is absorbed by enterocytes of the small intestine in ferrous ($Fe^{2+}$) form and transferred to the serum where it is converted to the ferric ($Fe^{3+}$) form and bound to transferrin (Goyer and Clarkson, 2001). In normal animals, the majority of fecal iron comes from ingested iron which is not absorbed. Once absorbed, the body vigorously retains ingested iron unless bleeding occurs with daily iron loss limited to about 0.01% (of the body total) per day (Goyer and Clarkson, 2001). It has been found that even in the face of hemolytic anemia with destruction of erythrocytes, less than 1% of the iron is excreted in the urine and feces (Underwood, 1977).

In the bloodstream, serum iron is primarily bound to transferrin with lesser amounts bound to ferritin. Iron in the serum forms a pool from which it enters, is transported, leaves, and re-enters at a variable rate for the synthesis of hemoglobin, ferritin, cytochromes, and other iron-containing proteins. Of the total iron in the body, approximately two-thirds is bound to hemoglobin and 10% to myoglobin and iron-containing enzymes, with the remainder bound to the storage proteins ferritin and hemosiderin (Goyer and Clarkson, 2001). Ferritin and hemosiderin are found throughout the body with the main concentrations being in the liver, spleen, and bone marrow. They are protective in that they keep cellular iron in a bound form. Ferritin contains up to 20% iron while hemosiderin is up to 35% iron. In the normal animal, non-viable RBCs are removed from the circulation by cells of the reticuloendothelial system in the liver, spleen, and bone marrow. There, heme is broken down and the iron recycled for further use. In aged animals, when large amounts of iron are injected and rapidly cleared from the serum, or during chronic iron storage disease, the iron is preferentially deposited as hemosiderin thereby increasing intracellular concentrations and giving rise to the hemosiderosis that can be seen histologically (Underwood, 1977; Goyer and Clarkson, 2001).

## MECHANISM OF ACTION

For many functions, the body utilizes ferrous ($Fe^{2+}$) iron to bind molecular $O_2$. In this way, $O_2$ is transported by hemoglobin to cells in the peripheral tissues, myocytes bind $O_2$ for intracellular utilization, mitochondrial proteins of the electron transport chain bind $O_2$ for energy production, and P450 enzymes bind $O_2$ for its use in phase I metabolism of endogenous and xenobiotic chemicals. However, because of its reactivity, iron in its ferrous state must be carefully sequestered away to prevent the formation of highly ROS which can elicit severe cellular damage. Ferrous iron ($Fe^{2+}$) and other transition metal ions, $Cu^{+}$, $Cr^{5+}$, $Ni^{2+}$, or $Mn^{2+}$ can catalyze the formation of hydroxyl ion ($HO^{-}$) and the extremely reactive and dangerous hydroxyl radical ($HO^{\bullet}$) from the reduction of endogenous hydrogen peroxide (HOOH) via the *Fenton reaction*:

$$HOOH + Fe^{2+} \rightarrow Fe^{3+} + HO^{-} + HO^{\bullet} \qquad 30.1$$

The Fenton reaction causes site specific accumulation of free radicals and initiates biomolecular damage. Free radicals are molecules or molecular fragments that contain one or more unpaired electrons in their outer orbital shell. If produced in great enough quantities to overwhelm the cellular antioxidant and radical-quenching protective mechanisms, hydroxyl radicals promote the formation of more hydroxyl radicals and other ROS such as superoxide. Superoxide combines with nitric oxide and forms peroxynitrite, which is as detrimental as hydroxyl radical. These ROS/RNS damage and destroy proteins and DNA by causing cross-linking, which inhibits their normal functions, or by initiating extensive damage and spontaneous degeneration of molecules such as lipids. ROS/RNS not only cause DNA damage, but also inhibit repair activities. ROS induce lipid peroxidation which if not quenched, can initiate a chain reaction of lipid destruction and ROS formation destroying vital cell membranes in mitochondria, nuclei, and the cell periphery. Together, these effects can be of great enough magnitude to cause cell death, organ dysfunction, and death. However, it is also of interest to note that iron is necessary for the normal functioning of macrophages and other leucocytes during the respiratory burst in inflammation to catalyze the formation of bactericidal hydroxyl radical (Gregus and Klaassen, 2001).

# TOXICITY

## General

Iron poisoning is not common in animals although potentially it could occur in any species. Clinical cases of acute iron toxicosis have been reported in dogs, pigs, horses, cattle, and goats (Greentree and Hall, 1983; Ruhr *et al.*, 1983; Osweiler *et al.*, 1985; Holter *et al.*, 1990). Toxicity can occur through ingestion or parenteral administration. Because of their indiscriminate eating habits and close proximity to people and their nutritional supplements, dogs are the species most likely to ingest large quantities of iron-containing vitamins. Baby pigs are iron deficient at birth and require iron supplementation, which can result in peracute or acute toxicity. Limited cases of iron poisoning have occurred in horses and cattle through the use of iron supplements. In general, toxicity occurs in the GI mucosa (oral exposure), liver, myocardium, and other tissues when the iron binding capacity of the body is overwhelmed, and free iron causes oxidative damage. Genetic iron storage diseases are uncommon, but have been reported in mynah birds, toucans, Saler cattle, Egyptian fruit bats, and rarely in horses.

## Acute toxicity in dogs, cattle, pigs, and adult horses

Acute iron toxicity has been reported in dogs (Greentree and Hall, 1983), cattle (Ruhr *et al.*, 1983), pigs (Velasquez and Aranzazu, 2004), horses (Arnbjerg, 1981), and humans. In dogs, toxicosis primarily occurs through the accidental ingestion of large amounts of iron-containing vitamins or other iron supplements. In cattle, horses and pigs, it has occurred through accidental administration of excess amounts of iron supplements by oral or parenteral routes. Diagnosis is based on history, appropriate clinical signs, and radiography in small animals as iron-containing pills are radiodense. In general, if the animals remain asymptomatic for greater than 8 h following a single exposure, it is reported that they are unlikely to develop iron toxicity. In all species, ingestion of a toxic dose (roughly greater than 20 mg/kg in dogs) initially results in necrosis of the GI mucosal cells. This is followed by fluid loss, direct cardiotoxicity, and widespread organ damage through the mechanisms described above. Fluid loss and decreased cardiac output can lead to circulatory shock. Iron toxicity has been described as occurring in four stages. Stage I occurs 0–6 h post-ingestion and is characterized by vomiting, diarrhea, abdominal pain, and depression. Stage II occurs from 6 to 24 h post-ingestion and is characterized by apparent recovery. Stage III begins at 12–96 h with commencement of additional vomiting, diarrhea, abdominal pain, GI hemorrhage, weakness, shock, and possibly death. Stage IV, if it occurs, begins 2–6 weeks after ingestion and is characterized by GI fibrosis and obstruction (Greentree and Hall, 1983).

## Neonatal pigs

Paradoxically, iron toxicity in piglets resulting from oral supplementation or parenteral injection occurs because of the very low liver iron stores in newborn pigs and the need to supplement the small amounts of iron that they receive in sow's milk. Because of their low iron stores at birth, iron-deficiency anemia can occur in non-supplemented baby pigs within 2–4 weeks after birth. This is manifested clinically in the pigs as dyspnea, anorexia, increased infections, and poor growth with some deaths. It is prevented by oral or parenteral injection of iron-containing compounds (Underwood, 1977; Osweiler *et al.*, 1985). When comparing routes of administration of the same iron compound the potential for toxicity is the greatest after intravenous injection followed by intramuscular injection with oral administration being the least toxic. In acute iron toxicosis of pigs, two syndromes are recognized. The first is a peracute syndrome which is characterized by sudden death minutes to a few hours after iron injection. In some ways this resembles an anaphylactic reaction in its rapidity of onset, vascular collapse, and death, but the exact mechanism is not known. This peracute syndrome has also been reported in horses following administration of iron compounds (Lannek and Persson, 1972; Bergsjoe, 1974). The second syndrome described in pigs is a subacute to acute syndrome characterized by GI necrosis, severe depression, coma, and death which can occur in the four stages described above. Pigs born to sows deficient in vitamin E and selenium are reported to be more susceptible to iron toxicosis (Osweiler *et al.*, 1985; Velasquez and Aranzazu, 2004).

## Neonatal horses

Although reports of iron toxicosis in horses and ponies are rare, several cases in the 1980s are of note. Newborn foals, 2–5 days old, were given an oral nutritional supplement containing ferrous fumarate. They became ill, icteric, weak, and died of liver failure within 1–5 days following administration. The histologic lesions in the livers of these foals were remarkable in that they had the appearance of longer-term chronic lesions even though they were as little as 24 h old. These hepatic lesions consisted of prominent bile ductule proliferation, hepatic cell necrosis, and periportal fibrosis (Divers *et al.*, 1983; Acland *et al.*, 1984). Through experimental administration, it was determined that ferrous fumarate, administered orally to foals within the first few days after birth, caused the liver failure seen in the earlier clinical cases (Mullaney and Brown, 1988). The

increased sensitivity of the neonatal foals is thought to be from increased absorption in the GI tract and lower systemic iron binding capacity (Poppenga, 2002). The iron overload in these foals resulting from oral administration of ferrous fumarate caused hepatic necrosis with bile ductule proliferation and fibrosis. It is speculated that what was histologically interpreted as proliferation of bile ductules was, in fact, proliferation of hepatic stem cells (oval cells) in response to the severe hepatic damage (personal observation). Experimentally, adult ponies have been administered iron as ferrous sulfate at 50 mg/kg/day orally for up to 8 weeks. Through the study and for 20 weeks after the end of dosing, no adverse clinical signs or hepatic damage were reported (Pearson and Andreasen, 2001).

### Iron storage disease

Iron storage disease resulting in hemosiderosis and hemochromatosis has been reported in several different species of animals. Hemochromatosis is the pathologic accumulation of iron in tissues, while hemosiderosis is the non-pathologic accumulation of iron. In birds, iron storage disease has been reported in mynah birds, toucans, birds of paradise, and quetzals. The clinical signs are dyspnea, hepatic damage/insufficiency, and death in mynah birds. Sudden death has been reported in toucans. It has been shown that the cause in mynah birds is due to maintenance of iron uptake from the GI tract, despite excess hepatic iron accumulation (Mete *et al*., 2003). The treatment in birds can consist of a low iron diet with phlebotomy or the use of iron chelators (Rodenbusch *et al*., 2004). A genetic, inheritable defect resulting in hemochromatosis, clinical wasting, and skeletal defects can occur in Salers cattle beginning at 9–22 months of age (O'Toole *et al*., 2001; Norrdin *et al*., 2004). Egyptian fruit bats (*Rousettus aegyptiacus*) are also known to have genetic iron storage disease. In these bats, it was found that if the sum of transferrin saturation and serum iron was greater than 51, the individual bat had a high probability of having iron overload. When the sum was greater than 90, there was a high probability of having hemochromatosis (Farina *et al*., 2005). In addition, although rarely reported, hemochromatosis with liver damage has also been reported in horses (Pearson *et al*., 1994) and captive Northern fur seals (Mazzaro *et al*., 2004). Finally, one case of hemochromatosis secondary to repeated blood transfusions every 6–8 weeks for 3 years for the treatment of red cell aplasia has been reported in an aged miniature schnauzer (Sprague *et al*., 2003).

## TREATMENT

Treatment of iron toxicity varies with the inciting cause, dose, and duration of the disease. General therapy is to limit absorption (although activated charcoal is ineffective at binding iron), provide symptomatic and supportive care, remove gastric bezoars of sticky iron-containing pills, surgically if necessary, and increase excretion. Because the body has limited ability to excrete excess iron (other than through bleeding), urinary excretion can be enhanced through the use of a chelating agent. A specific chelator of iron, deferoxamine has been used in the treatment of iron toxicity. Deferoxamine has a strong affinity for iron, a low affinity for calcium, and competes effectively for iron in ferritin and hemosiderin, but not in transferrin, hemoglobin, or heme-containing enzymes. It is poorly absorbed orally, and so is given parenterally by slow intravenous drip. Since it is excreted primarily by the kidneys, it should be given carefully to patients with renal insufficiency (Osweiler *et al*., 1985; Goyer and Clarkson, 2001; Poppenga, 2002).

## CONCLUDING REMARKS

Iron is essential for normal physiological functioning. Iron-deficiency anemia is common in humans and also occurs in piglets, veal calves, and parasitized animals. Therefore, iron supplements are readily available and widely used. In addition, some species have a propensity for genetic iron storage diseases. Fortunately, both acute and chronic iron toxicoses are rare in animals. When toxicosis does occur, cellular damage is caused by the presence of free iron in excess of the body's capacity to bind and sequester it. The free iron then initiates the generation of ROS in excess of cellular oxidant defenses resulting in lipid peroxidation of membranes, protein and DNA crosslinking, and cell death.

CHAPTER

# 31

# Lead

*Larry J. Thompson*

## INTRODUCTION

Lead is a bluish white to gray heavy metal that was probably the first toxic element recognized by man and yet still has great relevance today. The chemical symbol for lead, Pb, is short for the Latin word plumbum, meaning liquid silver. The main source of lead is the ore named galena, which contains lead sulfide. The main use of lead today is in lead–acid storage batteries but historically it has had widespread usage in paints (white, yellow and red pigments) and as a gasoline additive (tetraethyl lead) although these latter uses have essentially been phased out. A debate still continues as to the role lead played in the fall of the Roman Empire. Although lead was indeed used in some Roman water pipes (the word plumbum leading to our modern word, plumber) the main source of lead for the Romans was probably sapa, a syrup used to sweeten wine and preserve fruit, which was made by boiling grape juice in lead pots thereby adding lead acetate to the liquid. The use of lead continues in our modern world with lead-containing solder in our electronics as well as lead-containing glass, from cathode ray tube monitors to fine crystal. Among all the metals, lead poisoning is encountered with greatest frequency in certain species of animals and poses a serious concern to animal health. This chapter describes the toxicity of lead in mammalian and avian species.

## BACKGROUND

Lead is a toxic element and has not been shown to be an essential trace element for nutrition. The historical use of lead in gasoline, paint, construction materials and many other products has resulted in lead being one of the most significant environmental contaminants in the world. Additional sources of lead have included lead weights (e.g. for fishing or curtains), small lead trinkets and toys, lead shot and bullets for weapons, lead arsenate pesticides and many other products as well as single source environmental contamination from mining, smelting and recycling operations. As a result of increased regulation of lead and the decreasing use of lead-containing products, the overall incidence of lead poisoning (also called plumbism) in animals and humans has been decreasing. While environmental contamination with lead does not resolve readily, the overt poisoning of domestic animals from environmental sources (e.g. from contaminated forages, plants, water or other food sources) has been decreasing in number. Still lead poisoning in animals encountered with greatest frequency compared to any other metal.

## TOXICOKINETICS

The main route of entry of lead into the body is the digestive tract with absorption dependent upon the chemical form of lead and the physiological state of the animal. Organic lead compounds are, in general, more readily absorbed than either inorganic lead salts or the metallic form of lead. Dermal absorption of organolead compounds can be significant but the salt or metallic forms of lead are not absorbed dermally. The fumes from heated lead or very fine particles ($<0.5\,\mu m$) of lead can enter the lung alveoli and be absorbed with the larger particles lodging in the ciliated portion of the bronchial tree. These larger particles can be transported up by mucociliary action and then swallowed with absorption through the

gastrointestinal tract. Fine particles of lead and lead salts can be solubilized in the acid environmental of the stomach and the small intestine is the site of most lead absorption. Absorption of lead from the alimentary tract is usually influenced by dietary factors and by the size of lead particles. High dietary fat and mineral deficiency can increase lead absorption by 7- and 20-fold, respectively. In an experimental study, dogs maintained on a high fat, low calcium diet absorbed significantly more lead than those kept on a balanced diet (Hamir *et al*., 1988). Young animals absorb a larger portion of the lead from the gastrointestinal tract than do adults. Animals with a calcium deficiency have increased absorption of lead. Pregnancy or lactation as well as deficiencies of iron, zinc or vitamin D can also enhance lead absorption. Lead crosses the placental barrier and the residue can be detected in significant amounts in fetal blood and organs. Among the fetal organs, the highest concentrations are found in the blood and liver (Kelman and Walter, 1980; O'Hara *et al*., 1995). Lead also passes through the milk.

Nonruminant animals absorb approximately 10% of dietary lead, and ruminants absorb less than 3%. Young animals can absorb up to 90% of the ingested lead. Following absorption, a large proportion of lead is carried on erythrocyte membranes (60–90%, species dependent) with most of the remainder of lead bound to protein or sulfhydryl compounds, with only a very small proportion found free in the serum. Lead is widely distributed in the body, including crossing the blood–brain barrier (Seimiya *et al*., 1991). In the soft tissues lead binds to various proteins as well as metallothionein but accumulates in the active bone matrix (about 90%) serving as a relatively inert reservoir of lead in the body. This reservoir can be mobilized by lactation, pregnancy or the action of chelating agents. Otherwise lead has a very slow turnover rate from the bone. Lead is normally very slowly excreted via the bile with very little in the urine. Chelation therapy greatly increases the urinary output of lead.

## MECHANISM OF ACTION

Lead interferes with several biochemical processes in the body by binding to sulfhydryl and other nucleophilic functional groups causing inhibition of several enzymes and changes in calcium/vitamin D metabolism. Lead also contributes to oxidative stress within the body. Lead inhibits the body's ability to make hemoglobin by interfering with several enzymatic steps in the heme pathway. Specifically, lead decreases heme biosynthesis by inhibiting delta-aminolevulinic acid dehydratase and ferrochelatase activity. These changes contribute to the anemia that develops in chronic lead poisoning. An increased fragility of red blood cells also contributes to the anemia.

From various experimental studies, biochemical and pathological evidence suggests that lead is neurotoxicant, as it significantly disrupts certain brain structures and functions. High dose exposure to lead (i.e. blood levels in excess of 4 $\mu$M) disrupts the blood–brain barrier. Molecules such as albumin that normally are excluded, freely enter the brain of immature animals exposed to these concentrations of lead (Clasen *et al*., 1973; Goldstein *et al*., 1974; Bressler and Goldstein, 1991). Ions and water follow and edema is produced. Intracranial pressure rises as edema accumulates in the brain because of the physical restraint of the skull. When the intracranial pressure approaches the systemic pressure, cerebral perfusion decreases and brain ischemia occurs.

Many of the neurotoxic effects of lead appear related to the ability of lead to mimic or in some cases inhibit the action of calcium as a regulator of cell function (Bressler and Goldstein, 1991). At a neuronal level, exposure to lead alters the release of neurotransmitters (dopamine, acetylcholine and $\gamma$-aminobutyric acid) from nerve endings. Spontaneous release is enhanced and evoked release is inhibited. The former may be due to activation of protein kinases in the nerve endings and the latter to blockade of voltage-dependent calcium channels.

Brain homeostatic mechanisms are disrupted by exposure to higher levels of lead. The final pathway appears to be a breakdown in the blood–brain barrier. Again, the ability of lead to mimic or mobilize calcium and activate protein kinases may alter the properties of endothelial cells, especially in immature brain, and disrupt the barrier. In addition to a direct toxic effect upon the endothelial cells, lead may alter indirectly the microvasculature by damaging the astrocytes that provide signals for the maintenance of blood–brain barrier integrity, and necrosis in neurons with shrunken cytoplasm, pyknotic nuclei and increased perineuronal space.

## TOXICITY

Mammals, birds and reptiles have all been found to develop lead poisoning. The toxic dose of lead has been determined for several species but is difficult to apply to clinical cases where the exposure history is unclear (Gwaltney-Brant, 2004). In general, young animals are more susceptible to lead toxicosis because they are more prone to lead pica and have a higher rate of absorption (about 90%) from the intestinal tract. Cattle have been most widely reported with lead toxicosis, probably due to their propensity to ingest discarded lead–acid batteries and construction materials including paints. Dogs are also commonly reported with lead toxicosis, probably due to their chewing habits and ingestion of small lead objects around the house. Both cats and dogs have been

exposed to lead by the renovations of older homes containing leaded paints. The main route seems to be the ingestion of fine dust by the grooming habits of indoor pets and their tendency to ingest small objects.

Clinical signs of lead toxicosis vary with the species involved, duration of exposure and amount of lead absorbed. The major systems affected by lead poisoning are gastrointestinal, central nervous system and hematological system. Abdominal pain and diarrhea can be common clinical signs in animal exposed to excess lead. Anorexia is common as well as vomiting in those species that are able. Neurological signs including depression, weakness and ataxia can progress to more severe clinical signs of muscle tremors or fasciculations, head pressing (especially in ruminants), blindness, seizure-like activity and death. Many animals with chronic lead poisoning will show subtle and non-specific clinical signs such as abdominal discomfort, vague gastrointestinal upsets, anorexia, lethargy, weight loss and behavior changes. Horses develop acute lead toxicosis and show clinical signs of laryngeal paralysis and "roaring", in addition to colic and seizure-like activity. Evidence suggests that horses may be more susceptible to chronic lead toxicosis than cattle. Horses exposed to daily intake as low as 1.7 mg/kg body weight (approximately 80 ppm Pb in forage dry matter) were poisoned (Aronson, 1972). Clinical signs of lead toxicosis in avians vary with waterfowl and raptors mainly displaying a chronic wasting disorder with apparent peripheral neuropathy. Psittacines are more likely to display gastrointestinal problems and neurological abnormalities.

Gross lesions in animals dying of lead poisoning are often minimal and non-specific, although lead-containing objects may be visible in the gastrointestinal tract. Histologically, there may be degeneration and necrosis of the renal tubular epithelium or the presence of acid-fast inclusion bodies (Hamir *et al.*, 1988; O'Hara *et al.*, 1995). Brain lesions in a calf poisoned with lead included multiple focal or laminar lesions of neuronal necrosis in the cerebral cortex, caudatum and medial nuclei of thalamus, predominantly at the tips of gyri in the occipital and parietal lobes. The lesions spread occasionally to the deeper region of the gyri along the sulci (Seimiya *et al.*, 1991). The affected neurons were shrunken and angular, sometimes triangular in outline with pale eosinophilic cytoplasm. The nuclei showed pyknosis and rhexis. Edematous dilation of perivascular and perineuronal spaces with spongiotic state of neuropil was observed from the molecular layer to outer zone of the white matter. Astrocytic proliferation was also observed. Blood capillaries were congested with enlarged and increased endothelial cells. Meningeal blood vessels were prominently congested with mild lymphocytic infiltration. Edema of Purkinje cell layer in the cerebellum and mild neuronal degeneration in the nucleus of mesencephalon were seen.

Diagnosis of lead poisoning in animals should be made with a combination of history, clinical or necropsy findings, and lead analysis of tissue. Basophilic stippling of erythrocytes and inhibition of hemoglobin synthesis are characteristic hematological features of lead poisoning. From a living animal, whole blood is the best sample for laboratory determination of lead. The normal background concentration of lead in the blood of mammals is below 0.1 ppm. With clinically affected animals, lead concentrations above 0.35 ppm are compatible with a diagnosis of lead toxicosis. Postmortem samples of choice are kidney and liver with lead concentrations above 10 ppm on a wet weight basis being diagnostic for lead toxicosis in domestic species.

## TREATMENT

Acute lead poisoning in animals is usually fatal if the animals are not treated promptly. Treatment approach for lead poisoning in animals includes stabilizing and supporting the animal especially if severe clinical signs are present, preventing additional exposure to lead and chelation therapy to quickly reduce the body burden of lead. The exposure history of the animal should be reviewed for potential sources of lead and the need for gastrointestinal decontamination. The use of chelating agents when large amounts of lead are present in the gastrointestinal tract may actually enhance the absorption of lead into the body. Physical removal of lead-containing objects by surgical means may be necessary with larger objects. The parenteral use of calcium disodium ethylenediaminetetraacetic acid (CaEDTA) has been commonly used for several decades as a chelation agent in domestic animals (Kowalczyk, 1984).

Although other chelators may be superior, CaEDTA is still widely used in veterinary medicine, especially in large animals. CaEDTA is given intravenously (IV) or subcutaneously (SQ) and chelates and mobilizes the lead from bone resulting in a transient increase in blood lead levels. This increase in blood lead can increase soft tissue lead levels leading to an exacerbation of clinical signs. Preceding CaEDTA usage with a chelator that specifically targets lead in the soft tissue (e.g. British Anti-Lewisite or BAL) has been recommended but is difficult to accomplish in most practice settings. CaEDTA can be nephrotoxic, especially in situations where the animal is dehydrated. Recommended treatment with CaEDTA for large animals is 73 mg/kg/day, divided into two or three doses given over the course of a day given by slow IV. For example, a 6.6% solution of CaEDTA (in normal saline or 5% dextrose) can be given IV at a rate of 1 ml per 2 pounds (0.9 kg) of body weight per day, in divided doses. Treatment should continue for 3–5 days. If additional treatment is needed, a rest period of 2 days with continued supported care is

suggested before the additional 3–5-day second treatment period. An alternative treatment regime is to administer CaEDTA at 110 mg/kg IV twice daily for 2 days. If additional treatment is needed first apply the 2-day rest period of supportive care before initiating the second treatment period of 2 days at 110 mg/kg twice daily. Thiamine has been shown to be a valuable adjunct to the treatment of lead poisoning in ruminants (Bratton *et al.*, 1981) and is recommended for other species as well. A dose of 2 mg/kg/day for calves and 250–2000 mg/day for adult cattle has been recommended.

If commercial CaEDTA is unavailable, a stock solution can be formulated for emergency antidotal usage. A 10% stock solution can be made by dissolving 101.1 g of tetrasodium EDTA ($Na_4EDTA$) plus 30 g of anhydrous calcium chloride ($CaCl_2$) in distilled water to a final volume of 1000 ml. From the stock solution a working 2.22% solution can be made by mixing 220 ml of the 10% stock solution with 780 ml distilled water. Using the 2.22% solution, the daily dosage of 73 mg/kg/day is equal to approximately 3.5 ml/kg of bodyweight. This should be divided into two or three separate administrations (Thompson, 1992). Tetrasodium EDTA should never be administered by itself as it may cause hypocalcemia.

Recommended treatment with CaEDTA for dogs is 100 mg/kg/day in four divided doses. Treatment should continue for 2–5 days and a second round of treatment is rarely needed but a 5-day rest period is recommended before applying additional treatment. CaEDTA concentration should be 10 mg/ml and may be administered by slow IV or by SQ route. Cats can be treated with 27.5 mg in 15 ml normal saline or 5% dextrose SQ every 6 h for 5 days or the same dose as a slow IV infusion.

Succimer (meso-2,3-dimercaptosuccinic or DMSA) is an orally administered chelating agent that is less likely to have adverse side effects associated with CaEDTA. The recommended treatment in dogs is an oral dose of succimer at 10 mg/kg, repeated 3 times daily for 10 days (Ramsey *et al.*, 1996). Succimer has also been used orally in caged birds at a dose of 25–35 mg/kg twice daily for 5 days. Several weeks of therapy may be needed in avians. In initial experimental work, succimer given to experimentally lead-poisoned calves IV at 25 mg/kg/day for 4 days was more effective than CaEDTA at decreasing lead concentrations in the liver and kidney (Meldrum and Ko, 2003).

## CONCLUDING REMARKS

While cases of lead toxicosis in animals have been decreasing, it should remain on the clinician's list of rule-outs for seizure-like activity, blindness, and vague neurological and gastrointestinal disorders. At a minimum, the environment of the animal should be reviewed for possible lead sources.

CHAPTER

# 32

# Mercury

*Ramesh C. Gupta*

## INTRODUCTION

Mercury (Hg) is a naturally occurring element that is found in the environment. It exists in several forms, such as elemental (metallic), inorganic, and organic. About 80% of the mercury released in the environment is metallic mercury, and comes from human activities, such as fossil fuel combustion, mining, smelting, and from solid waste incineration (ATSDR, 1999). Human activity can lead to mercury levels in soil as much as 200,000 times higher than natural levels. Metallic mercury in a pure form looks like a shiny-white liquid substance at room temperature. It is commonly used in thermometers, barometers, blood pressure devices, batteries, electric switches, dental fillings (amalgams), etc. Inorganic mercury compounds, or mercury salts, occur when it combines with other elements, such as chlorine, sulfur, and oxygen. Most of these compounds are white, except mercuric sulfide or cinnabar ore (i.e. red, but it turns black after exposure to light). Some of mercury compounds are used as fungicides, while others are used for medicinal purposes, e.g. laxatives, deworming agents, antiseptics, and disinfectants. When mercury combines with carbon, it is called organic mercury (organomercurials). Methylmercury, ethylmercury, and phenylmercury are a few examples. In the environment (by bacteria and fungi) and mammalian systems, various forms of mercury are interchangeable. For example, inorganic mercury can be methylated to methylmercury, and methylmercury can change to inorganic or elemental mercury. The animals at the top of the food chain tend to bioaccumulate methylmercury in their bodies. Therefore, poisoning by mercury is due to consumption of meat or grain contaminated with mercury. Poisoning can also result from excessive exposure to inorganic and organic mercury compounds from misuse or overuse of mercury-containing products. Much of the information presented in this chapter is from experimental studies conducted in laboratory animals and poisoning incidences.

## BACKGROUND

Mercury exists naturally in the environment, and as a result everyone is exposed to very low levels. Aristotle named it "Quicksilver". Animal poisoning by mercury is rare because of strict federal, state, and local regulations. Most of the mercury found in the environment is in the form of metallic mercury and inorganic compounds. The most common natural forms of mercury found in the environment are metallic mercury, mercury sulfide (cinnabar ore), mercuric chloride, and methylmercury. Methylmercury is of particular concern because it can bioaccumulate in certain edible freshwater and saltwater fish and marine mammals to levels that are many times greater than levels in the surrounding water. As a result, the larger and older fish living in contaminated water build up levels of mercury in their bodies. Inorganic mercury does not bioaccumulate in the food chain to any extent. Cultivation of edible mushrooms, where waste as compost material with high levels of mercury is used, can also accumulate high levels of mercury (Bressa *et al.*, 1988). The release of methylmercury into an ocean bay (Minamata) in Japan in the 1950s led to a massive health disaster, and the clinical syndrome was named Minamata disease (Tsubaki and Krukuyama, 1977). Thousands of people were poisoned, and hundreds of them had severe brain damage.

The Food and Drug Administration (FDA) estimates that on average most people are exposed to about 50 ng mercury/kg of body weight/day in the food they eat. This level is not enough to cause any harmful effects. A large part of this mercury is in the form of methylmercury and the

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
ISBN: 978-0-12-370467-2

*Copyright © 2007, Elsevier Inc. All rights reserved.*

majority of that comes from eating fish. Fish for food consumption are not allowed to have more than 1 ppm. This level is below a level that can be associated with adverse effects. Foods other than fish that may contain higher levels of mercury include wild animals, birds, and mammals (bears) that eat large amounts of contaminated fish (ATSDR, 1999). Meat and/or fat from fish, marine mammals, fish-eating wildlife, and birds; and mercury-based fungicides-treated grains have the highest-mercury levels. Certain species of commercially available saltwater fish, such as shark, swordfish, kingfish, and tilefish, can contain high levels of methylmercury. In addition, edible mushrooms can have unsafe levels of mercury. These are the potential sources of mercury poisoning. In horses, mercury toxicity occurs from wound dressings (blisters) when dimethyl sulfoxide (DMSO) is applied simultaneously, because DMSO enhances absorption of mercury (Schuh *et al.*, 1988).

## TOXICOKINETICS

Absorption of mercury from oral ingestion depends on the form of mercury. Metallic mercury is maximally absorbed (about 80%) from the lungs, while very little is absorbed from the gastrointestinal (GI) tract. Once mercury enters the circulation, it is rapidly distributed to other tissues, but more so in the kidneys, where it accumulates. Metallic mercury can stay in the body for weeks and months. Due to its high lipophilicity, metallic mercury can readily cross the blood–brain barrier and placental barrier. When metallic mercury enters the brain, it is readily converted to an inorganic divalent mercury (oxidized by the hydrogen peroxidase–catalase pathway), and it gets trapped there for a long time. The inorganic divalent cation can, in turn, be reduced to metallic mercury. Most of the absorbed metallic mercury excretes in the urine and feces, some amount passes in the milk, and very little in the exhaled air.

Inorganic mercury compounds (e.g. mercurous chloride and mercuric chloride) are absorbed 10–40% from the GI tract on ingestion, distributed to different organs, and mainly accumulate in the kidneys. In an experimental study, female Sprague–Dawley rats given a single dose of mercuric chloride (7.4 or 9.2 mg Hg/kg, p.o.) showed 12.6 and 18.9 ppm mercury, respectively, in the kidneys when sacrificed 14 days post-exposure (Lecavalier *et al.*, 1994). Trace amounts were also detected in the liver, brain, and serum. These compounds do not readily cross the blood–brain barrier or placental barrier. Inorganic mercury excretes in the urine and feces, and only detectable levels pass through the milk.

Organic mercury (e.g. methylmercury) readily gets absorbed from the GI tract (about 95%). From circulation it gets distributed to other organs. The distribution of methylmercury is similar to that of metallic mercury, i.e. a relatively large amount of mercury can accumulate in the brain and fetus (compared to inorganic mercury) because of its ability to penetrate the blood–brain and placental barriers and its conversion in the brain and fetus to the inorganic divalent cation mercury (ATSDR, 1999). However, the extent of conversion is less than with metallic mercury. In the brain, methylmercury can be changed to inorganic mercury and can remain in this tissue for a long time. Organic mercury excretes in the form of inorganic mercury in the feces over a period of several months. Some organic mercury also excretes in the urine and milk.

Depending on the route of exposure, dose, and single versus repeat exposure, toxicokinetics of mercury can follow one- or two-compartment model. Studies have shown that repeat or continuous exposure to any form of mercury can result in the accumulation of mercury in the body. Retention of mercury in the brain may persist long after cessation of short- and long-term exposures. Blood levels of mercury are closely related to whole-body retention of mercury during the first 3 days after administration. After the initial 3 days, the amount of mercury in the blood declines more rapidly than the whole-body burden.

Evidence suggests that the metabolism of all forms of mercury is similar for humans and animals. Mercury is metabolized through the oxidation–reduction cycle that takes place in intestinal microflora and after absorption in many tissues and in the red blood cells (RBCs). Elimination rates for methylmercury appear to vary with species, dose, sex, and strain. The elimination half-life in the blood of monkeys receiving inorganic and organic mercury was found to be 26 days (Vahter *et al.*, 1994). In a study of organs from sled dogs fed methylmercury-laden meat and organs from predatory marine animals, the highest concentration of total mercury was found in the mesenterial lymph nodes, followed by liver and kidneys, indicating that the lymphatic system may play an important role in the transport of mercury to target organs (Hansen and Danscher, 1995). The tissue concentrations of mercury observed in this study were found to be age related, and the results suggest that demethylation takes place in all organs, except the skeletal muscles. Demethylation of methylmercury was found to be lower in the brain than in other organs.

## MECHANISM OF ACTION

Mechanism of action for the toxic effects of organic and inorganic mercury is similar. Toxicities of the different forms of mercury are related, in part, to its differential accumulation in sensitive tissues. This theory is supported by the observation that mercury rapidly accumulates in the kidneys and specific areas of the brain (the two

major target organs). High-affinity binding of the divalent cationic mercury to thiol or sulfhydryl (SH) groups of proteins is believed to be a major mechanism involved in the toxicity of mercury. As a result, mercury can cause inactivation of various enzymes, structural proteins, transport proteins, and alteration of cell membrane permeability by the formation of mercaptides. In addition, mercury may induce one or more of the following effects: increased oxidative stress, mitochondrial dysfunction, changes in heme metabolism, glutathione depletion, increased permeability of the blood–brain barrier; and disruption of microtubule formation, protein synthesis, DNA replication, DNA polymerase activity, calcium homeostasis, synaptic transmission, and immune response (ATSDR, 1999).

The nervous system is especially sensitive to mercury. The degree of damage depends on the form of mercury and its dose. Metallic mercury at high doses causes irreparable damage to the brain. In many poisoning incidents, permanent damage to the brain and kidneys occurred by methylmercury. Since inorganic mercury does not readily cross the blood–brain barrier, it is highly unlikely that inorganic mercury may cause any damage to the brain or nerves. Most of the information concerning neurotoxicity in humans following oral exposure to organic mercury comes from reports describing the effects of ingesting contaminated fish or fungicide-treated grains, or meat from animals fed such grains. Studies conducted in experimental animals strongly indicate that organic mercury is a potent neurotoxicant.

Evidence suggests that a single dose of mercuric chloride (0.74 mg/kg) caused disruption of the blood–brain barrier in rats (Chang and Hartman, 1972). These investigators also administered mercuric chloride to rats at the same dose daily for 11 weeks. Within 2 weeks, there were coagulative or lucid changes in cerebellar granule cells and fragmentation, vacuolation, and cytoplasmic lesions in the neurons of dorsal root ganglia. Neurological disturbances consisted of severe ataxia and sensory loss, with an accompanying loss in body weight. It is expected that mercuric chloride administered via subcutaneous route would be much more toxic than that administered orally because of the poor absorption of inorganic forms of mercury from the GI tract.

Neurotoxic effects seen in the Minamata (Japan) and Eraqi poisonings have been associated with neuronal degeneration and glial proliferation in the cortical and cerebellar gray matter and basal ganglia (Al-Saleem, 1976), and derangement of basic developmental processes such as neuronal migration (Matsumoto *et al.*, 1965; Choi *et al.*, 1978) and neuronal cell division (Sager *et al.*, 1983). In the brain, Purkinje, basket, and stellate cells were severely affected. In the brain, methylmercury selectively damages specific focal areas such as the granule cells of the cerebellum and the neurons in the interstices of the visual cortex.

Methylmercury selectively inhibits protein synthesis in the brain (reversibly in neurons from the cerebrum and Purkinje cells; and irreversibly in granule cell of cerebellum), and this effect usually precedes the appearance of clinical signs. This selective action on the brain may be due to the fact that certain cells are susceptible because they cannot repair damage from methylmercury. Cheung and Verity (1985) identified the most sensitive step in the protein synthesis, i.e. the peptide elongation can be affected by the high concentrations of mercury, but the first stage of synthesis associated with tRNA may be the most sensitive. Methylmercury inhibits one or more of the amino acyl tRNA synthetase enzymes. Microtubules are essential for cell division (main component of the mitotic spindle), and methylmercury reacts with the SH groups on tubulin monomers, and thereby disrupts the assembly process. The dissociation process continues, and that leads to depolymerization of the tubule.

In all forms, mercury accumulates in the kidneys, and thereby it causes greater damage to this organ. The kidney damage appears to be dose dependent, and that means recovery can occur if exposure is at low level. Following entry of the mercuric or methylmercuric ion into the proximal tubular epithelial cells via transport across the brush-border or basolateral membrane, mercury interacts with thiol-containing compounds, such as glutathione and metallothionein. This interaction initially produces alterations in membrane permeability to calcium ions and inhibition of mitochondrial function. Subsequently, by unknown signaling mechanisms, mercury induced the synthesis of glutathione, glutathione-dependent enzymes, metallothionein, and several stress proteins. Furthermore, in the kidney, epithelial cell damage occurs as a result of excess free radical formation and lipid peroxidation.

## TOXICITY

In general, toxic effects of mercury depend on the form of mercury, the amount and duration of exposure, and the route of exposure. Mercury, in all forms, has been found to be toxic to both man and animals. There are many similarities in the toxic effects of the various forms of mercury, but there are also differences. Exposure to mercury, however, does not necessarily mean that adverse health effects will occur. Each form and route leads to different effects. Practically, it is organic mercury, which is more toxic and often encountered in poisonings. In both humans and animals, exposure to mercury is more frequently encountered by oral ingestion. The major targets of toxicity following oral exposure to inorganic and organic mercury are the kidneys and the central nervous system (CNS), respectively.

In humans, deaths resulting from organic mercury ingestion have been documented following outbreaks of

poisoning (Minamata disease) after consumption of methylmercury-contaminated fish in Minamata Bay, Japan (Tsubaki and Takahashi, 1986) and after consumption of grains contaminated with methylmercury and ethylmercury in Iraq (Bakir *et al*., 1973; Al-Saleem, 1976). Noninflammatory damage to the brain was the primary cause of deaths, while pneumonia and nonischemic heart damage were reported as secondary cause of death.

The signs of mercury acute toxicity in animals are similar to those described in humans. Signs and symptoms associated with short-term exposure to metallic mercury may include nausea, vomiting, diarrhea, increase in blood pressure or heart rate, skin rashes, and eye irritation. Inorganic mercury, if swallowed in large quantities, may cause damage to the kidney, and also in stomach and intestine, including nausea, diarrhea, and ulcers. Animal studies revealed that long-term oral exposure to inorganic mercury salts causes kidney damage, increase in blood pressure and heart rate, and effects on the stomach. Studies also show that nervous system damage occurs after long-term exposure to high levels of inorganic mercury. Short-term, high-level exposure of laboratory animals to inorganic mercury has been shown to affect the developing fetus and may cause termination of the pregnancy.

Laboratory animals exposed to long term, high levels of methylmercury or phenylmercury showed damage to the kidneys, stomach, and large intestine, changes in blood pressure and heart rate, and adverse effects on the developing fetus, sperm, and male reproductive organs; and increases in the number of spontaneous abortions and stillbirths.

In livestock animals, clinical signs of mercury poisoning vary greatly. In cattle, toxicity signs include ataxia, neuromuscular incoordination, and renal failure, followed by convulsions and a moribund state. Average time from ingestion to death is reported to be about 20 days. Ingestion of phenylmercuric acetate may cause sudden death with massive internal hemorrhage, without other signs of toxicity (Puls, 1994). In horses, signs of acute toxicity include severe gastroenteritis and nephritis. In chronic cases, signs may include neurological dysfunction, laminitis, in addition to renal disease which is characterized by glycosuria, proteinuria, phosphaturia, reduced urine osmolarity, reduced glomerular filtration rate, azotemia, and elevated creatinine and blood urea nitrogen. In sheep, the poisoning is characterized by severe neurological symptoms, and tetraplegia. Pigs show incoordination, unstable gait, lameness, recumbency and death.

Some of the toxic effects are described in detail for each organ/system affected by mercury exposure.

## Nervous system

Adverse effects on the nervous system of animals occur at lower doses than do harmful effects to most other systems of the body. This difference indicates that the nervous system is more sensitive to mercury than are other organs in the body. Animal studies also provide evidence of damage to the nervous system from exposure to methylmercury during development, and evidence suggests that the effects worsen with age, even after the exposure stops. The reason for this greater susceptibility is that mercury affects processes unique to the developing nervous system, namely cell migration and cell division (Clarkson, 1987).

Both human epidemiology and experimental animal studies indicate that organic mercury is a potent neurotoxicant. Studies suggest that cats and monkeys are more sensitive than rodents to the neurotoxic effects of mercury (especially methylmercury). In several animal species, the major effects that are seen across the studies include motor disturbances, such as ataxia and tremors, as well as signs of sensory dysfunction, such as impaired vision. The predominant pathological feature is degenerative changes in the cerebellum, which is likely to be the mechanism involved in many of the motor dysfunctions. In a chronic study, cats fed tuna contaminated with methylmercury, showed degenerative changes in the cerebellum and the cortex (Chang *et al*., 1974). Neonatal monkeys exposed to methylmercuric chloride at 0.5 mgHg/kg/day for 28–29 days exhibited stumbling, and falling, blindness, crying, tember tomtrums, and coma. Histopathological analysis revealed diffuse degeneration in the cerebral cortex, cerebellum basal ganglia, thalamus, amygdala, and lateral geniculate nuclei (Willes *et al*., 1978).

Rats acutely intoxicated with methylmercury (19.9 mg Hg/kg, oral gavage) showed signs of lethargy and ataxia, which was not accompanied by histopathological changes. Symptoms disappeared within 2–3 h. Administration of a single dose of methylmercuric chloride (0.8 mg Hg/kg) produced blood–brain barrier dysfunction in rats (Chang and Hartman, 1972) similar to that described for inorganic mercury.

Following inhalation exposure to metallic mercury vapors, the CNS has been found to be the most sensitive organ in guinea pigs, rats, and mice. With increasing concentrations of mercury, damage to CNS becomes irreversible. Rabbits appear to be less sensitive.

In rabbits given 5.5 mgHg/kg as methylmercuric acetate for 1–4 days, widespread neuronal degenerative changes in cervical ganglia cells, cerebellum, and cerebral cortex have been observed without accompanying behavioral changes (Jacobs *et al*., 1977). In similar studies, mice exposed to 1.9 or 9.5 mgHg/kg/day as methylmercury in the drinking water for 28 weeks exhibited degeneration of Purkinje cells and loss of granular cells in the cerebellum (MacDonald and Harbison, 1977). At higher doses, hind limb paralysis was observed. Neuronal degeneration and microgliosis were observed in the corpus striatum, cerebral cortex, thalamus, and hypothalamus, accompanied by hind leg weakness, in mice given with 1 or 4 mgHg/kg/day as methylmercuric chloride by gavage for 60 days (Berthoud *et al*., 1976).

Neurotoxic signs observed in rats exposed to methylmercury (4 mg Hg/kg/day for 8 days) include muscle spasms, gait disturbances, flailing, and hind limb crossing (Inouye and Murakami, 1975; Fuyuta *et al.*, 1978; Magos *et al.*, 1980, 1985). Histopathological examination of the nervous system of affected rats has shown degeneration of cerebellar granule cells and dorsal root ganglia (Magos *et al.*, 1980, 1985) and degenerative changes in peripheral nerves (Fehling *et al.*, 1975; Miyakawa *et al.*, 1976).

## Renal system

Mercury, in all forms, has been shown to cause renal toxicity (structural and functional damage) in humans and animal species that are tested. Renal toxicity has been observed in rats (Fisher 344) and mice ($B6C3F_1$) following acute, intermediate, and chronic exposures to mercuric chloride (Dieter *et al.*, 1992; NTP, 1993). In a 14-day study, male and female rats were exposed by gavage to 0.93–14.8 mgHg/kg/day as mercuric chloride for 5 days a week. There was a significant increase in the absolute and relative kidney weights of males beginning at the 1.9 mgHg/kg/day dose level. An increased incidence of tubular necrosis was observed in rats exposed to at least 3.7 mgHg/kg/day. Severity was dose dependent. In chronic studies, mercuric chloride produced a variety of pathological changes in kidneys (Carmignani *et al.*, 1992; Hultman and Enestrom, 1992; NTP, 1993). Degenerative effects have been found in the kidneys of animals exposed to moderate-to-high levels of metallic mercury vapors following acute or subacute exposures (Ashe *et al.*, 1953). Effects ranging from marked cellular degeneration to tissue destruction and widespread necrosis were observed in rabbits exposed to mercury vapor at a concentration of 28.8 $mg/m^3$ for 2–3 h. In rats, slight degenerative changes (i.e. dense deposits in tubule cells and lysosomal inclusions) in the renal tubular epithelium were evident following exposure to 3 $mg/m^3$ mercury vapor for 3 h/day, 5 days a week, for 12–42 weeks (Kishi *et al.*, 1978). Low-level, long-term exposure to mercury (0.1 $mg/m^3$) has not been found toxic to kidneys of rats, rabbits, and dogs (Asche *et al.*, 1953). Exposure to organic mercury via inhalation is extremely rare.

## Cardiovascular system

Mercury has been shown to have adverse effects on cardiovascular system. A decrease in heart rate was observed in male rats given two gavage doses of 2 mgHg/kg as methylmercuric chloride (Arito and Takahashi, 1991). An increase in systolic blood pressure was observed in male rats after daily oral gavage doses of 0.4 mgHg/kg/day as methylmercuric chloride for 3–4 weeks (Wakita, 1987). This effect began approximately 60 days after initiation of exposure and persisted for at least 9 months.

## GI tract

Ingestion of mercuric chloride is highly irritating to the tissues of GI tract. Inflammation and necrosis of the glandular stomach were observed in mice that were given oral doses of 59 mg/kg as mercuric chloride 5 days a week for 2 weeks (NTP, 1993). In a 2-year gavage study, an increased incidence of forestomach hyperplasia was observed in male rats exposed to 1.9 or 3.7 mgHg/kg/day as mercuric chloride compared to the control group. Mice showed ulceration of the glandular stomach compared to the control group. It showed ulceration of the glandular stomach after 2 years of dietary exposure to methylmercuric chloride at 0.69 mg Hg/kg/day (Mitsumori *et al.*, 1990). In experimental studies, methylmercury has been found very strain- and sex-specific in mice. A single oral dose of methylmercuric chloride at 16 mgHg/kg resulted in the death of 4 of 6 male mice (C57BL/6N Jc1 strain) but no death was noted in females (Yasutake *et al.*, 1991). Mortality in female mice (4 of 6) was noted at 40 mg Hg/ kg dose. In a chronic study, 26 weeks of dietary exposure to methylmercuric chloride resulted in increased mortality in both male and female mice (ICR strain) at 3.1 mgHg/kg/day (Mitsumori *et al.*, 1981).

## Hematopoietic system

In general, acute mercury toxicity does not produce any characteristic hematological changes. In a chronic study conducted in rats, phenylmercuric acetate given in water at a dose of 4.2 mgHg/kg/day caused decreases in hemoglobin, hematocrit, and RBC counts (Solecki *et al.*, 1991). The anemia observed in this study may have been secondary to blood loss associated with the ulcerative lesions in the large intestine. However, methylmercuric chloride at low dose (0.1 mgHg/kg/day for 2 years) given in diet for 2 years caused no changes in hematological parameters (Verschuuren *et al.*, 1976).

## Other effects

In laboratory animals, mercury has been found to have potential for inducing genotoxicity (Ghosh *et al.*, 1991), carcinotoxicity (Solecki *et al.*, 1991; NTP, 1993), reproductive and developmental toxicity (Fuyuta *et al.*, 1979), and immunotoxicity (Thuvander *et al.*, 1996).

## Diagnosis

Presently there are reliable and accurate ways to measure mercury levels in the body. These tests involve mercury analysis in blood, urine, milk, hair, and liver and kidney. Levels found in blood, urine, and hair may be used together to predict possible health effects that may be

caused by the different forms of the mercury. Mercury levels in the blood provide more useful information after recent exposures than after long-term exposures. Mercury in urine is determined to test for exposure to metallic or inorganic mercury, while whole blood or hair is used to determine exposure to methylmercury. Kidney is an ideal specimen for mercury analysis from dead animals.

## TREATMENT

Activated charcoal (1–3 g/kg body weight, p.o.) is very effective in reducing further absorption of mercury. Specific treatment of mercury poisoning rests with the use of chelators along with protein solutions to bind and neutralize mercury compounds. The use of a particular chelator is dependent on the type of mercury exposure. Among several chelators, dimercaprol (British anti-Lewisite (BAL), 3 mg/kg, i.m.) has been found to be the most effective against mercury poisoning. However, chelation releases mercury from soft tissues which can be redistributed to the brain. Oral administration of sodium thiosulfate (1 g/kg) can assist in eliminating mercury. Animal studies suggest that antioxidants (particularly vitamin E) may be useful for decreasing the toxicity of mercury. Improved chelation and drug therapies for treating acute and chronic mercury poisonings are greatly needed.

## CONCLUSION

Toxicity by mercury depends on the form of mercury, dose, duration, and route of exposure. Organic mercury tends to bioaccumulate in the higher food chain, and as result, the maximum concentrations are found in the meat of fish, marine mammals, and fish-eating birds and wildlife. Methylmercury is the most toxic among the mercury species because of its volatility and its ability to pass through biological membranes such as the blood–brain barrier and the placental barrier. Nervous system and kidneys are the two major target organs. Not all forms of mercury cross the blood–brain barrier (e.g. inorganic mercury), but in all forms it accumulate in the kidney and thereby causes damage to this organ. Chelation therapy appears to be the best treatment.

## ACKNOWLEDGMENT

I would like to thank Mrs. Denise M. Gupta for her assistance in preparation of this chapter.

CHAPTER

# 33

# Molybdenum

*Jeffery O. Hall*

## INTRODUCTION

Molybdenum (Mo) is an essential nutrient in plants and animals. Thorough reviews on Mo have been published (Dick, 1956; Underwood, 1977; Ward, 1978; Friberg and Lener, 1986; Mills and Davis, 1987; Rajagopalan, 1988; Nielsen, 1996; Johnson, 1997; NRC, 2006). In plants and microbes, reduction of nitrate to nitrite and nitrogen fixation requires Mo (Williams and daSilva, 2002). Higher animals require Mo for oxygen transfer reactions of aldehyde oxidase, sulfite oxidase, and xanthine oxidase, where Mo is bound to a pterin nucleus (Johnson *et al*., 1980). Although dietary clinical deficiencies have not been reported under natural conditions (Mills and Davis, 1987), deficiency has been produced in animals fed purified Mo deficient diets (Mills and Bremner, 1980; Anke *et al*., 1985). Functional Mo deficiency has been caused by genetic disorders in humans (Reiss, 2000) and competitive replacement of tungsten for Mo in enzymes (Nell *et al*., 1980). And, iatrogenic Mo deficiency, resulting in aberrant sulfur-containing amino acid metabolism, has been reported following prolonged total parenteral nutrition (Abumrad *et al*., 1981).

Mo toxicity is intricately tied to interactions with copper and sulfur. Predominant manifestations of Mo poisoning are associated with secondary copper deficiency, but not all clinical symptoms are alleviated by copper supplementation. The copper–sulfur–Mo interactions are complex and vary greatly in degree of severity among species.

## BACKGROUND

Mo is a transition metal within group VI of the periodic table. It has an atomic number of 42, an atomic weight of 95.95, and has 7 different naturally occurring atomic masses from 92 to 100 (Rosman and Taylor, 1998). Mo can occur in a variety of oxidation states that range from (-II) to (VI) (IMOA, 2006), but valence states IV, V, and VI are the most common in biological systems (Johnson, 1997). Mo is utilized in the production of oxidation catalysts, pigments, corrosion-resistant steel, smoke suppressants, lubricants, fertilizers, and metal alloys. Although uniformly found in nature, the United States has the greatest producible Mo reserves.

Mo is commonly found in low concentrations in most dietary constituents (Rajagopalan, 1988), but excess intake can occur from plants grown on soils naturally high in Mo or from areas contaminated by mining or smelting operations. Daily dietary requirements for all species are such that requirements are met, even with low intake.

## PHARMACOKINETICS/ TOXICOKINETICS

### Absorption

Mo absorption differs between monogastrics and ruminants. In monogastrics, Mo absorption occurs from the stomach throughout the intestinal tract (Bell *et al*., 1964; Miller *et al*., 1972; Nielsen, 1996;). In contrast, ruminant absorption occurs in the intestinal tract, as an extensive delay in peak blood concentration would indicate that rumen absorption does not occur. This mucosal absorption is via an active carrier-mediated process that is also utilized by sulfate (Mason and Cardin, 1977). Absorption is quite efficient, being from 40% to 90% (Friberg and Lener, 1986; Turnlund *et al*., 1995). But, Mo absorption does not appear to be regulated at the point of mucosal

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

absorption, as increasing Mo concentrations presented to the mucosa results in concomitant increased absorption (Miller *et al*., 1972; Turnlund *et al*., 1995; ).

Dietary constituents can limit Mo absorption. Dietary sulfate present at the point of absorption can competitively inhibit Mo uptake (Mason and Cardin, 1977). Furthermore, in the presence of sulfur/sulfates, the reductive rumen metabolism results in di-, tri-, and tetra-thiomolybdates, which can then bind copper and form a non-absorbable complex (Dick, 1956; Price *et al*., 1987; Gooneratne *et al*., 1989).

### Distribution

Mo is widely distributed in tissues, but has highest concentrations in the liver, kidney, and bone (Schroeder *et al*., 1970; Friberg and Lener, 1986). In light of the essential nature of Mo, it is somewhat unusual that very little tissue retention/reserve is maintained. Post-absorptive circulation occurs by transport bound to the red blood cell proteins or as free ionic molybdate (Allway *et al*., 1968; Versieck *et al*., 1981). But, absorbed or systemically produced thiomolybdates can bind copper and result in circulating copper–thiomolybdate complexes which are not biologically available for tissue utilization.

### Elimination

Mo is eliminated from the body fairly rapidly, with little, and only short-term, tissue retention. Although urinary is the primary route of elimination, biliary elimination also occurs (Friberg and Lener, 1986; Vyskocil and Viau, 1999; NRC, 2006) and likely is the primary route of elimination in ruminants (Grace and Suttle, 1979; Pott *et al*., 1999). Urinary elimination is concentration dependent, resulting in relatively rapid elimination even with very large exposures. In lactating animals, Mo is excreted in the milk with content being dependent on the concentration being ingested (Archibald, 1951; Anke *et al*., 1985). Thus, exposure can be approximated by analysis of urine or milk for Mo content across time and extrapolating back to the time of exposure (Lesperance *et al*., 1985). Just as sulfate can inhibit the absorption of Mo, it can also compete for reabsorption sites in the renal tubules and enhance the rate of elimination (Friberg and Lener, 1986).

## MECHANISM OF ACTION

The mechanism by which Mo is active in biologic systems is through it redox activity in functional molybdo-enzymes (Mills and Davis, 1987). The readily changeable oxidation states of Mo lend it to functional utilization in these types of reactions.

The primary mechanisms by which Mo is toxic are directly tied to its interactions with sulfur and copper. These interactions result in functional or overt copper deficiency. But, these interactions differ significantly among species, with ruminants being much more susceptible than monogastrics. The reducing environment of the rumen converts sulfate or sulfur from sulfur-containing amino acids to sulfide, which then forms mono-, di-, tri-, and tetra-thiomolybdates (Price *et al*., 1987; Spears, 2003). Thiomolybdates binding of copper in the digestive tract prevents absorption of ingested copper, while systemic binding renders it non-bioavailable for tissue utilization (Gooneratne *et al*., 1989; Suttle, 1991). These copper–thiomolybdate complexes also result in enhanced copper excretion (Howell and Gooneratne, 1987). Price *et al*. (1987) found that the ruminal binding was predominantly via tri- and tetra-thiomolybdates, while systemic effects were predominantly via di- and tri-thiomolybdates. In practical means, the thiomolybdates serve as effective chelators of copper and deplete functional body stores.

Most of the clinical syndromes of Mo poisoning can be tied to deficiencies in copper-containing enzyme systems (NRC, 2006). Although most clinical effects of Mo poisoning are reversed by supplementation of copper, Mo may have some direct toxic effects. It is possible that permanent tissue damage, caused by severe copper depletion, results in non-response to copper supplementation in clinically affected animals. The exact mechanisms of non-copper responsive toxic effects of Mo are poorly defined or investigated, but high Mo concentrations can inhibit the *in vivo* activity of succinic acid oxidase, sulfide oxidase, glutaminase, cholinesterase, and cytochrome oxidase (Venugopal and Luckey, 1978).

## TOXICITY

Both acute and chronic toxicity of Mo varies greatly among species. Monogastric animals are much less sensitive than ruminants, due to the rumen metabolism of sulfur and formation of thiomolybdates. The relative tolerance to Mo has been ranked: horses > pigs > rats > rabbits > guinea pigs > sheep > cattle (Venugopal and Luckey, 1978), but more recent literature suggests horses may be more sensitive (Ladefoged and Sturup, 1995). In total, the toxicity of Mo needs to be evaluated with consideration of dietary sulfur/sulfates and copper. This is with knowledge that sulfates competitively inhibit uptake from the intestinal tract, but in ruminants results in the formation of thiomolybdates which will enhance the toxic effects on copper status.

Natural toxic effects of Mo are primarily via ingestion, but toxicity has been demonstrated by both inhalation and injection in laboratory rodents. Intraperitoneal $LD_{50}$ of Mo in rats ranges from 99 to 228 mg/kg body wt. (Venugopal and Luckey, 1978), with similar lethal doses in mice and guinea pigs. Chronic inflammatory lesions and hyaline degeneration within the respiratory tree was induced by Mo trioxide exposure of 10–100 mg/m$^3$ 6 h per day, 5 days a week (Chan *et al.*, 1998). Increased incidence of respiratory adenomas was also seen in the rats and mice.

Concentrations of Mo required to produce acute poisoning orally differ significantly among species. For cats, rabbits, and guinea pigs, the oral $LD_{100}$ for Mo is 1310, 1020, and 1200 kg/kg body wt., while the oral $LD_{50}$ for rats is 125–370 mg/kg body wt. (Venugopal and Luckey, 1978). Little acute toxicity data are available for domestic animals, but cattle have been acutely poisoned with feed containing 7400 mg Mo/kg diet (group average intake of 31 mg Mo/kg body wt./day) and Mo was acutely lethal in sheep at 132–137 mg Mo/kg body wt./day for 2–3 days (Swan *et al.*, 1998).

Clinical signs and pathologic lesions in acutely poisoned animals differ from those seen with more chronic poisonings. Acutely poisoned cattle and sheep developed feed withdrawal, lethargy, weakness, hind limb ataxia that progressed to the front limbs, and recumbency (Swan *et al.*, 1998). The cattle also had profuse salivation, ocular discharge, and mucoid feces. Hydropic hepatocellular degeneration/necrosis and hydropic degeneration/necrosis of the proximal and distal renal tubules was observed in both cattle and sheep.

Relative chronic toxicity of Mo is just as species dependent as acute poisoning. Lethal doses of Mo administered chronically to laboratory animals (rats, mice, guinea pigs, and rabbits) range from 60 to 333 mg Mo/kg body wt./day, while cattle are poisoned with as little as 3 mg Mo/kg body wt./day (NRC, 2006). Literature reports of toxic dietary Mo content range from 10 to 1200 ppm for rats, 300 to 8000 ppm for poultry, 200 to 4000 ppm for rabbits, 1000 to 8000 ppm for Guinea pigs, 2.5 to 20 ppm for sheep, and 2 to 400 ppm for cattle (Pitt, 1976). Ruminants commonly succumb to molybdenosis when Mo intake is greater than 20 ppm in the diet. However, due to the intrinsic nature of the Mo–copper–sulfur interactions, chronic Mo poisoning in ruminants can be divided into three classes: dietary Mo greater than 20 ppm, low Cu:Mo ratio ($\leq$2:1), and high dietary sulfur with normal copper and Mo (Ward, 1978). The desired Cu:Mo ratio in ruminants is between 6:1 and 10:1 (Thompson *et al.*, 1991). Thus, Mo toxicosis can occur at much low concentrations in copper deficient animals than those on diets adequate in copper.

Most clinical signs of chronic Mo poisoning are associated with induced copper deficiency. Commonly, the first recognized clinical sign of chronic Mo poisoning is severe diarrhea (Dick, 1956; Pitt, 1976; Underwood, 1977; Ward, 1978; Friberg and Lener, 1986; Mills and Davis, 1987; Rajagopalan, 1988; Nielsen, 1996; Johnson, 1997; Coppock and Dziwenka, 2004; NRC, 2006). "Teart" is used to refer to soil or plants that contain unusually high amounts of Mo, thus the term teart scours is commonly used to describe the diarrhea associated with excessive Mo intake. Although the exact mechanism is not well defined, copper supplementation alleviates this clinical sign. Other common clinical signs of chronic Mo poisoning include poor body weight gain, weight loss, anemia, decreased milk production, achromotrichia, alopecia, limb deformities, bone fractures, periostosis, lameness, lack of libido, and ataxia. Abortions have been reported in horses.

Pathologic alterations of chronic Mo poisoning are not specifically diagnostic. These lesions are secondary to induced copper deficiency and include emaciation, periostosis, and epiphyseal plate growth abnormalities. Because of the nature of chronic Mo poisoning, primary copper deficiency must always be ruled out when these lesions are identified.

## TREATMENT

The two primary mechanisms of treating Mo toxicosis involve removal from the source of high Mo and copper supplementation, but administration of sulfate to monogastrics will enhance elimination rates. With rapid clearance from the body, removal from the high Mo source will quickly remove excess Mo from the body. However, permanent damage may be present that results in sustained animal deaths for weeks to months post-exposure (Swan *et al.*, 1998). Supplementation of copper in Mo poisoned animals must be done with care, especially in sheep, to prevent excessive copper accumulation and subsequent copper toxicosis.

## CONCLUDING REMARKS AND/OR FUTURE DIRECTION

The known mechanisms of Mo poisoning are a complex interaction with sulfur and copper that differ significantly across animal species. But, some clinical effects of Mo poisoning have not been related to absolute or functional copper deficits. These clinical effects of Mo poisoning need further investigation to delineate the mechanism by which Mo is producing adverse animal health.

# Selenium

*Jeffery O. Hall*

## INTRODUCTION

Selenium is an essential nutrient that has a relatively narrow window between ingested amounts that result in deficiencies and those that cause toxicoses. Historically, occurrences of livestock disease that mimic clinical presentation of chronic selenium poisoning were recorded in the 13th century (Martin, 1973). Marco Polo wrote of such cases in western China in 1295. In 1560, Father Simon Pedro described human cases of presumably chronic selenosis in Columbia (Benavides and Mojica, 1965). The first documented record of selenium poisoning in livestock was reported in 1860 by US Army surgeon (Martin, 1973). T.W. Madison described a fatal disease of horses that grazed near Fort Randall, South Dakota. It also has been speculated that the horse illness that slowed General Custer's Cavalry relief may have been due to selenium, but chronic selenosis generally takes weeks to develop.

Selenium deficiency had been historically linked to a variety of clinical effects. Since 1949, vitamin E, cysteine and a "factor 3" were known to protect rats from fatal liver necrosis (Schwarz and Foltz, 1957). When rats were fed torula, a brewer's yeast, they developed liver necrosis that could be avoided by use of baker's yeast (*Saccharomyces sp.*). It was postulated that an essential nutrient, "factor 3", was deficient in torula. After much research, the active, preventative element present in "factor 3" was identified as selenium. Several metabolic diseases of previously unknown origin were later found to relate to selenium deficiency, including "white muscle disease" (WMD) in calves and lambs (Muth *et al*., 1958; Godwin and Fraser, 1966), hepatosis dietetica in pigs (Eggert *et al*., 1957), exudative diathesis in poultry (Patterson *et al*., 1957), and pancreatic degeneration in poultry (Thompson and Scott, 1969).

Since its first discovery as an essential nutrient, selenium has been found to act in numerous body systems. In 1973, Se was identified as an essential component of glutathione peroxidase (GSH) enzyme (Flohe *et al*., 1973; Rotruck *et al*., 1973). Selenium was shown to be essential in humans when added dietary selenium prevented a cardiomyopathy known as "Keshan disease" (Chen, 1986). Selenium supplementation may also be protective against certain types of cancer (Combs, 1997), cardiovascular disease (Duthie *et al*., 1989), and viral infections (Schrauzer, 1994; Levander, 2000). Because of the essential nature of selenium, poisoning cases from both natural plant accumulations of selenium and nutritional overdoses are encountered.

The identified essential functions of selenium are still increasing. The most notable is GSH, where selenocysteine is a required component of the enzyme system (Brown and Arthur, 2001). Reduced GSH is the primary physiologic first defense against free radical damage to tissues, helping to maintain functional membrane integrity. Several subclasses of GSH are now recognized (Cohen and Avissar, 1994; Sunde, 1994). To date over 30 selenoproteins have been identified, many of which have vital enzymatic functions (Tiwary, 2004). Thioredoxin reductase I, II, and III (Brown and Arthur, 2001), 5′ triiodothyronine deiodinase (Arthur and Beckett, 1994), and "selenoprotein" are also selenium dependent. In addition, selenium plays several roles in normal immune function, reproductive function, hepatic biotransformation reactions, neurotransmitter turnover, and anti-carcinogenic functions.

## BACKGROUND

Selenium is a member of the non-metallic elements within group VIa of the periodic table. It has an atomic number of 34, an atomic weight of 78.96, and has six different naturally occurring stable isotopic masses from 74 to 82

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

(Rosman and Taylor, 1997). Selenium has four natural oxidation states: −2 (selenides), 0 (elemental), +4 (selenites), and +6 (selenates) (Barceloux, 1999). Selenium was first identified in 1817 by Jons Jakob Berzelius, a Swedish chemist, who investigated worker illnesses in a sulfuric acid plant at Gripsholm, Sweden (Fredga, 1972). He named this element after "Selene", the green moon Goddess.

Many areas within the Northern Great Plains of the United States, such as the Dakotas, Wyoming, Montana, Nebraska, and Kansas, have high soil selenium content (4–5 ppm Selenium or more), resulting in high plant uptake and subsequent Se toxicosis in herbivores (Rosenfeld and Beath, 1964). High soil selenium also occurs in alkaline soils of some localities in Algeria, Argentina, Australia, Bulgaria, Canada, China , Columbia, Ireland, Israel, Mexico, Morocco, New Zealand, South Africa, the former Soviet Union, Spain, and Venezuela (NRC, 1983). However, total soil selenium is not the best indicator of potential selenium poisonings, as Hawaii and Puerto Rico have areas of high soil selenium that is not available to the plants due to the acidic soil types, which result in lowered water soluble, bioavailable selenium for plant uptake (Lakin, 1961).

Inorganic forms of selenium are the primary form in soil. Only the water soluble forms are readily available for plant uptake, with the greatest absorption being in the form of selenate via the sulfate transporter. Elemental selenium and precipitated metal-selenides are not bioavailable for plant uptake. Some "indicator plants" or "obligatory selenium accumulator plants" can accumulate several thousand ppm selenium and are often found in selenium rich areas, since they require high selenium for growth (Rosenfeld and Beath, 1964). These plants include genera such as *Astragalus* (milk vetch), *Xylorhiza, Machaeranthera* (woody aster), *Haplopappus* (golden weed) – formerly known as *Oonopsis* and *Stanleya* (prince's plume). Selenium content as high as 14,990 ppm have been reported for a sample of *Astragalus racemosus* (Beath, 1937). Although these indicator plants have poor palatability, during times of limited forage, they are eaten. Secondary or facultative accumulating plants can survive with high selenium content, but do not require it for growth. These plants are often more palatable than the indicator plants and include *Aster*, *Atriplex* (salt bush), *Castilleja* (paintbrush), *Gutierrezia* (snakeweed), *Grindelia* (gumweeds), *Sideranthus* (ironweed), *Eurotia* (winter fat), *Mentzelia, Machaeranthera*, and *Gyria sp.,* as well as some crop plants such as western wheat grass, barley, wheat, alfalfa, onions, and Swiss chard (Beath *et al.*, 1935; Williams and Byers, 1936).

Most of the selenium in plants and other biological matrices is in an organic form, but small amounts of inorganic selenate and selenite can also be present. The vast majority of plant selenium, especially in non-indicator plants, is in the form of selenomethionine, but selenocysteine and a variety of other seleno-amino acid derivatives can also be found (Peterson and Butler, 1962; Olson *et al.*, 1970; Whanger, 2002). In contrast, the majority of selenium in indicator plants, such as *Astragalus*, is a water soluble Se-methyl-selenocysteine (Shrift, 1973), but can also have selenocystathionine (Lewis, 1976). Garlic was found to contain significant selenomethionine, as well as glutamyl-Se-methyl-selenocysteine and possibly $\gamma$-glutamyl-selenomethionine (Kotrebai *et al.*, 1999). The non-protein associated selenium compounds may be a protective mechanism of the plants to prevent excessive replacement of methionine in plant proteins resulting in misfolding and altered protein properties (Peterson and Butler, 1962). Some microbial populations, as well as plants, can reduce selenium to volatile chemical forms (Shrift, 1973).

## PHARMACOKINETICS/ TOXICOKINETICS

### Absorption

The majority of ingested selenium compounds are absorbed from the duodenum, with lesser amounts in the jejunum and ilium (Wright and Bell, 1966; Whanger *et al.*, 1976). Little to no absorption reportedly occurs from the stomach and rumen. However, one report suggests that minimal absorption of selenomethionine occurs through the rumen wall and into the blood (Hidiroglou and Jenkins, 1973).

The chemical form of selenium greatly impacts the overall absorption. Selenite absorption is via passive diffusion through the brush border membranes (Vendeland *et al.*, 1992, 1994). In contrast, selenate has little affinity for the brush border membranes. Selenate is absorbed via a sodium co-transport system that is also utilized by sulfate (Wolffram *et al.*, 1988). Selenium in the form of seleno-amino acids, selenomethionine, and selenocysteine are absorbed through active amino acid transport mechanisms and are more bioavailable than selenite or selenate (McConnell and Cho, 1967; Ammerman and Miller, 1974; Vendeland *et al.*, 1994). The selenium status did not affect overall absorption, indicating that absorption was not under homeostatic regulation.

In monogastrics, the relative selenium absorption is greater than in ruminants, ranging from 45% to 95% (Thomson and Stewart, 1974; Furchner *et al.*, 1975; Bopp *et al.*, 1982). And organic forms of selenium are better absorbed (Robinson *et al.*, 1978). In ruminants, the relative absorption ranges from 29% to 50% (Wright and Bell, 1966; Suttle and Jones, 1989). The decreased absorption in ruminants is due to microbial reduction of selenium forms in the rumen to selenides and elemental selenium which are not bioavailable (Cousins and Cairney, 1961; Whanger *et al.*, 1968; Peter *et al.*, 1982). This reduction in

bioavailability is generally exacerbated by high carbohydrate diets, but can be altered by differing rumen microbial populations (Hudman and Glenn, 1984; Koenig *et al.*, 1997). Some rumen microbes more efficiently reduce selenium, while others effectively incorporate it into selenium containing amino acids. The incorporation of selenium into microbial proteins, as well as systemic absorption, can be competitively inhibited by natural methionine and cysteine (Serra *et al.*, 1996).

## Distribution

Tissue distribution is dependent on the chemical form of selenium absorbed. Selenium is generally utilized for synthesis of selenoproteins, incorporated into tissue proteins, or eliminated. Selenomethionine can be non-specifically incorporated into tissue proteins in place of methionine (Awadeh *et al.*, 1998), but selenocysteine is not (Burk *et al.*, 2001), with highest incorporation occurring in tissues with high rates of protein synthesis (Hansson and Jacobsson, 1966). The non-specific incorporation of selenomethionine effectively serves as a pool of selenium reserve with a long biological half-life (Schroeder and Mitchener, 1972). Highest total selenium content is typically found in the kidney and liver, with lesser amounts in all other tissues (Muth *et al.*, 1967; Levander, 1987; Echevarria *et al.*, 1988; Davidson and Kennedy, 1993). Both specific and non-specific selenium incorporation into proteins was greater in selenium deficient animals.

Time to peak tissue concentrations is tissue dependent. Peak selenium content of blood, liver, muscle, kidney, spleen, and lung was reached within 24 h after an injection of $^{75}$Se as selenite (Muth *et al.*, 1967). In contrast, brain, thymus, and reproductive organs do not reach maximal content until much later (Brown and Burk, 1973; McConnell *et al.*, 1979; Smith *et al.*, 1979; Behne *et al.*, 1988).

Selenium is efficiently transferred across the placenta into feti during gestation. The overall maternal selenium content is positively correlated with fetal and newborn selenium status (McConnell and Roth, 1964). Newborns get some selenium from milk, with much higher content in colostrums than in milk later in lactation.

## Metabolism

Selenite is metabolized in red blood cells to hydrogen selenide (Gasiewicz and Smith, 1978). Sequential methylation reactions result in the formation of monomethylselenide, dimethylselenide, and trimethylselenide (Kajander *et al.*, 1991; Itoh and Suzuki, 1997). These reactions utilize *S*-adenosylmethionine for methyl groups which are transferred by methyltransferases (Kajander *et al.*, 1991). These sequential reactions can deplete available *S*-adenosylmethionine, which would limit the degree of methylation. In rats given selenomethionine, trimethylselenide occurred in the urine more rapidly than in rats given sodium selenite or selenocysteine, indicating that selenomethionine may be converted to methylselenol which is easily further methylated.

Selenomethionine is metabolized by demethylation to selenocysteine. This set of pathways is similar to the metabolism of methionine. The selenocysteine is then metabolized by selenocysteine-β-lyase in the liver and kidney to alanine and selenide (Soda *et al.*, 1987).

## Elimination

Selenium is primarily excreted in the urine and feces, but the form and extent of elimination by different routes are dose and species dependent. In monogastric animals, urinary elimination predominates, irrespective of the route of exposure (Leng *et al.*, 2000), with less than 10% recovered in feces (Burk *et al.*, 1972). Some literature suggests that urinary eliminated selenium is predominantly metabolites of selenium, with trimethylselenide predominating at higher doses (McConnell and Roth, 1966; Palmer *et al.*, 1969; Zeisel *et al.*, 1987; Itoh and Suzuki, 1997), but monomethylselenide is more abundant at lower doses. Human elimination is tri-exponential for selenite and selenomethionine (Alexander *et al.*, 1987). The terminal elimination phase was 8–20 and 230 days for selenite and selenomethionine, respectively. Overall selenium retention and maintenance of adequate seleno-enzymes are for a much longer time period in animals supplemented with selenomethionine than selenite. Elimination rate is dose dependent, with half-lives of 19.5 and 1.2 days with selenite of 0.1 and 1.0 ppm in the diet, respectively (Burk *et al.*, 1972). Due to non-specific protein incorporation of selenomethionine, urinary and fecal recovery after dosing was less than 30% of that for selenite or selenate (Thomson, 1998).

The literature suggests that the predominant selenium elimination in ruminants is fecal when ingested, but urinary with parenteral administration or in non-ruminating young animals. This is actually an error in terminology, as the fecal loss of selenium is primarily in the forms of elemental selenium and precipitated selenides from ruminal reduction (Langlands *et al.*, 1986). Thus, this selenium is just non-absorbed material and not truly being eliminated from the central compartment. However, a small amount of metabolized selenium excesses is excreted in the bile (Cousins and Cairney, 1961). The metabolic metabolites eliminated in the urine follow a similar pattern to that seen with monogastrics. Urinary elimination is predominant with parenteral administrations and in non-ruminating young animals (NRC, 1983).

Renal selenium elimination is dependent of glomerular filtration and degree of re-absorption. Increasing renal fluid absorption did not increase the selenium content in urine, indicating a tubular re-absorptive process (Oster and Prellwitz, 1990). Thus, dehydration or renal insufficiency would decrease rates of elimination. Excretion and renal clearance rates correlate with creatinine, indicating glomerular filtration is the mechanism of elimination.

Some selenium is eliminated via respired air, but the relative importance of this route is dose dependent. At normal intake, only about 10% or less is eliminated from the respiratory tract (Burk *et al.*, 1972), but as dose increases the percent eliminated in respired air increases (Jacobsson, 1966; McConnell and Roth, 1966). Dimethylselenide and dimethyldiselenide are the predominant forms eliminated in respired air at toxic doses. Dimethylselenide predominates when mice were dosed with selenite or selenocysteine, while dimethyldiselenide is most abundant when rats were dosed with selenomethionine. Respiratory elimination is primarily when renal elimination thresholds are maximized, which results in most respiratory elimination occurring in a short-time period soon after exposure to toxic doses (McConnell and Roth, 1966; Tiwary *et al.*, 2005).

## MECHANISM OF ACTION

Although much research has been conducted with regard to selenium poisoning, the exact mechanism of the toxic effects in the body are still not clear. With acute poisoning, one theory is the depletion of intermediate substrates, such as glutathione and *S*-adenosylmethionine, which disturbs their respective enzyme activities (Vernie *et al.*, 1978). Another potentially interactive theory is the production of free radicals by reaction of selenium with thiols, causing subsequent oxidative tissue damage (Hoffman, 2002; Kaur *et al.*, 2003; Balogh *et al.*, 2004). A third theory is the incorporation of selenium compounds in place of sulfur, such as in proteins, in which it disrupts normal cellular functions (Raisbeck, 2000). This is an especially likely mechanism for the hair and hoof lesions of chronic selenium poisoning, with the loss of disulfide bridges which provides structural integrity to these tissues. This would also apply to inhibition of DNA methylation by *S*-adenosylmethionine or indirect inhibition by increased *S*-adenosyl homocysteine content (Hoffman, 1977). And, it is possible that each of these proposed mechanisms is valid with respect to specific chemical forms of selenium.

## TOXICITY

Selenium poisoning cases generally fall into three types of exposure history. The first is from ingestion of selenium in plants that have accumulated it from naturally seleniferous soils. The second is from accidental overdoses by injection or errors in feed mixing. And the third is from environmental contamination, which often results in exposure from plant accumulation. With each of these types of poisonings, one may see acute, subacute, or chronic selenium poisoning, depending upon the daily exposure rate. However, one must understand that an animal's age plays a role in susceptibility to selenium poisoning, as young animals are less tolerant than adults (Raisbeck, 2000).

Acute oral selenium poisoning occurs with sudden exposure ranging from 2.2 mg/kg (Rosenfeld and Beath, 1964) to greater than 20 mg/kg body wt. (Miller and Williams, 1940; Mahan and Moxon, 1984) across species. The relative acute toxicity of selenium containing compounds is dependent on their solubility, with poorly soluble selenides and elemental selenium being much less toxic than soluble selenates, selenites, and organic selenium (NRC, 2006). Minimum lethal dose for rabbits, rats, dogs, and cats is 1.5–3 mg/kg body wt. (NRC, 1983). The $LD_{50}$ for oral selenite has been estimated to be 1.9–8.3 mg/kg body wt. in ruminants (Grace, 1994), but other references suggest it to be 9–20 mg/kg body wt. (Puls, 1994). In poultry, the acute oral $LD_{50}$ of selenium is 33 mg/kg body wt. Injectable selenium is more acutely toxic than oral, with intramuscular $LD_{50}$ of 0.5 mg/kg in lambs (Caravaggi *et al.*, 1970). Subcutaneous $LD_{50}$ of selenium is 1 mg/kg in lambs and 1.9 mg/kg in adult cattle (Grace, 1994).

Clinical manifestation of acute selenium poisoning begins as early as 8–10 h, but can be delayed for up to 36 h (Franke and Moxon, 1936; NRC, 1983; Raisbeck, 2000; Tiwary *et al.*, 2006). Early in the clinical syndrome, one can smell the garlicky smell of dimethylselenide on the breath. Clinical signs that follow include by respiratory distress, restlessness or lethargy, head down, droopy ears, anorexia, gaunt appearance, salivation, watery diarrhea, fever, sweating, tachycardia, teeth grinding, tilted gait, tetanic spasms, and/or death. Clinical signs tent to progress quickly after first observed. Gross and histologic lesions include systemic congestion, pulmonary edema, and petechial hemorrhages in and on the myocardium.

"Blind staggers" has historically associated with subacute to chronic selenium. However, this association was due to its occurrence in known seleniferous areas. The areas with seleniferous soils also tend to have highly alkaline soils with high potential for excessive sulfur exposure. It has been stated that blind staggers cannot be reproduced with pure selenium compounds alone and likely involves other factors, such as alkaloid poisoning, starvation, or polioencephalomalasia (O'Toole and Raisbeck, 1995). However, one can still find references that tie it to selenium (Underwood and Suttle, 1999; NRC, 2006).

Chronic selenosis, often referred to as "alkali disease", is the results of long-term ingestion of seleniferous forages (NRC, 1983; Raisbeck, 2000 NRC, 2006;). High selenium intake is generally for greater than 30 days and, due to

plant selenium content, is usually associated with facultative accumulators, not indicator plants, although chronic selenosis can also be reproduced by long-term feeding of high inorganic selenium (Kaur *et al*., 2003). Calves were chronically poisoned with selenite at 0.25 mg/kg body wt. daily for 16 weeks. In a similar study in yearlings, selenium as selenite at 0.8 mg/kg/day and as selenomethionine at 0.28 mg/kg/day resulted in alkali disease (O'Toole and Raisbeck, 1995). However, other studies did not produce alkali disease with selenium doses as high as 11.9 mg/kg of diet in feeders or 118 mg/kg body wt. daily for 128 days in dairy cows (Ellis *et al*., 1997 Lawler *et al*., 2004;). Differences in susceptibility to chronic selenium poisoning may be a product of historical exposure and variability in rumen microbial population. As stated previously, certain microbes can reduce selenium to non-bioavailable forms, resulting in decreased systemic absorption. Pigs develop chronic selenosis with exposure to selenium as low as 8 mg/kg of diet (Goehring *et al*., 1984; Mahan and Magee, 1991; Stowe and Herdt, 1992). And horses exposed to 20 mg Se/kg DM for 3 weeks developed lesions (Stowe and Herdt, 1992).

Clinical signs of chronic selenosis include depression, weakness, emaciation, anemia, hair loss, anorexia, diarrhea, weight loss, lameness, and death (Rosenfeld and Beath, 1964; O'Toole and Raisbeck, 1995; Underwood and Suttle, 1999 Raisbeck, 2000;). Hoof wall abnormalities are frequently identified in cattle, horses, and pigs and include swelling of the coronary band, hoof deformities, and/or separation and sloughing of the hoof wall. Hair loss from the base of the tail and switch in cattle, horses, and mules is sometimes referred to as "Bobtail disease". Interestingly, sheep do not develop the alopecia or hoof lesions that are seen in cattle, but they have decreased wool growth rates. In pigs, goats, and horses, there may be a general alopecia (Franke, 1934). Pigs also develop neurologic signs of paralysis (Goehring *et al*., 1984).

Pathologic lesions of chronic selenium poisoning are generally related to hoof lesions and to the effects of starvation (Raisbeck, 2000). Lesions of nephritis, hepatic cirrhosis, and myocardial necrosis can be expected. In pigs, bilateral malacia of the gray matter in the spinal cord can be seen.

Reproductive abnormalities are seen in several species when excessive selenium is ingested. Field reports indicate that reproductive performance can be reduced without the other typical signs of alkali disease at 5–10 ppm Se in diet (Olson *et al*., 1970), but direct experimental evidence is lacking (Raisbeck, 2000). Decreased conception rate and an increased fetal resorption rate in cattle, sheep, and horses were observed when they were fed natural diets containing 20–50 mg Se/kg diet (Harr and Muth, 1972). In addition, it must be noted that Se accumulates in the fetus at the expense of the dam (Puls, 1994). Thus, higher accumulation of selenium in the fetus may result in abortions, stillbirths, or weak/lethargic calves. However, at least some of the adverse effects on reproduction caused by excess selenium in ruminants are caused by interference with absorption and retention of copper that results in copper deficiency.

Selenosis in poultry has major effects in reproduction. Poor hatchability, embryonic deformities, and embryonic death are common sequelle to selenium poisoning (Latshaw *et al*., 2004).

## TREATMENT

The most effective treatment is to prevent excessive exposure. Although the maximal tolerable level for selenium was once set at 2 mg/kg of diet per day for all species, this has now been changed to 5 mg/kg of diet per day for ruminants (NRC, 2006). It is stated that this new tolerance for ruminants is appropriate for horses as well. Swines have a maximum tolerance level of 4 mg/kg of diet, for poultry it is set at 3 mg/kg of diet, and for fish it is set at 2 mg/kg of diet.

As there is no specific mechanism of chelation and removal of selenium in animals, the primary treatment protocol is of supportive care with both acute and chronic selenium poisoning. With chronic poisoning, it is important to understand the long-term commitment necessary to allow an animal with hoof lesions time to re-grow the hoof wall once exposure has been stopped. Especially with organic selenium's incorporation into body proteins, the time necessary to just decrease the body load of selenium, once excessive exposure has stopped, is quite long.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Selenium deficiency and toxicity are problems that veterinarians, nutritionists, and animal owners need to understand. The small difference between deficiency and toxicity in terms of dietary intake makes the risk of accidental selenium poisoning high. Many areas of the world have seleniferous soils which can cause poisoning via ingestion of natural forages grown on them. As there is no specific treatment for selenium toxicosis, it is critical that appropriate education be utilized in order to minimize the risks to the livestock industry.

Future research needs to address the mechanisms of physiologic damage caused by both acute and chronic selenium poisoning with differing chemical forms of selenium. With an understanding of the cellular mechanisms of selenium poisoning, more specific means of treatment might be developed. In addition, a clearer understanding of thresholds for chronic selenium poisoning is needed.

With the knowledge that certain ruminal microbes can reduce various forms of selenium to non-absorbable forms, preventative use of these microbes in seleniferous areas to prevent systemic accumulation and poisonings should be investigated.

CHAPTER

# 35

# Sodium chloride (salt)

*Larry J. Thompson*

## INTRODUCTION

Sodium chloride is often referred to as table salt, common salt or just simply as salt. Salt is an essential nutrient and can give an attractive taste to foods and feeds. It has been stated that salt is the only mineral compound for which animals can truly develop a craving.

Salt is a necessary nutrient for the health of animals and many nutrition texts divide it into separate requirements for sodium (Na) and chloride (Cl). Daily requirements for salt will increase due to lactation, exertion and increases in ambient temperatures. These same conditions will also require an increase in water intake, which must always be considered in any discussion concerning salt intake.

An excess of salt intake can lead to the condition known by various names including salt poisoning, hypernatremia, sodium ion toxicosis and water deprivation-sodium ion intoxication. The last name in this list is the most descriptive, giving both the result (sodium ion intoxication) and the most common predisposing condition (water deprivation).

## BACKGROUND

Sodium is the main cation and chloride is the main anion in the regulation of osmotic balance in the extracellular fluid (ECF) of the body. Serum sodium concentration and serum osmolarity are normally maintained under precise control by homeostatic mechanisms involving thirst, antidiuretic hormone and renal reabsorption of filtered sodium. Normal reference ranges for serum sodium in adult animals (given in mmol/l) include porcine 135–150, bovine 132–152, canine 141–152, feline 147–156 and equine 132–146 (Kaneko *et al*., 1997). For sodium concentration measurement, mmol/l = mEq/l and can be used interchangeably. Hyponatremia is the result of the loss of excess sodium compared to loss of water and can be the result of a large number of disease processes and conditions. For a more complete explanation on the recognition and correction of hyponatremia the reader is directed to other references (Angelos and Van Metre, 1999).

Salt is normally present in animal diets at 0.5–1%. Production animals are often given free access to salt blocks or mineral mixes as supplements to the diet. Additional sources of salt may include high-saline ground water, brine or seawater. The use of whey as a feed or to produce wet mash can add dramatically to sodium intake. High concentrations of salt in the diet (up to 13%) have been used to limit feed intake of cattle. In general, animals can tolerate high concentrations of salt in the feed if they have free access to fresh water. Salt-deprived animals or animals not acclimated to high-salt feeds can overconsume these feeds making the animal prone to hypernatremia. Improperly formulated or improperly mixed feed can be an additional source of excess salt. Companion animal exposures to excess salt have included the use of salt as an emetic (this practice is no longer recommended) and the consumption of various salt-containing objects including rock salt and dough-salt mixtures. Hypernatremia has also been reported in animals treated with improperly mixed oral electrolyte solutions and remedies for diarrhea.

Excess ingested salt can be irritating to mucosal surfaces and can result in anorexia, vomiting or diarrhea. Ingested dietary salt is approximately 90% absorbed across the gastrointestinal tract. Ingestion of excess sodium on an acute basis can result in hypernatremia with this condition being variously termed direct sodium ion toxicosis, acute sodium ion toxicosis or acute hypernatremia. Clinical signs develop within 1–2 days. The more common form of hypernatremia develops due to restricted water intake and is termed indirect sodium ion toxicosis, chronic

sodium ion toxicosis or chronic hypernatremia. Clinical signs will develop over a period of 4–7 days but the early changes may be missed or ignored. There are several common reasons for restricted water intake including frozen water sources, unpalatable water sources, mechanical failure, overcrowding or naïve animals and owner neglect.

## PHARMACOKINETICS/MECHANISM OF ACTION

An increase in sodium intake leads to a rise in sodium concentration in the serum and a rapid distribution throughout the body. Osmolarity of the ECF is monitored by osmoreceptors in the hypothalamus and the body reacts to increases by stimulating thirst for increased water intake. Additionally, the release of antidiuretic hormone from the posterior pituitary will cause increased water retention by the kidneys. These responses should function to quickly restore normal osmolarity but may only be effective if the osmolar changes are gradual and sufficient water is available to the animal. As the sodium ion concentration of the serum increases, water will move out of the interstitium and intracellular fluid into the ECF along the osmotic gradient. Sodium will passively diffuse across the blood–brain barrier increasing the sodium concentration of the cerebral spinal fluid above the normal range (135–150 mmol/l). During this developing hypernatremia, the cells of the brain will also increase their intracellular osmolarity to prevent excess water loss to the ECF, which would cause cell shrinkage. If the hypernatremia develops too quickly and this protective mechanism fails, significant cell shrinkage occurs and the entire brain shrinks and pulls away from the calvarium resulting in the disruption of the blood supply to the brain. This can result in subarachnoid, subdural or intravascular hemorrhages (Hardy, 1989). In severe cellular dehydration, the result can be seizure-like activity and death. If the increase in sodium concentration of the brain cells continues, there will be an inhibition of glycolysis and a decrease in the energy available in the cell. While sodium will passively diffuse into the brain, it is an energy-requiring active process that transports sodium out. Thus the brain response to a rapid decrease in serum sodium is delayed and the developing osmotic gradient will cause water to move into the brain causing swelling, cerebral edema and the development of clinical signs.

Changes in cellular osmolarity will occur in both acute and chronic hypernatremia situations, but changes to osmolarity on a chronic basis will involve the accumulation of more osmotically active organic compounds, termed idiogenic osmoles. These include taurine, myoinositol, glycerophosphoryl-choline, glutamate, glutamine, betaine and phosphocreatine. Maximum concentrations of idiogenic osmoles occur within 48–72 h and can account for 60% of the change in cellular osmolarity. Once the hypernatremia situation is corrected, the idiogenic osmoles will take 48–72 h to decrease back to normal levels. As in the acute situation, a rapid decrease in serum sodium will develop an osmotic gradient causing water to move into the brain with resulting cerebral edema and the development of clinical signs.

## TOXICITY

In all situations involving salt intake, the intake of water will have great impact and must also be considered. The acute toxic dose of sodium chloride is approximately 2.2 g/kg in swine, equine and bovine species with the ovine toxic dose approximately 6 g/kg (Osweiler *et al*., 1985). Swine appear to be most sensitive domestic animal and involve the greatest number of clinical reports. Both swine and poultry can be severely affected when water intake is severely restricted or with high-salt diets and only moderate water restriction. Increased water requirements will increase the susceptibility of lactating cows and sows to salt poisoning, making them more sensitive to sudden restrictions in water. The acute toxic dose of sodium chloride in dogs is given as 4 g/kg, but clinical signs have been reported for lesser ingestions (Barr *et al*., 2004) and an ingestion greater than this was reported with only mild clinical signs. Horses appear to be rarely affected with classic salt poisoning but can develop it with conditions of increased salt intake and sudden water restriction. Horses are, however, subject to dehydration and electrolyte abnormalities especially under conditions of exercise and high ambient temperatures (Cohen *et al*., 1993).

Clinical signs have best been described in swine and include loss of appetite, thirst, restlessness, pruritus and constipation. These early clinical signs can progress over several days to aimless wandering, head pressing, circling or pivoting around a limb. The animal may display seizure-like activity and assume a dog-sitting position, draw its head back in a jerking motion and fall over on its side (Osweiler *et al*., 1985; Niles, 2004). Terminally, the animal will be in lateral recumbency with paddling and opisthotonus. Cattle with acute excess salt intake may develop gastroenteritis, weakness, dehydration, tremors and ataxia. The cattle may appear to be blind and develop seizure-like activity or partial paralysis including knuckling over at the fetlocks. Terminally, cattle can also be in lateral recumbency with paddling and opisthotonus. Cattle can die within 24 h following the appearance of severe clinical signs. Recovered animals may drag the rear

feet or knuckle over at the rear fetlock without exhibiting pain (Osweiler *et al.*, 1985). Poultry and other birds may exhibit clinical signs of depression, weakness, dyspnea and sudden death. Excess salt intake in the dog will result in vomiting within several hours of ingestion. The clinical signs can progress to diarrhea, muscle tremors and seizure-like activity. Increased severity of clinical signs in the dog have been seen when serum sodium levels have been above 180 mEq/l (Barr *et al.*, 2004).

Post mortem examination of salt-poisoned animals may include some degree of gastric irritation, including ulceration and hemorrhages. The content of the gastrointestinal tract may be abnormally dry. Histopathologic lesions may be limited to the brain and include cerebral edema and inflammation of the meninges. In swine, the appearance of eosinophilic perivascular cuffing is seen if the animal dies early in the syndrome with the lesion not found after 48 h. Brain sodium concentrations above 2000 ppm are considered diagnostic in cattle and swine. Upper normal brain sodium concentrations are 1600 ppm for cattle and 1800 ppm for swine, both on a wet weight basis. There is a paucity of data on normal brain sodium concentrations in other common domestic species but normal ranges should be similar. Serum sodium concentrations taken from the live animal will be significantly above the normal ranges listed previously. Post mortem analysis of aqueous humor, vitreous humor or cerebral spinal fluid will show a significant increase over values from normal animals (Osweiler *et al.*, 1995). Optimally, the values obtained should be compared to normal values for that species generated by the same laboratory.

## TREATMENT

Prior to the onset of clinical signs, the acute ingestion of salt can best be treated by allowing the animal full access to water and closely observing the animal for several hours. Emetics may be used in the dog if known ingestions occur and the animal is not yet showing clinical signs. However, most cases are discovered long after the excess salt ingestion or the water deprivation has occurred and the affected animals are showing obvious clinical signs. The overriding concept of treatment is to slowly return the animal to normal water and electrolyte balance over a 2–3-day period of time. Quickly lowering the serum sodium concentration will increase the osmotic gradient between the serum and the brain with water following the gradient into the brain increasing the likelihood of severe cerebral edema. The prognosis for an animal hypernatremic from salt ingestion/water deprivation with significant clinical signs on either an acute or chronic basis should be guarded at best.

On a herd basis with large animals, water intake should be limited to 0.5% of body weight at hourly intervals until normal hydration is accomplished. Monitoring serum sodium concentration is the first step in treatment on an individual animal basis. This information can be used to correct the free water deficit (*FWD*) in the animal, based on the following formula:

$$FWD\ (\text{l}) = 0.6 \times \text{bodyweight (kg)} \times [(\text{measured serum Na}/\text{normal serum Na}) - 1]$$

Not more than 50% of the *FWD* should be replaced in the first 24 h with the remaining deficit replaced in the following 24–48 h. Serum sodium levels should be lowered at a rate of 0.5–1.0 mEq/l/hour, with the slower rate recommended for cases of chronic hypernatremia (Schaer, 2000). In acute hypernatremia without clinical dehydration, the use of 5% dextrose solution in combination with a loop diuretic has been suggested at 3.7 ml/kg/h to decrease serum sodium at 1 mEq/l/hour (Barr *et al.*, 2004). Diuretics such as furosemide can be used to prevent the development of pulmonary edema during fluid therapy. The use of slightly hypertonic intravenous fluids has been recommended to reduce the likelihood of cerebral edema developing. Intravenous fluids should be made to approximate the serum sodium concentration of the animal, or the clinician may start with a solution containing 170 mEq/l of sodium and decrease this concentration as clinical signs improve (Angelos and Van Metre, 1999; Niles, 2004). If brain edema is suspected, the use of mannitol, dexamethasone or dimethyl sulfoxide may aid in control.

## CONCLUDING REMARKS

While the term "salt poisoning" may not be the most accurate way to describe the above syndrome, it is certainly in common usage. A similar and confusing term is "water intoxication" which has been used to describe the situation of excess water intake or infusion over a short period of time which can dramatically decrease the serum sodium concentration and make the serum hypoosmolar. Water intoxication has been used to describe the exacerbation of cerebral edema when the correction of hypernatremia occurs too quickly. Water intoxication has also been used to describe the brain swelling and seizure-like activity which occurs when a normal animal drinks excessive amounts of water over a short period of time. In addition to the possible neurological effects, hemolysis has also been described (Middleton *et al.*, 1997). In the above situations, acute and dramatic osmotic changes are the cause.

# Sulfur

*Jeffery O. Hall*

## INTRODUCTION

Sulfur is a necessary dietary component that can be toxic at excessive concentrations. Animal bodies are about 0.15% sulfur by weight (NRC, 1989, 2006). Sulfur is incorporated into many essential molecules, including biotin, chondroitin sulfate, cartilage mucopolysaccharides, co-enzyme A, fibrinogen, glutathione, heparin, lipoic acid, mucins, and thiamine (NRC, 1989, 1998, 2006). In addition to these biologically active compounds, sulfur is an intricate component of sulfur containing amino acids, such as methionine, cysteine, cystine, homocysteine, and taurine. With the exception of thiamine and biotin, all sulfur containing compounds in the body can be synthesized from methionine (NRC, 1996). Thus, thiamine, biotin, and methionine are essential nutrients in the diet of monogastric animals, but ruminant microbes can synthesize these compounds from inorganic sulfate in the diet (Block *et al.*, 1951). Species differences are such that cats cannot synthesize taurine from methionine, making it an essential nutrient in their diets. Recommended daily dietary intakes of sulfur are 0.15%, 0.14–0.26%, 0.15–0.2%, and 0.2–0.25% of the diet for horses, sheep, beef cattle, and dairy cattle, respectively (NRC, 1985, 1988, 1989, 1996).

Ruminants tend to be more sensitive to the toxic effects of dietary sulfur/sulfate due to efficient microbial conversion to bioactive species in the rumen. But both dietary and water sources of sulfur/sulfate have similar toxic potential and must be factored into the total daily intake in order to establish potential risk.

In addition to dietary sulfur, other sulfur containing compounds can be toxic. Sulfur dioxide gas from industrial waste gas, as well as hydrogen sulfide gas from manure pits, natural gas production, and crude oil production, can be toxic to livestock. The toxic effects of these gaseous forms of sulfur are better summarized separately from the dietary toxicoses.

Plants can accumulate high sulfur concentrations. High sulfate water can cause a dual increase in total daily sulfur intake by way of the water and ingested proximal vegetation. Plant sulfur concentrations have been shown to increase with increasing sulfate in the soil (Reddy *et al.*, 1981; Hardt *et al.*, 1991; Leustek and Saito, 1999). In soil matrixes, sulfate can be actively reduced and precipitated; however, this only sequesters the sulfur until environmental change allows the re-oxidation of the sulfur back to sulfate. During drought conditions, precipitated sulfur is exposed to oxygen and re-oxidized. The resultant sulfate is then bioavailable for plant uptake.

## BACKGROUND

Sulfur is a non-metal within group VIA of the periodic table. This group is sometimes referred to as the chalcogenides or ore-formers, since many metal ores are sulfide or sulfate salts. Sulfur has an atomic number of 16, an atomic weight of 32.07, and has four different naturally occurring atomic masses from 32 to 36 (Rosman and Taylor, 1998). It can occur in four different oxidation states: −2 (sulfide), 0 (elemental sulfur), +4 (sulfite), and +6 (sulfate). All valence states, except elemental sulfur, are found in biologic molecules. Sulfur is utilized in the production of sulfuric acid, fertilizers, pigments, dyes, drugs, explosives, rubber, insecticides, and detergents, as well as many inorganic salts and esters. Although uniformly found in nature, industrialized countries are the largest users of sulfur materials.

## PHARMACOKINETICS/ TOXICOKINETICS

When evaluating the absorption of sulfur, the chemical form must be considered. The intestinal mucosal absorption of sulfate is via an active carrier mediated process that is also utilized by molybdate (Mason and Cardin, 1977). Active intestinal absorption of sulfate has been shown in sheep, rats, dogs, rabbits, and hamsters (Bird and Moir, 1971). Similarly, the sulfur containing amino acids and other sulfur containing compounds are absorbed via specific transport mechanisms across the intestinal mucosa (NRC, 2006). These specific transport processes are specific for the individual compounds. Rumen microbes convert a percentage of dietary sulfur containing compounds to sulfide, which can then be incorporated into microbial sulfur containing amino acids, thiamine, biotin, other microbial sulfur metabolites, or absorbed as sulfide. In addition to gastrointestinal absorption of sulfides, hydrogen sulfide can be absorbed across the respiratory epithelium. Large amounts of sulfide, as hydrogen sulfide, produced in the rumen can be eructated, inhaled, and absorbed (Dougherty *et al*., 1965). And, the inhaled sulfide is important in the toxicosis, as sheep that had trachea blocked to prevent eructation and inhalation of sulfide did not succumb while those without tracheal blockage were poisoned (NRC, 2006).

Sulfur is widely distributed in the body. All tissues in the body have significant sulfur components, with the body being made up of approximately 0.15% sulfur (NRC, 2006). Absorbed sulfides and thiomolybdates, the primary toxic sulfur metabolites, are well distributed in the body. This is evidenced by the facts that thiomolybdates can deplete tissue stores of copper and sulfides can cross the blood–brain barrier causing neurological effects.

Sulfur containing amino acids and sulfate are extensively metabolized in order to produce biologically utilized sulfur compounds. In comparison, absorbed sulfide is efficiently metabolized in the liver to sulfate, with a high first pass clearance (NRC, 2006). Inhaled sulfide would not be subject to this rapid hepatic removal, resulting in increased circulating concentrations that can result in neurologic effects.

Sulfur containing compounds are eliminated by both renal and biliary routes. Just as molybdate can compete for the intestinal absorption sites for sulfate, it can also compete for re-absorption sites in the renal tubules (Friberg and Lener, 1986). The relative quantities of sulfur elimination from renal and biliary routes can differ depending on the form ingested. In sheep, Bird (1972) found the greatest percent elimination of sulfate was via urine, while taurine was predominantly eliminated in the bile. Intestinally absorbed sulfide efficiently undergoes hepatic metabolism to sulfate, which is eliminated in the urine (NRC, 2006).

## MECHANISM OF ACTION

Acute oral poisoning with elemental sulfur results in formation of hydrogen sulfide, as well as many other potential metabolites. The gastric and respiratory effects are postulated to be due to coagulative effects of rumen produced sulfurous acids and the irritating effects of hydrogen sulfide, respectively (Julian and Harrison, 1975; Kandylis, 1984; Gunn *et al*., 1987). However, the exact mechanisms are not well delineated. Inhaled sulfide at high concentrations may act in a similar mechanism to high concentrations of hydrogen sulfide gas, causing acute respiratory paralysis.

The mechanism of sub-acute sulfur poisoning is much better researched. This condition is correlated with the reduction of the sulfate or other forms of sulfur to sulfide in the rumen (Gould *et al*., 1991, 1997; Loneragan *et al*., 1998). The current literature suggests that inhibition of cytochrome C oxidase, which is essential for cellular respiration, is the primary mechanism (Smith *et al*., 1977; Beauchamp *et al*., 1984). But, cerebral vasospasms and regional ischemia could also account for the localization of the lesions (Siesjo, 1984; McAllister, 1991). Although once thought to be associated with a true thiamine deficiency from either inhibition of rumen microbial production or cleavage of thiamine (Edwin and Jackman, 1982), it has been shown that systemic thiamine concentrations are within the normal range for most animals (Olkowski *et al*., 1992; Gould, 2000). Slight decline in the blood thiamine concentration can also being seen in some animals (Olkowski *et al*., 1991). And, thiamine supplementation in the presence of high sulfate/sulfur-associated polioencephalomalacia (PEM) alleviates the clinical disease (Olkowski *et al*., 1992). This would indicate that the sulfide or some other sulfur metabolite is either competitively inhibiting the cellular uptake/utilization of thiamine or therapeutic doses of thiamine diminish the effects of sulfide on the cytochrome C oxidase enzyme.

The sub-acute to chronic, indirect effects of excessive sulfur are seen in ruminants, due to the efficient conversion of sulfur compounds to sulfide. The sulfide can form insoluble salts with copper and zinc (Suttle, 1974), but it can also form thiomolybdate complexes which bind copper making it non-bioavailable (Suttle, 1991) (see Molybdenum-mechanism of action). Systemic copper decreases, associated with increased sulfur/sulfate, have been reported in sheep (Moshtaghi-Nia *et al*., 1989; Van Niekerk and Van Niekerk, 1989a, b) and cattle (Wittenberg and Boila, 1988). High forage and water sulfur have also been associated with selenium deficiency (Ivancic and Weiss, 2001). Decreased serum and wool selenium has been reported with increasing dietary sulfate (White and Somers, 1977; White, 1980). In addition, increased soil sulfur inhibits the plant uptake of selenium, thereby increasing the potential for inducing a

selenium deficiency in ingesting herbivores (Newman and Schreiber, 1985), which may be an important mechanism in grazing animals.

## TOXICITY

Toxicity of sulfur can be divided into three main categories that are likely to be encountered. The first is acute oral poisoning. The second is sub-acute to chronic direct toxicosis. And the third is sub-acute to chronic indirect toxicosis, as a secondary interference with other essential minerals that result in mineral deficiencies.

Reports of acute oral sulfur poisoning are scarce in the literature. In a group of Holstein heifers, sulfur ingested at 0.85–3.8 g/kg body weight resulted in high morbidity and moderate mortality (Gunn *et al.*, 1987), while 20 heifers given 250 g sulfur in grain had high mortality (Julian and Harrison, 1975). Ewes fed a barley–sulfur mix that provided approximately 40–45 g sulfur/ewe were poisoned (White, 1964). Five horses administered 300 g sulfur succumbed to sulfur poisoning (Ales, 1907).

Clinical and pathologic manifestations of acute oral sulfur poisoning are similar across species (White, 1964; Julian and Harrison, 1975; Gunn *et al.*, 1987). Abdominal pain, colic, rumen stasis, fetid diarrhea, dehydration, metabolic acidosis, tachypnea, recumbency, and hydrogen sulfide smell are expected clinical signs. Irritation, edema, and hemorrhage of the gastrointestinal tract and respiratory tract should be expected. In addition, renal tubular necrosis can be seen.

Monogastric animals are much less susceptible to the sub-acute direct and indirect toxic effects of excessive sulfur intake than ruminants. Pigs can tolerate 1000 mg/l sulfur in the drinking water with only a mild cathartic effect (Paterson *et al.*, 1979) and 0.42% in the diet for several months without adverse effects (Dale *et al.*, 1973). Similarly, chicks had decreased growth rates at 1.2% dietary sulfur (Leach *et al.*, 1960). And, chickens had decreased egg production, decreased feed intake, and deaths at 4000 mg/l sulfate in their drinking water (Adams *et al.*, 1975). Since the indirect toxic effects of excessive sulfur are related to rumen conversion to sulfide, these effects are not observed in monogastric animals.

In contrast, for sheep, beef cattle, and dairy cattle the maximum tolerable content of sulfur in the total diet is 0.4% (NRC, 1985, 1988, 1996), while concentrations slightly below this tolerable content can occasionally result in toxic effects (Gould *et al.*, 1991). Since dietary toxicity is not mutually exclusive, as sulfur and sulfate ion can have the same clinical effects, total doses of sulfur/sulfate from both water and dietary material must be taken into account when evaluating potential toxicity (Suttle, 1974). For ruminants, the typical clinical presentation is one of ataxia, weakness, blindness, recumbency, seizures, and death.

Sub-acute ingestion of toxic doses of sulfate/sulfur has been associated with PEM, a necrotizing lesion of the brain (Beke and Hironaka, 1991; Gould *et al.*, 1991; Olkowski *et al.*, 1992; Hamlen *et al.*, 1993; McAllister *et al.*, 1997). Gross and histologic lesions are primarily in the brain, but ruminal changes can be observed. Gross pathologic lesions include a darkening of the rumen contents from precipitated sulfide salts, swelling of the cerebral hemispheres, softening of the cerebral hemispheres, and yellow discoloration of the cortical gray matter. Histological lesions include necrosis of the cortical gray matter and occasional areas of necrosis in the thalamus or midbrain. The clinical condition can be an additive effect of the total sulfur in the diet and sulfate in the drinking water (Beke and Hironaka, 1991). PEM has been associated with high sulfur/sulfate ingestion in cattle (Beke and Hironaka, 1991; Gould *et al.*, 1991; Hamlen *et al.*, 1993), pigs (Dow *et al.*, 1963), and sheep (Olkowski *et al.*, 1992). However, sodium ion poisoning in the pigs was likely the primary causative factor, as the exposure was to sodium sulfate.

The peak rumen production of hydrogen sulfide can be somewhat delayed from the time of initiating high sulfur intake. Peak rumen gas cap sulfide occurred at 1–3 weeks after placing cattle on a high sulfur diet (Gould *et al.*, 1997). But, continued exposure resulted in a gradual decline in the sulfide content. This would indicate an adaptation of the rumen microbes to favor direct utilization of the sulfide or diminished rates of production.

Sub-acute to chronic sulfur-induced mineral deficiencies can result in severe health problems. Copper deficiency can cause poor growth, weakness, poor immune function, poor reproductive function, and death. In addition, sulfur-induced copper deficiency may play a role in PEM (Gooneratne *et al.*, 1989). Severe copper deficiency also causes myelin degeneration (enzootic ataxia) in lambs, deer, and other ruminants (Cordy, 1971; Faye *et al.*, 1991; Audige *et al.*, 1995). Sulfate-induced selenium deficiency can cause poor growth, weakness, poor immune function, poor reproductive function, damage to the cardiac or skeletal muscles, and death.

## TREATMENT

Treatment for acute sulfur poisoning is predominantly supportive in nature, with removal of the causative material, as well as administration of fluids and electrolytes. However, the human literature points to successful treatment of acute hydrogen sulfide poisoning by induction of methemoglobinemia with nitrite to allow for the formation of sulfmethemoglobin, similar to therapeutic protocols for

treatment for cyanide poisoning (Stine *et al*., 1976; Peters, 1981). This type of therapy may also be beneficial in the treatment of sub-acute direct sulfur poisoning. Since sulfides act on and split disulfide bridged, the use of oxidized glutathione or other simple disulfide compounds could be protective or antidotal (Smith and Abbanat, 1966). The use of thiamine in the treatment of PEM has been suggested to be beneficial, even though there is no overt thiamine deficiency. The primary treatment of indirect mineral deficiencies resultant from high sulfur intake would also include supplementation of copper and potentially selenium.

In addition to direct treatment, management can play a role in the prevention of sulfur poisoning. Testing of water and dietary materials will identify high sulfur prior to utilization. With this information, management strategies can be utilized that would incorporate the sulfur at gradually increasing content in an attempt to allow for microbial adaptation.

## CONCLUDING REMARKS AND/OR FUTURE DIRECTION

Although much is known about the different clinical disease conditions that excessive sulfur can cause, treatment remains only somewhat effective. Thus, it is important to evaluate the use of nitrite or disulfide containing compounds in the treatment of domestic animals.

CHAPTER

# 37

# Zinc

*Tam Garland*

## INTRODUCTION

Zinc (Zn) is a transitional metal in group XII on the periodic chart and is the fourth most commonly used metal today. It is a moderately reactive metal with a common valence state of +2. It is also an essential element in mammals and birds and is a component of approximately 200 metaloenzymes. Although zinc has an essential role in nutrition and consequences of nutritional deficiency, this chapter will focus on its toxicity.

## BACKGROUND

As the fourth most commonly used metal it is expected to be found in a variety of places with a multitude of uses. Zinc is an economical metal to use and is relatively non-toxic. Table 37.1 details some of those uses. Since zinc has nutritional qualities, it is not uncommon to find it added as a supplement to feed. Problems with toxicity generally occur when the levels are 1000 parts per million (ppm) or greater.

**TABLE 37.1 Uses and purposes of zinc**

| Uses | Purposes |
|---|---|
| Galvanized steel | Prevent corrosion |
| Parkerize steel | Prevent rust and corrosion |
| Used in numerous metal alloys | Brass, nickelled silver, typewriter metal, various soldering formulas, German silver |
| Primary metal | American Pennies, nuts and bolts |
| Die casting | Automotive industry |
| Zinc oxide | Paints, sun protectants, rubber activator, diaper rash ointments |
| Wall tiles | Germicidal properties |
| Zinc chloride | Wood preservative and deodorant |
| Zinc methyl ($Zn(CH_3)_2$) | number of organic syntheses |
| Zinc stearate | a lubricative plastic additive |

## PHARMACOKINETICS/ TOXICOKINETICS

Ingested zinc is primarily absorbed from the duodenum and the intestine by a carrier-mediated mechanism. Approximately 25–50% of ingested zinc is absorbed. However, absorption of zinc in influenced by many factors, including whether or not food is in the stomach. Plant phytates can bind zinc and in an alkaline pH environment can form insoluble complexes. Similarly zinc absorption is decreased in the presence of phosphates and calcium in the diet. However, the presence of some peptides, amino acids and the presence of ethylenediamine tetra acetic acid disodium (EDTA) may cause an increase in absorption. Generally, the stomach acid provides for rapid release of zinc from ingested metallic objects.

Once zinc has been absorbed it is bound to plasma albumin and to macroglobulins, and transported to the liver. Zinc is extracted by the liver and returned to the bloodstream for distribution to the liver, pancreas, kidney, and spleen which all rapidly accumulate the zinc. These tissues, as well as muscle and prostate, are induced to synthesize methallothionein in the cells.

Under normal dietary conditions, excess zinc is excreted through the feces. Nevertheless, excretion of zinc, especially in toxic situations, is limited. Excretion occurs through the bile and feces but may also occur through urine (Abdel-Mageed and Oehme, 1990), and saliva.

## MECHANISM OF ACTION

The mechanism of action producing clinical signs is not well defined or understood. The characteristic clinical signs are more easily recognized. The most recognized abnormality observed is severe intravascular hemolysis and gastroenteritis. This may be a result of excess zinc interfering with copper and iron storage and utilization, resulting in a suppression of hematopoiesis.

Diets high in zinc interfere with hepatic copper storage and may compete with calcium for intestinal absorption.

## TOXICITY

The different forms of zinc have different toxicities. The zinc salts have a median lethal dose ($LD_{50}$) of approximately 100 mg/kg body weight. Zinc oxides are less toxic. Zinc oxides are frequently found in ointments, such as for preventing sunburn or treating diaper rash. Dogs often ingest it when it is applied topically to them or to someone they can lick it off. Dogs also ingested the ointment by chewing on the tube container. It has been estimated that the toxic dose is approximately 108 g of zinc in the dog (Breitschwerdt *et al.*, 1986).

The ingestion of pennies, which are 96% zinc (Latimer *et al.*, 1989), by dogs has resulted in the development of a subacute zinc toxicosis. The pennies remain in the acidic environment of the stomach and slowly release metallic zinc. It is unclear how many pennies are required to produce a toxicosis. The pennies can be vomited up or passed in the feces prior to presentation at the veterinary clinic.

Other forms of zinc containing hardware such as transport kennel bolts or machine nuts and bolts have caused problems in animals. Analysis of these objects has shown them to be about 97% zinc (Breitschwerdt *et al.*, 1986; Torrance and Fulton, 1987). They remain in the stomach producing a subclinical toxicosis or are vomited or passed out prior to the animal's presentation.

Other sources of toxicity have been galvanized wire used in cages in aviaries (Reece *et al.*, 1986) and for housing ferrets (Straube *et al.*, 1980).

An additional component of zinc toxicosis is acute renal failure observed in some dogs. (Breitschwerdt *et al.*, 1986). The clinical findings include hypercreatinemia, azotemia, hyperphosphatemia, and granular casts in the urine (Breitschwerdt *et al.*, 1986; Torrance and Fulton, 1987; Latimer *et al.*, 1989). Other signs of acute intoxication are signs of pancreatitis and acute arthritis. Also, non-viable new-borns may be observed in zinc intoxication.

Foals are susceptible to zinc intoxication. It appears to be a chronic zinc toxicosis. Initially, the foals have non-painful joint enlargement lasting 7–21 days. They are reluctant to rise and have stiff gait and increased joint fluid (Gunson *et al.*, 1982).

Other livestock have early signs of lethargy and anorexia followed by diarrhea. Later, they display a decreased rate of gain or decreased milk production. As the toxic condition progress, the animals have anemia and icterus. Other signs include exophthalmia, polydipsia, polyphagia, and seizures.

Generally most species display some degree of hemolytic anemia, often with an erythrocytic regenerative response. Additionally, there is renal damage with hematuria, urinary casts, and proteinuria. Diagnostically, there may be a radiodense area in the gastrointestinal tract indicating the presence of zinc or some other metal such as lead. Postmortem lesions include renal tubular necrosis, hepatocyte necrosis and gastroenteritis.

## TREATMENT

As with many metal intoxications, removal of the source of the toxin from the animal, followed by supportive therapy are critical to the patient's recovery. This procedure with zinc will result in dramatic drops in serum and tissue levels within a relatively short time. Removal of the source will allow the normal excretory pathways to work appropriately.

Particularly when treating foals it is important to evaluate the copper status of the animal. Copper and zinc seem to work in tandem and adding copper to copper deficient animals may help decrease the overriding effects of zinc.

Supportive care is critically important as the gastroenteritis and anemia must be addressed. The vomiting, in species capable of vomiting, has resulted in usually a severe gastroenteritis. Vomiting may be controlled with metoclopramide (0.2–0.4 mg/kg) administered every 6 h intramuscularly, subcutaneously or per os. Blood transfusions may be in order to address the anemia. Additionally, fluid therapy with a balanced solution such as Lactated Ringers solution should be considered. Good supportive care includes continuous monitoring of various blood parameters such as red blood cells, platelets, packed cell volume, and serum chemistries including liver enzymes, serum urea nitrogen, and electrolytes. Treatment efforts must be directed at correcting pancreatic, renal and/or liver dysfunctions that are so closely associated with zinc intoxication.

Chelation therapy is an option in the patient's care. Chelation therapy is effective but not without risk and so must be evaluated with regard to the patient's condition. Patient conditions requiring evaluation include the hydration status, the degree of dysfunction of the excretory organs and the severity of the serum zinc concentration.

Another important factor is whether the offending object could be removed from the patient. The most commonly suggested chelator is calcium disodium EDTA. Calcium disodium EDTA is most commonly used to treat lead intoxication and the dose for zinc intoxication has thus been extrapolated (100 mg/kg, divided into four doses per day administered subcutaneously, diluted in 5% dextrose in water to decrease local irritation). Especially with chelation therapy, daily monitoring of the patient is essential to determine the length of therapy.

## CONCLUSIONS

Evidence of pancreatitis, liver and kidney dysfunction must be considered along with gastroenteritis and a hemolytic event when considering the differentials. The clinical sign of acute gastroenteritis is common to viral and bacterial diseases, parasitic diseases and various neoplasms. Gastroenteritis and a hemolytic event must be differentiated from other metal intoxications such as copper poisoning. Additional considerations include acetaminophen or onion intoxication, mustard poisoning, immune mediated diseases, and certain snake bites.

As zinc is a very economically useful metal it is likely to be found in more products that animals are exposed to in various fashions. It would be beneficial to have a larger array of safe chelation products. Unfortunately, the importance of chelation therapy outweighs the available markets for the product. Therefore, it is unlikely research dollars will be directed to finding new chelation therapies.

## CHROMIUM

Chromium is a metallic element that can exist in six valence states, with the trivalent chromium form most commonly found in nature as ferrochromite ores. Both trivalent and hexavalent (+6) are widely used in various industrial and manufacturing processes. Chromium is an essential trace element and functions in a number of metabolic processes including glucose, lipid and amino acid metabolism. Hexavalent chromium is considered to be more toxic than the trivalent form which may be a direct result of its increased systemic availability.

While hexavalent chromium is considered to be a human carcinogen, acute chromium toxicosis in animals is probably of minimum concern in all but the most unusual circumstances. Both hexavalent chromium and dichromate are easily converted to trivalent chromium in mammalian systems but the burning of chromium-treated lumber does not produce enough heat to convert the dichromate to the trivalent chromium form. Oil field contamination with hexavalent chromium has been associated with cases of cattle death (Thompson *et al.*, 1991) and a solution of strong, oxidizing chromium was responsible for dairy cattle deaths when the solution dripped on cattle and was absorbed dermally (Talcott *et al.*, 2005). Acute chromium toxicosis is associated with severe congestion and inflammation of the digestive tract, kidney damage and liver damage. Chronic toxicosis has been associated with gastroenteritis and dermatitis.

## IODINE

Iodine is a non-metallic element of the halogen group that occurs as a purple-black crystalline solid but has several common other forms including iodide ($I^{-1}$) and iodate ($IO^{-3}$). Iodine is widely distributed in nature in both organic and inorganic forms but only in low concentrations. Iodine is essential for the normal synthesis of thyroid hormones and a deficiency of iodine can result in thyroid enlargement or goiter. Deficiencies may occur from eating feeds grown on iodine-deficient soils or from the presence of goitrogenic substances (NRC, 2005a). High dietary iodine for a prolonged period of time can reduce the iodine uptake by the thyroid, causing the clinical syndrome of iodine deficiency.

Common dietary sources of iodine include iodized salt, ethylenediamine dihydroiodide (EDDI) and calcium iodate. Iodized salt can contain 0.01% iodine (100 ppm) and has not been associated with excess iodine exposure. EDDI has been used to prevent and treat foot rot in cattle, although its efficacy is unclear (Morgan, 2004). Toxic effects of iodine excess have been reported in cattle consuming iodine-containing feed additives (Thompson *et al.*, 1991). Clinical signs include decreased feed intake, decreased milk production, rapid breathing, nasal and ocular discharge, dry hair coat and non-responsive hock lesions. Affected cattle were on high intakes of iodine (68–600 mg/head/day and above) for several weeks before obvious clinical signs appeared. Young calves exhibited chronic coughing and profuse nasal discharge at 100–200 ppm dietary iodine. Removal of the excess iodine from the diet and supportive care usually results in rapid return to normal.

## PHOSPHORUS

Most phosphorus in nature exists in combination with oxygen in the form of phosphates, primarily in igneous

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

and sedimentary rocks. Inorganic phosphates are commonly used as chemical fertilizers, food and feed supplements and have many industrial uses. Phosphorus is abundant in the animal body primarily as a structural component of crystalline hydroxyapatite in bone and teeth but also as required components of phospholipids, nucleic acids, nucleotides and enzyme cofactors. Phosphate ions also function in acid–base balance and other essential body functions. Phosphorus is an essential macroelement in nutrition and is an important consideration in the formulation of animal diets. The largest dietary source of phosphate will be in the form of inorganic phosphate supplements and other dietary sources may include plant-origin feeds as well as bone, meat, poultry and fish meals. Normal phosphorus nutrition and metabolism requires adequate calcium in the diet with an appropriate calcium-to-phosphorus ratio (Ca:P). While adverse effects of excess phosphorus are rare, they can occur with either excess dietary phosphates or deficient dietary calcium. If the Ca:P ratio is balanced, usually no wider than 2:1, animals can tolerate a wide range of dietary phosphorus levels (NRC, 2005b).

Excess phosphorus in the diet of ruminants, especially sheep, can result in the formation of urinary calculi in the kidney or bladder. This formation of stones can obstruct or completely block urine flow, especially in males, resulting in the bladder filling with urine and eventually rupturing into the abdominal cavity causing death. The problem can be prevented by correctly balancing calcium and phosphorus in the diet. Excess phosphorus in the diet of horses has resulted in nutritional secondary hyperparathyroidism, a condition usually associated with a high grain diet without appropriate calcium supplementation. The high dietary phosphate will depress the intestinal absorption of calcium with a decrease in plasma calcium and an increase in plasma phosphate levels. Low plasma calcium will stimulate the secretion of parathyroid hormone which will increase bone mineral resorption activity. The skeletal bones will lose calcium and the demineralized bone will be replaced by fibrous connective tissue with the facial bones often becoming enlarged (Joyce *et al*., 1971), leading to the common term of big head disease in horses. It is also known as bran disease, since feeding high dietary levels of bran, which is high in phosphate and low in calcium, has historically been a cause of the disease. In all animals, optimum animal performance will be closely associated with optimum dietary calcium and phosphorus balance.

Phosphorus, in the form of white or yellow phosphorus, has historically been used as a rodenticide but is uncommon today. Initial clinical signs following ingestion would include gastroenteritis with vomiting and diarrhea. If the animal survived several days it would often develop a secondary phase of severe liver damage with renal insult also occurring.

# Organophosphates and carbamates

*Ramesh C. Gupta*

## INTRODUCTION

Organophosphates (OPs) and carbamates (CMs) are commonly used as pesticides in agriculture, industry, and around the home/garden throughout the world. In addition, these chemicals are used as parasiticides in veterinary medicine. Both types of chemicals produce their toxicity by virtue of inhibition of acetylcholinesterase (AChE) enzyme, which terminates the action of the neurotransmitter acetylcholine (ACh) at the synapses in nervous tissue and at the neuromuscular junctions. These chemicals are referred to as "anticholinesterases". Some of the OPs with strong AChE inhibiting potential are also used as nerve agents or nerve gases.

Many compounds of both classes are extremely toxic and lack species selectivity, and therefore their inadvertent/accidental use continues to pose a threat to the environment, human and animal health, wildlife, and aquatic systems. Small animals often encounter poisoning with these insecticides by malicious activity, while livestock by ingesting freshly sprayed crop or contaminated feed. Although these compounds are neurotoxicants, they produce a variety of cholinergic and non-cholinergic effects. Latest evidence suggests that while cholinergic mechanisms play a critical role in the initial stage of toxicity, neuronal damage/death appears to occur through non-cholinergic mechanisms. OPs and CMs are discussed here together because they produce similar toxic effects in poisoned animals. This chapter covers various aspects of toxicity of OP and CM compounds and therapeutic measures in animals. For more details, readers are referred to Gupta (2006).

## BACKGROUND

The first OP compound, tetraethyl pyrophosphate, was synthesized in 1854 by Philipe de Clermont. In 1932, Lange and Kruger described the synthesis of dimethyl and diethyl phosphorofluoridate. Based on the chemistry of these compounds, Gerhard Schrader (a chemist at the I.G. Farbenindustrie) led the exploration of OP class of compounds that could be used as insecticides. One of the earliest OP insecticides synthesized by Schrader was parathion, which is still used worldwide. Prior to World War II (WWII), the German Ministry of Defense developed highly toxic OP compounds of G series (tabun, sarin, and soman) and diisopropyl phosphorofluoridate. In the 1950s, OP compounds with super toxicity, such as VX and VR, were synthesized in the United Kingdom and Soviet Union. After WWII, thousands of OPs have been synthesized in the search for compounds with species selectivity, i.e. more toxic to insects and less toxic to mammals. Malathion is an example. This compound has been used for about half-a-century as the most popular insecticide. Today, more than 100 OPs are in use for a variety of purposes, such as protection of crops, grains, gardens, homes, and public health.

The first CM compound, physostigmine (eserine alkaloid), was isolated from calabar beans (ordeal poison) of a perennial plant *Physostigma venenosum* in the mid-1860s. The compound was used to treat glaucoma. About 50 years later, an aromatic ester of carbamic acid, neostigmine, was synthesized and used in the treatment of myasthenia gravis. Most of the CMs (esters of carbamic acid) that are used as pesticides were synthesized in the 1960s and 1970s. Carbaryl was the first CM compound used as an insecticide.

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

To mimic the structure of acetylcholine (ACh), aldicarb was synthesized which has a toxicity greater than any other compounds of this class. Like OPs, thousands of CMs have been synthesized, but less than two dozen compounds have been used practically. Today, CMs are preferred for pesticide use over OPs because some OPs have been found to be extremely toxic, whereas others cause delayed neuropathy in animals as well as in humans. In essence, both OPs and CMs have broad applications in agriculture and veterinary medicine and as a result of their indiscriminate use acute poisonings often result in animals, birds, fish, and wildlife.

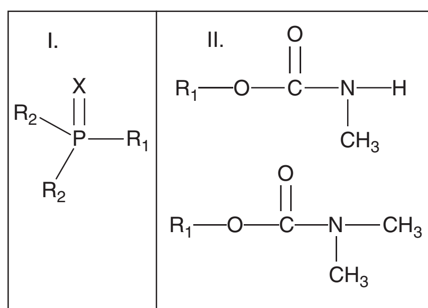

**FIGURE 39.1** General structure for organophosphorus (I) and CM (II) insecticides (adapted from Timchalk, 2006).

## TYPES OF OPs AND CMs

Basic structures of organophosphorus and CM compounds are shown in Figure 39.1. There are at least 13 types of OPs (see Table 39.1). Despite differences in chemical structures, all OPs share one thing in common: they all have a pentavalent phosphorus atom and a characteristic phosphoryl bond (P = O) or thiophosphoryl bond (P = S). Essentially, OPs are esters of phosphoric acid with varying combinations of oxygen, carbon, sulfur, and/or nitrogen attached. Of course, the chemistry of these compounds is much more complex. The OPs that are derivatives of phosphoric or phosphonic acid possess anticholinesterase activity, unlike those that are derivatives of phosphinic acid. Usually, OP compounds have two alkyl substituents and an additional substituents group (leaving group, which is more labile to hydrolysis than the alkyl group (Marrs, 1993). Basically, some OPs (such as dichlorvos, monocrotophos, and trichlorfon) are direct AChE inhibitors, while those of phosphorothioates type (such as bromophos, diazinon, fenthion, and parathion) possess minimal or no anticholinesterase (anti-AChE) activity and require desulfuration to the analogous oxon before acquiring anti-AChE activity. Also, OPs which are used as defoliants (*S*,*S*,*S*-tributyl phosphorotrithioate and *S*,*S*,*S*-tributyl phosphorotrithioite) and

herbicides (glyphosate and gluphosinate) are of very low mammalian toxicity.

Chemical structures of some of the commonly used OP pesticides are shown in Figure 39.2.

## OP PESTICIDES

The majority of OP compounds are used as pesticides, and a brief chemical description for commonly used compounds is given in Table 39.2.

## OP NERVE GASES/AGENTS

OP nerve agents include tabun (GA), sarin (GB), soman (GD), cyclosarin (GF), VX, and VR. These compounds are highly toxic and pose continuous threats for the lives of

TABLE 39.2 Brief chemical description of commonly used OP pesticides

| Chemical | Chemical name | Molecular weight | Oral $LD_{50}$ in rat (mg/kg) | Dermal $LD_{50}$ in rabbit (mg/kg) |
|---|---|---|---|---|
| Acephate | *O,S*-dimethyl acetylamidothiophosphate | 183.17 | 866 | >2000 |
| Azinphos-ethyl | *O,O*-diethyl *S*-[(4-oxo-1,2,3-benzotriazin-3(4*H*)-yl)methyl] dithiophosphate | 345.38 | 13 | 250 |
| Azinphos-methyl | *O,O*-dimethyl *S*-[(4-oxo-1,2,3-benzotriazin-3(4*H*)-yl)methyl] dithiophosphate | 317.32 | 5 | 220 |
| Bromophos | *O*-(4-bromo-2,5-dichlorophenyl) *O,O*-dimethyl thiophosphate | 366.00 | 1600 | 2188 |
| Cadusaphos | *S,S*-di-*sec*-butyl *O*-ethyl dithiophosphate | 270.40 | 391 | 143 |
| Carbophenothion | *S*-{[(4-chlorophenyl)thio] methyl} *O,O*-diethyl dithiophosphate | 342.87 | 6 | 22 |
| Chlorethoxyphos | *O,O*-diethyl *O*-(1,2,2,2-tetrachloroethyl) thiophosphate | 336.00 | 1.8 | 12.5 |
| Chlorfenvinphos | 2-chloro-1-(2,4-dichloro-phenyl)vinyl diethyl phosphate | 359.57 | 12 | 3200 |
| Chlorpyrifos | *O,O*-diethyl *O*-(3,5,6-trichloropyridin-2-yl) thiophosphate | 350.59 | 135 | 2000 |
| Chlorpyrifos-methyl | *O,O*-dimethyl *O*-(3,5,6-trichloropyridin-2-yl) thiophosphate | 322.53 | 941 | 2000 |
| Coumaphos | *O*-(3-chloro-4-methyl-2-oxo-2*H*-chromen-7-yl) *O,O*-diethyl thiophosphate | 362.77 | 13 | – |
| Crotoxyphos | 1-phenylethyl (2*E*)-3-[(dimethoxyphosphoryl)oxy]but-2-enoate | 314.27 | 125 | 385 |
| Cyanophos | *O*-(4-cyanophenyl) *O,O*-dimethyl thiophosphate | 243.22 | 610 | 800 |
| Demeton-O | *O,O*-diethyl *O*-[2-(ethylthio)ethyl] thiophosphate | 258.34 | 2.5 | 8 |
| Diazinon | *O,O*-diethyl *O*-(2-isopropyl-6-methylpyrimidin-4-yl) thiophosphate | 304.35 | 300 | 379 |
| Dichlorvos | 2,2-dichlorovinyl dimethyl phosphate | 220.98 | 25 | 59 |
| Dicrotophos | (1*E*)-3-(dimethylamino)-1-methyl-3-oxoprop-1-en-1-yl dimethyl phosphate | 237.19 | 22 | 223 |
| Dimethoate | *O,O*-dimethyl *S*-[2-(methylamino)-2-oxoethyl] dithiophosphate | 229.26 | 250 | 400 |
| Disulfoton | *O,O*-diethyl *S*-[2-(ethylthio)ethyl] dithiophosphate | 274.40 | 2 | 6 |
| Ethion | *O,O,O′,O′* -tetraethyl *S,S′* -methylene bis(dithiophosphate) | 384.48 | 27 | 915 |
| Famphur | *O*-{4-[(dimethylamino)sulfonyl]phenyl} *O,O*-dimethyl thiophosphate | 325.34 | 35 | 2730 |
| Fenamiphos | ethyl 3-methyl-4-(methylthio)phenyl isopropylamidophosphate | 303.36 | 15.3 | – |
| Fenitrothion | *O,O*-dimethyl *O*-(3-methyl-4-nitrophenyl) thiophosphate | 277.23 | 250 | 1300 |
| Fenthion | *O,O*-dimethyl *O*-[3-methyl-4-(methylthio)phenyl] thiophosphate | 278.33 | 255 | 330 |
| Fonofos | *O*-ethyl *S*-phenyl ethylphosphonodithioate | 246.33 | 8 | 25 |
| Glyphosate | *N*-(phosphonomethyl)-glycine | 169.07 | 4300 | >5000 |
| Gluphosinate ammonium | 2-amino-4-[hydroxy(methyl)phosphoryl]butanoic acid ammoniate | 198.16 | 2000 | >4000 |
| Glyphosine | *N,N*-bis(phosphonomethyl)glycine | 263.08 | 3925 | >5010 |
| Isazophos | *O*-(5-chloro-1-isopropyl-1*H*-1,2,4-triazol-3-yl) *O,O*-diethyl thiophosphate | 313.75 | 40 | >3100 |
| Isofenphos | isopropyl 2-{[ethoxy(isopropylamino)phosphorothioyl] oxy}benzoate | 345.40 | 32 | 162 |
| Malathion | diethyl 2-[(dimethoxyphos-phorothioyl)thio] succinate | 330.36 | 885 | 4000 |
| Methamidophos | *O,S*-dimethyl amidothiophosphate | 141.13 | 13 | 110 |
| Methidathion | *S*-[(5-methoxy-2-oxo-1,3,4-thiadiazol-3(2*H*)-yl)methyl] *O, O*-dimethyl dithiophosphate | 302.33 | 25 | 200 |
| Methyl parathion | *O,O*-dimethyl *O*-(4-nitrophenyl) thiophosphate | 263.21 | 9 | 63 |
| Mevinphos | methyl (2*E*)-3-[(dimethoxyphos-phoryl)oxy]but-2-enoate | 224.15 | 3 | 16 |
| Monocrotophos | dimethyl (1*E*)-1-methyl-3-(methylamino)-3-oxoprop-1-en-1-yl phosphate | 223.16 | 8 | 354 |
| Omethoate | *O,O*-dimethyl *S*-[2-(methylamino)-2-oxoethyl] thiophosphate | 213.19 | 50 | 1400 |
| Paraoxon | diethyl 4-nitrophenyl phosphate | 275.19 | 1.8 | – |
| Parathion | *O,O*-diethyl *O*-(4-nitrophenyl) thiophosphate | 291.26 | 3 | 6.8 |
| Phenthoate | ethyl [(dimethoxyphosphorothioyl)thio] (phenyl)acetate | 320.36 | 200 | 4000 |
| Phorate | *O,O*-diethyl *S*-[(ethylthio)methyl] dithiophosphate | 260.38 | 1.6 | 2.5 |
| Phosmet | *S*-[(1,3-dioxo-1,3-dihydro-2*H*-iso-indol-2-yl)methyl] *O, O*-dimethyl dithiophosphate | 317.32 | 147 | 3160 |
| Phosphamidon | (1*Z*)-2-chloro-3-(diethylamino)-1-methyl-3-oxoprop-1-en-1-yl dimethyl phosphate | 299.69 | 15 | 125 |
| Phoxim | phenylglyoxylonitrile oxime, *O, O*-diethyl phosphorthioate | 289.30 | 1845 | 1126 |

humans as well as animals, because they can be used as chemical weapons of mass destruction. So far these agents have been used by dictators and terrorists. These compounds produce toxicity by directly inhibiting AChE, and are much more potent than OP pesticides, as they cause lethality to animals in the submilligram range. Their chemical structures are shown in Figure 39.3. For details of toxicity of these compounds, refer to Watson *et al.* (2006).

## CARBAMATES

The CM compounds are esters of carbamic acid. Unlike OPs, CM compounds are not structurally complex. Currently, CMs are used as pesticides in agricultural crops and gardens and in veterinary medicine as parasiticides.

## CM PESTICIDES

Currently, the volume of CMs used exceeds OPs because they are comparatively safer than OPs. Some of the commonly used *N*-methyl CM insecticides are briefly described in Table 39.3. For other CMs, readers are referred to Gupta (2006).

| Xylylcarb | 3,4-dimethylphenyl methylcarbamate | 179.22 | 384 | – |

## PHARMACOKINETICS OF OPs AND CMs

Pharmacokinetics deals with the processes of absorption, distribution, metabolism, and excretion (ADME). The ADME of OP and CM insecticides have been studied in animals (Tomokuni *et al.*, 1985; Moody and Franklin, 1987; Gupta, 1994; Wu *et al.*, 1996; Tos-Luty *et al.*, 2001; Timchalk *et al.*, 2002, 2004; Poet *et al.*, 2004). These insecticides gain entry into the body mainly through oral, dermal, or inhalation exposure. Ingestion encounters with contaminated feed/food with pesticides residue, while dermal exposure is more relevant when these insecticides are used as ectoparasiticides in the form of dust, dip, or oily solution. Inhalation of airborne insecticides occurs during or soon after aerial spray, particularly due to chemical drift. Once the insecticide reaches a portal of entry, it is available for absorption. It is established that following absorption, these insecticides are well distributed in tissue throughout the body. OP insecticides may follow either activation or detoxification, or both. Activation implies that the metabolite is more toxic than the parent compound, e.g. the conversion of malathion to malaoxon. This process is often referred to as "lethal synthesis". On the other hand, detoxification implies that the metabolite is less toxic than the parent compound, e.g. the conversion of malathion to malathion monoacid and malathion diacid. Unlike OPs, CMs are metabolized to less toxic or non-toxic metabolites, though some of the metabolites of CMs are quite toxic. For example, the two major metabolites of carbofuran (3-hydroxycarbofuran and 3-ketocarbofuran) have a significant impact on overall toxicity of carbofuran. A bulk of the metabolic activation and detoxification reactions occur within the liver (Sultatos *et al.*, 1984a, b; Sultatos, 1988). Finally, due to extensive metabolism in the body, only few metabolites are excreted in the urine that can be used as biomarkers of insecticides exposure (Figure 39.4).

Residues of some OPs and CMs can also be detected in the feces, saliva, and milk.

## MECHANISM OF ACTION

OP and CM insecticides share a common mode of insecticidal and toxicological action associated with their ability to inhibit the enzyme AChE within nerve tissue and at the neuromuscular junctions. Both types of insecticides have a high affinity for binding to and inhibiting the enzyme AChE, an enzyme specifically responsible for the destruction of the neurotransmitter ACh. Since the cholinergic system is widely distributed within both the central and peripheral nervous systems, chemicals that inhibit AChE are known to produce a broad range of well-characterized symptoms of anticholinesterases (Savolainen, 2001; Timchalk, 2006). A graphic representation for the comparison of the AChE inhibition dynamics for the interaction of ACh, carbaryl (CM), or chlorpyrifos-oxon (OP) with AChE is shown in Figure 39.5 (Timchalk, 2006).

The cholinesterases (ChE) are serine hydrolases that catalyze the breakdown of ACh through an acyl-transfer, where water is the acceptor molecule to which the substrate acyl moiety is transferred. A serine oxygen of the active site gorge in ChEs carries out a nucleophilic attack on the electrophilic carbon of the carbonyl group of ACh, resulting in an acetylated enzyme intermediate and the release of choline. Deacetylation occurs when an attacking water molecule (hydroxyl ion) acts as a more effective nucleophile, thereby releasing acetate (Sultatos, 2006). The molecular interactions between OPs and AChE (see Figure 39.6) have been studied in much more detail than

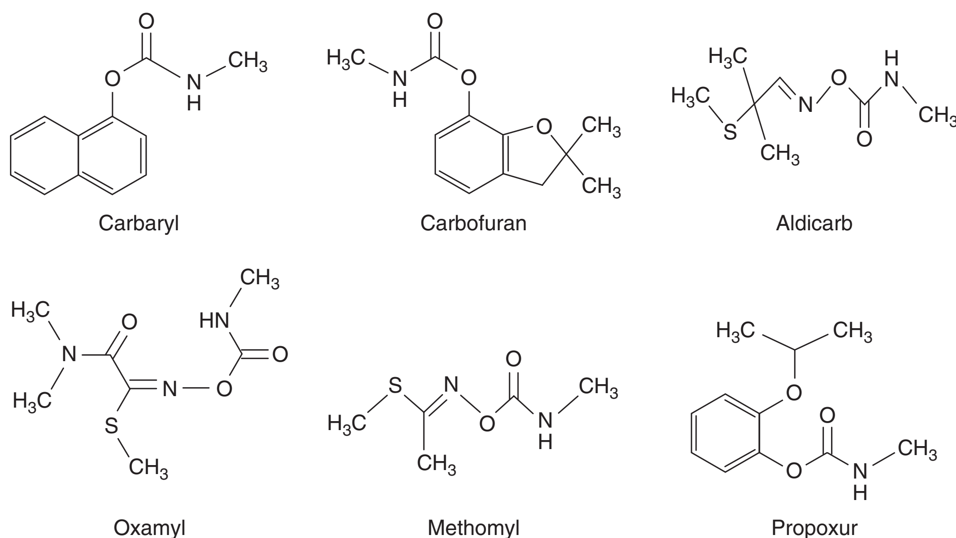

**FIGURE 39.4** Chemical structures of commonly used CM pesticides.

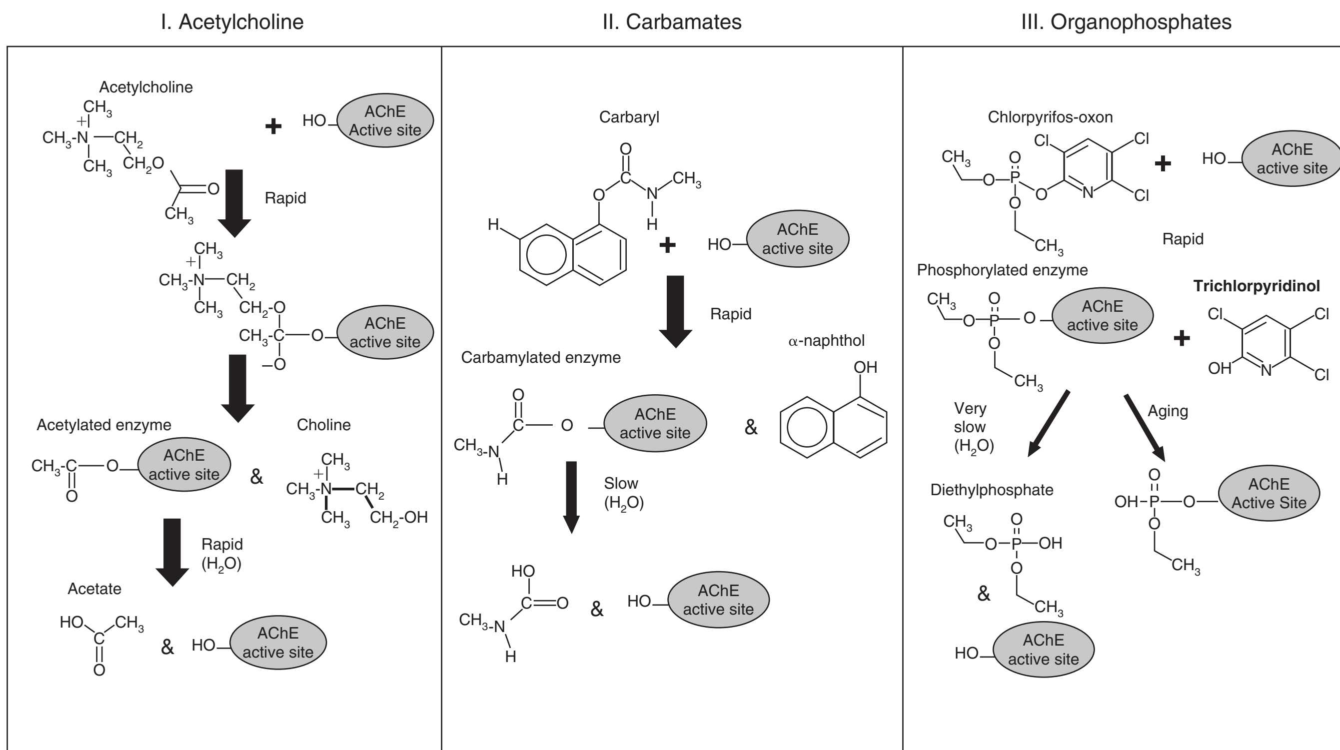

**FIGURE 39.5** Interaction of acetylcholine (I), the CM carbaryl (II), and the OP chlorpyrifos-oxon (III) with the active site of AChE. The general rate of bound AChE hydrolysis is ACh>carbaryl>chlorpyrifos-oxon (Timchalk, 2006).

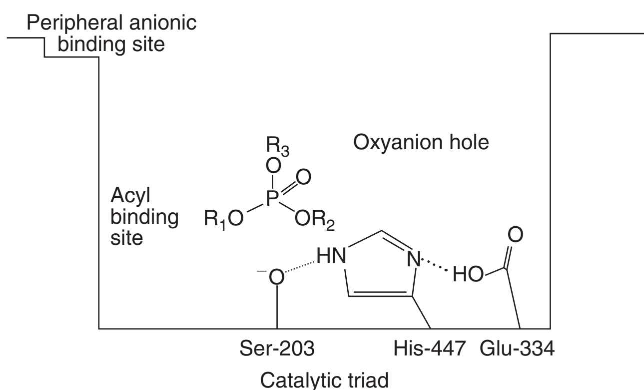

**FIGURE 39.6** Schematic drawing of the active site gorge of AChE, with the entry of an OP molecule. $R_1$ and $R_2$ on the OP are usually identical alkyl chains, whereas $R_3$ is the leaving group. The catalytic triad consists of Ser203, His447, and Glu334. The acyl binding site is likely important in positioning the inhibitor for the nucleophilic attack from Ser203 (Ordentlich *et al*., 1996), whereas the oxyanion hole may polarize the P=O bond, thereby facilitating the nucleophilic attack (Ordentlich *et al*., 1998). Binding of ligand to the peripheral anionic site can lead to inhibition or activation. Additionally, the peripheral anionic site plays an important role in the stereoselectivity of AChE toward methylphosphonates (Ordentlich *et al*., 2004). Adapted from Sultatos (2006).

between CMs and AChE. The rates of hydrolysis and reactivation of AChE following carbamylation and phosphorylation of the active site appear to be drastically slower than for the hydrolysis of the acetylated enzyme. The turnover time for ACh is of the order of ~150 μs, whereas the carbamylated enzyme *t*½ for hydrolysis is substantially slower (~15–30 min). The phosphorylated enzyme is highly stable (*t*½ ~days), and further dealkylation of the phosphorylation group produces an "aged" AChE that is irreversibly inhibited (Sogorb and Villanova, 2002; Taylor, 2006; Timchalk, 2006). In general, OPs and CMs are considered as irreversible and reversible AChE inhibitors, respectively. Details of ChEs, interaction of OPs and CMs with ChEs, and reactivation/regeneration of ChEs are described elsewhere (Radic and Taylor, 2006; Sultatos, 2006; Timchalk, 2006).

# TOXICITY

Most animal poisoning cases in the field are acute in nature. Onset of clinical signs usually occurs within 15 min to 1 h, which is soon followed by the signs of maximal severity, although these timings tend to vary depending upon the OP compound and its dose, and species. For example, onset of clinical signs is delayed with chlorpyrifos (Dursban) and dimethoate (Rogor). Clinical signs observed in poisoned animals can be divided into local and systemic effects. The local effects involve the eyes and the lungs, owing to their exposure to vapors or droplets of the insecticides. These effects, however, are of significance in the case of animals only when exposure is via spraying.

**TABLE 39.4 Normal acetylcholinesterase (AChE) activity in brain cortex of different species**

| Species | AChE (μmol/g/h) |
|---|---|
| Cattle | 160 |
| Swine | 163 |
| Sheep | 170 |
| Horse | 124 |
| Chicken | 1098 |
| Dog | 200 |
| Rat | 255 |

The systemic effects are primarily on the brain, skeletal muscles, lungs, heart, and other organs.

The clinical signs can also be classified as muscarinic, nicotinic, and central. Muscarinic receptor-associated effects are manifested by vomiting, abdominal and chest pain, salivation, lacrimation, urination, diarrhea (SLUD), miosis (pinpoint pupils), tracheobronchial secretion, lung edema, and cyanosis. The nicotinic receptor-associated effects are produced on autonomic ganglia and skeletal muscles, and the affected animals show twitching of muscles, tremors, followed by convulsions, and seizures. This condition may lead to paralysis. The central effects include apprehension, stimulation, followed by depression. The affected animals may also show restlessness, ataxia, stiffness of the neck, and coma. Death occurs due to respiratory failure and cardiac arrest. It is important to mention that all poisoned animals may not show all the clinical signs (as described above) with every OP or CM compounds. In other words, there is a great variation in symptomatology among the individual cases of poisoning. Surviving animals usually recover within 3–6 h with CMs and within 24 h with OPs.

Poisoning cases of OP or CM are usually diagnosed by determining the level of inhibition of AChE activity in blood from a live animal and brain from a dead animal. Inhibition of AChE activity >70% is considered positive case of poisoning. It should be noted that great species variability exists in normal values of AChE activity (Table 39.4). Also, analyzing the cortex of the brain and not the striatum for AChE analysis is preferred, since more than 6-fold variability exists (Gupta, 2004). Therefore, interpretation should be made with great caution. Residue analysis of an insecticide and/or its metabolite(s), followed by confirmation with GC/MS or LC/MS, seems an ideal approach for diagnosis.

## TREATMENT OF ACUTE POISONING

Before instituting antidotal therapy, monogastric animals, such as dog, should be given gastric lavage. Animals of any species can be given activated charcoal to stop further absorption of insecticides. Animals should be washed thoroughly with water if they are exposed to insecticides dermally. Intravenous (IV) fluid therapy is always beneficial.

In the case of OP poisoning, antidotal treatment requires the combined use of atropine sulfate and pyridine-2-aldoxime methochloride (2-PAM). Atropine sulfate acts by blocking the muscarinic receptors from ACh. In ruminants, one-fourth of the total recommended dose (0.5 mg/kg) can be given as a slow IV injection, and the remainder through intramuscular (IM) or subcutaneous (SC) injection (Gupta, 1984). The total dose of atropine sulfate for an average size horse is about 65 mg, and for a dog is about 2 mg. Atropine sulfate treatment can be repeated at an interval of every hour until all hyper-secretory signs have subsided. 2-PAM reactivates the AChE inhibited by OPs. The recommended therapeutic dose of 2-PAM is 20 mg/kg, IV. The injection of 2-PAM can be repeated once after 1 h at half of its initial dose. Care should be taken that only a freshly prepared solution of 2-PAM be used. It needs to be emphasized that the combined therapy of atropine sulfate and 2-PAM is superior to any other treatment till today in the case of OP poisoning. Although many other oximes have been tested against many OPs, none has been proven to be better than 2-PAM. Furthermore, depressant drugs, such as morphine and barbiturates, are contraindicated, since they aggravate the condition. Diazepam without atropine sulfate also accentuates the toxicity of OPs.

Unlike with OP poisoning, 2-PAM and other oximes are ineffective in CM poisoning cases. In fact, in the case of some CMs, such as carbaryl and carbofuran, 2-PAM therapy accentuates the toxicity. Some anticonvulsant drugs, such as barbiturates and diazepam, also aggravate the toxicity of CMs. Therefore, atropine sulfate, with doses as described for OPs, is the only preferred antidote. When the animals are exposed to very higher doses of CMs, atropine sulfate does not appear to be a life saving antidote.

## OP-INDUCED DELAYED POLYNEUROPATHY

OP compounds that produce delayed neurotoxic effects are esters of phosphorus-containing acids. Over 35 years ago, tri-*o*-cresyl phosphate (TOCP) was known to produce delayed neurotoxic effects in man and chicken, characterized by ataxia and weakness of the limbs, developing 10–14 days after exposure (Johnson, 1969). This syndrome was called OP-induced delayed neuropathy (OPIDN). In recent literature, the syndrome has been renamed as OP-induced delayed polyneuropathy (OPIDP). OPIDP is characterized by distal degeneration of long- and large-diameter motor and sensory axons of both peripheral nerves

and spinal cord. Among all animal species hen appears to be the most sensitive and therefore used as an animal model. TOCP and certain other compounds have minimal or no anti-AChE property, however they cause phosphorylation and aging (dealkylation) of a protein in neurons called neuropathy target esterase (NTE), and subsequently lead to OPIDP. Studies on the sensitivity of the target enzymes of a variety of OPs showed that the comparative inhibitory power of OPs against hen AChE and NTE *in vitro* correlates with their comparative effects *in vivo* (i.e. delayed neuropathy or death). The relationship between the degree of NTE inhibition and the severity of OPIDP changes according to the compound involved. For example, certain compounds cause OPIDP with a minimum of 70% NTE inhibition, while others require almost complete inhibition to cause OPIDP. However, the cascade of events from NTE inhibition/aging to impairment of retrograde axonal transport and axonal degeneration is yet to be explained (Moretto and Lotti, 2006). Today, many compounds, such as DFP, *N,N′* -diisopropyl phosphorodiamidic fluoride (mipafox), tetraethyl pyrophosphate (TEPP), paraoxon, parathion, *o*-cresyl saligenin phosphate, and haloxon, are known to produce this syndrome. For the details of OPIDP syndrome, refer to Moretto and Lotti (2006). Treatment of this syndrome is symptomatic.

## OP-INDUCED INTERMEDIATE SYNDROME

OP insecticide-induced intermediate syndrome (IMS) was reported for the first time in human patients in Sri Lanka in 1987 (Senanayake and Karalliedde 1987). Thereafter this syndrome has been diagnosed in OP-poisoned patients in South Africa (1989), Turkey (1990), Belgium (1992), the United States (1992), Venezuela (1998), France (2000), and elsewhere. To date, OPs that are known to cause IMS include bromophos, chlorpyrifos, diazinon, dicrotophos, dimethoate, disulfoton, fenthion, malathion, merphos, methamidophos, methyl parathion, monocrotophos, omethoate, parathion, phosmet, and trichlorfon. IMS is usually observed in individuals who have ingested a massive dose of an OP insecticide either accidentally or in a suicide attempt. IMS is clearly a separate clinical entity from acute toxicity and delayed neuropathy. Clinically, IMS is characterized by acute paralysis and weakness in the areas of several cranial motor nerves, neck flexors, facial, extraocular, palatal, nuchal, proximal limb, and respiratory muscles 24–96 h after poisoning. Generalized weakness, depressed deep tendon reflexes, ptosis, and diplopia are also evident. These symptoms may last for several days or weeks depending on the OP involved. A similar syndrome has also been observed in dogs and cats poisoned maliciously or accidentally with massive doses of certain OPs. It should be noted that despite severe AChE inhibition, muscle fasciculations and muscarinic receptor-associated hyper-secretory activities are absent.

Although the exact mechanism involved in pathogenesis of IMS is unclear, studies suggest that decrease of AChE and nicotinic ACh receptor mRNA expression occurs after oral poisoning with disulfoton in rats. Based on electromyographic (EMG) findings from OP-poisoned patients and experimental studies on laboratory animals, it has been found that the defect in IMS is at the neuromuscular endplate and postsynaptic level, but the effects of neural and central components in producing muscular weakness have not been ruled out. It seems clear that some OPs are greatly distributed to muscles and have higher affinity for nicotinic ACh receptors. Currently, very little is known about the type of damage at the motor endplate or about risk factors contributing to its development. There is no specific treatment, and therapy relies upon atropine sulfate and 2-PAM. The administration of atropine sulfate and 2-PAM should be continued for a long period, even if efficacy of these drugs on the development of IMS appears to be limited. For further details about IMS, readers are referred to Gupta (2005) and De Bleecker (2006).

## TOLERANCE DEVELOPMENT

Tolerance development to the toxicity of OPs was noted more than 50 years ago. Following prolonged exposure to an OP, the physiological effects often diminish more than expected from the degree of AChE inhibition or repeated additions of OP give lower responses with time. Tolerance to AChE inhibiting OPs (such as DFP, disulfoton, methyl parathion, and others) has been observed using different forms of administration and in different species, such as mice, rats, guinea pig, and man (Fonnum and Sterri, 1981; Gupta, 2004; Gupta and Dettbarn, 1986; Gupta *et al.*, 1986; Fonnum and Sterri, 2006).

Tolerance to OP toxicity can develop in several ways. Most often, it occurs due to receptor changes either in the number of receptors or by decreased affinity of the receptor molecule. However, it can also occur due to the presence of other proteins that can bind or inactivate the inhibitor and thereby make it less readily available. Some of the examples for binding to the OPs are carboxylesterases (CarbEs), butyrylcholinesterases (BuChEs), or other binding proteins such as albumin. In addition, tolerance can be achieved through more rapid metabolism of the OP compounds by OP-hydrolyzing enzymes such as paraoxonases (PONs) and somanases (Fonnum and Sterri, 2006).

ACh receptors (both mAChRs and nAChRs) are involved in the development of tolerance to OP toxicity. Treatment

with a cholinergic agonist for a prolonged time leads to a decrease in the muscarinic ACh receptors (mAChRs). This is common for G protein-linked receptors. In some studies, OPs have been found to cause decrease in the numbers of mAChRs in the brain, while in others both the number of mAChRs and the affinity to the ligand in ileum and striatum. Significant reductions in nAChRs numbers ($B_{max}$), without change in affinity ($K_D$), have been found in the brain of tolerant rats treated with disulfoton (Costa and Murphy, 1983) in skeletal muscle of rats treated with DFP (Gupta and Dettbarn, 1986; Gupta *et al*., 1986). In tolerant rats, significant recovery of CarbEs and BuChEs has also been found. In essence, tolerance development following subchronic or chronic treatment with AChE inhibiting OPs occurs through multiple mechanisms.

## CONCLUSIONS AND FUTURE DIRECTIONS

OPs and CMs constitute a large number of chemicals that are used in agriculture primarily as insecticides and in veterinary medicine as parasiticides. These chemicals exert a broad range of toxic effects, varying from mild effects as salivation and tremors to as serious as convulsions, seizures, paralysis, and death. Basically, OPs and CMs are neurotoxicants, but directly or indirectly several vital organs are affected, as these chemicals produce a variety of toxicological effects on the central nervous system, peripheral nervous system, cardiovascular, pulmonary, ocular, neurobehavioral, immunological, reproductive, placental, cutaneous, and other body systems. In addition, these insecticides cause neurodegeneration, oxidative stress, endocrine disruption, and many other complications. In general, OPs produce more serious and lingering health effects than CMs. For example, some of the complex syndromes like OPIDP and IMS have devastating effects, and have yet to be thoroughly characterized mechanistically and need to be well defined. It is expected that newer compounds of both OP and CM classes will be developed with greater selective toxicity. Also, newer antidotes need to be developed that can be effective in patients with OPIDP or IMS, or against CMs.

# Organochlorines

*Steve Ensley*

## INTRODUCTION

Chlorinated compounds, cyclodienes such as aldrin and dieldrin, used as insecticides, became available for use in the 1940's. Many methods have been used and developed to control or eliminate insects and other plant and animal pests that have threatened man and his food supply. There were major changes in the development and use of insecticides in the 1930s when the synthetic organic chemical industry began developing compounds to control insects. Dichlorodiphenyltrichloroethane (DDT) became available during World War II (WWII) and was used extensively as an insecticide worldwide. One of the reasons that organochlorines were effective insecticides was their ability to persist in the environment (Leonard *et al.*, 1999; Hites *et al.*, 2004; Hoekstra *et al.*, 2005). Because of that persistence, most have been eliminated from use today. Lindane (gamma-hexachlorocyclohexane) and endosulfan are the most biodegradable organochlorines and are still used today.

The diphenyl aliphatic organochlorines such as DDT, affect the peripheral nerves and brain by slowing sodium ($Na^+$) influx and inhibiting potassium ($K^+$) outflow. This results in excess intracellular $K^+$ in the neuron, which partially depolarizes the cell. In the 1980s, the mechanism of toxicity for the cyclodiene organochlorine insecticides was determined. These compounds were found to be non-competitive antagonists acting on the chloride ion channel of the gamma-aminobutyric acid A (GABA) receptor.

## BACKGROUND

Even though DDT was first synthesized by Othmar Zeidler in 1874, it was another 40 years before this compound was used as an insecticide. Paul Mueller, a Swiss chemist, rediscovered DDT in 1939 while investigating insecticides for use against clothes moths and carpet beetles. Mueller won the Noble Prize in 1948 for this work. This pleasant smelling, greasy white powder (DDT) has had an influence on human ecology perhaps unmatched by any other chemical discovery including gunpowder, sulfanilamide, penicillin, and plutonium (Metcalf, 1973).

The insecticidal properties of technical hexachlorocyclohexane (t-HCH; commonly known as benzene hexachloride) and the first cyclodiene insecticides (e.g., aldrin, dieldrin, chlordane) were discovered as a result of the commercial interest in new uses for chlorine and hydrocarbons such as cyclopentadiene and benzene. The first use of the chlorinated hydrocarbons was for dielectrics and as fire retardants. The use of these compounds as insecticides occurred when benzene was added to liquid chlorine in the field and it was noted that the product killed insects.

As with many insecticides there are many unintentional secondary effects for every insecticide (Uzoukwu and Sleight, 1972; Furie and Trubowitz, 1976; Hathway, 1977). The following is a brief discussion about the organochlorines and some of the intermediates used in their production. Hexachlorocyclopentadiene, a raw material used in manufacturing chemicals, was known to be stable and was found to react easily with cyclopentadiene in a Diels–Alder reaction, which leads to the production of chlordane. It was discovered later to react with norbornadiene (a bicyclic hydrocarbon) to produce aldrin. Allylic chlorination of chlordane produces heptachlor. The intermediate, hexachloronorbornadiene (HCNB), reacts with cyclopentadiene to produce isodrin and after epoxidation, dieldrin and endrin are produced. The t-HCH can be used to produce the gamma isomer, lindane. One of the problems with the production of lindane is the inefficiency of the process; for every ton of lindane produced; 8–10 tons of the inactive alpha and beta isomers are formed. Because of the widespread worldwide use of t-HCH, the environment

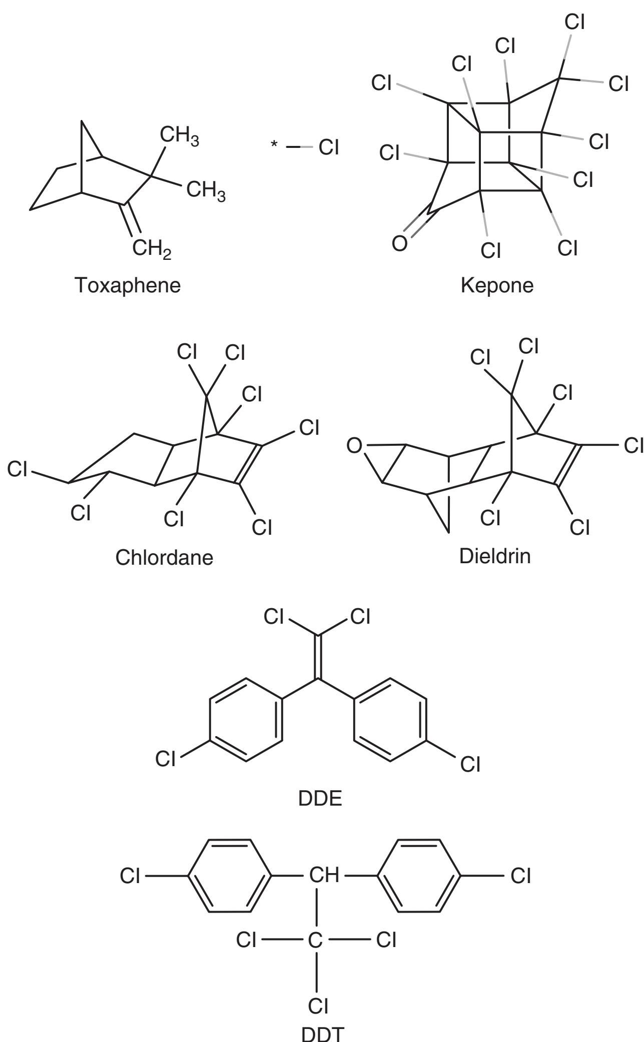

**FIGURE 40.1** Structures of common organochlorines.

has become contaminated with the inactive alpha- and beta-HCH isomers.

Overcoming the problem of insect resistance to the organochlorines has also been associated with toxicity. A major mechanism of insect resistance to DDT was found to be enzymatic dechlorination of DDT to dichlorodiphenyldichloroethylene (DDE) (Bonner and Yarbrough, 1988). While working to overcome resistance to DDT, it was discovered that certain non-toxic DDT analogs and other compounds suppressed resistance when co-applied with DDT. Toxicity to parent compounds as well as congeners has been associated with use of the organochlorines.

The beginning of the science of toxicology can be traced to the problems associated with use of DDT and the subsequent impact on man and the environment. Rachel Carson's book "Silent Spring" brought the problems associated with the use of DDT to national attention in 1962.

The structures of various organochlorine insecticides are shown in Figure 40.1.

## PHARMACOKINETICS/ TOXICOKINETICS

Organochlorine insecticides can be absorbed orally and topically, with absorption being rapid due to the lipid solubility of these compounds (Buck *et al*., 1976; Marth *et al*., 1989). Organochlorine insecticides are not highly volatile, so inhalation is not a normal route of exposure (Jaeger *et al*., 1973). Distribution is to the liver, kidney, brain, and adipose tissue (Buck and Van Note, 1968; Buck, 1970; Booth and McDowell, 1975). Acute toxicity caused is of concern, but bioaccumulation from chronic exposures is equally important (Starr and Clifford, 1972). Chlorinated hydrocarbons are highly lipid soluble and persist in the environment; as a result bioaccumulation occurs in the food chain from the environment to animals and humans (Mount *et al*., 1980; Oehme, 1991; Safe and Krishnan, 1995; Watanabe *et al*., 1999; Backer *et al*., 2001; Smith and Gangolli, 2002; Harris *et al*., 2005 ).

As with all xenobiotics, the toxicity of the organochlorines is related to the absorption, distribution, metabolism and elimination (Jaeger *et al*., 1975; Beasley *et al*., 1994). The diphenyl aliphatics, such as DDT, are dechlorinated by mixed function oxidases (MFOs). Aryl hydrocarbons, like paradichlorobenzene, undergo glucuronidation and sulfation. The cyclodiene insecticides, such as endrin are rapidly converted to epoxides by MFOs. Methoxychlor is rapidly eliminated compared to DDT by dechlorination and oxidation. The intermediates of organochlorine insecticide production may be more toxic than the parent compound.

The major excretory route of organochlorines is from bile into the digestive tract, and as a result enterohepatic recycling can occur. Metabolites are also lipophilic, will move into adipose tissue and are released slowly from lipid depot storage (Sell *et al*., 1977). The half-life of some diphenyl aliphatics, such as DDT and the cyclodienes may range from days to years (Council for Agricultural Science and Technology, 1974). Elimination can sometimes be explained by a two compartment model, where the first phase is rapid elimination and the second is prolonged.

## MECHANISM OF ACTION

There are at least two different mechanisms of action for organochlorine insecticides (Shankland, 1982; Narahashi, 1987; Osweiler, 1996). DDT-type organochlorine (dichlorodiphenylethanes) insecticides affect the peripheral nerves and brain by slowing sodium ($Na^+$) influx and inhibiting potassium ($K^+$) efflux. That results in excess intracellular $K^+$ in the neuron, which partially depolarizes the cell.

The threshold for another action potential is decreased, resulting in premature depolarization of the neuron.

The aryl hydrocarbons and cyclodienes, in addition to decreasing action potentials, may inhibit the post-synaptic binding of GABA (Bloomquist and Soderlund, 1985; Lummis *et al*., 1990; French-Constant, 1993; Hahn, 1998; Carr *et al*., 1999). The cyclodiene organochlorine insecticides act by competitive inhibition of the binding of GABA at its receptor, causing stimulation of the neuron, as described below (Joy, 1976, 1982; Gandolfi *et al*., 1984).

GABA is a neurotransmitter in the mammalian and insect central nervous system and the inhibitory neurotransmitter for insects at the neuromuscular junction. $GABA_A$ receptors, present in mammalian and insect synapse, are ligand gated chloride ion channels. In mammals, $GABA_B$ receptors are coupled to calcium and potassium channels and the action of GABA is mediated by G-proteins. $GABA_B$ receptors are not important in insect physiology. When GABA is released in the synapse it diffuses to the pre-synaptic terminal of another nerve, where it binds to a $GABA_A$ receptor. This causes chloride ions to enter the synapse resulting in hyperpolarization of the terminal and inhibition of release of other neurotransmitters. Because of this inhibition, post-synaptic stimulation of other nerves by other transmitters (e.g. acetylcholine) is reduced. When GABA is inhibited, there is no synaptic down-regulation and other neurotransmitters can be released in excess. The inhibitory mechanism of GABA explains the cholinergic effects (over stimulation by acetylcholine) of dieldrin and lindane on some species.

## TOXICITY

Cats are the most sensitive species to organochlorine insecticides, with the $LD_{50}$ for endrin in cats of 3–6 mg/kg. The cyclodiene organochlorine insecticides cause more seizure activity and have a lower $LD_{50}$ than the DDT-type insecticides in most species. The oral $LD_{50}$ for DDT in rats is 113–2500 mg/kg and the IV $LD_{50}$ is 47 mg/kg. In humans, toxic signs from oral exposure to organochlorines can be observed at 10 mg/kg. Shown below is a Table 40.1 with the acute toxicity to rats and the housefly of other chlorinated insecticides.

A description of the $GABA_A$ receptor in the human brain is presented in Figures 40.2 and 40.3 to clearly describe the chloride ion channel. The $GABA_A$ receptor of the human brain consists of four or five 50–60 kDa glycoprotein subunits, each of which contains four ($M_1$–$M_4$) hydrophobic domains. The five $M_2$ domains are arranged to form a 5.6 Å diameter ion channel.

In addition to the effects on the nervous system, DDT metabolites can inhibit the output of the adrenal gland by selective necrosis of the zona fasciculata and the zona reticularis.

Chronic exposure to DDT has been documented to cause eggshell thinning and reduced fertility in wild birds.

**TABLE 40.1 Toxicity data for some organochlorines**

| Compound | Rat acute oral $LD_{50}$ (mg/kg) | Rabbit dermal $LD_{50}$ (mg/kg) |
|---|---|---|
| Lindane | 76–190 | 500 |
| Aldrin | 39–60 | 65 |
| Dieldrin | 40 | 65 |
| Endrin | 3 | 12 |
| Chlordane | 283–1,100 | 580 |
| Endosulfan | 18–76 | 74 |
| Mirex | 235–3000 | 800 |
| Kepone | 95–125 | 345 |
| Toxophene | 40–127 | 600 |

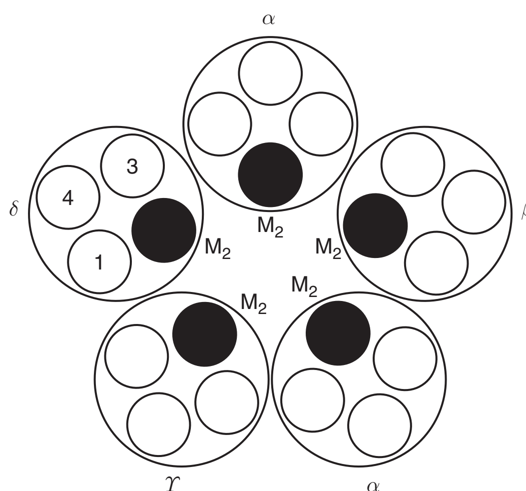

**FIGURE 40.2** Illustration of the $GABA_A$ receptor of the mammalian brain. The $M_2$ segments form the chloride ion channel (McDonald and Olsen, 1994).

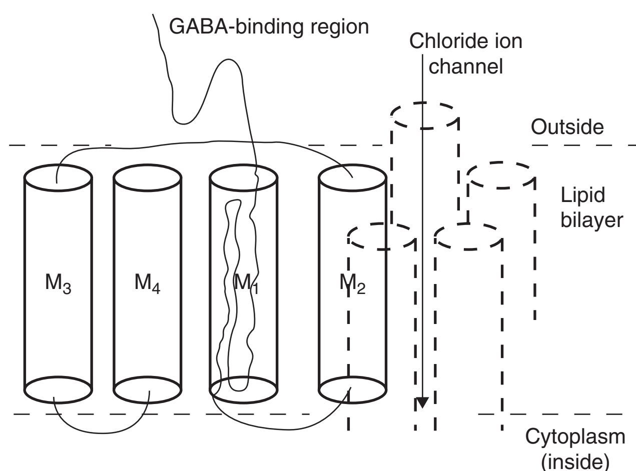

**FIGURE 40.3** Illustration of the $GABA_A$ receptor of the mammalian brain (McDonald and Olsen, 1994).

## TREATMENT

No specific antidotes for organochlorine insecticides are available (Osweiler, 1996). Detoxification is the most essential component of therapy for organochlorine toxicity. If dermal exposure has occurred, the animal should be thoroughly washed with a detergent and water to remove the insecticide so absorption ceases. The hair of heavily contaminated long-haired animals should be clipped. Personnel treating animals should exercise caution and prevent themselves from becoming contaminated with the insecticide by wearing gloves, aprons, or raincoats.

For oral exposure to organochlorines, activated charcoal (1–2 g/kg) should be administered orally. An alternative but less effective treatment is mineral oil. The insecticide can dissolve in mineral oil, which decreases its absorption systemically. The approximate oral dose of mineral oil is 2–6 ml in cats, 5–15 ml in dogs, and 1–3 l in large animals. Charcoal or non-absorbable oils are most effective when given within 4 h of ingestion of the pesticide (Aslani, 1996).

General supportive care includes the use of antiseizure medications such as diazepam, phenobarbital, or pentobarbital. Animals should to be placed in a warm and comfortable area to minimize trauma when they are seizuring. Animals recovering from organochlorine insecticide exposure may have to be monitored long term because organochlorines can persist in the body for months or years. The source of the exposure must be identified and removed to stop exposure. One decontamination strategy is to reduce feed intake so that the animal loses body fat, thereby reducing organochlorine residues in adipose tissue. Lactating animals rapidly eliminate organochlorine residues because the residues are excreted in milk. An additional treatment option in large animals is to feed activated charcoal (500–1000 g/day) to reduce enterohepatic recycling.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

The use of organochlorine insecticides is decreasing in the United States but they are still used worldwide. In the United States, with the ability of these compounds to persist in the environment and bioaccumulate, the organochlorine insecticides will continue to be an important toxicants for many years (Custer *et al.*, 2005).

# Pyrethrins and pyrethroids

*Steve Ensley*

## INTRODUCTION

Pyrethrins are the insecticidal compounds obtained from the flowers of the plant *Tanacetum cinerariaefolium*, also called *Chrysanthemum cinerariaefolium* or *Pyrethrum cinerariaefolium*. Pyrethrum denotes extracts from the flowers that contain the active pyrethrin compounds (Proudfoot, 2005). The use of pyrethrum in insecticide preparations dates back to Persia, about 400 BC Pyrethroids are synthetic analogs of pyrethrins. Because of stability problems with the natural pyrethrins, these insecticides were replaced by the more stable organophosphate and organochlorine insecticides developed after World War II (Valentine, 1990). As a result of the toxicity and environmental contamination associated with the organophosphate and organochlorine insecticides, interest in the use of pyrethrins and pyrethroids re-emerged in the 1970s. Pyrethrin and pyrethroid insecticides are effective against a variety of insect pests on companion animals and livestock, and are used on farms, in the home and garden and have many public health applications because of the safety associated with these compounds.

## BACKGROUND

There are six compounds that comprise the natural pyrethrins: pyrethrin I and II, jasmolin I and II and cinerin I and II. Synthetic pyrethroids have been developed because the natural pyrethrins breakdown quickly when exposed to air, light, and heat. The synthetic pyrethroids can be classified as first and second generation. First generation pyrethroids are esters of chrysanthemic acid and an alcohol, having a furan ring and terminal side chain moieties. Second generation pyrethrins have 3-phenoxybenzyl alcohols derivatives in the alcohol moiety, and have had some of the terminal side chain moieties replaced with a dichlorovinyl or dibromovinyl substitute and aromatic rings. Addition of the alpha-cyano group to the 3-phenoxybenyl alcohol group in the second generation pyrethroids (type II) has increased the insecticidal potency.

Pyrethrins cause hyperexcitability with very little cytotoxicity. The molecular targets of the pyrethrins and pyrethroids are similar in mammals and insects and include voltage gated sodium, chloride, and calcium channels, gamma-aminobutyric acid (GABA)-gated chloride channels, nicotinic receptors, membrane depolarization, and intercellular gap junctions (Forshaw and Ray, 1990; Song and Narahashi, 1996a). Mammals are less susceptible to pyrethrin and pyrethroid toxicoses than insects primarily because they have a faster metabolic clearance, higher body temperatures, and a lower affinity for the pyrethrins/pyrethroids (Song and Narahashi, 1996b) (Figure 41.1).

## PHARMACOKINETICS/ TOXICOKINETICS

Determination of the toxicity of pyrethroids *in vivo* is difficult because they have low water solubility, easily partition into lipids, and will bind to plastics and glass. The reported toxicity of this class of insecticides has high variability.

Most pyrethrin and pyrethroid products are applied dermally in animals, but because of grooming, there can be oral and inhalation exposures too. Less than 2% of topically applied pyrethrin and pyrethroids insecticides are

*Veterinary Toxicology, Edited by Ramesh C. Gupta*

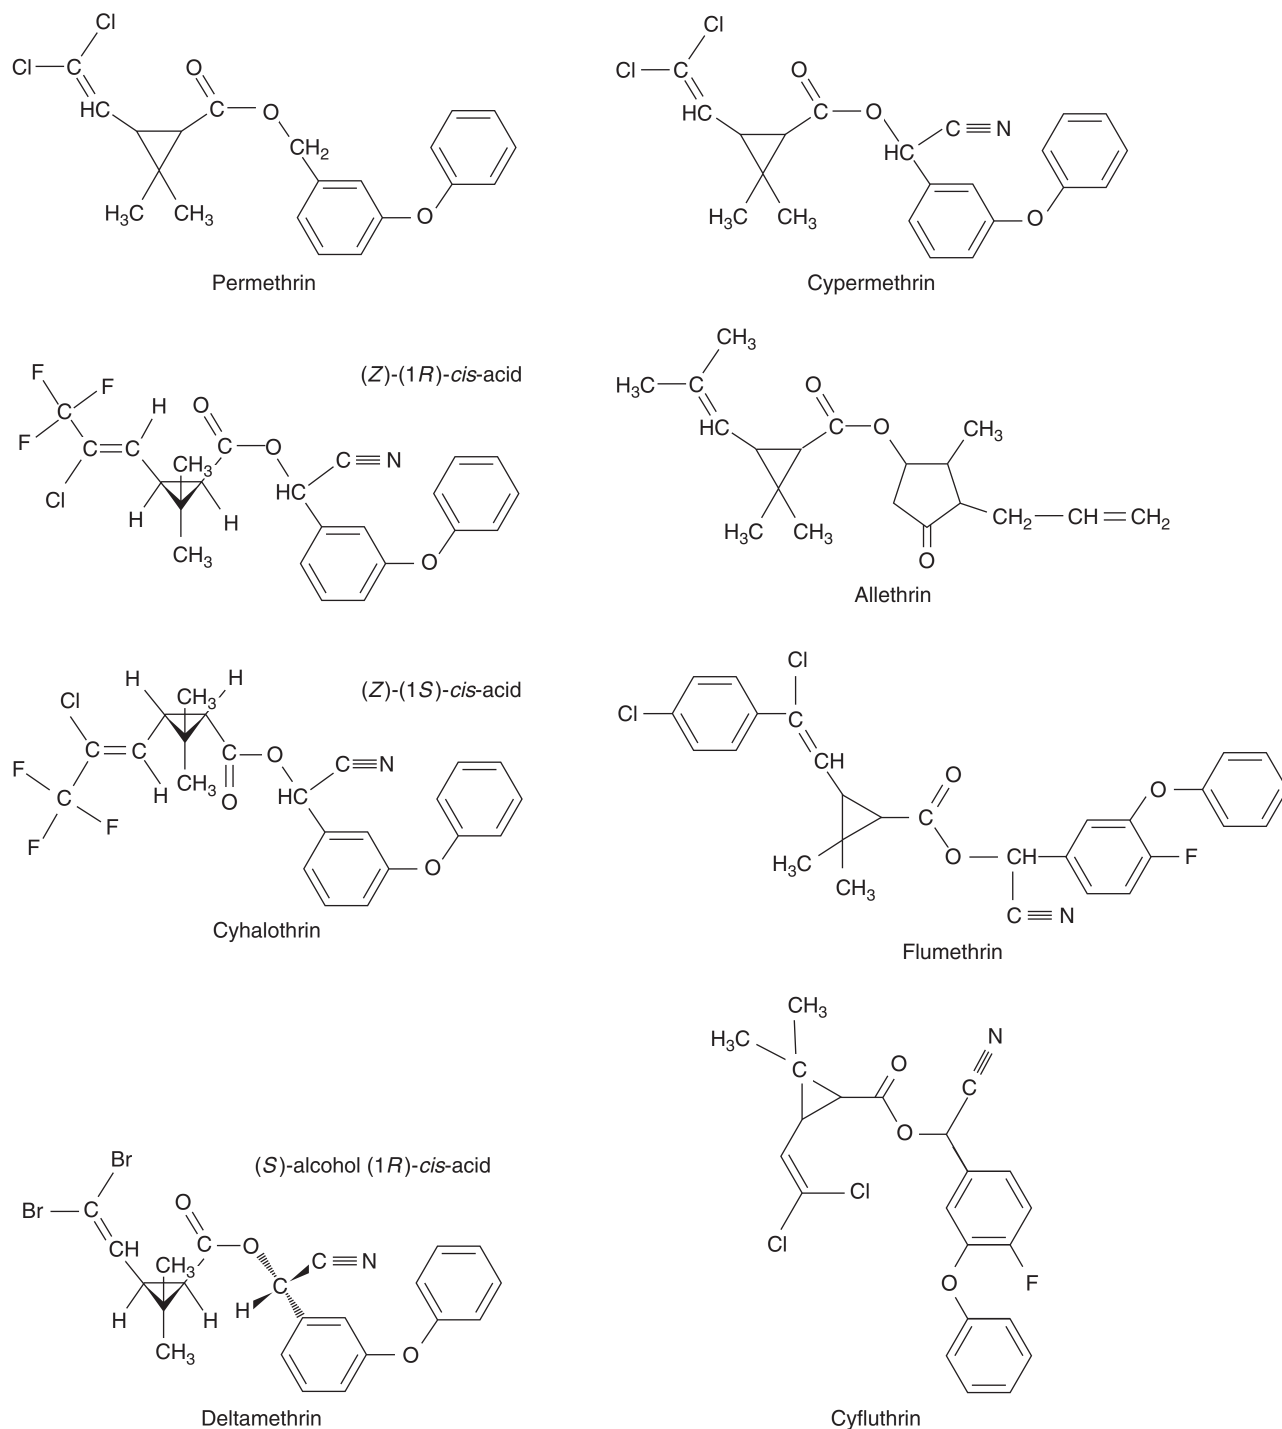

**FIGURE 41.1** Structures of selected pyrethrins and pyrethroids.

absorbed dermally (Wollen *et al.*, 1992). One study confirmed that absorption of cypermethrin across human skin is minimal and peak excretion rates after dermal application were not observed until 12–36 h after dosing. Pyrethrins may be sequestered in the skin and slowly released into the systemic circulation (He *et al.*, 1989). Oral or inhalation exposure results in faster systemic exposure (Anadon *et al.*, 1996). Approximately 40–60% of an orally ingested dose is absorbed. When cypermethrin was administered orally to six adult male volunteers, oral absorption ranged from 27% to 57% of the administered dose and peak excretion rates were measured in the urine between 8 and 24 h after dosing. When adult human males were exposed to cyfluthrin at 160 $\mu g/m^3$, 93% of the metabolites

were excreted within the first 24 h with peak excretion rates ranging from 0.5 to 3 h.

Pyrethroids are lipophilic and will distribute to tissues with high lipid content such as fat, and nervous tissue in addition to liver, kidney, and milk.

Pyrethroids and pyrethrins are rapidly hydrolyzed in the gastrointestinal tract. Once absorbed these compounds are metabolized by mixed function oxidases and esterases. Metabolism of the pyrethroids results in water-soluble metabolites. Metabolism includes hydrolysis of the central ester bond, oxidation at several sites, and conjugation with glycine, sulfate, glucuronide, or glucosides. Cleavage of the ester bond results in substantial reduction in toxicity. The presence of the alpha-cyano group, as in type II pyrethroids, will decrease the rate of hydrolysis of the ester bond. Cleavage of the alpha-cyano group results in rapid conversion of the cyano group to thiocyanate. Pyrethroids are eliminated by first order kinetics and most of the dose is eliminated in the first 12–24 h after absorption. The primary routes of excretion are urinary and fecal, as a mix of parent compound and metabolites.

## MECHANISM OF ACTION

Pyrethroids primarily affect the sodium channel of cells, but chloride and calcium channels are also affected. Pyrethrins and pyrethroids slow the opening and closing of the sodium channels, resulting in excitation of the cell (Marban *et al.*, 1989; Conley and Brammar, 1999). The increase of sodium in the sodium channels results in a cell that is in a stable, hyperexcitable state. The duration of the sodium action potential is much longer for type II pyrethroids than for type I. Type I pyrethroids result in primarily repetitive charges and in type II pyrethroid toxicity cell membrane depolarization is the main mechanism of action. Paresthesia results from the direct action of pyrethroids on sensory nerve endings, causing repetitive firing of these fibers. Less than 1% of sodium channels must be modified by pyrethroids to produce neurological signs. High concentrations of type II pyrethroids may also act on GABA-gated chloride channels (Bloomquist *et al.*, 1986).

Pyrethrins also affect the voltage-dependant chloride channels. These channels are found in the brain, nerve, muscle, and salivary gland and control cell excitability. There are many different functional types of chloride channels in contrast to sodium channels. Most pyrethroid-sensitive channels belong to the Maxi chloride channel class. Maxi channels are activated by depolarization, have high conductance, are calcium independent, and are activated by protein kinase C phosphorylation. Pyrethroids cause a decrease in the Maxi chloride channel current, which increases excitability of the cell just as the action of pyrethroids on the sodium channel.

The decreased sensitivity of mammals to this class of compounds compared to insects is due to several factors. Pyrethroids bind more strongly with the sodium channel at low temperatures than at high temperatures. Insects ambient temperature is approximately 25°C compared to mammals at 37°C. Mammalian sodium channels are at least 1000 times less sensitive to pyrethroids than insect sodium channels. Mammalian sodium channels recover much more quickly from depolarization than do insect sodium channels. Mammals are much more likely to detoxify pyrethroids before they reach their target site than are insects.

Pyrethroids cause a phenomenon in insects called "knock down" (Narahashi, 1985). Knock down is caused by inhibiting the cell but not causing a lethal effect. Knock down is caused by the ability of the sodium channels to retain many of the normal functions, such as selectivity for sodium ions and conductance after exposure to pyrethroids. After exposure to moderate doses of pyrethroids, cells function in a new state of hyperexcitability. If the level of sodium in the ion channel does not exceed the ability of the sodium pump to remove it, the cell continues to function normally. High concentrations of pyrethroids or hyperactivity beyond what the cell can tolerate, will cause depolarization and conduction block. The pyrethroids that hold the sodium channel open the longest will cause the greatest amount of depolarization.

There is marked stereospecificity of the action of pyrethroids on the sodium channel; some isomers are more toxic than others (Soderland, 1985). The *cis* isomers are usually more toxic than the *trans* isomers. As an example, the 1*R* and 1*S cis* isomers bind competitively to one site, and the 1*R* and 1*S trans* isomers bind non-competitively to another (Narahashi, 1986). In mammals the 1*R* isomers are active and the 1*S* isomers inactive, making the 1*S* isomers non-toxic. Deltamethrin has been produced using stereospecificity to produce a high degree of selective toxicity. This is the reason that the toxicity of different batches of pyrethroids can vary. The rat oral $LD_{50}$ of commercial permethrin can vary from 430 to 8900 mg/kg, with toxicity depending on the amount of *cis* isomer present in the batch.

## TOXICITY

Dermal exposure to pyrethroids is most common (Osweiler, 1996). In humans, the bioavailability of pyrethroids applied dermally is approximately 1%. Absorption after oral exposure in humans is 36%, mostly from the stomach. Once absorbed, the pyrethroids are rapidly distributed due to their lipophilicity. Systemic distribution produces effects

that can be difficult to control and may be confused with poisoning by other pesticides, such as organophosphates which also cause increased salivation and hyperexcitability. Many pyrethroid formulations also contain solvents which can also cause toxicity. Cats are very sensitive to pyrethroid exposure (Meyer, 1999).

The half-life of pyrethroids in general in plasma is in hours, while oral exposure can be equally short. Cyfluthrin has a plasma half-life of 19–86 min. Intravenous $LD_{50}$'s for pyrethroids range from 0.5 to 250 mg/kg. The major neurotoxicity observed in adults with pyrethroids toxicity is acute toxicity with no chronic or cumulative toxicity being observed. The excitatory motor signs are generated at the spinal level.

Fish are highly sensitive to pyrethrin and pyrethroid products, and contamination of lakes, streams, ponds, or any aquatic habitat should be avoided (Bradbury and Coats, 1986, 1989; Ansari and Kumar, 1988). Household exposure of fish can occur when the premise is sprayed or fogged with insecticides and especially when the aquarium aerator is left on. The tank and aerator should be covered during use of insecticides and the home should be well ventilated before uncovering and starting the pump.

Most avian species are thought to be tolerant of pyrethrin and pyrethroid products but carriers or propellants in spray formulations may be hazardous (Bradbury and Coats, 1982). There is very little literature about pyrethrin or pyrethroid toxicity of exotic avian species, reptiles, or lagomorphs.

Tables 41.1 and 41.2 refer to oral toxicity of some types I and II pyrethroids.

In dogs, cats, and large animals the clinical signs are similar for both type I and II compounds. Clinical signs include salivation, vomiting, hyperexcitability, tremors, seizures, dyspnea, weakness, prostration, and death (Murphy, 1996). In rats with type I toxicity there is an increased response to stimulation, muscle tremors, excitement, and paralysis (Beasley *et al.*, 1994). These clinical signs can also be compatible with strychnine toxicities. Type II over exposure will cause increased salivation, weakness, and choreoathetosis.

**TABLE 41.1** Toxicity of selected type I pyrethroids

| Type I compounds | Oral $LD_{50}$ (mg/kg body weight) in rat |
|---|---|
| Pyrethrin I | 900 |
| Allethrin | 680 |
| Tetramethrin | 4640 |
| Resmethrin | 100 |
| Permethrin | 2000 |

**TABLE 41.2** Toxicity of selected type II pyrethroids

| Type II compounds | Oral $LD_{50}$ (mg/kg body weight) in rat |
|---|---|
| Cypermethrin | 500 |
| Deltamethrin | 31 |
| Fenvalerate | 450 |
| Fluvalinate | 1000 |

## TREATMENT

There is no specific antidote for pyrethroid toxicity, animals should be treated symptomatically. The main treatment for dermal exposure is to wash the animal with a mild detergent and water. Do not use any shampoos that contain additional insecticides as that could increase exposure to insecticides. Large and small animals should be treated the same way. The pyrethroids bound to the skin cannot be removed by washing with soap and water, but dermal paresthesia can be reduced by applying corn oil to the site(s) of application. For oral exposure, emetics or gastric lavage can be used to empty the stomach, if within 1–2 h of ingestion. Activated charcoal and a saline or sorbitol cathartic will reduce oral absorption and increase elimination.

Supportive therapy using diazepam or barbiturates to control hyperexcitability or seizures can be used. Phenothiazine tranquilizers should not be used because they can lower the threshold for seizures. Atropine can be used to control excess salivation or gastrointestinal hypermotility.

The prognosis for pyrethroid toxicity is usually good because of the low toxicity.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Pyrethroid insecticides, being of plant origin, are attractive to people that prefer to use organic insecticides on their companion animals or livestock, or who are engaged in organic food production. Pyrethrin insecticides, while toxic to selected species, have a wider margin of safety than organophosphate or organochlorine insecticides. Biomarkers of exposure to pyrethroids are being investigated. Urine is the matrix that is being most heavily investigated to determine which metabolites can be used to identify exposure to the parent compound. Advances in analytical methods to detect low concentrations of the pyrethroid metabolites will allow improved assessment of exposure in the future.

# 42

# Rotenone

*Ramesh C. Gupta*

## INTRODUCTION

Rotenone is one of the oldest botanical insecticides, which has been used for centuries and is still used worldwide. Rotenone is the trivial name of the main insecticidal component of certain plant of "*Derris*", "*Lonchocarpus*", and "*Tephrosia*" species. Rotenone has also acaricidal properties. It has molecular formula of $C_{23}H_{22}O_6$ and molecular weight 394.42. Its chemical structure is shown in Figure 42.1. It is present in the form of colorless crystals, but readily oxidized by light, and becomes yellow, orange, and then deep red. Rotenone and its formulatory products have other names, such as Barbasco, Chem-Fish, Cubé, Cuberol, Derris, FishTox, Haiari, Nicouline, PrenFish, Prentox, Rotacide, SprenFish, Tubatoxin, and Tox-R. It is also marketed as Control Garden Dust, Chem-Mite, Cibe Extract, Curex Flea Dust, Derrin, and Green Cross Warble Powder.

Rotenone is formulated along with other pesticides such as carbaryl, pyrethrins, piperonyl butoxide, lindane, and others in pesticide products to control insects, mites, ticks, lice, spiders, and undesirable fish. In general, rotenone is used in home gardens for insect control, for lice and ticks on pets, and fish eradications as part of water body management. In veterinary medicine, rotenone is used in the powder form to control parasitic mites on chickens and other fowl, and for lice and ticks on dogs, cats, and horses. According to a survey conducted by Environmental protection Agency (EPA) in 1990, rotenone was found to be one of the pesticides most commonly used in and around the home. Rotenone has been found toxic to humans, animals, and fish.

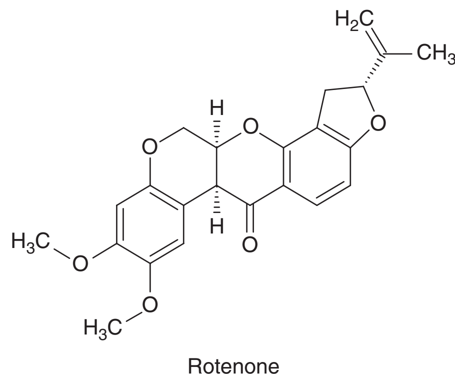

**FIGURE 42.1** Chemical structure of rotenone.

## BACKGROUND

Rotenone and rotenoids have been used as crop insecticides since 1848, when they were applied to plants to control leaf eating caterpillars (Ware, 1994). These compounds have been used for centuries (since 1649) in South America to paralyze fish, causing them to surface. Rotenone and rotenoids are extracted mainly from the roots, but also from the seeds and leaves of certain plants grown in Malaya, East Indies, and Central and South America. Presently, Peru is the major source of the root of the plant, which may be ground as a dust or extracted to provide concentrates. Other rotenone-related compounds such as deguelin, tephrosin, and toxicarol have been isolated from various parts of rotenone-containing plants, such as legume shrubs. Rotenone has been a registered pesticide in the United States under Federal Insecticide Fungicide Rodenticide Act (FIFRA) since 1947. It is a selective and non-specific insecticide with some acaricidal properties. Its formulations include crystalline preparations (about 95%), emulsified solutions (about 50%), and dust (0.75%). Rotenone dust is used for insects, lice, and ticks on animals; and beetles and aphids on vegetables, fruits, berries, and flowers. Rotenone emulsions are used for eliminating unwanted fish in the management of bodies of water.

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

It is a very safe compound when properly used, but in higher doses it is toxic to humans, animals, and fish. Rotenone has been involved in suicidal attempts, in which acute congestive heart failure was the characteristic feature at autopsy.

Selective toxicity of rotenone in insects and fish versus mammals can be explained based on metabolism of this compound. Rotenone converts to highly toxic metabolites in large quantities in insects and fish, while it converts to non-toxic metabolites in mammals.

## PHARMACOKINETICS/ TOXICOKINETICS

Absorption of rotenone from the gastrointestinal (GI) tract is low and incomplete. In animals, rotenone has been found to be hundreds of times more toxic by IV route than by oral route. Fats and oils increase the absorption of rotenone from the GI tract. Rotenone is metabolized in the liver by nicotinamide adenine dinucleotide phosphate (NADP)-linked hepatic microsomal enzymes. Several metabolites have been identified as rotenoids, such as rotenolone I and II, hydroxyl and dihydroxyrotenones, etc. (Hayes, 1982; Gosselin *et al.*, 1984). It has been reported from the studies conducted on rats and mice that approximately 20% of a dose is excreted in urine within 24 h of oral administration (Hayes, 1982). Unabsorbed rotenone from the GI tract excretes in feces.

## MECHANISM OF ACTION

In insects, rotenone is both contact and systemic insecticide. It is used as a broad-spectrum insecticide that works by inhibiting the transfer of electrons from Fe–S centers in Complex I to ubiquonone in electron transport chain. This prevents NADH from being converted into usable cellular energy, i.e. adenosine triphosphate (ATP).

In mammals and fish, rotenone inhibits the oxidation of reduced nicotinamide adenine dinucleotide (NADH) to nicotinamide adenine dinucleotide (NAD), thereby blocking the oxidation by NAD of substrates such as glutamate, $\alpha$-ketoglutarate, and pyruvate. Rotenone is a strong inhibitor of mitochondrial electron transport. It inhibits the mitochondrial respiratory chain between diphosphopyridine nucleotide and flavine. Following chronic exposure of rotenone, fatty acid synthesis is altered in mitochondria, resulting in fatty changes in the liver (Hayes, 1982; Gosselin *et al.*, 1984). In *in vitro* studies, Hayes (1982) demonstrated that the aerobic oxidation of pyruvic acid was completely inhibited by rotenone in the isolated rat liver mitochondria. In a recent study, Nianyu *et al.* (2003) showed that rotenone can cause cell death via apoptosis by excess production of mitochondrial reactive oxygen species. In addition, rotenone causes a definite anesthetic effect when it comes in contact with nerve axons (Hayes, 1982).

## TOXICITY

Rotenone is a naturally occurring chemical with insecticidal, acaricidal, and fish-killing properties. Rotenone is toxic to humans as well as animals. WHO classifies rotenone as a moderately hazardous Class II pesticide.

In mammals, the acute toxicity of rotenone is moderate and widely varies between and within species (Ellenhorn and Barceloux, 1988). The oral $LD_{50}$value of rotenone in rats is approximately 60–135 mg/kg body weight, while in mice the value is approximately 350 mg/kg. $LD_{50}$ intraperitoneal (IP) in mice is 2.8 mg/kg. Rotenone is more toxic to female rats than the males. Rotenone is less toxic in mice and hamsters than in rats. The pig seems to be especially sensitive. In rabbits, the $LD_{50}$ values for rotenone following intravenous (IV), oral, and dermal routes are 0.35–0.65, 1.5, and 100–200 mg /kg, respectively.

Following oral ingestion, rotenone induces mild irritation to vomition because of irritant effect on mucus membranes (Gosselin *et al.*, 1984). Inhalation of dusts of rotenone is known to cause severe pulmonary irritation. In the rats and dogs, experimental inhalation of rotenone dust produced onset of signs earlier than following oral ingestion (Hayes, 1982). Toxicity is greater if the particles are of smaller size, because these particles can enter deep regions of the lungs.

In general, depression and convulsions are the common clinical signs with acute toxicity of rotenone. Following oral ingestion, clinical signs of toxicosis may include pharyngitis, nausea, vomiting, gastric pain, clonic convulsions, muscle tremors, lethargy, incontinence, and respiratory stimulation followed by depression (Hayes, 1982; Gosselin *et al.*, 1984). In animals, severe signs of hypoglycemia and liver failure are evident. Rotenone causes alterations in arterial blood gases and acid–base balance. It induces hypoxemia and hypercapnia due to respiratory depression and seizures. In addition, rotenone can impair myocardial contractile force.

Following inhalation exposure, rotenone causes severe pulmonary irritation and asphyxia. Studies suggest that following parenteral administration, rotenone can induce vomiting, incoordination, muscle tremors, clonic convulsions, and respiratory failure. Terminal symptoms of rotenone poisoning are convulsions and cardio-respiratory failure (Gosselin *et al.*, 1984; Ellenhorn and Barceloux, 1988). Most often, cardiovascular effects

include tachycardia, hypotension, and impaired myocardial contractility.

Rotenone is a neurotoxicant. In the rat model, IV infusion of rotenone (2–3 mg/kg/day) is known to produce Parkinson's-like pathology.

In a chronic study, dogs receiving rotenone (10 mg/kg/day) for 6 months showed weight loss and hematological changes. Chronic exposure to rotenone may produce fatty changes in the liver (Windholz, 1983). A no observed adverse effect level (NOAEL) of 0.4 mg/kg/day has been determined in rats and dogs.

Studies suggest that rotenone has no potential to induce teratogenicity or mutagenicity (Waters *et al.*, 1982; Moriya *et al.*, 1983) or endocrine disruption. Its potential to cause carcinogenicity is controversial. Rotenone may produce tumors only in vitamin-deficient animals (Gosalvez, 1983).

Rotenone is highly toxic to fish, while posing low risk to wildlife if properly used.

### Diagnosis

Cases of rotenone poisoning in animals are rare. Diagnosis can be based on circumstantial evidence and detection of rotenone residue in blood, urine, feces, and vomitus. It is expected that rotenone residue is more likely to be present in the liver. Rotenone residue can be determined using high pressure liquid chromatography (HPLC) coupled with fluorescence detector.

## TREATMENT

There is no specific antidote available for rotenone or rotenoids. Treatment relies upon symptomatic and supportive measures. Wash contaminated skin to decontaminate rotenone residue. Avoid emesis if convulsions are present or the ingested product has petroleum distillate. Perform gastric lavage if a large amount of rotenone is ingested. Control seizures and agitation with diazepam and correct hypoglycemia with glucose (5%, IV).

CHAPTER

# 43

# Fipronil

*Ramesh C. Gupta*

## INTRODUCTION

Fipronil is a member of a new class of insecticides called phenylpyrazoles. Chemically, it is a (5-amino-1-[2,6-dichloro-4-(trifluoromethyl)phenyl]-4-[(trifluoromethyl)sulfinyl]-1*H*-pyrazole). Chemical structure of fipronil is shown in Figure 43.1. Fipronil is an active ingredient of one of the popular ectoparasiticide products, Frontline™. There are currently two forms of Frontline preparation commercially available (the spray and the spot on application) for dogs and cats. The product is meant to kill fleas and all stages of brown dog ticks, American dog ticks, lone star ticks, which may carry Lyme disease, and mites (Cutler, 1998; Hutchinson *et al*., 1998; Anonymous, 2000). Fipronil is also formulated as insect bait for roaches, ants, and termites; sprays for pets; and as a granular turf control and mole crickets. Presently, Fipronil is widely used for soil treatment and seed coating.

Currently, fipronil-based products with various trade names (Chipco®, Choice, ICON 6.2FS™, and Over n' Out™, TeckPac) have gained the popularity worldwide for pest management, including residential insect control, rice and cotton production, and turf-grass management. The Environmental Protection Agency (EPA) has determined fipronil to be safe for use on dogs and cats, with no harm to humans who handle these dogs and cats (EPA, 1997). Poisoning cases from accidental or misuse of fipronil occur in animals. This chapter describes the toxicity of fipronil in various species of animals and birds.

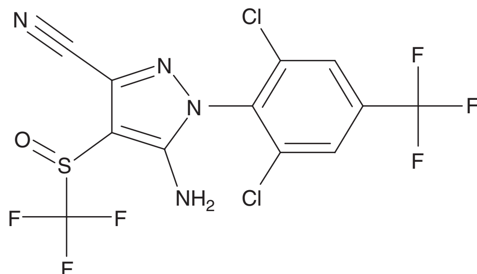

**FIGURE 43.1** Chemical structure of fipronil.

## BACKGROUND

Fipronil was discovered for the first time by Rhone-Poulenc Agro in 1987. It represents the second generation of insecticides that acts through a different mechanism compared to other conventional insecticides. In 1996, it was registered as a pesticide in the United States (Bobe *et al*., 1998). It can be formulated as roach or ant baits, flea and tick sprays for pets, and in granular turf products to control mole crickets (Kidd and James, 1991; EPA, 1996). In addition, fipronil is used for soil treatment and on crops to protect from insects.

Most of the time poisoning cases of fipronil occur in dogs and cats due to accidental ingestion or licking the product Frontline. Frontline preparation for dogs contains 132 mg fipronil in a volume of 1.3 ml tube that is meant for a topical application. In humans, poisoning is mainly due to accidental or suicidal attempt. In a recent report, the Paris Poison Center, France, recorded 81 human cases of fipronil exposure from 1994 to 1999. Out of these 81 cases, 57 involved veterinary ectoparasiticides and 7 used domestic insecticide preparations (Gasmi *et al*., 2001).

## PHARMACOKINETICS/ TOXICOKINETICS

Fipronil in Frontline preparation (132 mg in a 1.34 ml liquid) is placed between the dog's shoulder blades at the

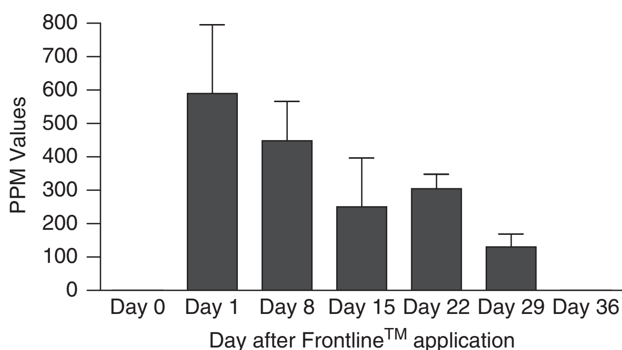

**FIGURE 43.2** Transferable residue of fipronil from the dog coat after a single application of Frontline spot-on.

nape of the neck. After application, fipronil spreads and sequesters in the lipids of the skin and hair follicles, and continues to be released onto the skin and coat, resulting in long-lasting activity against fleas and ticks. Residue of fipronil lasts on dog's hair coat for about a month. The maximum concentration of fipronil on the canine hair coat is found 24 h after a single application of Frontline top spot (Jennings *et al.*, 2002). With a descending concentration trend fipronil residue can be detected on dog's hair coat for a period of 30 days (Figure 43.2). Although fipronil binds to the lipids of the skin cells and hair follicles, the transferable residue can be detected up to a month after application. Studies have revealed that in rats, fipronil is excreted mainly in the feces (45–75%) and little in the urine (5–25%).

Fipronil is degraded by sunlight to produce a variety of metabolites, one of which is fipronil desulfinyl. This metabolite is extremely stable, bioaccumulates in the fatty tissues, and is more toxic than the parent compound in insects (EPA, 1998). Information on other metabolites of fipronil in the living system and nonliving system can be found elsewhere (Feung and Yenne, 1997: Aajoud *et al.*, 2003). This photoproduct exerts high neurotoxicity by blocking the $\gamma$-aminobutyric acid (GABA)-regulated chloride channels. Fortunately, this metabolite is not formed in mammals. However, it does have high-affinity toward the insect's GABA system, thereby contributing to fipronil's selective toxicity toward insects.

## MECHANISM OF ACTION

In mammalian system, the mechanism of fipronil is quite different from other classes of insecticides, and it is better understood in insects than in mammals. Fipronil sulfone is a major metabolite of fipronil in mammals and insects. In insects, fipronil or its metabolite noncompetitively inhibits GABA-induced ion influx by targeting the GABA-regulated chloride channels (Cole *et al.*, 1993). Consequently, fipronil binding blocks the inhibitory action of GABA, leading to hyperexcitation and, in appropriate concentrations, death (Bobe *et al.*, 1998). Fipronil exhibits >500-fold selective toxicity to insects over mammals, primarily because of affinity differences in receptor binding between insect and mammalian receptors (Cole *et al.*, 1993; Grant *et al.*, 1998; Hainzl *et al.*, 1998; Kamijima and Casida, 2000; Ratra *et al.*, 2001; Zhao *et al.*, 2005). In essence, fipronil binds more tightly to $GABA_A$ receptors in insects than in mammals. It is important to note that since fipronil sulfone is rapidly formed *in vivo*, the toxicological effects are likely due to the sulfone metabolite (Zhao *et al.*, 2005).

## TOXICITY

Fipronil produces toxicity in insects and mammals by the same mechanism, however due to selective action, the toxicity is much more severe in insects than in mammals. Fipronil exerts neurotoxicity by blocking the GABA-regulated chloride channels of neurons.

There are numerous reports regarding the effects of fipronil in small animals, birds, and fish (http://www.cdpr.ca.gov/docs/empm/pubs/fatememo/fipronil.pdf). Adequate acute toxicity data is available from small animals. The oral $LD_{50}$ value for rats and mice is reported to be 97 and 95 mg/kg body weight, respectively. It is slightly toxic to nontoxic via the dermal route, with a reported dermal $LD_{50}$ of greater than 2000 mg/kg in rats (EPA, 1996). In rabbits also, dermal $LD_{50}$ is 2000 mg/kg (WHO, 1998-1999). In general, dermal absorption of fipronil is less than 1% after 24 h and therefore dermal toxicity is considered low. Fipronil has moderate inhalation toxicity with an acute $LC_{50}$ of 0.682 mg/l in rats (EPA, 1996). On an acute and subchronic level fipronil is practically nontoxic to waterfowl with an acute oral $LC_{50}$ of >2000 g/kg and a 5-day dietary $LC_{50}$ of >5000 mg/kg for mallard ducks. The oral $LC_{50}$ for Bobwhite quail is 11.3 mg/kg, and the $LC_{50}$ for 5-day dietary is 49 mg/kg (EPA, 1996). The sulfone metabolite is more toxic than the parent compound to certain bird species. This metabolite has shown a very high toxicity in game birds and moderate toxicity in waterfowl (EPA, 1996; Bobe *et al.*, 1997). Fipronil is highly toxic to rainbow trout and very highly toxic to bluegill sunfish with an $LC_{50}$ of 0.246 and 0.083 ppm, respectively. WHO classifies fipronil as a Class II moderately hazardous pesticide.

Poisoning cases of fipronil occur in dogs and cats due to accidental ingestion/licking of Frontline product. There is some indication that dogs are more severely affected than cats. Application of Frontline top spot on dogs and cats can cause skin irritation and/or hair loss at the site of application. Common clinical signs of fipronil toxicosis

are of CNS hyperexcitability, including tremors, convulsions, seizures, and death (Grant *et al*., 1990; Hainzl *et al*., 1998; Kamijima and Casida, 2000). In rabbits, fipronil produces serious adverse reactions, suggesting that this species is unusually sensitive to fipronil. Young rabbits are especially more sensitive than adults. Frontline has been considered to be unsuitable for rabbits.

Diagnosis of a fipronil poisoning can be based on circumstantial evidence, clinical manifestations, and chemical confirmation. Fipronil residue can be detected in the blood, tissue, or hair using GC/MS. Transferable residue of fipronil can be detected on a dog hair coat up to 4 weeks after a single spot on application (Figure 43.2).

## TREATMENT

There is no specific treatment for the toxicity of fipronil, and therefore treatment relies upon symptomatic and supportive measures. If a dog or cat shows adverse reaction to topical application of Frontline, decontamination by washing at the site of application is advisable.

## CONCLUSIONS

Fipronil elicits neurotoxicity in mammals by inhibition of $GABA_A$-gated chloride channels, producing hyperexcitability of CNS. Overdosage due to accidental ingestion often leads to serious toxicosis. There is no specific antidote for the toxicity of fipronil.

# Imidacloprid

*Steve Ensley*

## INTRODUCTION

Imidacloprid is relatively new compound with many uses. Imidacloprid is a neonicotinoid compound that is used as an insecticide for dermal application on animals, for termite and grub control and as an insecticide for crop protection. The neonicotinoids act on nicotinic receptors in insects and vertebrates. To reduce toxicity to mammals and increase toxicity to insects, neonicotinic compounds have been selected that are highly specific for subtypes of nicotinic receptors that occur in insects. The neonicotinoids do not readily pass the blood–brain barrier, further reducing the potential for mammalian toxicity (Yamamoto *et al.*, 1995). When administered orally, imidacloprid is rapidly absorbed, metabolized primarily in the liver and excreted primarily in urine. Imidacloprid does not accumulate in the body, and it is neither carcinogenic, mutagenic, teratogenic nor a reproductive toxicant. Imidacloprid has a high margin of safety due to the high insecticidal specificity and low mammalian toxicity (Nagata *et al.*, 1999).

## BACKGROUND

The neonicotinoids were developed in the late 1970s by chemists at Shell Chemical Company doing research with the heterocyclic nitromethylenes for use as insecticides (Soloway *et al.*, 1978; Schroeder and Flattum, 1984). The neonicotinoids and chloronicotinyls are a separate class of compounds from the nicotinoids (Tomizawa and Yamamoto, 1993). Chemists at Nihon Bayer Agrochem discovered imidacloprid in 1984 when the 3-pyridylmethyl group was added to the nitromethylene heterocyclic parent molecule. This addition to nitromethylene greatly increased the insecticidal activity and reduced mammalian toxicity. After imidacloprid was discovered several other analogs with the 6-chloro-3-pyridylmethyl moiety have been developed, such as acetamiprid, nitenpyram and thiacloprid (Takahashi *et al.*, 1992; Minamida *et al.*, 1993; Yamada *et al.*, 1999).

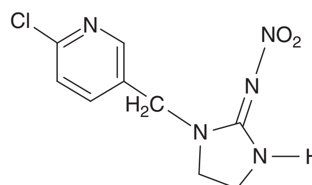

**FIGURE 44.1** Structure of imidacloprid.

## PHARMACOKINETICS/ TOXICOKINETICS

There are two routes of imidacloprid metabolism in mammals. The first route of metabolism involves oxidative cleavage of imidacloprid to imidazolidine and 6-chloronicotinic acid. The imidazolidine moiety is excreted in the urine. The 6-chloronicotinic acid is further degraded by glutathione conjugation to a derivative of mercapturic acid then to methyl mercaptonicotinic acid. The mercaptonicotinic acid is then conjugated with glycine to form a hippuric acid conjugate that is excreted. A second route of metabolism involves hydroxylation of the imidazolidine ring followed by elimination of water and formation of an unsaturated metabolite. Specific information on the toxicokinetics of the rat can be found in Thyssen and Machemer (1999) (Figure 44.1).

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

The following studies were conducted by Bayer CropScience (Sheets, 2001). Acute oral toxicity of imidacloprid in rats has been demonstrated at doses above 300 mg/kg with 100% mortality at 500 mg/kg. At doses in rats above 300 mg/kg, clinical signs were observed with 15 min of dosing and recovery was observed within 8–24 h. A subchronic 13-week oral dosing study of imidacloprid in rats also demonstrated toxicity at a dose of 300 mg/kg in male rats. At a dose of 300 mg/kg in male rats, hypertrophy of hepatocytes and sporadic cell necrosis was observed in the liver. This mild liver damage was not observed after a 4-week recovery period. Serum alkaline phosphatase and alanine aminotransferase were elevated in male and female rats treated at 300 mg/kg and above. In dogs, a 13-week oral dose of imidacloprid at 15 mg/kg and above produced a tremor that increased with dose. A 52-week study in dogs at oral doses up to 72 mg/kg/day of imidacloprid did not produce tremors. The no observed effective level (NOEL) for this chronic oral exposure dog study was 15 mg/kg. Carcinogenicity was not observed in rats dosed orally at doses up to 103 mg/kg for 2 years. These studies would indicate that imidacloprid is non-mutagenic, non-embryotoxic and non-teratogenic.

The most common adverse effects observed with dosing of neonicotinoids at low levels (40 mg/kg) in rodents is decreased activity. At higher doses (150 mg/kg) tremors, impaired pupillary function (dilated or pin point pupils), incoordinated gait, and hypothermia is observed. At lethal doses (307 mg/kg), deaths are observed within 4 hours of dosing. If death did not occur, recovery was observed within 8 to 24 hours of dosing.

## MECHANISM OF ACTION

Absorption and distribution of imidacloprid in rats occurs within 1 h following oral administration. In rats more than 90% of a dose of imidacloprid is eliminated within 24 h. Approximately 80% of the dose is excreted by the urine with the remainder eliminated in the feces. Imidacloprid is not distributed to the central nervous system, fatty tissues or bone. This indicates that the blood–brain barrier allows little distribution to the central nervous system for imidacloprid in particular and the neonicotinoids in general.

The neonicotinoids act on post-synaptic nicotinic receptors (Buckingham *et al.*, 1997). These receptors are located entirely in the central nervous system of insects. Imidacloprid acts on at least three different subtypes of nicotinic receptors in the cockroach. Neonicotinoids cause a bi-phasic response: an initial increase in the frequency of spontaneous discharge followed by a complete block to nerve propagation. Insecticidal activity is increased by adding synergists that inhibit oxidative degradation (Liu M-Y, Casida IE, 1993).

Mammalian tissue also contains multiple subtypes of nicotinic receptors. The various subtypes are formed from different combinations of nine $\alpha$ , four $\beta$ , $\gamma$ , $\delta$ and $\varepsilon$ subunits (Tomizawa *et al.*, 1999). Nicotinic receptors in mammals are located in the autonomic ganglia, skeletal muscle, spinal cord and in different regions of the brain. Neonicotinoids have much lower activity in vertebrates compared to insects due to the different binding properties of the various receptor subtypes (Yamamoto *et al.*, 1998). Acute toxicity of the neonicotinoids in mammals is related to the potency at the $\alpha_7$ nicotinic receptor subtype with the activity at the $\alpha_4$, $\beta_2$, $\alpha_3$ and $\alpha_1$ receptors having a decreasing effect on toxicity. Toxicity in mammals involves complex interactions at multiple receptor sites with some of the receptor types even having a combination of agonist and antagonist effects on the synapse.

## TREATMENT

There is no specific antidote to treatment of overdoses of imidacloprid. Treatment is symptomatic. If the exposure is dermal, washing the affected animal with soap and water is indicated. If the exposure is oral, emetics, adsorbents or cathartics could be used depending on what clinical signs are being observed. Absorption and elimination of imidacloprid is rapid so immediate supportive care should allow for rapid recovery.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

The neonicotinoids have a wide safety margin in mammals and the insecticidal activity can be targeted so this class of compounds will have wide future use as an insecticide.

CHAPTER

# 45

# Ivermectin and selamectin

*Ramesh C. Gupta*

## INTRODUCTION

### Ivermectin

Ivermectin is a semi-synthetic macrocyclic lactone which was first obtained from *Streptomyces avermitilis.* Ivermectin is a mixture of homologues, i.e. $B_{1a}$ and $B_{1b}$, and their structural formulas are shown in Figure 45.1. It was introduced to the market in 1981, as a potent antiparasitic animal health drug. It has been found to be effective against virtually all external and internal parasites thus far tested, except trematodes and cestodes. The drug is approved at very low dosage for the control of parasites in many animal species (cattle, sheep, swine, horse, cat, and dog), but not approved in lactating cows, sheep, and goats. In agriculture, ivermectin is used for its miticidal, insecticidal, and acaricidal activities.

Although ivermectin poisoning has been reported in many animal species due to inadvertent or misuse of the product, major concern of ivermectin toxicity is in collie dogs (Paul *et al*., 1987), which are very sensitive to this drug. In addition, an Old English sheepdog (Houston *et al*., 1987), Murray Grey Cattle (Seaman *et al*., 1987), and in general, young animals are more sensitive to ivermectin toxicity.

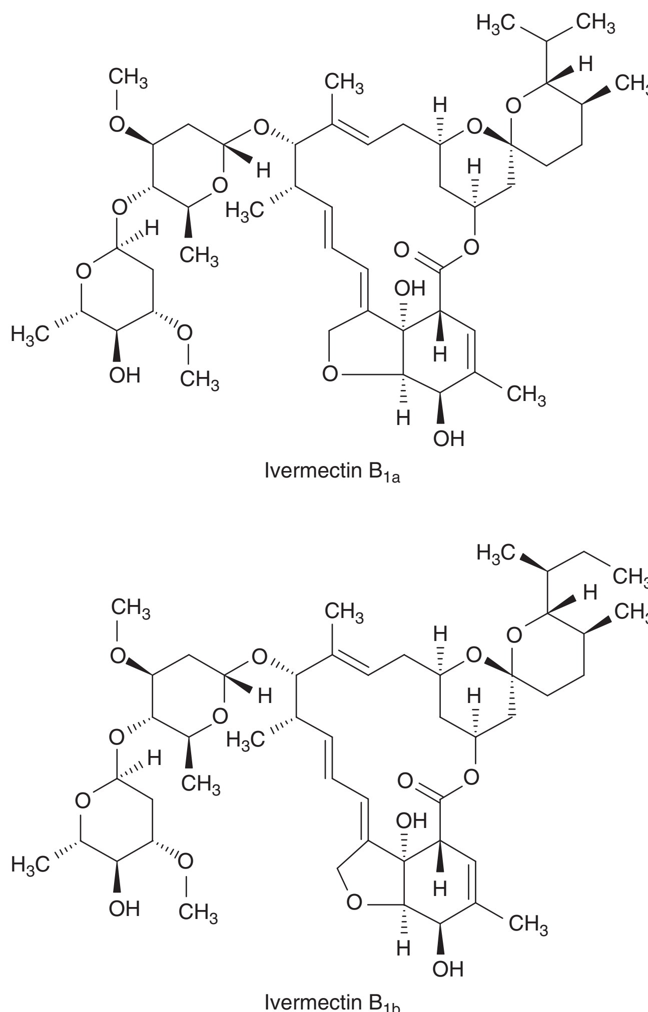

**FIGURE 45.1** Chemical structure of ivermectin $B_{1a}$ and $B_{1b}$.

### Selamectin

Selamectin is a novel semi-synthetic avermectin (Figure 45.2), which is marketed as Revolution. Revolution is a topical antiparasitic preparation recommended for use in dogs and cats 6 weeks of age and older. Selamectin is used to kill fleas (*Ctenocephalides felis*) and ear mites (*Otodectis cynotis*) in dogs and cats. It is also indicated for the treatment and

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

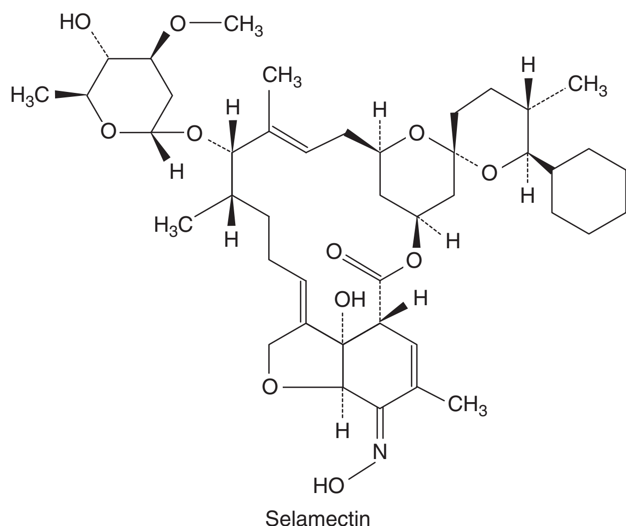

**FIGURE 45.2** Chemical structure of selamectin.

control of sarcoptic mange (*Sarcoptes scabiei*) and for the control of ticks (*Dermacentor variabilis*) infestations in puppies, and the treatment of hookworm (*Ancylostoma tubaeforme*) and roundworm (*Toxocara* cati) infections in kittens. Selamectin is also used to prevent heartworm disease caused by *Dirofilaria immitis*. It is recommended in the dogs and cats at a dose of 6 mg/kg body weight.

This chapter describes toxicity of ivermectin and selamectin in animals.

## BACKGROUND

### Ivermectin

Ivermectin is a mixture of homologues, i.e. not less than 80% of 22,23-dihydroavermectin $B_{1a}$ and not more than 20% of 22,23-dihydroavermectin $B_{1b}$. The mixture is commercialized as abamectin. Ivermectin is a drug of choice because of its broad spectrum nematicidal, insecticidal, and acaricidal properties, and has been approved for prophylactic use against heartworm (*Dirofilaria immitis*) in dogs.

Ivermectin is recommended at very low dosage. It is effective against a wide range of helminths in sheep and cattle in single oral or parenteral dose of 0.1 mg/kg body weight (Egerton *et al*., 1979). It is recommended in dogs, cats, sheep, goats, swine, feedlot beef cattle, horse, and reindeer. The tolerances for beef cattle, reindeer, swine, and sheep are 15, 15, 20, and 30 ppb ivermectin $B_{1a}$ (Code of Federal Regulation, 1990). Ivermectin is not approved for lactating animals.

In the case of beagle dogs the dose required for prevention of heartworm disease is 6 μg/kg body weight, while the $LD_{50}$ of this drug in the same breed is 80,000 μg/kg body weight (Pullium *et al*., 1985). However, certain dogs, primarily rough-coated collies, exhibit signs of toxicity when given ivermectin at doses in the range of 100–2500 μg/kg body weight (Easby, 1984; Houston, 1987). Although this dosage level exceeds the recommended dose for dogs, it has been administered inadvertently by improper use of formulations which were meant for cattle, sheep, horses, and swine. Poisoning in several animal species has been reported due to overdosage of ivermectin. Young animals in general are more sensitive than adults because their blood–brain barrier (BBB) is more permeable to ivermectin (Sanford *et al*., 1988).

### Selamectin

Topical application of Revolution (6 mg selamectin/kg body weight) has been shown to have a broad range of efficacy against many external and internal parasites of dogs and cats (Jacobs, 2000; Dryden *et al*., 2001). Following topical administration of Revolution to a single site on the skin, selamectin is absorbed by the animal through the skin, enters the blood stream and the gastrointestinal (GI) tract, and is ingested by the external and internal parasites as they feed on the treated host. Selamectin has been shown to have a direct parasiticidal effect following ingestion (Bishop *et al*., 2000; Pfizer, 2001). Selamectin is a very safe drug, but the poisoning can occur due to overdosage or accidental exposure.

## PHARMACOKINETICS/ TOXICOKINETICS

### Ivermectin

The pharmacokinetics of ivermectin differs according to the animal species, formulation, and route of administration. In general, the pharmacokinetic properties of these compounds are characterized by their large volume of distribution, slow elimination from the body, and linear relationship to dose, as well as differences between species and variation within individuals of the same species. Bioavailability and pharmacokinetic studies, based upon plasma analysis, revealed that ivermectin was slowly eliminated with a terminal half-life in the range of 5–7 days (Lo *et al*., 1985; Prichard *et al*., 1985). Tissue distribution of ivermectin residues in cattle and sheep has been studied (Tway *et al*., 1981) and it was shown that the major simple component in the edible tissue of the animals was the unaltered drug. In this regard, the liver is the tissue in which the drug is most persistent, as the residue was detected over a period of 28 days post-administration. Due to high lipid solubility,

ivermectin also deposits in adipose tissue, which act as a reservoir that contributes to the long persistence of this drug in the body. The half-life of ivermectin is 4.03 d in goat, 3.68 d in sheep, and 3.66 d in horse following a subcutaneous dose (Prichard *et al.*, 1985; Alvinerie *et al.*, 1993).

Pharmacokinetics of ivermectin in a foal has been found to be similar to that reported in sheep (Prichard *et al.*, 1985 Godber *et al.*, 1995; ). In pigs, ivermectin is distributed to all tissues and body fluids (GI tract contents, GI tract wall and mucus, lungs, skin, earwax, feces) following a subcutaneously injection at 300 μg/kg (Scott and McKellar (1991). Due to high lipid solubility, ivermectin also concentrates in the skin and earwax. The mean elimination half-life of ivermectin was 41.5 h, and the residue was detectable in the plasma for 6–10 days.

Ivermectin residues can be detected in the milk up to 3–4 weeks post-administration (Alvinerie *et al.*, 1987, 1993). These authors determined the pharmacokinetics and mammary excretion of ivermectin in goats following a single subcutaneous (SC) injection (0.2 mg/kg). Kinetic analysis of plasma and milk, using one-compartment model, revealed that the maximum plasma concentration of 6.12 ng/ml occurred at 2.85 d. Ivermectin was detected in the milk as early as 0.3 d, and for at least 25 d. Comparison of the milk and plasma data shows the parallel disposition of the drug in milk and plasma with a milk–plasma concentration ratio of 1.08±0.23. Ivermectin is highly lipid soluble, and it has been found that its concentrations in the milk of cows (Alvinerie *et al.*, 1987; Bogan and McKellar, 1988), ewes (Marriner *et al.*, 1987) and goats (Alvinerie *et al.*, 1993) were similar to the plasma concentrations. Furthermore, following oral or pour-on administration, the excretion pattern of ivermectin is similar (Scott *et al.*, 1990). Ivermectin in the milk of goats can excrete 0.31±0.21 % of the administered dose (Alvinerie *et al.*, 1993), 4.0% of the dose in sheep (Marriner *et al.*, 1987), and 5.46% in cows (Toutain *et al.*, 1988). This large difference appears to be related to differences in the volume of milk produced in the various species and to fat content of the milk (Alvinerie *et al.*, 1993).

Regardless of the method of application (oral, subcutaneous, topical), ivermectin is excreted in bile (Chiu *et al.*, 1990), with high concentrations in feces of the treated animals, where it is associated with reductions in number of dung breeding insects. For further details of pharmacokinetics of ivermectin in animals and humans, readers are referred to Fink and Porras (1989).

## Selamectin

The pharmacokinetics of selamectin has been evaluated in dogs and cats following intravenous (IV) (0.5, 0.1, and 0.2 mg/kg), topical (24 mg/kg), and oral (24 mg/kg) administration (Sarasola *et al.*, 2002). After IV administration of selamectin, the mean maximum plasma concentrations and area under the concentration (AUC)–time curve were linearly related to the dose, and mean systemic clearance ($Cl_b$) and steady state volume of distribution ($Vd_{ss}$) were independent of dose. Plasma concentrations decline polyexponentially in cats and biphasically in dogs with mean terminal phase half-life ($t_{1/2}$) of approximately 69 h in cats and 14 h in dogs. After topical administration, the mean $C_{max}$ in cats was 5513 ± 2173 ng/ml reached at a time ($T_{max}$) of 15 ± 12 h post administration; in dogs, $C_{max}$ was 86.5 ± 34.0 ng/ml at $T_{max}$ of 72 ± 48 h. Bioavailability was 74% in cats and 4.4% in dogs. There is no evidence of sex differences in the pharmacokinetics of selamectin in dogs or cats.

In dogs and cats, selamectin is rapidly absorbed from the skin into the bloodstream, where it kills heartworms. Selamectin excretes into the intestinal tract where it kills intestinal parasites. Finally, selamectin is selectively distributed from the bloodstream into the sebaceous glands of the skin, forming reservoirs that provide persistent efficacy against fleas, ear mites, and sarcoptic mites. Active concentrations of selamectin are found in the plasma for at least 30 days. It is excreted mostly in the feces and a small unmetabolized amount in the urine. Selamectin eliminates more slowly in cats than in dogs following IV administration, as reflected in longer $t_{1/2}$ (69 h versus 14 h) and slower body clearance (0.47 versus 1.18 ml/min/kg). These findings indicate that selamectin persists longer in cats than in dogs, possibly because of differences in metabolism and/or another elimination process between the species.

In dogs, following a single topical application of Revolution, transferable residue of selamectin persists up to a period of 30 days (Gupta *et al.*, 2005) (Figure 45.3). Blood analysis at the 24 h interval revealed no residue of selamectin, but at 72 h the concentration was 10.26±1.06 ng/ml. By day 7, no selamectin residue was

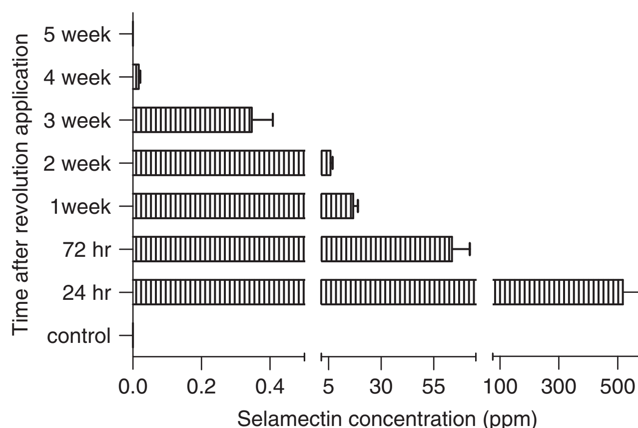

**FIGURE 45.3** Transferable selamectin residue in gloves (ppm) following a single topical application of Revolution (240 mg selamectin per dog).

present. The findings suggested that due to rapid elimination of selamectin from circulation, by day 7, all traces of selamectin in the blood were no longer present.

# MECHANISM OF ACTION

## Ivermectin

Ivermectin is effective against all external and internal parasites, except trematodes and cestodes. This is because of the fact that the drug acts as a $\gamma$-aminobutyric acid (GABA) agonist (Pong and Wang, 1982), and trematodes and cestodes apparently lack a GABA system.

In mammals, ivermectin exerts toxicity by blocking the post-synaptic transmission of nerve impulses by potentiating the release and binding of GABA, and thus blocking GABA-mediated transmission (Campbell and Benz, 1984; Bennett, 1986; Barragry, 1987). In mammals, GABA system is found only in the central nervous system (CNS). Although ivermectin does not readily cross the BBB, there are several reports of ivermectin-induced CNS toxicosis in collie dogs (Campbell and Benz, 1984; Pullman *et al.*, 1985; Bennett, 1986; Barragry, 1987; Paul *et al.*, 1987), and in other domestic animals (Houston, 1987; Houston *et al.*, 1987). Some adverse effects seen in dogs, horses, and cattle given ivermectin may be due to GABA-mediated cholinergic effects (Basudde, 1989). It has been observed that serum pseudocholinesterase levels are significantly increased following SC or IV injection of ivermectin.

## Selamectin

Selamectin binds to glutamate gated chloride channels in the parasite's nervous system, causing them to remain open. This causes chloride ions to continuously flow into the nerve cell, changing the charge of the cell membrane. The continuous flow of chloride ions blocks neurotransmission, and transmission of stimuli to muscles is prevented. Selamectin binding is irreversible causing prolonged channel opening and permanent hyperpolarization. Selamectin has no such effect in the mammalian nervous system, and therefore, it is much safer than common insecticides and parasiticides.

# TOXICITY

## Ivermectin

Ivermectin is a mixture of homologues, in which $B_{1a}$ and $B_{1b}$ components differ from each other by a single methylene group. $B_{1a}$ is the principal component of the mixture (>80%). $B_{1a}$ and $B_{1b}$ have very similar biological and toxicological properties and can, for all practical purposes, be considered equipotent (Campbell, 1989).

The clinical signs and symptoms of ivermectin toxicosis in collie dogs have been reported in several studies (Pullium *et al.*, 1985; Paul *et al.*, 1987; Tranquilli *et al.*, 1987). Ivermectin is a neurotoxicant, as it exerts its toxic effects on the CNS of these sensitive dogs. Further support for CNS involvement was the finding that the ivermectin concentrations in the brain were higher in dogs displaying symptoms of ivermectin toxicosis than in non-sensitive dogs (Pullium *et al.*, 1985). These findings not only suggest the involvement of CNS, but also suggest a difference in the BBB permeability to ivermectin in sensitive versus non-sensitive dogs. However, no differences in the binding characteristics of ivermectin in plasma (albumin and the high density lipoprotein) from ivermectin sensitive and non-sensitive Collies were found (Rohrer and Evans, 1990). The difference between sensitive and non-sensitive dogs lies within the anatomy or physiology of BBB itself or in the presence of high affinity binding sites within the brain rather than difference in the bioavailability of the drug (Kitagawa *et al.*, 1988; Sasaki *et al.*, 1988; Tranquilli *et al.*, 1989). A collie dog after ingesting ivermectin at about 200 μg/kg (in an equine anthelmintics paste) exhibited signs of dehydration, bradycardia, respiratory depression, cyanosis, dilated pupils, and a diminished gag reflex (Heit *et al.*, 1989). Toxic signs may also include vomiting, ataxia, tremors, hypersalivation, coma, and death. Toxic reactions in cats receiving ivermectin (500 μg/kg, sc) showed signs such as vocalization, ataxia, tremors, sternal recumbency, coma, and death. Ivermectin should not be given to kittens, as it can cross the BBB in young animals. The kittens also showed signs of mild diarrhea, posterior ataxia, and mild miosis (Song, 1991). In contrast, in mammals in which ivermectin does not readily cross the BBB, the drug has a wide margin of safety and at least 10 times the therapeutic dose is required to produce toxic effects in most normal mammals (Campbell *et al.*, 1983; Bennett, 1986).

Ivermectin given IV or SC to 8-month-old jersey bull calves at 600 μg/kg caused depression, ataxia, diarrhea, dyspnea, tachycardia, and miosis. Signs were less severe after SC than were after IV injection. Some of these signs were associated with GABA-mediated cholinergic effects. Calves receiving 8.0 mg/kg developed ataxia and recumbency within 24 h after ivermectin exposure. Calves developed depression, increased respiratory rates, muscular fasciculations, mydriasis, and extensor rigidity of the limbs. In cattle, maximum tolerated dose of $B_{1a}$ is about 1.0 mg/kg. In sheep, with higher dose of ivermectin, the toxicity is characterized by depression and incoordination.

Horses exposed to higher doses of ivermectin (6–10 times greater than therapeutic dose) showed ataxia,

depression, and vision impairment within 24 h. With a dose of 60 times the recommended dose (12 mg/kg) horses showed depression, mydriasis, ataxia, depressed respiratory rate, and drooping lower lip (Leaning, 1983).

### Selamectin

In acute cases, signs of toxicosis may include hair loss at the site of application, vomiting, diarrhea with or without blood, anorexia, lethargy, salivation, tachypnea, pruritis, urticaria, arythema, ataxia, and fever. In rare instances, seizures followed by death occur with overt acute overdose. In chronic cases, in dogs and cats, seven monthly treatments of 60 mg/kg (10 times the recommended dose) produced no adverse reactions when given to 6-week-old kittens or puppies. An exposure of 18 mg/kg (3 times the recommended dose) produced no effect on reproduction in females or males. Three monthly doses of 30 mg/kg produced no adverse effects in ivermectin sensitive collies. There have also been rare reports of muscle spasms, seizures, ataxia, and other neurological signs. In a recent study, dogs treated with a single topical application of Revolution (6 mg/kg body weight) showed no signs of any poisoning (Gupta *et al*., 2005).

### Diagnosis

Diagnosis of ivermectin/selamectin can be based on history of exposure to a product containing ivermectin or selamectin, clinical signs, and residue analysis in the body tissue or fluids. These compounds are analyzed using high performance liquid chromatograph coupled with UV detector fluorescence detector, or photo diode array detector (Maynard and Maynard, 1989; Rabel *et al*., 1993; Payne *et al*., 1995; Reising *et al*., 1998; Anastaseo *et al*., 2002; Gupta *et al*., 2005). GI content, liver, fat, and feces are usually the specimens analyzed for ivermectin residue.

## TREATMENT

There is no specific antidote for ivermectin or selamectin toxicity. If poisoning occurs by oral ingestion, the initial therapy should focus on ivermectin removal by the use of oral activated charcoal and saline cathartics (Roder and Stair, 1998). With symptomatic and supportive therapies, even severely affected animals can recover from toxicosis, although recovery is slow. In severely intoxicated cases, use of physostigmine has been found to be beneficial, but physostigmine should not be considered as an antidote.

## CONCLUSIONS

Acute toxicity is more often encountered with ivermectin than selamectin. Poisoning occurs in dogs (especially collies) and cats due to inadvertent or misuse of the product meant for another species. In general, young animals are affected with a greater frequency than the adults. Treatment relies upon symptomatic and supportive therapies.

## ACKNOWLEDGMENTS

I would like to thank Mrs. Joan Jenkins, Debra Britton, and Denise Gupta for their assistance in preparation of this chapter.

CHAPTER

# 46

# Amitraz

*Ramesh C. Gupta*

## INTRODUCTION

Amitraz is a triazapentadiene compound, which is a member of the formamidine pesticide family. It has a chemical formula of $C_{19}H_{23}N_3$ and molecular weight 293.33. Its chemical structure is shown in Figure 46.1. Amitraz is commonly used in agriculture and horticulture as an insecticide and acaricide to control red spider mite, leaf miners, scale insects, aphids, and other infestations. Amitraz is used to control ticks, mites, lice, and many other pests on dogs, sheep, cattle, pigs, and horses. Amitraz is available in the form of a wetable powder or a pour-on powder, emulsifiable liquid, and spray. It is also used as a synergist and formulated with other insecticides. Amitraz is sold with various products names, including Aazdieno, Acadrex, Acarac, Amitik, Amitraze, Baam, Bumetran, Ectodex, Edrizan, Kenaz, Mitac, Maitac, Metaban, Preventic, Tickoff, Taktic, Triatix, Ovasyn, Ovidrex, and many others. Amitraz poisoning is frequently encountered in dogs and cats (Grossman *et al.*, 1993; Hugnet *et al.*, 1996). In children the poisoning occurs due to widespread use of amitraz veterinary products (Ertekin *et al.*, 2002). This chapter describes the toxicity of amitraz in animals with a special focus on dogs.

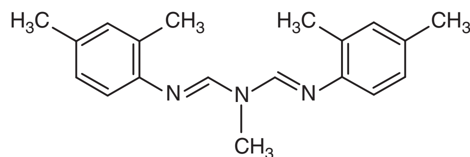

**FIGURE 46.1** Chemical structure of amitraz.

## BACKGROUND

Amitraz is a broad spectrum insecticide and acaricide used in veterinary medicine and in agriculture and horticulture throughout the world since 1974. Amitraz has rapid action on the control of animal ectoparasites, such as mites, ticks, kids, etc., and it persists on hair and wool long enough to control all stages of the parasites. Amitraz was a restricted use pesticide in 1985 because some studies showed it caused cancer in mice. But re-evaluation of the evidence has led to the current classification of amitraz as an unrestricted or general use pesticide. In veterinary medicine, the most common use of amitraz is in tick collars, which contains 9% amitraz as an active ingredient. A collar for a large size dog contains 2.4 g of amitraz (Hugnet *et al.*, 1996). Amitraz is available as a 19.9% topical solution for dogs. All tickicide dips for cattle and sheep contain 0.025% amitraz as the active ingredient. In France, tick collars contain 8–9% amitraz, and external lotions contain 5–12.5%. The amitraz containing product Metaban, which is a liquid concentrate and labeled for veterinary use, is commonly used for demodectic mange (*Demodex canis*) in dogs (Farmer and Seawright, 1980). This product is not recommended for cats and horses (Auer *et al.*, 1984; Gunaratnam *et al.*, 1993). Amitraz is used to control ectoparasites on cattle, sheep, goats, and pigs. There are several reports that have described side effects and toxic effects of amitraz in animals (Turnbull, 1983; Auer *et al.*, 1984; Hsu *et al.*, 1984; Grossman *et al.*, 1993). In the case of dogs, most of the time poisoning is associated with accidental ingestion of the collar, resulting in severe and sometimes fatal poisoning (Grossman *et al.*, 1993; Hugnet *et al.*, 1996). Amitraz should not be used in diabetic animals as it affects the levels of glucose and insulin.

## PHARMACOKINETICS/ TOXICOKINETICS

Dogs receiving amitraz (100 mg/kg, PO) in a gelatin capsule revealed the pharmacokinetic parameters as follows: area under the curve ($AUC_{0-48\,h}$ = 265.3 ± 12.3 mg/h/ml), elimination $t_{1/2}$ (23.4 ± 2.3 h), time to reach peak plasma concentration ($t_{max}$ = 5.0 ± 0.7 h), and mean peak plasma concentration ($C_{max}$ = 20.7 ± 2.3 mg/l) (Hugnet *et al.*, 1996). From these data it is clear that amitraz has a long elimination half-life and a significant amount is absorbed. Although some amount of amitraz degrades into two metabolites in the stomach, a substantial amount of amitraz is absorbed which is accountable for most of the observed signs. There is a strong association between plasma amitraz concentration and clinical/hematological modifications (Hugnet *et al.*, 1996). In ponies and sheep, amitraz has a brief half-life after intravenous (IV) administration because it is hydrolyzed in blood by formaminidases (Pass and Mogg, 1995).

Hugnet *et al*. (1996) observed that clinical signs of toxicosis usually appeared around 1 h after ingestion, with plasma concentration around 5 mg/l, and lasted until the concentration of amitraz decreased. This information can be used to monitor accidental ingestion of amitraz by dogs (Hugnet *et al.*, 1996).

The amitraz gets hydrolyzed into two metabolites such as 2,4-dimethylaniline and *N*-(2,4-dimethylphenyl)-*N'*-methylformamidine. The former metabolite is a relatively weak methemoglobin-former in dogs and man. These metabolites are further metabolized to 2,4-demethylaniline and ultimately to 4-amino-3-methylbenzoic acid, which is the principal metabolite found in the urine and liver (Aronson *et al.*, 1988; Jones, 1990).

## MECHANISM OF ACTION

Amitraz kills mites and ticks by interfering with their nervous system. The tick's sharp barbed mouth parts become paralyzed and cannot pierce the skin, thereby inhibiting the tick from feeding on dogs. Attached ticks detach.

Amitraz adversely affects the nervous system of animals if exposed to higher doses. Amitraz stimulates $\alpha_2$-adrenoceptor resulting in impairment of consciousness, respiratory depression, convulsions, bradycardia, hypotension, hypothermia, and hyperglycemia. Amitraz has been shown to produce side effects and toxicity in several animal species by targeting $\alpha_2$-adrenergic receptors. It produced effects similar to that produced by a pure $\alpha_2$-adrenergic agonist drugs such as clonidine (Costa *et al.*, 1988; Jorens *et al.*, 1997). As a pharmacologically active compound, amitraz in higher doses is responsible for neurotoxic and preconvulsant effects. In addition to $\alpha_2$-adrenergic agonist, amitraz is a potent inhibitor of monoamine oxidase (MAO) enzyme (Aziz and Knowles, 1973; Moser and Macphail, 1988).

It is suggested that the central $\alpha_2$-agonist activity of amitraz is responsible for central nervous system (CNS) depression (Cullen and Reyoldson, 1990). Other toxic effects associated with $\alpha_2$-agonist are hypothermia and increased heart rate.

Amitraz acts centrally to influence blood pressure and heart rate by $\alpha_2$-adrenoceptor agonism which causes a reduction in peripheral sympathetic tone (Kobinger, 1978; Cullen and Reyoldson, 1990). In the peripheral vasculature both $\alpha_1$ and $\alpha_2$ adrenoceptors are involved in contributing to a vasopressor action of amitraz which results in hypotension.

## TOXICITY

Acute toxicity data of amitraz is available for laboratory animals. Oral $LD_{50}$ is 650 mg/kg in rats and 1600 mg/kg in mice. Values of dermal $LD_{50}$ in rabbit and rat are >200 and 1600 mg/kg, respectively. The inhalation $LC_{50}$ (6 h) of amitraz for rats is 65 mg/l of air. The oral $LD_{50}$ in birds (bobwhite) is estimated at 788 mg/kg, and dietary $LD_{50}$ in mallard is 7000 mg/kg and in Japanese quail is 1800 mg/kg. $LC_{50}$ in rainbow trout is 0.74 ppm and in bluegill is 0.5 ppm and in harlequin fish is 3.2–4.2 ppm. The Environmental Protection Agency (EPA) classifies amitraz as a Class III- slightly toxic pesticide.

Signs of acute amitraz poisoning in male and female rats treated with 440 and 365 mg/kg, respectively, include coolness to touch, reduced spontaneous activity, episodes of increased induced activity such as aggression in response to handling, and signs of debilitation (Hayes and Laws, 1991). Due to its widespread use, acute amitraz poisoning is often encountered in dogs and cats. Poisoning may occur by oral, inhalation, or dermal exposure, but poisoning is most often by oral route. Onset of clinical signs is noted within 30 min to 2 h after ingestion. Clinical signs of poisoning include gastrointestinal (GI) disturbance, nausea, and vomiting (in species capable of vomition), CNS and respiratory depression, bradycardia, hypotension, and hypothermia. Biochemical changes include hyperglycemia and elevation of liver enzyme (transaminases) activity. When amitraz is formulated in xylene and propylene oxide, signs such as depression, ataxia, stupor, and coma are likely attributed to the xylene and propylene oxide (Jones, 1990). Generally, signs and symptoms of amitraz toxicity subside within 24 h; while in some cases it may take 7–10 days.

In dogs and cats, common side effects of the medication include anorexia, sedation, and a dry skin and hair coat.

Serious side effects include low blood pressure, hypothermia, hyperglycemia, mydriasis, bradycardia, slow intestinal rate, incoordination, ataxia, vasoconstriction, vomiting, diarrhea, seizures, and in rare instances death. Clinical signs in humans are similar to those described in animals, especially dogs. In brief, clinical signs include CNS depression, hypothermia, bradycardia, hypotension, hyperglycemia, vomiting, and respiratory failure (Aydin *et al.*, 1997; Kennel *et al.*, 1996; Ulukaya *et al.*, 2001). Death occurs due to cardiac and respiratory failure.

Evidence from animal studies suggests that amitraz is neurotoxicant (Moser and Macphail, 1988). Amitraz has been shown to produce many behavioral and physiological changes in rats. Amitraz at a dose greater than 100 mg/kg caused inhibition of MOA within 2 h of dosing and lasted up to 7 days. Amitraz appears to be more selective for type MAO-B when given *in vivo*, although MAO-A was also inhibited at doses ≥300 mg/kg. However, no selectivity was indicated by the $IC_{50}$ values determined *in vitro* ($IC_{50}$ = 31 and 28 μM for MAO-A and MAO-B, respectively). The findings revealed that the MAO inhibition is probably not due to amitraz-induced alterations in motor activity. Amitraz produced only negligible inhibition of acetylcholinesterase at very high doses. In a dose-dependent manner, amitraz produced depressed arousal and rearing activity, hypothermia, body- weight loss; and autonomic changes including ptosis, chromodacryorrhea resulting in facial crustiness, loss of the pupil reflex, and decreased defecation in rats (Moser, 1991).

Animals exposed to amitraz may show signs of CNS depression or CNS stimulation, depending on the dose level and to some extent the species involved. Generally, high doses have a CNS depressive effect with reduced spontaneous activity, bradycardia, respiratory depression, and hypothermia. Death results from respiratory failure. At low doses CNS stimulation may occur, as manifested by hyperactivity to external stimuli such as handling, and considerably increased food consumption (Pfister and Vim, 1977).

Studies suggest that amitraz exerts endocrine disrupting activity. In dogs, following a topical application, amitraz has been shown to increase plasma glucose and decrease insulin release when dogs were dipped at twice the recommended concentration (Hsu and Schaffer, 1988).

Most of the time, poisoned animals survive and show complete recovery from all signs and symptoms in about 7–10 days, even when exposed to higher doses (Bonsall and Turnbull, 1983).

In chronic 2-year feeding trials, rats receiving 50 mg/kg/day in their diet or dogs receiving 0.25 mg/ kg/day of amitraz did not show any ill effects. Male and female rats receiving amitraz at 200 mg/kg/day for 10 weeks showed decreased fertility. Female mice treated with amitraz orally (50 mg/kg/day) for 5 days and then mated showed a slight increase in loss of fetuses and decrease in the number of living offspring. When male mice were given the same dose and same duration and then mated, the resulting embryos were significantly less likely to grow in the mother's uterus. Rabbits who received 25 mg/kg/day of amitraz from days 6 to 18 of pregnancy had fewer and smaller litters (Meister, 1994).

Studies in laboratory animals have shown that amitraz has no potential for mutagenic activity and does not cause damage to DNA (Hayes and Laws, 1991). Amitraz can cause tumors in female mice but not in male mice or male or female rats. Amitraz also has potential for teratogenic activity. In rats treated with 12 mg/kg/day of amitraz from days 8 to 20 of pregnancy, the offspring were heavier but had less bone development than the offspring of untreated rats (Hayes and Laws, 1991). EPA has established the teratogenic no observed effect level (NOEL) in rats at 12 mg/kg/day (Walker and Keith, 1992). The teratogenic NOEL of rabbits is 25 mg/kg/day. Amitraz and its metabolite 2,4-dimethylaniline have been shown to induce teratogenic effects in frog embryos (Osano *et al.*, 2002). In addition, amitraz has potential for endocrine disruption.

Most of the time, poisoning in animals (especially dogs and cats) with amitraz is acute. Diagnosis is based on history of exposure, clinical signs of toxicity associated with stimulation of $\alpha_2$-adrenoceptor, and residue analysis. Due to a long half-life, residue of amitraz and its major metabolites can be detected in the plasma of a poisoned animal using gas chromatography (GC) coupled with nitrogen–phosphorus detection (Ameno *et al.*, 1991) or high-performance thin-layer chromatographic (HPTLC) coupled with UV detection (Hugnet *et al.*, 1996).

## TREATMENT

Studies from animals suggest that the $\alpha_2$-adrenoceptor antagonists (yohimbine and atipamezole) can reverse amitraz-induced toxicity. In dogs, yohimbine has been found to be very effective. Bradycardia and hypotension respond to yohimbine administration (Hsu and Schaffer, 1988). Severely poisoned dogs with amitraz have been successfully treated with low doses (50 μg/kg, IM) of the potent $\alpha_2$-receptor antagonist atipamezole (Hugnet *et al.*, 1996). Doses of atipamezole can be repeated after 3–4 h, if necessary. Atipamezole can control all the clinical effects of amitraz within 20 min. In most cases, symptomatic and supportive therapies are of great value. Remove the tick collar or any other source of amitraz from pets. In the case of dermal exposure, bathing is helpful. For oral ingestion, induction of vomiting and gastric lavage is recommended. Administration of activated charcoal with a saline cathartic is also beneficial. Animals should be kept in a room

with warm temperature, as amitraz causes hypothermia. Continuous monitoring of cardiovascular, respiratory, and CNSs, and of glucose and insulin levels is advised. With good care and aggressive treatment, even severe cases can be recovered.

## CONCLUSIONS

Amitraz is widely used as an insecticide and acaricide in veterinary medicine. Dogs and cats are intoxicated due to accidental ingestion of amitraz-containing tick collars and other products. Major toxic signs are associated with $\alpha_2$-adrenergic receptor agonism, such as CNS depression, hypotension, bradycardia, and hypothermia. Increased blood glucose and decreased insulin secretion are characteristics of amitraz poisoning and are also due to $\alpha_2$-receptor stimulation. With timely administration of a $\alpha_2$-adrenoceptor blocker (yohimbine or atipamezole), and conventional therapeutic measures, even seriously intoxicated cases can recover.

## ACKNOWLEDGMENTS

I would like to thank Mrs. Debra A. Britton and Mrs. Denise M. Gupta for their assistance in preparation of this chapter.

# Metaldehyde

*Ramesh C. Gupta*

## INTRODUCTION

Metaldehyde is a cyclic polymer of acetaldehyde (Figure 47.1), which is found in the form of white or colorless crystalline solid or powder. It is used primarily as a molluscicide to control slugs and snails in a very wide range of gardens and croplands, worldwide. Secondary use of this pesticide is for the control of fish, leeches, and frogs. Metaldehyde is commonly used in many pesticide products along with other compounds, such as carbamates, organophosphates, and arsenates. In addition, metaldehyde is a main ingredient of solid fuel used for making camp fires (fire starter; camp fuel for portable stove) or in small heaters, and is also marketed as a color flame tablet for party goods (ENGELFIRE). Metaldehyde has been involved in suicide attempts. Oral ingestion of metaldehyde in the forms of molluscicide and fuel tablets is the most common route of exposure. In recent years, there has been a widespread concern about the increasing number of poisoning incidents that have occurred in pets, birds, and wild animals. Poisoning cases have also been encountered in large animals. This chapter describes the toxicity of metaldehyde and its metabolites in mammalian and avian species.

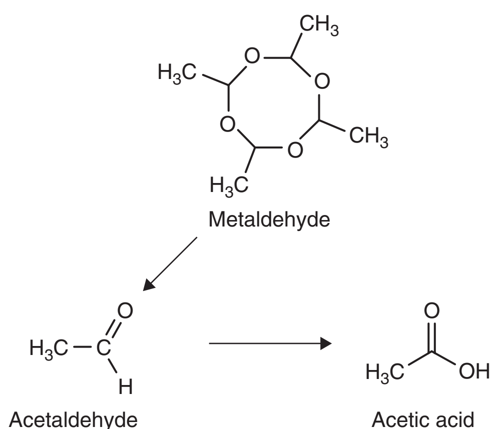

FIGURE 47.1 Chemical structures of metaldehyde and its two major metabolites (acetaldehyde and acetic acid).

## BACKGROUND

Metaldehyde is a molluscicide used in a variety of vegetables and crops in the field, gardens, and greenhouses. It is applied in the form of liquid, granules, sprays, dusts, or pelleted/grain bait to kill slugs, snails, and other garden pests. Usually, the commercial baits contain 4% or less metaldehyde as active ingredient. Some of the granule baits can have up to 5–10% metaldehyde. In Europe, the bait can have up to 50% metaldehyde. Baits formulated in pellets resemble dog food and are flavored with bran or molasses to attract snails. Unfortunately, the flavor attracts dogs and other pets as well. Acute poisoning is common in pets, birds, domestic, and wild animals. A very small amount of metaldehyde is required to cause poisoning or death. The major target organs for metaldehyde toxicity include central nervous system (CNS), liver, kidney, and lung. Animals that ingest metaldehyde may exhibit a variety of toxicological signs including vomiting, tachycardia, ataxia, tremors, seizures, and death (Dobler, 2003). Upon dermal contact, metaldehyde may cause irritation. Currently, there is an increase in the number of metaldehyde poisoning cases attributed to accidental/inadvertent or malicious use of this chemical in baits.

## TOXICOKINETICS

Metaldehyde and its metabolites are readily absorbed from the gastrointestinal (GI) tract. Metaldehyde can also be absorbed from the lungs and skin. Following oral ingestion, maximal concentrations in the circulation and tissues can be attained within 1–3 h. Metaldehyde secretes back into the GI tract because it gets trapped in enterohepatic circulation (Sax, 1984; Dreisbach, 1987; Knowles, 1991). Residues of metaldehyde have been detected in the brain, blood, and liver of mice (NLM, 1995; Puschner, 2001).

Metaldehyde undergoes hydrolysis reaction at acidic pH in the stomach forming acetaldehyde as a major degradation product. Acetaldehyde is then oxidized to acetic acid (Figure 47.1). Metaldehyde, but not acetaldehyde, was found in plasma and urine of dogs given a single oral dose of 600 mg/kg body weight (Booze and Oehme, 1986). Similar findings were reported in a human case (Moody and Inglis, 1992). Metaldehyde can be excreted in urine and feces. Urinary excretion is found to be less than 1% of the oral dose (600 mg/kg, p.o.) administered in dogs (Booze and Oehme, 1986). Its elimination half-life is reported to be 27 h (Olson, 1999).

## MECHANISM OF ACTION

Pesticidal action of metaldehyde in mollusks and snails is due to contact, making them torpid and increasing the secretion of mucus leading to fatal dehydration (RSC, 1987).

In mammalian and avian species, the toxicity of metaldehyde is characterized by CNS signs, metabolic acidosis, and respiratory alkalosis; and the exact mechanisms involved are yet to be elucidated. The proposed mechanism of action is that the acetaldehyde, which is formed from metaldehyde at low pH in the stomach, is responsible for the toxic effects observed with metaldehyde exposure (Knowles, 1991). Other toxic products are probably also formed. Metaldehyde and its metabolite acetaldehyde can cross the blood–brain barrier, as evidenced by their neurotoxic effects in animals (NLM, 1995). Acetaldehyde acts as a releasing factor for 5-hydroxytryptamine (5-HT) and norepinephrine. CNS signs of metaldehyde toxicosis may be due to decreased brain concentrations of γ-aminobutyric acid (GABA), norepinephrine, and 5-HT, and increased monoamine oxidase (MAO) activity (Dobler, 2003). Acetaldehyde competitively inhibits biogenic amine oxidation, which in turn decreases 5-hydroxyindoleacetic acid, a metabolite of 5-HT, by competitively inhibiting 5-HT oxidation. Acetaldehyde also increases MAO activity and decreases central 5-HT levels (Booze and Oehme, 1985). The old theory that the toxicity of metaldehyde is attributable to its metabolite acetaldehyde is questionable, because acetaldehyde was not present in the plasma and urine of dogs or serum of rats that were given metaldehyde (Shintani *et al.*, 1999; Puschner, 2001). Metaldehyde also affects electrolyte and acid–base balances, which can cause metabolic acidosis that is often associated with CNS depression and hyperpnea (Puschner, 2001).

## TOXICITY

Metaldehyde is toxic to all animals. Secondary poisoning is also not uncommon. It is highly toxic by inhalation, moderately toxic by ingestion, and slightly toxic by dermal absorption. Ingestion is the most common route of poisoning. WHO classifies metaldehyde as a moderately hazardous pesticide; and Environmental Protection Agency (EPA) classifies it as a slightly toxic chemical (Toxicity Class II or III). This chemical has a label of "Restricted Use Pesticide" because of its potential short- and long-term effects on wildlife.

The oral $LD_{50}$ of metaldehyde is 100 mg/kg body weight in dogs, 60 mg/kg in horses, 207 mg/kg in cats (Beasley, 1999; Plumlee, 2001), 227–690 mg/kg in rats, 200 mg/kg in mice, 175–700 mg/kg in guinea pigs, and 290–1250 mg/kg in rabbits (Knowles, 1991; NLM, 1995). The toxic dose of metaldehyde in dogs and cats is reported to be 45 mg/pound of body weight. $LC_{50}$ values of metaldehyde in rainbow trout and bluegill are 62 and 10 ppm, respectively.

Metaldehyde is primarily a neurotoxicant, as it produces CNS depression, convulsions, and violent muscular contractions in several mammalian species following acute exposure. Acute metaldehyde poisoning is often encountered in pets, especially dogs and cats. Onset of signs of metaldehyde toxicosis usually appear within 15 min to a few hours after ingestion. Clinical signs of maximal severity occur within 1–3 h of ingestion. In general, toxicity signs of mild metaldehyde poisoning include anxiety, hyperesthesia, foaming at the mouth, and muscle twitching. Signs of severe poisoning include hypotension and tachycardia, panting, nystagmus, mydriasis, dehydration, hyperthermia, respiratory depression, convulsion, continuous tonic seizures, coma, ataxia, respiratory failure, and death. Not every poisoned animal may show all these signs. In dogs, hemorrhagic gastroenteritis, hypersalivation, and vomiting are also seen. Clinical signs in cats are similar to those described for dogs, but nystagmus is more prevalent in cats (Beasley, 1999).

It is a common observation that exposed pets either die within a few hours from an early episode of acute toxicity or within a few days from liver, kidney, and respiratory failure. Symptoms of metaldehyde poisoning in domesticated and wild mammals include inability to stand,

blindness, change in respiratory rate, dehydration, excessive sweating and salivation, seizures and sudden death (Grant and Schuman, 1993).

In practical situations, chronic toxicity is very rare. Usually, dosages which are not toxic when given singly do not cause illness when repeated (Dreisbach, 1987; Knowles, 1991). In a 2-year chronic toxicity study (three-generation reproductive studies) in rats, changes in liver enzyme activity, and increased liver and ovary weight were found at dietary doses of about 12.5 mg/kg/day; 50% of female rats given this dose showed paralysis. At higher doses, metaldehyde is known to adversely affect reproduction and the survival rate of offspring (Sax, 1984). Pregnancy exacerbates the toxicity of metaldehyde.

In cattle, sheep, and horses, mild poisoning is evidenced by hypersalivation, ataxia, and hyperpnea. In severe poisoning, symptoms include convulsions, sweating, tachycardia, and muscle spasms. Death occurs within the first 48 h of accidental ingestion, and is attributable to respiratory failure (Von Burg and Stout, 1991). Pathological lesions can be found in liver, kidney, lungs, and GI tract.

Metaldehyde-related poisonings and deaths have been reported in avian species (Baker, 1967; Reece *et al.*, 1985; Andreasen, 1993). A minimal lethal dose of 500 mg/kg body weight for chickens and 300 mg/kg body weight for ducks has been determined. The clinical signs in avians include excitability, incoordination, tremors, muscle spasms, torticollis, diarrhea, and difficult or rapid breathing. Death of geese and ducks has been reported following accidental exposure. Metaldehyde is considered practically nontoxic to aquatic organisms.

From experimental studies, there is no evidence that metaldehyde is teratogenic (Verschuren *et al.*, 1975), mutagenic (Quinta and Martire, 1981), or carcinogenic (Verschuren *et al.*, 1975).

Diagnosis of metaldehyde poisoning can be established based on a history of exposure and clinical signs. Confirmation can be made by demonstrating metaldehyde/acetaldehyde in vomitus or GI tract content, blood, or urine. The odor of acetaldehyde in stomach content is suggestive of metaldehyde exposure. Although pathological findings are nonspecific, lesions can be found in liver, kidney, lungs, and GI tract.

## TREATMENT

There is no specific antidotal treatment for metaldehyde poisoning. So, treatment rests with supportive and symptomatic measures that usually consist of (1) removal of remaining metaldehyde from the GI tract, (2) prevention of absorption by activated charcoal, (3) control of seizures, (4) re-establishing ventilation and administer of oxygen, and (5) restoring fluid and electrolyte balance to correct acidosis. Administration of 2–5% sodium bicarbonate solution can reduce the conversion of metaldehyde to acetaldehyde.

In the case of dogs, if the patient is asymptomatic, immediately induce vomiting by syrup of ipecac (one teaspoon) or a mixture of hydrogen peroxide and water (one tablespoon), followed by gastric lavage using milk or water. The milk helps decrease the further absorption of the metaldehyde. Simple osmotic diuresis is helpful. Administration of activated charcoal (1–4 g/kg, p.o.) is found to be beneficial, as it prevents further absorption of metaldehyde from intestine. If necessary, charcoal treatment at half the original dose can be repeated at 6–8 h interval. Charcoal treatment has been found to reduce absorption of metaldehyde by more than 45% (Shintani *et al.*, 1999). Cathartics can also be used with activated charcoal to assist in removing the metaldehyde from the intestinal tract. Gastric lavage and cathartics are found to be effective treatment for up to 12–24 h after metaldehyde ingestion. Muscle twitch and spasms in dogs and cats can be controlled by methocarbamol (55–220 mg/kg, i.v.). Seizures can be treated by using diazepam (0.5–2 mg/kg, i.v.; repeat if necessary) or sodium phenobarbital (30 mg/kg, i.v.). Urinary acidosis can be corrected by the administration of sodium bicarbonate. In an experimental study conducted on mice, administration of diazepam (10 mg/kg, i.p.) or clonidine HCl (0.5 mg/kg, i.p.) decreased the toxicity of metaldehyde (100 mg/kg, p.o.). Diazepam at low dose (0.5 mg/kg body weight) was without any protective effect.

In the case of pigs, barbiturates can be used to anesthetize poisoned animals for a period of 6–12 h, so as to allow excretion of metaldehyde and its metabolites.

## CONCLUSIONS

Most of the time, metaldehyde poisoning is acute in nature and results from accidental or malicious activity. The poisoning is characterized by neurological signs, such as violent convulsions and seizures. Without timely and aggressive treatment, death ensues due to respiratory failure. Since no specific antidote is available, treatment relies upon supportive and symptomatic therapies.

*Michael J. Murphy*

## INTRODUCTION

The origin of oral anticoagulant therapy and anticoagulant rodenticides traces back to investigations of moldy sweet-clover poisoning in the 1920s. This disease of cattle in Wisconsin was characterized by high mortality and internal bleeding. Investigations revealed that the diseased cattle had been fed moldy sweet-clover hay.

An association between vitamin K and coagulopathies was made in the 1930s (Dam, 1935; Fieser *et al.*, 1939). Soon, thereafter Prof. Link reported the discovery of dicoumarol in the moldy hay (Last, 2002). Naturally occurring coumarin in sweet-clover hay is converted by fungi to dicoumarol. Dicoumarol was found to be the causative agent of the disease, so the elements needed for the disease were coumarin-containing plant material plus mold growth. Subsequently a range of molecules were synthesized. One named warfarin became the most popular (Duxbury and Poller, 2001). Warfarin takes its name, in part, from the Wisconsin Alumni Research Foundation. Warfarin and dicoumarol found application as both oral anticoagulants and as rodenticides. Sweet clover requires the action of molds to form dicoumarol, Giant fennel does not.

Giant fennel, *Ferula communis*, grows in Mediterranean countries. It has a naturally occurring anticoagulant effect. An association between the plant and anticoagulation was first reported in the 1950s (Costa, 1950a, b; Carta, 1951). It was further investigated in Italy (Mazzetti, 1957; Corticelli and Deiana, 1957; Corticelli *et al.*, 1957; Cannava, 1958) then Israel (Shlosberg and Egyed, 1983). The anticoagulant activity of the plant in Morocco has recently been reviewed (Lamnaouer, 1999).

Five coumarins and eleven daucane derivatives have been isolated from *F. communis* (Arnoldi *et al.*, 2004). Previously identified chemicals included allohedycaryol (Zhabinskii *et al.*, 1996), fercoperol (Miski *et al.*, 1986), and ferulenol.

The toxicity of ferulenol in rats, mice, and sheep has been reported. Ferulenol is a 4-hydroxycoumarin with the expected anticoagulation effects (Fraigui *et al.*, 2002). The single oral $LD_{50}$ of ferulenol in albino mice is 2100 (Fraigui *et al.*, 2002). This value is quite similar to oral $LD_{50}$ values of 1650 and 2000 for rats and mice, respectively using fessoukh, the resinous gum of *Ferula* (Fraigui *et al.*, 2001). This supported prior studies in rats (Aragno *et al.*, 1988; Tagliapietra *et al.*, 1989).

Anticoagulation activity of the plant in sheep was reported in 1985 (Shlosberg and Egyed, 1985). Subsequently, ferulenol has been measured in the serum of sheep experimentally dosed with 600 g of powdered plant material (Tligui and Ruth, 1994). Ferulenol was detected at 6 h after dosing and for about 12 h after cessation of dosing. The prothrombin time (PT) was elevated to 6 times normal about 70 h after the last dose and returned to normal by day 5 (Tligui and Ruth, 1994; Tligui *et al.*, 1994).

*Ferula* has also been examined for chemotherapy (Poli *et al.*, 2005), antimycobacterial (Appendino *et al.*, 2004; Mossa *et al.*, 2004), and microtubule effects (Bocca *et al.*, 2002) and testicular and epididymal changes in rams (Gil *et al.*, 2002) much like the warfarin and other oral anticoagulants now have. It is found in Morocco (Fraigui *et al.*, 2001), Israel (Shlosberg and Egyed, 1983), and Italy (Tagliapietra *et al.*, 1989).

The phrase oral anticoagulants normally refer to these chemicals when used therapeutically. The oral

*Veterinary Toxicology, Edited by Ramesh C. Gupta*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

anticoagulants are briefly discussed before the detailed discussion of the application of the dicoumarol progeny as anticoagulant rodenticides.

Warfarin and its congeners are still used as therapeutic agents. Oral anticoagulants available therapeutically in Europe include warfarin, phenprocoumaron, and nicoumalone – also called acenocoumarol (Shetty *et al.*, 1993). Oral anticoagulants are used therapeutically to reduce thromboembolic events. Warfarin examples include a reduction in catheter-related thrombosis (Guidry *et al.*, 1991; Magagnoli *et al.*, 2006), early venous thrombosis after operations (Calnan and Allenby, 1975; Pan *et al.*, 2005), including hip surgery, atrial fibrillation (Middlekauff *et al.*, 1995; Reiffel, 2000), and myocardial infarction (Asperger and Jursic, 1970). Dicoumarol is also used in the therapy of thrombotic occlusion of intracoronary stents (Alonso Martin *et al.*, 1997), prosthetic valves (Dalla, 1994), and other types of venous thromboses (Piovella *et al.*, 1995; Ferlito, 1996) or thrombophlebitis (Byrne, 1970; Creutzig, 1993).

Warfarin may also reduce the recurrence of malignant melanoma (Thornes *et al.*, 1994) or small cell lung cancer (Aisner *et al.*, 1992). This anti-metastatic activity may be associated with distribution of metastatic cells on thrombi (McNiel and Morgan, 1984; Smith *et al.*, 1988).

Low-dose warfarin therapy has been adopted by the US, Europe, and World health Organization (Duxbury and Poller, 2001). Internationalized Normalized Ratio (INR) is now used to measure anticoagulation (Duxbury and Poller, 2001).

Oral anticoagulants have been used for decades and a number of adverse events have been recognized. Most are related to drug interactions (Dayton and Perel, 1971). Although controversy exists as to whether acetaminophen induces an adverse effect on warfarinized patients in therapeutic doses (Toes *et al.*, 2005). The acetaminophen metabolite NAPQI (*N*-acetyl-para-benzoquinoneimine) seems to interfere with vitamin-K-dependent $\gamma$-carboxylase. Such interference may lead to potentiation of the anticoagulant effect of warfarin (Thijssen *et al.*, 2004). COX-2 inhibitors may interfere with control of warfarin anticoagulation in elderly patients (Savage, 2005) and rifampin may interfere with warfarin metabolism due to induction of P-450 activity (Strayhorn *et al.*, 1997; Finch *et al.*, 2002). Inconsistent anticoagulation has been recognized in generic versus prescription warfarin (Burns, 1999) and a single case of hemothorax with eosinophilia has been reported in a warfarin overdose (Nasilowski and Krenke, 2002).

Complementary or alternative medical therapies may also interfere with warfarin metabolism (Tumova, 2000; Wood *et al.*, 2003). For example, Passionflower, hydroalcoholic extracts, juniper, and verbena contain vitamin $K_1$ so they can lessen the anticoagulation effect of warfarin therapy (Argento *et al.*, 2000). On the other hand, genoderma, japonicum, papaw, *Salvia miltiorrhiza*, ginseng, devil's claw, garlic, quinine, ginkgo, ginger, red clover, and horse chestnut may reinforce the anticoagulant effect of warfarin by various mechanisms (Argento *et al.*, 2000).

A "coumarin-induced hepatitis" has been reported a number of times in warfarinized patients (Rehnqvist, 1978; Bint and Burtt, 1980; Tanaka *et al.*, 1985; Hohler *et al.*, 1994; Matsukawa *et al.*, 1994; Ehrenforth *et al.*, 1999; Bamanikar and Hiremath, 2002; Biagini *et al.*, 2006). Liver damage has also been reported in a brushtail possum (*Trichosurus vulpecula*) dosed with the anticoagulant rodenticide pindone (Jolly *et al.*, 1994). Pindone has also been associated with an increased frequency of sex chromosome loss in *Drosophila melanogaster* (Santoro *et al.*, 1993). The remainder of the chapter is devoted to the application of the chemical progeny of dicoumarol to pest control.

# BACKGROUND

## Anticoagulant rodenticides

In the 1940s, a small British pharmaceutical company suggested that dicoumarol might have rodenticidal properties. Trials carried out by Armour and Barnett (1950) confirmed the idea and started the era of anticoagulant rodenticides. Warfarin was the first anticoagulant rodenticide introduced into the market shortly after World War II and became widely used in many countries. Other anticoagulant compounds with potency similar to that of warfarin were also synthesized. These early anticoagulant rodenticides have often been called "first-generation anticoagulant rodenticides." These first-generation compounds generally have moderate toxicity, with acute $LD_{50}$ values ranging from 10 to 50 mg/kg body wt. (Table 48.1). The first-generation compounds often needed continuous bait exposure for rodent control.

Many rodent species developed a resistance to warfarin (Jackson *et al.*, 1975) presumably due to continued exposure and widespread use. Consequently, new chemical structures were synthesized and used as anticoagulant rodenticides. These newer compounds are generally more toxic than warfarin with acute $LD_{50}$s of 0.2–3.9 mg/kg body wt. For example, a bait concentration of only 50 ppm of brodifacoum is adequate to give control in a single feeding for most rodents and non-commensal species (Matolesy *et al.*, 1988). These newer compounds were called "second-generation anticoagulant rodenticides" and are often now referred to as "superwarfarins" in the contemporary medical literature (Chong *et al.*, 1986; Greeff *et al.*, 1987; Swigar *et al.*, 1990; Wallace *et al.*, 1990; Routh *et al.*, 1991; Wilton, 1991; Exner *et al.*, 1992; Rauch *et al.*, 1994; Hui *et al.*, 1996; Tecimer and Yam, 1997; Gallo, 1998; Chua and Friedenberg, 1998; Pavlu *et al.*, 2005; Sharma and Bentley, 2005; Dolin *et al.*, 2006).

TABLE 48.1 The oral $LD_{50}$ values (mg/kg body wt.) of some anticoagulant rodenticides

| Animals | Bromadiolone | Brodifacoum | Difenacoum |
|---|---|---|---|
| Rat (acute) | 0.65 | 0.27 | 1.8 |
| Rat (chronic) | (0.06–0.14) x 5 | (0.05–0.08) x 5 | 0.15 x 5 |
| Mouse | 0.99 | 0.4 | 0.8 |
| Rabbit | 1.0 | 0.2 | 2.0 |
| Pig | 3.0 | 10.0 | 80.0 |
| Dog | 10.0 | 3.5 | 50.0 |
| Cat | 25.0 | 25.0 | 100.0 |
| Chicken | 5.0 | 10.0–20.0 | 50.0 |
| Guinea pig | 2.8 | – | – |
| Opossum | – | 0.17 | – |
| Sheep | – | 10.0 | 100.0 |

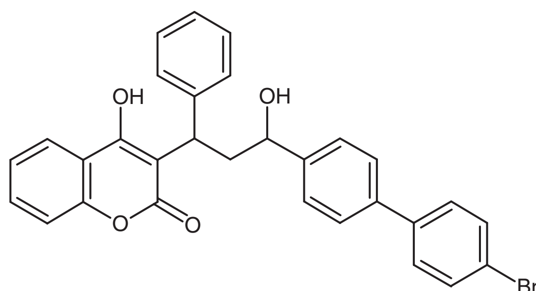
Anticoagulant rodenticides are also categorized by chemical structure. The chemical structure of the currently marketed products fits in one of two chemical classes:

1 *Hydroxycoumarins*: This group of compounds have a 4-hydroxycoumarin ring with different side-chain substituents at the 3-position. Commonly used anticoagulant rodenticides in this group are bromadiolone, brodifacoum, coumafuryl, coumatetralyl, difenacoum, and warfarin.
2 *Indanediones:* This group of compounds has a 1,3 indanedione structure with different side-chain substituents at the 2-position. The most common anticoagulant rodenticides in this group are chlorophacinone and diphacinone. Examples of each of these compounds are briefly summarized.

A few representative chemicals are described below. A number of other chemicals have now been developed.

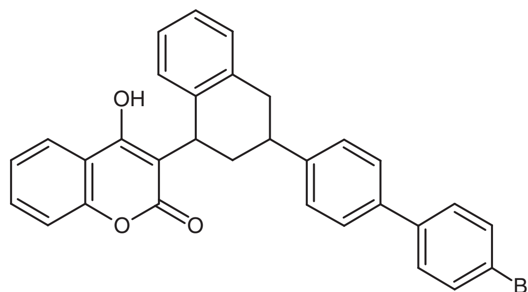
### 1 Hydroxycoumarins

*A Bromadiolone*



Bromadiolone {3-(3-(4′-bromobiphenyl-4-yl)-3-hydroxy-1-phenyl propyl)-4-hydroxycoumarin} was synthesized and marketed by the French company Lipha SA during the mid-1970s. It is used widely for control of commensal and field rodents in many countries. Technical grade bromadiolone is 97% pure. It is a yellowish powder and stable up to 2000°C (Chalermchaikit, 1992). It is very soluble in dimethylformamide (730 g/l), but less soluble in ethyl acetate (25 g/l), and ethanol (8.2 g/l), and sparingly soluble in water (0.019 g/l). Bromadiolone is considered more palatable to rodents than most other anticoagulants. Its concentration in baits is usually 50 ppm (Chalermchaikit *et al.*, 1993). Although bromadiolone is considered a "second-generation anticoagulant rodenticide", some resistance problems have been reported with *Rattus norvegicus* and *Mus musculus* in the UK and Denmark (Rowe *et al.*, 1981).

*B Brodifacoum*



Brodifacoum {3-(3-(4′-bromobiphenyl-4-yl)-1,2,3,4-tetrahydro naphth-1-yl)-4-hydroxycoumarin} is one of the newer and more potent second-generation anticoagulant rodenticides. It was introduced in 1977 by Sorex Ltd. of London, then developed by the Imperial Chemicals Incorporated (ICI) Plant Protection Division (Chalermchaikit *et al.*, 1993).

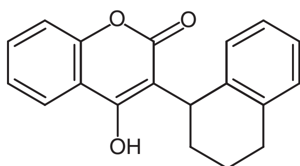
Pure brodifacoum is off-white to fawn colored powder with a solubility of 6–20 g/l in acetone, 3 g/l in chloroform, 0.6–6 g/l in benzene, and less than 10 mg/l water. It is very stable in the environment with no loss after 30 days exposure to direct sunlight (Chalermchaikit *et al.*, 1993).

Brodifacoum has been marketed in several countries for the control of a wide range of rodent pest species. It is available as a 0.005% pellet for rat and house mouse control, a smaller 0.001% pellet for field rodent control, and as 29-g wax blocks for sewer rat control. It is the only anticoagulant rodenticide found to produce 100% mortality in most rodent species after only a 24-h dose

(Chalermchaikit *et al.*, 1993). Brodifacoum was effective against warfarin-resistant rats and mice in 1984, but the possibility of resistance has been raised (Lund, 1984).

There is variation in the susceptibility of species to brodifacoum. The average pig, sheep, or chicken must consume considerable quantities of prepared bait to be endangered. However, dogs are susceptible and are commonly exposed to potentially toxic quantities of brodifacoum (Chalermchaikit *et al.*, 1993).

*C Coumatetralyl*

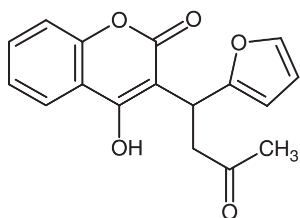


Coumatetralyl {3-(alpha-tetralyl)-4-hydroxycoumarin} was introduced by Bayer AG with the trademark name of Racumin. It has been used for commensal control in many countries. It is formulated as a dry bait (0.0375%), a liquid bait of its sodium-salt, and a 0.75% tracking dust (Chalermchaikit *et al.*, 1993).

Pure coumatetralyl is a colorless powder which is stable at temperatures below 150ºC. Its solubility is 20–50 g/l in propan-2-ol, 50–100 g/l in methylene dichloride, and 4 mg/l in water. The acute and chronic $LD_{50}$'s to *R. norvegicus* are 16.5 and 0.3 mg/kg for five consecutive doses, respectively. Chickens are quite resistant to coumatetralyl, with a chronic $LD_{50}$ of 50 mg/kg for eight consecutive doses. Signs did not appear in fish until the concentration of coumatetralyl reached 1000 mg/l in water (Chalermchaikit *et al.*, 1993).

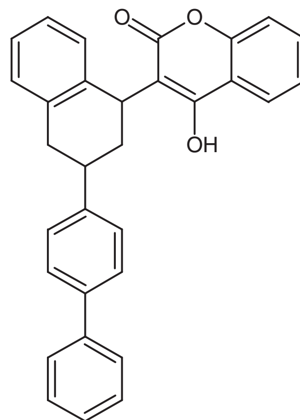
In spite of its low toxicity, it is reported to be a little more effective than warfarin against *R. norvegicus*, apparently due to a higher palatability. Coumatetralyl was introduced after the detection of warfarin-resistant rat populations and showed considerable success for a number of years, but resistant pests have been reported in the UK and Denmark (Rowe and Redfern, 1968).

*D Coumafuryl*



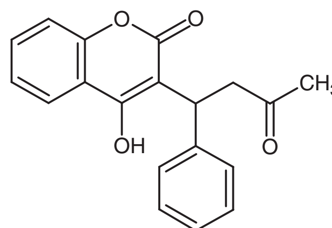
Coumafuryl {3-(alpha-acetonylfurfuryl)-4-hydroxycoumarin} is a German anticoagulant, introduced in 1952, and is used at 0.025–0.05% in baits. Its toxicity is considered equal to warfarin for *R. norvegicus* but slightly less efficient against *M. musculus*. The chronic $LD_{50}$ in *R. norvegicus* is 1.4 mg/kg for five repeated doses. Cats and dogs seem to be almost as susceptible as rats, with dogs being killed by 2 mg/kg for five repeated doses and cats by 10 mg/kg for four repeated doses (Chalermchaikit *et al.*, 1993).

*E Difenacoum*



Difenacoum {3-(3-*p*-diphenyl-1,2,3,4-hydronaphth-1-yl)-4-hydroxycoumarin} was synthesized in the UK and marketed in 1975 by Sorex Ltd. under the trademark "Neosorexa", and by ICI Plant Protection Division under the trademark "Ratak" as a 0.005% pelleted bait, and as a wax block. Pure difenacoum is an off-white powder with a solubility of greater than 50 g/l in acetone, 600 mg/l in benzene, and less than 10 mg/l in water. It is more toxic than warfarin, but less palatable. Difenacoum is still effective against many populations of warfarin-resistant rats (Desideri *et al.*, 1979), but resistance may be developing in the UK (Greaves *et al.*, 1982).

*F Warfarin*



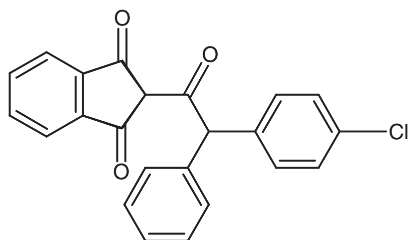
Warfarin {3-(a-acetonylbenzyl)-4-hydroxycoumarin} was the first anticoagulant rodenticide introduced shortly after

World War II after development by the Wisconsin Alumni Research Foundation. Warfarin is still used widely, especially for the control of *R. norvegicus* in areas where resistance has not developed. In its racemic form, warfarin is colorless and crystalline, insoluble in water, but readily soluble in acetone, dioxane, and moderately soluble in alcohols. Warfarin is formulated as dry bait (0.005–0.05%) as well as a liquid bait, based on the sodium salt, and a tracking dust (0.5–1.0%). It is generally applied as the S-isomer, which has a toxicity 10 times greater than the R-isomer. The acute and chronic $LD_{50}$s for *R. norvegicus* are around 10–12 and 0.75 mg/kg for five repeated doses, respectively (Colvin and Wang, 1974).

Warfarin is sometimes combined with an antibacterial agent, sulfaquinoxaline, in order to reduce the bacterial production of vitamin K in the rat intestine, but the effectiveness of this combination has not been proven. Warfarin is considered one of the safest anticoagulants, as far as domestic and other non-target animals are concerned. Serious resistance problems have been reported in Europe. It has recently been evaluated against sewer rats in London (Channon *et al.*, 2000).

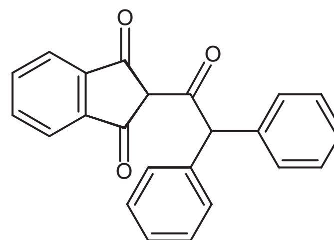
### 2 Indanedione group

*A Chlorophacinone*



Chlorophacinone {2-(alpha-4-chlorophenyl-a-phenylacetyl)-1,3-indandione} was first introduced during the mid-1960s by Lipha S.A. of France, at concentrations of 0.05% in baits and 0.2% in tracking dust. Pure chlorophacinone is a yellow crystalline solid which is very soluble in acetone, ethanol, ethyl acetate, but is sparingly soluble in water. It is quite stable and resistance to weathering. Chlorophacinone does not induce "bait-shyness" and is compatible with cereals, fruits, roots, and other potential bait substances. Its acute $LD_{50}$s in *R. norvegicus* is about 20.5 mg/kg which is less toxic than warfarin, but it has a stronger initial effect on rats and mice. For control of house mice populations, a prolonged feeding period is needed. Chlorophacinone is not effective against warfarin-resistant rodents (Chalermchaikit *et al.*, 1993).

*B Diphacinone*



Diphacinone (2-diphenylacetyl-1,3-indandione) is an old anticoagulant rodenticide, introduced by Vesicol Chemical Corp. and the Upjohn Co. It has been produced and used primarily in the US as a 0.005% dry or liquid bait. Pure diphacinone is a yellow powder which is very soluble in chloroform (204 g/kg), toluene (73 g/kg), xylene (50 g/kg), and acetone (29 g/kg), but sparingly soluble in water (0.30 g/l). It will decompose in water due to sunlight. The acute $LD_{50}$s in *R. norvegicus* are 22.7 mg/kg in females and 43.3 mg/kg in males. It is more toxic than warfarin to rats, mice, and dogs, but its palatability is somewhat lower. Diphacinone is not effective against warfarin-resistant rodents (Chalermchaikit *et al.*, 1993).

The anticoagulant rodenticides are marketed to have efficacy against a number of target pest species. These species are listed below by chemical compounds.

## Target species

### Brodifacoum

One day of feeding on a 0.005% brodifacoum or difenacoum bait is successful in controlling the lesser bandicoot rat (*Bandicota bengalensis*) in Burma (Brooks *et al.*, 1980). Within 3 days, a 0.005% brodifacoum bait gave complete control of golden hamsters (*Mesocricetus auratus*) resistant to 0.005% warfarin and difenacoum (Bradfield and Gill, 1984). A 20-ppm brodifacoum bait gave virtually complete control of Norway rats (*R. norvegicus*) in 21–73 days after other treatments had failed (Greaves *et al.*, 1982). At a 0.005% bait concentration brodifacoum was more effective at 8 days in controlling *Meriones shawi* than warfarin at 0.025%, coumatetralyl at 0.0375%, difenacoum at 0.005%, and bromadiolone at 0.005% (Gill and Redfern, 1983). Brodifacoum's efficacy has also been shown for *Tatera indica* (Rehman and Ahmad, 1983), *T. indica*, *Nesokia indica*, *B. bengalensis* (Greaves and Rehman, 1977), field mice *Mus booduga* Gray (Balasubramanyam *et al.*, 1984) *Rattus rattus* and *B. bengalensis* (Deobhankar, 1985) eight rodent species (Lund, 1981, 1988), the Egyptian spiny mouse (*Acomys cahirinus*) (Mahmoud and Redfern, 1981), non-resistent (Mosterd and Thijssen, 1991), and warfarin-resistant rats (Rennison and Dubock, 1978). A number of early studies

were conducted under the designation WBA 8119 (Rowe and Bradfield, 1976; Rowe *et al.*, 1978). A number of different rodenticides have been tested for efficacy against rodents in cucumber (*Cucumis sativus*) plantings (Sabhlok *et al.*, 1997).

### *Bromadiolone*

Bromadiolone has been effective against warfarin-resistant rats and mice (Redfern and Gill, 1980). It is effective against the Norway rat (*R. norvegicus*) (Richards, 1981; Kamil, 1987). Bromadiolone residues have been examined in tissues of *Arvicola terreteris* (Giraudoux *et al.*, 2006) and coypu (*Myocastor coypus*) (Jeantet *et al.*, 1991) after field use. Its effects on the breeding performance of house mice have also been investigated (Twigg and Kay, 1995).

### *Chlorophacinone*

The efficacy of chlorophacinone against mice, voles, and squirrels has been established. At a 25-ppm bait concentration, chlorophacinone is more effective than coumachlor in controlling common mice (*M. musculus*) in Egypt (Mesban *et al.*, 2003). It can control common voles (*Microtus arvalis*) (Nikodemusz *et al.*, 1981), palm squirrels (*Funambulus pennanti*) (Mathur and Prakash, 1980), and house mice (*M. musculus*) (Lund, 1971).

### *Coumafuryl*

Coumafuryl is more effective on *R. rattus*, *R. norvegicus*, and *B. bengalensis* than fumarin and warfarin when used in liquid form (Renapurkar, 1982). It was effective in controlling the cotton rat (*Sigmodon hispidus*) at concentrations used to control *R. rattus* and *R. norvegicus* (Gill and Redfern, 1980), and *Mastomys natalensis* (Gill and Redfern, 1979).

### *Coumatetralyl*

Median survival time was 4.7 and 11.2 days in *B. bengalensis* and *R. rattus* exposed to 0.0375% coumatetralyl bait (Chopra and Parshad, 1985).

### *Diphacinone*

Diphacinone has been shown to control rats (Elias and Johns, 1981), vampire bats (Burns and Bullard, 1979, 1980; Thornton, 1980), *B. bengalensis* (Brooks *et al.*, 1980), and coyotes (Szuber and Diechtiar, 1968; Sterner, 1979).

### *Difenacoum*

Fifty percent of male mice exposed to 0.5 mg difenacoum/kg body wt. died within 9 days, whereas no female mice died (Winn *et al.*, 1989). Norway rats (*R. norvegicus*) fed 25 ppm difenacoum bait for 5, 10, or 20 days had whole carcass residues of 0.52–0.74 mg/kg body wt. with the higher amount being present after the longer feeding period (Rennison and Hadler, 1975; Redfern and Gill, 1980; Atterby *et al.*, 2005). A symptom-dependent taste aversion of the brown rat (*R. norvegicus*) has been reported because the taste aversion is only present when signs are present in the animal (Smith *et al.*, 1994).

### *Flocoumafen*

Flocoumafen has been demonstrated to control *R. rattus*, *B. bengalensis* (Parshad and Chopra, 1986), *R. norvegicus* (Buckle, 1986), and the house mouse *(M. musculus)* (Rowe *et al.*, 1985a). Flocoumafen gave a quicker and equally effective kill of 68 mice *(M. musculus*) exposed to a 0.005% oatmeal bait when compared to difenacoum, bromadiolone, and brodifacoum at the same bait concentrations (Rowe *et al.*, 1985a). A non-biliary intestinal elimination of flocoumafen has been reported in rats (Huckle *et al.*, 1989) and metabolic and toxicological studies have been reported (Veenstra *et al.*, 1991). Accumulation of flocoumafen in rats after repeated exposure has been examined (Huckle *et al.*, 1988).

### *Flupropadine*

Flupropadine is nearly as effective as calciferol/warfarin in control of the house mouse (*M. musculus*) (Rowe *et al.*, 1985a).

### *Warfarin*

The efficacy of warfarin has been evaluated against squirrels (Chambers and Chambers, 1983) and a host of other species.

## Non-target species

Unfortunately non-target species may also be exposed to anticoagulant rodenticides. Anticoagulant rodenticides are a potential hazard to all species of mammals and birds. The environmental, avian, and wildlife species so exposed are summarized briefly before the discussion of non-target exposure in humans and domestic animals below.

### *Environmental*

Anticoagulant rodenticides may be detected in water, soil, and invertebrates. A method of detecting warfarin in water has recently been reported (Badia and Diaz-Garcia, 1999), perhaps since anticoagulant rodenticides are used in rice paddies (Baskaran *et al.*, 1995) and accidental discharges of brodifacoum bait may occur in fresh water or a marine environment (Primus *et al.*, 2005). The toxicity of anticoagulant rodenticides in soil may be related to the portion not bound to humic acid (Andre *et al.*, 2005). Testing for the halogenated biphenyl side chain has been suggested as a way to determine soil exposure to rodenticides (Townsend *et al.*, 1995).

Diphacinone has been detected in snails and slugs in Hawaii. It ranged from 0.8 to 2.5 ppm in *Oxychilus* sp. snails, from 1.3 to 4.0 in *Deroceras laeve* slugs, and up to 1.8 ppm in *Limax maximus* slugs (Primus *et al.*, 2006).

### Wildlife

Anticoagulant rodenticides have been detected in polecats and mink in the wild. Recently, difenacoum and bromadiolone were detected in 35% of male (13 of 37) and 38% of female (5 of 13) polecats (*Mustela putorius*) collected in England and Wales in areas where the baits had been used (Shore *et al.*, 2003). Spatial and temporal residues in polecats in Britain have also been reported (Shore *et al.*, 2003). A previous study found difenacoum in 7 of 24 livers (Shore *et al.*, 1996). In France, populations of the free-ranging European mink (*Mustela lutreola*) have declined. Investigators found bromadiolone and chlorophacinone residues in the livers of four species of free-ranging mink and raised the question of the risk to European mink from anticoagulant rodenticides (Fournier-Chambrillon *et al.*, 2004). See also the risks of brodifacoum in non-target birds and animals (Eason *et al.*, 2002). Secondary poisoning of fox after broadcast of anticoagulant rodenticides for voles has been proposed (Raoul *et al.*, 2003). Bromadiolone toxicosis of coypu has also been reported (Morin *et al.*, 1990).

### Avian

Anticoagulant rodenticide toxicosis of birds has been reported throughout the United States, and in Australia (Reece *et al.*, 1985). Brodifacoum and difenacoum residues have been detected in a number of non-target avian species. Offspring of turkey vultures (*Cathartes aura*) died after being fed brodifacoum-poisoned mice in a zoo setting. Similar residues have been detected in other carnivorous birds including *Dacelo novae-guinae* and *Tockus deckeni*.

Ten percent of barn owls collected in England had detectable residues of difenacoum or brodifacoum in their liver. Liver concentrations of difenacoum and brodifacoum ranged from 5 to 106 ng/g and 19 to 515 ng/g, respectively. Mice were fed difenacoum and brodifacoum baits and died in 2–11 days. Poisoned mice were fed to barn owls for 1, 3, or 6 days. All six owls fed difenacoum mice survived and coagulation times returned to normal in 5–23 days. Four of six owls fed brodifacoum-dosed mice died 6–17 days after feeding. Dead owls had 630–1250 ng/g brodifacoum in their livers (Newton *et al.*, 1990). A white-winged wood duck has been treated for brodifacoum toxicity (James *et al.*, 1998) and secondary poisoning of stone martens (*Martes foina*) fed bromadiolone poisoned mice (Lund and Rasmussen, 1986) has been suspected.

Brodifacoum has also been implicated in poisoning of non-target wildlife in 80% of 55 animals investigated in the New York area. Diphacinone, bromadiolone, chlorophacinone, and coumatetralyl were also implicated. Exposure of raptors including great-horned owls (*Bubo virginianus*) and red-tailed hawks (*Buteo jamaicensis*) constituted half the cases, with gray squirrels (*Scirurus carolinensis*), raccoons (*Procyon lotor*), and white-tailed deer (*Odocoileus virginianus*) constituting the others (Stone *et al.*, 1999).

Broadcast diphacinone has also been implicated in avian toxicoses. Poouli is an endangered avian species in Hawaii. For example, a 3% and an 8% probability of mortality have been determined for adult and juvenile Poouli after a 5-day exposure to broadcast diphacinone. Diphacinone residues in snails apparently increase the risk of mortality in juvenile birds (Johnston *et al.*, 2005).

Diphacinone, dicoumarol, and pival have all been shown to increase the PT in chicks (Charles *et al.*, 1966). Bromadiolone was detected both in fox (*Vulpes vulpes*) and buzzards (*Buteo buteo*) in France (Berny *et al.*, 1997).

Chlorophacinone has also been examined. A "no observed effect" concentration of chlorophacinone in feed is 1 mg chlorophacinone/kg feed in Japanese quail (*Coturnix japonica*) (Riedel *et al.*, 1990). Emaciated California quail (*Callopepla californica*) were found to have impacted crops due to parafinized chlorophacinone pellets attributed to the paraffin, since PT were normal (Blus *et al.*, 1985). Chlorophacinone has also been studied in captive kestrels (Radvanyi *et al.*, 1988). A 100% mortality occurred in 1-week-old chicks fed coumestral in wood–straw mats (Munger *et al.*, 1993).

## Mechanism of action

The biochemical mechanism, metabolism, and kinetics of the anticoagulant rodenticides are summarized. The mechanism of action of all anticoagulant rodenticides is similar to that of warfarin, i.e. inhibition of vitamin $K_1$ epoxide reductase (Park *et al.*, 1979; Leck and Park, 1981; Breckenridge *et al.*, 1985). In the coagulation cascade, the clotting factors II, VII, IX, and X must bind calcium ions to be active in clot formation. The $Ca^{2+}$-binding ability requires converting glutamyl residues on these clotting factors to γ-carboxyl glutamyl residues by the process of carboxylation. This carboxylation uses vitamin $K_1$ hydroquinone as a cofactor. This vitamin-K-dependent carboxylase reaction converts vitamin $K_1$ hydroquinone to its epoxide form, vitamin $K_1$ 2,3-epoxide. In the normal cycle, vitamin $K_1$ 2,3-epoxide is reduced to the original vitamin $K_1$ (phylloquinone) by enzyme epoxide reductase, and is thus recycled (Figure 48.1). Anticoagulant rodenticides produce their effect by interfering with the enzyme vitamin $K_1$ epoxide reductase, resulting in the depletion of vitamin $K_1$ and subsequently impairing the synthesis of normal clotting factors II, VII, IX, and X (Craciun *et al.*, 1997, 1998). Clinical coagulopathy soon follows the depletion of

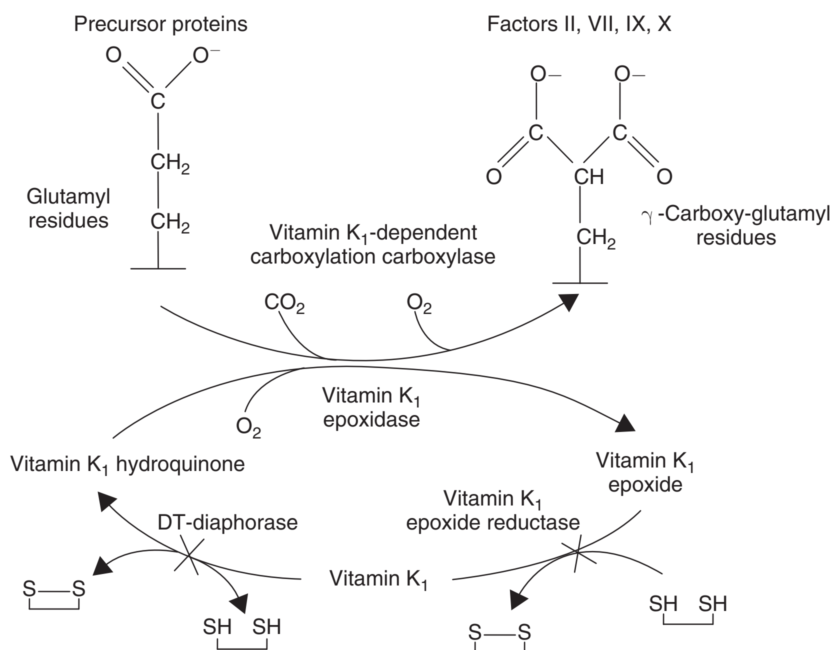


**FIGURE 48.1** Liver metabolism of vitamin K. The dithiol-dependent vitamin $K_1$ epoxide reduction and vitamin $K_1$ (phylloquinone) reduction are the metabolic steps inhibited by anticoagulant rodenticides.

vitamin $K_1$ in the liver. Since these clotting factors in the dog have plasma half-lives of 41, 6.2, 13.9, and 16.5 h, respectively, a lag time of 3 to 5 days is commonly observed between ingestion of a bait and the onset of clinical signs (Jackson and Suttie, 1977; Suttie, 1986; Murphy and Gerken, 1989). The interrelationship of vitamin K, prothrombin, γ-carboxyglutamic acid are reviewed in Stenflo (1978). The interaction of warfarin and vitamin K are reviewed in Suttie (1990).

### *Biochemistry*

Microsomal vitamin-K-dependent carboxylase, vitamin K epoxidase, vitamin $K_1$ epoxide reductase, and cytosolic vitamin K reductase (DT-diaphorase) are involved in vitamin K reduction (Hildebrandt and Suttie, 1982). The physiologically important site of action of the anticoagulant rodenticides is vitamin $K_1$ epoxide reductase (Hildebrandt and Suttie, 1982). Anticoagulant rodenticides act by inhibiting vitamin $K_1$-2,3 epoxide reductase and consequently the synthesis of clotting factors II, VII, IX, and X. S-warfarin and difenacoum are more potent in complete inhibition of clotting factor synthesis than racemic warfarin, R-warfarin, or brodifacoum (Breckenridge *et al.*, 1985).

The greater potency and duration of action of the long acting or "superwarfarins" has been attributed to (1) a greater affinity for vitamin $K_1$-2,3-epoxide reductase, (2) ability to inhibit the vitamin $K_1$ epoxide cycle at more than one point, (3) hepatic accumulation, and (4) unusually long-half-lives due to lipid solubility and enterohepatic circulation (Watt *et al.*, 2005).

As it turns out, rat liver has two pathways for vitamin K reduction. One is responsible for the therapeutic effect of vitamin $K_1$ therapy. This pathway is DT-diaphorase (EC.1.6.99.2) and a microsomal dehydrogenase that has 3.6-fold higher activity with nicotinamide adenine dinucleotide hydrogen (NADH) than with nicotinamide adenine dinucleotide phosphate hydrogen (NADPH). It is not a cytochrome P-450 or cytochrome-b5 reductase (Wallin, 1986) Although, dicumerol, warfarin and diphenadione inhibit NAD(P)H in rat liver *in vitro*, only dicumerol inhibited the enzyme in rats dosed *in vivo* (Schor *et al.*, 1983).

Pathway I is inactive in warfarin and difenacoum intoxicated rats. Vitamin $K_1$ epoxide reductase was also inactive, so this may be part of Pathway I *in vivo*. Pathway II mediates the therapeutic effect of vitamin $K_1$ and resulting carboxylation *in vitro* (Wallin, 1986).

Vitamin K and vitamin $K_1$ epoxide can be measured in serum (Bjornsson *et al.*, 1978, 1979; Donnahey *et al.*, 1979) and tissue. A number of vitamin K detection methods have been reported (Williams *et al.*, 1972; Haroon *et al.*, 1980, 1986, 1987; Haroon and Hauschka, 1983; Hart *et al.*, 1984; including detection in human plasma (Langenberg and Tjaden, 1984) and serum (Lefevere *et al.*, 1979) using high-pressure liquid chromatography (HPLC) with electrochemical detection (Takani and Suttie, 1983) or fluorimetric detection in liver (Usui *et al.*, 1989). The mode of action of vitamin K has been reviewed (Olson, 1966).

Because anticoagulant rodenticides inhibit the vitamin $K_1$ reductase reaction (Pelz *et al.*, 2005) vitamin $K_1$ epoxide is elevated and vitamin $K_1$ is reduced. For example, diphenadione (Mount and Kass, 1989) and warfarin-exposed dogs (Carlisle and Blaschke, 1981) have elevated vitamin $K_1$ epoxide after subcutaneous vitamin $K_1$ administration.

Also, vitamin $K_1$ concentrations are low to non-detectable in rats 24 h after exposure to difenacoum (Winn *et al.*, 1987). Measurement of the epoxide in serum has been proposed as a method to detect surreptitious exposure (Bechtold and Jahnchen, 1979; Bechtold *et al.*, 1983). The disposition of vitamin K in anticoagulant rodenticide poisoning was examined some years ago (Park *et al.*, 1984).

### *Resistance*

Resistance to anticoagulant rodenticides is largely transmitted as an autosomal dominant trait. Initial investigators postulated that a genetic mutation in the resistant rodents produced an enzyme epoxide reductase with a reduced binding affinity for warfarin and similar anticoagulants that resulted in resistance to warfarin (Bell and Caldwell, 1973; Zimmerman and Matschiner, 1974; Hadler and Shadbolt, 1975; Misenheimer *et al.*, 1994). This theory seems to have been born out.

Eight different mutations in the vitamin K reductase reaction have been identified in laboratory strains of brown rats and house mice, and in wild caught brown rats. Five mutations are of only two amino acids. Resistance to warfarin is largely influenced by mutations at Tyr139 (Pelz *et al.*, 2005). Previously the genomic assignment of the warfarin-resistant locus (Kohn and Pelz, 1999) and a gene-anchored map of the rat warfarin-resistant locus (Kohn and Pelz, 2000) were reported. These followed on reports of the biochemical basis of warfarin and bromadiolone resistence in house mice (Misenheimer *et al.*, 1994). However, warfarin-resistant rats are not resistant to coumatetralyl, so more than on mechanism of resistence may be found (Bell *et al.*, 1976).

Feeding of difenacoum and menadione (vitamin $K_3$) for 4 days is currently used as a test to determine the degree of resistance of laboratory Norway rats (*R. norvegicus*) and wild rats to difenacoum (Gill *et al.*, 1993). Chemical differences of the side-chains at the 3-position of the second-generation 4-hydroxycoumarins may provide a point of attachment to a lipophilic site on the epoxide reductase enzyme, where warfarin and other first-generation rodenticides do not bind strongly (Hadler and Shadbolt, 1975). This increased binding increases their toxicity and may reduce the development of resistance in rodents.

An absolute requirement for vitamin $K_1$ in Danish Norway rats (*R. norvegicus*) (Markussen *et al.*, 2003) and others resistant to warfarin remains as another theory (Trivedi *et al.*, 1988).

### *Antioxidant*

The anticoagulant rodenticides and oral anticoagulants are also of interest in cancer research. In part, because catalyzing obligatory two-electron reductions of quinones to hydroquinones, NAD(P)H: quinone reductase (QR1) protects cells against the deleterious effects of redox cycling of quinones and their ability to deplete glutathione and produce neoplasia (Dinkova-Kostova and Talalay *et al.*, 2000). DT-diaphorase and coenzyme Q appear to have antioxidant and prooxidant functions in quinone metabolism (Cadenas, 1995; Beyer, 1994).

### *Metabolism*

Warfarin is metabolized by CYP 2C9 and 2C19 in humans (Goldstein, 2001; Brandon *et al.*, 2005). The CYP 2C9 enzyme has several inherited polymorphisms (Kirchheiner and Brockmoller, 2005). Chlorophacinone elimination may be enhanced by phenobarbital administration (Burocoa *et al.*, 1989; Lagrange *et al.*, 1999) perhaps due to CYP induction. The effect of phenobarbitone on vitamin $K_1$ metabolism (Wilson and Park, 1984) can be compared to that of the rabbit (Winn *et al.*, 1988).

## Toxicokinetics

### *Bioavailability*

Most anticoagulant rodenticide toxicoses occur after oral exposure. However, a diphacinone-induced coagulopathy has been reported after dermal exposure to a liquid preparation (Spiller *et al.*, 2003). A quite unusual case is exposure to brodifacoum after donation and transplantation of multiple organs (Ornstein *et al.*, 1999).

The oral bioavailability of warfarin, chlorophacinone, and bromadiolone were estimated at 79%, 92%, and 88% respectively, in sheep. These anticoagulants degraded by about 15% over 24 h in rumen extracts (Berny *et al.*, 2006). The bioavailability of warfarin is influenced by dietary protein (Barber and Colvin, 1980).

### *Distribution*

Sixty percent of $^{14}C$ labeled diphacinone is eliminated in feces and 10% in urine over 4 days in mice and 8 days in rats (Yu *et al.*, 1982). Tissue distribution indicated that liver had the most $^{14}C$ activity, with the lowest amounts in brain, muscle, blood, and fat (Yu *et al.*, 1982). The disposition and pharmacodynamic properties of brodifacoum have also been characterized in rats (Bachmann and Sullivan, 1983). Similarly, 30% of $^{14}C$ labeled flocoumafen is eliminated in feces and less than 3% in urine within 3 days in rats (Huckle *et al.*, 1988). About 60% of $^{14}C$ flocoumafen is liable to beta-glucuronidase and most radioactivity is found unchanged in the liver. Elimination is biphasic with rapid phase of 5 days, then a prolonged phase of 100 days in Japanese quail (Huckle *et al.*, 1989).

Alteration of parental behavior was speculated to be a cause of 54% lethality in offspring in the face of 40% lethality of lactating female albino rats dosed with coumatetralyl (Marchini and Turillazzi, 1978). However, passage into milk is an alternative theory.

### *Elimination*

The different chemical structures give different elimination kinetics for the various anticoagulant rodenticides. Elimination kinetics is estimated from human or animal clinical cases in many instances. Such cases are presented for the 4-hydroxycoumarins warfarin, brodifacoum, difenacoum, bromadiolone, difethialone, and chlorophacinone.

Warfarin has a terminal half-life of 5.6 + 0.7 h with a mono-exponential decay (Breckenridge *et al.*, 1985). Brodifacoum and difenacoum have a bi-exponential decay of 60 ± 1.9 and 83 ± 10 h, respectively, in rabbits (Breckenridge *et al.*, 1985). Although an estimated median half-life of brodifacoum elimination has been estimated to be 2.4 days in 7 dogs (Robben *et al.*, 1998), the data may reflect the first elimination phase. Plasma half-life for brodifacoum was xxx in a zzz (Hollinger and Pastoor, 1993).

A 41-year-old man had a terminal half-life of 11.7 days for difenacoum after covert administration of an unknown amount of the drug (McCarthy *et al.*, 1997). A second individual had a peak serum concentration of 600 ng/ml of difenacoum (Butcher *et al.*, 1992).

A peak serum concentration of 440 μg/l then an elimination half-life of 140 h was reported in a 55-year-old man who ate an unknown amount of bromadiolone (Grobosch *et al.*, 2006). Elimination half-lives of 2.2 and 3.2 days have been reported in two dogs with difethialone exposure (Robben *et al.*, 1998). A half-live of 5 days is reported in sheep dosed with pindone (Robinson *et al.*, 2005).

### *Duration*

Despite reported elimination half-lives, the duration of anticoagulant effect provides an indication of the clinically relevant treatment times. Brodifacoum and difenacoum cases seem to have the longest duration of anticoagulant effect in animals and humans.

Rabbits are anticoagulated 6 weeks after oral exposure to 1 mg/kg body wt. brodifacoum (Park and Leck, 1982). Although clotting times were prolonged for 7 months after a person's exposure to an unknown amount of difenacoum (McCarthy *et al.*, 1997), elevated concentrations of vitamin $K_1$ 2,3-epoxide were detected for 18 months after exposure of two factory workers to brodifacoum and difenacoum despite normal PTs (Park *et al.*, 1986).

Duration of treatment has also been reported for bromadiolone and chlorophacinone cases, and pindone-dosed sheep. A patient exposed to bromadiolone had to be treated for 6 months (Haug *et al.*, 1992). An 18-year-old woman's PT normalized 7 weeks after deliberate ingestion of 100 mg chlorophacinone (Vogel *et al.*, 1988). Pindone has been detected for up to 14 days, in blood, 17 days in fat, and 39 days in liver of sheep dosed with it (Robinson *et al.*, 2005).

## Toxicity

### *Occurrence*

Anticoagulant rodenticides are the most common rodenticide exposure of dogs (Murphy and Hornfeldt) and the most common toxin seen in many US veterinary practices (Beasley and Trammel, 1989). Dogs suspected of anticoagulant rodenticide poisoning in the Netherlands had brodifacoum (19), bromadiolone (14), difenacoum (8), difethialone (6), and chlorophacinone (1) (Robben *et al.*, 1997). Assessment of potential toxicity of pindone for domestic animals has also been made (Martin *et al.*, 1991).

### *Dose*

Humans: A 25-year-old man attempted suicide by eating four 42-g boxes of 0.005% brodifacoum bait and succeeded in developing a coagulopathy (Kruse and Carlson, 1992). A 33-year-old man ate 1875 mg of chlorophacinone (Lagrange *et al.*, 1999) and an 18-year-old female deliberately ingested 100 mg chlorophacinone (Vogel *et al.*, 1988) and became anticoagulated. Sheep dosed orally with 10, 3, or 2 mg/kg body wt. pindone also developed coagulopathies (Robinson *et al.*, 2005). Coumatetralyl poisoning has been reported in pigs (Dobson, 1973) and pest species (Rowe and Redfern, 1968; Greaves and Ayres, 1969).

Rodenticides may be more toxic when repeatedly ingested over several days than when an equal amount is consumed in a single feeding (Dorman, 1990). Susceptibility may be greater in hypoprothrombinemic juveniles or animals with malabsorption syndromes. Also the concurrent administration of highly protein-bound drugs, e.g. phenylbutazone, aspirin, or disease states, such as chronic renal disease may increase the susceptibility of individuals to anticoagulant rodenticide poisoning (Beasley and Buck, 1983; Mount *et al.*, 1985).

## Diagnosis

### *History*

A clinical diagnosis of anticoagulant rodenticide poisoning is most often dependent on a history of exposure, or clinical signs, evidence of a coagulopathy, and response to vitamin $K_1$ therapy. The most pragmatic approach for determining the specific anticoagulant rodenticide involved is to read the product package. This approach alone is not definitive because as much as 25% of anticoagulant rodenticide intoxicated dogs do not have the anticoagulant in serum the owners suspect (Murphy).

Most anticoagulant rodenticide toxicoses is accidental, however some is intentional (Mack, 1994) in both humans and animals. Intent may become a legal issue in malicious

poisoning cases. Spontaneous hemorrhage after accidental brodifacoum exposure in a child is known to occur rarely (Watts *et al.*, 1990; Travis *et al.*, 1993). Iatrogenic cases in adults occur with more frequency (Weitzel *et al.*, 1990; Waien *et al.*, 2001; Walker and Beach, 2002) and combinations of anticoagulant rodenticides and glass (Tsutaoka *et al.*, 2003) or ethylene glycol (Seidelmann *et al.*, 1995). Human bromadiolone toxicosis has recently been reported in China (Shi *et al.*, 2005) and is known elsewhere (Shanberge, 1988). Consequently, a history of exposure or lack thereof, is not always present or reliable.

### *Clinical signs*

A history of exposure to anticoagulant rodenticides is not always available, so the toxicity must be inferred from the clinical signs. Clinical signs have been reported in a number of human and animal cases. Humans have dosed themselves or their children (Babcock *et al.*, 1993). Most clinical signs are related to the coagulopathy. Animals exposed to toxic doses of anticoagulant rodenticides remain asymptomatic until depletion of the active clotting factors occur. Therefore, clinical signs generally do not develop until 1–2 days (Dorman, 1990) or 3 to 5 days (Murphy and Gerken, 1989) postingestion.

A 55-year-old man had red sputum after ingesting an unknown amount of bromadiolone (Grobosch *et al.*, 2006). Epistaxis, gingival bleeding, widespread bruising, hematomas, hematuria, menorrhea, GI bleeding, rectal bleeding, and hemorrhage into any body organ and anemia are reported (Watt *et al.*, 2005). A 36-year-old woman had abdominal pain, hematuria, and red blood in her stool with diffuse cutaneous hematomas after ingesting difenacoum for several weeks. She had hemoperitoneum, and urethral hematoma on tomography (Barlow *et al.*, 1982; Berry *et al.*, 2000; Terneu *et al.*, 2003), and diffuse alveolar hemorrhage (Barnett *et al.*, 1992).

A 51-year-old woman who later admitted chronic ingestion of difenacoum was admitted with hemoperitoneum and intramural hematoma of the small intestine (Soubiron *et al.*, 2000). Epistaxis, hematoma, purpuria, and bruising have also been observed in a 41-year-old man with difenacoum (McCarthy *et al.*, 1997). Frank hematuria (Butcher *et al.*, 1992), neck pain, and cervical hematoma have also been observed in humans with diphenacoum exposure (Nighoghossian *et al.*, 1990). Acquired coagulopathy has been reported due to anticoagulant rodenticide exposure (Humphry, 1989; Huic *et al.*, 2002).

Human pleural, pericardial, mediastinal, and subarachnoid hemorrhages are reported with brodifacoum exposure (Kruse and Carlson, 1992). Cases of chlorophacinone poisoning in humans have also been reported (Murdoch, 1983; Dusein *et al.*, 1984). Hemoperitoneum from brodifacoum overdose has been observed (Morgan *et al.*, 1996). A number of other cases of brodifacoum (Braithwaite, 1982; Corke, 1997; Stanziale *et al.*, 1997; Casner, 1998; Bruno *et al.*, 2000), bromadiolone (Chow *et al.*, 1992), and other anticoagulant rodenticide exposure are present in the human literature (Ross *et al.*, 1992).

Clinical signs in animals are largely from canine cases (Woody *et al.*, 1992). Sometimes the only clinical signs in anticoagulant poisoned animals are dyspnea, lethargy, or anorexia but more often depression, weakness, pallor, and ventral hematomas are present (DuVall *et al.*, 1989). In addition, pulmonary edema, pleural effusion, pericardial effusion (Schulman *et al.*, 1986), intratracheal hemorrhage (McGuire *et al.*, 1999), thymic hemorrhage (Elsinghorst, 2003), laryngeal obstruction (Peterson and Streeter, 1996), pericardial effusion, and cardiac tamponade (Petrus and Henik, 1999), renal subcapsular hemorrhage (Radi and Thompson, 2004), and hematometra (Padgett *et al.*, 1998) have been reported.

Additional cases of diphacinone (Schulman *et al.*, 1986; Troy, 1988) and brodifacoum toxicosis (McSporran and Phillips, 1983; Booth, 1989; Grayson, 1982; Baker *et al.*, 2002) in dogs are reported. Horses have been exposed experimentally (Boermans *et al.*, 1991) and in the field (McConnico *et al.*, 1997) to these rodenticides. Brodifacoum may have been observed in neonatal puppies (Munday and Thompson, 2003) and has been successfully treated in a pregnant bitch (Hornfeldt and Phearman, 1996).

In clinical settings, prolonged bleeding from injection sites is usually noticed. A few clinical signs are reported that are not directly attributable to the coagulopathy. A paradoxical venous thrombosis was reported in person with chlorophacinone exposure (Papin *et al.*, 2006). Death, reduced breeding performance, stillborn, and non-viable lambs, as well as reduced sperm motility of rams is reported in sheep dosed with pindone (Robinson *et al.*, 2005).

### *Coagulopathy*

Evidence of a coagulopathy is the second element of the diagnosis. Coagulation tests are normally run on live animals and a necropsy on dead animals to support the presence of a coagulopathy. The basic mechanisms of clotting have been reviewed (Seegers, 1969).

Hematology: The anticoagulant rodenticides reduce activity of factors II, VII, IX, and X in circulation. The one-stage prothrombin time (OSPT) for evaluating factor VII is the most sensitive tool for early diagnosis because factor VII has the shortest half-life of the vitamin $K_1$ dependent clotting factors, namely about 6.2 h in dogs. Activated partial thromboplastin time (APTT) tests for all coagulation factors except factor VII, are usually used in conjunction with OSPT. Activated coagulation time (ACT) is used in the same way as the APTT. ACT is easiest to use in a clinic setting since it only requires

diatomaceous earth tubes and a heater block or water bath (Byrne, 1970).

Laboratory test results of abnormal prolonged OSPT, APTT, and ACT in presence of normal thrombin time (TT), fibrinogen, circulating fibrin degradation products (FDPs), and platelet counts is consistent with anticoagulant rodenticide poisoning. However, animals with severe anemia may have elevated FDPs and reduced platelet counts.

The diagnostic protocol based on these coagulation factor evaluation tests (OSPT, APTT, ACT) cannot differentiate between short- and long-acting anticoagulant rodenticide poisoning. The ability to recognize long-acting anticoagulants is critical, since therapeutic success may be based on the duration of vitamin $K_1$ treatment. The ability to identify the specific anticoagulant rodenticide involved using analytical chemistry is discussed below.

Coagulation testing is not always indicated after minor exposure. Of 110 children ingesting anticoagulant rodenticides, 8 had prolonged PTs. Seventeen percent (6 of 34) were prolonged 48 h after exposure while only 1.9% (2 of 104) at 24 h after exposure. 24 and 48 h after exposure is recommended time to check for PTs in children exposed (Smolinske *et al.*, 1989). Routine measurement of the INR is unnecessary in young children because the amounts ingested are invariably small (Watt *et al.*, 2005).

Although some bias in pediatric brodifacoum exposure data (Osterhoudt and Henretig, 2003) is suspected, prospective studies of acute, unintentional, pediatric superwarfarin ingestions managed without (Ingels *et al.*, 2002) or with (Smolinske *et al.*, 1989) decontamination have been conducted. Some argue against the need for a PT in unintentional pediatric superwarfarin exposures (Mullins *et al.*, 2000). See also cases of acute pediatric brodifacoum ingestions (Shepherd *et al.*, 2002). Although less treatment is often better (Kanabar, 2002) for accidental pediatric brodifacoum exposures, some pediatric cases have coagulopathies despite early treatment (Montanio *et al.*, 1993).

In all other cases, the INR should be measured 36–48 h post exposure. If the INR is normal at this time, even in the case of long-acting formulations, no further action is required (Watt *et al.*, 2005).

The most significant elevation of PT, partial thromboplastin time (PTT) and proteins induced by vitamin K antagonism (PIVKA) was observed 72 h after a single dose of diphacinone of 2 mg/kg in ground squirrels (*Spermophilus beecheyi*) although elevations were seen at 24 h (Whisson and Salmon, 2002). The increase in ACT, APTT, and OSPT are often used to support a clinical diagnosis of anticoagulant rodenticide poisoning in dogs (Dorman, 1990). Coagulation factor synthesis may be inhibited for up to 30 days in diphacinone-exposed dogs (Mount and Feldman, 1983).

PT should be checked 48 h after stopping vitamin $K_1$ therapy to detect any recurrence of coagulopathy (Chataigner *et al.*, 1989). PT times in sheep were stable in samples stored at 0, 20, and 30 degrees for 24 h (Shlosberg and Egyed, 1985).

Vitamin-K-dependent factor activity has been suggested for rapid identification of surreptitious brodifacoum poisoning (Miller *et al.*, 2006).

#### ***Necropsy/autopsy***

Pleural, pericardial, mediastinal, and subarachnoid hemorrhages have been reported in humans with brodifacoum exposure (Kruse and Carlson, 1992).

Hemoperitoneum, hemothorax, and pulmonary hemorrhage are the most common necropsy findings in dogs and cats with anticoagulant rodenticide residues in liver (DuVall *et al.*, 1989). Pulmonary edema, pleural effusion, pericardial effusion (Schulman *et al.*, 1986), and intratracheal hemorrhage are reported as well (McGuire *et al.*, 1999).

Many cases of anticoagulant poisoning are subacute in nature, but sudden death may occur as the result of acute internal hemorrhage. Evidence of external hemorrhage, such as melena, epistaxis, hematemesis, hematuria, gingival bleeding, or excessive bleeding from an open wound, may or may not be seen. However, internal hemorrhage involving the lungs, pleural and or peritoneal cavities, and facial planes are commonly reported (Murphy and Gerken, 1989; DuVall *et al.*, 1989). Massive tracheal and esophageal hemorrhage 2 days after bait ingestion is reported in a dog (Stowe *et al.*, 1983). In New Zealand, where brodifacoum was used in wild rabbit population control, 43 rabbits carcasses were found with massive hemorrhage in the abdominal cavity (52%), thoracic cavity (17%), and the remaining 31% of cases were found with hemorrhage of muscles, cecum, stomach, kidney, mesentery, and placenta of pregnant does (Rammell *et al.*, 1984). Postmortem findings in warfarin poisoning have been described by Dakin (1968).

##### *Response to vitamin $K_1$ treatment*

Remission of the coagulopathy 24 h after vitamin $K_1$ treatment supports a clinical diagnosis of a vitamin $K_1$ responsive coagulopathy (Tvedten, 1989). A clinical diagnosis is not sufficient in all cases. Some cases require that an etiological diagnosis be made. Analytical chemistry testing is required in such cases.

#### ***Analytical chemistry***

A number of analytical methods have been reported for detecting anticoagulant rodenticides in various matrices. Fluorimetric and GC methods have been commonly used to detect warfarin in serum (O'Reilly *et al.*, 1962; Corn and Berberich 1967; Lewis *et al.*, 1970; Welling *et al.*, 1970; Mildha *et al.*, 1974; Vessell and Shivley, 1974; Fasco *et al.*, 1977; Hanna *et al.*, 1978; Lee *et al.*, 1981).

Warfarin-specific methods were generally not adequate for the anticoagulant rodenticides, so a number of other methods were developed. These include thin layer chromatography (TLC), HPLC, mass spectroscopy (MS), and antibody-mediated tests. Coumarin anticoagulant rodenticides were initially detected using TLC (Lau-Cam and Chu-Fong, 1972; Mallet *et al.*, 1973). A high-performance TLC method with an estimated detection limit of 200 ppb and 87% recovery from liver has recently been reported (Berny *et al.*, 1995).

Early HPLC methods were focused on an individual chemical. For example, methods to detect chlorophacinone in formulations (Grant and Pike, 1979; Vigh *et al.*, 1981), brodifacoum in serum (Murphy and Gerken, 1989), brodifacoum (Koubek *et al.*, 1979; Keiboom and Rammel, 1981; Hoogenboom and Rammell, 1983; Ray, *et al.*, 1989), bromadiolone (Hunter *et al.*, 1988; Subbiah *et al.*, 2005), chlorophacinone (Hunter *et al.*, 1984), difethiolone (Goldade *et al.*, 1998), and difenacoum (Mundy and Machin, 1977) in tissue have been reported. Then a method was developed to look for all the anticoagulant rodenticides on the market at a time. It succeeded in extracting and detecting eight anticoagulant rodenticides in serum and liver using fluorescence and ultraviolet (UV) detection. Samples are extracted with acetonitrile then cleaned up on solid phase columns. Four hydroxycoumarins are detected by fluorescence with excitation at 318 nm and emission at 390 nm. The indanediones are detected at 285 nm. An extraction recovery of 75% for serum and 69% from liver was reported. Hydroxycoumarins may be detected down to about 1 ng/ml of serum and 1 ng/g of liver, and indanediones down to 10 ng/ml of serum and 10 ng/g of liver (Felice and Murphy, 1989; Felice *et al.*, 1991; Chalermchaikit *et al.*, 1993). Another HPLC method for detecting brodifacoum in serum and liver using difenacoum as the internal standard has been reported (O'Bryan and Constable, 1991). Method for simultaneous detection of five superwarfarin rodenticides in human serum has been described by Kuijpers *et al.* (1995). Other serum methods have been reported with detection limits of 3–12 ng/ml for fluorescence and 20–75 ng/ml for UV detection (Mura *et al.*, 1992; Kuijpers *et al.*, 1995; McCarthy *et al.*, 1997; Feng *et al.*, 1999).

Tissue methods include a solid phase cartridge extraction from liver with a recoveries ranging from 52% for difenacoum to 78% for warfarin. The limit of detection is 10 ppb for warfarin and difenacoum, and 110 ppb for chlorophacinone (Jones, 1996; Fauconnet *et al.*, 1997; Addison, 1982).

HPLC methods have also been published to distinguish cis and trans isomers of difenacoum with detection limits of 5 ng/ml (Kelly *et al.*, 1993). An early interesting approach was using a post-column pH shift to enhance fluorescence detection (Hunter, 1985; Hunter *et al.*, 1988). Several HPLC methods have also bee reported (AOAC, 1976a, b; Mundy and Machin, 1982; Hunter 1983a, b) for diphacinone (Bullard *et al.*, 1975, 1976) with fluorescence detector for bromadiolone (Deepa and Mishra, 2005), brodifacoum (Fu *et al.*, 2006), brodifacoum in tissues (Hagenboom and Rammell, 1983), difenacoum (Hadler and Shadbolt, 1975), and determination of Rozol in parafinized formulations (Kawano and Chang, 1980), and bromadiolone in tissues (Nahas, 1986).

A recent method uses diode array detector (Yang *et al.*, 2001). An interesting new method uses HPLC to detect anticoagulant rodenticides in soft drinks (Dimuccio *et al.*, 1991).

An ion pair liquid chromatography method has been reported to detect chlorophacinone and diphacinone in oats (Primus *et al.*, 1998).

Contemporary confirmatory methods use MS. Most recently liquid chromatography–electrospray ionization–mass spectroscopy (LC-ESI-MS) has been reported for the analysis of 10 anticoagulant rodenticides with a limit of quantitation of about 5 ug/l (Grobosch *et al.*, 2006). Other recent methods use LC MS-MS for unknown drugs including warfarin (Marquet *et al.*, 2003) and LC-ESI-MS and HPLC-UV to detect anticoagulant rodenticides as low as 20 ng on column (Mesmer and Flurer, 2000). One of the earlier MS methods used a direct probe technique to detect indanedione residues in food animals (Braselton *et al.*, 1992).

A cell culture/ELISA assay has recently been developed to detect anticoagulant rodenticides in treated grain (Lawley *et al.*, 2006). A prior immunoassay was developed to detect diphacinone and chlorophacinone (Mount *et al.*, 1988). Enantiomers of warfarin, coumachlor, and coumafuryl can be separated chromatographically (Armstrong *et al.*, 1993).

Serum concentration of dogs with anticoagulant rodenticide poisoning ranged from less than 10–851 ng/l for brodifacoum, difethialone, and difenacoum (Robben *et al.*, 1998).

## Treatment

General, supportive, and specific treatment areas are available for anticoagulant rodenticide toxicosis. Prospective study of the outcome of patients with excessive warfarin exposure is described by Hylek *et al.* (2000).

### *General*

Emetic, adsorbent, and cathartic therapies are indicated if the ingestion of the anticoagulant rodenticide has occurred within the last few hours. Peak serum concentrations of brodifacoum occur 2 h after oral dosing, however so the coagulation status of the animal should be monitored at 24 and 48 h after exposure.

Clinical coagulopathy normally occurs 2–5 days after oral exposure, so emetics and cathartic at the time of

presentation are not normally indicated. Oral-activated charcoal therapy however, may be useful for those chemicals that undergo enterohepatic circulation.

### *Supportive*

Recommendations for humans with anticoagulant rodenticide toxicosis have recently been reported by Watt *et al.* (2005). If active bleeding occurs, prothrombin complex concentrate (which contains factors II, VII, IX, and X) 50 units/kg, or recombinant-activated factor VII 1.2–4.8 mg or fresh frozen plasma 15 ml/kg if no concentrate is available, and phytomenadione 10 mg intravenous (i.v.) (100 μg/kg body wt. in a child) should be given. If there is no active bleeding and the INR is $<$ or $=4.0$, no treatment is required; if INR is $>$ or $=4.0$ phytomenadione 10 mg should be administered i.v. (Watt *et al.*, 2005).

Animals with severe clinical bleeding or markedly reduced packed cell volumes (PCVs) should receive fresh plasma or blood transfusions because of the 4–8 h often required to increase clotting factor activity following vitamin $K_1$ therapy (Chalermchaikit *et al.*, 1993). These recommendation are consistent with those of others (McCarthy *et al.*, 1997; Soubiron *et al.*, 2000; Terneu *et al.*, 2003).

### *Specific*

Vitamin $K_1$ therapy is recommended in humans (McCarthy *et al.*, 1997; Soubiron *et al.*, 2000; Terneu *et al.*, 2003) and animals with elevated coagulation times after exposure to anticoagulant rodenticides (Murphy *et al.*, 1989; Robben *et al.*, 1998; Mount *et al.*, 1982). Vitamin $K_1$ (phylloquinone) is the most effective form for the treatment of anticoagulant rodenticide intoxication because of its immediate availability for the synthesis of new clotting factors (Chalermchaikit *et al.*, 1993).

The pharmacological half-live of vitamin $K_1$ is $1.7 + 0.1$ h in rabbits dosed with brodifacoum (Park and Leck, 1982). Prothrombin activity reaches peak improvement 4 h after administration of vitamin $K_1$ to rabbits anticoagulated with brodifacoum or difenacoum (Park and Leck, 1982).

The duration of vitamin $K_1$ treatment is prolonged (Butcher *et al.*, 1992) for the longer-acting chemicals. It may be required for up to 2 weeks in diphacinone-exposed dogs (Mount and Feldman, 1983). Daily doses of vitamin $K_1$ in the range of 0.25–2.5 mg/kg for 1 week are recommended for exposure to short-acting rodenticides, and 2.5–5.0 mg/kg for 3–4 weeks is recommended for exposure to long-acting rodenticides (Mount *et al.*, 1985). Prolonged anticoagulation in rat poisoning has been reported by Jones *et al.* (1984) and Lipton and Klass (1984).

The two most commonly recommended routes of vitamin $K_1$ administration are oral and subcutaneous. Intramuscular injections in a hypoprothrombinemic animal can produce hematoma and i.v. administration of vitamin $K_1$ has been associated with anaphylaxis, therefore these routes are discouraged in the therapeutic regimen (Clark and Halliwell, 1963).

Vitamin $K_1$ therapy may be reduced in a step-wise manner as long as the PT remains normal (Robben *et al.*, 1998). The length of treatment is presently decided by evaluation of OSPT values for 2 days after the cessation of vitamin $K_1$ administration. If prolonged OPST is found, treatment is commonly continued for another week, but if it remains normal for 5–6 days, the vitamin $K_1$ treatment is usually terminated (Murphy *et al.*, 1989).

### *Diagnosis*

Diagnostic approach to the bleeding patient has been described by Johnstone (1989). A diagnostic protocol should utilize more than one coagulation test, since it is necessary to differentiate rodenticide poisoning from other coagulopathies, such as disseminated intravascular coagulopathy, congenital factor deficiencies, hyperviscosity syndromes, platelet deficiencies or functional defects, von Willebrand's disease, and canine ehrlichiosis. Hypovitaminosis K associated bleeding has been reported in cats with malabsorption syndrome (Edwards and Russell, 1987).

## STRYCHNINE

### Introduction

Strychnine is an alkaloid derived from the seeds and bark of a tree, *Strychnos nux-vomica*, that is native to Southeast Asia (India, West Indies, Sri Lanka, Indonesia) and Australia. Strychnine is also found in *Strychnos ignatii.* Strychnine is a white, odorless, crystalline powder, which has chemical formula $C_{21}H_{22}N_2O_2$ and molecular weight of 334.41. Its structural formula is shown in Figure 49.1.

Nux-vomica/strychnine has been used for at least five centuries for both pests and people. Its major use is as a pesticide (rodenticide, avicide, and insecticide), but it is also used as a therapeutic agent in human ailments (laxative, appetizer, and central nervous system (CNS) stimulant). In addition, strychnine in small amounts is known to be added to lysergic acid diethylamide (LSD), heroin, cocaine, and other "street drugs", and has been known to cause poisoning (O'Callaghan *et al.*, 1982). In the 1960s, strychnine was the title of a song by the Garage Rock Band "The Sonics", which includes the lines: "Some folks like the water, some folks like the wine; I like the taste of straight strychnine". Strychnine has many names and is sold under various trade names including Boomer-Rid, Certox, Dog-button, Dolco mouse Ceral, Gopher Bait, Gopher Gitter, Kwik-kill, Stricnina, Mole death, Mouse-nots, Mouse-rid, Mouse-tox, Ro-dex, Strychnos, Sanaseed, and others. Strychnine poisoning in animals occurs from ingestion of baits designed for use against rodents. The most common domestic animal to be affected is the dog, either through accidental ingestion or intentional poisoning.

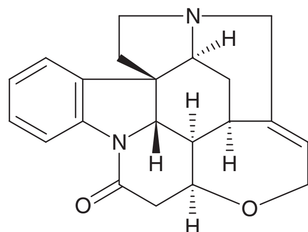

**FIGURE 49.1** Structural formula of strychnine.

### Background

Strychnine was first discovered in 1818 by two French scientists (Joseph-Bienaime Caventou and Pierre-Joseph Pelletier) in the *Saint ignatii* beans. *S. ignatii* is a woody climbing shrub found in the Philippines. In general, the beans have the same properties as the species *S. nux-vomica*. Strychnine is also found in other species of *Strychnos* (*Strychnos colubrine*, and *Strychnos tieute*), and is accompanied by another alkaloid brucine. The ripe seeds of *Strychnos* look like flattened discs, which are very hard and covered with satiny hairs. The properties of strychnine are substantially those of the nux-vomica. Strychnine is an extremely toxic alkaloid primarily used to kill rodents, moles, predatory animals, and birds, or trapping fur-bearing animals. Pharmaceutically, strychnine is an unjustifiable component of traditional tonics, cathartic pills, and CNS stimulant.

### Toxicokinetics

Following ingestion, strychnine is readily absorbed from the gastrointestinal (GI) tract, but mainly from the small

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

intestine. Soon after absorption, strychnine readily distributes to various tissues within 5 min (Reynolds, 1982). Strychnine is readily metabolized in the liver. In fact, the metabolism is rapid enough that approximately two lethal doses can be given over 24 h without cumulative effects. Its half-life has been reported to be about 10 h in humans. Elimination of strychnine is also rapid, as its unchanged residue can be detected in the urine within few minutes of exposure. The elimination constant ($K_{el} = 0.07\,h^{-1}$) indicates that 7% of the strychnine in the serum at any one moment would be eliminated in 1 h (Edmunds *et al.*, 1986). Following exposure to a sublethal dose of a strychnine, about 50% of the dose is eliminated within 6 h (Boyd *et al.*, 1983), 10–20% within 24 h, and almost complete in 48–72 h (Cooper, 1974).

## Mechanism of action

Pharmacologically, because of its bitter taste, strychnine strongly stimulates salivary and gastric secretions. This increases appetite and as a result strychnine has been used for a long time to counteract the loss of appetite associated with illnesses.

Strychnine is a potent convulsant. It increases reflex excitability in the spinal cord and that results in a loss of the normal inhibition of spread of motor cell stimulation, so that all muscles contract simultaneously. Strychnine causes excitation of all parts of the CNS. It increases the level of neuronal excitability by interfering with inhibitory influences on the motor neurons. The site of mechanism of action of strychnine is the post-synaptic membrane. The convulsant action of strychnine is due to interference with the post-synaptic inhibition that is mediated by the amino acid glycine. Glycine is an inhibitory transmitter to motor neurons and interneurons in the spinal cord. Strychnine acts as a selective competitive antagonist to block the inhibitory effects of glycine at the glycine receptors. Studies indicate that strychnine and glycine interact with the same receptor, but at different sites. There is also evidence of an increase in brain levels of glutamic acid, an amino acid that acts as a transmitter for excitatory nerve impulses that excite muscle contraction. The result of these effects is that skeletal muscles become hyperexcitable. With a little sound or touch, uncontrollable convulsions and seizures become eminent, followed by suffocation and death. Death occurs due to respiratory failure.

## Toxicity

### *Animals*

Strychnine has been studied for acute toxicity in many species, and all species that were tested were found susceptible. Strychnine is an extremely poisonous substance with an $LD_{50}$ of 2.3 mg/kg in rats (Ward and Crabtree, 1942), 2 mg/kg in mouse (Prasad *et al.*, 1981), 0.6 mg/kg in rabbits (Flury and Zernik, 1935), and 0.5 mg/kg in cats and dogs (Moraillon and Pinault, 1978). An approximate lethal dose for a dog is 0.75 mg/kg body wt. So, 5 g bait having 0.3% strychnine could be enough to kill a 20 kg dog. Toxicity data of strychnine for other species are given in Table 49.1.

Presently, strychnine is used as rodenticide, avicide, and insecticide. Among animals, poisoning occurs with greatest frequency in dogs due to accidental ingestion or malicious intent. The onset of signs can occur within 15–30 min or occasionally 60 min after oral exposure, depending on whether the stomach is empty or full. The clinical signs are associated with CNS effects. Onset of signs includes restlessness, anxiety, muscle twitching, and stiffness of the neck. The poisoned dogs usually show the signs of mydriasis, tonic convulsions, contractions of striated muscles, seizures, opisthotonus, and death. The animal becomes sensitive to touch, sound, noise, or any other sudden change in the environment. A minor stimulation can trigger violent convulsions. Muscular contractions are easily triggered by external stimuli, accompanied by hypothermia, lactic acidosis, and rhabdomyolysis.

Although strychnine has no direct effects on skeletal muscles, all voluntary muscles contract simultaneously. The increase in muscle tone is caused by the central action of strychnine. The most powerful effects are seen on the muscles of joints. Respiratory muscles (diaphragm, thoracic, and abdominal) contract, respiration ceases, and eventually death ensues due to respiratory failure.

Birds poisoned by strychnine exhibit the signs of ataxia, ruffled feathers, wing droop, salivation, tremors, and convulsions. Death occurs due to respiratory failure. On postmortem, lesions are only observed in the lungs, i.e., pinpoint hemorrhages resulting from death due to asphyxia. Rigor mortis occurs shortly after death and persists for days. Occasionally, wildlife species are also inadvertently poisoned by strychnine.

There is no evidence of cumulative toxicity from strychnine (Gosselin *et al.*, 1984). From animal studies there is no

**TABLE 49.1 Acute toxicity data of strychnine**

| Species | Route of administration | $LD_{50}$ (mg/kg) |
|---|---|---|
| Rat | Oral | 16.00 |
| | i.p. | 2.50 |
| | s.c. | 1.20 |
| | i.v. | 0.96 |
| Mice | Oral | 2.00 |
| | i.p. | 0.98 |
| | s.c. | 0.474 |
| | i.v. | 0.41 |
| Duck | Oral | 3.00 |
| Pigeon | Oral | 21.00 |

NIOSH (1983–1984).

evidence that strychnine has potential for reproductive and developmental toxicity, and mutagenic and carcinogenic activity.

#### *Humans*

Humans are very sensitive to strychnine poisoning. Exposure to strychnine usually occurs through ingestion or inhalation. It has been reported that the lethal oral dose is 1.5–2.0 mg/kg body wt. (Gosselin *et al.*, 1984). The fatal dose is usually in the range of 100–200 mg, but as little as 30 mg in adults and 15 mg in children has proved fatal. Onset of clinical signs such as muscle spasms at the neck and head can occur within 10–20 min after exposure. Then muscle spasms spread to every muscle in the body, are nearly continuous, and get worse at the slightest stimulus. The condition progresses in intensity and frequency until the backbone arches continually. Seizures are the major symptoms of strychnine poisoning and are caused by excitation of all parts of the CNS. Death occurs from paralysis of the respiratory center and muscle. Rigor mortis sets in immediately, with the eyes left wide open.

The major identifying clinical features of strychnine poisoning through ingestion are severe painful spasms of the neck, back, and limbs, and convulsions with an intact sensorium. In severe cases, symptoms progress to coma, although tachycardia and hypertension are common effects (Edmunds *et al.*, 1986; Flomenbaum, 2002). The muscle contractions caused by strychnine produce characteristic contractions of the body, arched backward so that only the heals and the top of the head touch the ground, and of the face, a fixed grin known as the *risus sardonicus*.

The prognosis for strychnine poisoning is good if the patient's condition can be maintained over the first 6–12 h (Boyd *et al.*, 1983). If the convulsions are not treated, the patient may die within 1–3 h after exposure to a fatal dose (Perper, 1985). The diaphragm, chest, and abdominal muscles are in a sustained spasm and breathing becomes difficult. The occurrence of hypoxia and cyanosis is usually followed by death.

#### *Diagnosis*

Diagnosis of strychnine poisoning is based on: (1) history of exposure to a strychnine bait or presence of cracked corn in the digestive tract, (2) clinical signs of tetanic convulsions, seizures, hypersensitivity to external stimuli, and muscle stiffness, and (3) chemical identification of strychnine in the stomach content, blood, urine, or visceral organs (liver and kidney). Strychnine residue can be detected and quantified using gas chromatography-flame ionization detector (GC-FID) or gas chromatography-mass spectrometry (GC-MS). It is important to mention that strychnine causes elevation of serum enzymes, including glutamic oxaloacetic transaminase (GOT), creatine phosphokinase (CPK), and lactate dehydrogenase (LDH). In addition, lactic acidosis, hyperkalemia, and leukocytosis are the characteristic laboratory findings. In differential diagnosis, tetanus must be ruled out.

### Treatment

There is no specific antidote for strychnine poisoning, so treatment rests with symptomatic and supportive therapies. Seizures need to be controlled as soon as possible with diazepam or phenobarbital. Artificial respiration can be used for apnea. Once the seizures are controlled, detoxification can be performed using gastric lavage with potassium permanganate. Given activated charcoal with saline cathartic. Animal should be kept in a quite environment, and should be protected from any secondary sensory input.

### Conclusion

Strychnine is an extremely toxic plant alkaloid, which is primarily used as rodenticide. Due to inadvertent use or malicious intent the poisoning is frequently encountered in dogs. Onset of clinical signs appears very quickly, and the poisoning is characterized by convulsions, seizures, and hypersensitivity to any external stimulus. Treatment is symptomatic and warranted immediately.

## BROMETHALIN

### Introduction

Chemically, bromethalin is a diphenylamine compound with an appearance of a pale, odorless, and solid crystalline powder. It has a chemical formula of $C_{14}H_{17}Br_3F_3N_3O_4$ with a molecular weight of 577.93. Its chemical structure is shown below in Figure 49.2. It is commonly used as rodenticide for the control of rats and mice. Bromethalin has many other names and is sold under the brand names such as Assault, Trounce, Vengeance, and Wipe Out.

### Background

Bromethalin was developed for use against warfarin-resistant rodents. It is a restricted use rodenticide used in and around buildings and sewers, and inside transportation and cargo vehicles. It is extremely toxic and only a single dose of bromethalin is needed to cause death in rats and mice. Bromethalin is marketed in a 0.01% formulation (2.84 mg of bromethalin per ounce of bait) and comes in bait pellets, bars, and packs. It is important to mention that

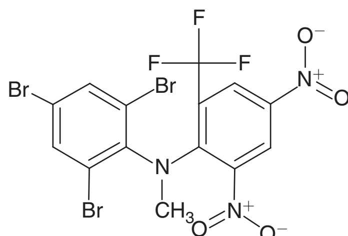

**FIGURE 49.2** Structural formula of bromethalin.

bromethalin cannot be distinguished from other rodent baits by color or appearance alone. Secondary poisoning usually occurs in dogs and cats that eat a mouse killed by bromethalin.

## Toxicokinetics

Toxicokinetic information on bromethalin is available from laboratory animals, like rats. Bromethalin is rapidly absorbed following oral ingestion. Plasma concentration peaks in about 4 h. The metabolism takes place in the liver, where bromethalin undergoes *N*-demethylation, forming des-methyl bromethalin. This metabolite is toxic, as its $LD_{50}$ is 7.5 mg/kg body wt. Plasma half-life of bromethalin is about 6 days (Dorman *et al.*, 1990a), suggesting slow elimination. Excretion occurs mainly in bile, as it enters in enterohepatic circulation.

## Mechanism of action

Bromethalin is a neurotoxicant and affects the CNS. It uncouples oxidative phosphorylation in the mitochondria thereby decreasing ATP synthesis. With a marked decrease in ATP, very little energy is available to maintain $Na^+$, $K^+$-ATPase pumps. As a result, cells lose their ability to maintain osmotic control, $Na^+$ is retained intracellularly, and the cells swell with water. This leads to fluid accumulation within myelin sheaths and vacuolation of the nervous system, resulting in nerve conduction impairment. Damage to neuronal axons and increased intracranial pressure occurs, which is followed by convulsions, paralysis, and death (Dorman *et al.*, 1992).

## Toxicity

Bromethalin is a single-dose rodenticide. It is classified as very highly toxic if swallowed or inhaled, and highly toxic if absorbed through skin. The acute oral $LD_{50}$ of bromethalin is 2.38–5.6 mg/kg in bait is for dog and 0.4–0.71 mg/kg in bait for cats (Dorman *et al.*, 1990a). Its $LD_{50}$ is 2 mg/kg in mice, 5 mg/kg in rats, 13 mg/kg in rabbits, and 0.25 mg/kg in pigs.

In field cases, most of the time poisoning occurs in pets including dogs and cats. Signs of bromethalin appear within 10 h to several days after exposure and may last up to 12 days. In most cases the poisoning is acute in nature characterized by cerebral edema and paralysis of the hind limbs. In general, clinical signs in pets include severe muscle tremors, hyperexcitability, hyperesthesia (hypersensitivity to touch), and seizures. Symptoms with mild exposure to bromethalin occur with slow progress in several days, and include loss of ability to bark, loss of appetite, vomiting, depression, lethargy, tremors, paralysis, lateral recumbency, coma, and death. Following exposure to a large dose of bromethalin animals can show the signs of muscle tremors and seizures, hyperexcitability, ataxia and paddling, hyperthermia, potential loss of vocalization, loss of tactile sensation, and forelimb extensor rigidity (Schiff–Sherrington posture), and death within 2–4 days. Death can occur with a low or high dose, and is usually caused by respiratory paralysis. Poisoned dogs show the signs of tremors, ataxia, depression, tachypnea, hyper-reflexia of the hind limbs, loss of vocalization, recumbency, anorexia, vomiting, and death (Dorman *et al.*, 1990b). Poisoned cats exhibit the signs of ataxia, seizures, vocalization, rigidity, decreased proprioception, abdominal distension, recumbency, depression, and death (Dorman *et al.*, 1990c, 1992). Other signs of poisoning may include generalized seizures, head pressing, hyperesthesia, coma, hyperexcitability, ataxia, extensor rigidity, nystagmus, hyperthermia, cyanosis, miosis, and drooling (Moorman, 2001). Overall, cats are much more sensitive than dogs to bromethalin.

Histopathological changes have been described in dogs receiving a single oral dose of bromethalin (6.25 mg/kg). Histologic lesions included diffuse white matter spongiosis, mild microgliosis, optic nerve vacuolization, mild thickening of Bowman's capsule, and occasional splenic megakaryocytes. Ultramicroscopic examination of mid-brain stem revealed occasional swollen axons, intramyelinic vacuolization, and myelin splitting at the intraperiod line (Dorman *et al.*, 1990a). These authors have also reported histopathological changes in cats induced by bromethalin (Dorman *et al.*, 1992). In brief, ultrastructural changes include separation of myelin lamellae at the interperiod lines with the formation of intramyelinic vacuoles (intramyelinic edema), rupture and coalescence of intramyelinic vacuoles into larger extracellular spaces (spongy change), and pronounced cytosolic edema of astrocytes and oligodendroglial cells. Histopathology of the brain and spinal cord of rodents receiving multiple low or sublethal doses of bromethalin revealed a spongy degeneration of the white matter which was shown upon ultramicroscopic examination to be intramyelinic edema (Van Lier and Cherry, 1988).

According to the World Health Organization and US Environmental Protection Agency, bromethalin is considered carcinogenic.

### *Diagnosis*

Diagnosis of bromethalin poisoning is based on history of exposure to bromethalin bait, clinical signs, and identification of bromethalin in bait, GI content, brain, and visceral organs. Residue of bromethalin or its major metabolite (desmethyl bromethalin) can be quantified using gas chromatography (GC) coupled with electron capture (ECD) (Dorman *et al.*, 1990a), high-pressure liquid chromatography (HPLC) coupled with ultraviolet detector or with negative-ion atmospheric pressure chemical ionization (APCI) – mass spectrometric (MS) detection (Mesmer and Flurer, 2001). The highest concentrations of bromethalin are found in fat, liver, kidney, and brain (Dorman *et al.*, 1990a). Differential diagnosis should rule out for lead, ethylene glycol, organophosphates, strychnine, metaldehyde, zinc phosphide, and tremorgenic mycotoxins.

## Treatment

There is no specific antidote for bromethalin poisoning. Symptoms can be treated with corticosteroids, but clinical studies indicate that symptoms return as soon as the corticosteroids are discontinued. Emesis should be induced using apomorphine or 3% hydrogen peroxide, if the animal is not exhibiting the signs of convulsions and seizures. Alternatively, perform gastric lavage and give activated charcoal with saline cathartic. Activated charcoal needs to be repeated if the dog or cat is exposed to a large dose of bromethalin. The animal needs to be monitored and treated for cerebral edema. Intravenous (i.v.) fluids can be administered with great caution so as not to worsen cerebral edema. Diazepam or barbiturate can be given for controlling seizures.

## Conclusion

Bromethalin is a commonly used rodenticide, which is encountered in poisoning in dogs and cats. Bromethalin exerts toxicity by uncoupling oxidative phosphorylation in mitochondria, thereby decreasing ATP synthesis. CNS is the target organ, and the toxicity is characterized by cerebral edema, convulsions, and paralysis. There is no specific antidote, so treatment is symptomatic and supportive.

# CHOLECALCIFEROL

## Introduction

Cholecalciferol is a form of vitamin D, also called vitamin $D_3$ that is commonly used as rodenticide. Vitamin $D_3$ is a

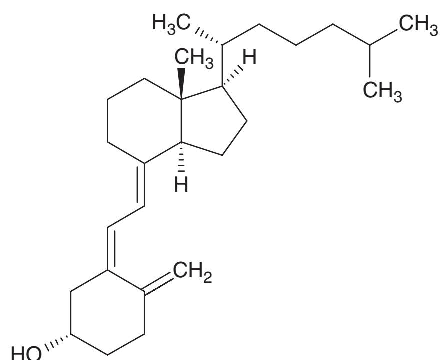

**FIGURE 49.3** Structural formula of cholecalciferol.

secosteroid and structurally similar to other steroids, such as cholesterol, testosterone, and cortisol. It has chemical formula $C_{27}H_{44}O$ with a molecular weight 384.64. Its structural formula is shown above in Figure 49.3. Cholecalciferol has other names and is marketed as a rodenticide under the brand names Quintox, True Grit Rampage, Ortho Rat-B-Gone; and as a feed additive, Viactive.

## Background

Cholecalciferol is a rodenticide which is used in and around buildings, and inside of transport vehicles. Vitamin $D_3$, as such, does not have significant biological activity, but in two steps, it is metabolized in the body to make an active form. In liver, cholecalciferol is hydroxylated to 25-hydroxycholecalciferol (calcifedion) by the enzyme 25-hydroxylase. In kidney, 25-hydroxycholecalciferol serves as a substrate for 1-$\alpha$-hydroxylase, forming 1,25-dihydroxycholecalciferol (calcitriol), which is the biologically active form. Cholecalciferol is formulated in the granular form (0.075% bait) and has been found very effective against Norway rats, roof rats, and house mice.

## Toxicokinetics

Very little information is available on toxicokinetics of cholecalciferol. Cholecalciferol is transported in blood bound to carrier proteins. The major carrier protein is vitamin-D-binding protein. The half-life of 25-hydroxycholecalciferol is several weeks, while that of 1,25-dihydroxycholecalciferol is just a few hours.

## Mechanism of action

Ingestion of cholecalciferol-containing bait is known to cause a marked increase in calcium level in blood and tissues. Cholecalciferol not only increases the absorption

of calcium but also mobilizes calcium and phosphorus from bones to circulation. High calcium causes heart problems and bleeding secondary to mineralization of the vessels, kidneys, stomach wall, and lungs. Mineralization of the kidney leads to renal failure and death. Cholecalciferol and its metabolites exert their effects by binding to vitamin D receptors in tissues. 1,25-dihydrocholecalciferol is the most metabolically active form that binds to the vitamin D receptors 500 times greater than 25-hydroxycholecalciferol and 1000 times greater than cholecalciferol.

## Toxicity

Cholecalciferol is of low toxicity to mammalian species, as it is classified as a Class III toxic chemical. The oral $LD_{50}$ of cholecalciferol in rats is 43.6 mg/kg and in mice is 42.5 mg/kg. The dermal $LD_{50}$ in rabbits is 2000 mg/kg. Studies suggest that cholecalciferol is of low toxicity to birds (oral $LD_{50}$ = >2000 mg/kg in mallard ducks and dietary $LC_{50}$ = 4000 ppm in mallard ducks, and 2000 ppm in bobwhite quail).

Pets, such as dogs are poisoned by ingesting rodenticide bait, while the farm animals are affected by overdose of additive vitamin $D_3$ in the feed. Signs and symptoms of poisoning are similar to hypercalcemia, such as anorexia, fatigue, headache, itching, weakness, nausea, vomiting, and diarrhea. In acute cases, cholecalciferol causes severe polyneuropathy. Dogs poisoned with cholecalciferol-containing rodenticide bait usually show the signs of depression, anorexia, vomiting, bloody diarrhea, cardiac irregularities, hypertension, seizures, and death. In dogs, signs of poisoning may occur with as little as 2 mg/kg dose, and death may occur with 10 mg/kg dose of cholecalciferol.

## Treatment

Decontamination, including induction of emesis, gastric lavage, and administration of activated charcoal, is beneficial. Administration of i.v. fluids helps in reducing serum calcium levels by increasing urine production and calcium excretion. Biphosphonate pamidronate disodium is used to decrease the serum calcium levels. Seizures can be controlled by diazepam or barbiturates. Treatment needs to be continued for 2–3 weeks, since the elimination half-life of cholecalciferol is more than 2 weeks. Poisoned animals should receive the feed devoid of vitamin $D_3$.

## Conclusion

Cholecalciferol is a single- or multiple-dose rodenticide, which has low toxicity to mammalian and avian species. It produces toxicity by marked increases in calcium and mineralization of tissues. Once the animals develop severe signs, they usually die.

# RED SQUILL

## Introduction

Red squill, which is also known as sea onion, is obtained in the powder form from a plant *Urginea maritima.* The plant is native to the Mediterranean region. It resembles to onion whose bulb extracts and dried powders have been used for the control of rodents since the 13th century. Although red squill has many alkaloids, scilliroside is the most toxic and provides rodenticidal activity. It has chemical formula $C_{32}H_{44}O_{12}$ with a molecular weight of 620.7. Its structural formula is shown below in Figure 49.4. The compound is sparingly soluble in water and thermostable. Scilliroside is formulated in the powder form (Dethdiet) and liquid extract (Rodine), and has many other names, including Sea squill, Scilla maritima, Silmurin, Silmine, Sea onion, Squill, etc. It was demonstrated long ago by Winton (1927b) that only red squill has rodenticide activity, and not the white squill. The red squill is mixed in baits and applied at a 10% concentration and mixed with meat, fish, and cereals (Thomson, 1991–1992).

## Background

Red squill bulbs were an ancient source of rodenticide products replaced later by warfarin and other modern anti-coagulant rodenticides. Since rats have developed resistance to such products there is now renewed interest in the red squill. Studies suggested that the white squill-drug is used as a diuretic, stimulant, and expectorant,

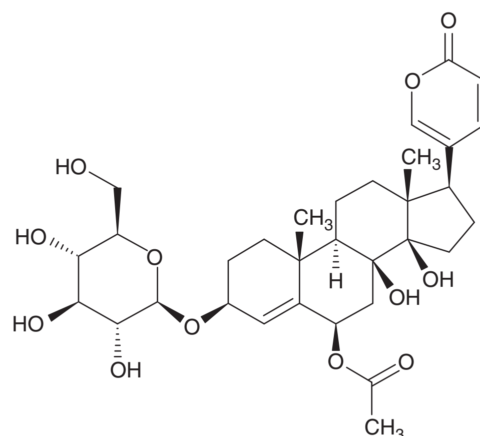

**FIGURE 49.4** Structural formula of scilliroside.

while the red squill is used mostly as a rat poison. Many glycosides and aglycones have been isolated from the red squill bulb. Krenn *et al.* (1994) and Pascual-Villalobos (2002) isolated five different bufadienolides as pure substances (proscillaridin A, scillaren A, scilliroside, gamma-bufotalin, and scillirosidin). Scilliroside is the most toxic bufadienolide glycoside (Verbiscar *et al.*, 1986a, b).

Scilliroside has an emetic property. So, if rodents ingest a product-containing scilliroside, because they are incapable of vomiting, they develop glycoside intoxication and pulmonary edema. However, the compound has rarely been associated with toxicity in humans because humans are capable of vomiting and exhibit poor GI absorption.

## Toxicokinetics

Scilliroside is inefficiently absorbed from the GI tract. Its metabolism is not well studied, though the unmetabolized scilliroside is rapidly excreted in the urine.

## Mechanism of action

Red squill bulbs contain many glycosides, but scilliroside is the major component which has rodenticidal property. The compound is cardiotoxic similar to digitalis, i.e., injection of scilliroside induces cardiac impulse condition and arrhythmias. In very early experiments, red squill preparations administered to rats induced convulsions and paralysis (Winton, 1927a). Female rats succumb to doses of red squill, at half the dose that required to kill males.

## Toxicity

The red squill plant (mainly the bulb) contains scilliroside, a highly toxic bufadienolide glycoside. It adversely affects cardiovascular and CNS, causing convulsions and death. The oral $LD_{50}$ of scilliroside is 0.7 mg/kg in male rats and 0.43 mg/kg in female rats; and 0.35 mg/kg in mice. Studies revealed that pigs and cats survived 16 mg/kg, and fowls survived 400 mg/kg (Worthing, 1983). It is classified as Class I, i.e., highly toxic chemical.

Red squill contains several compounds that have emetic properties. Due to poor GI absorption and decreased potency, red squill has seldom been associated with toxicity in humans, dogs, cats, and pigeons. However, rats and mice are unable to vomit, and they die within a few hours after ingesting lethal dose of scilliroside.

In toxic doses, red squill produces inflammation of the GI and genito-urinary tracts, manifested by nausea, vomiting, abdominal pain, and purging. Other signs of poisoning include convulsions, hypothermia, enfeebled circulation, blurred vision, and sometimes death. Convulsions are seen in humans, as they have been observed in rats. Higher doses of red squill can cause serious heart rhythm alterations resulting in death. Farm animals require large quantities for intoxication. There are field cases, where dogs, cats, and pigs have been poisoned. Signs of poisoning include vomiting, ataxia, and hyperesthesia, followed by paralysis, depression, or convulsions. Cardiac arrest occurs due to bradycardia and cardiac arrhythmias. Generally, animals exposed to a sublethal dose can recover in less than 48 h.

## Treatment

Treatment is based on symptomatic and supportive therapies. In case a significant amount of red squill is retained in the stomach, decontamination (gastric lavage with saline cathartic) is rewarding. The patient needs to be monitored for cardiac arrhythmias and conduction disturbances. Atropine sulfate subcutaneous (s.c.) at 6–8 h intervals may prevent cardiac arrest. Phenytoin at 35 mg/kg, TID, should be given to dogs to suppress arrhythmias.

## Conclusion

Red squill is a botanical rodenticide and exerts toxicity due to cardiac effects. Treatment is symptomatic and supportive.

# FLUOROACETATE

## Introduction

Sodium fluoroacetate (compound 1080) is an extremely toxic white powder that has been used as rodenticide around the world. The compound has chemical formula $C_2H_2FO_2.Na$ with a molecular weight 100.02. Its structural formula is shown in Figure 49.5. It is used to control rats, mice, squirrels, prairie dogs, foxes, wolves, dogs, coyotes, and rabbits. The compound is also used to control brush-tail possums, deers, wild pigs, wallabies, and rooks. It is very toxic to birds, domestic animals, and carnivores. Secondary poisoning is very common in birds and carnivores from eating poisoned carcasses.

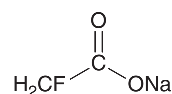

**FIGURE 49.5** Structural formula of sodium fluoroacetate.

Sodium fluoroacetate has many other names and sold under the trade names, such as Nissol, 1080 gel, 1080 paste, 1080 solution, Tenate, Tenate 1080, etc. The commercial products are provided with a black dye called nigrosine (0.5%).

## Background

Sodium fluoroacetate was discovered by German military chemists during World War II. But later on, American chemists discovered its use as rodenticide. The name "1080" refers to the catalog number of the poison, which became its brand name. The compound is an extremely toxic substance, which is commonly used as rodenticide. Inhalation of dust or swallowing can also be fatal. The compound can also be absorbed through cuts or abrasions in the skin and lead to poisoning.

It is important to mention that sodium fluoroacetate is also formed naturally in about 40 plants that are native to Australia, Brazil, and Africa, after fluoride uptake from soil, water, or air. Some of the examples of plants that contain sodium fluoroacetate are *Dichapentalum cymosum*, *D. toxicarum*, *Chailletia toxicaria*, *Gastrolobium grandiflorum* (poison peas), *Oxylobium parviflorum*, and *Acacia georginae*. Consumption of these plants has resulted in many serious cases of livestock poisoning and high stock losses (Oelrichs and McEwan, 1962). Poisoning has also been documented in field workers exposed to fluoroacetate (Suh *et al.*, 1970).

## Toxicokinetics

Sodium fluoroacetate (1080) is rapidly absorbed from the GI tract. Dust formulations are easily absorbed by inhalation, which is not usually the route for poisoning cases; 1080 is not readily absorbed through intact skin but it can be absorbed in the case of cuts, abrasions, or dermatitis (Brockman *et al.*, 1955). It is reported that sublethal doses of compound 1080 are completely metabolized and excreted in 4 days.

The bioavailability of sodium fluoroacetate appears to be similar for oral, injected, and inhaled doses. Dermal absorption is lower since a s.c. $LD_{50}$ is 10 to 15-fold higher than the oral dose. Distribution studies suggest that the plasma levels of sodium fluoroacetate are twice that of tissues. Sheep receiving sodium fluoroacetate (0.1 mg/kg) contained the residue in plasma, kidney, heart, muscle, spleen, and liver as 0.098, 0.057, 0.052, 0.042, 0.026, and 0.021 (Eason *et al.*, 1993). The plasma $t_{1/2}$ is found to be 3.6–6.9 h in goats, 6.6–13.3 h in sheep, 1.1 h in rabbits, and 1.6–1.7 h in mice (Eason *et al.*, 1993; Gooneratne *et al.*, 1995). Metabolism of fluoroacetate (i.e., defluorination) takes place in the liver. Fluoroacetate and fluorocitrate salts are excreted mainly in the urine.

## Mechanism of action

In the body, the fluoroacetate (1080) is converted to fluorocitrate which is a potent inhibitor of the enzyme aconitase in the tricarboxylic acid cycle (Krebs cycle) (Elliot and Kalnitsky, 1996). As a result, the elevated levels of citrate in blood become observable 30 min and maximum levels at 4 h after administration. It has been shown that citrate levels are directly influenced by thyroid hormone, i.e., free $T_3$ (Maruo *et al.*, 1992). Accumulation of citrate causes the toxicity due to reduction of ATP levels by inhibiting energy production in most cells of the body, leading to a slow and painful death as the body "suffocates from within". Compound 1080 causes damage to tissue of high energy needs, such as brain, heart, lungs, and fetus.

Accumulated levels of citrate cause chelation of divalent metal ions, especially $Ca^{2+}$. Depletion of these ions in CNS may be responsible for seizures in certain species (Hornfeldt and Larson, 1990).

Fluoroacetate/fluorocitrate also affects activities of other enzymes, including mitochondrial citrate carriers, pyruvate dehydrogenase kinase (Taylor *et al.*, 1977), succinate dehydrogenase (Mehlman, 1967), glutamine synthetase, phosphofructokinase (Godoy and del Carmen Villarruel, 1974), and ATP-citrate lyase (Rokita and Walsh, 1983).

## Toxicity

Most species are susceptible to fluoroacetate (1080), however, rodents and dogs are the most susceptible species. The oral $LD_{50}$ of 1080 in rats is 0.1–0.22 mg/kg, mice 0.1 mg/kg, rabbits is 0.34 mg/kg, and guinea pigs is 0.3 mg/kg. The oral $LD_{50}$ of this compound in the house sparrow, red winged blackbird, starling, and golden eagle are 3.0, 4.22, 2.37, and 1.25–5 mg/kg, respectively. Measured $LD_{50}$ of this rodenticide in mammalian wildlife, such as in mule deer is 0.22–0.44 mg/kg, male ferrets 1.41 mg/kg, and in bears 0.5–1.0 mg/kg.

In general, fluoroacetate is very toxic to mammalian, bird, and wildlife species, while it is of low toxicity to fish. Toxicity of 1080 is different according to route of exposure, i.e., ingestion or inhalation, and symptoms vary widely among species. Species have been categorized into four groups according to symptomatology (Chenoweth, 1949):

1. *Rabbit, goat, horse, sheep, and spider monkey*: CNS effects are not observed, and death is due to cardiac effects with ventricular fibrillation.
2. *Cat, pig, rhesus monkey, and human*: Heart and CNS are affected, death usually resulting from respiratory failure

during convulsions, but occasionally due to ventricular fibrillation.

3 *Dog and guinea pig*: Epileptiform convulsions predominate, with death being due to cessation of respiratory activity following running movements like those of strychnine poisoning.

4 *Rat and hamster*: Respiratory depression and delayed bradycardia is the main feature.

In general, 1080 produces convulsions, involuntary urination, vomiting, and ventricular fibrillation. The onset of symptoms of poisoning usually appears between 30 min and 4 h after exposure. The common symptoms are vomiting, involuntary hyper-extension of the limbs, convulsions, and finally cardiac and respiratory failure. Dogs usually show CNS signs, such as convulsions and uncontrollable running, while sheep and cattle show predominantly cardiac signs. Dogs appear to be highly sensitive to fluoroacetate, and mass poisonings of dogs eating contaminated poultry have been documented (Egyed, 1979).

The main target organs affected are the CNS, cardiovascular, and respiratory system. This causes metabolic derangement that includes alteration in transaminase, calcium, and glucose levels apart from acidosis and renal failure.

Clinic effects are associated with neurological and cardiac systems. CNS effects include tremulousness, hallucinations, convulsions, and respiratory depression. Cardiac effects include arrhythmias, ventricular fibrillation, and cardiac arrest. If the patient survives the first 24 h after ingestion of sodium fluoroacetate, recovery is favorable. Acute exposure often results in complete recovery or death. Of course, in some cases, exposure results in cardiac damage.

Severity of signs is found to be dose related. The oral route is the most important in cases of poisoning of 1080. Dust formulations are easily absorbed by inhalation, which is not usually the route for poisoning cases; 1080 is not readily absorbed through intact skin, but it can be absorbed in the case of cuts and dermatitis.

The fluorocitric acid is itself highly toxic, and therefore sodium fluoroacetate can cause secondary poisoning, i.e., poisoning in an organism which has consumed a part of an organism already poisoned.

In humans, one-fourth of a gram of sodium fluoroacetate could kill a grown man. The onset of signs such as nausea, mental apprehension followed by epileptiform convulsions, can occur 30 min to 2 h after oral ingestion. After a period of several hours, ventricular fibrillation occurs, which is followed by cardiac arrest and death.

The development of tolerance to increasing doses of fluoroacetate has been reported in rats and mice, whereby a dose of 0.5 mg/kg protects rats against a dose of 5 mg/kg for a period of 48 h (Chenoweth, 1949). The mechanism of fluoroacetate resistance in certain species is not well understood, but rate of defluorination does not appear to play a significant role (Mead *et al.*, 1985).

Studies suggest that sodium fluoroacetate has no carcinogenic, mutagenic, and teratogenic potential.

### *Diagnosis*

Diagnosis is based on evidence of exposure, clinical signs, necropsy findings, and chemical confirmation. Samples for chemical confirmation should include suspected bait, vomitus, stomach content, liver, and kidney. Testing for 1080 should be performed on the vomited stomach contents. In case of ruminants, rumen content needs to be analyzed for fluoroacetate. Significant elevation of citric acid levels in blood and kidney is a reliable biochemical marker of fluoroacetate or fluorocitrate poisoning (Bosakowski and Levin, 1986). Hyperglycemia, hypocalcemia, and hypokalemia are characteristic laboratory findings. Other metabolic/biochemical changes include metabolic acidosis resulting from a build up of citric acid, lactic acid, and ammonium in blood and organs. Metabolic acidosis is also associated with elevated serum creatinine and transaminase levels.

Differential diagnosis should include lead, strychnine, chlorinated hydrocarbons, and plant alkaloids.

## Treatment

There is no specific antidote for 1080 poisoning. Use of glyceryl monoacetate has shown some positive results, as it provides acetate ions to allow continuation of the cellular respiration process which the 1080 has disrupted. Other symptomatic and supportive measures following decontamination procedures (to prevent further absorption by activated charcoal) include use of anti-convulsants, muscle relaxants, and mechanical ventilation. It is important to mention that induction of emesis is contraindicated because of potential arrhythmias and convulsions. Special attention should be paid to stabilize cardiac and CNS functions.

Acetate and ethanol have been found potentially effective in mice, guinea pigs, and rabbits, but not in dogs (Tourtellotte and Coon, 1950). A combination of calcium gluconate and sodium succinate has proven effective in mice (Omara and Sisodia, 1990). Calcium chloride has antidotal effects in cats (Roy *et al.*, 1980).

## Conclusion

Fluoroacetate converts to fluorocitrate, which is an extremely toxic metabolite. Symptoms vary markedly between species. For example, carnivores exhibit more signs related to CNS, herbivores related to cardiac effects, and omnivores show signs of both CNS and cardiac. Treatment relies upon symptomatic and supportive measures.

# ALPHA-NAPHTHYL THIOUREA

## Introduction

Alpha-naphthyl thiourea (ANTU) is a colorless, odorless, crystalline powder, which is exclusively used as rodenticide. Technical product is gray powder. It has chemical formula $C_{11}H_{10}N_2S$ with a molecular weight of 220.28, and its structural formula is shown in Figure 49.6.

ANTU has several other names, such as alpha-naphthyl thiocarbamide, 1-naphthyl-thiourea, N(1-naphthyl)-2 thiourea, Alrato, Anturat, Bantu, Dirax, Krysid, Rat-tu, and Rattrack, etc.

## Toxicokinetics and mechanism of action

Following ingestion, ANTU is rapidly absorbed from the GI tract. ANTU has a specific effect on the capillaries of the lungs leading to the rapid development of pleural effusion and pulmonary edema. This results in anorexia and respiratory failure.

## Toxicity

All animals are susceptible to ANTU, but lethal doses differ widely. Lethal doses of ANTU (expressed in terms of mg/kg) in various species are as follows: rats (3), dogs (10), pigs (25), horses (30), cows (50), cats (75), and fowl (2500). The acute oral $LD_{50}$ of ANTU in rats is 6 mg/kg and in dogs 0.38 mg/kg.

Clinical signs of poisoning due to ANTU include vomiting, abdominal pain, dyspnea, shortness of breath, seizures, bluish discoloration, coarse pulmonary rales, pulmonary edema, and liver damage.

In a time course study, ANTU at the dose rate of 5 mg/kg induced lung edema in adult albino rats (Vivet *et al.*, 1983). After 6 h, pulmonary extravascular water increased by 50% in ANTU-treated rats and the volume of the pulmonary effusion reached 3.4 ± 0.1 ml. The most characteristic feature is the absence of hypoxemia in the ANTU-treated rats. The absence of hypoxemia is common with normobaric oxygen. ANTU can produce hyperglycemia of 3 times normal in 3 h.

Chronic sublethal exposure to ANTU may cause enlarged thyroid gland (goiter) and interfere with normal thyroid function.

It is important to mention that repeated sublethal doses in rats leads to the development of tolerance so that resistance to several lethal doses is developed (Peoples, 1970).

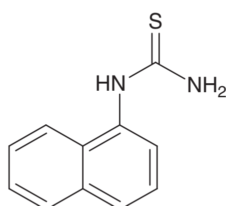

**FIGURE 49.6** Structural formula of ANTU.

### *Diagnosis*

Diagnosis of ANTU poisoning is based on evidence of rodenticide exposure, clinical signs, lung and liver damage, and chemical confirmation. ANTU can be quantified using HPLC.

## Treatment

There is no specific antidote. So, treatment relies upon symptomatic and supportive measures. Induce vomition if the patient is not showing convulsions and seizures.

Decontamination procedure includes administration of activated charcoal.

# ZINC PHOSPHIDE

## Introduction

Zinc phosphide is an inorganic compound with appearance of gray crystalline powder and a decaying fish or garlic odor. It has chemical formula $Zn_3P_2$ with a mol. wt. of 258.1. Its structural formula is shown in Figure 49.7. Zinc phosphide was first synthesized in 1740 and was first used as a rodenticide in 1911–1912 by the Italians. But in the United States it was not used until 1939. In the 1970s, there was a renewed interest in zinc phosphide for rodent control in agriculture. Presently, zinc phosphide is used worldwide for the control of a range of animals, including mice, rats, voles, ground squirrels, prairie dogs, moles, muskrats, rabbits, and gophers. Pelleted zinc phosphide is sold extensively under the brand names such as Arrex, Blue-ox, Gopha-rid, Kil-rat, Mous-con, Phosvin, Pollux, Ratol, Ridall, Rodenticide AG, Zinc-tox, and ZP. It is also used on crop/non-crop areas, including lawns, golf courses, and around wetlands.

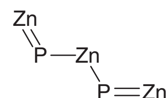

**FIGURE 49.7** Structural formula of zinc phosphide.

## Background

The history of use of zinc phosphide as a rodenticide dates back almost a century. In the early years, technical zinc phosphide and highly concentrated paste were sold in shops and used by consumers to make up their own baits for rodents. This led to use of the technical material for suicide or accidental deaths in small children and pets.

Zinc phosphide is recognized as the slowest acting of the commonly used rodenticides. It can cause toxicity and death in rodents after one feeding, if adequate dose is consumed. But bait must be continuously available to be effective. In fact, zinc phosphide is recommended as the rodenticide of choice because it is fairly specific for rodents and the secondary poisoning is rare, except in dogs and cats.

Presently, rodenticide-grade zinc phosphide usually comes as a black powder containing 75% of zinc phosphide and 25% of antimony potassium tartrate, an emetic to cause vomiting if the material is accidentally ingested by humans or domestic animals.

## Toxicokinetics

Zinc phosphide can be absorbed into the body by oral ingestion, inhalation, and through damaged skin. Following oral ingestion, zinc phosphide reacts in the stomach and intestine with water and hydrochloric acid to liberate phosphine gas. Metabolism of zinc phosphide can occur via oxidation of the phosphorus to various phosphorus oxyacids or via reduction of the phosphorus to phosphine gas. Zinc phosphide excretes in the urine either as a hypophosphite or as dissolved phosphine. The presence of strong reducing substance in the urine is a common feature of poisoning with zinc phosphide. Other metabolites include phosphoric acid and phosphate. Phosphine gas is also exhaled from the lungs.

## Mechanism of action

The overall toxicity of zinc phosphide is due to both zinc and phosphine gas, but it is primarily from phosphine. Phosphine can enter the blood stream and adversely affects the lungs, liver, kidneys, heart, and CNS. Phosphine causes CNS depression, irritation of the lungs, and damage to the blood vessels and erythrocyte membranes, and eventually cardiovascular collapse and irritation of the alimentary tract. Zinc phosphide also causes damage to the liver and kidney.

## Toxicity

Zinc phosphide is an extremely toxic compound. The oral $LD_{50}$ in rats is 41 mg/kg body wt. In sheep the $LD_{50}$ ranges from 60 to 70 mg/kg. It is very toxic to cows, sheep, goats, pigs, rabbits, and other animals. Following oral ingestion, both zinc phosphide and phosphine are absorbed from the GI tract, although the majority of acute effects are caused by phosphine. Zinc phosphide causes damage to the liver and kidney. Phosphine causes CNS depression, irritation of the lungs, and damage to the liver, kidney, heart, and CNS. Death occurs as a result of heart failure, and more commonly pulmonary edema, although there are reports of heart failure accompanied by kidney damage. Following a large dose, death usually occur within an hour, while with smaller doses, death can occur between 4 and 72 h. Symptoms usually appear after 20–25 min. Animals are prostrated with deep slow respiration, finally terminating in convulsions. It is important to mention that following repeated exposure, cumulative effects occur in the liver, kidney, and lungs.

In humans, the symptoms of acute toxicity include nausea, shock, weak heartbeat, low blood pressure, and loss of consciousness. Other symptoms include vomiting, diarrhea, cyanosis, restlessness, and fever. There are documented cases of adults dying from massive doses of the zinc phosphide (4–5 g), while others have survived acute exposure of as high as 25–100 g of zinc phosphide if vomiting occurred early and absorption was limited (Ecobichon, 1991). The inhalation of zinc phosphide or phosphine gas also results in acute toxicity.

Zinc phosphide is highly toxic to wild animals and birds, and freshwater fish. The most sensitive bird species which have been evaluated are geese ($LD_{50}$, 7.5 mg/kg). Pheasants, morning doves, quails, mallard ducks, and horned larks are very susceptible to this rodenticide. The fish species which have been found susceptible to zinc phosphide include bluegill sunfish, rainbow trout, and carp.

### *Diagnosis*

Diagnosis of zinc phosphide in animals is based on detection of zinc phosphide, phosphine, and zinc. At necropsy, stomach content smells like acetylene. Zinc phosphide level at or above 50 ppm in stomach content is considered significant and is indicative of zinc phosphide poisoning.

## Treatment

There is no specific antidote and treatment is mainly symptomatic. Vomiting should be induced as soon as possible after ingestion, followed by the administration of activated charcoal. Sodium bicarbonate can be given orally to stop liberation of phosphine gas. Calcium gluconate and sodium lactate can be given i.v. to combat acidosis.

## Conclusions

Zinc phosphide is a rodenticide of high toxicity. At acidic pH in stomach, zinc phosphide generates phosphine gas which is responsible for the majority of toxic effects. There is no specific antidote and treatment is symptomatic.

CHAPTER

# 50

# Avitrol

*Ramesh C. Gupta*

## INTRODUCTION

Avitrol (4-aminopyridine) is white, odorless, crystalline sand-like material. It has a chemical formula of $C_5H_6N_2$ with a molecular weight of 94.1 kDa. Its chemical structure is shown below in Figure 50.1.

4-aminopyridine was developed by Phillips Petroleum Company and marketed in 1963 as an avicide under the name "Avitrol". It was also considered bird repellent. Presently, it is a product of Avitrol Corp. (Tulsa, Oklahoma). Avitrol has many other names, including 4-AP, 4-pyridylamine, 4-pyridamine, and amino 4-pyridine. Presently, avitrol is used to control overpopulation of certain birds that are considered as pest birds, including pigeons, red-winged blackbirds, blackbirds, cowbirds, grackles, sparrows, starlings, gulls, crows, and others.

Depending upon the bird species to be controlled, the formulation can be prepared in grain/corn or bread. Avitrol is available in various formulations, such as grain baits (0.5%, 1%, and 3%), powder concentrate (25% and 50%), and powder mix (50% and 25% concentrate). Presently, according to EPA, grain bait formulations of 4-aminopyridine are in toxicity Class III, while powder concentrate formulations are in toxicity Class I. Avitrol is intend to make few birds in the flock sick, i.e., the sick birds thrash around and scare off the other birds. In higher doses, avitrol can not only be toxic or lethal to birds, but it can also be lethal to non-target species. This chapter describes toxicity of avitrol in birds, mammals, and fish.

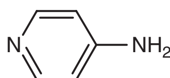

**FIGURE 50.1** Structural formula avitrol.

## BACKGROUND

Scientists have been seeking an ideal way to control pest birds that destroy crops, feed/grain meant for livestock, and ruin the look of beautiful buildings and monuments. A number of chemicals have been investigated for their ability to repel birds (Clark, 1998; Dolbeer *et al.*, 1998; Stevens and Clark, 1998). Presently, avitrol (4-aminopyridine) is the most popular avicide which is registered at the EPA for control of certain pest birds that feed on cattle feed lots, field corn, wheat, sorghum, sunflowers, peanuts, pecans, grain, feed processing plants, etc. Avitrol is also used to drive away birds from monuments, airports, warehouse premises, and other public buildings (Thomson, 1991–1992). Upon ingestion, in certain birds avitrol causes utter vocalization and physical distress (i.e., hyperactive), which acts as an area repellency to the remainder of the flock, so-called "flock frightening syndrome" (Spyker *et al.*, 1980; Meister *et al.*, 1984). Avitrol is toxic to birds, mammals, and fish. Wildlife feeding on treated bait can also be killed. In recent years, use of avitrol has been banned in many cities, including New York, NY; San Francisco, CA; and Boulder, CO, because of its toxicity to non-target species. Many field cases of avitrol poisoning have been reported in birds, domestic, wildlife, and zoo animals (Schafer, 1972; Schafer *et al.*, 1974; Nelson *et al.*, 1976; Ray *et al.*, 1978; Spyker *et al.*, 1980; Frank *et al.*, 1981; Nicholson and Prejean, 1981; Conover, 1994).

## TOXICOKINETICS

Like other aminopyridines, 4-aminopyridine is rapidly absorbed from the gastrointestinal (GI) tract into circulation.

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

The compound is readily metabolized in the liver and metabolites are excreted in urine. About 90% of the administered dose, following intravenous (i.v.) or oral administration, excretes in the urine.

## MECHANISM OF ACTION

In acute toxicity, central nervous system (CNS) is the target organ, while in chronic toxicity CNS and liver are the target organs. 4-aminopyridine blocks potassium ion channels and increases acetylcholine (ACh) levels at the synapses and neuromuscular junctions (Rowan, 1985). This results in hyperactivity, convulsions, and seizures. In acute toxicity, birds and animals suffer immensely. Avitrol impairs bird's nervous system, and as a result birds become disoriented and exhibit erratic flight and tremors and violent convulsions for hours before they finally succumb to death. Avitrol also causes excess methemoglobin formation, which is unable to carry oxygen to tissues and that leads to respiratory distress.

## TOXICITY

Avitrol is highly toxic to all species of birds. It is also toxic to mammals, humans, fish, and wildlife. The oral acute $LD_{50}$ values (expressed as mg/kg body weight) for avitrol are reported to be as 10–12 (chickens), 8 (gulls), 3 (crows), 5.6 (pheasants), 15 (bobwhite quail), 8 (mourning dove), and 3.8–4 (sparrows), 5–6 (starlings), 4–7 (pigeons), 9 (blackbirds), and 3.2 (boat-tailed grackle) (NPCA, 1972). The oral acute $LD_{50}$ value in rats is 20 mg/kg (Meister *et al.*, 1984) and in dogs is 3.7 mg/kg (NPCA, 1972). The dermal $LD_{50}$ of technical grade 4-aminopyridine in rabbits is 326 mg/kg (NPCA, 1972).

Avitrol produces toxicity in birds in a dose-dependent manner, i.e., birds exposed with a low dose exhibit utter distress calls, while with higher dose they become incapacitated and die. Birds exposed to avitrol usually show onset of signs within 5–15 min and signs of severe intoxication for a period of 30–60 min. Poisoned birds become disoriented and exhibit erratic flight. Eventually, they are unable to stand or sit in sternal position, and show tremors and convulsions for a brief period to hours (Conover, 1994). In a case report, Bischoff *et al.* (2001) described the primary signs of poisoning in crows as frequent vocalization, CNS abnormalities, and inability to fly or walk. "Downed" birds either die or recover within 1–15 h (NPCA, 1972). Intoxicated birds with avitrol that react and alarm a flock usually die.

It is important to mention that non-target species including mammals are equally sensitive to the toxicity of avitrol. In mammals, avitrol produces symptoms like epileptic seizures. Doses near $LD_{50}$ exert a usual sequence of symptoms including hyperexcitability, salivation, tremors, muscle incoordination, convulsions, and cardiac and respiratory failure. Most of these symptoms are associated with hypercholinergic activity. In general, onset of signs occurs within 10–15 min and death occurs within 15 min to 4 h. It needs to be mentioned that predators such as raptors, foxes, hawks, cats, and dogs die from secondary poisoning after feeding on the dead or dying birds. Secondary poisoning has also been found in endangered birds, including red-tailed hawks and peregrine falcons, as they died by ingesting the remains of pigeons and other birds poisoned with avitrol.

In humans, avitrol is known to cause seizures. Exposed individuals exhibit weakness, diaphoresis, altered mental status, and hypertension. Other symptoms include thirst, nausea, dizziness, weakness, ataxia, tremors, dyspnea, and tonic–clonic convulsions. Avitrol also produces metabolic acidosis, leukocytosis, and elevations of serum enzymes (GOT, LDH, and alkaline phosphatase) as notable laboratory findings. Death occurs due to respiratory failure.

Dermal exposure to avitrol can lead to systemic intoxication or general overall poisoning. Very few chronic studies have been done and no conclusive findings are reported. Presently, studies are not available to suggest that avitrol has any potential for mutagenic, teratogenic, or carcinogenic activity.

In fish, avitrol has been found to be moderately toxic (Extoxnet). Fish become increasingly sensitive with increased exposure. The $LC_{50}$ ranges from 4 mg/l (in soft water) to 2.43 mg/l (in hard water) in channel cat fish. The $LC_{50}$ is 3.40 mg (in soft water) to 3.2 mg/l (in hard water) in bluegill.

Diagnosis of avitrol poisoning is based on history of exposure, clinical signs, pathologic findings, and residue determination of 4-aminopyridine in crop, GI content, or tissues. The crop and GI content have the highest content of 4-aminopyridine. Small residue can also be found in the liver, heart, muscle, kidney, brain, and lung. The residue of 4-aminopyridine can be determined by TLC, HPLC, or GC/MS.

## TREATMENT

Pancuronium is a pharmacologic antidote and is recommended in severely poisoned human patients. Propranolol appears to block some of the cardiac toxicity (such as cardiac arrhythmias) of 4-aminopyridine. Seizures can be treated with diazepam (0.1 mg/kg, i.v.). In severe cases,

phenobarbital or phenytoin can be given, if no response to diazepam. In case of avitrol ingestion, general symptomatic and supportive treatment includes emesis, gastric lavage, activated charcoal, and cathartic sodium thiosulfate. Bicarbonate should be added to the fluids to treat acidosis.

## CONCLUSIONS

Avitrol is commonly used to deter pest birds from roosting and nesting. The compound is toxic to all species of birds. It is also toxic to mammals, birds, and fish. Secondary poisoning is very common in non-target birds and dogs. Avitrol produces toxicity by affecting CNS, and as a result, toxic signs are of hyperactivity, such as convulsions and seizures.

# Toxicity of herbicides

*P.K. Gupta*

## INTRODUCTION

Herbicides are phytotoxic chemicals used for destroying various weeds or inhibiting their growth. They have variable degree of specificity. Some, for example paraquat, kill all green plants, whereas phenoxy compounds are specific for certain group of plants. The worldwide consumption of herbicides is almost 48% of the total pesticide usage. The consumption of herbicides in developing countries is low because weed control is mainly done by hand weeding (Gupta, 2004). Many of the earlier chemicals used as herbicides include sulfuric acid, sodium chlorate, arsenic trioxide, sodium arsenate, petroleum oils, etc. Iron and copper sulfate or sodium borate were generally hard to handle and/or were toxic, relatively non-specific, or phytotoxic to the crop as well as the unwanted plant life if not applied at exactly the proper time. The biochemical differences in plant make it possible to design herbicides that have selective toxicity potential against various species of plants. In the past two decades, the herbicides have represented by the most rapidly growing section of the pesticide industry due in part to (i) movement into monoculture practices and (ii) mechanization of agricultural practices because of increased labor costs. The result has been a plethora of chemically diverse structures rivaling the innovative chemistry so as to develop synthetic organic herbicides that are quite selective for specific plants and have low mammalian toxicity. The aim is to protect desirable crops and obtain high yields by selectively eliminating unwanted plant species, thereby reducing the competition for nutrients.

Most of the animal health problems that result from exposure to herbicides are due to their improper use or careless disposal of containers. Very few problems occur when these chemicals are used properly. However, there is increased concern about the effects of herbicides on animal health because of run-off from agricultural applications and entrance into drinking water supply (Gupta, 1986, 1988).

## BACKGROUND

The first discovery in the field of selective weed control was the introduction of 2,4-dinitro-*o*-cresol (DNOC) in France in 1933. This is very toxic to mammals and can cause bilateral cataract in man. In 1934, phenoxy herbicides were developed and 2,4-dichlorophenoxyacetic acid (2,4-D) was introduced as a potent herbicide (Gupta, 1985). During World War II, considerable effort was directed toward the development of effective, broad-spectrum herbicides with a view to both increasing food production and finding potential chemical warfare agents (Gupta, 1989). One chemical class of phenoxy derivatives including the acids, salts, amines, and esters were the first commercially available products evolving from this research in 1946. This class of herbicides has been in continuous, extensive, and uninterrupted use since 1947 and is the most widely used family of herbicides. The chemical class of herbicides deserving particular attention is the bipyridyl group, specially paraquat and diquat. Weidel and Russo first described the structure of paraquat in 1882. In 1933, Michaelis and Hill discovered its redox properties and called the compound methyl viologen. Its herbicidal properties were discovered by ICI in 1955 and it became commercially available in 1962 (Smith, 1997).

Ureas and thioureas are a group of herbicides used for general weed control in agricultural and non-agricultural practices. The first urea herbicide, *N*,*N*-dimethyl-*N*′ (chlorophenyl)-urea was introduced in 1952 by Du Pont

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

under the common name of monuron. In subsequent years, many more derivatives of this class of compounds have been marketed (Liu, 2001).

Protopyrinogen oxidase (Protox)-inhibiting herbicides have been used since 1960s and now represent a relatively large and growing segment of the herbicide market. Nitrofen was the first Protox-inhibiting herbicide to be introduced for commercial use in 1964. This diphenyl ether (DPE) herbicide was eventually recognized as a relatively weak inhibitor of Protox, but was a lead compound of an entire class of structurally related herbicides that were much more active. Subsequently several DPE herbicides have been successfully commercialized (Nandihalli *et al.*, 1992; Anderson *et al.*, 1994).

Subsitituted aniline, an alachlor herbicide was registered and introduced in 1967 for the pre-plant or pre-emergent control of a broad spectrum of grass, sedge, and broad leaf weeds (Heydens *et al.*, 2001). Recently inhibitors of aromatic acid biosynthesis herbicides (organic phosphorus) such as glyphosate, broad-spectrum, non-selective, post-emergent, systemic herbicide with activity on essentially all annual and perennial plants have been developed. Monsanto discovered the herbicidal properties of glyphosate in 1970, and the first commercial formulation was introduced in 1974, under the Roundup brand name. There are other triazine and triazole herbicides, which are extensively used in agriculture in the United States and other parts of the world for more than 40 years (Steven and Summer, 1991). The triazines inhibit photosynthesis (Gysin and Knuesli, 1960). Dicamba is another organic (benzoic) acid herbicide that acts by mimicking the effects of auxins (i.e. natural plant growth hormones), causing enhanced but uncontrolled growth rates, alterations in plant function homeostasis, and death (Harp, 2001). Another class of synthetic chemical compounds called the imidazolinone herbicides was discovered in the 1970s, with the first US patent awarded in 1980 for imazamethabenz-methyl. New families of herbicides introduced since 1970s account for increasing shares of use and include bipyridyl (paraquat), bentazon, fenaxalactogen, oxyfluorfen, clomazone, clorpyralid, fluazifop, norfluorazon, etc. Now the use of newer compounds having low toxicity is quite common (Osteen and Padgitt, 2002).

## TOXICOKINETICS

Toxicokinetics is associated with the absorption, distribution, metabolism, and excretion of drugs and xenobiotics. Toxicokinetics studies provide important data on the amount of toxicant delivered to a target as well as species-, age-, and gender-specific metabolism. Animals are exposed to herbicides of different chemical classes. They may be ingested or absorbed through the skin or the respiratory system. Different factors regulate their absorption, distribution, metabolism, and excretion (Gupta, 1985). In general, liver is the primary site for biotransformation and may include activation as well as detoxification reactions through cytochrome P450-dependent monooxygenase system, the flavin-containing monooxygenase, esterases, and a variety of transferases, most notably the glutathione (GSH) *S*-transferases (Hodgson and Meyer, 1997).

Absorption of phenoxy acid derivatives occurs rapidly from stomach and intestines and peak levels reach in 10 min to 24 h depending on species, dose, and chemical form. Following oral exposure to 2,4-D plasma half-lives, range from 3.5 to 18 h approximately. The compound is protein bound *in vivo* and is rapidly distributed to the liver, kidneys, and brain. 2,4-D is not metabolized to reactive intermediates, does not accumulate in tissues, and is excreted predominantly as the parent compound. The salts and esters of 2,4-D undergo acid and/or enzymatic hydrolysis to form 2,4-D acid, may be small amounts are conjugated with glycine or taurine. Excretion can be markedly enhanced by ion trapping using alkaline agents, as most of these herbicides are organic acids (Erne, 1966a, b; Pelletier, *et al.*, 1989).

Another organic acid herbicide dicamba is rapidly and non-selectively distributed to most of the organs. Ninety per cent excretion is through urine and small amounts in feces. Dicamba is mostly unmetabolized but may be conjugated with glucuronic acid or glycine. Elimination occurs rapidly, and there is no evidence of bioaccumulation in mammalian system (Harp, 2001).

Bipyridyl derivative paraquat is rapidly but incompletely absorbed from the gastrointestinal (GI) tract of laboratory animals and humans, with plasma concentration of 20–90 min and poorly absorbed through contact skin. Distribution studies show higher radioactivity in Type I and Type II epithelial cells and the Clara cells of the rodent and human lungs, which are the major target cells for paraquat toxicity (Smith, 1997). The presence of radioactive has also been detected in choroid plexus, muscle, and melanin in addition to excretory pathways such as the proximal tubules of the kidney, urine, liver, gall bladder, and intestinal contents of the mouse indicating some biliary excretion (Waddell and Marlowe, 1980). Paraquat is taken up into the brain via the neural amino acid transporter, thus may be a factor in the etiology of Parkinson's disease. The amount of paraquat excretion in feces corresponds to 60–70% of the ingested dose (Van Dijck *et al.*, 1975). Paraquat is very poorly metabolized and bulk is excreted unchanged in the urine and feces. The transport mechanism for organic cations in renal proximal tubular cells is not fully understood, however, presence of two membrane proteins, organic cation transporter 1 (OCT1) and organic cation transporter 2 (OCT2) have been isolated from rat kidney. The OCT1 located at the basolateral membrane will transport tetra ethyl ammonium, and this can be inhibited by other organic cations such as quinine. The OCT2 stimulates the uptake of

tetra ethyl ammonium and this can be markedly inhibited by cimetidine. The transport of paraquat can be blocked by the addition of the divalent cation quinine, cimetidine, and to a lesser extent tetra ethyl ammonium suggesting that paraquat may be transported by both transport systems, an electro neutral organic cation/$H^+$ exchange and P-glycoprotein (Chan *et al.*, 1998). A schematic representation of the proposed transport systems for paraquat across renal tubular is shown in Figure 51.1.

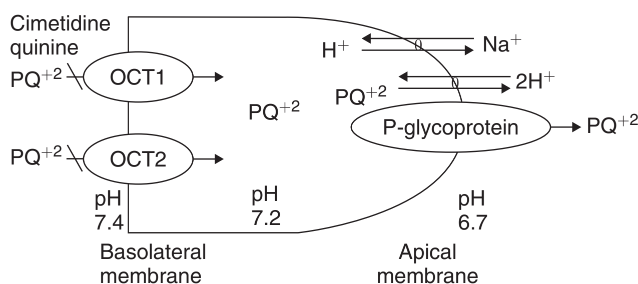

**FIGURE 51.1** A schematic representation of the proposed transport systems for paraquat across renal tubular cells. The transporters are OCT1 and OCT2 at the basolateral membrane and P-glycoprotein and the cation/$H^+$ exchange system at the brush border membrane. From Chan *et al.* (1998). Reproduced with permission.

Unlike paraquat, diquat does not accumulate in the lungs, however, the presence is observed in liver, kidney, plasma, and adrenal gland. Diquat does not enter the brain (Rose *et al.*, 1976). Following oral administration 90–98% of the dose is eliminated via the urine (Daniel and Gage, 1966). Metabolism studies indicate some unidentified metabolites of diquat in the urine of rabbits and guinea pigs. In rat, diquat monopyridone has been identified in the feces, at about 5% of an oral dose, while diquat–dipyridone has been detected in urine. These results indicate that diquat, probably is metabolized by GI bacteria (JMPR, 1993).

Ureas and thioureas such as diuron and linuron are mainly metabolized by dealkalization of the urea methyl groups. Hydrolysis of diuron to 3,4-dichloroaniline and oxidation to 3,4-dichlorophenol as well as dehydroxylation at carbon 2 and/or 6 of the benzene ring, have also been reported. The predominant metabolite of diuron in urine is *N*-(3,4-dichlorophenyl)-urea. Diuron is partially excreted unchanged in feces and urine (Boehme and Ernst, 1965; Hodge *et al.*, 1967). The storage of diuron does not occur in tissues.

Organo phosphorus herbicides such as glyphosate and glufosinate are poorly absorbed both orally and via dermal route. There is rapid elimination, these are not biotransformed and do not accumulate in tissues. More than 70% of an orally administered dose of glyphosate is rapidly eliminated through feces and 20% through urine. The main metabolite of glyphosate is aminomethylphosphonic acid (AMPA); the AMPA is of no greater toxicological concern than its parent compound (JMPR, 2004).

The Proton class of oxidase inhibitor herbicides is either not readily absorbed and/or are rapidly degraded by metabolism and/or excreted. The mammalian metabolites are similar to photochemical degradation products. In mammals, there are remarkable species differences in the levels of porphyrin accumulation resulting from exposure to Protox inhibitors. There is no bioaccumulation risk in animals. Metabolism of Protox inhibitors have been studied in a number of species, including rats, rabbits, goats, sheep, cattle, and chicken. In general, the metabolic degradation of these compounds by animals includes nitro reduction, de-esterification, and conjugation to GSH, cysteine, and carbohydrates. Most of the metabolites are excreted in urine, with small amounts excreted in feces and milk. In chickens, approximately 95% of the metabolites are eliminated in excreta, with small amounts (0.09%) eliminated in the eggs (Hunt *et al.*, 1977; Leung *et al.*, 1991).

The carboxyester group of the triazolinone herbicide carfentrazone ethyl is initially metabolized to a carboxylic acid group. Other metabolites identified in rats and lactating goats include hydroxymethylpropionic acid and cinnamic acid derivatives, which are further metabolized to yield a benzoic acid derivative (Aizawa and Brown, 1999).

Substituted anilines are well absorbed in rats orally. The dermal penetration in monkeys is relatively slow. The metabolism of alachlor in rats is complex due to extensive biliary excretion, intestinal microbial metabolism, and enterohepatic circulation of metabolites. The main route of excretion is urine and feces, and nearly 90% of the dose is eliminated in 10 days. The metabolism in rats and mice is similar, however, there are significant quantitative differences between the two species. In contrast, alachlor is metabolized in monkeys to a limited number of GSH and glucuronide conjugates which are excreted primarily via kidney. Excretion in monkeys is more rapid than rodents with approximately 90% being excreted in the urine within 48 h. Alachlor metabolites undergo biliary excretion and hepatic circulation in rodents, whereas, biliary excretion is limited in monkeys. In rats, acetochlor is rapidly metabolized to several polar metabolites and more than 95% are quickly excreted in urine and feces. The metabolites are the result of the mercapturic acid pathway formed by initial GSH conjugation. As in case of alachlor, acetochlor and propachlor also undergo glucuronide conjugate, and enterohepatic circulation (Millburn, 1975; Heydens *et al.*, 2001).

Dimethenamid, an amide derivative is slowly but well absorbed after oral administration (90% in rats) and is extensively metabolized in rats. The maximum concentration in blood is not achieved until about 72 h. Excretion is primarily via bile. By 168 h after treatment, an average of 90% of the administered dose is eliminated. In rats, the concentration of radioactivity in blood decreases more slowly than in other tissues and is associated with specific binding to globin (not in human). Metabolism is primarily via the GSH conjugation pathway, but racemic dime-thenamid is

also metabolized by cytochrome P450 enzymes via reductive dechlorination, oxidation, hydroxylation, *O*-demethylation, and cyclization pathways, as well as conjugation with glucuronic acid. Unchanged dimethenamid in excreta accounts for only 1–2% of the administered dose, more than 40 metabolites have been detected (JMPR, 2005).

In rats, the triazolopyrimidine compounds are rapidly absorbed and urinary elimination is rapid with half-lives ranging from 6 to 12 h. The excretion is mainly through urine and small amounts are excreted in feces. The only metabolite present is the 4-OH phenyl derivative and/or oxidation product. In metosulam toxicity, demethylation of the 3-methyl moiety of the phenyl ring and of the 3-methoxy moiety of the pyridine ring and other conjugation products of the parent material have been observed. Other minor metabolites include hydroxylated products of the pyridine ring, though the position of hydroxylation has not been identified. Due to rapid elimination, there is little potential to accumulate in the tissues (Hanley and Billington, 2001).

## MECHANISM OF ACTION

There are a number of biochemical changes or free radical-mediated processes; some may also be produced by other mechanisms that have been used to assess tissue injury. For example, the loss of tissue GSH may reflect alkylation reactions, not oxidation. Furthermore, the some free radical-mediated changes that may cause injury are also the result of injury. This is exemplified by the phenomenon of lipid peroxidation that is invoked as a toxic mechanism in many situations, but also occurs subsequent to cell death and membrane lysis. Under most of the situations, it becomes difficult to pin point the exact mechanism of action. The mechanism of action of phenoxy derivatives, triazines, triazolopyrimidines, imidazolinones, dinitroaniline, and many other classes of herbicides is not precisely known. However, phenoxy compounds are known to depress ribonuclease synthesis, uncouple oxidative phosphorylation, and increase the number of hepatic peroxisomes. The relationship of these biochemical changes to clinical effect is not clear. In dogs these herbicides may directly affect muscle membranes (Sandhu and Brar, 2000). Herbicides such as 2,4-D, 2,4,5-T, and dicamba act as peroxisome proliferators. Oxadiazinon causes hepatic porphyria in both mice and rats. The phenyl urea herbicides linuron and monuron are rodent liver carcinogens. The chloroacetanilide and metolachlor have shown weak hepatocarcinogenicity in female rats and is non-genotoxic suggesting a tumor-promoting action. The dinitro compounds markedly stimulate respiration while simultaneously impair adenosine triphosphate synthesis. The main toxic action is uncoupling of oxidative phosphorylation, converting all cellular energy in the form of heat and causing extreme hyperthermia. In addition, the gut flora in ruminants is able to further reduce the dinitro compounds to diamine metabolites which are capable of inducing methemoglobinemia.

The available information on substituted anilines indicates that there is non-genotoxic mechanism of action and lack of relevance to human for the nasal turbinate, stomach, and/or thyroid oncogenic effects produced in rats. The data support grouping for alachlor, acetochlor, and butachlor with respect to a common mechanism of toxicity for nasal turbinate and thyroid tumors, and alachlor and butachlor for stomach tumors (Heydens *et al.*, 2001).

The mechanism of action of paraquat and diquat is very similar at the molecular level and involves cyclic reduction–oxidation reactions, which produce reactive oxygen species and depletion of nicotinamide adenine dinucleotide phosphate hydrogen (NADPH). However, the critical target organ differs with the two compounds, so that the mammalian toxicity is quite different. While both herbicides affect kidneys, paraquat is selectively taken up in the lungs. Paraquat causes pulmonary lesions as a result of Type I and Type II pneumocytosis. The primary event in the mechanism of toxicity within cells is its ability to undergo a single electron reduction from the cation to form a free radical that is stable in the absence of oxygen. If oxygen is present, a concomitant reduction of oxygen takes place to form superoxide anion ($O_2^-$). Superoxide radical in turn is non-enzymatically converted to singlet oxygen, which attacks polyunsaturated lipids associated with cell membranes to form lipid hydroperoxides. Lipid hydroperoxides are normally converted to non-toxic lipid alcohols by the selenium-containing GSH-dependent enzyme, GSH peroxidase. Selenium deficiency, deficiency of GSH, or excess lipid hydroperoxides allows the lipid hydroperoxides to form lipid-free radicals. Lipid hydroperoxides are unstable in the presence of trace amounts of transition metal ions and decompose to free radicals, which in turn cause further peroxidation of polyunsaturated lipid in a process that is slowed down by vitamin E. Peroxidation of the membranes could, in turn, cause cellular dysfunction and hence lead to cell damage or death (Smith, 1997). A schematic diagram incorporating these elements of the mechanism of paraquat toxicity is shown in Figure 51.2.

The mechanism of action of diquat differs somewhat from paraquat because it undergoes alternate reduction followed by reoxidation, a process known as redox recycling. Like paraquat, diquat can redox cycle, the major difference being that diquat can more readily accept an electron than paraquat (Gage, 1968). The major target organs are the GI tract, the liver, and the kidneys. Unlike paraquat, diquat shows no special affinity for the lung and does not appear to involve the same mechanism that selectively concentrates paraquat in the lung (Rose and Smith, 1977).

Glyphosate, a member of phosphonomethyl amino acid group selectively inhibits the enzyme 5-enolpyruvoylshikimate 3-phosphate synthetase. The enzyme plays

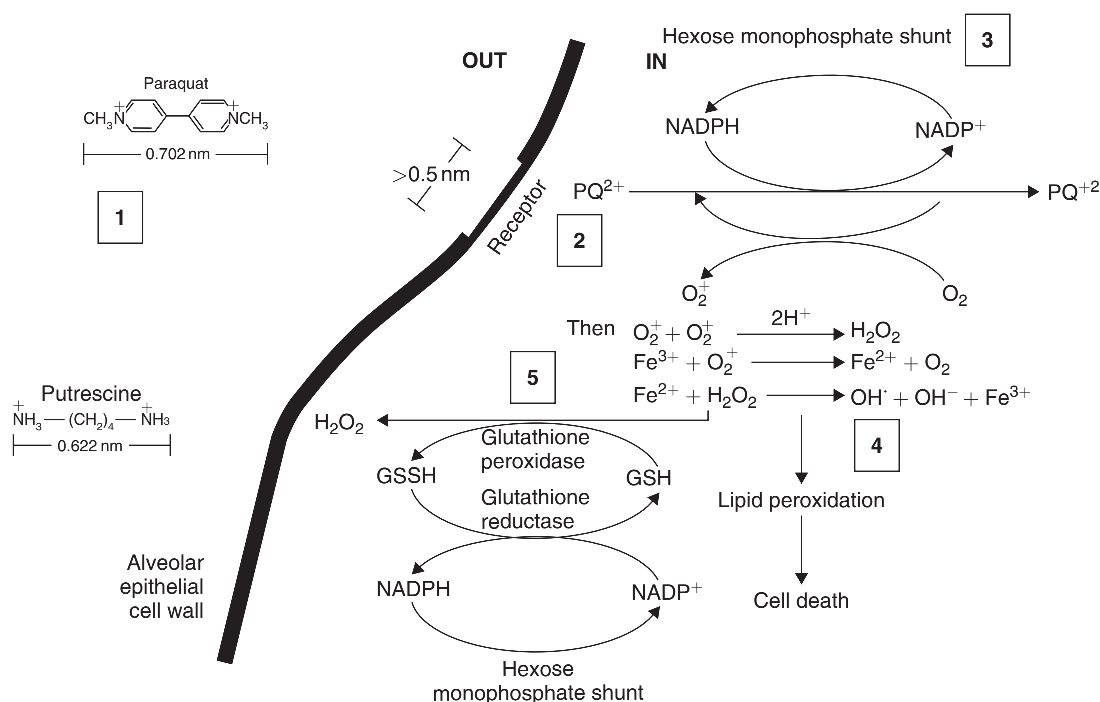

**FIGURE 51.2** Schematic representation of mechanism of toxicity of paraquat. (1) Structure of paraquat and putrescine; (2) putative accumulation receptor; (3) redox cycling of paraquat utilizing NADPH, (4) formation of hydroxyl radical ($OH^{\bullet}$) leading to lipid peroxidation; and (5) detoxication of $H_2O_2$ via GSH reductase peroxidase couple, utilizing NADPH. From Smith (1997). Reproduced with permission.

a key role in the biosynthesis of the intermediate, chorismate, necessary for the synthesis of the essential amino acids phenylalanine, tyrosine, and tryptophan. This aromatic amino acid biosynthesis pathway is found in plants as well as fungi and bacteria but not in insects, birds, fish, mammals, and humans, thus providing a specific selective toxicity to plant species (Franz *et al.*, 1997). Another compound of this group, glufosinate acts by inhibiting the enzyme glutamine synthetase in animals. Glutamine synthetase in mammals is involved in ammonia homeostasis in many organs and the glutamine–glutamate shunt between gamma-aminobutyrate and glutamate in the central nervous system (CNS). However, the enzyme is normally working at a small fraction of its capacity, and considerable inhibition is required in mammals before ammonia levels increase. Hence this does not lead to a problem in ammonia metabolism, the mammals obviously compensating by using other metabolic pathways (Hack *et al.*, 1994; JMPR, 2000).

## TOXICITY

There are more than 200 active ingredients used as herbicides, however, some of them are believed to be obsolete or discontinued for use. Out of these, several of them have been evaluated for their toxic potential and acceptable daily intake has been recommended by Joint Meeting on Pesticide Residues (IPCS, 2002). The herbicides may be classified by their chemical structure but this is not very enlightening because of overlapping biological effects of a variety of chemical structures. The second method of classification is on the basis of their use such as how and when the agents are applied. For example, pre-planting herbicides are applied to the soil before a crop is seeded; pre-emergent herbicides are applied to the soil before the usual time of appearance of the unwanted weeds. Post-emergent herbicides are applied to the soil after the germination of the crops and/or weeds. Another way of classification is based on their mechanism of action in plants; their action is referred to selective (toxic to some species), contact (direct contact), or translocated (through absorption via the soil or through the foliage into the plant xylem and phloem). WHO has recommended classification of pesticides by their acute hazardous nature. Individual products are classified according to the oral or dermal toxicity of technical products, and its physical state. The comparative toxicity of selected herbicides by hazards along with their $LD_{50}$ values in rats is summarized in Table 51.1.

These values are intended to be for the guide only because the toxicity of herbicides may be due to the presence of

**TABLE 51.1 WHO recommended category (hazardous nature) of major chemical classes of technical grade herbicides with representative examples of acute $LD_{50}$ values in rats**

Ib: Highly hazardous; II: moderately hazardous; III: slightly hazardous; U: unlike to present acute hazard in normal use; O: obsolete or discontinued for use as herbicide; d: liquid; “c”: before $LD_{50}$ reflects variable values. Compiled from IPCS (2002) and JMPR (2005).

other ingredients (such as surfactants, emulsifiers, etc.) present in the formulation. The details of guidelines for their hazard evaluation and their classification have already been summarized (IPCS, 2002; Gupta, 2006). With a few exceptions, most of the newly developed chemicals have a low order of toxicity to mammals. However, some herbicides are known to have adverse effects on developing embryo. A list of selected herbicides having teratogenic potential is summarized in Table 51.2. In this chapter, herbicides classified by their chemical nature and mechanisms by which they exert biological effects have been reviewed.

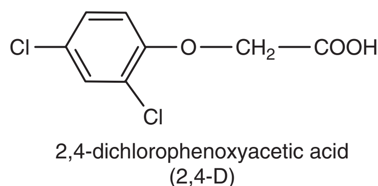
## Inorganic herbicides

Substances such as sodium arsenite, arsenic trioxide, sodium chlorate, ammonium sulfamate, borax, and many others were formerly used on a large scale. Indeed the Romans are reputed to have sterilized the soil of Carthase with common salt after the Romans' victory in 146 BC. The disadvantage with such herbicides from agricultural point of view, is that they are non-selective so their use has declined due to availability of better and selective organic preparations (Marrs, 2004).

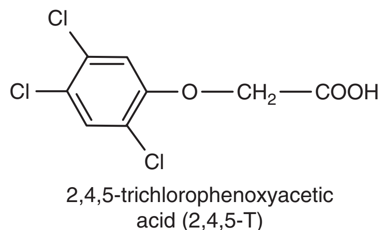
## Phenoxy acid derivatives

This class of herbicides include 2,4-D {2,4-dichlorophenoxyacetic acid}, 2,4,5-T {2,4,5-trichlorophenoxyacetic acid}, 2,4-DB {4-(2,4-dichlorophenoxy) butyric acid}, dalapon, dichlorprop or 2,4-DP {2-(2-methyl-4-chlorophenoxy) propionic acid}, mecoprop (MCPP), {2-(4-chloro-2-methylphenoxy) propionic acid}, MCPA {2-methyl-4-chlorophenoxyacetic acid}, and Silvex {2-(2,4,5-trichlorophenoxy) propionic acid}. The phenoxy derivatives are no longer the agents of choice because of formation of chlorinated dibenzofurans and dibenzodioxins, particularly 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), as a consequence of poorly monitored manufacturing practices. Some formulations of 2,4,5-T contain dioxin contaminants that increase the toxicity of technical grade herbicides and therefore the safe use of phenoxy herbicides has been questioned. The published reports indicate the possibility of occurrence of three rare forms of cancer (Hodgkin's disease, soft tissue carcinoma, and non-Hodgkin's lymphoma) in workers exposed to these herbicides (Kennepohl and Munro, 2001). However, they are still used in developing countries around the world, their toxicology cannot be ignored. The structural formulae of selected phenoxy derivatives are given as below.

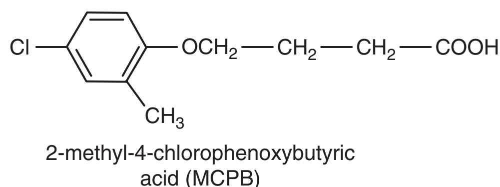
A tremendous amount of mammalian toxicity data has been collected over the past 50 years. As a group, these are essentially non-toxic and acute oral/dermal exposure to phenoxy herbicides is slight to moderately hazardous in



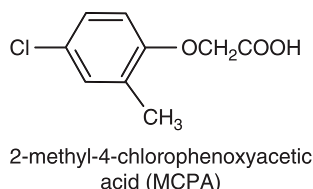
2,4-dichlorophenoxyacetic acid (2,4-D)



2,4,5-trichlorophenoxyacetic acid (2,4,5-T)



2-methyl-4-chlorophenoxybutyric acid (MCPB)



2-methyl-4-chlorophenoxyacetic acid (MCPA)

normal use (Table 51.1). Dermal irritation in rabbits is considered slight for the acid form of 2,4-D and minimal for the salt and ester forms. Eye irritation in rabbits, on the other hand, is severe for the acid and salt forms, but minimal for the ester. The oral $LD_{50}$ for 2,4-D and 2,4,5-T in dogs ~100 mg/kg b.w. The dog is more sensitive and may develop myotonia, ataxia, posterior weakness, vomiting, bloody diarrhea, and metabolic acidosis because of difficulty in the renal elimination of such organic acids (Gehring *et al.*, 1976). Kidney effects consisting of reduced cytoplasmic eosinophilia of the epithelial cells lining and some convoluted tubules have been reported in dog. 2,4-D does not produce any testicular damage or induce any abnormal reproductive disorders, however, some workers have reported their teratogenic potential in animals (Table 51.2). The group of compounds neither induces adverse effects in the nervous system nor has any potential to induce cancer or mutagenicity in laboratory animals (Yano *et al.*, 1991a, b; Munro *et al.*, 1992).

Phenoxy acid derivatives can potentiate the toxic effects of some plants. They may increase the nitrate content of some plant species and can increase the palatability of certain toxic plants (Sudan grass), thus increasing poisoning risks from these plants. Dogs are the most sensitive animals, whereas pigs, sheep, cattle, and poultry are less susceptible (Table 51.3).

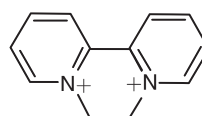
Compiled from Lorgue *et al.* (1996).

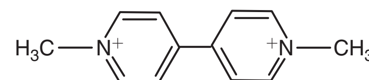
Animals can tolerate repeated oral doses of phenoxy herbicides without showing significant signs of toxicity; suggesting that there is very little cumulative effect on target organs. At high dosages, two types of clinical symptoms, i.e. related to GI tract and/or nervous system have been observed. GI signs include anorexia, rumen atony, diarrhea, ulceration of oral mucosa, bloat, and rumen stasis in cattle and vomiting, diarrhea, salivation, etc. in dogs and pigs. Neuromuscular signs include depression and muscular weakness in cattle, and ataxia, posterior weakness (particularly pelvic limbs), and periodic clonic spasms (at high doses) in dogs. Silvex is unusual for this group because it is very toxic and small doses (2–6 mg/kg b.w.) may cause ill effects in dogs (Sandhu and Brar, 2000).

## Bipyridyl derivatives

This chemical class of herbicides includes paraquat (1,1′-dimethyl-4,4′-bipyridylium dichloride) and diquat (1,1′-ethylene-2,2′-bipyridylium dibromide).



Diquat



Paraquat

Paraquat is usually formulated as dichloride salt (also known as methyl viologen). The bis (methyl sulfate) salt is no longer commercialized. Paraquat is a non-selective, and is a fast-acting contact herbicide. This compound is the most toxic of the commonly used herbicides and the toxicity varies in different animals depending upon the formulation and species used. The toxic doses of paraquat and diquat in rats range from 150 to 231 mg/kg body wt. and this class of herbicides is classified as moderately hazardous (Table 51.1). Mice are less sensitive than the rats to orally administered paraquat, while guinea pigs, cats, monkeys, and rabbits are more susceptible (Murray and Gibson, 1972; Bus *et al.*, 1976a, b; Nagata *et al.*, 1992; Lorgue *et al.*, 1996). The cattle and sheep are more sensitive than other species. The comparative toxic oral doses (TD) of paraquat and diquat in different species are summarized in Table 51.4.

As indicated previously, paraquat and diquat have somewhat different mechanisms of action. Diquat exerts most of its harmful effects in the GI tract. The major cause of death after paraquat is due to lung damage. Rabbits, however, do not show signs of respiratory distress. Immediate toxic effects include convulsions or depression and in-coordination, gastroenteritis, and finally difficult respiration due to pulmonary edema and alveolar fibrosis (2–7 days). Animals that survive first few days develop dehydration, pallor or cyanosis, tachycardia, tachypnea, harsh respiratory sounds, and emphysema or pneumomediastinum. Studies have shown that mice lacking copper/zinc superoxide dismutase show a marked increase in sensitivity to paraquat (Ho *et al.*, 1998).

On long-term exposure, there is progressive pulmonary fibrosis and increased respiratory distress. The morphological changes seen in animals include degeneration and

Compiled from Lorgue *et al*. (1996).

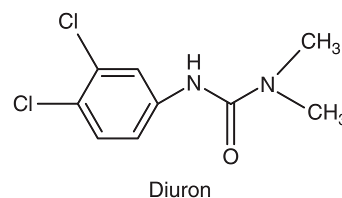
vacuolization of pneumocytes, damage to Type I and Type II alveolar epithelial cells, destruction of the epithelial membranes, and proliferation of fibrotic cells. The animals die as a consequence of reduced gas exchange and development of severe hypoxia.

Gross lesions include pulmonary congestion, edema, and hemorrhages. Lingual ulcers may be seen. Other findings include failure of lungs to collapse when chest is opened and areas of hemorrhages, fibrosis, and atelectasis. Microscopic lesions include necrosis of Type I alveolar epithelial cells followed by progressive alveolar and intestinal fibrosis and alveolar emphysema. Renal proximal tubular degeneration and moderate centrilobular hepatic degeneration may also be seen (Smith, 1997). It has neither carcinogenic nor mutagenic potential, however, high doses injected into pregnant rats and mice on various days of gestation may cause significant maternal toxicity but does not produce teratogenic effects (Bus and Gibson, 1975).

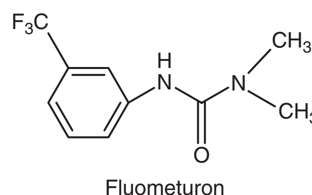
Diquat is formulated as the dibromide salt and is slightly less toxic to dogs than paraquat (Table 51.4). After chronic exposure, the major target organs are the GI tract, the liver, and the kidneys, however, lungs are not affected (Hays, 1982). Presence of cataracts in both dogs and rats has been observed. Similar signs of toxicity have been seen in mice, guinea pigs, rabbits, dogs, and monkeys. On histopathology injury to the lining of the stomach and GI tract has been observed but these are not life threatening (Clark and Hurst, 1970; Cobb and Grimshaw, 1979). Diquat has no effect on fertility, is not teratogenic, and only produces fetotoxicity at doses that are maternally toxic. In the multigeneration study, at high-doses cataract has been observed in rats (Lock and Wilks, 2001).

## Ureas and thioureas

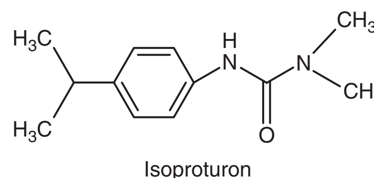
The ureas and thioureas (polyureas) are available under different names such as diuron, fluometuron, isoproturon, linuron, buturon, chlorbromuron, chlortoluron, chloroxuron, difenoxuron, fenuron, methiuron, metobromuron, metoxuron, monuron, neburon, parafluron, siduron, tebuthiuron, tetrafluron, and thidiazuron. Of these, diuron and fluometuron are the most commonly used in the United States, whereas isoproturon is mostly used in other countries including India.



Diuron



Fluometuron



Isoproturon

In general, polyureas have low acute toxicity and are unlikely to present any hazard in normal use, except tebuthiuron, which may be slightly hazardous (Table 51.1). In general, the cattle are more sensitivity to polyurea herbicides than sheep, cats, and dogs. The comparative toxic values of polyurea herbicides are summarized in Table 51.5.

Diuron and Monuron are potent inducers of hepatic metabolizing enzymes compared to those polyurea herbicides with one or no halogen substitutions (chlortoluron and isoproturon). Male rats are more sensitive than females to the enzyme-inducing activity of diuron and can lead to detoxication of EPN and *O*-demethylation of *p*-nitro anisole. *N*-demethylation of aminopyrine increases for 1–3 weeks, then return to normal (Hodgson and Meyer, 1997). Recovery from diuron intoxication is quick (within 72 h) and no signs of skin irritation or dermal sensitization have been reported in guinea pigs. After repeated administration, hemoglobin levels and erythrocyte counts are significantly reduced, while methemoglobin concentration and white blood cell counts are increased. Increased pigmentation (hemosiderin) in the spleen is seen histopathologically. Linuron in sheep causes erythrocytosis and leucocytosis with hypohemoglobinemia and hypoproteinemia, hematuria and ataxia, enteritis, degeneration of the liver, muscular dystrophy. In chickens it leads to loss of weight, dyspnea, cyanosis, and diarrhea. It is non-toxic to fish (Lorgue *et al.*, 1996). Fluometuron is less toxic than diuron. In sheep, depression, salivation, grinding of teeth, chewing

TABLE 51.5 TD of ureas and thioureas in animals

| | Species | mg/kg b.w. |
|---|---|---|

No deaths were reported in dogs, chickens, quail, or ducks at a dosage of 500 mg/kg b.w. of tebuthiuron. Compiled from Lorgue *et al.* (1996).

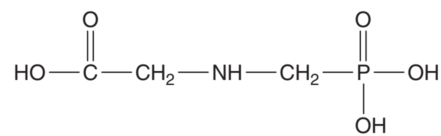
movements of the jaws, mydriasis, dyspnea, in-coordination of movements, and drowsiness is commonly seen. On histopathology severe congestion of red pulp with corresponding atrophy of the white pulp of spleen and depletion of the lymphocyte elements have been reported (Mehmood *et al.*, 1995). The acute $LD_{50}$ of isoproturon in rats is almost similar to diuron and does not produce any overt signs of toxicity, except at very high doses. Single oral dose of isoproturon in mice may produce some neurotoxic effects at very high doses and may reduce spontaneous and forced locomotor activity (Sarkar and Gupta, 1993a, b).

Polyurea herbicides have been suspected to have some mutagenic effects but do not have carcinogenic potential (Liu, 2001). In general, the compounds do not cause developmental and reproductive toxicity, except monolinuron, linuron, and buturon are known to cause some teratogenic abnormalities in experimental animals (Table 51.2).

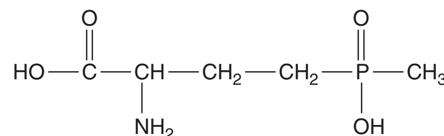
## Phosphonomethyl amino acids or inhibitors of aromatic acid biosynthesis

Two organophosphorus compounds glyphosate (Roundup, Vision) {*N*-(phosphonomethyl)glycine} and glufosinate (Basta) {*N*-(phosphonomethyl)homoalanine} are broad-spectrum, non-selective systemic herbicides. While they exist as free acids but due to their slow solubility they are marketed as the isopropyl amine or trimethylsulfonium salts of glyphosate and the ammonium salt of glufosinate.

Glyphosate has low acute oral toxicity in mice and rats and is unlikely to pose acute hazard in normal use (Table 51.1). The $LD_{50}$ of trimethylsulfonium salt is 750 mg/kg b.w. The animals most affected are cattle, sheep, and dogs. Dogs and cats show eye, skin, and upper respiratory tract signs when exposed during or subsequent to an application to weeds or grass. Nausea vomiting, staggering, and hind



Glyphosate acid



Glufosinate

leg weakness have been reported in dogs and cats that were exposed to fresh chemical on treated foliage (Susan, 2003). Glyphosate is not a dermal irritant and does not induce photosensitization; formulations can cause severe occupational contact dermatitis. Glyphosate is an ocular irritant in the rabbit and human with minor to moderate conjunctival irritation and slight iritis that usually disappears within 48 h after exposure (Acquavella *et al.*, 1999; JMPR, 2004). Common signs of toxicity include loss of body weight, diarrhea, and serum chemistry changes. In rats, it may lead to increased incidence of cataract and degenerative ocular lens changes, alterations in the parotid and sub maxillary glands, and increased liver weights. Formulations of glyphosate can cause intoxication in human beings, which may be due to the presence of surfactants, polyoxyethyleneamine. This class of surfactants has been associated with hemolysis and with GI and CNS effects (Talbot *et al.*, 1991). There is no evidence of mutagenic or carcinogenic potential of glyphosate. It does not have adverse effect on reproductive performance in animals, except at very high doses that elicits maternal toxicity (JMPR, 2004).

The acute oral toxicity of glufosinate is low and is slightly more hazardous than glyphosate (Table 51.1). Common signs of toxicity include CNS excitation and hypothermia in animals (Ebert *et al.*, 1990; Hack *et al.*, 1994). Glufosinate is not considered to be mutagenic, teratogenic, or carcinogenic, except in whole-embryo culture. Teratogenic effects in mice have been observed, the effect being apoptosis in the neuroepithelium of developing embryo (Watanabe, 1997). Glufosinate ammonium formulation has been involved in a number of poisoning cases (cardiovascular and CNS adverse effects) may be due to surfactant-induced penetration into the CNS (Watanabe and Sano, 1998).

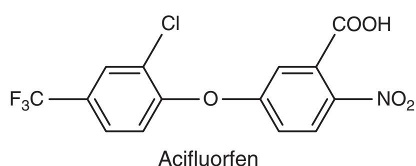
## Protoporphyrinogen oxidase inhibitors

Earlier the protoporphyrinogen oxidase (Protox)-inhibiting herbicides were often termed “DPE-type herbicides” and almost all of the Protox inhibitors were DPEs. This nomenclature led to some confusion in herbicide classification, because other DPE herbicides have an entirely

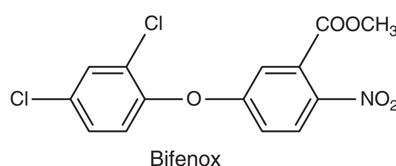
different molecular site of action (i.e. inhibition of acetyl CoA carboxylase). Now many other structurally related Protox inhibitors have been commercialized. In general, the newer products are more potent Protox inhibitors, resulting in lower application rates than the older herbicides of this class. Some of them appear to be analogs of the substrate or a substrate/product transition state of the enzyme (Reddy *et al.*, 1998).

Protox inhibitors may be DPE or non-DPE Protox inhibitors. Amongst DPE Protox inhibitors, nitrofen was the first Protox-inhibiting herbicide introduced in 1964. Although many of the older commercialized DPEs have a *p*-nitro phenyl substitution, newer DPE-like herbicides commonly contain *p*-trifluoromethyl phenyl substitutions. After the first generation of Protox inhibitors (with the exception of oxadiazon), which was based on the DPE, numerous other non-oxygen-bridged compounds (non-DPE Protox inhibitors) with the same site of action (carfentrazone, JV 485 and oxadiargyl) have been commercialized (Dayan *et al.*, 2001). The structural formulae of commercially available DPE, DPE-type, and non-DPE Protox-inhibiting herbicides are given as below.

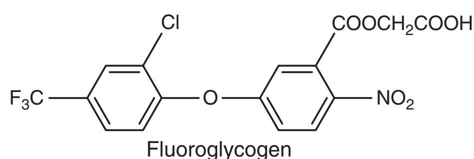
Protox inhibitors have little acute toxicity and are unlikely to pose any acute hazard in normal use (Table 51.1).



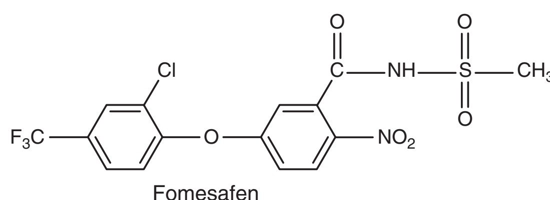
Acifluorfen



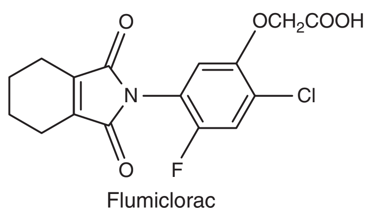
Bifenox



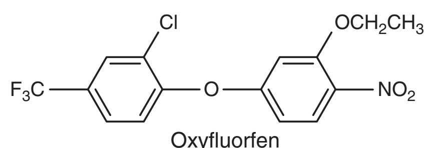
Fluoroglycogen



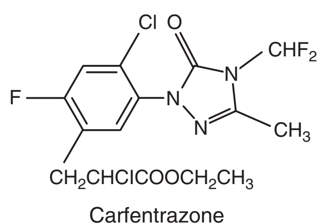
Fomesafen



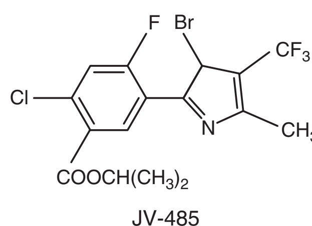
Flumiclorac



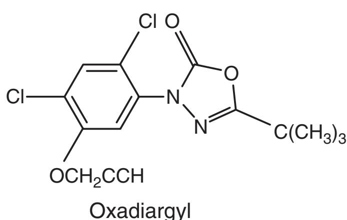
Oxyfluorfen



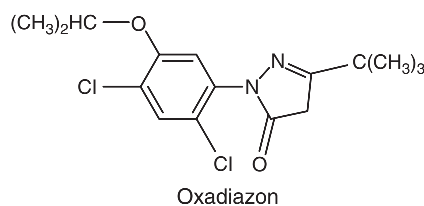
Carfentrazone



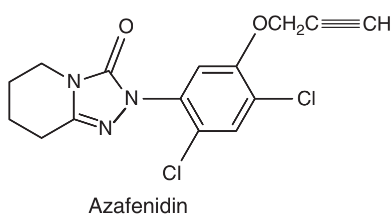
JV-485



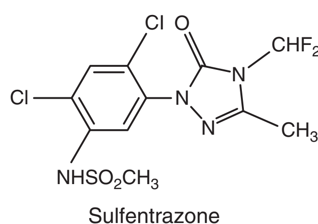
Oxadiargyl



Oxadiazon



Azafenidin

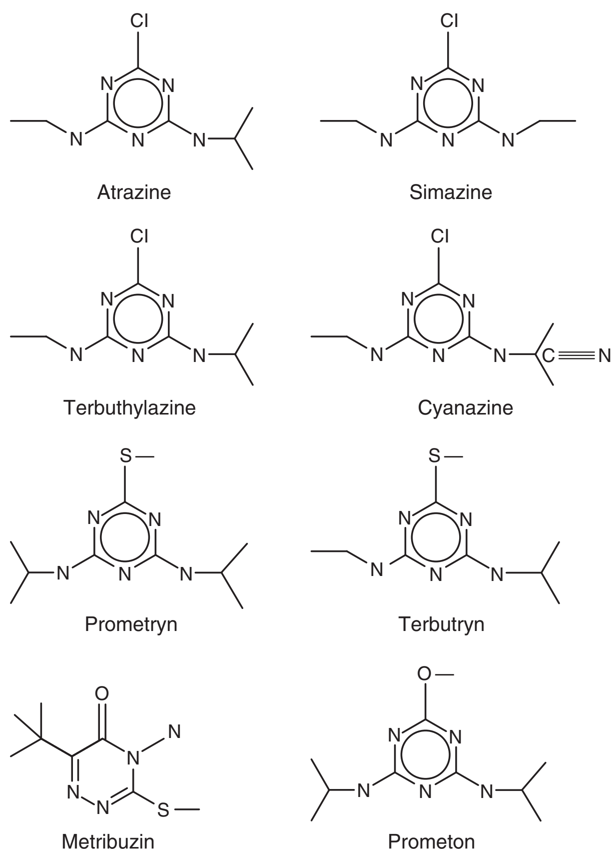


Sulfentrazone

These compounds increase the porphyrin levels in animals when administered orally and the porphyrin levels return to normal within a few days. Rats and mice are sensitive and Variegate porphyria-like symptoms can be generated in mice with high doses of Protox inhibitors. Majority of these compounds are neither mutagenic nor carcinogenic in nature and the development toxicity correlates with Protox accumulation (Dayan *et al.*, 2001).

## Triazines and triazoles

Triazines and triazoles have been used extensively as selective herbicides for more than 40 years. These herbicides are inhibitors of photosynthesis and include both the asymmetrical and symmetrical triazines. Examples of symmetrical triazines are chloro-*S*-triazines (simazine, atrazine, propazine, and cyanazine); the thiomethyl-*S*-triazines (ametryn, prometryn, terbutryn), and the methoxy-*S*-triazine (prometon). The commonly used asymmetrical triazine is metribuzin. The structures of symmetrical and asymmetrical triazines are given as below.



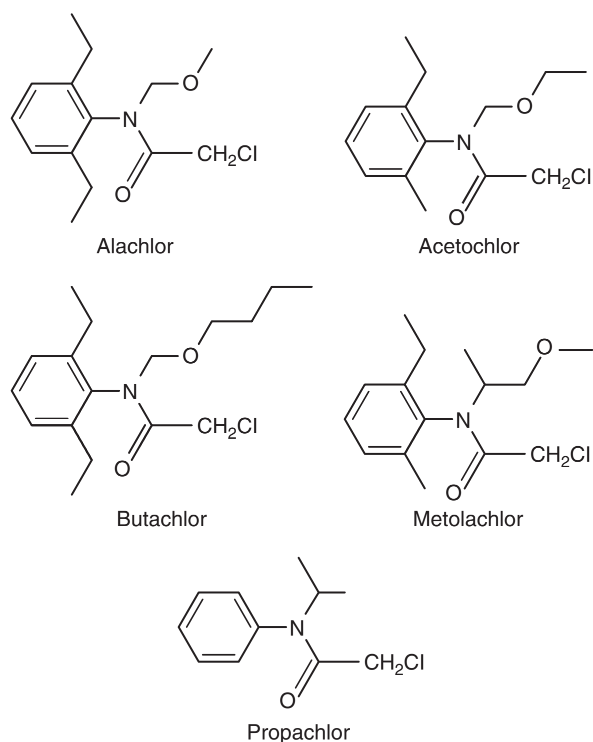
These herbicides have low oral toxicity and are unlikely to pose acute hazards in normal use, except ametryn and metribuzin, which may be slight to moderately hazardous (Table 51.1). They are neither irritant to the skin or eye, nor are skin sensitizers. The exceptions are atrazine, which is skin sensitizer and cyanazine, which is toxic by the oral route. But sensitivity of sheep and cattle to these herbicides is appreciably high. The oral $LD_{50}$ for rats is >5 g/kg b.w. The main symptoms are anorexia, hemotoxia, hypothermia, locomotor disturbances, irritability, tachypnea, and hypersensitivity (Sandhu and Brar, 2000). Doses of 500 mg/kg of simazine or 30 mg/kg atrazine for 30–60 days are lethal to sheep. Deaths have been reported in sheep and horses grazing triazine-treated pasture 1–7 days after spraying. Cumulative effects are not seen. Metribuzin is slightly more toxic than simazine but does not produce any harmful effects in dogs fed at 100 ppm in the diet. Simazine is excreted in milk, so it is of public health concern (Susan, 2003). Atrazine is more toxic to rats, but comparatively less toxic to sheep and cattle than simazine. When cultured human cells are exposed to atrazine, splenocytes are damaged, bone marrow cells are not affected. This class of herbicides is liver microsomal enzyme inducer and is converted to *N*-dealkylated derivatives. In contrast to simazine, it is not excreted in milk. Triazines seem to have no potential to be mutagenic or to produce carcinogenicity in animals. The exception is cyanazine, which is more acutely toxic, week mutagenic, and results in developmental toxicity, presumably because of the presence of cyano moiety (Hodgson and Meyer, 1997).

## Substituted anilines

Substituted anilines are used as systemic herbicides. The commonly used herbicides are alachlor, acetochlor, butachlor, metolachlor, and propachlor. The structural formulae of selected ones are given as below.

This class of herbicides is slightly hazardous, except butachlor, which is not likely to pose any hazard (Table 51.1). The compounds are non-irritant to eye, slight-to-moderate skin irritant, and produce skin sensitization in guinea pigs. Lower doses in rats and dogs do not produce any adverse effects, however, long-term exposure to dogs cause liver toxicity, hepatotoxicity, and spleenic effects. The ocular lesions produced by alachlor is considered to be unique to the Long–Evans rat because the response has not been observed in other strains of rats, mice, or dogs. This effect has not been observed in human beings involved in manufacture of alachlor. At high oral doses, it may lead to maternal and fetal toxicity but may not cause any adverse effect on reproduction. It is neither teratogenic nor produces any microbial genotoxicity. Alachlor has the potential to produce thyroid tumors and adenocarcinomas of the stomach and nasal turbinates of Long–Evans rats and in the lungs of CD-1 mice. It is considered to be a human carcinogen (Ahrens, 1994; Monsanto, 1997a, b).

Long-term exposure of acetochlor to rats has no adverse effects on reproductive performance in animals. Acetochlor is converted into a rat-specific metabolite that



may be related to the nasal tumors, thus posing no genetic or carcinogenic hazard to humans (Ashby *et al.*, 1996). Butachlor does not adversely affect reproductive performance or pup survival. It is non-genotoxic and there is no carcinogenic potential in animals. Metolachlor can increase the incidence of liver tumors in rats and has been classified as possible human carcinogen (Monsanto, 1991; Wilson and Takei, 1999).

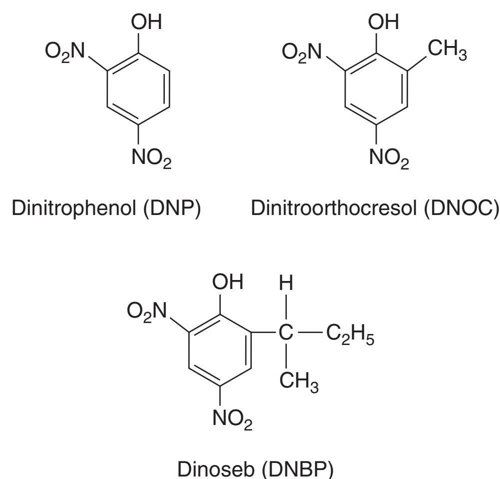
As compared to other substituted anilines, propachlor is severely irritating to the eye and slightly irritating to the skin. Propachlor produces skin sensitization in guinea pigs. High doses of propachlor produce erosion, ulceration and hyperplasia of the mucosa, and herniated mucosal glands in the pyloric region of stomach, hypertrophy, and necrosis of the liver in rats. In dogs, there is poor diet palatability, which results in loss of weight and poor consumption of food. Propachlor may produce slight development or adverse reproductive effects (Table 51.2). It is not genotoxic or clastogenic in mammals. However, there is evidence that it produces benign hepatic tumors in male mice (Heydens *et al.*, 2001).

## Amides and acetamides

The commonly used amides and acetamides include bensulide, dimethenamid-P, and propanil and are slightly to moderately hazardous in normal use (Table 51.1). Dimethenamid is a racemic mixture of the M and P stereoisomers, whereas P isomer has useful herbicidal activity. Both substances produce only mild reversible skin and eye irritation and skin sensitization in guinea pigs. Comparison of racemic dimethenamid with dimethenamid-P indicates that there is little difference in their toxicological profiles. The signs of toxicity in mice, rats, and dogs are similar, with reduced body-weight gain and liver enlargement with induction of liver xenobiotics metabolizing enzyme. There is strong binding to hemoglobin in rats, but this has no relevance to humans. Dimethenamid-P and racemic dimethenamid produce very similar effects in the liver of rats. Both substances neither produce any signs of neurotoxicity nor adverse effects in developmental toxicity or on reproductive performance. Dimethenamid can reduce fetal body weights but is not teratogenic. There is no compound-related mutagenic or carcinogenic potential (JMPR, 2005).

## Dinitrophenol compounds

Several substituted dinitrophenols alone or as salts such as DNP (2,4-dinitrophenol), DNOC (dinitro-*o*-cresol), and dinoseb {2-(1-methylpropyl)-4,6-dinitro} are used as insecticides, fungicides, acaricides, and herbicides. The main source of poisoning in animals are human negligence in removing the preparation if it spills, in disposing off the containers and preventing animals access to treated fields. The structural formulae of DNP, DNOC, and dinoseb are given as under.



In general, the dinitro compounds are not very water-soluble and are highly hazardous to animals (Table 51.1). The oral acute $LD_{50}$ of DNOC in mice, guinea pigs, rabbits, hens, dogs, pigs, and goats ranges from 25 to 100 mg/kg b.w. (Table 51.6). In sheep, dosage of 25 mg/kg/day causes toxicosis in 2–4 days. Clinical signs include fever, dyspnea, acidosis, oliguria, muscular weakness, tachycardia and convulsions, followed by coma and death with a rapid onset of rigor mortis. Abortions have been reported in sows. In cattle and ruminants, methemoglobinemia, intravascular hemolysis, and hemoproteinemia have been observed. Cataract can occur with chronic dinitrophenol intoxication.

TABLE 51.6 TD of DNOC and dinoseb in animals

| TD | Cattle | 25 for 8 days |
| | Sheep | 25 for 10 days |

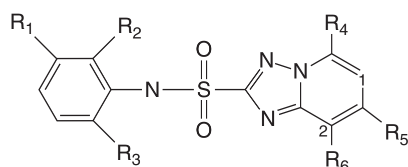
Compiled from Lorgue *et al.* (1996).

Exposure to these compounds may cause yellow staining of skin, conjunctiva, or hair (Lorgue *et al.*, 1996).

## Triazolopyrimidine herbicides

Triazolopyrimidine herbicides include cloransulam-methyl, diclosulam, florasulammethyl, flumetsulam, and metosulam. The generic structure of the triazolopyrimidine herbicides connected to a substituted phenyl ring through a sulfonamide bridge is given as under. The substituents of the various members of this class are summarized in Table 51.7.

The acute oral toxicity of triazolopyrimidine herbicides is very low. On repeated exposure, the primary organs are the kidney (rat and mouse), liver (rat, mouse, and dog), and thyroid (rat). Slight decreases in red cell parameters and urine-specific gravity in males, and slightly increased cecal and liver weights, slight to moderate hypertrophy of collecting renal tubule epithelial cells and/or slight vacuolization of proximal tubular epithelium, hepatocellular vacuolation, and slight thyroid follicular hypertrophy have been observed (Hanley and Billington, 2001). In most of the cases the histopathological changes represent adaptive responses. Analysis of $^{14}C$ activity of dog eyes indicated that this organ is a target of toxicity in dog, exhibited an affinity for the radiotracer not seen in other species (Timchalk *et al.*, 1996). No adverse effects on neurotoxicity, reproductive performance, mutagenic abnormalities have been observed. The compound has no carcinogenic potential in humans (EPA, 1997a, b).



Generic structure of the triazolopyrimidine herbicides

## Imidazolinones

Imidazolinone herbicides include imazapyr, imazamethabenzmethyl, imazapic, imazethapyr, imazamox, and imazaquin. These are selective broad-spectrum herbicides discovered in 1970s. The structural formulae of this class of herbicides are given as below.

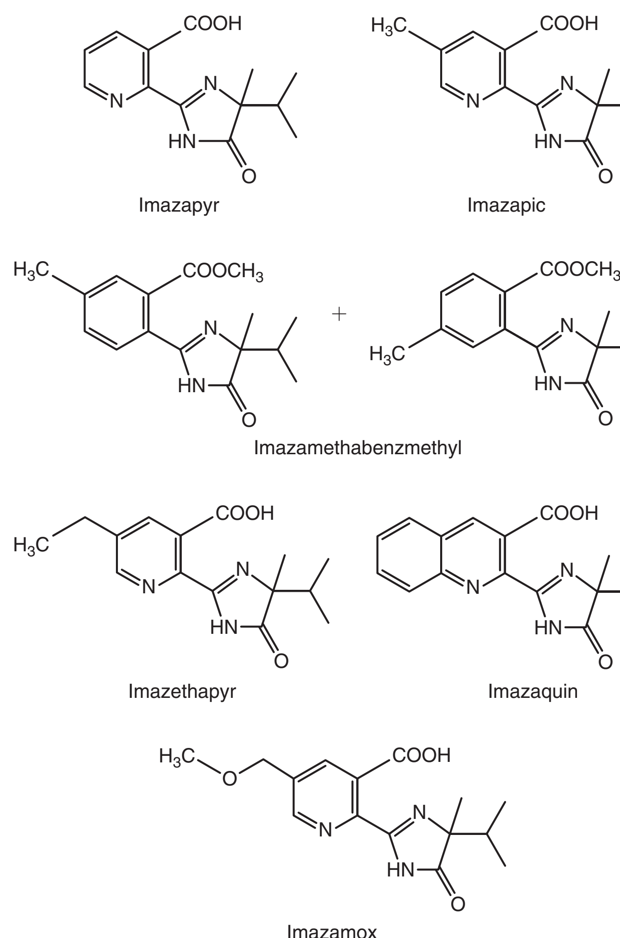


TABLE 51.7 Substituents of triazolopyrimidine sulfonamide herbicides

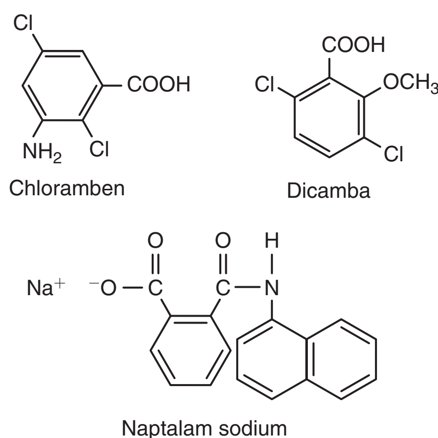
| | 1 | 2 | $R_1$ | $R_2$ | $R_3$ | $R_4$ | $R_5$ | $R_6$ |
|---|---|---|---|---|---|---|---|---|
| Cloransulam-methyl | N | C | H | $CO_2CH_3$ | Cl | $CO_2CH_3$ | F | H |
| Diclosulam | N | C | H | Cl | Cl | $OCH_2CH_3$ | F | H |
| Florasulam | N | C | H | F | F | $OCH_3$ | H | F |
| Flumetsulam | C | N | H | F | F | H | $CH_3$ | – |
| Metosulam | C | N | $CH_3$ | Cl | Cl | $OCH_3$ | $OCH_3$ | – |

From Hanley and Billington (2001). Reproduced with permission © 2001.

These herbicides are relatively non-toxic (Table 51.1). Result from primary eye irritation studies ranges from no irritation (imazaquin) to slightly irritating (imazamethabenzmethyl) and to moderately irritating (imazapic and imazethapyr), showing complete recovery within 7 days post-dosing. The rabbit primary irritation study with imazapyr showed irreversible irritation. Toxicological effects of imidazolinone herbicides are slight-to-moderate skeletal myopathy and/or slight anemia in dogs occurring in the 1-year dietary toxicity studies with three structurally similar imidazolinones (imazapic, imazaquin, and imazethapyr). There is no evidence of any adverse effect on reproductive performance and on fetal abnormalities in the rat and the rabbit. Neither mutagenicity nor any carcinogenicity has been reported in either of these species (Hess *et al.*, 2001).

## Benzoic acids

The herbicides in this group include chloramben, dicamba, and naptalam. These have a low order of toxicity and the $LD_{50}$ values in rats are summarized in Table 51.1. The structural formulae of selected herbicides are given as under.



In practice, dicamba is often combined with other herbicides and is used to control a wide spectrum of weed control. The signs and lesions are similar to those described for the chlorophenoxy acids. Poisoning after normal use has not been reported in domestic animals. The compound does not show any adverse effects in a three-generation study in rats (Harp, 2001).

Dicamba induces peroxisomal enzymes in rat liver and causes transcription upregulation of the peroxisome proliferated-activated receptor. Dicamba induces tumors in rats, which may be due to its action as peroxisome proliferators, however, exact implications of these findings are not clear and may require further study (Espandiari *et al.*, 1998).

## Carbamates, thiocarbamates, and dithiocarbamate compounds

The compounds in this category include derivatives of carbarnic acid (asulam, barban, chlorpropham, chlorbufam, karbutilate, and phenmedipham), derivatives of thiocarbarnic acid (butylate, cycloate, di-allate, EPTC, molinate, and tri-allate) and derivatives of dithiocarbarnic acid (metham-sodium). These herbicides have low-to-moderate toxicity in rats and do not pose acute hazards (Table 51.1). They are used at low concentrations, and poisoning problems have not been reported. In general, these herbicides do not produce skin or eye irritation. With repeated exposure, there is possibility of alopecia for some time after ingestion. The toxic doses of asulam and di-allate in animals are summarized in Table 51.8.

**TABLE 51.8 TD of asulam and di-allate in animals**

| | Species | mg/kg b.w. |
|---|---|---|
| *Asulam* | | |
| $LD_{50}$ | Rabbits | >2000 |
| | Chickens | >2000 |
| | Dogs | >5000 |
| *Di-allate* | | |
| $LD_{50}$ | Dogs | 510 |
| TD | Chickens | 150 for 10 days or 250 for 7 days |
| | Cattle | 25 for 5 days or 50 for 3 days |
| | Sheep | 25 for 5 days or 50 for 3 days |

Compiled from Lorgue *et al.* (1996).

In ruminants, di-allate results in anorexia, ataxia, muscular contractions, exhaustion, prostration, and alopecia in sheep which is an indication of chronic poisoning. Thiobencarb has induced toxic neuropathies in neonatal and adult laboratory rats. It appears to increase permeability of the blood–brain barrier. The non-specific lesions include hepatic, renal and pulmonary congestion, enteritis, ascites, and hydrothorax (Susan, 2003).

## Others

Bromacil and terbacil are commonly used methyluracil compounds. These compounds can cause mild toxic signs at levels of 50 mg/kg b.w. in sheep, 250 mg/kg in cattle, and 500 mg/kg in poultry when given daily for 8–10 days. Signs of toxicity include bloat, in-coordination, depression, and anorexia. Toxic doses of bromacil can be hazardous,

TABLE 51.9 TD of bromacil in animals

| Species | mg/kg b.w. |
|---|---|
| Cattle | 250 |
| Chickens | 500 for 10 days |
| Sheep | 50 for 10 days or |
| Sheep | 250 for 8 days |

Compiled from Lorgue *et al.* (1996).

especially for sheep, but no field cases of toxicity have been reported (Table 51.9).

The nitrile herbicides, ioxynil and bromoxynil, may uncouple and/or inhibit oxidative phosphorylation. Ioxynil, presumably due its iodine content, causes enlargement of the thyroid gland in the rat (Marrs, 2004). Members of polycyclic alkanoic acids (diclofop, fenoxaprop, fenthiaprop, fluazifop, haloxyfop) have moderately low toxicity, whereas, haloxyfop-methyl is an exception having high toxicity. They tend to be more toxic, if exposure is dermal. The dermal $LD_{50}$ of diclofop in rabbits is only 180 mg/kg (Susan, 2003). Some members of amide group such as bensulide and propanil are used as plant growth regulators, and some of them are more toxic than others (Table 51.1). A lethal dose of bensulide for dogs is ~200 mg/kg.

The prominent clinical sign is anorexia; other signs and lesions are not definitive and are similar to those of chlorophenoxy acid poisoning. Hemolysis, methemoglobinemia, and immunotoxicity have occurred after experimental exposure to propanil (Lorgue *et al.*, 1996). The toxicity of sulfonylureas (chlorsulfuron, sulfometuron, metsulfuron, chloremuron, kensulfuron) appears to be quite low (Susan, 2003).

A number of substances are used as defoliants in agriculture: sulfuric acid to destroy potato haulms and two closely related trialkylphosphorothioate (DEF and merphos) to defoliate cotton. A notable feature of the later is that they produce organophosphate-induced delayed neuropathy in hens (Baron and Kohnson, 1964). Chlomequat is used as growth regulator on fruit trees. The signs of toxicity in experimental animals indicate that it is partial cholinergic agonist (JMPR, 2000).

## TREATMENT

The successful management of herbicide poisoning depends on: (1) the clinicians' understanding of the mechanism of herbicide toxicity and applying them to the treatment options, (2) accurate diagnosis and assessment of the severity of intoxication, (3) maintenance of vital body functions and adequate clinical monitoring, (4) minimization of further absorption of the compound, and (5) appropriate use of specific treatment. Since majority of the herbicides have relatively low acute and chronic toxicity, therefore, no attempt has been made to find out any antidote for intoxication. However, a great deal of controversy over purported chronic effects of phenoxy derivatives such as 2,4-D and 2,4,5-T, due to the potential for contamination of 2,4,5-T with the highly toxic and unwanted by-product commonly referred to as dioxin, has surfaced. Treatment is usually symptomatic and supportive. Intravenous fluid should be given to promote diuresis. Adsorbents and drugs, which aid in restoration of liver functions, are recommended. Similarly, there is no specific treatment for bipyridyl herbicide poisoning. The therapy of bipyridyl poisoning may be focused on prevention of absorption from the GI tract. Paraquat binds tightly to diatomaceous clay. Oral administration of adsorbents such as bentonite or Fuller's earth (clay) along with a cathartic such as magnesium sulfate may be helpful. Toxicity of paraquat is enhanced by selenium/vitamin E deficiency, oxygen, and low tissue GSH peroxidase activity. Therefore, vitamin E and selenium with supportive therapy may be useful in early stages of intoxication. Excretion of bipyridyl compounds may be accelerated by forced diuresis induced by mannitol infusion and furosemide administration. Oxygen therapy and fluid therapy are contraindicated (Clark, 1971; Smith *et al.*, 1974).

An effective antidote for dinitrophenol compounds is not known. Affected animals should be cooled and sedated to help control hyperthermia. Phenothiazine tranquilizers are contraindicated, however, diazepam can be used to calm the animal. Atropine sulfate, aspirin, and antipyretics should not be used but use physical cooling measures, e.g. cool baths or sponging and keeping animal in a shaded area are advocated. Intravenous administration of large doses of sodium bicarbonate (in carnivores) solutions, parenteral vitamin A, and intense oxygen therapy, where possible may be useful. If toxin is ingested and the animal is alert, emetic should be administered; if the animal is depressed, gastric lavage should be performed. Treatment with activated charcoal should follow. Dextrose-saline infusions in combination with diuretics and tranquillizers (not barbiturates) are very useful. In ruminants, for methemoglobinemia, methylene blue solution, and administration of ascorbic acid are useful (Lorgue *et al.*, 1996).

## CONCLUSION

Herbicides are used routinely to control noxious plants. Most of these chemicals, particularly the more recently developed synthetic organic herbicides are quite selective for specific plants and have low toxicity for mammals; other less selective compounds (e.g. arsenicals, chlorates,

dinitrophenols) are more toxic to animals. Most animal health problems result from exposure to excessive amounts of herbicides because of improper or careless use or disposal of containers. The residue potential for most of these chemicals is low. However, some areas of herbicidal toxicity such as the isozyme specificity for metabolism, induction, and inhibition in interaction of herbicides with hepatic P450, flavin-containing monooxygenase-dependent oxidations, and phase I and phase II enzymes need special attention because these are not clear. A number of other questions such as what interactions at portals of entry and site of toxic action take place? Can this information help to understand the mechanism of action? In addition, during reproduction, physiological changes occur in virtually every maternal organ systems as consequence of, and in order to support, the rapid growth of the fetus and reproductive tissues. These changes may have a profound effect on the toxicokinetics of the chemical. For example, 2,4,5-T, is more slowly eliminated in mice as gestation progresses due to increased tissue residence, resulting in potentially higher fetal exposure during the later stages of pregnancy. Indeed, clearance of chemicals from the developing fetus appears to be progressively decreased during gestation in rats. It is, therefore, a challenge to predict maternal or embryo/fetal exposure at various times during pregnancy. A good understanding of pregnancy-related anatomical and physiological changes in animals and their potential impact on the chemical kinetic is required.

CHAPTER

52

# Toxicity of fungicides

*P.K. Gupta and Manoj Aggarwal*

## INTRODUCTION

Fungicides are agents which are used to prevent or eradicate fungal infections from plants or seeds. In agriculture, they are used to protect tubers, fruits and vegetables during storage or are applied directly to ornamental plants, trees, field crops, cereals and turf grasses. Numerous substances having widely varying chemical constituents are used as fungicides (Gupta, 1988). Fungicides have been classified according to chemical structures or have been categorized agriculturally and horticulturally according to the mode of action (Ballantyne, 2004). According to the mode of application, fungicides are grouped as foliar, soil and dressing fungicides. *Foliar fungicides* are applied as liquids or powders to the aerial green parts of plants, producing a protective barrier on the cuticular surface and systemic toxicity in the developing fungus. *Soil fungicides* are applied as liquids, dry powders or granules, acting either through the vapor phase or by systemic properties. *Dressing fungicides* are applied to the post-harvest crop as liquids or dry powders to prevent fungal infestation of the crop, particularly if stored under less than optimum conditions of temperature and humidity. Thus effective fungicides must be protective, curative or eradicative and should possess the following properties: (1) low toxicity to the plant/animal but high toxicity to the particular fungus; (2) activity *per se* or ability to convert itself (by plant or fungal enzymes) into a toxic intermediate; (3) ability to penetrate fungal spores or the developing mycelium to reach the site of action; (4) low ecotoxicity and (5) formation of a protective, tenacious deposit on the plant surface that will be resistant to weathering by sunlight, rain and wind (Phillips, 2001). With a few exceptions, most of the newly developed chemicals have a low order of toxicity to mammals. Public concern has focused on the positive mutagenicity tests obtained with many fungicides and the predictive possibility of both teratogenic and carcinogenic potential. The estimated quantity of fungicides used on the major crops increased by 2.3 times between 1964 and 1997. Shares of quantity declined for inorganics (primarily copper compound) and dithiocarbamates since the 1960s but increased to 90% for captan, chlorothalonils and other organic materials. The share of newer groups, such as benzimidazoles, conazoles, dicarboximides and metal organic compounds accounted for about 10% of quantity (Osteen and Padgitt, 2002). In this chapter, fungicides have been discussed using chemical classification system.

## BACKGROUND

The earliest fungicides were inorganic materials like sulfur, lime, copper and mercury compounds. The use of element sulfur as a fungicide was recommended as early as 1803. The mercury-containing fungicides have been responsible for many deaths or permanent neurological disability. Some of the earlier inorganic metallic fungicides have been withdrawn in many countries because of their toxicity and adverse environmental effects (Ballantyne, 2004). Another compound hexachlorobenzene (HCB) was extensively used from the 1940s through the 1950s as a fungicidal dressing applied to seed grains as a dry powder. Between 1955 and 1959, an epidemic of poisoning occurred in Turkey and resulted in a syndrome, called black sore, and caused deaths of over 4000 individuals. While this agent has largely fallen by the wayside, it is still being used in developing countries. It is a highly toxic compound and can lead to severe skin manifestations including hypersensitivity (Hays, 1982; Gupta, 1985a). Since

then many compounds have been developed and used to control fungal diseases in plants, seeds and produce. Carbamic acid derivatives including ethylenebisdithiocarbamates (EBDCs) are a group of fungicides that have been used widely throughout the world since 1940s. The important members of this class include mancozeb, maneb, metiram, zineb and nabam. All the members have an EBDC backbone with different metals associated with the individual compounds. Captan, folpet and captafol have been in use for over 50 years. These compounds belong to chloroalkylthiodicarboximide class of fungicides due to the presence of chlorine, carbon and sulfur in side-chain. Related compounds associated with this fungicide class are dichlofluanid and tolylfluanid. These later two compounds have a fluorine atom substituted for one of the terminal chlorine atoms. Another compound chlorothalonil, a halogenated benzonitrile fungicide, was first registered for use as an agrochemical in the United States in 1966. Chlorothalonil also has wider biocidal applications including its use in paints and lubricant fluids. The benzimidazole fungicides – benomyl and carbendazim – have been in use for over 35 years. Recently anilinopyrimidines, a new class of fungicides (cyprodinil, mepanipyrim and pyrimethanil), has been introduced (cyprodinil by Ciba in France in 1993) for application on cereal grains (Ollinger *et al.*, 2001).

## TOXICOKINETICS

Toxicokinetic studies provide important data on the amount of toxicant delivered to a target as well as species-specific metabolism. Animals are exposed to fungicides either through ingestion or are absorbed through the skin or the respiratory system. Different factors regulate their absorption, distribution, metabolism and excretion. In general, the liver is the primary site for biotransformation and may include activation as well as detoxification reactions (Gupta, 1986). Some fungicides do not undergo any metabolism and bind with other active binding sites. The aryl organomercurials, methyl or ethyl mercury chloride are poorly excreted and tend to accumulate in muscle, brain and other tissues, while the aryl organomercurials, phenyl mercury is more readily excreted via the kidney and less likely to accumulate in brain and muscles. Similarly, HCB possesses all the properties of chemical stability, slow degradation and biotransformation, environmental persistence, bioaccumulation in adipose tissue and organs containing a high content of lipid membranes (Ecobichon, 2001). The newly introduced class of fungicides is rapidly absorbed, metabolized and excreted and does not accumulate in tissues, whereas some of them are partially absorbed from gastrointestinal tract (GIT). For example absorption of chlorothalonil from the GIT is of the order of 30–32% of the administered dose. At least 80% of the administered dose is excreted in feces within 96 h. Highest concentrations are observed in the kidneys, approximately 0.1% of the dose. In this case gut microflora play a role in the disposition and metabolism in the rats. Glutathione conjugation plays a central role in the metabolism and subsequent complex metabolic processing of these conjugates results in selective renal uptake and urinary excretion of thiol-derived metabolites. Hepatic glutathione levels are decreased and renal glutathione levels are elevated. The depletion of hepatic glutathione is considered a direct consequence of glutathione conjugation within the liver utilizing tissue resources. The increase in renal glutathione content is more difficult to explain but may be a consequence of urinary excretion of glutathione conjugates (Parsons, 2001).

The captan is rapidly degraded to 1,2,3,6-tetrahydrophthalimide (THPI) and thiophosgene (via thiocarbonyl chloride) in the stomach before reaching the duodenum. THPI has a half-life of 1–4 s and thiophosgene is detoxified by reaction with cysteine or glutathione and is rapidly excreted. No captan is detected in blood or urine. It is, therefore, unlikely that these compounds or even thiophosgene would survive long enough to reach systemic targets such as the liver, uterus or testes. Due to the rapid elimination, meat, milk or eggs from livestock/poultry would be devoid of the parent materials. Humans appear to metabolize captan in a similar manner to other mammals (Krieger and Thongsinthusak, 1993; JMPR, 2004). Cyprodinil, a fungicide of anilinopyrimidine class, is rapidly absorbed from GIT into systemic circulation in rats. Approximately 48–68% of the administered dose is excreted in the urine, whereas 29–47% is found in the feces. Total excretions reach 92–97% of the administered dose within 48 h. Cyprodinil is almost completely metabolized. No unchanged parent molecule is found in urine, whereas minor amounts of unchanged cyprodinil are found in feces. Most of the administered cyprodinil is metabolized by sequential oxidation of the phenyl and pyrimidine ring. In urine and feces, there is no difference in the metabolite patterns of the phenyl or pyrimidyl labeled cyprodinil. Seven urinary, two biliary and two fecal metabolites have been identified, which in total accounts for 65–80% of the administered dose. Cyprodinil is absorbed in goats to a lesser extent and more slowly than in rats. The major route of excretion is in urine and feces, whereas excretion via the milk is minimal. In laying hens, cyprodinil is rapidly and completely eliminated. Residues in eggs and edible tissues are very low (Waechter *et al.*, 2001).

Carbamic acid derivative fungicides, such as EBDCs, are only partially absorbed, then rapidly metabolized and excreted with no evidence of long-term bioaccumulation. Absorption of oral doses is rapid and is excreted within 24 h with about half eliminated in the urine and half in the feces. Their common metabolite is ethylenethiourea (ETU). Only low-level residues are found in tissues particularly

in the thyroid. Another compound of this class, propamocarb is rapidly and nearly completely absorbed, distributed with concentration reaching peak levels within 1 h. Elimination from tissues is rapid; with half-lives ranging from 11 to 26 h, urine is the main route of excretion (about 75–91% within 24 h). Up to 6% of the administered dose is excreted in feces. Propamocarb is extensively metabolized and unchanged is found only in small quantities in urine. The metabolism involves aliphatic oxidation of the propyl chain (to form hydroxyl propamocarb) and by *N*-oxidation and *N*-demethylation of the tertiary amine resulting in propamocarb *N*-oxide and mono demethyl propamocarb, respectively (JMPR, 2005). Both benomyl and carbendazim are well absorbed after oral exposure (80–85%) but poorly absorbed after dermal exposure (1–2%) in rats, mice, dogs and hamsters. The major pathway of clearance is the urinary elimination in rats and mice but in dogs the majority of the dose (83.4%) is eliminated via feces with only 16.2% of the dose is eliminated in the urine after 72 h of dosing. In animals benomyl is converted into carbendazim through the loss of the *n*-butylcarbamyl side-chain prior to further metabolism (Gardiner *et al.*, 1974). In dogs and rats, carbendazim undergoes aryl hydroxylation–oxidation at the 5 and 6 positions of benzimidazole ring followed by sulfate or glucuronide conjugation before elimination. The urinary excretion half-life of carbendazim in both male and female rats is approximately 12 h. Benomyl, carbendazim and/or its metabolites are cleared rapidly from blood and exhibit minimal potential for bioaccumulation in rats exposed orally or intravenously (Mull and Hershberger, 2001).

Similarly, amide fungicides are rapidly absorbed and eliminated. Metalaxyl-M and metalaxyl can lead to stimulation of hepatic and renal cytochrome P450 and some other drug metabolizing enzymes. Tolylfluanid is rapidly and extensively absorbed followed by rapid metabolism and almost complete excretion, mainly in the urine and to a lesser extent in the bile, within 48 h. High tissue concentration has been seen soon after dosing in the kidney and liver, with lower concentrations in the peri-renal fat, brain, gonads and thyroid. In most of the species, the concentration of fluoride in the bone and teeth increases in a dose-related manner (JMPR, 2002, 2005).

Conazole fungicides such as triadimenol and triadimefon after oral dose are rapidly absorbed and widely distributed in liver and kidney. Excretion and metabolism is rapid and extensive; predominantly through oxidation of *t*-butyl methyl group. Propiconazole indicates rapid and extensive absorption (80% of the administered dose) and are widely distributed, having highest concentration in the liver and kidney. Excretion is more than 95% in the urine and feces in 48 h. There is extensive enterohepatic recirculation. The compound is extensively metabolized with oxidation of propyl side-chain, hydroxylation of phenyl and triazole rings, plus conjugation. The cleavage of dioxolane is significantly different according to species and sex (JMPR, 2004). The other compound, fludioxonil, is rapidly and extensively (80%) absorbed, widely distributed, extensively metabolized and rapidly excreted, primarily in feces (80%), with a small amount being excreted in the urine (20%). The maximum blood concentration is reached within 1 h after administration. Elimination is biphasic, with half-lives of between 2 and 5 h for the first phase and between 30 and 60 h for the second phase. The compound is extensively metabolized involving primarily oxidation of the pyrrole ring (57% of the administered dose) and a minor oxopyrrole metabolite (4% of the administered dose), followed by glucuronyl and sulfate conjugation. There is no potential of accumulation in the tissues. Trifloxystrobin is rapidly absorbed (66%) in 48 h and is widely distributed with highest concentration in blood, liver and kidney. Within 72 h, 72–96% of the administered dose is eliminated in the urine and feces. The metabolism is extensive and the compound undergoes hydroxylation, *O*-demethylation, oxidation, conjugation, chain shortening and cleavage between glyoxylphenyl and trifluoromethyl moieties (JMPR, 2004).

## MECHANISM OF ACTION

There are a series of biochemical changes or free radical-mediated processes; some may also be produced by other mechanisms that have been used to assess tissue injury. This is exemplified by the phenomenon of lipid peroxidation that has been invoked as a toxic mechanism in many situations, and also occurs subsequent to cell death and membrane lysis. However, in most of the situations it becomes difficult to pinpoint the exact mechanism of action. For example, in fungicides containing mercury, the mercury ions inhibit sulfhydryl group of enzymes involved in the transfer of amino acids across the blood brain barrier and then interfere with protein synthesis. Organomercurials can also release some mercury ions in the body, but their toxicity is not believed to be a primary action of mercury ions (Sandhu and Brar, 2000). There are several theories regarding the mechanism by which sulfur produces its toxic action. The oxidized sulfur theory attributes toxicity to its oxidation products, such as sulfur dioxide, sulfur trioxide, thiosulfuric acid or pentathionic acid. The reduced sulfur theory ascribes toxicity due to hydrogen sulfide. Direct action theory suggests toxicity due to cross linking of proteins, formation of other cellular components by free radicals of sulfur or polysulfides, or from extensive oxidation of thiol groups leading to loss of function or structural integrity of proteins. Pentachlorophenol (PCP), a halogenated substituted monocyclic aromatic, acts cellularly to uncouple oxidative phosphorylation, the target enzyme being $Na^+$, $K^+$-ATPase. Oxygen consumption is increased, while adenosine triphosphate (ATP) formation is decreased. The

energy is lost as heat instead of being stored as high-energy phosphate bonds. The electron transport chain responds by using up more and more available oxygen (increased oxygen demand) in an effort to produce ATP, but much of the free energy is lost as body heat. This leads to depletion of energy reserves (Eaton and Gallagher, 1997). Similarly organotin compounds, particularly triethyltin, uncouple oxidative phosphorylation, whereas other agents (such as sulfur) in the presence of sulfiting agents such as sulfur dioxide, thiamine is cleaved into its constituent pyrimidine and thiazole moieties, rendering it inactive.

Although the mechanism(s) by which captan and its analogs exert their cellular toxicity has not been established, captan is known to react with cellular thiols to produce thiophosgene, a potent and unstable chemical capable of reacting with sulfhydryl-, amino-, or hydroxyl-containing enzymes (Cremlyn, 1978). Thiols reduce the potency of captan. A volatile product of captan is responsible for mutagenic activity, the intermediate being short-lived and forming more quickly at higher levels at an alkaline pH. There are other several mechanisms by which these chemicals can induce cellular toxicity. For example, mouse tumors develop with oral administration above a threshold if maintained for at least 6 months. As shown in Figure 52.1, epithelial cells that comprise the villi are damaged first by exposure to captan and sloughed off into the intestinal lumen at an increased rate. Second, the basal cells in the crypt compartment that normally divide at a rate commensurate with the normal loss of villi cells from the tips of the villi increase resulting in high cell proliferation, which is not carcinogenic *per se*, but does play a role in tumor development (Gordon, 2001).

Chlorothalonil fungicide is a reactive molecule toward thio (—SH) groups. It is a soft electrophile with a preference for sulfur nucleophiles rather than nitrogen/oxygen nucleophiles. Such chemicals tend to show reactivity toward protein containing critical S electrophiles rather than toward DNA (containing critical O and N nucleophiles). A mechanistic interpretation for the carcinogenicity of chlorothalonil has been published by Wilkinson and Killeen (1996). Repeated administration of chlorothalonil causes hyperplasia in the forestomach of rats and mice. The data are consistent with a temporal sequence of events starting with increased cell proliferation, multifocal ulceration and erosion of the forestomach mucosa, regenerative hyperplasia and hyperkeratosis, ultimately progressing to the formation of gastric tumors within the forestomach. In dogs, there is neither any evidence of neoplastic development nor any evidence for the occurrence of pre-neoplastic lesions in the kidney or stomach. The absence of stomach lesions in the dog is attributable to the anatomical differences between rodents and dogs, that dogs do not possess a forestomach. Continued administration of chlorothalonil leads to the development of a regenerative hyperplasia within the renal proximal tubular epithelium. Continued regenerative hyperplasia ultimately results in progression of the kidney lesion to tubular adenoma and carcinoma. Initial cytotoxicity and regenerative hyperplasia within the proximal tubular epithelium are essential prerequisites for subsequent tumor development. The

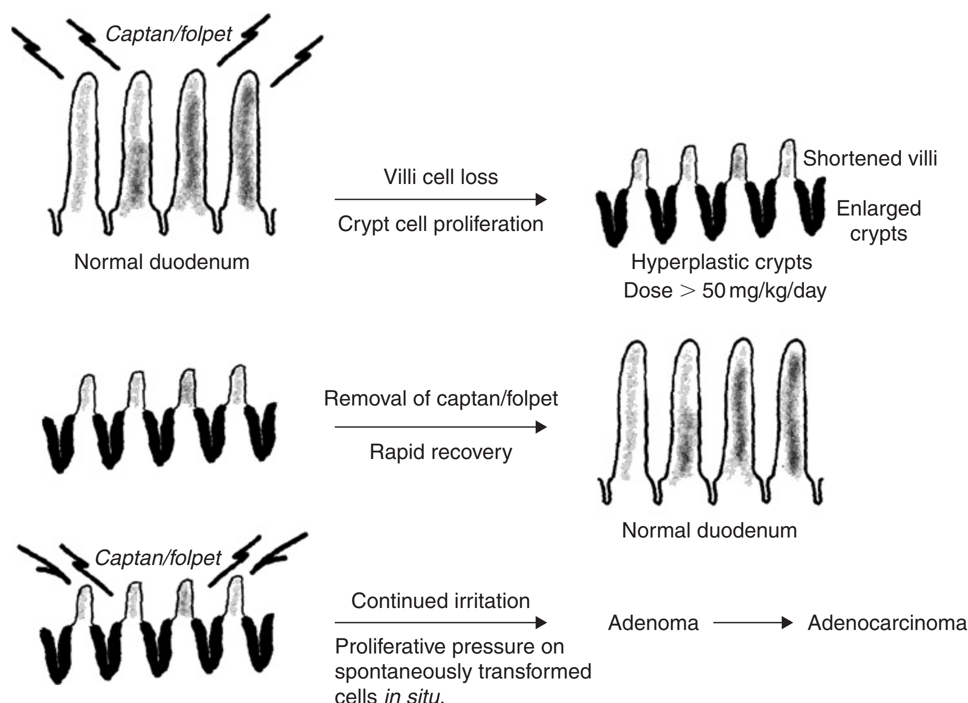

**FIGURE 52.1** Mode of action for captan and folpet in the mouse duodenum. From Gordon (2001) reproduced with permission.

proposed mode of action for the induction of renal toxicity in rodents is outlined in Figure 52.2.

The toxicology database supporting mechanism of action of carbamic acid derivatives such as EBDCs and their common metabolite ETU has been explained using modern studies with mancozeb, maneb and metiram because the principal target organ is the thyroid. These compounds inhibit the synthesis of thyroid hormone, thyroxine (T4) and triidothyronine (T3), leading to elevated levels of thyroid stimulating hormone (TSH) via feedback stimulation of the hypothalamus and pituitary (Atterwill and Aylard, 1995). Prolonged and continuous elevation of TSH levels results in hypertrophy and hyperplasia of the thyroid follicular cells in rats, mice, hamsters, monkeys and dogs, leading to development of follicular nodular hyperplasia, adenoma and/or carcinoma in rats and mice

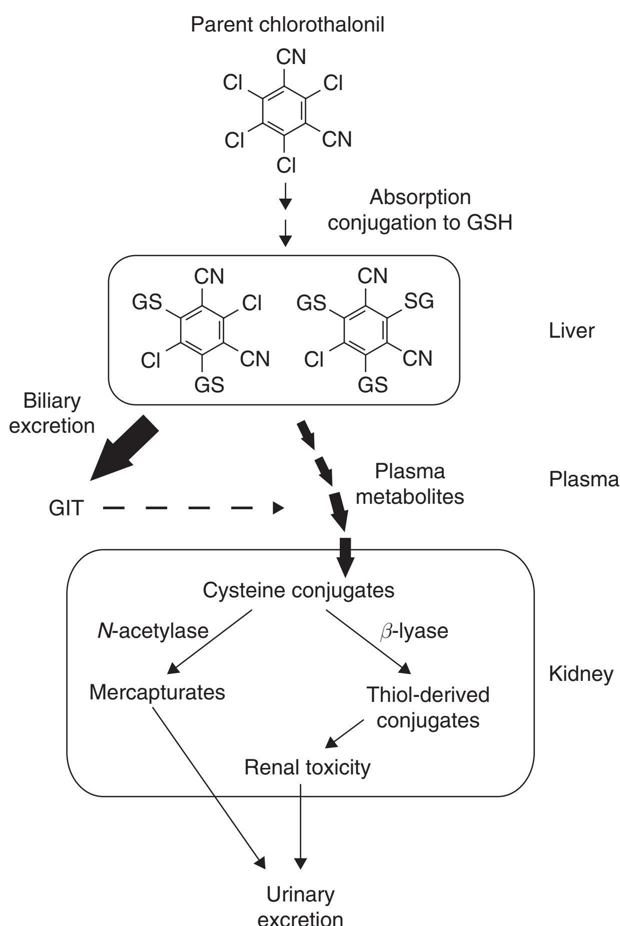

**FIGURE 52.2** Schematic outlining potential pathways of chlorothalonil metabolism in the rat that leads to formation of toxic metabolites within the kidney. Following absorption from the GIT, chlorothalonil is conjugated to glutathione in the liver. Further metabolic processing results in the formation of cysteine conjugates that may be detoxified via *N*-acetylase or activated to toxic thiol-derived species. GSH: glutathione; GIT: gastrointestinal tract. From Parsons (2001) reproduced with permission.

(Ollinger *et al.*, 2001). Conazoles such as propiconazole has phenobarbital-type mode of action leading to cell proliferation, increase in liver weight and microsomal enzyme induction (JMPR, 2004).

# TOXICITY

The spectrum of the chemical structure of fungicides is wide and diverse covering both inorganic and organic substances, thus leading to toxicity to livestock. Some of them are believed to be obsolete or discontinued for use. Till date several fungicides have been evaluated by WHO for their toxic potential and acceptable daily intake has been recommended by the Joint Meeting on Pesticide Residues (JMPR). A number of livestock poisoning cases from fungicides result from treated grains or potatoes, etc. Most of the available toxicity data are from laboratory animals; however, little information is available for farm animals and pets. In general, newer classes of fungicides have low-to-moderate toxicity. Chemical classes of fungicides by acute hazards along with their $LD_{50}$ values in rats as recommended by WHO have been summarized in Table 52.1.

These values are intended to be a guide only because the toxicity of fungicides may be due to the presence of other ingredients (such as surfactants, emulsifiers, etc.) present in the formulation. The details of guidelines for their hazard evaluation and their classification have already been summarized (IPCS, 2002; Gupta, 2006). Fungicides are believed to have a higher overall incidence than other pesticides in causing developmental abnormalities (Table 52.2) and oncogenesis. More than 80% of all oncogenic risk from the use of pesticides comes from a few fungicides, however, only a small proportion of pesticide-related deaths from fungicides have been reported (NAS, 1987; Costa, 1997).

## Inorganic fungicides

This class of fungicides includes potassium azide, potassium thiocyanate and titrated or sublimed sulfur. Sulfur had been in use in the 19th and early 20th century. Elemental sulfur and crude lime sulfur (calcium polysulfide and barium polysulfide) are commonly used as fungicides. Now, its use has declined due to availability of organic fungicides. The use of sulfur does not present a toxicological problem. Only micronized sulfur is responsible for sulfur poisoning. Lethal doses in cattle are 100–1000; sheep, 1000–1500; horses, 1000–1500 mg/kg b.w. The most affected animals are cattle, sheep, goats and dogs. Sulfur poisoning may lead to GI, neurological and pulmonary effects. On post-mortem congestion of the stomach and intestine, hemorrhagic suffusions and

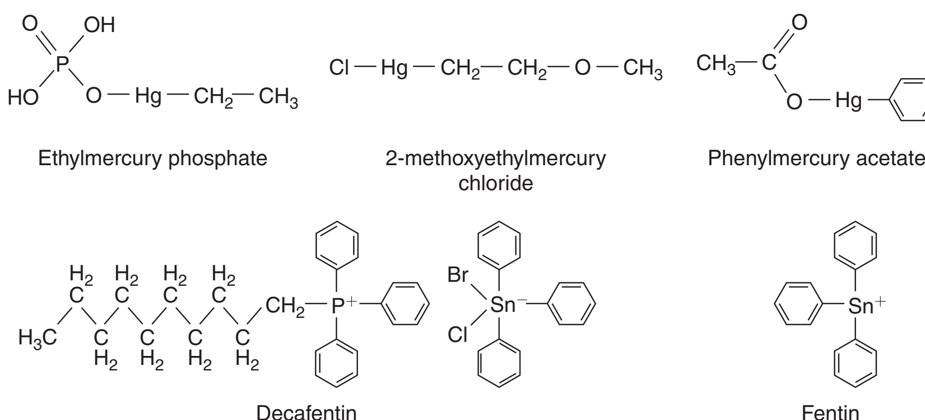
a: withdrawn by manufacturers; b: obsolete; ???: variable results and needs further studies. Compiled from Schardein (2000).

petechiae along the GIT and occasionally on the surface of bladder have been observed. Barium polysulfide after reaction with gastric acid yields barium chloride which is super purgative (Lorgue *et al.*, 1996; Sandhu and Brar, 2000; Ballantyne, 2004).

## Metallic fungicides

Inorganic metallic fungicides were first used in agriculture. They are protective and preventive. Mercuric and mercurous compounds have been withdrawn because of their toxicity. Ethylmercury phosphate, 2-methoxyethylmercury chloride, phenylmercury chloride and phenylmercury acetate are used as seed treatments for cereals and fodder beet (Lorgue *et al.*, 1996). Cattle, sheep and pigs are the most affected species. The oral $LD_{50}$ range from 10 to 500 mg/kg b.w. depending on the species and the particular compound involved. The organic metallic fungicides are both aliphatic and aromatic. Many are of moderate-to-high mammalian toxicity, several being immunotoxic and neurotoxic. Livestock exposed to mercurials may develop CNS and skin changes. The CNS signs include incoordination and ataxia, body swaying followed by prostration, convulsions and death. CNS stimulation is seen in calves, dogs, cats, rats and humans. However, other species (adult cattle, swine and fowls) manifest CNS depression. Other signs associated with organomercurials are bronchopneumonia, hyperpyrexia, epistasis, mucous membrane hemorrhages, hematuria and bloody feces. Skin lesions include eczema, pustules, ulceration, keratinization, dehydration, weakness and death (Sandhu and Brar, 2000). Typical organotins are di- and tri-alkyl and triphenyl tins. In general, they are severely irritant to the skin, eye and mucosae, and several are hepatorenotoxic and immunotoxic. They have been shown to increase susceptibility to infection, decrease lymphopoiesis and decrease T-lymphocyte production. Tri-alkyl tins cross the blood–brain barrier and are centrally neurotoxic (WHO, 1990).



## Halogenated substituted monocyclic aromatics

This class of chemicals includes chlorothalonil, dicloran, HCB, quintozene, PCP, dichlorophen, dinocap, tecnazene and chloroneb. Chlorothalonil is a non-toxic halogenated benzonitrile fungicide (Table 52.1). Dermal irritation has been observed following repeated exposure in the rat and rabbit, indicating the potential for chlorothalonil to cause skin irritation. Chlorothalonil causes irreversible and severe ocular lesion in rabbits. Signs of toxicity include decreased body weight and decreased hematological parameters, increased absolute kidney weight, vacuolar degeneration in the proximal tubular epithelium and hyperplasia of forestomach. Chlorothalonil is not genotoxic *in vivo*.

Treatment-related increase in renal tubular adenoma and carcinoma, squamous cell adenoma and carcinomas of the forestomach of both species have been reported. Chlorothalonil is not a developmental or reproductive toxicant when tested up to doses that cause significant maternal toxicity and maternal death; however, significant increase in the incidence of post-implantation loss due to early embryonic death has been observed (Parsons, 2001). Tecnazene has an oral rat $LD_{50}$ of 2047 mg/kg b.w. and is a mild irritant in the rabbit eye. The compound has the potential to produce pulmonary adenoma but it is neither embryotoxic nor teratogenic in mice (Ballantyne, 2004). Chloroneb, quintozene and dicloran have low toxicity (Table 52.1), and dinocap is a moderate eye irritant and has a human skin sensitizing potential. HCB, like other organochlorine compounds, possesses all the properties of chemical stability, slow degradation and biotransformation with potential to accumulate in adipose tissues and organs containing a high content of lipid membranes, and the ability to induce a range of tissue cytochrome-P450 as well as conjugate enzymes. Repeated exposure in animals results in hepatomegaly and porphyria as well as focal alopecia with itching and eruptions, followed by pigmented scars, anorexia and neurotoxicity expressed as irritability, ataxia and tremors. The compound can increase hepatic and thyroid tumors in hamsters and is teratogenic in mice (renal and palate malformations) and in rats (increased incidence of 14th rib). HCB is also toxic to developing perinatal animals (Table 52.2) and causes adverse effects on the immune system (Ecobichon, 2001). PCP has oral rat $LD_{50}$ of 150–210 mg/kg b.w. Common signs of toxicity are increased breathing rate, increased temperature, tremors, convulsions, loss in righting reflex and asphyxial spasms. Corneal injury may result from splashes or vapor over exposure. Toxicity is more due to contamination by commercial grade PCP. Technical grade PCP causes hepatic porphyria, increased microsomal monooxygenase activity and increased liver weight. Lethal dose in cattle and sheep is in the range of 120–140 mg/kg b.w. Chronic toxicity leads to emaciation, loss of weight, lowering of productivity (milk, eggs, meat, etc.) and increased mortality in poultry (ATSDR, 1994; Lorgue *et al.*, 1996).

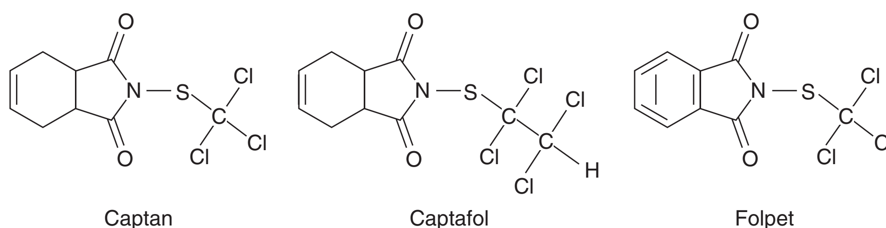
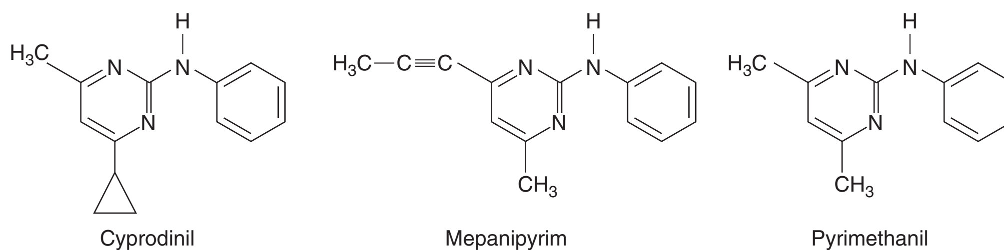
## Chloroalkylthiodicarboximides (phthalimides)

This class of chemicals contains broad-spectrum fungicides (captan, captafol and folpet) used as surface protectants on many crops. They are usually non-toxic to mammals. The oral $LD_{50}$ in rats is captan, >9000; folpet, >10000; and captafol, >5000 mg/kg b.w. (Table 52.1); however low-protein diet makes the animal more sensitive. Of this class of chemicals, folpet and captafol, true phthalimides have been deregistered and only captan, being structurally different (see structural formulae) with a cyclohexene ring, is being used. The compound is a severe eye irritant because of its high reactivity. Folpet induces incidences of diarrhea, vomiting, salivation, reduced food intake and reduced body weight gain. Testes weights are reduced in dogs. Single dose applied to the skin results in mild-to-low irritation. Long-term exposure to rats causes hyperkeratosis and acanthosis of the esophagus and stomach, particularly after folpet. Amongst ruminants, cattle is the most affected and captan produces toxicity (oral TD, 250–500 mg/kg b.w.) with labored respiration, anorexia, depression, hydrothorax, ascites and gastroenteritis (Sandhu and Brar, 2000). Mutagenicity may be associated with these agents at exceptionally high doses required to elicit biological effects. However, duodenal tumors in mice have been reported. Some compounds of this class cause teratogenicity (Table 52.2) whereas others are not proved because of, and/or masked by, maternal toxicity and possible nutritional deficits (Ecobichon, 2001). Captan induces hyperplasia of the crypt cells. Following treatment with folpet, the immune function is reduced, villi length is reduced and crypt compartments are expanded thereby reducing the villi-to-crypt ratio in mice (JMPR, 1990; Tinston, 1995; Waterson, 1995). The most characteristic pathologic finding consists of necrotizing and proliferative changes in the non-glandular portion of the stomach, dilation of the small intestine and focal epithelial hyperplasia in the proximal part of the small intestine in mice following treatment with captan. Captafol differs from captan and folpet in a number of areas including structure as well as chemical activity.



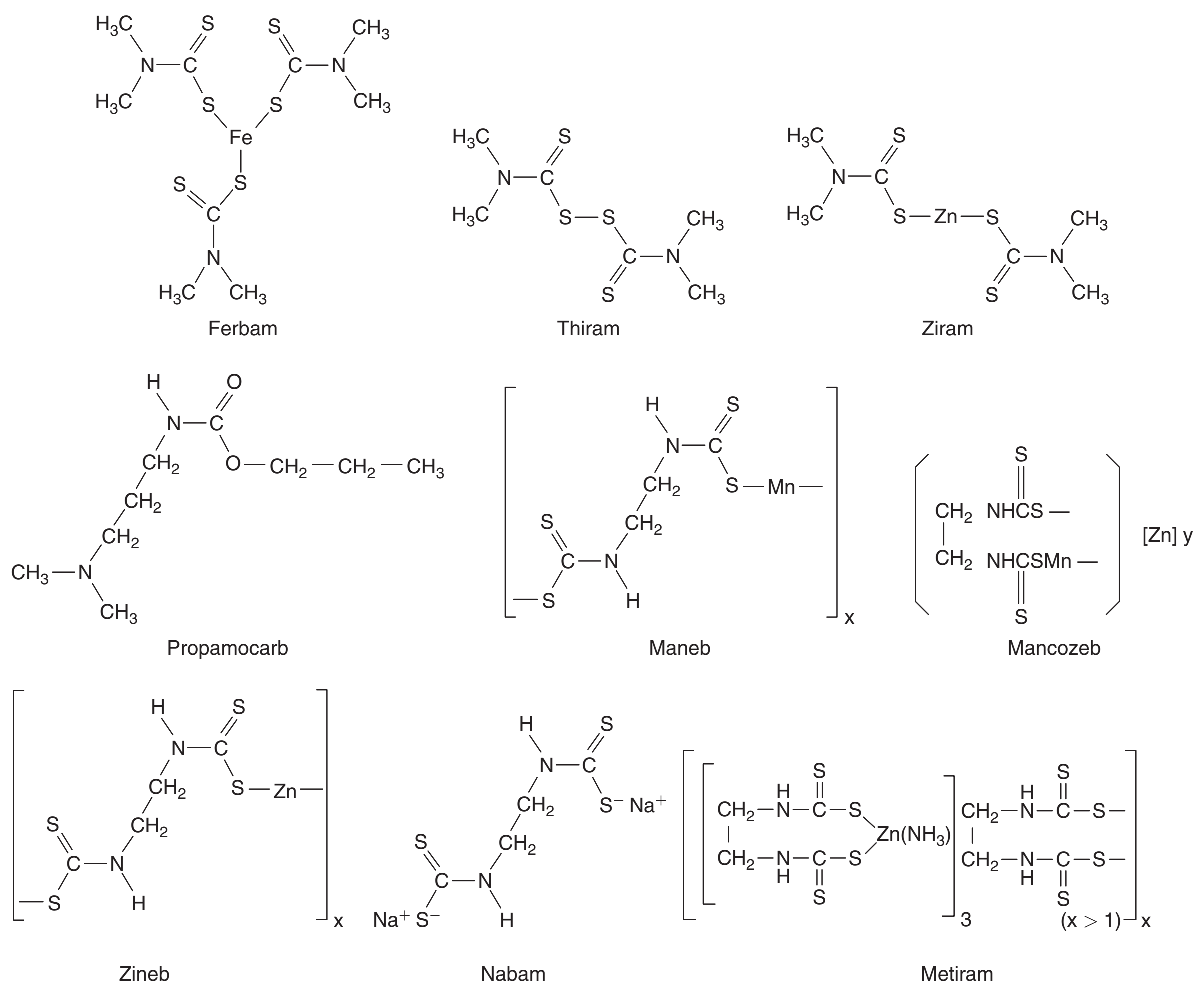
## Anilinopyrimidines

Anilinopyrimidine class of fungicides includes cyprodinil, mepanipyrim and pyrimethanil. The compounds have low toxicity and are unlikely to present acute hazards in normal use (Table 52.1). Cyprodinil produces hepatomagaly with hepatocellular hypertrophy and increased thyroid weights associated with follicular cell hypertrophy and hyprochromasia in rats. The compound also causes single cell necrosis in male and depletion of glycogen in female mice, while in dogs increased blood platelets have been observed at high doses. Mepanipyrim causes hepatocellular fatty vacuolation and lipofuscin deposition in Kupffer cells and hepatocytes of dogs, whereas such changes are not observed in cyprodinil-treated rats (Terada *et al.*, 1998). Pyrimethanil produces thyroid follicular cell tumors in rats and enhancement of hepatic thyroid hormone metabolism which may be responsible for thyroid tumorigenesis (Hurlety, 1998). In general, anilinopyrimidines do not have adverse effects on development toxicity. They are neither genotoxic nor have any carcinogenic potential (Waechter *et al.*, 2001).



## Carbamic acid derivatives

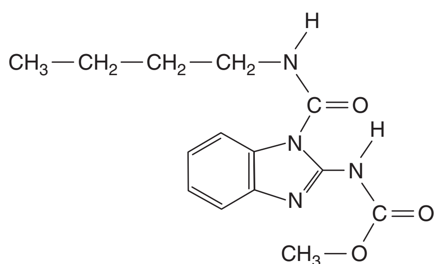
The carbamic acid class of fungicides includes dithiocarbamates (ferbam, thiram, ziram, propamocarb, etc.) and EDBCs (maneb, mancozeb, zineb, nabam, metiram, etc.). In general, carbamic acid derivatives have low or moderate acute toxicity by the oral, dermal and respiratory routes, except nabam (Table 52.1). The main features of toxicity include anorexia, diarrhea and flatulence followed by neurological effects, ataxia, muscular contractions and prostration. With repeated ingestion, there is a possibility of cutaneous effects, alopecia, risk of antithyroid effects specially with maneb. Certain compounds inhibit ovulation and egg laying (thiram, ziram). On histopathology, hepatic, renal and pulmonary congestion is common. Occasionally hepatic degeneration, ascites, enteritis and hydrothorax have been observed (Lorgue *et al.*, 1996). Propamocarb is non-irritating to the eye or skin. It induces sensitization in a Magnusson–Kligman maximization test. The signs of toxicity include hypokinesia, lethargy, hunched posture, body tremors, clonic convulsions, nasal hemorrhages, piloerection, staggering gait and ataxia. Vacuolar changes in various tissues including choroid plexus in the brain and reduction in organ weights have been observed in the rat and dog. The common development and reproductive abnormalities include reduction in copulation index (female rats) and body weight, retardation in ossification (rat) and increased post-implantation loss (rabbit) (JMPR, 2005). The principal target organ upon repeated exposure to EBDCs is thyroid. These fungicides alter thyroid hormone levels and/or weights. The developmental toxicity includes (Table 52.2) malformations and embryo-fetotoxic effects at maternally toxic dose levels with EBDCs in rats (Ollinger *et al.*, 2001).



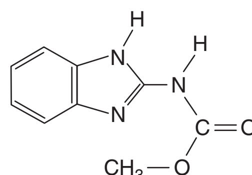
## Benzimidazoles

The major benzimidazole fungicides include benomyl, carbendazim and fuberidazole. Benomyl and carbendazim have low toxicity, whereas fuberidazole has moderate toxicity (Table 52.1). Both benomyl and carbendazim produce reproductive and developmental toxic effects in laboratory animals at high oral doses (Table 52.2). Reproductive toxic effects include decreased sperm count, decreased

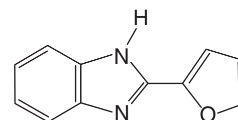
testicular weights and histopathological changes, while developmental toxic effects include reduced fetal weight and anomalies of eyes (micropthalmia or anopthalmia), skull and head (hydrocephaly). The effects observed on the oocytes and uterine weight in female rats are direct and are not mediated by endocrine changes (Jeffay *et al.*, 1996; Spencer *et al.*, 1996). High dose of carbendazim causes increased incidence of diffuse proliferation of parafollicular cells of the thyroid in female rats. Both of these compounds are not carcinogenic in rats; however, lifetime exposure to mouse shows benign (not malignant), hepatocellular neoplasms and adenomas. Carbendazim is a developmental toxicant and teratogen (JMPR, 2005).



Benomyl



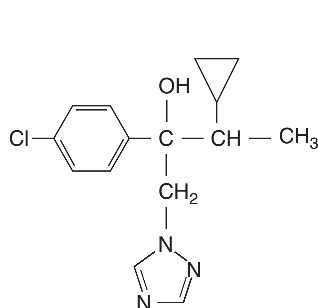
Carbendazim



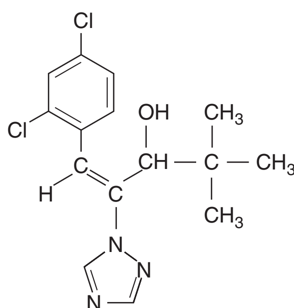
Fuberidazole

## Conazoles

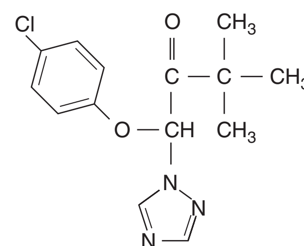
The conazole class of fungicides includes cyproconazole, diniconazole, triadimefon, triadimenol, propiconazole, imazalil, etc. and has low-to-moderate acute toxicity (Table 52.1). Triadimenol is triazole and triadimefon is closely chemically related to triadimenol with increasing toxicity for increasing isomer ratios of A (isomer B is less toxic). Triadimenol is non-irritating, whereas technical grade triadimefon is sensitizing. The other symptoms of toxicity include liver toxicity and central nervous system effects (general restlessness, alternating phases of increased and reduced motility and aggressive behavior). Liver adenomas have been observed in female mice. Developmental toxicity indicates increased ovary and testes weights, increased



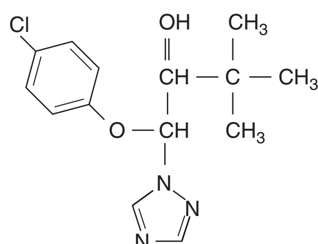
Cyproconazole



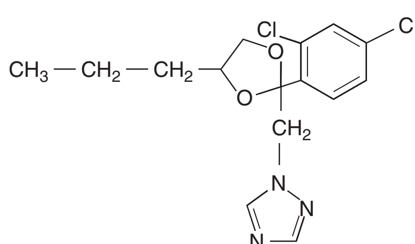
Diniconazole



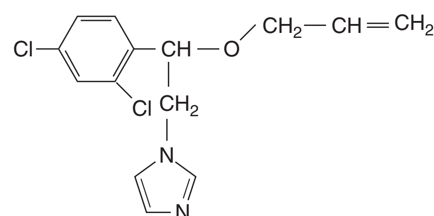
Triadimefon



Triadimenol



Propiconazole

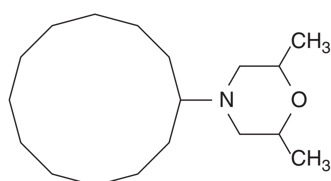


Imazalil

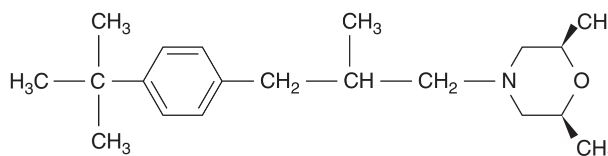
supernumerary lumber ribs with triadimenol, increased scapula malformations at maternal toxic doses in rabbits after triadimefon (JMPR, 2004). Propiconazole is not an eye irritant in rabbits, but is irritating to rabbit skin and is a skin sensitizer in guinea pigs. The compound causes reduction in body weights, liver toxicity and adverse changes in erythrocytes (rat) and in stomach (dog). On long-term exposure, liver hypertrophy and tumors (mice), uterine lumen dilation (rats), developmental toxicity indicative of reduced pup weight at parentally toxic dose and skeletal variations in laboratory animals have been observed (JMPR, 2004).

## Morpholines

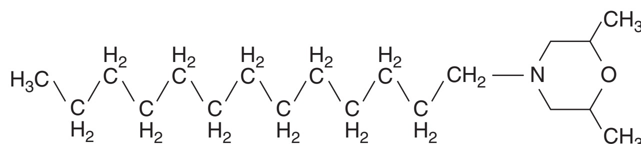
The class of morpholine fungicides includes dodemorph, fenpropimorph and tridemorph. These compounds are unlikely to cause acute hazards, except tridemorph which is moderately hazardous (Table 52.1). Dodemorph acetate is moderately irritating to rabbit skin and severely irritant to rabbit eye. Fenpropimorph is a mild irritant to rabbit skin, whereas tridemorph is non-irritant. Tridemorph and fenpropimorph lead to developmental toxicity (Table 52.2) with an increase in the total number of malformations (JMPR, 2004).



Dodemorph



Fenpropimorph



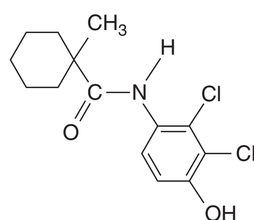
major component – 2,6-dimethyl-4-tridecylmorpholine

Tridemorph

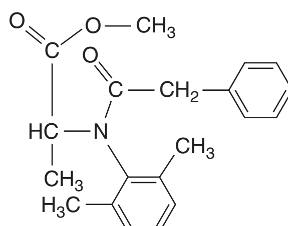
## Amides

Commonly used amide fungicides are fenhexamid, benalaxyl, metalaxyl, flutolanil tolylfluanid and dichlofluanid. The compounds are of low toxicity, except metalaxyl which is slightly hazardous (Table 52.1).

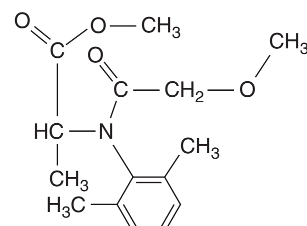
On long-term exposure, benalaxyl causes liver steatosis and hematological changes (rats) and atrophy of seminiferous tubules in dogs. In mice, increased mortality associated with amyloidosis has been observed. Reproductive abnormalities in rats include decreased body-weight gain,



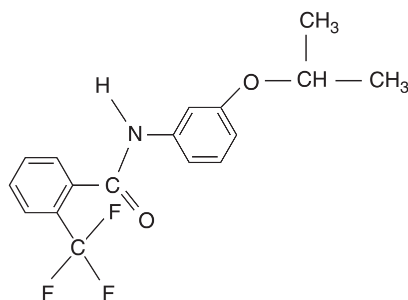
Fenhexamid



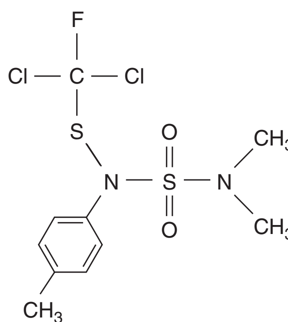
Benalaxyl



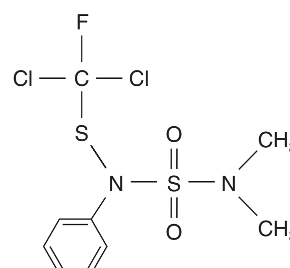
Metalaxyl



Flutolanil



Tolylfluanid

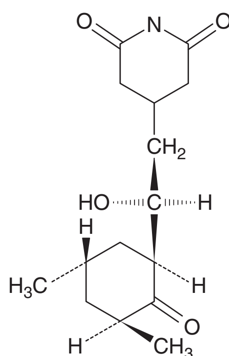


Dichlofluanid

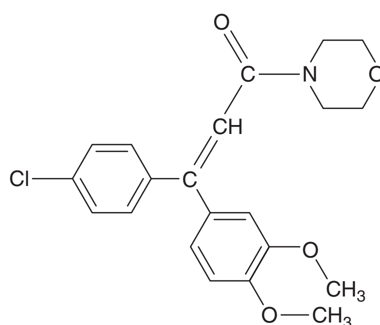
increased liver weight of pups and delayed ossification of cranial bones. Minor skeletal deviations at maternally toxic levels have been reported in rabbits (JMPR, 2005). Metalaxyl is a 1:1 mixture of R-enantiomer and S-enantiomer. Technical grade metalaxyl-M consists of a minimum of 97% of the R-enantiomer and 3% of the S-enantiomer. The two compounds are used as fungicides and are severe irritants to the rabbits. The dog is the most sensitive species with liver as the target organ. Both substances cause hepatocellular enlargement in rats, while dogs show changes in blood biochemical parameters indicative of hepatocellular damage (JMPR, 2002). Dichlofluanid and tolylfluanid have a fluorine atom substituted for one of the three chlorine atoms on the trichloromethylthio moiety of captan and folpet. Both compounds do not share a common mechanism of action with captan and folpet with regard to mouse duodenal tumors, principally because they do not induce these tumors. Flutolanil is slightly irritating to the eye. On long-term exposure, it leads to enlargement of liver, decreased body weights and mild hematological disturbances, with some evidence of increase in thyroid weight in rats and dogs. On long-term exposure to fenhexamid, the major target organ is the kidney in rats and mice, and the hematopoietic system (increase in Heinz bodies) and adrenal gland in dogs. At higher dose, delayed ossification has been observed in rabbits but is not teratogenic (JMPR, 2005). Tolylfluanid is a skin sensitizer and can lead to sedation, decreased motility, disturbed behavior and dyspnea. After intraperitoneal injection, signs consistent with local irritation, altered liver enzyme activity, increased liver weights and histopathological changes which are indicative of liver toxicity in mice, rats and dogs have been reported. At higher doses, the signs of renal toxicity and discoloration of bones and teeth, particularly the skull cap and incisors, have been observed. Alterations in thyroid hormones levels have also been observed in the number of studies in rats. The compound causes decreased pup viability at maternally toxic doses but is not teratogenic. These amides are neither genotoxic nor have any carcinogenic potential in animals (JMPR, 2002).

## Others

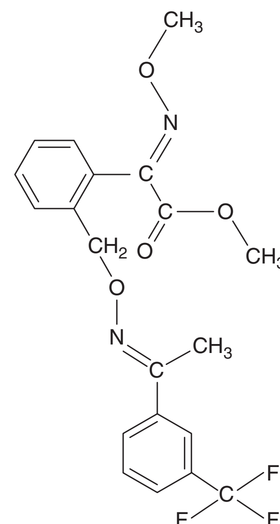
There are several other antibiotic substances, thiocarbonates and cinnamic acid derivatives which are used as fungicides. For example, sodium tetrathiocarbonate, a thiocarbonate fungicide, is moderately toxic. The rat oral $LD_{50}$ is 631 mg/kg b.w. It is a severe irritant to rabbit skin and a marked irritant to rabbit eye. Another compound cycloheximide is extremely toxic including development toxicity (Table 52.2) and has mutagenic potential. Dimethomorph has low oral toxicity in rats, is not an irritant to rabbit skin and is a minimal irritant to rabbit eye. Acute

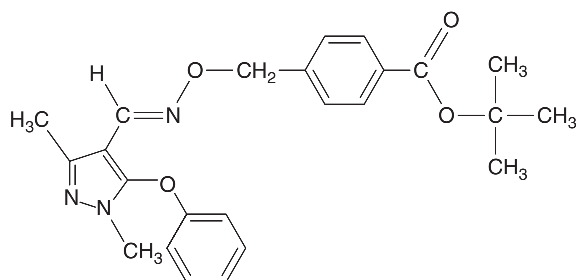


Cycloheximide

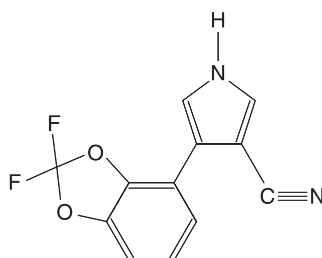


Dimethomorph





Fenpyroximate



Fludioxonil

Trifloxystrobin

oral $LD_{50}$ of fenpyroximate is 245 and 480 mg/kg b.w. in male and female rats, respectively. The compound may cause developmental toxicity in rats. Fludioxonil, a phenylpyrrole fungicide, and trifloxystrobin have low acute toxicity in rats. Fludioxonil is a slight eye irritant in rabbits, but is neither a skin irritant in rabbits nor a skin sensitizer in guinea-pigs. On long-term exposure it causes liver necrosis, kidney nephropathy and mild anemia, blue coloration of the urine and perineal fur. Reproductive toxicity indicates decreased pup weight gains in rats at parentally toxic doses. Trifloxystrobin is non-irritating but may be a skin sensitizer. Toxic symptoms are associated with liver toxicity, changes in kidney weight, atrophy of pancreas and spleen abnormalities. Development toxicity indicates decreased body-weight gain of pups accompanied by delayed eye opening at parentally toxic doses (JMPR, 2004).

## TREATMENT

In some cases there is no treatment, whereas in others supportive therapy as required by condition is indicated: (a) in the initial stages, use of emetics, gastric lavage or activated charcoal may be helpful for removal of residual material from GI tract; (b) oxygen should be provided immediately to suffice oxygen demand; (c) body temperature should be lowered (use of cool baths, cool sponging, placing the animal in the shade or in a cool, or in a quiet room); (d) phenothiazine tranquilizers by intramuscular route are advised to decrease exertion and stress and to facilitate handling of animal; however, these should not be used to sedate or comatose the animal; (e) balanced electrolyte solution should be administered to prevent dehydration and (f) animal should be removed immediately from the exposure site. In case of metallic poisoning, there is no satisfactory treatment of organomercurial toxicosis in farm or pet animals. Once developed, brain lesions are irreversible and treatment in such cases is meaningless. Traditional chelators like dimercaprol (BAL) or sodium thiosulfate have been recommended for many years, but have no or little value due to their poor affinity for organo-mercury compounds (Gupta, 1985b).

## CONCLUSION

Fungicides vary widely in chemical structure and thus in toxicity to livestock. The main hazard to livestock from fungicides is likely to arise from their use as dressings for the protection of stored grains, potatoes, etc. A number of livestock poisoning cases result from feeding of treated grains. More available toxicity data are from laboratory animals; however, little information is available for farm animals and pets. In general, fungicides have low-to-moderate toxicity. However, several fungicides such as alkyldithiocarbamic acid (manganese, zinc and ammonium salts), halogenated substituted monocyclic aromatics (dinocap), carbamic acid derivatives (maneb and zineb metabolite ethylenethiuram monosulfide), ferbam, mancozeb and maneb metabolites, HCB, benzimidazoles (benomyl and carbendazim), bis(tri-*n*-butyltin)oxide, chloroalkylthiodicarboximides (captafol and folpet), tridemorph, etc. are known to cause developmental toxicity and oncogenesis. More than 80% of all oncogenic risk from the use of pesticides come from a few fungicides, only a small proportion of pesticide-related deaths from fungicides have been reported. In view of teratogenicity several fungicides including cycloheximide have been deregistered or banned in many countries but still see some use in other, less regulated parts of the world. Other fungicides are undergoing re-evaluation because of suspected toxicity, particularly as teratogens or carcinogens and incomplete or outdated toxicity database.

# Alcohols and glycols

*Mary Anna Thrall and Dwayne W. Hamar*

## INTRODUCTION

Alcohols comprise a class of organic compounds composed of a hydrocarbon chain and a hydroxyl group. Alcohols that have one hydroxyl group are called monohydric, which include methanol, ethanol, and isopropanol, which are the three alcohols most commonly responsible for alcohol toxicosis. Alcohols are also classified as primary, secondary, or tertiary, according to the number of carbon atoms bonded to the carbon atom to which the hydroxyl group is bonded. Ethanol and methanol are primary alcohols, and isopropanol is a secondary alcohol. Glycols have two hydroxyl groups in their molecules and are dihydric. Ethylene glycol (EG) is the most common glycol responsible for poisonings, and EG poisoning is significantly more common in domestic animals than is alcohol toxicosis. Propylene glycol and butylene glycol are much less toxic than EG.

Alcohols and glycols are initially metabolized by hepatic alcohol dehydrogenase (ADH). Toxicosis from alcohols and glycols results in central nervous system (CNS) depression, ranging from decreased motor function to decreased consciousness, hypothermia, hypotension, coma and death from respiratory depression, and cardiovascular collapse. However, metabolites of the alcohols and glycols vary greatly in their toxicity. Metabolites of EG are nephrotoxic and result in acute renal failure. In primates, metabolites of methanol may result in blindness and permanent neurologic abnormalities.

## BACKGROUND

Reports of alcohol toxicosis are relatively quite rare in domestic animals when compared to the reported incidence in human beings. Ethanol, methanol, and isopropanol poisoning are all quite common in man. Methanol and isopropanol are usually ingested by adults as a substitute for ethanol, or in an attempt to commit suicide. In children, ingestion is usually accidental. Propylene glycol toxicosis is relatively rare in both human beings and domestic animals. Butylene glycol toxicosis is also rare, but the incidence in humans has increased recently as it is regarded as a neuromodulatory "recreational" drug (Irwin, 1996). EG toxicosis is relatively common, both in human beings and domestic animals (Barton and Oehme, 1981; Mueller, 1982; Rowland, 1987; Hornfeldt and Murphy, 1998). In humans, it is ingested either accidentally, as a substitute for ethanol, or to commit suicide; approximately 5000 episodes are reported in the United States each year (Litovitz *et al.*, 1997). The vast majority of these poisonings are unintentional, and approximately one-third of the cases occur in children (Litovitz *et al.*, 1997). EG is the most common cause of human poisoning in some countries such as Poland (Sienkiewicz and Kwiecinski, 1992).

Most incidents of EG toxicosis in domestic animals are also accidental, although malicious poisonings also occur. The mortality rate in dogs is reported to range from 50% to 70% (Barton and Oehme, 1981; Rowland, 1987; Connally, 1996) and is likely even higher in cats. EG intoxication is the second most common cause of fatal poisoning in animals, according to the American Association of Poison Control Centers (Hornfeldt *et al.*, 1998).

The first reported case of EG intoxication in a human being occurred in 1930 (Anonymous, 1930), but the toxicity of EG was not fully realized until 1938, when 76 people died after consuming an elixir of sulfanilamide containing 96% diethylene glycol (Geiling and Cannon, 1938). Since then, many reports of EG poisoning in humans and animals have been published.

# ALCOHOL TOXICOSES

## Ethanol toxicosis

Ethanol (ethyl alcohol) has the structural formula $C_2H_5OH$, a molecular weight of 46 Da, and is the alcohol in alcoholic beverages. The percentage of ethanol in alcoholic beverages is one-half of the drink's proof value. It is also used in perfumes and mouthwashes. Ethanol toxicosis in dogs has been associated with ingestion of bread dough (Thrall, 1984a; Suter, 1992; Means, 2003). Uncooked bread dough contains *Saccharomyces cerevisiae* (common brewer's and baker's yeast), which metabolizes carbohydrate substrates to ethanol and carbon dioxide. Ethanol poisoning in dogs has also been associated with rotten apples (Kammerer *et al.*, 2001), and alcoholic beverages (van Wuijckhuise and Cremers, 2003). Ethanol toxicosis can also occur in dogs and cats when ethanol is given intravenously (IV) as a competitive substrate to treat EG toxicosis. In a study in which cats were experimentally poisoned with EG and then treated with intraperitoneal (IP) ethanol at a dose of 5 ml of 20% ethanol/kg body weight every 6 h, serum ethanol concentrations ranged from as low as 16 mg/dl at 6 h post-IP ethanol to as high as 240 mg/dl 30 min post-IP ethanol. Cats with serum ethanol concentrations of more than 200 mg/dl appeared to be near respiratory arrest and were hypothermic (Thrall *et al.*, 1988).

### Toxicokinetics

Ethanol is rapidly absorbed from the gastrointestinal (GI) tract; the rate of absorption can be slowed by the presence of food in the stomach or small intestine. Clinical findings in dogs and cats with ethanol intoxication can be correlated with blood ethanol concentration (BEC). Clinical signs include ataxia, lethargy, sedation, hypothermia, and metabolic acidosis. Time of onset of clinical signs is dependent on the dose ingested, and the amount of food present in the GI tract, but usually occurs within an hour of ingestion. Although respiratory depression usually develops when the concentration is between 400 and 500 mg/dl, death has been reported in a human being with BEC as low as 260 mg/dl (Maling, 1970).

### Mechanism of action

The mechanism of action of alcohol on the CNS is related in part to its interactions with biomembranes and its probable inhibition of gamma-amino butyric acid (GABA) receptors (Valentine, 1990).

### Diagnosis and treatment

A diagnosis can be made based on history, clinical signs, increased plasma osmolality and osmole gap, metabolic acidosis, and BEC, which can be measured by most laboratories. Hyperosmolality as a result of alcohol toxicosis must be determined using a freezing-point depression osmometer, as vapor pressure osmometers do not detect the osmotic effects of alcohols (Champion *et al.*, 1975). It is important to differentiate EG toxicosis from alcohol toxicosis. The clinical signs and early laboratory findings can be similar. However, patients with EG toxicosis must be given ADH inhibitors such as 4-methylpyrazole to prevent the formation of toxic metabolites, while patients with ethanol toxicosis can be treated supportively. Severe ethanol intoxication usually requires mechanical ventilation using a cuffed endotracheal tube. Hypothermia may develop, and alterations in hydration, electrolyte, and acid–base status should be corrected (Richardson, 2006).

## Methanol toxicosis

Methanol (methyl alcohol, wood alcohol) has the molecular structure $CH_3OH$, a molecular weight of 32 Da, and is widely used as a solvent, fuel (Sterno), gasoline additive, antifreeze, and windshield washer fluid (30–40% methanol). The minimum lethal dose in dogs is between 5.0 and 11.25 ml/kg, and in human beings is 1.25 ml/kg (Valentine, 1990). Methanol toxicosis is rare in dogs, but has been reported in a dog that chewed open a bottle of 98% methanol antifreeze (Hurd-Kuenzi, 1983).

### Toxicokinetics

Ingested methanol is absorbed quickly from the GI tract, and peak methanol concentrations occur within 30–60 min following ingestion (Barceloux *et al.*, 2002). Toxicosis has also been reported following inhalation or dermal absorption. Methanol is much more toxic to human beings and non-human primates than it is to other mammals. Methanol is metabolized by ADH to formaldehyde, which is oxidized to formic acid by formaldehyde dehydrogenase. In mammals other than primates, formic acid is metabolized relatively rapidly to carbon dioxide and water. Formic acid is metabolized less efficiently in primates.

### Mechanism of action

Formic acid is responsible for ocular and CNS lesions in primates as a result of inhibition of cytochrome oxidase (Roe, 1982). Blindness and permanent neurological abnormalities are common sequel in primates.

### Diagnosis and treatment

Clinical signs in animals other than primates are similar to those seen with ethanol toxicosis and are primarily related to CNS depression and metabolic acidosis. Vomiting and abdominal pain may be seen. In primates, following the

initial nausea and CNS depression, a latent period of approximately 12–24 h is followed by metabolic acidosis and impaired visual function. Laboratory findings in primates include hyperosmolality, increased anion gap, and severe metabolic acidosis (Bischoff, 2006a). Diagnosis can be made by history and measurement of blood methanol concentrations (or formic acid in primates).

Treatment in non-primates is symptomatic, and similar to treatment for ethanol toxicosis. Primates are treated with 4-methylpyrazole to compete with ADH and inhibit metabolism (Barceloux *et al*., 2002), or alternatively, with ethanol. Hemodialysis is also used to remove formic acid. Folic acid is given IV to enhance formic acid metabolism. It is probably inappropriate to treat methanol toxicosis in non-primates with ethanol because ethanol contributes to the sedation, and the metabolites of methanol do not cause blindness in dogs, as they do in primates.

## Isopropanol toxicosis

Isopropanol (isopropyl alcohol) has the structural formula $CH_3CH(OH)CH_3$, of a molecular weight of 60 Da, and is found in rubbing alcohol (70%), antifreeze, detergents, window cleaning products, and disinfectants. Ingestion is the usual cause of poisoning in human beings, although toxicity from inhalation and topical absorption has been reported. Isopropanol toxicosis is rare in domestic animals, possibly owing to its bitter taste. It has been reported in a horse that was mistakenly administered isopropanol via nasogastric intubation for colic; the isopropanol was mistaken for mineral oil (Somerville and Plumlee, 1996).

### *Toxicokinetics*

Isopropanol is approximately twofold more toxic than ethanol. It is rapidly absorbed from the GI tract, and approximately 80% is metabolized to acetone, which is also a CNS depressant, but acetone has a much longer half-life (16–20 h) than does alcohol.

### *Diagnosis and treatment*

Clinical signs associated with isopropanol toxicosis are similar to those for ethanol toxicosis, and include CNS depression, hypotension, vomiting, and abdominal pain due to severe gastritis, which is secondary to direct irritation. The breath of patients that have ingested isopropanol has a characteristic acetone-like odor (Somerville and Plumlee, 1996). Treatment is supportive and includes fluids, correction of acid–base abnormalities, and assisted respiration if necessary (Oehme and Kore, 2006). Hemodialysis is effective in removing isopropanol and acetone, and 4-methylpyrazole will prevent the metabolism of isopropanol to acetone.

# GLYCOL TOXICOSES

## Propylene glycol toxicosis

Propylene glycol (1,2-propanediol) has the structural formula $C_3H_8O_2$ and a molecular weight of 76 Da. It is one of the least toxic of the glycols, and is used as automotive antifreeze, an industrial and pharmaceutical solvent, in cosmetics, and a processed food additive for human and animal consumption. Although it is considered non-toxic when compared to EG, it causes CNS depression and lactic acidosis when ingested in large quantities. When used as an additive in semi-moist cat food, it historically caused Heinz body formation in erythrocytes, but did not cause an anemia when ingested in those small quantities (Christopher *et al*., 1989a, b; Weiss *et al*., 1990; Bauer *et al*., 1992a, b). However, cats eating such diets were more susceptible to other additional causes of oxidative injury, and even though overt anemia may not occur, red cells with Heinz bodies have a reduced life span. Consequently, it is no longer used as an additive in cat foods.

The oral median lethal dose for propylene glycol in dogs has been reported to be as low as 9 ml/kg (Bischoff, 2006b). Fatal cases of malicious propylene glycol toxicosis have been reported in dogs (Bischoff, 2006b). It is considered relatively unpalatable to dogs (Marshall and Doty, 1990). Fatal propylene glycol toxicosis was reported in a horse that was inadvertently given 7.6 ml/kg propylene glycol orally instead of mineral oil for potential grain overload (Dorman and Haschek, 1991). The horse had a serum concentration of 900 mg/dl propylene glycol at the time of death, 28 h following ingestion. Cause of death was presumably respiratory arrest. Propylene glycol toxicosis has been reported in at least two other horses with colic in which propylene glycol was mistaken for mineral oil (Myers and Usenik, 1969; McClanahan *et al*., 1998); both of these horses survived. In both cases, the horses were given approximately 6 ml/kg body weight via nasogastric tube. Heinz body formation also occurs in horses ingesting propylene glycol (McClanahan *et al*., 1998). Propylene glycol may be used to treat and prevent bovine ketosis, which may partially explain the availability and apparent ease with which it is confused with mineral oil.

### *Toxicokinetics*

It is rapidly absorbed in the GI tract and oxidized by ADH to D and L isomers of lactic acid, resulting in lactic acidosis. Almost all propylene glycol is metabolized within 24 h of ingestion.

### *Diagnosis and treatment*

Clinical signs depend on the quantity ingested and may include depression, ataxia, muscle fasciculations, hypotension, osmotic diuresis, respiratory arrest, and circulatory

collapse. Clinical signs in ruminants are similar to those seen in other species, and included ataxia, depression, and recumbency (Pintchuck *et al.*, 1993). Laboratory findings include metabolic acidosis, increased anion gap, and hyperosmolality of the plasma and the presence of Heinz bodies in cats and horses. Diagnosis is usually based on history of exposure, and can be confirmed by measuring propylene glycol concentrations in urine and serum by gas chromatography. Treatment for all species is supportive and includes correction of hydration and acid–base abnormalities.

## Butylene glycol toxicosis

Butylene glycol (1,2-, 1,3-, and 1,4-butanediol) has the structural formula $C_4H_{10}O_2$ and a molecular weight of 90 Da. Butylene glycol is used as antifreeze, an industrial cleaner, in cosmetics, is a component of polyurethane, and is used to make Spandex. Although no published reports of butylene glycol toxicosis in domestic animals were found in the literature, there are numerous reports of human intoxications from butylene glycol or the metabolite gamma-hydroxybutyrate (Dyer, 1991; Mack, 1993). Butylene glycol and the metabolite gamma-hydroxybutyrate are used as "recreational" drugs and were once marketed by health food stores as a food additive for bodybuilders, and to treat depression and insomnia.

1,3-butanediol has been used as an antidote for experimental EG toxicosis in dogs, since it a competitive substrate for ADH (Thrall *et al.*, 1982; Murphy *et al.*, 1984; Cox *et al.*, 1992). Although it was found to be a more effective antidote than ethanol, in that more unmetabolized EG was excreted in the urine in patients treated with 1,3-butanediol, CNS depression was as severe or more severe than that induced by ethanol therapy, and plasma hyperosmolality and metabolic acidosis were more severe than with ethanol therapy (Thrall *et al.*, 1982).

### *Toxicokinetics*

Butylene glycol is metabolized by ADH to acetoacetate and gamma-hydroxybutyrate, the so-called "date-rape" drug.

### *Mechanism of action*

Butylene glycol is a CNS depressant much like ethanol, due to the effect of the gamma-hydroxybutyrate on the CNS, and in large quantities can result in seizures and respiratory arrest.

### *Treatment*

Therapy for butylene glycol toxicosis in human beings is supportive, similar to therapy for ethanol toxicosis.

## EG toxicosis

EG has the structural formula $C_2H_6O_2$ and a molecular weight of 62 Da. EG is used primarily as an antifreeze and windshield de-icing agent. Its small molecular weight makes it very effective in lowering the freezing point of water. EG is also used as a cryoprotectant for embryo preservation, in the manufacture of polyester compounds, as a solvent in the paint and plastic industries, and as an ingredient in photographic developing solutions, hydraulic brake fluid and motor oil, and inks and wood stains (Davis *et al.*, 1997). The most readily available source of EG in the home is antifreeze solutions, which consist of approximately 95% EG.

### *Toxicokinetics*

Unlike the other alcohols (with the exception of methanol in primates) and glycols, the metabolites of EG are very toxic. EG is initially oxidized to glycoaldehyde by ADH, and glycoaldehyde is then oxidized to glycolic acid and then to glyoxylic acid. Glyoxylic acid is primarily converted to oxalic acid but may follow several metabolic pathways; end products may also include glycine, formic acid, hippuric acid, oxalomalic acid, and benzoic acid. Calcium is bound to oxalic acid, resulting in calcium oxalate crystal formation. Calcium oxalate crystal deposition is widespread but is most severe in the kidney, and crystalluria is a consistent finding in animals producing urine (Grauer *et al.*, 1984; Thrall *et al.*, 1984b).

### *Mechanism of action*

EG *per se* has no major effects other than GI irritation, and increased serum osmolality. Glycoaldehyde, the first metabolite, is thought to be primarily responsible for CNS dysfunction; respiration, glucose, and serotonin metabolism are depressed; and CNS amine concentrations are altered (Parry and Wallach, 1974; Gordon and Hunter, 1982). Hypocalcemia secondary to calcium oxalate deposition may contribute to CNS signs, although the concurrent metabolic acidosis shifts calcium to the ionized active state, reducing the chances of hypocalcemia-associated clinical signs. Acidosis is also thought to lead to altered levels of consciousness and cerebral damage. Most of the metabolites are very cytotoxic to renal tubular epithelium, and some renal epithelial and interstitial damage may be associated with calcium oxalate crystal formation within the renal tubules (de Water *et al.*, 1999). Renal epithelial cell death appears to be due primarily to destruction of cytoplasmic organelles, especially mitochondria (Bachman and Goldberg, 1971). Metabolic acidosis is often severe and has a deleterious effect on multiple organ systems. Glycolic acid accumulation is the primary cause of the metabolic acidosis associated with EG intoxication (Jacobsen *et al.*, 1984), although other acid metabolites

also contribute. Glycolic acid accumulates because the lactic dehydrogenase enzyme that metabolizes glycolic to glyoxylic acid becomes saturated.

### *Toxicity*

Before it is metabolized, EG is no more toxic than ethanol, although EG is a more potent CNS depressant than ethanol (Berger and Ayyar, 1981). However, EG is biotransformed to highly toxic metabolites that result in severe metabolic acidosis and acute renal failure, hallmarks of EG poisoning (Thrall *et al*., 1984b; Dial *et al*., 1994a, b; Davis *et al*., 1997). The minimum lethal dose of undiluted EG is 6.6 ml/kg in the dog (Kersting and Nielson, 1966) and 1.5 ml/kg in the cat (Milles, 1946).

### *Clinical signs*

Clinical signs are dose dependent and can be divided into those caused by unmetabolized EG and those caused by its toxic metabolites. The onset of clinical signs is almost always acute. Early clinical signs are usually observed 30 min after ingestion and often last until approximately 12 h after ingestion; they are primarily associated with EG-induced gastric irritation and high EG blood concentrations. These signs commonly include nausea and vomiting, CNS depression, ataxia and knuckling, muscle fasciculations, decreased withdrawal reflexes and righting ability, hypothermia, and osmotic diuresis with resultant polyuria and polydipsia (Grauer *et al*., 1984; Thrall *et al*., 1984b; Connally *et al*., 1996). As CNS depression increases in severity, dogs drink less, but osmotic diuresis persists, resulting in dehydration. In dogs, CNS signs abate after approximately 12 h, and patients may briefly appear to have recovered. Cats usually remain markedly depressed and do not exhibit polydipsia. Animals may be severely hypothermic, particularly if housed outside during the winter months. Clinical signs associated with the toxic metabolites are primarily related to oliguric renal failure, which is evident by 36–72 h following ingestion in dogs and by 12–24 h following ingestion in cats. Clinical signs may include severe lethargy or coma, seizures, anorexia, vomiting, oral ulcers and salivation, and oliguria with isosthenuria. Anuria often develops 72–96 h after ingestion. The kidneys are often swollen and painful, particularly in cats.

### *Early laboratory abnormalities*

Abnormal laboratory findings can also be divided into those associated with early EG intoxication, which may be related to the presence of EG per se or to its toxic metabolites, and those associated with late EG intoxication, most of which are related to renal failure. Early abnormalities are primarily due to the presence of acid metabolites of EG in the serum that result in metabolic acidosis and include decreased plasma bicarbonate concentration and increased anion gap. Additionally, hyperphosphatemia may occur owing to ingestion of a phosphate rust inhibitor present in some commercial antifreeze products (Grauer *et al*., 1984; Connally *et al*., 1996). The decreased plasma bicarbonate ($HCO_3$) concentration can be seen as early as 1 h following EG ingestion. Metabolites of EG significantly increase the pool of unmeasured anions and cause an increased anion gap. The anion gap is increased by 3 h after ingestion, peaks at 6 h after EG concentration, which peaks 1–6 h following ingestion, and EG is usually no longer detectable in the serum or urine 48–72 h after ingestion (Thrall *et al*., 1982; Grauer *et al*., 1984; Dial *et al*., 1994a, b). Kits[1] are available that accurately estimate blood EG concentrations with a minimum detection limit of 50 mg/dl, and the results correlate well with other established methods of measuring EG concentrations such as gas chromatography (Dasgupta *et al*., 1995), although the presence of propylene glycol or glycerol in the blood may cause a false-positive test reaction. Ethanol and methanol do not result in a false-positive test result. Cats may be intoxicated with a lethal dose of EG that is below the 50 mg/dl detectable level of the EG test kit. Therefore, if the test kit is negative and historical findings as well as clinical signs are compatible with EG ingestion, the recommendation is to initiate appropriate therapy for EG intoxication as well as submit a serum sample to a reference laboratory capable of determining a quantitative concentration.

Determination of serum osmolality is also useful for diagnosing early EG toxicosis, although other osmotically active, small molecular weight alcohols and glycols also increase serum osmolality (Ammar and Heckerling, 1996). Serum osmolality is increased by 1 h after ingestion of EG, increasing in parallel with serum EG concentrations (Dial *et al*., 1994a, b). When measured serum osmolality (by osmometry) is compared to calculated serum osmolality, the difference is referred to as the osmole or osmolal gap. If calculated osmolality is not provided on the biochemical profile printout, osmolality in mOsm/kg may be calculated using the following formula:

$$1.86\ (Na^+ + K^+) + \text{glucose}/18 + \text{BUN}/2.8 + 9$$

Normal serum osmolality is 280–310 mOsm/kg, and the normal osmole gap is less than 10 mOsm/kg. Serum osmolality as high as 450 mOsm/kg and an osmole gap as high as 150 mOsm/kg may be seen 3 h after ingestion, depending on the quantity of antifreeze ingested (Jacobsen *et al*., 1982b; Grauer *et al*., 1984). Both the gap and the measured osmolality may remain significantly high for

[1] Ethylene Glycol Test Kit, PRN Pharmacol, Inc., 5830 McAllister Avenue, Pensacola, FL 32504 (Tel.: +1 800 874 9764).

approximately 18 h after ingestion. Multiplication of the osmole gap by 5 yields an approximate serum EG concentration in mg/dl (Burkhart and Kulig, 1990). Each 100 mg/dl increment increase in EG concentration contributes approximately 16 mOsm/kg $H_2O$ to the serum osmolality (Eder *et al.*, 1998). Simultaneous or sequential increases in osmole and anion gaps are very suggestive of EG intoxication. As EG is metabolized, its contribution to the osmole gap diminishes because the accumulating negatively charged metabolites do not contribute to the osmole gap (Eder *et al.*, 1998). Two types of instruments are used to measure osmolality, freezing-point osmometers and vapor pressure osmometers. Because EG is nonvolatile (boiling point, 197°C), it is detected by either the freezing-point or vapor pressure methods. However, methanol, ethanol, and other volatile compounds, while contributing to serum osmolality, may go undetected if assayed by the vapor pressure method. Most clinical laboratories use the freezing-point method (Kruse and Cadnapaphornchai, 1994). Osmolality can be measured using serum or plasma; if the latter is used, heparin is the preferred anticoagulant. Other anticoagulants, such as EDTA, can markedly increase osmolality and can result in spurious increases in the osmole gap (Kruse and Cadnapaphornchai, 1994).

Dogs are isosthenuric (urine specific gravity of 1.008 to 1.012) by 3 h following ingestion of EG owing to osmotic diuresis and serum hyperosmolality-induced polydipsia (Grauer *et al.*, 1984; Dial *et al.*, 1994a). The urine specific gravity in cats is also decreased by 3 h after ingestion but may be above the isosthenuric range (Dial *et al.*, 1994b; Fogazzi, 1996). Calcium oxalate crystalluria is a common finding and may be observed as early as 3 and 6 h after ingestion in the cat and dog, respectively, as a result of oxalic acid combining with calcium (Dial *et al.*, 1994a, b). Calcium oxalate monohydrate crystals are variably sized, clear, six-sided prisms (Figure 53.1) (Scully *et al.*, 1979; Godolphin *et al.*, 1980; Terlinsky *et al.*, 1981; Jacobsen *et al.*, 1982a; Kramer *et al.*, 1984; Foit *et al.*, 1985; Thrall *et al.*, 1985; Steinhart, 1990). In animals and people poisoned with EG, the monohydrate form is observed more frequently than the dihydrate form, which appears as an envelope or Maltese cross (Connally *et al.*, 1996; Eder *et al.*, 1998). Dumbbell or sheaf-shaped crystals are observed infrequently. The detection of calcium oxalate crystalluria, particularly the monohydrate form, provides strong supporting evidence for the diagnosis of EG poisoning (Fogazzi, 1996). Urinary pH consistently decreases following EG ingestion.

Another diagnostic procedure that may be helpful in detecting early EG intoxication is examination of the oral cavity, face, paws, vomitus, and urine with a Wood's lamp to determine whether they appear fluorescent. Many antifreeze solutions manufactured today contain sodium fluorescein, a fluorescent dye that aids in the detection of

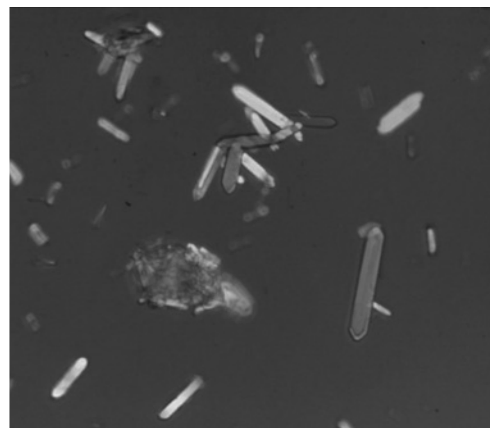

**FIGURE 53.1** Calcium oxalate monohydrate crystals (polarized light) from a dog with EG toxicosis. This figure is reproduced in color in the color plate section.

leaks in vehicle coolant systems. The dye is excreted in the urine for up to 6 h following ingestion of the antifreeze (Winter *et al.*, 1990). A negative test does not eliminate the possibility of EG ingestion, since not all antifreeze solutions contain the dye.

### *Late laboratory abnormalities*

With the onset of renal damage and subsequent decreased glomerular filtration, serum creatinine and blood urea nitrogen (BUN) concentrations increase. In the dog, these increases begin to occur between 24 and 48 h following EG ingestion. In the cat, BUN and creatinine begin to increase approximately 12 h after ingestion; however, since cats do not develop polydipsia, this may be in part due to dehydration. Serum phosphorus concentrations increase at this time owing to decreased glomerular filtration. Hyperkalemia develops with the onset of oliguria and anuria. Serum calcium concentration is decreased in approximately half of the patients (Thrall *et al.*, 1984b; Connally *et al.*, 1996), and is due to formation of insoluble calcium oxalate. Clinical signs of hypocalcemia are infrequently observed because acidosis results in a shift to the ionized, physiologically active form of calcium. Serum glucose concentration is increased in approximately 50% of dogs and cats (Thrall *et al.*, 1984b; Connally *et al.*, 1996) and is attributed to inhibition of glucose metabolism by aldehydes, increased epinephrine and endogenous corticosteroids, and uremia. Animals presenting with late EG poisoning are likely to have little to no osmole gap increase but will have an increased osmolality (whether calculated or measured) because of the azotemia and hyperglycemia. Animals remain isosthenuric in the later stages of toxicosis owing to renal dysfunction and impaired ability to concentrate urine. Calcium oxalate crystalluria persists for as long as animals are producing urine. Urine abnormalities

associated with renal damage may include hematuria, proteinuria, and glucosuria. Granular and cellular casts, white blood cells, red blood cells, and renal epithelial cells may be observed in the sediment of some patients (Thrall *et al.*, 1984b; Connally *et al.*, 1996).

### Treatment

Therapy for EG poisoning is aimed at preventing absorption, increasing excretion, and preventing metabolism of EG. Supportive care to correct fluid, acid–base, and electrolyte imbalances is also helpful. Although therapeutic recommendations have traditionally included induction of vomiting, gastric lavage, and administration of activated charcoal (Thrall *et al.*, 1995, 1998) it is likely that these procedures are not beneficial because of the rapidity with which EG is absorbed (Davis *et al.*, 1997). The most critical aspect of therapy is based on prevention of EG oxidation by ADH, the enzyme responsible for the initial reaction in the EG metabolic pathway (Parry and Wallach, 1974). Typically, dogs must be treated within 8 h following ingestion, and cats must be treated within 3 h for treatment to be successful (Dial *et al.*, 1994a, b). However, this is somewhat dependent on the amount of EG ingested. Historically, treating EG toxicosis has been directed toward inhibiting EG metabolism with ethanol, a competitive substrate that has a higher affinity for ADH than EG (Penumarthy and Oehme, 1975; Bostrom and Li, 1980). Ethanol has numerous disadvantages because it enhances many of the metabolic effects of EG. Both ethanol and EG are CNS depressants, and it is the compounded CNS depression that most limits the usefulness of ethanol as an antidote. Additional disadvantages of ethanol treatment include its metabolism to acetaldehyde, which impairs glucose metabolism and is a cerebral irritant. Ethanol also contributes to metabolic acidosis by enhancing the formation of lactic acid from pyruvate and may potentiate hypocalcemia (Money *et al.*, 1989). Moreover, ethanol compounds the effects of EG-induced osmotic diuresis and serum hyperosmolality (Kruse and Cadnapaphornchai, 1994).

4-Methylpyrazole (fomepizole) has become the preferred antidote in dogs (Grauer *et al.*, 1987; Dial *et al.*, 1989; Connally *et al.*, 1996), and more recently, cats (Connally *et al.*, 2002a, b; Thrall, 2006). Fomepizole is an ADH inhibitor, not a competitive substrate, and it does not induce CNS depression (in dogs), diuresis, or hyperosmolality at the recommended dosage. The recommended dose of fomepizole for dogs is 20 mg/kg body weight IV initially, followed by 15 mg/kg IV at 12 and 24 h, and 5 mg/kg IV at 36 h (Grauer *et al.*, 1987; Connally *et al.*, 1996; Thrall *et al.*, 2006). Cats must be given a much higher dose of fomepizole than dogs, because feline ADH is less effectively inhibited by fomepizole than is canine ADH (Connally *et al.*, 2000a, b). Cats are initially treated with 125 mg/kg fomepizole IV followed by 31.25 mg/kg IV fomepizole at 12, 24, and 36 h. The only adverse clinical sign that we have observed is CNS depression that appears to be fomepizole related (Connally *et al.*, 2002a, b). If ingestion of a large dose of EG is suspected, repeating serum quantification tests can be performed to determine whether continuation of therapy beyond 36 h is necessary. Alternatively, additional doses of fomepizole can be administered empirically. Fomepizole is commercially available as Antizol-Vet,[2] which can be conveniently reconstituted. Appropriate therapy also consists of IV fluids to correct dehydration, increase tissue perfusion, and promote diuresis. The fluid volume administered should be based on the maintenance, deficit, and continuing loss needs of the patient. Frequent measurement of urine production, serum urea nitrogen and creatinine, and blood pH, bicarbonate, ionized calcium, and electrolytes daily or twice daily will help guide fluid and electrolyte therapy (Grauer, 1998). Bicarbonate should be given slowly IV to correct the metabolic acidosis. Hypothermia can be controlled with blankets or the use of a pad with circulating warm water.

In animals that are azotemic and in oliguric renal failure on presentation, almost all of the EG has been metabolized, and treatment to inhibit ADH is likely to be of little benefit. However, ADH inhibitors should be given up to 36 h following ingestion to prevent the metabolism of any residual EG. Fluid, electrolyte, and acid–base disorders should be corrected and diuresis established, if possible. Diuretics, particularly mannitol, may be helpful. The tubular damage caused by EG may be reversible, but tubular repair can take weeks to months. Animals may take up to 1 year following EG toxicosis to regain concentrating ability, and some remain isosthenuric. Supportive care to maintain the patient during the period of renal tubular regeneration is necessary, and peritoneal dialysis may be useful (Shahar and Holmberg, 1985; Fox *et al.*, 1987; Crisp *et al.*, 1989). Hemodialysis has been attempted in dogs with EG-induced renal failure (DiBartola *et al.*, 1985) and has been shown to have a relatively good success rate in cats with acute renal failure (Langston *et al.*, 1997). Renal transplantation has also been used with variable success in cats with renal failure (Gregory *et al.*, 1992; Mathews and Gregory, 1997) and has been described in dogs (Nemeth *et al.*, 1997).

### Prognosis

EG has a very high potential for a lethal outcome, but with early recognition of the syndrome and timely institution of

[2] Antizol-Vet (fomepizole) for injection. Orphan Medical, Inc., 13911 Ridgedale Drive, Suite 475, Minnetonka, MN 55305. Available through The Butler Company (Tel.: +1 800 551 3861).

therapy, animals can be saved. The quantity of EG ingested, rate of absorption, and time interval prior to institution of therapy are variables that affect the prognosis. The prognosis is excellent in dogs treated with fomepizole within 5 h of ingesting EG. In a retrospective study of dogs with confirmed EG poisoning, all of the dogs that were azotemic when initially treated died. Of the dogs that did not have azotemia when initially treated, approximately 90% survived (Connally *et al*., 1996). The prognosis for cats is reasonably good if treatment is instituted within 3 h following ingestion (Dial *et al*., 1994b). In contrast, the prognosis in human beings who survive the initial syndrome of severe acidosis is very good. Terminal renal failure in human beings is rare, and most human patients regain renal function by 2 months following EG poisoning (Davis *et al*., 1997) likely owing to the effectiveness of hemodialysis therapy in humans (Christiansson *et al*., 1995).

## CONCLUSION

Ethanol, methanol, isopropanol, propylene glycol, butylene glycol, and marijuana toxicosis can produce ataxia and other CNS signs similar to those seen in acute EG poisoning but are much less common than EG toxicosis (Godbold *et al*., 1979; Hurd-Kuenzi, 1983; Thrall *et al*., 1984a; Suter, 1992). These disorders can be differentiated by the diagnostic laboratory tests discussed earlier. Other causes of an increased anion gap include diabetic ketoacidosis and lactic acidosis; these disorders can also be differentiated by appropriate laboratory tests. Other causes of increased osmolality include ethanol, isopropanol, methanol, and propylene glycol toxicosis. Ethanol, like EG, can also produce hypocalcemia (Money *et al*., 1989). Other differentials for acute renal failure include leptospirosis, ibuprofen and other non-steroidal anti-inflammatory drug toxicosis, aminoglycoside antibiotics, hemolytic–uremic syndrome, cholecalciferol toxicosis, grape and raisin toxicosis in dogs, and ingestion of oxalate-containing plants such as philodendron, and lily toxicosis in cats (Brown *et al*., 1985, 1996; Spyridakis *et al*., 1986; Gunther *et al*., 1988; Peterson *et al*., 1991; Holloway *et al*., 1993; Rivers *et al*., 1996; Vaden *et al*., 1997a, b; Poortinga and Hungerford, 1998; Forrester and Troy, 1999; Adin and Cowgill, 2000; Hovda, 2000; Rumbeiha *et al*., 2000; Singleton, 2001; Langston, 2002; Tefft, 2004). The majority of dogs with grape and raisin toxicosis are hypercalcemic, as are animals with cholecalciferol toxicosis (Fooshee and Forrester, 1990; Gwaltney-Brant *et al*., 2001); hypercalcemia is not associated with EG toxicosis (Thrall *et al*., 1984b; Connally *et al*., 1996). Acute renal failure must be differentiated from acutely decompensated chronic renal failure. Carbamylated hemoglobin concentration has been shown to be useful in making this differentiation (Vaden *et al*., 1997b; Heiene *et al*., 2001). Additionally, animals with chronic renal failure may be anemic and in poor body condition. A history of the duration of clinical signs is also helpful. Continuing to increase the awareness of the toxicity of EG, as well as other alcohols and glycols, will aid in preventing exposure and result in earlier presentation of animals.

# Petroleum

*Robert W. Coppock and Ralph G. Christian*

## INTRODUCTION

Intoxication of birds and animals with petroleum does occur. Land used for agriculture and land located in remote regions of the world are used for oil and gas production. Land uses include oil and gas well sites, tank battery sites, sweet and sour gas plants, compressor stations, and pipelines. Crude petroleum and chemicals used in the oilfields are spilled, and cattle and other animals do ingest spilled substances and can be subsequently poisoned. Birds and mammals have their feathers and fur soiled with oil. Intoxication occurs from dermal absorption and during preening. Emissions from oil and gas facilities occur. The production of sour gas (natural gas containing hydrogen sulfide, $H_2S$) and the removal of sulfur (sour gas processing plants) present toxicology issues. Animals are poisoned when petroleum products are used as medicaments, containers containing petroleum products are used for animal feedstuffs, and when petroleum containers are left open and unattended.

## OIL AND GAS WELL DRILLING AND COMPLETING

### Drilling

Oil and gas wells are drilled into oil and gas producing formations that exists at varying depths below the surface. During drilling operations, drilling fluids are used to cool and lubricate the drill bit, support the walls of the bore-hole, move the cuttings to surface. The weight of the drilling fluid (mud) controls subsurface pressure and aids in preventing blowouts. Different types of drilling fluids and additives are used for drilling the different geologic zones and penetrating the formation. There are individual preferences for different drilling fluids, cost considerations, and requirements of the drilling techniques employed. Wide variations in the chemical composition of drilling fluids are found within the same oilfield (Edwards and Gregory, 1991).

Two basic types of drilling fluids used are the water-based drilling fluid and the non-aqueous drilling fluids. Water-based drilling fluids generally consist of bentonite clay and barium sulfate for density and other chemicals are added to give desired properties such as lubrication and reduce foaming (Table 54.1). Brine or fresh water can be used in water-based drilling fluids. The non-aqueous drilling fluids (invert drilling fluids) have fresh or brine water emulsified in a hydrocarbon phase. Emulsifiers are used to disperse the water in the hydrocarbons. The water emulsion is generally less than 1 μm in diameter. Diesel fuel is often used as the hydrocarbon in land-based drilling operations. Hydrotreated mineral oil which has a low content of polyaromatic hydrocarbons can be used. Drilling mud can also contain heavy metals, especially aluminum, cadmium, chromium including chromate, copper, iron, lead, mercury, and zinc. If radioactive materials are encountered in the formations, radioactive materials and gas can be in drilling fluids and drill cuttings. Drilling and completion operations use a wide variety of chemicals (Table 54.1).

Regulations exist in most governmental jurisdictions to protect ground water reservoirs. During the drilling of the oil or gas well a surface casing is inserted and cemented in place to protect ground water. The regulations specify the depth the casing has to extend beyond freshwater aquifers.

**TABLE 54.1 Examples of drilling mud additives, substances used to stimulate oil and gas wells, and substances used in production of oil and gas**

| Function of substance | Compound |
|---|---|
| Acids used for well stimulation and other uses | Acetic acid |
| | Acetic anhydride |
| | Benzoic acid |
| | Formic acid |
| | Hydrochloric acid |
| | Hydrofluoric acid |
| | Sulfuric acid |
| Add weight to drilling fluid | Attapulgite |
| | Barium sulfate (barite) |
| | Bentonite |
| | Galena (lead sulfate) |
| | Hematite (iron oxide) |
| | Siderite (iron carbonate) |
| Anti-hydrate (block formation of hydrates) | Alcohols |
| | Methanol |
| | Glycols and polyglycols |
| Biocides | Acrolein |
| | Anhydrous ammonia |
| | Amines |
| | Chlorinated phenols |
| | Formaldehyde |
| | Glutaraldehyde |
| | Isopropanol |
| | Methylene bisthiocyanate |
| | 2-(Thiocyanatomethylthio)-1,3-benzothiazole |
| | Thiazolin |
| | Quaternary ammonium |
| Breakers, emulsion/gels | Ammonium persulfate |
| | Benzoic acid |
| | Sodium acetate |
| | Sodium persulfate |
| Cement additives | Aluminum (coated) |
| | Calcium chloride |
| | Cellulose flakes |
| | Cellulose polymer |
| | Gilsonite |
| | Gypsum |
| | Latex |
| | Lignosulfonates |
| | Lime |
| | Long-chain alcohols |
| | Potassium chloride |
| | Sodium chloride |
| | Sodium metasilicates |
| Corrosion inhibitors | Acetylenic alcohols |
| | Amine formulations |
| | Ammonium bisulfite |
| | 2-Butoxyethanol |
| | Ironite sponge |
| | 4-4′-Methylene dianiline |
| | Paraformaldehyde |
| | Sodium chromate |
| | Sodium dichromate |
| | Sodium metasilicate |
| | Sodium polyacrylate |
| | Thiazolin |
| | Zinc carbonate |
| Corrosion inhibitor | Zinc oxide |
| | Zinc lignosulfonate |
| Deflocculants | Acrylic polymer |
| | Calcium lignosulfonate |
| | Chrome-free lignosulfonate |
| | Chromium lignosulfonate |
| | Iron lignosulfonate |
| | Quebracho |
| | Sodium acid pyrophosphate (SAPP) |
| | Sodium hexametaphosphate |
| | Sodium phosphate (oilfos) |
| | Sodium tetraphosphate |
| | Sodium tripolyphosphate (STP) |
| | Styrene, maleic anhydride co-polymer salt |

| | Silicones |
| | Tributylphosphate |
| Dispersant – thinner | Causticized metal lignite |
| | Ferrochrome lignosulphate |
| | Sodium tetraphosphate |
| | Lignite |
| | Lignosulfonates |
| Fluoride generators | Ammonium bifluoride |
| | Ammonium fluoride |
| Lubricants/friction reducers | Acrylamide methacrylate co-polymers |
| | Graphite |
| | Lead grease |
| | Lithium grease |
| | Mineral oil formulations |
| | Molybdenum grease |
| | Motor oil |
| | Organo-fatty acid salt |
| | Petroleum grease |
| | Reprocessed motor oil |
| | Sulphonates |
| | Vegetable oil formulations |
| Multiple uses | Ammonium nitrate |
| | Potassium nitrate |
| Oil-based drilling fluids | Amid-polymer formulations |
| | Amine-treated lignite |
| | Asphalt |
| | Diesel |
| | Gilsonite |
| | Mineral oil |
| | Organophilic clay |
| | Organophilic hectorite |
| | Petroleum distillate |
| | polyethylene powder |
| | Polymerized organic acids |
| Oxygen remover | Ammonium bisulfite |

**TABLE 54.1 (Continued)**

| Function of substance | Compound | Function of substance | Compound |
|---|---|---|---|
| pH control | Calcium hydroxide | | Diacetone alcohol |
| | Potassium hydroxide | | Diesel oil |
| | Soda ash (sodium carbonate) | | Ethylene glycol monobutyl ether |
| | Sodium bicarbonate | | Kerosene |
| | Sodium hydroxide | | Isopropanol |
| Propping agents | Bauxite | | Methyl ethyl ketone (MEK) |
| | Resin-coated sand | | Methyl isobutyl ketone (MIBK) |
| | Sand | | Methylene chloride |
| | Zirconium compounds | | Methanol |
| Salt solutions | Aluminum chloride | | Naphtha |
| | Ammonium chloride | | 1,1,1-Trichloroethane |
| | Calcium bromide | | Toluene |
| | Calcium chloride | | Turpentine |
| | Calcium sulfate | | Xylene |
| | Ferrous sulfate | | |
| | Potassium chloride | | |
| | Sodium chloride | Surfactants – emulsifiers | General categories |
| | Sodium sulfate | | Cationic |
| | Zinc bromide | | Non-ionic |
| | Zinc chloride | | Anionic |
| | Zinc sulfate | | Amides |
| Scale inhibitors | Ethylenediaminetetra acetic acid (EDTA) | | Arylalkyl sulfonic acid |
| | | | Fatty alcohols |
| | | | Glycols |
| | Inorganic phosphates | | Isopropanol |
| | Nitrilotriacetic acid (NTA) | | Modified tall oils (from tree rosin byproduct of wood pulp industry) |
| | Organic phosphates | | |
| | Phosphonates | | |
| | Polyacrylate | | Nonylphenol ethoxylates |
| | Polyphosphates | | Oxyalkylated phenolic compounds |
| Solvents | Acetone | | Petroleum naphtha |
| | Aliphatic hydrocarbons | | Polyamines (diethylenetriamine and triethylenetetramine) |
| | t-butyl alcohol | | |
| | Carbon tetrachloride | | |
| | Chloroform | | |

During the cementing operation, cement is pushed up around the casing and the hardened cement is the seal between the borehole and the casing. A blowout preventer is attached to the casing. The production tubing is inserted into the borehole and extends from the surface to the oil or gas bearing formation. Production of oil and gas is from the tubing. Poor cement jobs and casing failure can result in contamination of the ground water with crude oil and natural gas.

## Completing

Oil and gas bearing formations are porous with the oil and gas contained within the pores. To stimulate production the formation is fractured. In the past, fracturing was done with explosives. Hydraulic fracturing is done by pumping chemicals down the hole and fracturing the formation. Acids can be pumped down the formation at very high prssure to form fractures by dissolving the formation. Propping agents such as resin-treated sand are placed in the fractures to prevent closure.

Oil and gas production can use large quantities of surface and ground water. The use of water generally increases with depletion of oil in the underground reservoir. Large quantities of water can also be used for *in situ* extraction of bitumen. In both of these operations water or steam is injected into the formation, sometimes at very high pressure. The water remains in the formation and oil or liquid bitumen is extracted. The loss of surface water to underground formations is an issue in the more arid regions of the world including western United States and Canada.

# COALBED METHANE

The production of coalbed methane can create water issues and the process is the *in situ* removal of methane from coal

deposits. Estimates of trillions of cubic meters of methane coalbed methane reserves exist making this an attractive source of natural gas. The procedure to produce coalbed methane is to drill a well into the coal deposit and inject liquids under high pressure to hydraulically fracture (fracking) the coal seam (Cobb, 2003; Keith *et al.*, 2003). After fracking, water is pumped from the coalbed and the decrease in pressure allows methane to escape into the natural and man-made cleats (cracks in the coalbed). In coalbed methane production, generally a larger number of wells are drilled than for conventional natural gas production. Coalbeds can occur in aquifers. In coalbed methane production, huge quantities of water can be removed from underground aquifers and aquifer drawdown can affect an area as large as a township. In some regions the produced water is high in salts (total dissolved solids, TDS) and surface water and soil pollution from this water are a significant problem. The salt water produced in coalbed methane production can be high enough to cause sodium ion intoxication in livestock (see Chapter 35).

## SOURCES OF TOXIC SUBSTANCES

Chemicals associated with petroleum intoxication in cattle are the gaseous, liquid and solid crude petroleum which are associated with the production of natural gas, crude oil and bitumen, respectively. Crude natural gas as it comes from the wellhead has volatile liquids and may contain $H_2S$ and other forms of sulfur including the polyaromatic thiophenes (Kropp and Fedorak, 1998). Natural gas that contains $H_2S$ is called sour gas. Additionally, a large number of chemicals are used in the production of crude petroleum. Sour gas can have the $H_2S$ removed and the sulfur gas disposed of by burning in flare stacks (vertical pipe with a flame at the end).

### Emissions

Gas wells are production tested after completion. Production testing is done to remove chemicals from the formation that would corrode pipelines and to estimate the economic value of the gas well. Products of value are the methane, liquids (propane, butane, etc.), and sulfur. The gas well is connected to a flare and the emissions from the well are burned. Toxic emissions can include a wide variety of combustion products such as chlorinated dibenzodioxins and furans if chlorine is present and favorable combustion conditions exist (Buckland *et al.*, 2000) (see Chapter 55). Polyaromatic hydrocarbons can also be formed. Sulfur dioxide ($SO_2$), reduced sulfur compounds (including carbon disulfide and carbonyl sulfide), polyaromatic hydrocarbons, and other compounds are produced by burning sour well emissions by flaring. In flaring sour gas, it is likely that the production of chlorinated dioxins and chlorinated dibenzofurans does not occur because of the quenching effect of sulfur on chlorine.

Process gas is often flared during the production of crude petroleum. In addition to sulfur compounds (e.g., carbonyl sulfide, carbon disulfide) a large number of polyaromatic compounds including thiophenes are formed. Flaring is generally the most inefficient method in terms of products of incomplete combustion to burn unwanted gases. Flare efficiency is remarkably reduced by wind and the presence of liquids in the gas. Strosher (1996) provided insight into the chemical complexity of flare emissions. Incinerators are more efficient than flare stacks.

Tank heaters are used in the production of heavy oil and bitumen. Heating the tank prevents heavy oil from congealing and bitumen from foaming. The tank heaters drive off a variety of hydrocarbons and water vapor. Issues exist because tank emissions are vented to atmosphere.

### Production water

Production water defines water that is brought to the surface during the production of oil and natural gas. Production water can be high in TDS and ingestion of production water can induce salt (sodium ion) poisoning. Production water generally has a unique ratio of ions and this ratio generally is often distinctly different from TDS in ground water. Livestock producers in the more arid regions use production water that is low in TDS, and sometimes produced water may be lower in TDS than water from shallow aquifers. Production water can be high in sulfates. Cattle consuming water high in sulfate have increased risk for thiamine-responsive polioencephalomalacia, and the risk increases with decreased dietary copper (Gould, 1998) (see Chapter 36).

Different organic chemicals and solvents are used in oil and gas production and pipeline transportation of petroleum. The interior of pipelines become coated with waxes and biofilms. These accumulations are removed with a scraper called a "pig"; the scraping procedure is called "pigging the pipeline". Substances used in pigging operations include solvents to remove wax and tar-like deposits, biocides to prevent the build up of biofilms inside pipelines, and anti-corrosives. These chemicals are caught in a tank located at an instillation called a "pig trap". Massive amounts of these substances can be spilled at a pig trap and contamination of ground water used for livestock can occur.

### Well rework

A variety of chemicals is used during rework (maintenance of down-hole equipment) operations. Spillage of these

chemicals occurs, and livestock poisonings have been reported (Monlux *et al.*, 1971). Detergents and other surfactants can be used during rework operations (Table 54.1). Detergents generally increase the gastrointestinal absorption of hydrocarbons. Acids, solvents, anti-corrosives, and chelating compounds can also be used. Some of these compounds are intrinsically toxic, and can enhance the toxicity of other substances. Chelating and descaling agents may increase the bioavailability of chemicals that otherwise would be considered to have a low order of toxicity. Downhole equipment can be laid out at unsecured sites over the weekend and cattle will lick the petroleum and other substances from the equipment.

## Sumps and contaminated soil

The chemical composition of drilling sumps is highly variable. The chemicals and substances found in sumps reflect chemicals used in drilling oil and gas wells, heavy metals in formations penetrated by the drilling operation, and other substances disposed of in the sumps (Heitman, 1986; Wascom, 1986). Sumps may not be adjacent to oil and gas well sites. Remote sumps miles from any oil or gas wells were used for waste disposal and until environmental issues arise, the current landowner may not be aware of the site exists. Although environmental practices have changed, old sumps can be a cause of concern (Murphy *et al.*, 1986). A sump can literally be minature abandoned hazardous waste site that has defaulted to the legal land owner. Issues arise regarding cleanup of these old sites, and many jurisdictions have laws that declare that the legal landowner is responsible. Some banks in Canada have given farmland 0 value for loans because of old oil and gas well sumps. Rough lands with buried sumps have become desirable building sites. Houses and barns have been built on or adjacent to old sumps and individuals have planted gardens over old sumps. Some jurisdictions have limited or eliminated oilfield sumps because of toxicology issues. Water can extrude drilling waste from sumps and the extruded buried waste substances to surface and the extruded substances are a toxicological hazard (Mostrom *et al.*, 1993).

Drill cuttings and drilling fluids eventually become wastes. For example, a well 20 cm in diameter and 1000 m deep generates about 30 $m^3$ drill cuttings. The volume of drilling fluids accumulating in the drilling sump varies from 789 to >160,000 $m^3$. The general rule is 0.5 $m^3$ of drilling waste/m of depth. Some of the drilling wastes are spread on agricultural lands because of perceived value for the content of nitrogen, potassium, and other plant nutrients. Issues exist from this practice including puddling of the drilling fluids and cattle drinking from the puddles and water repellency of soil. Waste drilling fluids and drill cuttings are disposed of in sumps on the oil lease or in lease sites called remote sumps. Some disposal sites used a series of backhoe trenches instead of one large pit.

Rain and snow runoff water can extrude contaminants from sumps and contaminated soil. Extrusions from a drilling sump containing invert drilling fluid have been associated with maladies in cattle (Mostrom *et al.*, 1993). Extrusions from an invert sump contaminated a pasture. Cows grazing this pasture had calves that were stunted. Necropsy findings were abnormal epiphyseal plates in the long bones and myeloid-like bodies in the proximal tubular cells of the kidney (Mostrom *et al.*, 1993). The activities of polysubstrate mixed function oxidase enzymes were also elevated. Sheep have been poisoned following extensive rains that caused extrusion of natural gas condensate from contaminated soil (Adler *et al.*, 1992). Valve failure on a condensate storage tank contaminated the soil, and subsequent rains extruded condensate from the soil outside the perimeter fence of the lease. Eight ewes were found dead the 1st day, and the extrusion area was fenced, but ewes continued to succumb during a 21-day period. Clinical signs observed were depression, fever, gas-like odor to the breath, dyspnea, anorexia, ruminal atony, bloody diarrhea, weight loss, nasal discharge, and recumbency. A gasoline-like odor was detected in ewes necropsied 10 days, but not 18 days, after the last exposure.

## Ions

Drilling sumps can also contain high levels of sodium and potassium ions (Darley and Gray, 1988). Heavy rainfall can extrude potassium salts from old sumps. The extrusions can be confused with naturally occurring alkali areas. When given by oral or intravenous routes, $K^+$ has an essentially equal order of toxicity (Ward, 1966a). The oral lethal dose of $K^+$ in a 475 kg cow has also been reported at 238 mg of $K^+$ (as KCl)/kg of body weight (Ward, 1966b). Because of decreased renal excretion of $K^+$, calves are more sensitive to $K^+$ poisoning than cows (Blaxter *et al.*, 1960; Ward, 1966a). In high doses, $K^+$ targets the cardiac and skeletal muscles. In calves given $K^+$ by intravenous infusion, changes in the electrocardiograph (ECG) were observed. With increasing plasma concentrations of $K^+$, the QRS interval increases, the P–R interval decreases, P waves decrease, and the Q–T interval becomes very prolonged. With increasing concentrations of $K^+$ in plasma, the QRS complex becomes disorganized, and atrial flutter, atrioventricular block, and occasional ventricular to complete ventricular arrest occur. With increasing concentrations of $K^+$ in plasma, respiration also increases in rate and amplitude (Bergman and Sellers, 1953, 1954). Altering the $K^+$:$Na^+$ ratio in the rumen has been associated with bloat (Turner, 1981).

Sodium ion poisoning can also occur (see Chapter 35). Clinical signs are muscle twitching, ataxia, bruxism,

aggression, circling, and head pressing. Ingestion of brine water causes dehydration (sunken eyes and loss of plasticity of the skin). Sodium ion in the blood increases and the electrophysiology of excitable tissues is disrupted. The pathology of $Na^+$ poisoning in cattle can be variable (Scott, 1924; McCoy and Edwards, 1980; Sullivan, 1985). Ingestion of concentrated $Na^+$ produces marked congestion of the omasal and abomasal mucosa. Gut contents are fluid, and hemorrhage may cause dark discoloration. Edema of the skeletal muscles and hydropericardium can occur. Edema of the brain can also occur and an eosinophilic infiltration of the Virchow–Robin spaces may or may not be observed in cattle. Lesions of polioencephalomalacia can also be present.

## Non-pesticide organophosphate esters

Natural gas compressor stations use non-pesticide organophosphate esters to prevent foaming of lubricating oils (Coppock *et al.*, 1995a). Phosphate esters have multiple uses in the petroleum industry, and have been used in high-performance lubricants. The trivial chemical names describing the industrial grade generally refer to complex chemical mixtures of these compounds (Dollahite and Pierce, 1969; Beck *et al.*, 1977; Sugden, 1981). The use of non-pesticide organophosphate esters has been reduced in North America, but these compounds maybe buried in disposal sumps.

For the phosphate esters used in industrial applications, the majority of the individual compounds have fragmented toxicological data (Coppock *et al.*, 1995a). Studies relating the chemical structure of individual tricresol phosphate (TCP) compounds to neurotoxicity have allowed structural grouping of many of the neurotoxic compounds (Johannsen *et al.*, 1977; Sprague and Castles, 1987; Abou-Donia and Gupta, 1994). The neurotoxicity of organophosphate esters is related to the inhibition of cholinesterases, and the malady produced by inadvertent exposure to triaryl phosphate group (TAP) is known as organophosphate-induced delayed neurotoxicity (Metcalf, 1984). There is wide variation in species sensitivity and the effect of age on sensitivity within species (Abou-Donia and Gupta, 1994). The neurotoxicology of the TAP group of compounds has been described in cattle (Dollahite and Pierce, 1969; Nicholson, 1974; Julian *et al.*, 1976; Beck *et al.*, 1977; Sugden, 1981; Prantner and Sosalla, 1993), other livestock species (Wilson *et al.*, 1954; Dollahite and Pierce, 1969), and chickens (Hixson, 1984). Humans are also susceptible to TAPs (Craig and Barth, 1999). The TAPs have also been found to target the seminiferous tubules in rats (Somkuti *et al.*, 1987).

The most common source of TAPs in livestock poisonings results from their use as additives in lubricating and hydraulic oils operating under high pressure and temperature. Cattle will voluntarily ingest water and feedstuffs adulterated with TAP (Dollahite and Pierce, 1969; Nicholson, 1974; Beck *et al.*, 1977; Prantner and Sosalla, 1993). Oilfield-related exposures of cattle to TAP have been primarily from compressor oils and hydraulic fluids (Dollahite and Pierce, 1969; Beck *et al.*, 1977; Coppock *et al.*, 1995a). Compressor lubricating oils in recycled barrels used to store wet molasses were the source of TAP is an incident in which cattle were poisoned (Nicholson, 1974). An undetermined source of waste oil used to lubricate a feed bunk chain was the source of TAP in a poisoning incident in heifers (Prantner and Sosalla, 1993). Waste oil used to treat ringworm was the source of TAP poisoning in a herd of cattle (Julian *et al.*, 1976).

Clinical signs of TAP poisoning generally starts with clinical signs of neurotoxicity (Table 54.2), expressed as some form of paralysis, observed initially in a few animals (Coppock *et al.*, 1995a). Clinical signs in animals inadvertently exposed to TAP are those resulting from cholinesterase inhibition and neurological deficiency. The number of affected animals depends on the mass of TAP available dose, duration of exposure, and age. In cases of inadvertent poisoning, there was a delay of 2–25 days between exposure and onset of clinical signs of intoxication. The morbidity depends on the dose, duration of exposure, and age. The morbidity pattern will continue until all animals that have consumed a toxic dose of TAP develop clinical evidence of neurotoxicity.

A herd of 50 animals, consisting of cows, 2 bulls and a few heifers, was exposed dermally to approximately 1–2 l of waste hydraulic oil that was poured over the anterior regions as a treatment for ringworm (Julian *et al.*, 1976). The cattle also ingested the oil by preening themselves and other animals. During the pathogenesis, the cattle were bright, alert, and had good appetites; normal body temperatures, and miosis and clinical evidence of visual impairment were not observed. Just before and during the time of intoxication, 10 calves were born. Cows that were not recumbent nursed their calves, and the calves were asymptomatic. Treatment with atropine and pantothenic acid was ineffective. Another group consisting of yearlings and 2-year-old steers and heifers was exposed to repeated applications of waste hydraulic oil that was dabbed on ringworm lesions. Animals in this herd did not develop clinical signs of intoxication. TAP poisoning occurred in four heifers exposed when oil was used to lubricate chains in a mechanical feeding system (Prantner and Sosalla, 1993). The relationship between exposure and the onset of clinical signs was not given. The onset of clinical signs occurred at differing intervals, i.e., 6 weeks between the 1st and 2nd heifers, 1 week between the 2nd and 3rd heifers, and 6 weeks between the 3rd and 4th heifers. The 3rd heifer vomited after being drenched with a solution of copper sulfate, and subsequently died. A herd of cattle was exposed to TAP when a seal failed in a natural gas compressor (Beck *et al.*, 1977). The interval between exposure and onset of clinical signs was not given. The owner observed that the cows were mute

**TABLE 54.2 Clinical Signs of delayed neurotoxicity in cattle**

| Source | Time sequence* | Clinical sign | Reference |
|---|---|---|---|
| Waste hydraulic oil | 12 days | Diarrhea | Julian *et al.* (1976) |
| | 20 days | Posterior weakness, knuckling at fetlocks, ataxia, difficulty in rising, dog-sitting while attempting to rise | |
| | 20+ days | Diarrhea, coughing, ataxia, difficulty turning, knuckling and buckling of rear limbs, unable to rise but could walk on knees, decreased sensory and motor response in rear limbs | |
| | 34+ days | Increased severity of clinical signs, incoordination progressing to front legs, standing in a crouched position, muscular wasting, dribbling urine, tail raised, coughing, dyspnea after attempting to rise and deaths (14/50) | |
| Waste oil | NS | Roaring sounds | Prantner and Sosalla (1993) |
| | 2 days | Ataxia of hind limbs and knuckling over at metatarsophalangeal joints | |
| | 42 days | 2nd heifer with signs same as first | |
| | 7 days | 3rd heifer, ataxia, dysuria, polyuria, dyspnea | |
| | 42 days | 4th heifer, clinical signs same as for heifer | |
| Compressor sump water | NS | Cows mute when separated from calves | Beck *et al.* (1977) |
| | 7 days | Knuckling of fetlocks, dyspnea, coughing | |
| | 7 days | Goose-stepping, diarrhea, mute, posterior paralysis, dog-sitting, recumbency and inability to rise | |
| Barrels previously used for hydraulic oils | NS | Standing in a crouched position, elevated tails, dribbling urine, posterior weakness | Nicholson (1974) |
| | 2 days | Posterior weakness, recumbency, death | |
| Lubricating–hydraulic oils | NS | Rough hair coats, loss of condition, muscular weakness and incoordination, tympanites, dyspnea and roaring | Dollahite and Pierce (1969) |

* After exposure. NS: Not specified.

when separated from the calves. The calves remained asymptomatic, and a calf born to an affected cow was normal. Calves had decreased growth, a finding that was attributed to some degree of agalactia in the cows. Cattle were poisoned with tri-*o*-tolyl phosphate, a TAP (Nicholson, 1974). In this incident of delayed neurotoxicity in cattle, molasses was contaminated with tri-*o*-tolyl phosphate when it was stored in barrels used previously for hydraulic oil supplied to a local pipeline pumping station. Initial clinical signs were urinary incontinence, elevated tails, crouched position, and posterior weakness. Two days later, 2/42 animals were dead, 5/42 were recumbent, and 25/42 had varying degrees of posterior weakness. The clinical sequence was posterior weakness progressing over a 2-day interval to posterior paralyses.

The mechanism of action for delayed neurotoxic effects of organophosphate esters has been partially elucidated (Abou-Donia and Gupta, 1994; Gupta and Abou-Donia, 1994). The majority of compounds in this group inhibit a neuropathy target enzyme, known as neurotoxic esterase (neurotoxic target esterase) (Gupta and Abou-Donia, 1994). Irreversible covalent binding or ageing of the neuropathy target esterase is essential for the induction of anatomical neurotoxicity. The anatomical neurotoxic effects have been associated with alterations in the cytoskeleton and the transport of nutrients from the cell body to the terminal parts of the axon.

## Anti-hydrates and antifreezes

Large quantities of methanol are used by the oil and gas industry, and cattle have been poisoned by these sources (Edwards *et al.*, 1979; Rousseaux *et al.*, 1982). Methanol is used to prevent freezing of water in pipes, and to prevent hydrate formation in gas wells and pipelines. Intoxication of cattle by methanol has been reported. A herd of 600 cows had access to methanol barrels stored on a lease and 2 cows were found dead. Manure accumulation behind the cows was taken as evidence that the cows had been recumbent for some time before death (Rousseaux *et al.*, 1982). Rumen contents from the 2 dead cows contained 370 mg of methanol/100 ml of rumen fluid. In another incident, 12/15 cows were found dead or in a moribund condition (Sesevicka *et al.*, 1979). Clinical signs observed were: ataxia, decreased rate and depth of respiration, frequent chewing motions, impaired vision, and hypoesthesia to nociceptive stimuli. These heifers had access to a pit that received waste water from a gas processing plant. Clinical signs of experimentally induced methanol poisoning in

cattle were similar to those reported for field exposures (Fritz and Coppock, 1992).

Large quantities of diethylene glycol are used in oil and gas operations (Edwards *et al.*, 1979). Research has shown that cattle are a species sensitive to diethylene glycol (Fritz and Coppock, 1992; Khan *et al.*, 1992). A dose of 1.51 ml/kg of body weight is fatal to a cow. Diethylene glycol is toxic to the eye, liver, kidney, and nervous system. Diethylene glycol-induced ocular changes that are similar in appearance to those of pinkeye. Diethylene glycol causes a unique lace-like hypertrophy of the perineuronal amphicytes in the Gasserian ganglia in cattle. This lesion has not been reported in laboratory animals. Other glycols are used in oil and gas production (see Chapter 53, Ethylene Glycol).

### Chromate

Cattle are exposed to environmental chromates from oilfield sources (Reagor and McDonald, 1980). Gross pathological findings in a calf (8 months old) were icterus, tracheal froth, excessive pleural fluid, and petechiae over the pleura. The intestinal contents were black and mucus covered. Edema and hemorrhage were observed in the mesentery and omentum. Hepatomegaly, yellowing of the liver, and edema of the gall bladder were observed. Histopathological observations included diffuse hepatocellular swelling, vacuolation of hepatocytes, inspissation of bile, and moderate biliary hyperplasia. The kidneys were pale and hemoglobinuric vacuolation was observed in the cortical tubular epithelium. Proteinaceous exudate was observed in the lung, and epicardial hemorrhages were observed. Chromium concentration in the liver was 14.8 ppm (see Chapter 38).

## GREASE AND MOTOR OIL

Lithium (Li) intoxication in cattle from Li grease has been reported. Wallace and Blodgett (1996) reported Li poisoning in 1 cow after the animal consumed Li grease, and Johnson *et al.* (1980) reported on Li poisoning in 19/90 animals. In both the incidents, the source of Li grease was discarded drums that had been used previously for transporting and storing grease. In the incident reported by Wallace and Blodgett (1996), the cow was euthanized and in the incident reported by Johnson *et al.* (1980), all 19 animals died. In the animals that consumed Li grease, clinical signs included muscular tremors, ataxia, stiffness, apparent disorientation, ptyalism, diarrhea, rapid respiration, and periodic seizure-like activity. The concentrations of Li in grease for the incidents reported were 2050 μg of Li/g of grease and 1250 μg of Li/g of grease, respectively (Johnson *et al.*, 1980; Wallace and Blodgett, 1996). Clinico-pathological findings (1 cow) included leukopenia, lymphopenia, and

**TABLE 54.3 Summary of clinical signs of Li intoxication in cattle (Johnson *et al.*, 1980)**

| Oral dose* | Time | Clinical signs |
|---|---|---|
| 250 mg/kg (4) | 2–6 h | Ptyalism |
| | 4–6 h | Depression, anorexia, diarrhea |
| | 72 h | Diarrhea |
| | 9 days | Recovered |
| 500 mg/kg (5) | 3–4 h | Ptyalism (lasted for 4–6 h) |
| | After 4–6 h | Depression, anorexia, hypodipsia, anuria and diarrhea |
| | 7 days | 4 animals died |
| | 11 days | 1 animal died |
| 700 mg/kg (4) | 2 h | Ptyalism (continued for 4–6 h) |
| | After 2 h | Depression, anorexia, hypodipsia, anuria, ataxia and severe diarrhea |
| | 8 hours to 7 days | Deaths occurred |

*Number of cows in trial is given in parentheses.

hyperfibrinogenemia (Wallace and Blodgett, 1996). The parameters of protein, cytology, glucose in cerebral spinal fluid were normal. An oral dosing study with Li has been done in cattle (Johnson *et al.*, 1980). Cattle were administered single oral doses *per gavage* of 250, 500, or 700 mg of LiCl/kg body weight. The LiCl was in water (qs to dissolve the Li) plus an equal volume of water to rinse the stomach tube. Clinical signs were reported (Table 54.3). The most consistent finding at necropsy was gastroenteritis of varying severity. Histopathological findings were congestion of the gastrointestinal tract. Lesions in the liver included cloudy swelling, edema, and cirrhosis in the portal triad areas. Renal lesions included cloudy swelling of the proximal tubular cells and a mild interstitial nephritis. Lithium can also be present in process water.

Grease can contain other metallic substances. Lead grease has excellent water repellence properties. Lead grease is also a hazard to livestock (see Chapter 31).

Motor oil contains additives to prevent foaming, keep carbon deposits is suspension and to reduce friction and wear of parts at high temperatures, viscosity improvers, pour-point improvers, and antioxidants. Synthetic oils can contain molybdenum and surfactants. Anti-wear additives such as zinc dialkyldithiophosphate compounds and derivatives are added to lubricants to reduce friction. Micronized metals can be added to lubricating oils. Many additives are mixtures of substances and most companies closely guard their intellectual property.

## TOXICOLOGY OF PETROLEUM

Cattle ingest crude, refined, and waste petroleum (Coppock *et al.*, 1995b). The toxicology of petroleum has been

**TABLE 54.4 Chemical characteristics of crude oils used in the Rowe and Bystrom studies**

| Fraction | Pembina crude[a,b] | Texas sweet[c] | Texas sour[c] |
|---|---|---|---|
| Light gasoline | NA | 14.2% | 9.6% |
| Total gasoline or total naphtha | 22.1% | 43.0% | 31.6% |
| Kerosene | 15.3% | 22.3% | 4.7% |
| Lubricating | NA | 8.8% | 16.8% |
| Sulfur | 0.24% | <0.1% | 1.5% |
| Nitrogen | 0.1% | 0.083% | 0.074% |
| Nickel | 2.53 ppm | NA | NA |
| Vanadium | 1.17 ppm | NA | NA |

[c] Units in terms of percent mass or percent volume were not given.
NA: Not available.

reported for experimental studies and field incidents. Rowe (1972, 1973) found that sweet crude oil was more toxic in cattle than was sour crude oil (oil that contains sulfur) (Table 54.4). Administration of 8 ml of sweet crude oil/kg body weight/day caused death within 7–14 days in 4/5 calves. For the same dose of sour crude oil, 5/5 calves died between days 16 and 24; for kerosene, 5/5 calves died between days 9 and 23. Administration of 37 ml of sweet crude oil/kg was fatal within a few minutes. The majority of the surviving animals had pneumonia.

## Experimental studies on crude oil

Bystrom (1989) studied the acute effects of crude oil in cattle. The dosage levels (administered *per gavage*) were 20, 40, 60, or 80 ml of sweet crude oil/kg of body weight, or 80 ml of potable water/kg of body weight. The analytical characterization of the oil is given in Table 54.4. Following exposure, daily mean rectal body temperatures were normal. Ruminal motility was decreased after animals were dosed with oil and slowly increased to pre-treatment values by day 8 (study day 0 was the day that cattle were dosed). Vomiting was not observed in the animals dosed with water. Vomiting occurred in 10/12 of the animals dosed with oil and, in some animals, vomiting was characterized by a projectile expulsion of oil. Emesis recurred after forage or water was ingested. Ruminal tympanites was observed in the majority of the animals, but did not require medical intervention. Neurological abnormalities were not observed in control animals. Central nervous signs expressed by nystagmus, muscular tremors, and "petit mal-like" seizures were observed in treated animals. Depression was the most common clinical sign observed. These effects were attributed to the "anesthetic" effects of the volatile hydrocarbons. The neurological effects contributed to aspiration pneumonia.

Gas chromatographic methods were used to determine hydrocarbons in blood and feces (Bystrom, 1989). Oil was found in feces at 23 h after dosing for the 20 and 40 ml/kg groups, at 7–31 h for the 60 ml/kg group, and at 5–19 h for the 80 ml/kg group. Oil was not detected in feces from the control animals. Using head-space (space between the liquid and stopper) analysis, it was demonstrated that volatile constituents from the oil were present in blood. *N*-heptane was used as a representative hydrocarbon. Semiquantitative values for total light naphtha were estimated to be as high as 10 mg/l of blood. Aspiration of oil into the lungs increased the levels of *N*-heptane in the blood.

Considerable variations have been reported for the dose–response of cattle to mineral petroleum. These effects can be due to presence of surfactants or emulsifiers, and additives in refined petroleum. A 200 ml single oral dose of odorless kerosene (Vacuum Oil Company No. EF471W, New Zealand) administered to a mature dairy cow caused a 90.3% reduction in dry matter intake, and the same dose of Stanvac Odorless Solvent caused a 42.5% reduction in dry matter intake (Reid, 1957). These effects were considered to be "eliminated" by day 3 of the study. Emulsification of kerosene with a non-ionic surfactant decreased the interval between exposure and the onset of effects. Similar findings were observed when kerosene was placed directly into the omasum. Fistulation of the rumen did not alter the response to kerosene or solvent.

Exposure to petroleum can reduce body stores of fat-soluble vitamins. McDowall (1957) administered 75 ml of heavy liquid paraffin/cow/day by drench for 26 days. A 40% reduction in blood carotene occurred over 16 days, and a 20% reduction in blood vitamin A ester, and a 40% reduction in tocopherol (vitamin E) was also observed. After cessation of treatment, 21 days were required for recovery to pre-exposure levels.

## Ingestion of petroleum

Numerous reports exist in the scientific literature that cattle and other animals have voluntarily ingested petroleum and other oilfield substances (Coppock *et al.*, 1986a, 1995b). Cattle are attracted to and will ingest several gallons of petroleum (Monlux *et al.*, 1971; Oehme, 1977). Deaths have occurred after cattle drank tractor paraffin and vaporizing oil (Eaton, 1943). Heifers drank gasoline (Albert and Ramey, 1964), and Messerli (1969) reported that cattle greedily ingested diesel oil flowing from a storage tank. Cattle have drunk from petroleum puddles near a tank battery, from slush pits, from puddles of volatile petroleum and petroleum distillate (Edwards *et al.*, 1979). Crude oil, spilled by a pipeline break, has been consumed by cattle, and cattle have drunk from puddles of road-oil after it was applied for dust suppression (Coale, 1947; Bumstead, 1949). Cattle will drink used motor oil (Gardner, 1977), and

will also ingest petroleum-contaminated forage (Stober, 1962; Beck *et al.*, 1977). An entire herd of heifers was irreversibly poisoned by ingesting water from a stream that was contaminated with aviation turbine fuel (Barber *et al.*, 1987). Monlux (1971) reported that the majority of animals avoid oil, but they also reported that, in some instances, the entire herd, especially feeder calves, will be attracted to oil. Cattle have ingested sump oil with adverse effects on health (Ballantyne, 1950, 1955).

Other species also ingest petroleum. Sheep have ingested Bunker "C" fuel oil (a residual fuel oil) following the sinking of a tanker ship (MacIntyre, 1970). Ingestion of surface water contaminated with extrusions by rain water of natural gas condensate has caused fatalities in sheep (Adler *et al.*, 1992). Voluntary ingestion of kerosene by 2 goats was reported by Pathan (1961). In Iran, goats ingested diesel fuel leaking from an overturned truck tanker (Toofanian *et al.*, 1979).

Experimental studies on the ingestion of crude oil by cattle have been done. Rowe (1972, 1973) found that calves will drink sweet and sour crude oils. After water had been withheld for 48 h, calves drank 4 l of either a sweet or sour crude oil, but would not repeat the ingestion of crude oil after water had been withheld for a total of 96 h. Two of the calves that drank oil had previously been administered *per gavage* kerosene in a previous study. Calves that were not water deprived did not drink oil. These findings suggest that cattle may acquire some aversion to drinking crude petroleum.

## Experimental study on ingestion of petroleum

An experimental study demonstrated that cows on a balanced diet and having water *ad libitum* are attracted to crude mineral petroleum, and will ingest it (Coppock *et al.*, 1992). In a study on voluntary ingestion of crude oil, a stall was designed to minimize competition at the oil source. All of the animals explored the oil and 5/10 animals ingested oil. For 3/4 animals that drank oil, ingestion occurred most frequently in the first few days during which oil was available. The most frequent method of ingesting oil was by licking; the cyclic pattern suggested that cattle will go on oil-licking "binges". The neurochemical reasons for the attraction of cattle to oil are not currently known.

## Clinical observations and findings

Varied clinical signs have been observed in field incidents of petroleum poisoning (Table 54.5). A herd of 58 yearling steers had access to crude petroleum distillate (condensate) on an oil-lease property (Edwards and Zinn, 1979).

**TABLE 54.5 Clinical signs of petroleum poisoning in cattle**

| Acute signs (within 24 h) | Subacute signs (After 24 h) | Chronic signs |
|---|---|---|
| Ruminal tympanites* | Depression | Lethargy |
| Emesis | Pneumonia | Anorexia |
| Postural weakness | Anorexia | Loss of condition |
| Ataxia and incoordination | Constipation | Impaired reproductive performance |
| Seizures | Coughing | Chronic cough |
| Hyperthermia | Ileus | Abortion |
| Dyspnea | Recumbency | Laminitis |
| Bloody diarrhea | Ruminal atony | Loss of body weight |
| Strong petroleum-like odor to breath/feces | Abortion | Pain – hardware-like signs |
| Ruminal atony | Loss of weight | |
| Depression | Sweet petroleum-like odor to breath and feces | |
| | Lethargy | |

* Ruminal tympanites is not a consistent finding.

Following oral exposure, 17 animals became sick and 9 died. The sick cattle had petroleum distillate dripping from the nostrils, and present in their feces; they also had petroleum on their tails and rear quarters. Surviving animals had varied signs including anorexia and weight loss. Some of the more severely affected animals died. Edwards and Zinn (1979) also described clinical signs in 18/135 animals that had access to a sump pit. The surviving animals lost weight and were unthrifty ("poor-doers"). These authors also reported that, of 200 steers with access to petroleum in puddles, 12 were found dead, and 13 died 24 h later. Oehme (1977) attributed abortions to ingestion of petroleum products. Loss of body condition can also result from petroleum ingestion-linked chronic pneumonia and pleural adhesions. Clinical evidence of pain can be associated with pleural adhesions (signs similar to hardware disease). Cattle attracted to an area saturated with condensate can have laminitis-like clinical signs.

A herd located in Alberta had access to sump oil (Ballantyne, 1950). A 545 kg cow, representative of a malady observed in 20 other cows from a large herd, was necropsied. After ingestion of oil this cow had a reduction in body weight. Necropsy findings were: visible oil in the rumen, the mucous membranes of the abomasum were stained black, and areas of inflammation were observed in the gut. There were 213 ml of oil/l of rumen contents. In another report (Bumstead, 1949), cattle drank from a pool of oil. Two animals died, and all of the animals that had wandered into the pool of oil showed clinical signs of intoxication. One heifer had severe enteritis, was dehydrated and had cachexia. All of the animals treated by the veterinarian made what was considered to be a complete recovery, which was attributed to treatment that rapidly removed oil from the digestive tract, and prophylactic treatment with an anti-microbial chemotherapeutic. In another report (Coale,

1947), 5 dairy cows drank crude oil that had escaped from a broken pipeline. All 5 of the animals were sold 90 days later because of lost productivity.

Gibson and Linzell (1948) reported that dairy cows drank petroleum after 5 gal (23 l) were mistakenly dumped in a water trough. Clinical signs in 6/8 cows were central nervous system (CNS) depression including coma, coughing, salivating, head shaking, hypothermia, and petroleum odor on respired air and milk. The diesel-like odor on the breath and in the milk persisted for 5 days. Three animals died at 12, 24, and 48 h, respectively, after exposure. During the interval between exposure and death, all of the animals would eat and ruminate, but were dull in temperament and were constipated. Forty-eight hours after ingestion, 2 cows had abnormal respiratory sounds, which persisted for 14 days in 1 cow. The pathological findings were chemical pneumonia, and evidence of inflammation of the mammary gland. Another author reported clinical signs of vomiting and death after a lactating shorthorn animal ingested approximately 1 gal (4.5 l) of tractor paraffin (Eaton, 1943). Twenty-four hours after ingesting tractor paraffin, a 3-year-old bullock had signs of marked excitement to wildness, blindness, and incoordination. Clinical signs of anorexia and constipation were reported after cattle ingested tractor-vaporizing oil (low grade of kerosene) (Parker and Williamson, 1951). Pathological findings were fatty changes in the liver, degeneration of the kidney, and multiple small hemorrhages in the lungs.

A herd of 24 dairy cattle ingested diesel oil after the valve on a storage tank was opened, possibly by the cattle (Messerli, 1969). Clinical signs of intoxication were observed in 9/24 cows 30 h later and 4/24 were considered to be seriously affected. Milk from all the cows had a diesel odor. From this herd, a Brown Swiss cow in critical condition was examined in detail. Clinical signs observed in the cow were: elevated body temperature, bradycardia, decreased appetite, decreased peristaltic ruminal movements, diarrhea, muscular weakness, and decreased milk production. Eight days after ingesting diesel, swelling of the rear fetlocks was observed. Eighteen days after ingesting oil, the herd milk production was diminished by 75%; 2 months later, unsteady movements were observed and after an unspecified interval, the cow regained her health. Three of the other seriously affected animals required 1 month for recovery, and had retarded growth for a substantially longer interval. The feces had a diesel odor for 5 days.

Peterson (1963) reported that after a herd of cattle had access to heating oil-contaminated water for 12 h, 2 cows showed remarkable clinical signs. One cow was pyrexic (41.1°C, 106°F), and had severe dyspnea. Body temperature of the second cow was 38.8°C (102°F), and there was clinical evidence of abdominal pain. The first cow was treated with intravenous antibiotics and laxatives; she passed fuel oil in her feces and made a complete recovery. The second cow received similar treatment, did not eat for 2 weeks, developed septic metritis, followed by pneumonia, and subsequently died. Poor health and an abnormal liver in a heifer were attributed to her drinking gasoline 15 months previously (Albert and Ramey, 1964).

Barber reported an environmental incident with aviation turbine fuel (Barber *et al.*, 1987). Fifty-one heifers 12–18-month olds were exposed to water in a stream that had been contaminate with aviation turbine fuel. The duration of exposure was not determined and, when discovered, the contaminated waterway was immediately fenced, and the heifers were provided an alternative source of drinking water. At the initial examination, 2 heifers were dead, ataxia was observed in 5 animals. Over a 3-week interval 8 heifers died or were euthanized *in extremis*. Animals that survived were dull, did not show interest in strangers walking about the field, and had marked weight loss, and increased respiratory rate was observed in some animals. Six weeks after the initial examination, 41 of the surviving animals appeared unhealthy. At 121 days after the initial examination, the heifers were compared to siblings, and were found to have lost 50–100 kg. Because of apparent chronic, poor health, 41 of the heifers were slaughtered approximately 124 days after the initial exposure. One heifer died during transport to slaughter. Approximately 124 days after the initial farm visit, the animals were slaughtered and submitted for pathological examinations. All of the heifers were poorly fleshed for their skeletal size. Some of the animals had liver flukes, but lung worms were not observed. Essentially all of the lungs were considered to be grossly abnormal, as exemplified by enlargement and grayish-blue areas of varying size, and had firm consistency. However, histopathological abnormalities were not observed in the lungs and kidneys.

## Dermal toxicity of petroleum

Pesticides applied to cattle using "cattle oilers" are often diluted with diesel oil and kerosene. Petroleum distillates can be used as vehicles for fly sprays. Diesel fuel was considered to be the cause of a severe skin reaction to fly spray (Edwards and Niles, 1981). The abdomens and legs of the cows were sprayed each time the cows entered the barn and, when the cows exited the barn, the same mixture was rubbed on their backs. The fly spray was a mixture of 3.8 l of proprietary fly spray mixed with 53 l of diesel fuel. Erythema of the skin, swelling of the carpus, and varying severity of edema were observed on the front legs between the elbow and fetlocks. Skin on the back, rear legs, and udder was not affected. The authors postulated that the udder and rear legs were protected by washing before milking. The fly spray–diesel mixture produced similar lesions on the backs of guinea pigs. Treatment consisted of washing the front legs, application of scarlet oil, and

discontinuing the use of the fly spray mixture. Using a different diesel fuel for diluting the fly spray was considered significant in causing the dermatitis. The causative agent in the diesel fuel was not identified. The mixture of pesticide and kerosene and diesel oil can increase the rate of absorption of pesticide. Diesel oil–pesticide mixture can be spill from overturned oilers.

Cattle that were attracted to soil that had been saturated with crude condensate. Puddles of condensate were observed in the cattle tracks. Clinical signs of laminitis were observed in many of the animals in this herd. It is assumed that the petroleum was absorbed through the hoof wall and caused inflammation.

# VETERINARY MEDICAL USE OF PETROLEUM

## White oils

Mineral oils are purified and used for medical purposes, added to human foodstuffs and animal feedstuffs (IRAC, 1984). The mineral oils are highly refined naphthenic or paraffinic distillates. The unsaturated compounds that add color and taste have been removed. Treatment methods include solvent extraction and steeping with strong sulfuric acid can be used as well as adsorption with clay minerals. Alternatively hydrogenation can be used. These oils have a very low sulfur and polyaromatic hydrocarbon content. Uses are the food industry, lubricants in manufacturing of human foodstuffs, direct addition to foodstuffs and as a pharmaceutic. Purified mineral oils are mixed with surfactants (pasture spray oil) and sprayed on alfalfa (lucern) forage before grazing as a prophylactic for bloat in cattle.

## Kerosene and diesel oils

There is historical record of various mineral petroleum fractions being used as veterinary medicaments; lamp paraffin (kerosene) and other kerosene-like products were used as a veterinary medicament for treating animals with intestinal helminths, frothy bloat and diarrhea, and crude oil was used as an aperient. The unpredictable adverse reactions of orally administered kerosene are anorexia, ptyalism, indigestion, irritation of the digestive tract, respiratory difficulties, and death. These effects were attributed to its variability in chemical composition (Reid, 1957; Stober, 1962). Clinical signs have been described for a cow that was drenched with lamp oil. In the first incident (Shenton, 1937), the owner administered a pint (0.57 l) of paraffin oil to control bloat. Twenty-four hours later, the cow was examined and a rumen cannula inserted. Forty-eight hours later, there was an absence of rumen motility, and the cow would vomit after drinking water. On the 3rd day, a stomach tube was passed and gas and water were removed from the rumen. On the 4th day, the cow drank gruel and water, and died on the 5th day. Necropsy findings were severe inflammation and necrosis of the esophagus, inflammation of the abomasum, and the smell of paraffin in the ingesta. Munch (1956) advised that, because of unpredictable adverse effects, crude oil should not be used as a laxative for cattle. Exposure to mineral oil can deplete fat-soluble vitamins. McDowall (1957) administered *per gavage* 75 ml of heavy paraffin/cow/day by drench for 26 days. A 40% reduction in blood carotene occurred over 16 days, and a 20% reduction in blood vitamin A ester, and a 40% reduction in tocopherol (vitamin E) was also observed. After cessation of treatment, 21 days were required for recovery to pre-exposure levels.

# SOUR GAS WELL BLOWOUTS

Sour gas is natural gas that contains $H_2S$ and other sulfur compounds. Sour gas well blowouts constitute a unique hazard to livestock. In the blowout incidents which have been reported in the literature, cattle were confined by fences, corrals, etc. and generally could not escape the airborne emissions. Ranchers and their families may have been forced to evacuate leaving cattle and other livestock unattended. These events can cause major disruptions in animal husbandry. Sour gas is heavier than air and settles into low areas especially during cool temperatures. Low areas tend to be sheltered from the wind and less mixing of the air occurs. The toxic effects of sour gas have been summarized in Table 54.6.

During rework operations a sour gas well in western Canada a blowout occurred (EPS, 1973). The rate of flow and $H_2S$ concentrations were estimated at 11.6 $ft^3$/s and 4–8%, respectively. Ideal conditions for the dispersal of gas were reported to have existed during the blowout. Cattle in one herd were reported to have a watery discharge from eyes and nostrils. Cattle from 6 farms were examined by the veterinary laboratory. The diagnosed was pneumonia.

Cattle were studied in western Canada after a sour gas well blowout (Lodgepole blowout) that occurred in 1982 (October 17 to December 23). The duration of the blowout was essentially 67 days and the estimated flow rate was $>4.2 \times 10^6\,m^3$/day giving an estimated release of elemental sulfur ranged from 900 to 1400 metric tons/day. The well was ignited at 14:07 h on November 1, 1982, and burned until November 17. The well was ignited again at 12:53 h on November 25, 1982, and burned until it was extinguished during the capping process. The well was not on fire for 27 days, and it was ignited for approximately 40 days.

**TABLE 54.6 Summary of observed effects of blowout emissions in cattle**

| Blowout | Observation | Reference |
|---|---|---|
| Canada | Watery discharge from eyes and nostrils. Pneumonia was observed. | EPS (1973) |
| Canada, Lodgepole blowout | Ocular and respiratory irritation, abortions, other reproductive problems. | Round (1992) |
| | Number of aborted fetuses and diagnostic trends did not change for the Provincial Laboratory (Edmonton) during and after the blowout. | Klavano and Christian (1992) |
| | Maladies in cattle increased with decreasing distance from the well and were increased in geographically low areas, problems associated with trace mineral deficiency were observed as were changes in hair color, *inertia uteri*, calves that were born with deformed feet, calves had failure to thrive, decreased growth of replacement heifers, possible decreased birth weights, and 20% reduction in milk production by dairy cows, calving interval increased, herd returned to normal. | Harris (1992) |
| | Significant reduction in weaning weights of calves exposed as cow–calf pairs. | Whitelock (1992) |
| | Possible association with exposure to well emissions were: physical examinations were within the expected normal variation, pathological findings were of varied diagnosis, and were not considered to be unique, 3 calves from these cows raised at the laboratory grew at average to above-average rates, parameters used may not have been sensitive enough to detect irreversible toxicological effects, and the owner may have been biased in his evaluation of long-term effects. | Church (1992) |
| Mississippi (USA) | Irritation of the eyes and respiratory tract, respiratory distress, intolerance to exercise. | Edwards (1992) |
| Canada | Clinical signs mimicked shipping fever, but infective agents or clinical evidence of infection were not detected, extended feeding time to finish exposed feedlot cattle, loss of stamina in cattle, exercise intolerance in horses, exposure to sour gas may have contributed to shipping fever in recently weaned calves, and reproductive failures were not established. | Coppock *et al.* (1986b) |
| Canada, multiphase pipeline leak | Ocular and nasal irritation, evidence of immune and nervous system dysfunction, aggressive behavior in cows, *in estrus* behavior of pregnant cows, above-average mortalities in cows and calves, calves lacked sucking instinct, cows failed to nurture new born calves, and lesions in lymph nodes and trachea. | Mostrom *et al.* (1995) |

There were differences of opinion, regarding the impact on cattle, of emissions from the Lodgepole well. Round (1992) reported clinical signs of ocular and respiratory irritation that was locally described as "red-eye syndrome". Improvement of cattle with the red-eye syndrome was observed immediately after the well was capped. The well emissions were considered to be suspect in causing abortions and infectious causes of abortions were not identified. The number of aborted fetuses and diagnostic trends were reviewed for the interval before, during, and after the Lodgepole blowout (Klavano and Christian, 1992). For the submissions sent to the Animal Health Laboratory, the Lodgepole blowout did not change the number of fetuses submitted to the laboratory or the diagnostic trends established for aborted fetuses. A study was done on the attitudes and opinions of livestock producers regarding the long-term effects in cattle of the emissions from the Lodgepole blowout (Harris, 1992). The producer-based observations were on 1700 beef and 40 dairy cows. Problems associated with trace mineral deficiencies, including change in hair color, were more prevalent among exposed cattle; complaints of blowout-associated maladies in cattle increased with increasing proximity to the well. Complaints of blowout-associated maladies also were more common for cattle located in low-lying areas. Concerns over low birth weights were more common for producers who had not recorded birth weights. Other problems included difficult calving due to *inertia uteri*, calves born with deformed feet, and calves that were "poor-doers". Farmers complained of reduced growth in replacement heifers. The study included one dairy producer. Lactating cows exposed to the blowout gas had a 20% reduction in milk production. There was no report of decreased milk production in cows which freshened after the blowout. The calving interval increased to 13.9 months during 1983, and then returned to 11.8 months in the subsequent year. The owner considered his herd to have been affected by the blowout emissions and then returned to normal.

Whitelock (1992) reported his observations in cattle attributed to the emissions from the Lodgepole blowout.

He observed a statistically significant reduction in weaning weights after exposure of cow–calf pairs and weaned calves to emissions from the Lodgepole well. Church (1992) interviewed farmers, and evaluated cattle for toxic effects. In a 118-cow herd of pure-bred Angus cattle exposed to the well emissions, eight parameters may have been related to exposure to blowout emissions. These were: (1) average decrease of 15 pounds (7 kg) in birth weight, (2) a 100 pound (45 kg) decrease in weaning weights, (3) a 4.6% increase in birth defects or stillborn calves, (4) a 9.5% increase in abortions, (5) loss of hair color (fading and graying), (6) decreased growth and milking ability of heifers born in 1983, (7) breeding problems such as abnormal cycling, and (8) a 23% increase in culling rate. Three of ten control herds had two of the problems listed for the exposed herd. One of the farmers requested that his cows be evaluated by laboratory procedures (Church, 1992). Six cows, considered by the owner to be the worst affected, were examined in 1986. Conclusions of the laboratory findings were: (1) three calves from these cows raised at the laboratory grew at average to above-average rates; (2) findings of physical examinations were within the expected normal variation, (3) pathological findings were of varied diagnosis, and were not considered to be unique, (4) parameters used may not have been sensitive enough to detect irreversible toxicological effects, and (5) the owner may have been biased in his evaluation of long-term effects.

Edwards (1992) described the impact of emissions in cattle from a sour gas well blowout that occurred in 1985 in the southern United States. The well blew for 72 days at a pressure of 1340 kg/cm$^2$ (19,000 lb/in.$^2$); the well produced 1.1 million m$^3$ (40 million ft$^3$) of emissions/day. The emissions were ignited because the gas was composed of 35% $H_2S$. A herd of red and gray Brahmans was examined 5 days after the blowout started. Clinical findings were irritation of the eyes and respiratory tract. Of the 55 animals with signs of respiratory distress in 25–30 days after the blowout started, 15 remained clinically affected ~9 months later.

A sour gas well blowout occurred in western Canada in 1984, and was out of control for 88 h (Coppock *et al.*, 1986b). Flow rates for the well were estimated at 239,000 m$^3$/day, and the approximate concentration of sulfur-containing compounds is given in Table 54.7. Cattle were exposed to the blowout gas, and the impacts of well gas in cattle were investigated. A total of 195 measurements of $H_2S$ were made in the blowout area; the concentrations ranged from 0.014 mg of $H_2S$/m$^3$ of air to 4.90 mg of $H_2S$/m$^3$. It was concluded that, within 4 km of the well, exposure to the gas caused irritation of the respiratory tract. Clinical signs of effects of the well gas in feedlot cattle mimicked those of shipping fever. Extensive laboratory testing did not identify infectious agents, clinicopathological parameters did not suggest infectious disease, and the pathogenesis was atypical of shipping fever. Reasonable evidence was established that cattle in a feedlot within 2 km of the well were affected adversely, and the time for finish was extended. Also observed in these cattle were deaths during a severe windstorm, and death of an exposed steer from polioencephalomalacia. The relationship between exposure to well emissions and lack of stamina or polioencephalomalacia was not established. Other farmers complained of loss of stamina in cattle, and exercise intolerance in horses. Lesser effects may have occurred at a greater distance from the well, and exposure to well gas may have contributed to respiratory disease in weaned calves. Evidence of reproductive failures associated with well gas exposure(s) was not established.

**TABLE 54.7 Chemical Composition of Well Gas Emitted from a sour gas well blowout**

| Compound | Concentration (ppm) |
|---|---|
| Hydrogen sulfide | 11,400 |
| Methylmercaptan | 57.0 |
| Carbonyl sulfide | 22.0 |
| Ethylmercaptan | 14.7 |
| Propylmercaptan | 14.3 |
| Carbon disulfide | 4.8 |
| Butylmercaptan | 3.3 |
| Dimethyl disulfide | $<0.5$ |

Mostrom (1995, 1996) investigated the effects of a leak from a sour multiphase pipeline in 2 herds of cattle. One of the herds was located immediately adjacent to a river where the pipeline break occurred, and was later moved to a farm approximately 4.5 km from the site. The other herd was located approximately 4 km from the site. The herds were exposed to emissions from the pipeline, and also to emissions from the cleanup operations. River ice, river bottom, and riparian lands were reclaimed by burning fugitive sour condensate and washing river gravel. Emissions from the washing operations were released into the atmosphere. Over 1400 tissue specimens were collected. This investigation found clinical evidence of exposure to an irritating gas, and evidence of immune and nervous system dysfunction in cattle. Some cows developed aggressive behavior. Pregnant cows were observed *in estrus*. Both herds had above-average mortalities in cows and calves. Many of the calves lacked the suckling instinct, and cows failed to nurture newborn calves. Stair *et al*. (1996) reported on the histopathological findings in these herds.

## EXPERIMENTAL STUDIES ON $H_2S$

Nordstrom (1975) exposed calves to ammonia ($NH_3$) and $H_2S$ gases individually or in combinations. Calves were housed and exposed in uniquely designed exposure

chambers. A manure pack was established in each chamber to stabilize a background production of $NH_3$ at approximately 12.95 ± 5 ppm (9.0 ± 3.5 mg/m$^3$). $H_2S$ was not identified in the manure gas. Calves were placed in the chambers for a 7-day acclimation period, and were exposed to the background level of $NH_3$ during this interval. The acclimation interval was immediately followed by 7-day exposure to $H_2S$. A subsequent 7-day observation period completed the experiment.

The predominant clinical sign in all treatment groups was ocular irritation as indicated by erythema and excessive lacrimation. Ocular irritation was observed at the background levels of $NH_3$. Nasal irritation, based on serous discharge from the nose, was observed at 65 ppm (45.2 mg/m$^3$) of $NH_3$, and the serous discharge was profuse at 150 ppm $NH_3$ (104.3 mg/m$^3$). Dry coughing was also observed, especially at 150 ppm $NH_3$. At 150 ppm exposure, the calves kept their eyes closed and had irregular shallow breathing. Based on diminishing clinical signs during the exposure periods, the author concluded that the calves appeared to develop some adaptation to $NH_3$. The calves were distressed and depressed by all exposure levels of $H_2S$. Signs of distress were restlessness, pawing, head shaking, tail switching, blowing through the nose, licking of the nose, and slobbering with the tongue protruding. Signs of depression were heads lowered and eyes closed. Diarrhea and vomiting were observed in some calves. Breath holding, panting, dyspnea, shallow breathing, and spasmodic coughing were signs of respiratory distress. Epistaxis was also observed. Neurological effects (nystagmus and depression) were reported. Ocular irritation appeared to be profound and, at 150 ppm (208.6 mg of $H_2S$/m$^3$) of exposure, the effect was described as degenerative. Photophobia and refusal to open the eyelids were observed at 20 ppm (27.8 mg of $H_2S$/m$^3$) level of exposure. At the high-exposure level, corneal opacity was severe, and the animals were diagnosed as blind. Keratoconjunctivitis and vesicular keratitis were observed. At the end of the exposure interval, rupture of the cornea seemed imminent. The eyes of white-faced calves appeared to be more susceptible to the irritating and inflammatory effects of $H_2S$ than calves with pigmented skin around the eyes.

Clinical signs of the effects on the upper respiratory tract were more severe in calves exposed to $NH_3$ plus $H_2S$ (Nordstrom, 1975). The severity of epistaxis increased at the exposures to high levels of $H_2S$ plus $NH_3$, and the author considered the effects to be additive or synergistic. The combination of 150 ppm $H_2S$ plus 150 ppm $NH_3$ decreased respiration from a pre-exposure rate of 87–63/min. Based on clinical evaluations of the ocular lesions at the 150 ppm of $H_2S$ level of exposure, the author concluded that $NH_3$ at 150 ppm decreased the effects of exposure to 150 ppm $H_2S$. Rumen motility was considered to be decreased in both rate and intensity. Exposure to $H_2S$ plus background $NH_3$ decreased feed consumption by 3.5% and 26% for 20 and 150 ppm levels of exposure, respectively. Animals exposed to 20 ppm $H_2S$ tended to recover appetite at the latter part of the exposure interval. During the 7-day post-exposure interval, feed consumption increased and was higher than that for the background $NH_3$ values. At levels of 20 ppm $H_2S$ plus 65 ppm $NH_3$, appetite depression in the calves was more or less comparable to that of calves exposed to 20 ppm $H_2S$ plus background $NH_3$. Feed consumption in calves exposed to 20 ppm $H_2S$ plus 150 ppm $NH_3$ was decreased 6.5%, or essentially double the appetite depression observed in calves exposed to 20 ppm $H_2S$ plus background $NH_3$. Exposure to 150 ppm $H_2S$ plus 150 ppm $NH_3$ caused a 32.5% decrease in feed consumption compared to that of the calves exposed to 20 ppm $H_2S$ plus background $NH_3$. These observations suggest that the ratio of $H_2S$ to $NH_3$ in the exposure mixture alters the interactive effect.

Clinicopathology observations were reported. Sulfhemoglobin was not detected in the blood from calves exposed to 20 ppm $H_2S$. Statistically significant changes in levels of blood ammonia, urea nitrogen and uric acid, serum concentration of bilirubin, glucose, phosphorus, calcium, total protein, albumin and cholesterol, or the activities of the enzymes glutamic oxaloacetic transaminase, lactic acid dehydrogenase, and alkaline phosphatase were not observed. Leukocytosis was observed in 2 calves exposed to $H_2S$ plus background concentrations of $NH_3$.

Goats were essentially continuously exposed to $H_2S$ during a 96-h interval in an exposure-hood delivery system (Hayes, 1972). The exposure-hood controlled the ambient environment around the head and neck of the animals, but permitted the animals to eat and drink. Exposure concentrations of $H_2S$ were 0.0 ppm, 4 goats; 10 ppm (13.9 mg/m$^3$), 4 goats; 50 ppm (69.5 mg/m$^3$), 4 goats; and 100 ppm (139.1 mg/m$^3$), 5 goats. Goats exposed to 50 or 100 ppm $H_2S$ trembled during activity. A decrease in urinary volume corresponded to a decrease in water consumption. At 50 ppm of exposure, epiphora occurred 24 h after exposure and persisted for the remainder of the exposure interval. Epiphora also occurred with exposure to 100 ppm $H_2S$, and ocular injury was visible following 24–48 h of exposure. Corneal opacities, that were considered to be reversible, caused partial loss of vision. There was a trend for exposure to $H_2S$ to decrease intake of feed. In animals exposed to 10 ppm, there was a trend to recovery during the exposure period, and the overall decrease in feed consumption was 20%. Exposure to 50 ppm $H_2S$ decreased feed and water intake, especially on the 1st day of exposure. Although a trend to recovery was observed, complete recovery did not occur. For the 50- and 100-ppm exposure groups, feed consumption decreased on exposure day 2 (37% decrease for the 100 ppm group) and remained depressed through exposure day 4. For the 10-ppm group, there was a decrease in water consumption on exposure day 1, and a rebound on days 2 through 4.

For the 50 ppm group, there was a sharp decrease in water consumption on exposure day 2. For the 100-ppm group, water consumption was also decreased. The author concluded that there was a dramatic decrease in the desire of the goats to consume food and water. Plasma concentrations of cortisol were increased 48% and 55% in the 50 and 100 ppm groups, respectively. Respiratory and heart rates, and blood pressure were recorded each day at 08:00, 10:00, 13:00, and 16:00 h. These data suggest that initial exposure to $H_2S$ at the 10 and 20 ppm levels caused a decrease in respiratory rate on first day of exposure. The 0.0 and 10 ppm treatment groups were not different for respiratory rate; exposure to 50 ppm significantly decreased respiration from 19.8 respirations/min on exposure day 2 to 16.5 respirations/min on day 3; goats exposed to 100 ppm had a significant decrease in respiratory rate on the last 2 days of exposure. Exposure to $H_2S$ did not significantly alter heart rate, blood pressure, or rectal temperature; however, there was a trend for rectal temperature to increase during the exposure period.

## EXPOSURE TO ENVIRONMENTAL SULFUR

The impact of elemental sulfur on cattle, especially to producers in close proximity to sulfur stockpiles, is a concern to cattle producers. A study was done on the impact in cattle of fugitive sulfur and other pollution from sulfur mines in Poland (Janowski and Chmielowiec, 1981). The principal pollutants were sulfur dust, sulfur gases, $SO_2$, and sulfur hydride. Fifty-five cattle within 1 km of the mine were evaluated during the summer months on pasture, and during the winter months when the cattle were predominantly stabled. The control group of 27 cattle was kept in an area that was free of sulfur pollution, 20 km from the mine. Analyses for sulfur dust and sulfur compounds are summarized in Table 54.8. Clinical findings in the polluted area were: (1) decreased occurrences of infestation with external parasites and mycotic skin infections (ringworm) (2) increased body temperature, heart and respiratory rates; and (3) decreased excitement response to pain. Other findings were abnormal eyes (90.4%), respiratory disease (94.2%), and digestive disorders (21.1%). Clinical findings in the eye were epiphora, erythema of the conjunctiva, and edema of the eyelids. Abnormal findings of the respiratory system included dyspnea, coughing, mucopurulent nasal discharge, and abnormal pulmonary sounds. Digestive disorders included abnormal ruminal motility and diarrhea. Cattle were healthier when kept indoors. Cattle in areas polluted with sulfur, as compared to controls, had a decreased burden of parasites in the digestive tract. Pathological findings in the sulfur-exposed cattle were: the respiratory tract contained gray-yellow tinged mucus, inflammation of the trachea, thinning of cellular layers in the bronchi, almost to the point of squamous metaplasia, and interstitial inflammation. The authors concluded that sulfur pollution produces intoxication in the form of a chronic disease that they called sulfurosis (Janowski and Chmielowiec, 1981).

**TABLE 54.8 Concentrations of sulfur and sulfur compounds in sulfurosis study**

| Parameter | Study area* | Control area |
|---|---|---|
| Urinary sulfur | Barn 3.01 g/l<br>Outdoors 5.33 g/l | 0.52 g/l |
| Milk sulfur | 1.87 g/l | 0.30 g/l |
| Serum sulfur | 2.58 g/l | 0.46 g/l |

## TOXICOLOGY OF SULFUR DIOXIDE IN CATTLE

Inhalation studies (head only exposure) in cattle showed that sulfur dioxide had an effect on the immune system and an effect on metabolism and if cold temperature had an effect on $SO_2$ toxicity (Komarnisky, 2003). A brief summary of this study is given. Eight steers were progressively exposed to room air containing 1 ppm $SO_2$ for 10 days, 5 ppm $SO_2$ for 7 days, and 20 ppm for 7 days. Four steers were exposed to $SO_2$ at room temperature ~18.5ºC and 4 steers were exposed to $SO_2$ at –16ºC. In the cold environment, metabolic rate was increased by 33%, 39%, and 44% at 1, 5, and 20 ppm of $SO_2$, respectively. Exposure to $SO_2$ in the warm environment did not significantly alter metabolic rate. For a 500 kg steer intermittently exposed to 1 ppm of $SO_2$ the extra feed required for maintenance and growth would be equivalent to an additional 1.5 kg/day of grain or 2.1 kg/day of hay. Sulfur dioxide was shown to have immunotoxic effects in cattle. Exposure of steers to 5 and 20 ppm in the cold environment decreased the respiratory bursts in neutrophils. Exposure to $SO_2$ in the cold environment decreased the threshold dose for shedding of respiratory epithelial cells into broncho-alveolar lavage (BAL) fluid. Neutrophil numbers in BAL were increased by exposure to $SO_2$ and exposure to cold temperature further increased neutrophil numbers. Exposure to $SO_2$ decreased the number of pulmonary macrophages in BAL fluid. At the 20 ppm level, lactate dehydrogenase was increased in the BAL fluid.

# PATHOLOGY OF PETROLEUM AND OILFIELD CHEMICALS

## Clinical pathology

Barber (1987) reported on the toxicology of aviation turbine fuel in heifers. Ten animals were considered to have elevated serum activity of aspartate aminotransferase, interpreted as a reflection of acute hepatic dysfunction, activity of $\gamma$-glutamyl transpeptidase was considered to be within the normal range. Elevated concentrations of non-esterified fatty acids were observed in 11 of the animals, 2 had elevated concentrations of blood urea nitrogen and 5 had a leukocytosis. Six weeks after the initial farm visit, all the 41 animals had elevated serum activity of $\gamma$-glutamyl transpeptidase.

Bystrom (1989) found that sweet crude oil did not alter hematological parameters. There was a correlation between the severity of clinical signs and increased concentrations of plasma fibrinogen. The activity of hepatocellular enzymes in serum and serum glucose were not consistently increased after exposure to sweet crude oil, but serum calcium and potassium values consistently decreased and bilirubin values consistently increased. Rowe (1972) found that hematological parameters, especially leukocyte numbers were elevated as chemical pneumonia advanced. A single dose of sour crude oil caused a constant decline in plasma glucose. A transient decline in plasma glucose was observed in calves given sweet crude oil or kerosene.

Exposure to grease has been reported to cause changes in hematology and clinic chemical parameters (Wallace and Blodgett, 1996). A cow exposed to Li grease had leukopenia ($3.7 \times 10^9$ WBC/l), lymphopenia ($1.8 \times 10^9$ lymphocytes/l), and hyperfibrinogenemia (6 g/l and normal given as $<5$ g/l).

Clinicopathological observations are available for cattle. TAP have greater affinity for pseudocholinesterase, also known as plasma cholinesterase, and butyrylcholinesterase, than for acetylcholinesterase (Abou-Donia and Gupta, 1994). Erythrocytic acetylcholinesterase was inhibited for a short duration after a calf was initially dosed with 10 g of TAP/kg of body weight, and the dose was repeated as 5 g/kg on day 30, and as 10 g/kg on day 56 (Dollahite and Pierce, 1969). In four animals poisoned with tri-*o*-tolyl phosphate, changes in the routine automated clinicochemical and hematological parameters were not observed (Nicholson, 1974). In an experimental study, 3 calves were given oral doses at 5, 10, or 20 g of TAP/kg of body weight, with the total dose divided equally over 10 days (Beck *et al.*, 1977). On day 8 or 9, there was a 70–77% reduction in the activity of whole blood acetylcholinesterase. In 1 calf given 5 g/kg as a single oral dose, activity of whole blood acetylcholinesterase was reduced by 68% on day 2 and by 78% on day 9. In cows dosed with 0.5 or 1.0 g of TAP/kg, activity of whole blood cholinesterase was reduced by 50% and 63%, respectively on day 2, and by 56% and 61%, respectively, on day 7. The consensus is that a relationship between the inhibition of blood cholinesterases and organophosphate ester-induced delayed neurotoxicity does not exist (Abou-Donia and Gupta, 1994).

Exposure to nitrates from drilling fluids can cause methemoglobinemia. The concentration of nitrates can be determined in rumen fluid, aqueous humor (anterior chamber of the eye), urine, plasma, and serum. Exposure to $H_2S$ does not produce sulfhemoglobin.

## Pulmonary pathology of petroleum

The lung is a target for unweathered (unchanged by exposure to atmosphere) petroleum. Hydrocarbon-induced chemical (inhalation) pneumonia occurs when oil is inhaled. Aspiration of oil during emesis is the most common mechanism of inhalation exposure (Coppock *et al.*, 1986a, 1996).

Necropsy findings of oil-induced chemical pneumonia have been described (Dungworth, 1985, 1993). Generally, the cranioventral lobes of the lungs are affected first. During necropsy, oil may be identified in the lungs by oil discoloration and a petroleum odor, visible oil in the lung, oil floating to the surface when a piece of lung is immersed in water or formalin, or oil layering on the surface of the supernatant when a piece of lung is homogenized.

The pulmonary histopathology for unweathered petroleum is similar for the various forms of petroleum. Histopathological changes are proliferative, and macrophages with a foamy-appearing cytoplasm are found in and tend to fill the alveoli (Dungworth, 1985). In the pathogenesis, oil-containing macrophages are found in the lymphatics, especially those adjacent to blood vessels around bronchi. Fibrosis and proliferation of type II macrophages are prominent features. Foamy macrophages may be incorporated into the alveolar septa by fibroblastic proliferation. As determined by histochemistry and special stains, lipids are found in both intracellular and extracellular sites, and oil can be identified in the alveolar spaces. In the early stages, the lesion may be an acute necrotizing fibrinous bronchopneumonia. Generally, neutrophils, lymphocytes, and plasma cells surround the necrotic areas. Fibrinous exudate, inflammatory cells and amorphous eosinophilic and oily material can fill the alveolar spaces. Empty spaces in the tissues suggest that liquid foreign material may have been absorbed. Plant material from aspirated ingesta may also be seen in alveoli. Fibrin hemorrhages and a mixed population of mononuclear cells may be observed on the pleural surface. Extensive coagulative necrosis and suppuration may be observed in the consolidated areas. Bacteria may be present in the necrotic areas and alveoli. Hematogenous exposure of the lungs to

petroleum hydrocarbons also occurs. Volatile components of petroleum are absorbed by the gastrointestinal tract and are volatilized from the blood in the lungs. Oil emboli can occur in the lungs through absorption of oil from the gastrointestinal tract, and form oil emboli that block the small blood vessels in the lungs and brain. Oil emboli in blood vessels of the lungs and brain have not been reported in cattle intoxicated with crude petroleum. The pathogenesis and observed lesions may be altered by concurrent bacterial infection and cytotoxicity of the oil.

There are reports of field and experimental-induced petroleum intoxication. Ulceration of the ventral aspect of the trachea can occur in kerosene poisoning and the ulcers may be covered with a pseudomembrane (Rowe, 1972, 1973),. Areas of the lung can be consolidated and have a dark purple, reddened or tan-gray, mottled discoloration. The areas of consolidation often have a nodular appearance. Fibrinous pleural adhesions and serofibrinous pleural exudate can occur. Pulmonary abscesses can also be observed (Rowe, 1972, 1973). Multiple small hemorrhages were observed in the lungs of cattle poisoned with tractor-vaporizing oil (Parker and Williamson, 1951). Chemical pneumonia was reported in cattle dying from diesel fuel poisoning (Gibson and Linzell, 1948). Pneumonia and pulmonary abscesses-containing Gram-negative organisms were found in cattle that died acutely from drinking water contaminated with aviation turbine engine fuel (Barber *et al.*, 1987). The rumen contents smelled of oil, and the odor matched the source of the petroleum. The carcasses appeared to repel scavengers and flies, and appeared to have retarded putrefaction. Microscopic examination of tissues from the animals that died in the first 3 weeks showed fatty degeneration of hepatocytes and focal areas of hepatitis, and 1 of 4 had tubulonephrosis, renal vascular thrombi, and interstitial nephritis. A diagnosis of pneumonia, and abscesses-containing gram-negative organisms was made in 2/4 of the animals.

Approximately 124 days after the ingestion of aviation turbine fuel-contaminated water, the remaining cattle were necropsied. At slaughter, the lungs of the cattle were considered abnormal, and were characterized by enlargement and gray-blue areas of varying and abnormal firmness. However, histopathological abnormalities were not observed. Infection in the lungs can occur rapidly following chemical injury. Cattle that survive for 6 weeks or longer with chemical pneumonia usually have marked loss of weight and chronic ill health (Rowe *et al.*, 1973). Pulmonary lesions have been observed in sheep following a 1-day exposure to natural gas condensate-contaminated water (Adler *et al.*, 1992). Gross pathological observations included severe bilateral consolidations and tan to gray mottling of the ventral lobes. Histological diagnosis of the lesions was a necrotizing bronchopneumonia. There were extensive areas of coagulation necrosis bordered by a dense zone of neutrophils and lesser numbers of lymphocytes, plasmacytes, and macrophages. The alveoli were filled with fibrinous exudate and amorphous eosinophilic material. Plant material was also observed in the pulmonary parenchyma. The pleural surface was coated with fibrin, hemorrhages, and mononuclear cells. Pathogenic and potentially pathogenic bacteria (*Pasteurella haemolytica*, *Klebsiella pneumoniae*, *Fusobacterium necrophorum*, *Actinomyces* (*Corynebacterium*) *pyogenes*, *Escherichia coli* and *Pseudomonas* spp.) were isolated from the lungs of some of the sheep.

Experimental studies have been done in crude oil (Bystrom, 1989). Cattle were administrated a sweet crude oil *per gavage*. Many of the animals, especially those that received larger doses of oil, had black discoloration of the lungs. Visible oil was present in the cranioventral lobes. In one animal, it was estimated that 80% of the lungs were affected by black discoloration, and visible oil was observed. Pathological diagnoses included pulmonary consolidation, fibronecrotizing pneumonia, pleuritis, emphysema, atelectasis, multifocal interstitial pneumonia, proliferative alveolitis, bronchopneumonia, and alveolitis. In animals that survived 8 days, hyperplasia of type II epithelial cells was observed, and the alveoli were filled with foamy, alveolar macrophages.

Lung lesions can occur when animals are exposed to gaseous petroleum and sour gas. Stair *et al*. (1996) reported lesions of hyperplasia of the submucosal glands in the trachea of cattle exposed to emissions from a multiphase sour gas leak (Mostrom and Campbell, 1996). Other lesions observed included hyperplasia of tracheal, bronchial and bronchiolar glands, metaplasia of the tracheal mucosa, and loss of cilia from the respiratory epithelium. Lymphoid hypoplasia was also observed.

A study was done in feral cats that were exposed to emissions from fires in the Kuwait (Moeller *et al.*, 1994). The cats were collected in Kuwait approximately 8 months following ignition of the oil wells. To ensure that the cats had been exposed for the entire duration of the oilfield fires, only cats with permanent teeth were examined. Twelve cats were collected in Kuwait City, an area that was relatively smoke-free, and 14 cats were collected in Ahmadi, a city that was partially evacuated because of intense smoke from the fires in the adjacent Bergan oilfield. These findings have been summarized in Table 54.9. The authors concluded that these lesions were probably reversible, and were most likely caused by exposure to pollution from the oilfield fires. However, other causes such as infectious diseases and parasitism could not be completely eliminated.

## Hepatic pathology of petroleum

Hepatic pathology can be observed following exposure to oil. Parker and Williamson (1951) reported fatty changes in the liver from a cow that had ingested tractor-vaporizing

**TABLE 54.9 Respiratory tract lesions observed in feral cats exposed to emissions from the Kuwait oilfield fires**

| Lesion | Kuwait city | Ahmadi |
|---|---|---|
| Mild accumulation of anthracotic pigment | 5/12 | 11/14 |
| Hyperplasia of bronchial and bronchiolar glands | 3/12 | 5/14 |
| Scattered occurrence of bronchi that were dilated and filled with cellular debris and a few neutrophils, and connective tissue around bronchiolar glands contained lymphocytes and plasma cells | 1/12 | 1/14 |
| Hyperplasia of smooth muscle around terminal and secondary bronchioli | 4/12 | 10/14 |
| Tracheal gland hyperplasia, and segmental thickening of the submucosa | 3/12 | 4/14 |
| Multifocal squamous metaplasia of tracheal mucosa | 7/12 | 10/14 |
| Minimal hyperplasia of the submucosal glands of the larynx, some thickening of the laryngeal submucosa and slight goblet cell hyperplasia | 2/12 | 0/14 |
| Multifocal squamous metaplasia of the laryngeal epithelium | 2/12 | 3/14 |

oil. Fatty degenerative changes and focal areas of hepatitis were observed in cattle following ingestion of water contaminated with aviation turbine engine fuel (Barber *et al.*, 1987). An abnormal-appearing liver in a heifer was attributed to the ingestion of gasoline 15 months previously (Albert and Ramey, 1964). A sweet crude oil was found to be hepatotoxic in cattle. Pathological changes included swelling of the liver, increased friability, and centrilobular congestion (Bystrom, 1989). Cows dosed with crude oil had an increase in liver weights. Histologically, the hepatocytes contained numerous vacuoles, and these vacuoles were thought to have previously contained oil. Wallace and Blodgett (1996) reported the histopathological changes in the liver of a cow that consumed Li grease containing 2050 μg Li/g of grease. The observations were vacuolated and atrophied hepatocytes. Experimental oral exposure of cattle to Li produced similar hepatic lesions (Johnson *et al.*, 1980). Hepatic changes observed in sheep poisoned by natural gas condensate were fatty degeneration, and periportal infiltration of lymphocytes and plasma cells. Biliary hyperplasia and periportal fibrosis were also found (Adler *et al.*, 1992).

## Gastrointestinal pathology of petroleum

The gastrointestinal tract in oral exposure has primary contact with the oil. The chemical composition of the oil will cause variation in the pathology observed. Petroleum can be observed and the odor of petroleum can be detected in the rumen and intestinal tract (Wallace and Blodgett, 1996). Kerosene-induced ulcers of the esophagus have been reported (Rowe *et al.*, 1973). Bystrom (1989) reported pyloric ulcers of the abomasum of cattle exposed to unweathered sweet crude oil; also rectal lesions of mild congestion to mild hemorrhages and focal areas of inflammation were observed. Other gastrointestinal lesions were not reported. Bumstead (1949) reported oil to be very irritating to the intestinal tract of cattle. Ingestion of natural gas condensate was observed to produce reddening of the serosal surface of the gastrointestinal tract of sheep (Adler *et al.*, 1992). Hemorrhage into lumen of the gut was also observed. Histological observations were submucosal and mucosal congestion, and mucosal and serosal hemorrhage. An inflammatory response was observed in all areas of the gastrointestinal tract. Superficial erosions, mild acute cryptitis and neutrophilic and lymphocytic exudates were reported. Isolated necrosis of enterocytes was also observed. Lithium grease has been reported to cause gastroenteritis in cattle (Johnson *et al.*, 1980).

## Renal pathology of petroleum

The kidneys are also target organs for petroleum. Some animal species and gender within a species are more sensitive to the nephrotoxicity of petroleum than others. The sensitivity of cattle to the nephrotoxicity of petroleum has not been well defined. A cow that consumed Li grease had mild swelling and vacuolation of the proximal tubular cells (Wallace and Blodgett, 1996). Experimental oral exposure of cattle to Li grease containing 1250 μg Li/g of grease produced similar renal lesions (Johnson *et al.*, 1980). Parker and Williamson (1951) reported degeneration of the kidney in cattle after they consumed tractor-vaporizing oil. Tubulonephrosis, renal vascular thrombi, and interstitial nephritis were observed in cattle following environmental exposure to aviation turbine engine fuel (Barber *et al.*, 1987). Renal lesions were not observed in surviving animals slaughtered 124 days later. Renal lesions have been observed in cattle dosed with a light crude oil (Bystrom, 1989). These lesions were shrunken or collapsed glomeruli (2–5 in a 4 times field), mild focal necrosis of epithelial cells in the collecting ducts, and inflammatory cells that were observed in the renal cortex. In sheep poisoned with natural gas condensate, tubular epithelial necrosis was observed (Adler *et al.*, 1992). Granular eosinophilic casts (negative for hemoglobin) and protein droplets filled Bowman's space and many renal tubules. Inflammatory cells were seen around tubular casts.

## Nervous system pathology of petroleum

Cattle exposed orally to Li grease had slight hemorrhage into the cerebellar peduncles (Johnson *et al.*, 1980; Wallace

and Blodgett, 1996). Lesions in the CNS were observed in sheep poisoned by natural gas condensate (Adler *et al.*, 1992). Mild perivascular hemorrhage was seen in the pia mater and in the white mater of the cerebellum and cerebrum. Increased separation between the pia and arachnoid membranes was prominent, and edema was observed in the stroma of the choroid plexus. Lesions of the CNS were observed in harbor seals (*Phoca vitulina*) exposed to crude petroleum (Prudhoe Bay Crude Oil, PBCO) from the T/V *Exxon Valdez*, which grounded in Prince William Sound (Spraker *et al.*, 1994). Lesions were observed in neurons and axons of the midbrain. Histopathological observations included intramyelinic edema of the large myelinated axons, neuronal swelling, neuronal necrosis, and axonal swelling and degeneration of the midbrain. These lesions were most prominent in the thalamic nuclei. Lesions of the CNS also were observed in polar bears. The bears were dermally exposed to Midale crude oil (Oritsland *et al.*, 1981). The lesion consisted of degenerated and necrotic cells in the small cell pyramidal layer of the hippocampus. Other lesions observed were perineuronal vacuolation in the cerebral cortex. Enlargement of the Virchow–Robin spaces and extravasation of blood around small blood vessels occurred.

## Cardiac pathology of petroleum

Cardiac lesions associated with petroleum poisoning in cattle do not appear to have been reported, but have been observed in sheep exposed to petroleum condensate (Adler *et al.*, 1992). Gross pathological changes included epicardial hemorrhages, serosanguineous pericardial fluid, pale-appearing myocardium, and reddened endocardium. Microscopic observations were segmental myocardial necrosis and calcification. The myofibrils had loss of cross striations and a beaded appearance. There were multifocal areas infiltrated with lymphocytes, macrophages, and occasional neutrophils. The blood vessels were congested.

## Pathological effects of petroleum in embryos

Lesions in the bovine fetus linked to exposure to crude oil have not been reported. However, studies on the embryotoxicity of PBCO have been done. Couillard and Leighton (1989, 1990a, b) reported that PBCO was embryotoxic and that the toxicity was different from hypoxia induced by sealing the eggs with a sealing wax. Mineral oil (USP), used as a control, was not toxic to chicken embryos. Dosages ranged from 2 to 20 μl PBCO/egg; the oil was applied on the surface of the egg below the airspace. Hepatic lesions were hepatocellular necrosis, mineralization, and perivascular and multifocal accumulations of heterophils. Hepatocellular necrosis was dose dependent. The liver was observed to have superficial yellowish zones that were multifocal to diffuse. These yellowish zones and mineralization corresponded to areas of hepatocellular necrosis. Mineralization occurred in the necrotic areas. Vacuolation of the hepatocytes was observed. The number of mitotic figures in the liver increased with the dose. Renal lesions were limited to the mesonephrous. The capillaries of the glomeruli were distended and cellular casts and mineralization were observed in the renal tubules. Splenic lesions were limited to increased granulopoietic cells arranged in distinct cords. Other pathological findings were ascites and subcutaneous edema. Hepatic lesions were observed 2 days after treatment; renal and splenic lesions on the 3rd day. Edema fluid was more pronounced after the 3rd day.

In another study, the toxicity of PBCO was evaluated in chicken embryos (Lusimbo and Leighton, 1996). The chicken embryos were exposed to oil on day 9 of incubation. The oil was placed on the eggshell over a prominent blood vessel of the chorio-allantoic membrane. Dosages ranged from 0 to 16 μl PBCO/egg, and embryonal mortality was dose dependent. Exposure to PBCO at 4 μl decreased weight gains during a 3-week post-hatching observation period. Lesions were observed in the liver, subcutaneous tissues, bursa of Fabricius, and pipping muscle (musculus complexus). Hepatic lesions were multifocal to locally extensive areas of hepatic necrosis and mineralization. Large fluid-filled vesicles were observed on the dorsocaudal aspect of 5% and 16% of embryos dosed with 1 and 2 μl of PBCO respectively. The bursa of Fabricius had depleted lymphoid tissue and the interstitium was infiltrated with heterophils. Lesions in the pipping muscle were edema and hemorrhage, sparse multifocal fragmentation and occasional vacuolation of the myofibers.

## Pathology of $H_2S$ and Sulfur

Detailed reports on the pathology of $H_2S$ and sour gas in cattle do not appear to exist in the scientific literature. There are reports on the toxicopathology of $H_2S$ in other species. Massive pulmonary edema was the pathological finding in humans killed by accidental exposure to $H_2S$ and in rats experimentally exposed to high concentrations of $H_2S$ (Burnett *et al.*, 1977; Lopez *et al.*, 1986, 1987, 1988, 1989). Ocular lesions in rats included corneal edema and necrosis, and detachment of corneal epithelial cells has been reported for experimental $H_2S$ exposures of 56 mg/m$^3$ (40.3 ppm) (Beasly, 1963; Lopez *et al.*, 1989). Calves continually exposed to $H_2S$ by inhalation developed corneal opacity (Nordstrom, 1975; Beauchamp *et al.*, 1984). Unfortunately, the corneal pathology was not described in these reports.

Lopez *et al.* (1986) exposed rats to 0, 56 and 420 mg of $H_2S$/m$^3$ (0, 40.3 and 302 ppm) for 6 h. Mild pulmonary

edema was observed in rats immediately after exposure to atmospheres containing 56 mg $H_2S/m^3$ and in rats that were killed by exposure to 420 mg $H_2S/m^3$. Pulmonary edema was described as primarily perivascular, and edema fluid was rarely observed in the alveoli. Pulmonary edema was not observed in rats exposed to 56 mg/$m^3$ at 18 and 42 h after exposure. Lymphorhexia of the lymph nodes or thymus appeared to increase in severity and frequency in the high-dose group. Since nasal ulcers were observed in all of the rats, activation of the immune system could increase the sensitivity of lymphoid tissue to $H_2S$.

Lopez *et al.* (1987) reported that exposure of rats to $H_2S$ concentrations of 0, 10, 200, and 400 ppm (0, 13.9, 278.1 and 556.2 mg/$m^3$) for 4 h increased the cellularity of nasal saline washes by 0%, 139%, 483% and 817%, respectively. The cells present in the nasal washes were exfoliated epithelial cells and neutrophils. A 3000% increase in the protein concentrations in BAL fluids was observed 1-h post-exposure in rats exposed to 400 ppm $H_2S$. The increase in protein and leukocytes was considered to be the result of alterations of vascular permeability induced by $H_2S$.

Lopez *et al.* (1988) exposed rats to 0, 14, 280 or 560 mg of $H_2S/m^3$ (0, 10.1, 201.3, and 402.7 ppm), respectively. Squamous epithelium appears to be resistant to the corrosive effects of $H_2S$, and lesions were not observed in these regions of the nasal epithelium. Lesions of the respiratory and olfactory epithelium were observed in all of the rats exposed to 560 mg $H_2S/m^3$. Cellular necrosis, erosions, and ulcers of the respiratory epithelium were observed. Twenty hours after exposure, eroded or ulcerated areas were covered by a thin layer of basophilic cells, and a neutrophilic exudate was observed in the lamina propria and submucosa. At 44 h after exposure, the respiratory epithelium was covered with pre-ciliated secretory cells, and mitotic figures were observed. Specific lesions were observed in the olfactory epithelium. There were multifocal areas of cellular necrosis, and the lesions were more pronounced at 20 h after exposure. Evidence of healing was not observed at 44 h after exposure. The olfactory epithelium is considered a sensitive target in the nasal passages for $H_2S$. No report was found for cattle. However, lesions of the olfactory epithelium could alter maternal behavior by altering offspring recognition.

Ciliated cells in the nasal passages, trachea, and bronchi are sensitive targets for airborne irritants including $H_2S$, $SO_2$, and $NO_2$ (Lopez *et al.*, 1988). Ciliated cells transport mucus or foreign particulate matter from the lower respiratory tract toward the pharynx where it is swallowed, and from the nasal passages to exit at the nares. The cilia of the columnar epithelium are lost following exposure to irritating airborne substances. Loss of cilia or ciliated cells can increase the impact of particulate substances on the pulmonary tract. Rats exposed to 2317.6 mg of $H_2S/m^3$ or rats given intraperitoneal injections of sodium bisulfide (NaHS) died within 3 min (Lopez *et al.*, 1989). The rats that were exposed to $H_2S$ had massive extravasation of eosinophilic fluid into the broncho-alveolar space.

Pathological findings in environmental sulfur poisoning of cattle were gray-yellow tinged mucus in the respiratory tract, inflammation of the trachea, thinning of cells in the bronchus almost to the point of squamous metaplasia, and interstitial inflammation (Janowski and Chmielowiec, 1981). Sulfur dioxide produced histopathological evidence of severe irritation of the respiratory tract and eyes. Manure-gas poisoning produced congestion and edema of the lungs, gastroenteritis, and peritoneal effusions.

## Sour gas and sour condensate

Stair *et al.* (1996) reported on cattle that were exposed to sour gas/condensate from a break in a multiphase pipeline. Clinical signs in the cattle were estrus in cows in advanced pregnancy and failure of cows to bond with calves. Some cows had neurological signs of proprioceptive-locomotor deficiencies. Many of the calves failed to thrive, and a high occurrence of mortality was observed. Pathological findings in the respiratory tract included hyperplasia of the submucosal tracheal glands, discharged goblet cells, squamous metaplasia of the tracheal mucosa, and submucosal perivascular lymphoid infiltration. Also observed was hypoplasia of the lymph nodes. These effects were associated with exposure to sour gas/condensate in an area of intensive sour gas and crude oil production and processing.

## Non-pesticide organophosphorus esters

Non-pesticide phosphate esters are used as additives for lubricating oils operating under extreme conditions. Coppock (1995a) published a review of the neurotoxicity of these esters.

The pathology of the TAP esters has been described in several species. Specific pathological changes may not be observed during necropsy (Dollahite and Pierce, 1969; Nicholson, 1974; Beck *et al.*, 1977). Irritation and hemorrhage in the gut have been associated with TAP poisoning (Julian *et al.*, 1976). Histopathological changes of axonopathy may progress in severity toward the cell body (Maydew *et al.*, 1983; Jubb and Huxtable, 1992). The peripheral axonal lesion was described as demyelination and swelling (3–4 times) of the axonal cylinders (Dollahite and Pierce, 1969). Vacuolation and degeneration of axons were observed in the sciatic and femoral nerves (Julian *et al.*, 1976). Dollahite and Pierce (1969) observed demyelination in the spinal nerve roots, of which the ventral nerve roots were the most severely affected. Cytoplasmic vacuolation of the large motor neurons was also observed. Lesions of the spinal cord were described by Nicholson (1974) as axonal degeneration in the gray mater of the ventral horn and in the

ascending nerve tracts. Swelling of the axonal cylinder (20 times), with a transition from basophilic to acidophilic staining properties, were observed in the spinal cord of cattle inadvertently or experimentally exposed to TAP (Beck *et al.*, 1977). From lumbar to cervical regions, the lesions appeared to change in pattern and severity. Histological evidence of axonal degeneration was not observed in the L5 vertebral region, however, a few swollen axons were observed at the level of L2 and posterior thoracic (T12) vertebrae. A marked increase in degenerated axons appeared at the level of T5 and the seventh cervical vertebrae (C7). At the level of C3, the lesions were more severe at the tips of the dorsal and lateral horns. Axonal degeneration was not observed in the brain. Lesions of demyelination and degeneration were observed bilaterally in the ascending tracts of the cervical regions of the spinal cord (Julian *et al.*, 1976). The lesions were immediately ventral to the dorsolateral sulcus in the area of the spinocerebellar tract and in the fasciculus gracilis. The degenerating areas had large vacuoles containing eosinophilic globules. Prantner and Sosalla (1993) reported multifocal areas of spongiosis in the medial and lateral funiculi at the levels of vertebrae L2 through L5. Focal perivascular hemorrhages were also observed in the basal nuclei of the brain. The chemical composition of the TAP, age of the animal, and the ascending progression of lesions when they were observed may explain these discrepancies (Gupta and Abou-Donia, 1994).

## ANALYTICAL TOXICOLOGY

The best procedure is to phone the laboratory and request instructions for sampling containers and methods of preservation. The sampling procedure must be written out, signed, and dated. Labels must correspond with the description of the sample. The majority of samples can be stored by freezing. Care must be taken to ensure that samples do not break during freezing and the frost on the container during thawing does not alter the label. Glass containers should be used and the containers must be chemically clean. Plastic containers can have substances migrate into the sample and present expensive cleanup problems for the analytical laboratory. If aluminum foil is used to seal containers, the dull side has contact with the sample. Pictures should be taken and a description of the pictures written.

The tissues that should be collected at necropsy are rumen and stomach contents, contents from various areas of the gastrointestinal tract, liver, kidney, lung (including description of the lobe), perirenal or bone marrow fat, brain, soiled hair or feathers. Samples should be taken of the suspect petroleum. Environmental samples include soil, water with floating substances, and water plus sediment. The suspect water and oil should be sampled.

Petroleum and the compounds associated with petroleum and oil–gas field operations is difficult because of the complex mixture of chemicals. The most common approach used is to match chromatographic fingerprints. The chromatographs are extracts from tissues such as lung and tissues and chromatographs of the suspect petroleum. Chemicals in petroleum that are resistant to biodegradation are called biomarker chemicals (e.g., phytane and pristine). Many of the biomarkers in crude petroleum are sensitive to petroleum refining and up-grading processes. Some biomarkers accumulate in fat. The percent, of fat found in tissue extracts must be recorded along with the concentration of the biomarker of interest. If possible, multiple biomarkers should be used and the ratio of the biomarkers calculated for the suspect petroleum and the biomarkers found in tissue. For flare emission issues, analyses of tissues especially fat may show the presence of a number of polycyclic aromatic hydrocarbons (PAHs). The problem is that there are generally multiple sources of these PAHs.

Ions and heavy metal pollutants can be assayed. In addition to the concentration of the ions or metals, the ratio of the ions and metals can be helpful in identification. For example if production water has contaminated domestic water, the ratio of the ions in the domestic water should reflect the ion ratio found in the produced water. The same applies to gas from a gas well that have contaminated a domestic water supply.

## DIFFERENTIAL DIAGNOSIS

The diagnosis of petroleum toxicity can be straightforward or very difficult depending on the circumstances. If the exposure is current or recent and there is direct evidence of toxic substances in or on the animals and obvious detrimental effects, the diagnosis may still require careful assessment and testing, but should be accomplished relatively easily.

However, if the exposure has not been recent and clinical signs are not specific or are ones that may have several possible causes, the diagnosis can be very difficult. Pneumonic lesions associated with crude oil toxicity are easier to interpret if oil is still present in the gastrointestinal tract. The presence of vacuolated macrophages is helpful in differentiation from infectious causes of pneumonia. Pneumonia initiated by toxic gases is difficult to diagnose because the initial site of injury is at the broncho-alveolar junction, the same location as the initial site of infection for several viral and bacterial pathogens. The bronchiolitis and alveolar reactions of necrosis, edema, and cellular infiltration can be indistinguishable between toxic gas responses and infectious agent responses. As well toxic gases can interfere with the normal functions of cells lining

the trachea and bronchi leading to reduced resistance to infection (Dungworth, 1983). Multiple agents may also be present at the same time, making the determination of the initial cause impossible.

Acute neurological signs may result from sodium ion toxicity. The differential includes thiamine deficiency-linked polioencephalomalacia, which results in brain lesions that are indistinguishable from lead poisoning. The analysis for sodium levels in rumen content is essential.

The occurrence of delayed neurotoxicity signs requires an in-depth investigation of potential causes, including TAP's and organophosphorus pesticides, to determine possible exposure.

The occurrence of ocular and respiratory irritation in the presence of toxic gases is a typical sign. However, similar irritation may result from dry, dusty, and windy conditions and form irritating particles in feed. The measurement of toxic gas levels in the vicinity of the livestock is seldom possible and assumptions of exposure based on data from the emission source and nearby monitoring sites may be the only data available. Differentiation from infectious pinkeye may be made by isolating the infectious agent and ruling out toxic gas exposure.

Poor growth and weight loss may have many possible causes including nutritional deficiency, parasitism, chronic pneumonia, chronic intestinal disease, mycotoxicosis, and others. Temporal connection to petroleum sources such as crude oil and previous acute cases is important in the differentiation. The possible role of adverse effects of petroleum compounds on the immune system increasing susceptibility to infectious disease further complicates the situation.

Reproductive losses may have multiple causes. The time delay often present between exposure and clinical signs makes diagnosis very difficult, if not impossible. Abortions that result during an acute toxic episode are the easiest to associate with the toxin. The potential hormonal disruption from chemicals that disturb the endocrine hormone system relating to conception and pregnancy may not be possible to determine days or weeks after the exposure.

## CONCLUDING REMARKS AND/OR FUTURE DIRECTIONS

Domestic and wild animals ingest petroleum and chemicals used in exploration and production of oil and gas. Many of the chemicals used have limited toxicology information and the toxicology of chemical mixtures is unknown. The toxicology in aquatic organisms may be known because of the requirement for toxicology assessments before use on offshore platforms.

Areas that require future research are analytical methods and toxicological assessment in laboratory exposure systems. Definitive toxicology data is required before epidemiological studies can be accurately interpreted.

# Polychlorinated biphenyls, polybrominated biphenyls, polychlorinated dibenzo-*p*-dioxins and polychlorinated dibenzofurans

*Steven Bursian*

## INTRODUCTION

Polychlorinated biphenyls (PCBs), polybrominated biphenyls (PBBs), polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) form a large group of compounds, the polyhalogenated aromatic hydrocarbons (PHAHs), that are structurally related and are environmentally and biologically persistent (Safe, 1990, 1998; Van den Berg *et al.*, 1994; Fries, 1995; Huwe, 2002; Mandal, 2005; Schecter *et al.*, 2006).

PCBs and PBBs were produced commercially for a variety of applications while the PCDDs and PCDFs occur as by-products of industrial and natural processes. The structurally similar PCBs and PBBs are formed by substituting chlorine or bromine, respectively, for hydrogen on the biphenyl molecule that consists of two benzene rings (Figure 55.1). Theoretically, there are 209 possible PCB and PBB congeners considering the five chlorine or bromine binding sites on each ring. Each congener has been assigned a unique number from 1 to 209 in accordance with the rules of the International Union of Pure and Applied Chemistry (IUPAC). Commercial PCB and PBB products were mixtures of congeners that differed with respect to the extent and positions of chlorination or bromination. PCDDs are composed of two benzene rings connected by two oxygen atoms and contain four to eight chlorines, for a total of 75 congeners (Figure 55.1). PCDFs are also composed of two benzene rings. The rings have a single oxygen between them and have four chlorine binding sites available on each ring (Figure 55.1). There are 135 different PCDF congeners (DiCarlo *et al.*, 1978; Safe, 1990, 1998; Fries, 1995; Headrick *et al.*, 1999; Huwe, 2002; Mandal, 2005; Schecter *et al.*, 2006).

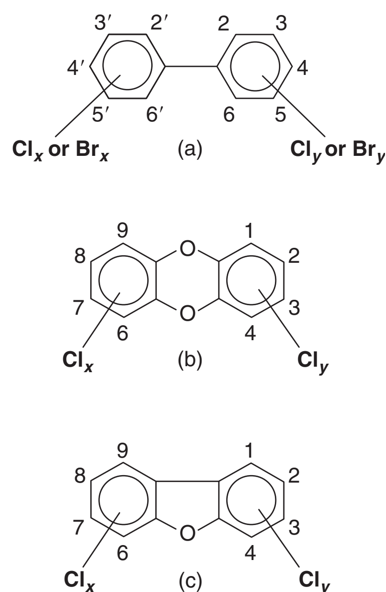

**FIGURE 55.1** Structures and numbering of generic (a) PCB/PBB, (b) PCDD and (c) PCDF molecules.

Certain approximate stereoisomers in this group, often referred to collectively as dioxins and dioxin-like compounds, induce a common suite of effects and have a common mechanism of action mediated by binding of the PHAH ligand to a specific high-affinity cellular protein.

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

This group of dioxins and dioxin-like chemicals includes 7 PCDD congeners, 10 PCDF congeners and 12 PCB congeners. While the PBB congeners analogous to the 12 PCB congeners could also be considered dioxin-like chemicals, the relatively short commercial lifespan and restricted environmental distribution of PBBs generally precludes them from consideration. The prototype for the dioxins is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). Toxicity and persistence of the PHAHs are determined by structure, with lateral substitutions on the ring resulting in the highest degree of toxicity. For the PCDDs and PCDFs, congeners with chlorines in the 2, 3, 7 and 8 positions fall into this category. The dioxin-like PCB congeners are the non-*ortho*- and mono-*ortho*-substituted compounds with none or no more than one chlorine (or bromine) on the 2, 2′ , 6 or 6′ position (Safe, 1990; Fries, 1995; Headrick *et al.*, 1999; Huwe, 2002; Mandal, 2005; Schecter *et al.*, 2006).

Mechanistic studies indicate that the toxic and biochemical effects associated with exposure to TCDD and its approximate stereoisomers are mediated by initial binding of the chemical to the cytosolic aryl hydrocarbon receptor (AhR) present in target tissues and organs. There is a correlation between the AhR binding affinity of these chemicals and their structure–toxicity relationships, which supports the idea that the AhR is involved in the mediation of responses induced by the TCCD-like PCDD, PCDF and PCB congeners (Okey *et al.*, 1994; Hahn, 1998, 2002; Safe, 1998; Denison *et al.*, 2002; Denison and Nagy, 2003; Mandal, 2005).

The common mechanism of action of TCDD and related compounds allows for use of the toxic equivalency factor (TEF) approach to estimate the TCDD-like toxicity of complex mixtures containing chemicals that resemble TCDD. The TEF value for a TCDD-like congener is defined as the potency of the individual congener relative to TCDD. Using the TEF concept, TCDD toxic equivalents (TEQs), which is the sum of the product of the concentration of each congener and its respective TEF, can be calculated for any complex mixture containing TCDD-like chemicals to provide an estimation of the total TCDD-like toxicity (Safe, 1998; Huwe, 2002).

The PCDDs, PCDFs and PCBs are widely distributed into the global environment and, due to long-range transport, can be very resistant to environmental degradation and metabolism. As a result, they readily accumulate in the food chain with the greatest tissue concentrations being found in species at the higher trophic levels. Residues have been detected in a variety of animal species, including humans (Van den Berg *et al.*, 1994; Safe, 1998). In some situations, the environmental concentrations of these contaminants are such that there is a health risk to animals and humans. Because of this risk, there continues to be an effort on the part of state, federal and international regulatory agencies to minimize exposure to this significant class of environmental contaminants.

# BACKGROUND

## Sources of PCBs, PCDDs, PCDFs and PBBs

### *PCBs*

PCBs were first synthesized by Schmidt and Schultz in 1881. Commercial production of PCBs for a variety of uses began in the United States in 1929 until 1977, primarily by the Monsanto Corporation (Kimbrough, 1987, 1995; Tanabe, 1988; Headrick *et al.*, 1999). They were used in closed use systems such as electrical transformers, capacitors, and heat transfer and hydraulic systems. For a period of time, PCBs also had a large number of open-ended applications. They were used in paints, polymers and adhesives, as lubricants, plasticizers, fire retardants, immersion oils, vehicles for pesticide application and as agents for the suspension of pigments in carbonless copy paper (Safe, 1990; Headrick *et al.*, 1999). The PCB products that were manufactured by Monsanto in the United States had the trade name Aroclor followed by four digits that identified the particular mixture. The first two digits referred to the 12 carbon atoms of the biphenyl molecule and the last two digits referred to the percent of chlorine in the mixture, by weight. Aroclors 1221, 1232, 1242, 1254 and 1260 were the commercial PCB products that were produced by Monsanto, containing 21%, 32%, 42%, 54% and 60% chlorine by weight, respectively. Similar commercial PCB mixtures were produced by other manufacturers worldwide including the Clophens (Bayer, Germany), Pheoclors and Pyralenes (Prodelec, France), Fenclors (Caffro, Italy) and Kanechlors (Kanegafuchi, Japan) (Kimbrough, 1987, 1995; Safe, 1994).

The physical and chemical properties of PCBs, such as high stability, inertness and dielectric properties, that were advantageous for many industrial purposes, led to the international use of PCBs in large quantities (Tanabe, 1988). For example, the estimated cumulative production of PCBs in the United States between 1930 and 1975 was 700,000 tons and 1.2 million tons were estimated to have been produced worldwide. Domestic sales of PCBs in the United States during this time period totaled 627,000 tons (Kimbrough, 1987, 1995; Tanabe, 1988). As a result of widespread use, PCBs were identified in environmental media and biota as early as the 1960s. After the discovery of their widespread environmental contamination in the 1970s, PCB production decreased and eventually ceased (Tanabe, 1988). In 1971, Monsanto voluntarily stopped production of PCBs for open-ended uses and subsequently only the lower chlorinated biphenyls were produced (Aroclor 1242 and 1016). In 1977, Monsanto ceased production entirely (Kimbrough, 1987, 1995).

Although PCBs are no longer used commercially because of their persistence, they are still present in the environment. About 31% (370,000 tons) of all the PCBs produced is

present in the global environment. It is estimated that 780,000 tons are still in use in older electric equipment and other products, deposited in landfills and dumps or in storage (Tanabe, 1988).

### *PCDDs and PCDFs*

PCDDs and PCDFs are by-products that are formed during the synthesis of certain industrial halogenated aromatics chemicals, by-products from other commercial processes and by-products of combustion (Safe, 1990). Some of the important industrial sources of PCDDs and PCDFs have included their formation as by-products in the production of PCBs, chlorinated phenols and chlorinated phenol-derived chemicals, hexachlorobenzene, technical hexachlorocyclohexanes, and chlorides of iron, aluminum and copper. PCDDs and PCDFs have also been identified in effluents, wastes, and pulp samples from the pulp and paper industry and in finished paper products. Emissions from municipal and hazardous waste incinerators as well as home heating systems that use wood and coal, diesel engines, forest and grass fires and agricultural and backyard burning contain PCDDs and PCDFs. Another contribution might come from naturally formed PCDDs and PCDFs, which have been detected in deep soils and clays from the southern United States and Germany (Safe, 1990; Huwe, 2002).

The United States Environmental Protection Agency (EPA) estimated that annual emissions of PCDDs and PCDFs decreased from 13.5 to 2.8 kg TEQ/year between 1987 and 1995. This was due primarily to improvements in incinerator performance and removal of incinerators that could not meet emission standards. Other regulations, including bans or restrictions on the production and use of chemicals such as the wood preservative pentachlorophenol (PCP), the phase-out of leaded gasoline that contained halogenated additives and the elimination of chlorine bleaching in the pulp industry also contributed to reducing concentrations of PCDDs and PCDFs (Huwe, 2002).

### *PBBs*

PBBs were manufactured for use as flame retardants in industrial and consumer products (Damstra *et al.*, 1982). It is estimated that approximately 13 million pounds were produced in the United States from 1970 to 1976 and used by more than 130 companies for incorporation into plastic products that included business machine housings, radios, televisions, thermostats, electric shavers, hand tools and various automotive parts (DiCarlo *et al.*, 1978; Headrick *et al.*, 1999). Three commercial PBB products were manufactured in the United States: hexabromobiphenyl, octabromobiphenyl and decabromobiphenyl (DiCarlo *et al.*, 1978; Hardy, 2000). Hexabromobiphenyl was the predominant product with approximately 11.8 million pounds being produced solely by Michigan Chemical Company (DiCarlo *et al.*, 1978). Over 98% of the hexabromobiphenyl was produced as FireMaster BP-6 with the remainder being produced as FireMaster FF-1 (Hesse and Powers, 1978) after addition of an anti-caking agent to FireMaster BP-6. Michigan Chemical Company stopped production of their PBB products in 1974 (DiCarlo *et al.*, 1978). White Chemical Company and Hexcel Corporation manufactured octa- and decabromobiphenyl in the United States until 1979 (IARC, 1986). Production of decabromobiphenyl was discontinued in Great Britain in 1977 and Germany stopped production of brominated biphenyls in 1985. In 2000, France discontinued the remaining commercial production of PBBs (Hardy, 2000).

While FireMaster BP-6 was sold as a hexabromobiphenyl, it consisted of 18 different congeners, some of which were tetra-, penta- hepta- and octabromobiphenyls. The predominant hexabromobiphenyl was 2,4,5,2′,4′,5′-hexabromobiphenyl. Commercial octabromobiphenyl contained at least four congeners; a heptabromobiphenyl, isomeric octabromobiphenyls and a nonabromobiphenyl, which constituted the majority of the mixture. Commercial decabromobiphenyl was over 95% decabromobiphenyl with the remainder being a nonabromobiphenyl and an octabromobiphenyl (DiCarlo *et al.*, 1978).

## Environmental fate of PCBs, PCDDs, PCDFs and PBBs

The release of PCBs into the environment primarily has been the result of leaks, spills and improper disposal. As stated previously in the section PCBs, it is estimated that approximately 370,000 tons of PCBs are present in the global environment (Tanabe, 1988). The volatility of PCBs allows their evaporation from water surfaces and movement through the atmosphere, resulting in widespread environmental dispersal (Headrick *et al.*, 1999). PCDDs and PCDFs are released into the atmosphere primarily by combustion sources and by evaporation from PCDD/PCDF-containing soils and water. Similar to PCBs, the PCDDs and PCDFs can be transported long distances by winds, contributing both to general background concentrations and to contamination of remote areas far from the original source. PCBs, PCDDs and PCDFs are removed from the atmosphere by physical processes such as wet and dry deposition and vapor uptake and are deposited on soils, surface waters and plant surfaces. Most of the PCBs, PCDDs and PCDFs that are deposited on surface waters sorb onto suspended sediments. Once bound to soil and sediment, these chemicals generally remain fixed except for bulk transport due to soil erosion, flooding and dredging (Dickson and Buzik, 1993). Ingestion of these compounds by animals results in their preferential bioaccumulation and biomagnification in higher trophic levels of the food chain (Safe, 1994).

Because PBBs were manufactured for a relatively short time and because of their restricted use, they are not considered to be a significant environmental contaminant with the exception of specific locations in Michigan related to production and disposal. Environmental losses of PBBs from manufacturing sites were estimated to be 0.11% into the atmosphere as particulate matter, negligible losses to storm sewers and 5% as solid waste to landfills. Soil samples collected from the loading and bagging area of the Michigan Chemical Company plant manufacturing FireMaster BP-6 and FF-1 contained 3500 and 2500 ppm (mg/kg) PBBs, respectively (DiCarlo *et al*., 19787). Like PCBs, PCDDs and PCDFs, PBBs are very stable compounds and persist in the environment. Studies have indicated that PBBs have a high affinity for soil and undergo very little degradation and translocation into vegetation (Fries, 1985). Like PCBs, PCDDs and PCDFs, the PBBs are very lipophilic and have the potential to bioaccumulate and biomagnify in the food chain (Damstra *et al*., 1982).

It is important to remember that the commercial PCB products and PCBs, PCDDs and PCDFs in environmental extracts are complex mixtures of congeners. Because of various physical and biological processes, the composition of the commercial PCB mixture and an environmental PCB/PCDD/PCDF mixture may vary significantly from one another. Thus, the impacts of PCBs, PCDDs and PCDFs on a environment and biota are due to the individual components of these mixtures and their additive and/or non-additive (synergistic/antagonistic) interactions with themselves and other classes of pollutants (Safe, 1994).

## Exposure to PCBs, PCDDs, PCDFs and PBBs

There are a number of ways by which animals can be and have been exposed to PCBs, PCDDs/PCDFs and PBBs. Some of the scenarios described involve ingestion of low concentrations of these chemicals through consumption of environmentally contaminated feed or feed components while other scenarios involve accidental incorporation of the chemical into the feed resulting in exposure to relatively high concentrations of the contaminant. Usually, food animal exposures to PCBs, PCDDs and PCDFs occur below concentrations resulting in acute toxicity. Clinical signs are not evident and there often is not a noticeable economic impact on the health of the animal, although there may be detectable contamination of food products such as milk, meat and eggs (Headrick *et al*., 1999).

### *PCBs*

During the 1940s and 1950s, silos constructed with concrete were sealed with a PCB-containing paint, which eventually peeled off from the walls resulting in contaminated silage. Dairy and beef cattle were exposed to the paint in the feed resulting in accumulation of PCBs in adipose tissue. As a result, food products such as milk and meat contained detectable concentrations of PCBs. Examples of other exposure incidents resulting in PCB residues in food animals were summarized by Headrick *et al*. (1999). These include consumption of tar paper by veal calves, consumption of fish viscera by swine, pullet consumption of feed containing PCB-contaminated fat added during processing, exposure of chickens to ceiling insulation and fiberglass insulation that contained PCBs and treatment of boars with a topical pesticide containing PCB-contaminated oil. In 1979, a spare electrical transformer in a Montana hog slaughter plant was damaged allowing PCBs to leak into the plant' s drainage system. The PCBs and animal wastes were processed into grease and animal feed, which was distributed and subsequently fed to hogs, beef cattle, dairy cattle, chickens and mink in 19 states in the United States and in Canada and Japan before the contamination was detected. Ultimately, 800,000 chickens, nearly 4,000,000 eggs, 4000 hogs, 74,000 bakery items, 800,000 lb of animal feeds and 1,200,000 lb of grease were destroyed with an estimated cost of recalls and destroyed products amounting to over $2 million (Headrick *et al*., 1999).

### *Michigan PBB Incident*

The most extensive exposure of food animals and humans to PBBs occurred in Michigan in the mid-1970s. In 1970, the Michigan Chemical Company began to manufacture PBBs under the trade name of FireMaster BP-6 in St. Louis, MI (Fries, 1985). FireMaster BP-6 was a mixture of PBB congeners containing two to eight bromines. The major constituents of FireMaster BP-6 were 2,2′,4,4′,5,5′-hexabromobiphenyl (56%) and 2,2′,3,4,4′,5,5′-heptabromobiphenyl (27%) (Damstra *et al*., 1982). In 1972, the company changed the formulation of the retardant by grinding BP-6 and adding 2% calcium silicate as an anti-caking agent. This new formulation, now called FireMaster FF-1, was a white powder as opposed to brown flakes, which was the appearance of BP-6 (Fries, 1985).

In May of 1973, 650 lb of FF-1 were mistakenly included in a shipment of feed-grade magnesium oxide to a feed mill in Climax, MI. Michigan Chemical Company, in addition to producing FireMaster FF-1, also produced the magnesium oxide product, which had an appearance identical to FireMaster FF-1 and was sold under the trade name NutriMaster. Normally the two products were packaged in paper bags with unique color codes. However, during a paper shortage, both FireMaster and NutriMaster were packaged in plain brown bags differentiated only by the product names stenciled on the bags. Both products were stored in the same warehouse (Dunckel, 1975; Fries, 1985).

A portion of the magnesium oxide that was shipped to the Climax feed mill was used to mix feeds primarily for

dairy cattle at that location, which were subsequently shipped to area farms or other retail units. The remaining magnesium oxide was shipped to other mills within the state and used in feeds mixed at those locations. Feeds that were not formulated to contain magnesium oxide also became contaminated because of carry-over from the contaminated feed-mixing equipment (Fries, 1985). In total, 101 feed mills were found to be affected (Dunckel, 1975).

Most of the high-level exposures occurred during the fall of 1973 before sale of the initial batch of feed was stopped in December 1973 because of dairy producer complaints of animal health problems. Three initial feed preparations containing different concentrations of PBBs were Feed No. 405, which had 2.4 ppm PBBs, No. 410 having 1790 ppm PBBs and No. 407, which contained 4300 ppm PBBs. The highest feed concentration reported was 13,500 ppm PBBs (DiCarlo *et al*., 1978; Damstra *et al*., 1982). Low-level contamination of feed continued beyond the chance identification of PBBs as the contaminant in April 1974 because of their persistence. In 1974, 68% of 1770 feed samples collected in Michigan contained PBB residues. Resampling in 1975 indicated that 6% of 1208 feed samples were contaminated and in 1976, only 0.3% of 663 samples contained PBBs (DiCarlo *et al*., 1978). Shortly after PBBs were identified as the feed contaminant, the US Food and Drug Administration (FDA) set a temporary guideline of 1 ppm PBBs in milk fat, meat and poultry, 0.1 ppm in whole eggs and 0.3 ppm in animal feeds (DiCarlo *et al*., 1978). The Michigan Department of Agriculture started to identify and quarantine all dairy herds with PBB concentrations in excess of 5 ppm. Because of the long half-life of PBBs, the decision was made to depopulate affected farms and to dispose of the animals at a burial site in northern Michigan. Initially, 9400 head of cattle, 2000 swine, 400 sheep and 2,000,000 chickens were buried in addition to 865 tons of feed and animal by-products such as cheese, butter, dry milk products and eggs (DiCarlo *et al*., 1978; Damstra *et al*., 1982; Fries, 1985; Headrick *et al*., 1999). In October of 1974, FDA lowered the guidelines for PBBs in milk and meat from 1 ppm to 0.3 ppm, which resulted in disposal of 20,000 additional head of cattle as well as 3900 swine and 1100 sheep (Damstra *et al*., 1982). In total, 507 farms were affected (Dunckel, 1975). In response to increasing concerns about the effects of PBBs on human and animal health, the Michigan legislature lowered the PBB tolerance to 0.02 ppm in body fat of all dairy cattle offered for slaughter in 1977. A small number of dairy producers who had repopulated after the initial quarantine in 1974 continued to have violative cattle because of residual contamination on their facilities, although this number was less than 2% of all culled cows. Over the next 5 years, the number of violative cattle diminished rapidly as they approached the end of production.

A potential environmental source of exposure to animals on contaminated farms was the soil, if animals had direct access to the contaminated soil. Four years after the initial PBB contamination incident, there were several farms in Michigan that exceeded the 20 ppb tolerance for PBBs in fat of cull cows even though farmers had depopulated, cleaned up the premises and repopulated with clean animals. The major route of animal exposure was through soil consumption because crops grown on contaminated soils did not accumulate PBBs (Fries, 1985). Major sources of PBBs on the farms were soils of fields on which manure had been spread and soil of unpaved exercise lots where feces were deposited and feed was spilled. It was shown that all of the problem farms were using unpaved lots that had been used in 1974 for some part of their production system and that ingestion of soil from unpaved lots was the major route of PBB exposure causing animal contamination on problem farms (Fries, 1995).

### *PCDDs and PCDFs*

For livestock, atmospheric deposition of PCDDs and PCDFs onto forage and soils is assumed to be the major source of exposure (Huwe, 2002). Extensive field studies in contaminated areas have demonstrated a positive correlation between PCDD and PCDF concentrations in animals and their soil contact (Van den Berg *et al*., 1994). The relative importance of soil depends upon the species of animal and the management system. Ruminants are expected to be more vulnerable to PCDD and PCDF exposure than poultry and swine because of their grazing activities. The use of pasture is of particular importance because consumption of contaminated plants is additive to soil ingestion of PCDDs and PCDFs. Volatilization of PCDDs and PCDFs from soil and deposition on plants is an important pathway of animal exposure when forage is abundant. However, that soil may be more important when grazing is sparse. The soil ingestion pathway is not limited to grazing animals. Cattle confined to unpaved lots consume small amounts of soil that can lead to product residues. Although most poultry and pork production is conducted in confined operations, the soil ingestion pathway of exposure may be important when these species have access to contaminated soil (Fries, 1995).

In addition to exposure to PCDDs and PCDFs through consumption of contaminated soil and/or forage, a number of other incidents of animal exposure to these compounds have been reported. The first known exposure to PCDDs occurred in the late 1950s. "Chick edema disease", as the condition was initially called, resulted from consumption of feed containing fat contaminated with a number of PCDD congeners originating from the production of PCP. In 1975, several horses died in Missouri as a result of exposure to TCDD-contaminated waste oil that was used for dust control on horse tracks. The oil contained waste from a hexachlorophene manufacturing plant and it had also been used for dust control on the unpaved streets of Times

Beach. The high concentrations of TCDD in the residential soils led to purchase and evacuation of the town by the US government (Fries, 1995). In a geographical survey, high concentrations of TEQs in cattle were strongly correlated to PCP-treated wood used for fence posts and feed bunks at several beef cattle operations across 13 states in the United States. Although the use of PCP was restricted in the 1980s, PCP was used heavily on farms as a wood preservative in the late 1970s (Huwe, 2002). In an EPA survey of poultry, two chicken samples were found with PCDD concentrations considerably above background. The origin of this contamination was ball clay, which had been added as an anti-caking agent to soy meal in the feed. This same contaminated feed was also used by the catfish industry and resulted in high TEQ concentrations in catfish from Arkansas (Huwe, 2002).

Several dioxin contamination incidents have occurred in Europe. In 1998, during routine monitoring, dairy products were identified that had dioxin concentrations that were 2–4 times higher than background concentrations. The source of the contamination was traced to citrus pulp used as a cattle feed component. The citrus pulp and contaminated feeds were immediately removed from the market. In another incident, PCB/PCDD/PCDF-contaminated oil was added to recycled fat used as an additive in animal feeds. The affected feeds contaminated Belgian poultry, dairy and meat, and were discovered only after toxic effects characteristic of "chick edema disease" were seen in chickens. Animals and products were quarantined, recalled and eventually destroyed. The incident led to international recalls and bans against Belgian products (van Larebeke *et al*., 2001; Bernard *et al*., 2002; Huwe, 2002).

## Differential toxicity

Comparison of the relative toxicities of PCDDs, PCDFs and PCBs as three separate classes suggests that the dioxins are more toxic than the furans, which in turn are more toxic than the PCBs. It was concluded that PBBs are slightly more toxic than their chlorinated counterparts (McConnell, 1985). Studies also suggest that the toxicity of commercial PCB formulations increases with increasing chlorine content (Aroclor 1221 $<$ 1232 $<$ 1242 $<$ 1248 $<$ 1254), but highly chlorinated Aroclors 1260, 1262, and 1268 are less toxic than Aroclor 1254 (Tanabe, 1988).

2,3,7,8-TCDD binds with the greatest affinity to the AhR and is the most potent isomer in terms of toxicity. PCDDs and PCDFs substituted with chlorines in at least three of the four lateral positions (2,3,7, 8; Figure 55.1) bind most strongly to the AhR. If chlorines are removed from these lateral positions or if chlorines are added to the non-lateral positions (1,4,6,9; Figure 55.1), binding affinities decrease markedly, as do toxicities. There are seven 2,3,7,8-substituted PCDDs (2,3,7,8-TCDD; 1,2,3,7,8-penta CDD; 1,2,3,4,7,8-hexaCDD; 1,2,3,6,7,8-hexaCDD; 1,2,3,7,8,9-hexaCDD; 1,2,3,4,6,7,8-heptaCDD and octaCDD) and ten 2,3,7,8-substituted PCDFs (2,3,7,8-TCDF; 1,2,3,7,8-pentaCDF; 2,3,4,7,8-pentaCDF; 1,2,3,4,7,8-hexaCDF; 1,2,3,6,7,8-hexaCDF; 1,2,3,7,8,9-hexaCDF; 2,3,4,6,7,8-hexaCDF; 1,2,3,4,6,7,8-heptaCDF; 1,2,3,4,6,7,8-heptaCDF and octaCDF) that induce TCDD-like toxicity. There are 209 theoretically possible PCB congeners having different toxic and biologic responses. The most toxic PCB congeners have four or more chlorine atoms at both the para (4,4′) and meta positions (3,3′,5,5′; Figure 55.1) in the biphenyl rings, but no chlorine (bromine) atoms in the ortho positions (2,2′,6,6′; Figure 55.1). Of the 209 PCB congeners, four PCB congeners (3,3′,4,4′-tetraCB (IUPAC 77), 3,4,4′,5-tetraCB (IUPAC 81), 3,3′,4,4′,5- pentaCB (IUPAC 126) and 3,3′,4,4′,5,5′-hexaCB (IUPAC 169)) are approximate stereoisomers of the highly toxic 2,3,7,8-TCDD and thus bind to the AhR and elicit toxic and biologic responses typical of TCDD, although at higher doses. These four congeners are considered to be coplanar because both rings of the biphenyl molecule lie in the same plane, which enables binding to the AhR (Tanabe, 1988). There are eight PCB congeners with chlorine substitution in one of the ortho positions (2,2′,6,6′). These congeners may have partial coplanarity and thus exhibit lower competitive binding affinities for the AhR and lower toxic potency. The mono-*ortho* PCB congeners are 2,3,3′,4,4′-pentaCB (IUPAC 105); 2,3,4,4′,5-pentaCB (IUPAC 114); 2,3′,4,4′,5-pentaCB (IUPAC 118); 2′,3,4,4′,5-pentaCB (IUPAC 123); 2,3,3′,4,4′,5-hexaCB (IUPAC 156); 2,3,3′,4,4′,5-hexaCB (IUPAC 157); 2,3′,4,4′,5,5′-hexaCB (IUPAC 167) and 2,3,3′,4,4′,5,5′-heptaCB (IUPAC 189) (Poland and Knutson, 1982; Tanabe, 1988; Safe, 1990, 1998; Giesy and Kannan, 1998; Huwe, 2002; Whyte *et al*., 2004).

## TEFs

The relationship between the structure of individual PCDD, PCDF and PCB congeners and their toxicity is the basis of TEFs and the TEQ approach. The TEQ approach is used to determine the toxic potency of complex mixtures of PCDDs, PCDFs and PCBs found in the environment. Assuming a similar mechanism of action (binding to the AhR), the potency of each chemical in a mixture to cause a particular toxic or biological effect can be expressed as a fraction of the potency of 2,3,7,8-TCDD to cause the same effect. Thus, the TEF is a ratio of EC50 (TCDD-like chemical)/EC50 (TCDD). 2,3,7,8-TCDD has been assigned a TEF value of 1.0. Based on a variety of biological endpoints, relative potency factors (RPFs) are assigned to the different TCDD-like congeners. All RPFs for an individual congener are evaluated to derive a consensus value (the TEF) that describes an order-of-magnitude potency for that

**TABLE 55.1 Summary of World Health Organization (WHO) 2005 Toxic Equivalency Factor (TEF) values***

congener. The toxic potency of a mixture of PCDDs, PCDFs and/or PCBs is estimated by multiplying the concentrations of individual congeners by their respective TEFs and summing the products to yield total TEQs. The total TEQs express the toxicity as if the mixture were pure TCDD (Safe, 1990, 1998; Dickson and Buzik, 1993; Van den Berg *et al*., 1994, 2006; Fries, 1995; Whyte *et al*., 2004; Schecter *et al*., 2006). Several assumptions are made when using the TEF approach: (1) the effects of individual PCDDs, PCDFs and/or PCBs in a mixture are additive; (2) only tissue and environmentally persistent organochlorine compounds have been assigned TEFs and (3) all of these compounds bind to the AhR and elicit receptor-mediated biochemical and toxic responses (Safe, 1998). The TEQ approach and current values (Table 55.1) have been adopted internationally as the most appropriate way to estimate the potential health risk of mixtures of TCDD-like chemicals (Schecter *et al*., 2006).

Table 55.2 illustrates how the TEF approach can be used. The table presents the concentrations of various PCDD, PCDF and PCB congeners found in fish collected downstream from the abandoned site of a manufacturing facility that used PCBs. By multiplying the congener concentration detected in the fish by the appropriate TEF value, the quantity of the TCDD-like toxicity contributed by each congener can be determined. In the example given, the PCDDs contribute 0.8 pg TEQ/g, the PCDFs contribute 3.8 pg TEQs/g and the non-*ortho* PCBs contribute 41 pg TEQs/g or over 90% of the TCDD-like activity in the fish sample. While the relative toxicities of the mono-*ortho* PCB congeners are relatively low, as indicated by their TEF values, their high concentrations in the fish allow them to contribute a measurable quantity of TCDD-like activity.

# TOXICOKINETICS

## PCBs and PBBs

Because commercial PCB and PBB products are mixtures of individual congeners that differ in the number and position of chlorine or bromine atoms and thus differ in terms of their biological activities, it is difficult to accurately assess their absorption, distribution, metabolism and elimination. A number of experiments have been conducted with a variety of species including cows, pigs, rats and birds on the absorption, distribution, metabolism and elimination of the commercial PBB mixture, FireMaster

BP-6, which have been summarized in an extensive review by Fries (1985). Because of the similarities between PCBs and PBBs, information pertaining to one can generally be applied to the other.

In general, PBBs are rapidly and extensively absorbed, with absorption being inversely dependent on the number of bromine atoms (Damstra *et al.*, 1982; Fries, 1985). For example, less than 10% of a dose of $C^{14}$-labeled 2,2′,4,4′,5,5′-hexabromobiphenyl was eliminated in rats (Matthews *et al.*, 1977; Fries, 1985) indicating almost complete absorption compared to 62% fecal elimination of $C^{14}$-labeled octobromobiphenyl 24 h after dosing suggesting incomplete absorption (Norris *et al.*, 1975; Fries, 1985).

PBBs are widely distributed throughout the body of all species studied. Initial concentrations are generally greatest in the liver and adipose tissue (Damstra *et al.*, 1982; Fries, 1985) with highest equilibrium concentrations on a wet tissue basis being in adipose tissue (Miceli and Marks, 1981; Damstra *et al.*, 1982; Fries, 1985). Concentrations of PBBs in muscle and organ tissues are usually an order of magnitude lower (Fries, 1985) compared to adipose tissue. Generally, differences in concentration between tissues can be attributed, at least in part, to variations in fat content of the tissues (Fries, 1985).

Individual PBB congeners in FireMaster BP-6 undergo hydroxylation by metabolic routes that are similar for the related PCBs with the rate of metabolism being determined primarily by the position of bromine atoms on the ring and secondarily by the bromine content of the molecule (Damstra *et al.*, 1982). *In vivo* studies suggest that, like PCBs, metabolism can occur if there are two adjacent unbrominated positions (Matthews *et al.*, 1978; Fries, 1985), although no studies indicated significant metabolism of congeners comprising the commercial PBB mixture (Fries, 1985).

Elimination of individual PBB congeners occurs at different rates with those congeners that are more slowly removed becoming more concentrated in tissues relative to those congeners that are more rapidly eliminated. The predominant congener in FireMaster BP-6, 2,2′4,4′,5,5′-hexabromobiphenyl, is the most persistent congener in the various species studied (Damstra *et al.*, 1982). PBBs are eliminated primarily by biliary excretion into the feces, but fecal concentrations are low compared to whole-body concentrations (Damstra *et al.*, 1982; Fries, 1985). For example, less than 7% of an intravenous dose of 2,2′, 4,4′,5,5′-hexabromobiphenyl was eliminated by rats over a 42-day period (Matthews *et al.*, 1977; Fries, 1985) and rhesus monkeys excreted on a daily basis approximately 0.5% of a single dose of the same congener from 10 to 42 days post-dosing (Rozman *et al.*, 1982; Fries, 1985).

Placental transfer of PBBs occurs to some extent, but the concentrations in fetal or offspring tissues are relatively small compared to concentrations in maternal tissues. Transfer of PBBs to the offspring during nursing results in much greater whole-body concentrations compared to PBB transfer during gestation. For example, pigs from sows that were fed PBBs during gestation and lactation had a 5-fold increase in body burden during the 4-week lactation period with residues accumulated during lactation accounting for 95% of the total body burden (Werner and Sleight, 1981; Fries, 1985).

As suggested above, milk is the major route of elimination of PBBs for lactating mammals, although in the case of females nursing their young, the contaminant is simply transferred from one animal to another. Concentrations of PBBs in milk fat generally exceed dietary concentrations, with bovine milk fat concentrations exceeding dietary concentrations by 3–4-fold (Fries and Marrow, 1975; Willett and Irving, 1976; Damstra *et al.*, 1982; Fries, 1985).

The egg is a major route of elimination for egg-laying birds with concentrations in chicken or Japanese quail eggs being 1–1.5 times that of dietary concentrations (Babish *et al.*, 1975; Fries *et al.*, 1976; Polin and Ringer, 1978a; Damstra *et al.*, 1982; Fries, 1985). Elimination of PBBs via the egg can account for as much as 50% of the daily dose if there is no deleterious effect on egg production (Fries, 1985).

Dairy cows at different stages of production were administered daily doses of FireMaster BP-6 ranging from 0.25 mg to 25 g for periods ranging from 1 to 202 days. Penta-, hexa- and heptabromobiphenyls in the commercial mixture were absorbed through the gastrointestinal tract and were detected in the plasma after 4 h and reached steady state concentrations after 15 days. The concentration of PBBs in tissues was, in general, correlated with the lipid content of the particular tissue with exception of the liver which contained relatively high concentrations of PBBs in relation to its lipid content. Fecal elimination was the predominant route of excretion in non-lactating cows, while milk fat was the major route of elimination in those animals that were lactating. Concentrations of PBBs in milk were approximately 3 times those in feces. The half-life of PBBs being excreted via lactation was 28 days (Willett and Durst, 1978; Damstra *et al.*, 1982).

Chickens fed FireMaster FF-1 for 5 weeks accumulated PBB residues at average ratios of tissue PBBs:diet PBBs of 3:1 for adipose tissue, 1.5:1 for whole egg, 0.8:1 for liver and 0.008:1 for muscle (Polin and Ringer, 1978a, b). The distribution of a chicken′ s daily intake of PBBs on reaching a steady state was estimated to be: excreta, 11%; eggs, 58%; adipose, 10%; muscle, 12%; liver, 2%; unknown, 7% (Ringer and Polin, 1977). A second chicken study demonstrated that after 63 days of consuming a diet containing PBBs, body fat concentrations were approximately 4 times greater than dietary concentrations (Fries *et al.*, 1976; Damstra *et al.*, 1982).

The concentrations of PBBs in adipose tissue of mink fed various concentrations of FireMaster FF-1 were about 60 times higher than dietary concentrations (Aulerich and Ringer, 1979).

The kinetics of some individual PBB congeners has been studied. Rats orally administered $^{14}C$-labeled 2,2′,4,

4′,5,5′-hexabromobiphenyl at doses up to 30 mg/kg over 4 days absorbed at least 90% of the congener. Twenty-four hours after the last dose, 40% of the radioactivity was measured in the muscle, 10% in the liver and 25% in the adipose tissue. After 7 days, adipose tissue contained 60% of the radioactivity while the liver and muscle contained 2% and 7%, respectively. Very little of the congener was metabolized and eliminated. It was estimated that less than 10% of the total dose would undergo fecal excretion (Matthews *et al*., 1977; DiCarlo *et al*., 1978). An octabromobiphenyl mixture consisting of hepta-, octa-, nona- and decabromobiphenyls that comprised approximately 11% of FireMaster BP-6 was fed to rats at a dietary concentration of 1000 ppm for 4 weeks. Bromine concentrations in the adipose tissue of these animals were approximately 600 times greater than bromine concentrations in the adipose tissue of untreated rats. Adipose tissue concentrations of bromine increased to 800 times greater than concentrations in untreated animals 18 weeks after the treated animals had been placed on clean feed. These results indicated that the octabromobiphenyl mixture was resistant to metabolism and elimination (Lee *et al*., 1975; Damstra *et al*., 1982).

PBBs can have a relatively long biological half-life in animals. Data suggested that only 10% of the total dose of 2,2′4,4′5,5′-hexabromobiphenyl would be eliminated during the lifetime of a rat (Matthews *et al*., 1977; DiCarlo *et al*., 1978). Rats receiving a single dose of $C^{14}$-octabromobiphenyl had biphasic fecal excretion with the initial half-life being less than 24 h and second phase half-life being greater than 16 days (Norris *et al*., 1975; DiCarlo *et al*., 1978). Studies with cows suggested biphasic elimination of PBBs via the milk with an initial half-life of 11 days and a second half-life of 58 days (Fries and Marrow, 1975; Gutenmann and Lisk, 1975; Fries *et al*., 1976; DiCarlo *et al*., 1978). In cases where observation periods were long, a biological half-life of 180 days was estimated for lactating cows (Fries, 1985). It was estimated that the concentration of FireMaster BP-6 in bovine milk fat would decrease from approximately 300 ppm to 0.3 ppm in 120 weeks (Detering *et al*., 1975; DiCarlo *et al*., 1978). A half-life of 17 days was calculated for FireMaster FF-1 in the eggs of chickens fed a diet containing the commercial mixture. Half-lives of 17 days and 31 days were calculated for muscle and liver, respectively and the concentration of PBBs in adipose tissue was essentially unchanged after 56 days (Ringer and Polin, 1977; Polin and Ringer, 1978b). It was estimated that a chicken exposed to 1 ppm PBB in the feed for at least 10 days (the minimum time required to attain a steady state concentration in the contents of a whole egg) would require 87 days of feeding uncontaminated feed to reach a concentration of 0.05 ppm in the whole egg (Ringer and Polin, 1977). The half-life of hexabromobiphenyl was 28 days and that of heptabromobiphenyl was 20 days in chicken eggs (Fries *et al*., 1976; DiCarlo *et al*., 1978).

## PCDDs and PCDFs

The absorption, distribution, metabolism and elimination of PCDDs and PCDFs have been extensively reviewed by Van den Berg *et al*. (1994). Absorption from the gastrointestinal tract of mammals is effective and can exceed 75% of the dose for the lower chlorinated congeners. With increasing molecular size, absorption from the intestines is greatly reduced, which is most apparent for the hepta- and octachlorinated congeners. The liver and adipose tissue are the major storage sites of PCDDs and PCDFs for most mammalian and avian species. The biotransformation of PCDDs and PCDFs depends on the number and position of the chlorine atoms on the molecule. Metabolic reactions include oxidation and reductive dechlorination as well as breakage of the oxygen bonds. Sulfur-containing metabolites have also been identified. In general, the urinary and biliary elimination of 2,3,7,8-substituted congeners depends on the metabolism of these compounds. Whole-body half-lives of the group of 2,3,7,8-substituted congeners in rodents range from a few to more than 100 days.

The absorption of PCDDs and PCDFs from the gastrointestinal tract has been studied for a number of individual congeners. The extent of absorption of 2,3,7,8-TCDD or related compounds is variable, depending on the vehicle and the substitution pattern of the congener. There appear to be no differences between species in terms of absorption of these compounds through the gastrointestinal tract. There are indications that passage across the intestinal wall is predominately limited by molecular size and solubility with the influence of these two parameters being most significant for hepta- and octachlorinated congeners, which exhibit decreased absorption. Studies with rats, mice, hamsters, guinea pigs, cows and chickens, in general, indicate that 2,3,7,8-tetra- and pentachlorinated congeners are well absorbed from the gastrointestinal tract (50–90%), and octachlorodibenzs P-dioxin (OCCD) is absorbed only to a limited extent (2–15%) (Pohjanvirta and Tuomisto, 1994; Van den Berg *et al*., 1994).

The tissue distribution of PCDDs and PCDFs has been extensively studied in laboratory experiments using rodents and non-human primates. Upon absorption, 2,3,7,8-substituted PCDDs and PCDFs are bound to chylomicrons, lipoproteins and other serum proteins and transported throughout the circulatory system. The liver and adipose tissue are the major storage sites of PCDDs and PCDFs for most mammalian and avian species, whereas, depending on species, the skin and adrenals can also act as primary sites for deposition. Several studies with rats, mice, hamsters, guinea pigs and monkeys indicated that the 2,3,7,8-substituted PCDDs and PCDFs are the predominant congeners retained in tissues and body fluids. In rats and mice, most of the 2,3,7,8-substituted penta- to octachlorinated congeners are retained in the liver at higher

concentrations than 2,3,7,8-TCDD and TCDF. In the hamster, the adrenal glands also appear to be a major storage site in addition to the liver and adipose tissue. Recent studies suggest that the tissue distribution of 2,3,7,8-TCDD and related compounds is dose dependent in that as the dose increases, so does the liver:adipose distribution ratio. In the liver, 2,3,7,8-TCDD induces both cytochromes CYP1A1 and CYP1A2. Induced CYP1A2, in turn, appears to be a crucial binding species for 2,3,7,8-TCDD and related compounds in rodents. The hepatocellular binding of 2,3,7,8-TCDD to CYP1A1 is so strong that only a very limited amount will be released back into the circulation. Placental transfer of 2,3,7,8-substituted PCDDs and PCDFs was found to be strongly dependent on molecular size with 2,3,7,8-TCDD being retained to the greatest extent in the fetus. In a number of mammalian species, the transfer of PCDDs and PCDFs from the mother to the offspring via lactation is quantitatively more important than transport to the fetus across the placenta. Excretion via lactation generally decreases as chlorine content increases, being most pronounced for the hepta- and octachlorinated congeners (Pohjanvirta and Tuomisto, 1994; Van den Berg *et al.*, 1994).

As in mammals, the liver and adipose tissue of avian species are the major sites for storage and accumulation of 2,3,7,8-substituted PCDDs and PCDFs. Hepatic deposition of 2,3,7,8-substituted PCDDs and PCDFs appeared to increase with increasing chlorination, resulting in a limited transfer of the more highly chlorinated congeners to the egg (Van den Berg *et al.*, 1994).

Metabolism of 2,3,7,8-TCDD and related compounds is necessary for urinary and biliary elimination, thus playing a major role in regulating the rate of excretion of these compounds. In rats, metabolic reactions include oxidation, preferably in the lateral positions and reductive dechlorination as well as oxygen bridge cleavage of the diphenyl ether in 2,3,7,8-substituted PCDDs. As with lower chlorinated PCDDs, oxidation of PCDFs preferably occurs on the 2 and 3 positions. Metabolism of 2,3,7,8-TCDF results in a number of metabolites containing one and two hydroxyl groups. However, in contrast to 2,3,7,8-TCDD, there was no cleavage of the oxygen bridge. In the 2,3,7,8-substituted PCDF molecule, the 4 and 6 positions are more susceptible to metabolic attack than the 1 and 9 positions. As a result, PCDFs with chlorines in the 4 and 6 positions are highly persistent in biota (Van den Berg *et al.*, 1994). Metabolism of PCDDs and PCDFs is generally thought to be a detoxification process, thus toxicity is attributable to the unchanged parent compound (Pohjanvirta and Tuomisto, 1994).

The induction of CYP1A1 and CYP1A2 enzyme activities by 2,3,7,8-substituted PCDDs and PCDFs has been shown to be one of the most sensitive parameters for biological activity of these compounds. The enzymes most studied are the CYP1A1-dependent ethoxy resorufin-*ortho*-deethylase (EROD) and aryl hydrocarbon hydroxylase (AHH). In addition, 2,3,7,8-substituted PCDDs and PCDFs also induce phase II enzymes (Van den Berg *et al.*, 1994).

In mammals, the liver and adipose tissue are the major compartments for the deposition of PCDDs and PCDFs. The elimination of polar metabolites of 2,3,7,8-substituted PCDDs and PCDFs occurs predominantly via the bile and feces, with urinary excretion playing a minor role. However, urinary elimination plays an important role in the hamster. In rats, the whole-body half-lives of PCDDs and PCDFs range from 17 to 31 days, depending on the dose and strain of rat used, while in hamsters and mice, the whole-body half-lives range from 11 to 15 days and 11 to 24 days, respectively. In rats, it was shown that lactation can reduce the half-life of these compounds while egg-laying can reduce the half-life in avian species. In lactating cows, mean half-lives ranged from 40 to 50 days for tetra- to heptaCDDs and CDFs . 2,3,7,8-Tetrachlorodibenzofuran is eliminated more rapidly than 2,3,7,8-TCDD, having a whole-body half-life of 2 days. The rapid elimination of 2,3,7,8-TCDF is thought to be due to its rapid metabolism. In contrast, 2,3,4,7,8-pentaCDF is eliminated very slowly in the rat, with a whole-body half-life of 64 days. The slow elimination rate is probably due to tight binding of this congener by CYP1A2, in addition to limited metabolism. As chlorine content increases, the rate of elimination of PCDDs and PCDFs decreases (Pohjanvirta and Tuomisto, 1994; Van den Berg *et al.*, 1994).

Interspecies differences in toxicity can only be partly explained by differences in toxicokinetics. The hamster is the species most resistant to the acute toxicity of 2,3,7,8-TCDD. Although the elimination rate of 2,3,7,8-TCDD is 2–3-fold greater in the hamster than the rat and mouse, this does not explain entirely the 10–100-fold difference in acute toxicity between the hamster and other rodent species. The guinea pig is most sensitive to the acute effects of 2,3,7,8-TCDD and it is the species with the slowest metabolism and elimination of 2,3,7,8-TCDD, suggesting that toxicokinetics in part explains the unique sensitivity of the guinea pig to the acute toxicity of 2,3,7,8-TCDD and 2,3,7,8-TCDF (Van den Berg *et al.*, 1994).

## MECHANISM OF ACTION

The AhR is a ligand-activated transcription factor that is involved in the regulation of a number of genes, including those for enzymes that play a role in the metabolism of xenobiotics as well as genes involved in cell growth regulation and differentiation (Okey *et al.*, 1994; Safe, 1994; Hahn, 1998, 2002; Denison *et al.*, 2002; Denison and Nagy, 2003; Mandal, 2005). The AhR plays an important role in the altered gene expression and species- and tissue-specific toxicity resulting from exposure to specific PCB, PCDD

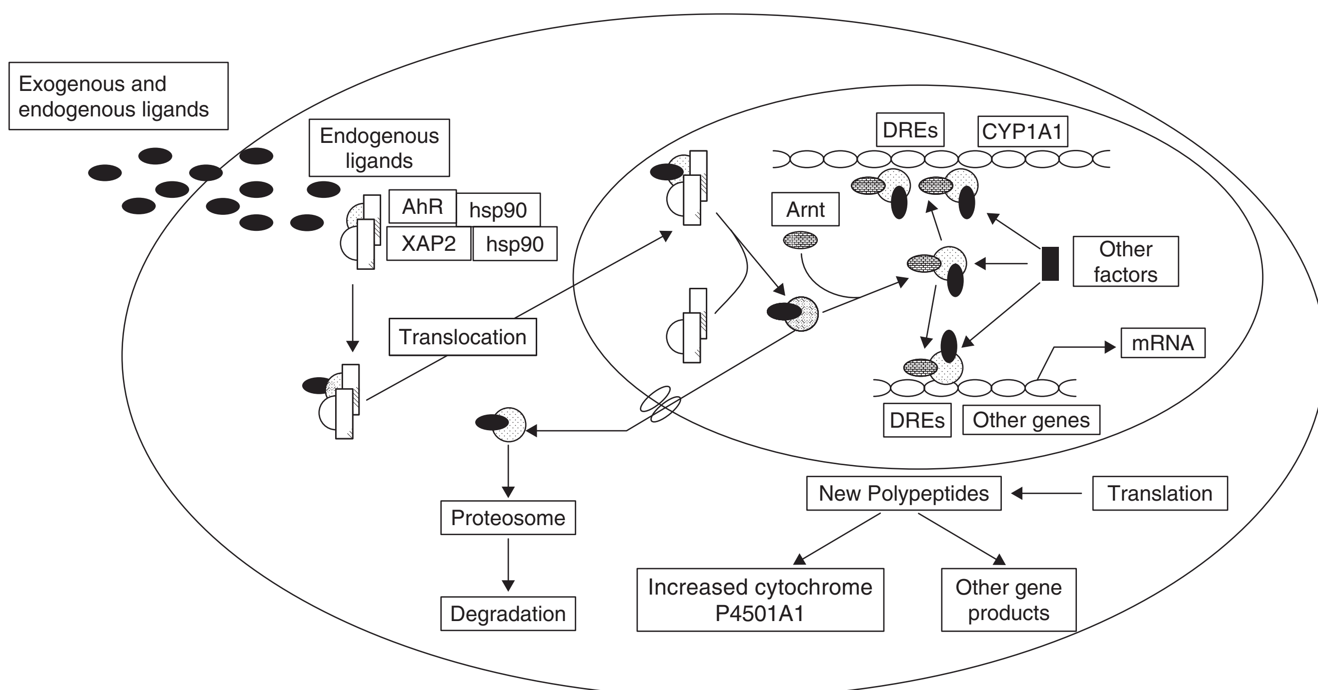

**FIGURE 55.2** The proposed molecular mechanism of action of 2,3,7,8-TCDD and TCDD-like chemicals. See text for details.

and PCDF congeners. It is now well established that the majority of the toxic effects attributed to 2,3,7,8-TCDD and TCDD-like chemicals require activation of the AhR. The toxicity of individual congeners is closely related to the affinity with which these compounds bind to the AhR with the most toxic compounds being those that bind with the greatest affinity (Okey *et al.*, 1994). There are large species and strain differences in sensitivity to TCDD and related chemicals. Mouse and rat strain differences in sensitivity to TCDD can be partially explained by differences in the ligand-binding affinity of their polymorphic AhR variants. A recent study in birds indicated that species differences in sensitivity to TCDD and related chemicals could be due, at least in part, to differences in amino acid composition of the ligand-binding domain of the AhR (Karchner *et al.*, 2006). However, differences in AhR concentration or binding affinity do not fully explain the differences in species susceptibility to TCDD and TCDD-like chemicals (Denison *et al.*, 1986).

The AhR is a basic helix–loop–helix (bHLH) and Per-Arnt-Sim (PAS) containing transcription factor (Denison *et al.*, 2002; Denison and Nagy, 2003). In the absence of a ligand, AhR occurs as a soluble multiprotein complex in the cytosol of the cell. The chaperone proteins are two molecules of hsp90 (a heat shock protein of 90 kDa), the X-associated protein 2 (XAP2) and p23 (a co-chaperone protein of 23 kDa). When TCDD or another ligand diffuses across the plasma membrane and binds to the AhR, the ligand AhR complex undergoes a conformational change that exposes a nuclear localization sequence (NLS) (Figure 55.2). The complex translocates into the nucleus of the cell and the chaperone proteins dissociate from the complex. The AhR–ligand then binds to the bHLH–PAS nuclear protein, AhR nuclear translocator or Arnt. The formation of this heterodimer initiates conversion of the complex into a form that binds to DNA with high affinity on a specific recognition site called the dioxin responsive element (DRE). Binding of the ligand–AhR–Arnt complex to the DRE stimulates transcription of genes encoding ctyochrome P450 enzymes in the CYP1A1 subfamily and other AhR-responsive genes that are located upstream of the DRE (Denison *et al.*, 2002; Denison and Nagy, 2003). Continuous and inappropriate modulation of gene expression is thought to be responsible for a series of biochemical, cellular and tissue changes that result in toxicity characteristic of TCDD and related compounds (Denison and Heath-Pagliuso, 1998; Mandal, 2005).

# TOXICITY

## PBBs

### *Laboratory studies*

Toxicological assessment of FireMaster FF-1 is complicated by the fact that the commercial product is a mixture of individual congeners of differing toxicities. In addition, the commercial mixture also contained traces of brominated

naphthalenes as impurities with their own toxicity. As with many chemicals, the type and severity of effects are influenced by species, age, duration of exposure and dose. None of the effects caused by PBBs are unique to this particular group of brominated congeners, but they are characteristic of polyhalogenated hydrocarbons including PBBs, PCBs, PCDDs and PCDFs. In general, the concentrations required to produce deleterious effects in animals are quite high.

The acute oral LD50s of FireMaster BP-6 as well as octabromobiphenyl and decabromobiphenyl are in the range of 2–22 g/kg body weight for a number of species (DiCarlo *et al.*, 1978; Fries, 1985). Death resulting from acute exposures can occur up to 2 weeks after dosing. Thus, the LD50 value is not a good indicator of PBB toxicity because it gives no consideration to subacute effects and acute effects that develop slowly. When observation periods are longer, the LD50 value tends to decrease (Fries, 1985). The PBB dose required to cause lethality is consistent among most mammalian and avian species. Generally, total doses exceeding 1000 mg/kg body weight or dietary concentrations in excess of 500 ppm are required. Notable exceptions include the guinea pig, which is one order of magnitude more sensitive and the mink, which is two orders of magnitude more sensitive to PBBs (Fries, 1985). However, as with other halogenated hydrocarbons, PBBs accumulate in adipose tissue upon chronic exposure and are toxic in animals at concentrations much lower than indicated from LD50 values (Ringer and Polin, 1977).

Generally speaking, prolonged exposure to low concentrations of PBBs causes more deleterious effects than exposure to a large, single dose (Damstra *et al.*, 1982). The appearance of clinical signs after a single dose may take a number of days. This delay in appearance of clinical signs in conjunction with the relatively long half-life of PBBs, which results in long-term exposure from a single dose, makes the distinction between acute and chronic toxicity less clear. The development of clinical signs is similar across species (Fries, 1985).

In most toxicity studies conducted with PBBs, the characteristic effects are a decrease in feed consumption with a concomitant decrease in body weight loss or body weight gain, which may not be entirely related to the decrease in feed consumption. Milk production and egg production may also decrease as a result, at least in part, of reduced feed consumption. Changes in hematology and serum clinical chemistry values generally were unremarkable in all species examined and with a few exceptions occurred only in conjunction with clinical signs indicative of severe toxicity. The most prominent gross morphological and histological changes occurred in the liver of most species examined, with the exception of cattle in which the kidney appears to be the target organ (Damstra *et al.*, 1982; Fries, 1985). In rodents, changes in the liver can include a dose-related increase in weight, which is associated with induction of microsomal enzymes (Sleight and Sanger, 1976; Fries, 1985). Microscopic lesions are characterized by swelling and vacuolation of hepatocytes with fatty infiltration (Corbett *et al.*, 1978; Kimbrough *et al.*, 1978; Gupta and Moore, 1979; Gupta *et al.*, 1981; Fries, 1985). Mitochondria increase in size and degenerate over time (Sleight and Sanger, 1976; Corbett *et al.*, 1978; Kasza *et al.*, 1978; Fries, 1985) and there is an increase in smooth endoplasmic reticulum (Sleight and Sanger, 1976; Corbett *et al.*, 1978; Kasza *et al.*, 1978; Gupta and Moore, 1979; Gupta *et al.*, 1981; Fries, 1985). At higher doses, livers become friable and the external surface is mottled (Gupta *et al.*, 1981; Fries, 1985). In birds, liver weights increased in addition to vacuolation and mitochondrial swelling within the hepatocytes (Dharma *et al.*, 1982; Fries, 1985). The livers of cattle exposed to PBBs were enlarged, but had minor histological changes (Moorehead *et al.*, 1977; Fries, 1985). In most species exposed to PBBs, there is minimal renal involvement with the exception of cattle. In cattle, the kidneys are the site of the most severe damage, which is characterized by enlargement and distension due to accumulation of fluid. Lesions included dilatation of collecting ducts and convoluted tubules as well as degeneration of tubular epithelium (Moorehead *et al.*, 1977; Fries, 1985). Both the thymus and the avian bursa of Fabricius decreased in size in some species at relatively low doses. There is a loss of cells specific to the respective tissue and a disruption of the normal architecture (Gupta and Moore, 1979; Gupta *et al.*, 1981; Dharma *et al.*, 1982; Fries, 1985).

Male rats fed FireMaster BP-6 at concentrations as low as 50 ppm for 10 weeks had increased liver weights (Harris *et al.*, 1978; Damstra *et al.*, 1982). Rats fed a diet containing 10 ppm PBBs for 30 days developed slight hepatotoxic effects and pups exposed to PBBs through lactation had microscopic and ultrastructural hepatic lesions (Sleight and Sanger, 1976; Gupta *et al.*, 1981). Rats administered 22 doses of FireMaster FF-1 ranging from 30 to 100 mg/kg body weight/day had decreased body weight gain accompanied by a decrease in feed intake, anemia and increased liver weights by the end of the 180-day trial. Histological assessment of tissues from these animals indicated lesions in the liver, kidneys, prostate gland and thyroid glands in males and hepatic involvement in the females. Animals receiving higher doses (300 and 1000 mg/kg body weight/day) died within 73 days and had atrophied thymuses and spleens (Gupta and Moore, 1979; Damstra *et al.*, 1982). A study involving administration of 22 oral doses up to 30 mg/kg body weight of FireMaster FF-1 or up to 16.8 mg/kg body weight 2,2′,4,4′,5,5′-hexachlorobiphenyl to rats and mice over a 30-day period with an additional 90 days holding period demonstrated hepatotoxicity in the females of both species with effects being more severe in the FireMaster FF-1 groups than the 2,2′,4,4′,5,5′ -hexabromobiphenyl groups. The liver was enlarged due to swelling of hepatocytes, fatty infiltration and proliferation of the endoplasmic reticulum (Gupta *et al.*, 1981). Mice that were fed diets containing 1000 ppm

FireMaster BP-6 for up to 14 days lost body weight and had enlarged livers at necropsy. Examination of hepatic ultrastructure indicated increased smooth endoplasmic reticulum and lysosomes, degeneration of the mitochondria and decrease glycogen content (Corbett *et al.*, 1978; Damstra *et al.*, 1982). Mink were fed diets containing FireMaster FF-1 at concentrations ranging from 1.0 to 15.6 ppm, a diet containing contaminated chicken that provided a PBB concentration of 1.5 ppm or a diet containing contaminated beef that provided a PBB concentration of 12.0 ppm for up to 10 months. The animals had decreased feed consumption accompanied by a decrease in body weights and unthrifty appearance. Kidneys and livers tended to be enlarged with the latter being characterized by fatty infiltration (Aulerich and Ringer, 1979). Chickens fed diets containing 125 ppm FireMaster FF-1 had reduced feed consumption (Polin and Ringer, 1978a). Japanese quail also had reduced feed consumption at similar PBB concentrations (Babish *et al.*, 1975; Ringer and Polin, 1977). Chickens fed diets containing 50–250 ppm FireMaster FF-1 had decreased body weights, which were due in part to a decrease in feed consumption. Additionally, weights of the comb, testes, spleen and bursa were decreased and liver and thyroid weights were increased. Hydropericardium and ascites were also observed. In a second experiment, chicks fed diets containing 75 or 150 ppm FireMaster FF-1 for 9 weeks developed an anemic condition characterized by decreased heart rate, cardiac output, packed cell volume and hemoglobin concentration (Ringer and Polin, 1977; Ringer, 1978). Rhesus monkeys fed 0.3 ppm FireMaster FF-1 for approximately 2 years had reduced body weights without a concomitant decrease in feed intake, prolonged menstrual cycles and decreased progesterone concentrations (Allen *et al.*, 1978; Damstra *et al.*, 1982). Monkeys fed greater concentrations of the commercial fire retardant had a decrease in serum cholesterol, enlarged livers with fatty infiltration, hyperplastic gastroenteritis, dry, scaly skin, alopecia, generalized subcutaneous edema and edema of the eyelids (Allen *et al.*, 1978; Lambrecht *et al.*, 1978; Damstra *et al.*, 1982).

There is some evidence, in addition to reported atrophy of lymphoid tissues in a variety of species, that exposure to PBBs causes suppression of the immune system (Moorehead *et al.*, 1977; Kimbrough *et al.*, 1978; Gupta and Moore, 1979; Gupta *et al.*, 1981, 1983; Fries, 1985). However, doses sufficient to cause other toxic effects are usually required to induce immunosuppression and there appears to be differences between species in terms of sensitivity (Damstra *et al.*, 1982; Fries, 1985). Dogs receiving FireMaster FF-1 for 61 days had depletion of lymphocytes in lymph nodes but only at doses that resulted in other toxic effects (Farber *et al.*, 1978; Damstra *et al.*, 1982). Alterations in B-cell and T-cell function occurred as a result of feeding rhesus monkeys 1.5 ppm PBBs for 5 months and 25 ppm for 10 weeks (Allen and Lambrecht, 1978; Damstra *et al.*, 1982). Decreased immunoresponsiveness was reported for rats receiving 3.0–30 mg PBBs/kg body weight/day for 30 days (Luster *et al.*, 1978; Damstra *et al.*, 1982) and for rats and mice receiving up to 10 mg/kg body weight/day (5 days/week) for 6 months (Luster *et al.*, 1980; Damstra *et al.*, 1982). Mice fed diets containing 1, 10 or 100 ppm PBBs had antibody responses to sheep red blood cells that were 80%, 30% or 12%, respectively, of control responses, although cell-mediated immunity was not affected (Fraker, 1980; Damstra *et al.*, 1982).

A number of studies have demonstrated PBB-induced reproductive effects in a variety of species. Exposure of poultry to deleterious concentrations of PBBs results in an initial decrease in feed consumption accompanied by a decrease in egg production. If concentrations are high enough, there is then a dose-related decrease in egg hatchability with embryo mortality occurring late in incubation (Fries, 1985). Dietary concentrations of FireMaster FF-1 greater than 30 ppm resulted in a significant decrease in egg production of chickens, which returned to control values from 2 to 6 weeks after withdrawal of the contaminated feed. Concentrations above 30 ppm also had an adverse effect on hatchability and subsequent survivability of chicks (Ringer and Polin, 1977; Polin and Ringer, 1978a). Edema of the abdominal and cervical regions of the chicken embryos and hatchlings was the prevalent pathological condition observed and was the only effect that had an increased incidence compared to the incidence of abnormalities observed in controls (Ringer and Polin, 1977; Polin and Ringer, 1978b). A dietary PBB concentration of 20 ppm had no effect on egg production and hatchability in Japanese quail, but 100 ppm resulted in a significant decrease in both parameters (Babish *et al.*, 1975). Rats administered FireMaster BP-6 at doses of 5 or 25 mg/kg body weight every other day for 14 days had a reduced number of implantation sites compared to controls at both doses and increased resorptions and fetal deaths at the higher dose (Beaudoin, 1977; Damstra *et al.*, 1982). Single doses of 400 and 800 mg/kg body weight caused a decrease in rat fetal weights at term as well as an increased incidence of cleft palate and diaphragmatic hernia (Beaudoin, 1977; Damstra *et al.*, 1982). Pregnant rats fed diets containing 100 and 1000 ppm FireMaster BP-6 experienced increased fetal mortality and fetal weights were reduced at term (Corbett *et al.*, 1975; Damstra *et al.*, 1982). Mice exposed to 200 ppm dietary PBBs on gestation days 4 through 16 had an increase in fetal deaths and resorptions as well as reduced fetal weights at term (Preache *et al.*, 1976; Damstra *et al.*, 1982). Exencephaly and cleft palate were observed in offspring of mice fed FireMaster BP-6 at concentrations up to 1000 ppm (Corbett *et al.*, 1975; DiCarlo *et al.*, 1978). The predominant congener in FireMaster BP-6, 2,2′,4,4′,5,5′-hexabromobiphenyl, did not cause any effects in offspring when administered to pregnant mice at a dose of 40 mg/kg body weight on gestation days 10 through 16 (Damstra *et al.*, 1982). Pigs that

were fed diets containing up to 200 ppm PBBs during gestation had normal young but as the offspring nursed, there was 50% mortality in those receiving 200 ppm via lactation and significant growth depression in offspring consuming 100 ppm in the milk (Werner and Sleight, 1981; Fries, 1985). Rhesus monkeys fed diets containing 0.3 ppm FireMaster FF-1 for 7 months prior to breeding had prolonged menstrual cycles and decreased progesterone concentrations. Offspring had depressed birth weights and growth rates through 16 weeks of age (Allen and Lambrecht, 1978; Damstra *et al.*, 1982). Mink were fed diets containing FireMaster FF-1 at concentrations ranging from 1.0 to 15.6 ppm, a diet containing contaminated chicken that provided a PBB concentration of 1.5 ppm or a diet containing contaminated beef that provided a PBB concentration of 12.0 ppm for up to 10 months. Adults experienced increased mortality at dietary concentrations of 6.25 ppm or greater. There was also a significant decrease in litter size, birth weights and kit survivability through 4 weeks of age at dietary concentrations from 1.0 to 2.5 ppm and greater. Results indicated that the PBB-contaminated poultry and beef were more toxic than the commercial mixture. A concentration lethal to 50% of the population (LC50) for FireMaster FF-1 was estimated to be 4 ppm when fed for over 300 days. This study indicated that PBBs were not as fetotoxic as two commercial PCB mixtures (Aroclors 1242 and 1254) but were lethal to adults at a lower dietary concentration (Aulerich and Ringer, 1979).

Commercial PBB mixtures have been shown to cause liver cancer in rats and mice (Damstra *et al.*, 1982; Fries, 1985). Sherman rats were administered a single dose of 1000 mg/kg FireMaster BP-6 and observed for 14 months. There was pronounced liver pathology in both sexes that included neoplastic lesions that were more prominent in the females (Kimbrough *et al.*, 1978). Subsequently, groups of female Sherman strain COBS rats given a single dose of 1000 mg/kg body weight of FireMaster FF-1, 12 doses of 100 mg/kg body weight or a single dose of 200 mg/kg body weight single or multiple doses of FireMaster FF-1 of 1000 mg/kg body weight or higher had an incidence of liver tumors. There was an incidence of hepatocellular carcinoma ranging from 41% to 68% at the two higher doses while animals in the lowest dose group had a 31% incidence of neoplastic nodules (Kimbrough *et al.*, 1981; Damstra *et al.*, 1982). Fischer 344 rats of both sexes had a significant incidence of neoplastic nodules, hepatocellular carcinomas and cholangiocarcinomas 23 months after receiving daily doses of FireMaster FF-1 at 10.0 mg/kg body weight/day for 6 months. Atypical foci in the liver of male rats occurred at doses as low as 0.3 mg/kg body weight. Hepatocellular carcinomas were noted in $D6C3F_1$ mice receiving the 10 mg/kg body weight dose (Gupta *et al.*, 1983; Fries, 1985). Studies have indicated no evidence of tumors in tissues other than the liver and that the commercial PBB mixture acts as a promoter rather than an initiator of carcinogenesis (Fries, 1985).

### *Michigan PBB Incident*

One dairy producer who received an early shipment of PBB-containing feed soon suspected that there was something wrong with the feed. The sequence of events that occurred on this particular farm as result of feeding the commercial PBB mixture was reported by Jackson and Halbert (1974) and provides one of the earliest accounts of PBB toxicity in a domestic animal. The producer had a 400-cow herd with a 305-day average of 15,000 lb of milk. Because soil concentrations of magnesium were low in the area, the herd was fed magnesium oxide that was added to pelleted feed at a rate of 8 lb/ton. Cows that produced more than 40 lb of milk/day had free access to the pelleted ration twice a day while being milked, which resulted in an estimated consumption of at least 15 lb/day. Cows that produced less milk consumed approximately 8 lb of the feed on a daily basis.

Early in September of 1973, the herd was provided the pelleted ration containing PBBs. By late September, milk production of the herd decreased from 13,000 lb/day to 7600 lb/day over a 20-day period and feed intake decreased by 50%. During this first phase of clinical signs, some cows had increased urination and lacrimation. Lameness also was apparent in some of the animals. Approximately 16 days after feeding of the suspect concentrate began the ration was changed by switching to alfalfa hay and eliminating the pelleted feed. Although feed consumption rapidly increased, milk production continued to be about 40% lower than the previous average. Also during this time period, it was observed that cows bred 4–6 weeks earlier came back into estrus, suggesting early fetal resorptions.

The second phase of clinical signs began about 30 days after the drop in milk production was observed. Hematomas developed in about 10% of the cows and animals continued to lose weight despite resumption of normal feed consumption. Approximately 60 days after initial observations, it was noted that the hooves of approximately 25% of the cows were abnormally long. Some cows had alopecia with thickened skin on the thorax, neck and shoulders. Cows consuming contaminated feed during the last trimester of pregnancy experienced dystocia and often the calf was born dead or died soon after parturition. Thirty freshening cows developed metritis in January of 1974 and in March, 20 non-lactating cows went off feed several weeks prepartum. Half of the latter cows died without calving.

From mid-October 1973 to mid-April 1974, 24 cows died. Gross findings at necropsy included hematomas and abscesses in the peritoneal and thoracic cavities. Pathology reports indicated liver lesions in seven of 10 cows assessed, including hemorrhagic necrotic hepatitis, fatty metamorphosis, large fat vacuoles and amyloidosis. Four cows also had kidney involvement characterized by interstitial nephritis (Jackson and Halbert, 1974).

## PCBs, PCDDs and PCDFs

The toxic and biochemical effects of various commercial PCB mixtures have been studied in various laboratory animals, fish and wildlife species and have been summarized by Safe (1994). Commercial PCBs cause a broad spectrum of toxic responses that are dependent on several factors including the chlorine content and purity of the commercial mixture, the route and duration of exposure as well as on the age, sex, species and strain of animal. The majority of effects caused by commercial PCB mixtures are the same as those induced by 2,3,7,8-TCDD because the responses caused by commercial PCB mixtures are due, in part, to the individual non-*ortho* coplanar and mono-*ortho* coplanar PCBs present in these mixtures that act as AhR agonists. Because some of the mono-*ortho* coplanar PCBs are present in relatively high concentrations in commercial mixtures and environmental extracts, this class of PCBs may contribute significantly to the TCDD-like activity of PCB mixtures (Safe, 1994).

There are a number of reports that describe the common effects induced by 2,3,7,8-TCDD and related PCDDs, PCDFs and PCBs. The only major difference in these compounds is their relative toxic potencies. These effects are thought to be mediated through initial binding to the AhR and are dependent on dose, age, sex, species and strain of animal. In most cases, if a given species is more sensitive to a given class of compound (e.g. PCBs), this species will also be sensitive to the other classes (PCDDs, PCDFs, PBBs). It has also been observed that in most instances young animals are more sensitive than adults and females more sensitive than males. Generally speaking, chickens, guinea pigs and mink are the most sensitive species of animals to the toxic effects induced by 2,3,7,8-TCDD and TCDD-like chemicals. In contrast, hamsters and amphibians appear to be fairly resistant to the toxic effects. The effects include acute lethality, wasting syndrome, thymic and splenic atrophy, impairment of immune responses, hepatotoxicity and porphyria, chloracne and related dermal lesions, tissue-specific hypo- and hyperplastic responses, disruption of multiple endocrine pathways, carcinogenesis, teratogenicity and reproductive toxicity (Poland and Knutson, 1982; McConnell, 1985; Safe, 1986, 1990, 1998; Dickson and Buzik, 1993; Fries, 1995; Schecter *et al.*, 2006).

TCDD causes lethality at very low doses in specific species. The oral LD50 values for various species are: 0.6-2.0 μg/kg body weight for the guinea pig, 22–45 μg/kg for the rat, 25–50 μg/kg for the chicken, 70 μg/kg for the monkey, 115 μg/kg for the rabbit, 100–200 μg/kg for the dog, 114–284 μg/kg for the mouse and 1157–5000 μg/kg for the hamster (Safe, 1990). There is a delayed appearance of lethality, irrespective of dose. Death typically does not occur earlier than 1 week after exposure and it may not occur until 6 weeks of exposure. Before death, the exposed animal generally undergoes a rapid and substantial weight loss called "wasting syndrome" (McConnell, 1985; Pohjanvirta and Tuomisto, 1994). This is accompanied by decreased food and water intake, which accounts for some, but not all of the weight loss. These may be the only signs observed in rats, mice, guinea pigs, mink and poultry after oral administration. However, skin lesions have been reported in hairless mice and acne-like lesions have been described in the ears of rabbits after local application. At times, poultry may show an increase in body weight prior to death due to accumulation of body fluids (subcutaneous edema, ascites, hydrothorax and hydropericardium). In addition to body weight loss, the clinical syndrome in monkeys and cattle is characterized by skin and eyelid lesions and abnormal growth of finger or toe nails or hooves. The lesions in monkeys are follicular dermatitis (acne) of the face, neck and forearms, enlarged tortuous Meibomian glands in the eyelid, and overgrowth and loss of nails of the hands and feet. Alopecia may be present, particularly in the areas of the body showing dermatitis. The skin of cattle is thickened and dry, particularly over the neck, shoulders and back (McConnell, 1985).

TCDD is a highly immunosuppressive chemical in laboratory animals. Effects include decreased host resistance to infectious disease and suppressed humoral and cell-mediated immune responses. Both pre- and post-natal exposure of mice and guinea pigs reduced both the delayed hypersensitivity and lymphoproliferative response. TCDD appears to selectively interfere with antigen-specific activation of T-cells. In addition to immune suppression, TCDD promotes inflammatory responses (Dickson and Buzik, 1993; Pohjanvirta and Tuomisto, 1994; Mandal, 2005).

Thymic atrophy is one of the most uniform and consistent findings in TCDD-exposed mammals. It consists of depletion of small immature cortical thymocytes, making a distinction between cortex and medulla difficult. Although both pyknotic and scattered necrotic lymphocytes have been reported, frank necrosis is not a typical feature of the lesion. At less toxic doses, the thymus might look normal histopathologically while being one half normal size (McConnell, 1985; Pohjanvirta and Tuomisto, 1994).

TCDD exposure results in hepatomegaly in all species investigated, but there is extensive variation among species in the severity of this lesion. The changes in the liver are accompanied by altered liver function characterized by enzyme induction, porphyria, impaired plasma membrane function and hyperlipidemia. Liver lesions are most severe in the rabbit, which displays extensive necrosis. In other species, such as the rat, mouse, mink and, to a lesser extent, the guinea pig, hamster, bovine and monkey, the predominant features are hepatocellular hypertrophy, multinuclear hepatocytes, steatosis and inflammatory cell infiltration, often accompanied by scattered focal necrosis with a preferentially centrilobular location. Female rodents are more susceptible to the hepatic effects of TCDD compared to males

(McConnell, 1985; Dickson and Buzik, 1993; Pohjanvirta and Tuomisto, 1994; Safe, 1994).

Intrahepatic bile duct hyperplasia has been described in rodents and monkeys, but is a more prominent feature in chronically exposed animals. Marked epithelial proliferation of the extrahepatic bile duct and gall bladder has been described in monkeys and cattle. Epithelial erosions, ulcers and inflammation are characteristic components of the lesion. Hyperplasia of the epithelium lining of the urinary tract has been described in guinea pigs, cattle and monkeys. The lesion extends from the renal pelvis to the urinary bladder stopping at the level of the urethra. The histological appearance of the epithelium appears normal with the exception of an increase in the number of cell layers. Monkeys exposed to TCDD-like compounds develop a lesion referred to as "simian gastropathy". In acute lethal exposures, the chief (acid-producing) cells are replaced by hyperplastic mucous-producing cells. In more chronic exposures, the hyperplastic change becomes more pronounced and at times appears to invade adjacent tissues. A similar, but much less severe lesion has been described in rats exposed to PBBs. The large intestine also shows hyperplastic changes in monkeys chronically exposed to these chemicals (McConnell, 1985).

The skin and associated structures in monkeys, rabbits and certain strains of mice show characteristic lesions as a result of exposure to TCDD and related chemicals. In monkeys, the lesion is characterized microscopically by mild epithelial hyperkeratosis and severe atrophy of sebaceous glands and hyperkeratosis of their ducts. The ducts become occluded with keratinaceous debris and grossly the lesion mimics an acne-like lesion. A similar lesion is observed in the Meibomian glands of the eyelid and ceruminous glands of the external auditory canal. Alopecia, dry scaly skin and fingernail loss are also features of exposure in monkeys. While most strains of mice do not show skin lesions, certain "hairless" strains show a similar skin lesion to that in monkeys. The inner surface of a rabbit' s ear also develops acne-like lesions if the compound is applied directly to the skin. Cattle also show a characteristic skin disease when exposed to these compounds (McConnell, 1985; Safe, 1994).

A relatively consistent hematological feature of exposure to TCDD and similar compounds across species, except for the guinea pig, is a shift in the proportional number of leukocytes with a trend toward an increase in neutrophils at the expense of lymphocytes. This is a classical manifestation of stress. Another common alteration is thrombocytopenia. There is an increase in hemoglobin concentration, hematocrit and red blood cell numbers that may result from hemoconcentration in the early phases of intoxication. In chronic studies, the most consistent hematologic finding is a mild to moderate degree of anemia. Porphyria and jaundice are typically seen as a result of prolonged exposure to TCDD. The porphyrinogenic effect of TCDD leads to an accumulation of hepatic porphyrins as a result of inhibition of uroporphyrinogen decarboxylase activity (McConnell, 1985; Pohjanvirta and Tuomisto, 1994).

The study of blood serum changes is one of the more complex features of intoxication by TCDD and related chemicals because the pathology varies between species. The liver damage induced by TCDD is reflected in increases in the serum activities of the liver-specific transaminases (alanine aminotransferase, aspartate aminotransferase and alkaline phosphatase) (McConnell, 1985; Pohjanvirta and Tuomisto, 1994).

TCDD reduces serum thyroxin ($T_4$) concentrations rapidly in rats. TCDD-induced changes in $T_4$ concentrations in other species are less consistent. The decrease in serum $T_4$ concentrations is thought to be due to accelerated clearance of the hormone. In addition to altering thyroid hormone concentrations, TCDD appears to modulate the concentration of thyroid hormone receptors. Other endocrine changes include alterations in corticosteroid concentrations and in the concentrations of hormones associated with the reproductive system in rodents, monkeys and birds (Pohjanvirta and Tuomisto, 1994; Safe, 1994; Ulbrich and Stahlmann, 2004).

It is assumed that the interaction of TCDD with the AhR regulates a number of genes, although CYP1A1 has been studied most thoroughly. Thus, in addition to monooxygenases dependent on cytochrome P4501A1, a number of other enzymes are induced (Pohjanvirta and Tuomisto, 1994; Huwe, 2002).

Effects on the nervous system are manifested as hyperactivity, impaired learning and changes in brain neurochemical concentrations in rats and monkeys (Safe, 1994).

PCBs appear to have a detrimental as well as enhancing effect on learning performance (Ulbrich and Stahlmann, 2004).

TCDD and approximate stereoisomers have been shown to affect female reproductive endpoints in a variety of animal studies. Among the effects reported are a decrease in the number of females mated in rats, mink and monkeys, fewer completed pregnancies in rats, mink and monkeys, lower maternal weight gain during pregnancy in rats, rabbits and monkeys, decreased litter size in rats, rabbits, mink and swine, effects on female gonads in guinea pigs and mice and altered estrous and menstrual cycles in mice, rats and monkeys. Decreased egg production and hatchability occur in a number of avian species. Numerous studies have indicated that TCDD and related chemicals are anti-estrogenic presumably due to increased metabolism of estrogen and a decreased number of estrogen receptors. One manifestation of the anti-estrogenic effect is the TCDD-induced decrease in uterine weight in rats. Occasionally, some signs of ovarian dysfunction such as anovulation and suppression of the estrous cycle have been reported (Golub *et al.*, 1991; Peterson *et al.*, 1993; Safe, 1994).

TCDD and related compounds decrease testis and accessory sex organ weight, cause abnormal testicular morphology, decrease spermatogenesis and reduce fertility when given to adult animals in doses sufficient to reduce feed intake and/or body weight. Some of these effects have been reported in chickens, rhesus monkeys, rats, guinea pigs and mice treated with overtly toxic doses of TCDD or TCDD-like chemicals. TCDD effects on spermatogenesis are characterized by loss of germ cells, the appearance of degenerating spermatocytes and mature spermatozoa within the lumens of seminiferous tubules and a reduction in the number of tubules containing mature spermatozoa. Effects of TCDD on the male reproductive system are thought to be due in part to an androgen deficiency. The deficiency in rats is caused by decreased plasma testosterone and dihydroxytestor-terone concentrations, and unchanged plasma clearance of androgens and luteinizing hormone (LH) (Dickson and Buzik, 1993; Peterson *et al.*, 1993; Safe, 1994).

Avian embryos are more sensitive to TCDD toxicity compared to mammals based on LD50 values. Among bird species, most of the developmental toxicity research has been done on the chicken, which is considered to be the most sensitive avian species to TCDD-like chemicals. Injection of TCDD or its approximate stereoisomers into fertilized chicken eggs causes a toxicity syndrome in the embryo characterized by pericardial and subcutaneous edema, liver lesions, inhibition of lymphoid development in the thymus and bursa of Fabricius, microophthalmia, beak deformities, cardiovascular malformations and mortality. Clinical signs in turkey embryos include microophthalmia, beak deformities and embryo mortality, but not liver lesions, edema or thymic hypoplasia while ring-necked pheasant embryos experienced only mortality. Thus, the clinical signs of toxicity of TCDD and its approximate stereoisomers are species dependent with embryo mortality being the only common effect (Peterson *et al.*, 1993).

Exposure to TCDD during pregnancy causes prenatal mortality in the mouse, rat, guinea pig, hamster, rabbit, mink and monkey. The time period during which exposure of the embryo/fetus to TCDD occurs is just as important as the dose of TCDD administered in terms of prenatal mortality. In most laboratory mammals, gestational exposure to TCDD produces a characteristic pattern of fetotoxic responses that consist of thymic hypoplasia, subcutaneous edema, decreased fetal growth and prenatal mortality. In addition to these common fetotoxic effects, there are other effects of TCDD that are highly species specific. Such effects include cleft palate formation in the mouse and intestinal hemorrhage in the rat. In the mouse, hydronephrosis is the sensitive sign of prenatal toxicity, followed by cleft palate formation and atrophy of the thymus at higher doses, and by subcutaneous edema and mortality at maternally toxic doses. In the rat, TCDD prenatal toxicity is characterized by intestinal hemorrhage, subcutaneous edema, decreased fetal growth and mortality. Structural abnormalities occur in the rat only at relatively large doses. In the hamster fetus, hydronephrosis and renal congestion are the most sensitive effects, followed by subcutaneous edema and mortality. In the rabbit, an increased incidence of extra ribs and prenatal mortality is found, whereas in the guinea pig and rhesus monkey, prenatal mortality is seen (Dickson and Buzik, 1993; Peterson *et al.*, 1993).

Normal development of male reproductive organs and imprinting of typical adult sexual behavior patterns require sufficient testosterone be secreted by the fetal and neonatal testes at critical times in early development before and shortly after birth. Perinatal exposure of male rats to TCDD can produce both prenatal and postnatal androgenic deficiencies that are manifested as a decrease in anogenital distance, a delay in testis descent, decreased plasma concentrations of testosterone, 5$\alpha$-dihydrotestosterone and LH and a decrease in the weights of the seminal vesicles and the ventral prostate. Perinatal exposure of the rat to TCDD also results in decreased spermatogenesis as well as decreased testis and epididymis weights. Additionally, demasculinization and feminization of sexual behavior has been reported (Golub *et al.*, 1991; Peterson *et al.*, 1993).

There have been several long-term bioassays for carcinogenicity of TCDD in several species with all studies producing positive results. Studies in Sprague Dawley rats indicated an increased incidence of hepatocellular hyperplastic nodules and hepatocellular carcinomas in female rats but not male rats. Additional lesions noted were squamous cell carcinoma of the tongue and nasal turbinates/hard palate in both sexes. In addition to the liver, tongue, nasal turbinates and hard palate, increased incidences of lung tumors were observed in the females (Kociba *et al.*, 1978; Lucier *et al.*, 1993). In a study with Osborne–Mendel rats and B6C3F1 mice, TCDD induced malignant liver tumors in female rats and male and female mice. The incidence of thyroid gland tumors increased in male rats while TCDD-induced neoplasms of the adrenal gland occurred in both male and female rats. Fibrosarcomas of the subcutaneous tissue occurred in both female rats and mice. Lymphomas and lung tumors were also observed in female mice (NTP, 1982; Lucier *et al.*, 1993). In the male Syrian Golden hamster, exposure to TCDD resulted in squamous cell carcinomas of the skin in the facial region with some of the lesion metastasizing to the lung (Rao *et al.*, 1988; Lucier *et al.*, 1993). B6C3 and B6C mice of both sexes administered TCDD developed thymic lymphomas and hepatic neoplasms (Della Porta *et al.*, 1987; Lucier *et al.*, 1993).

The studies summarized above by Lucier *et al.* (1993) indicate that TCDD is a multisite carcinogen in both sexes and in several species, it is a carcinogen in sites remote from the site of treatment and it increases cancer incidence at doses below the maximum tolerated dose (MTD). In

two-stage models for liver and skin cancer, it is clear that TCDD is a potent promoting agent with weak or no initiating activity. The consensus is that TCDD is an example of a receptor-mediated carcinogenesis in that; (1) interaction with the AhR appears to be a necessary early step; (2) TCDD modifies a number of receptor and hormone systems involved in cell growth and differentiation, such as epidermal growth factor receptor and the estrogen receptor and (3) hormones exert a profound influence on the carcinogenic actions of TCDD. Although tumor promotion data are limited for PCDFs and co-planar PCBs, it appears that these chemicals are liver tumor promoters with potencies dependent on their binding affinity to the AhR (Lucier *et al.*, 1993; Schwarz and Appel, 2005).

## TREATMENT

The PBB incident in Michigan that resulted in the contamination and subsequent disposal of thousands of animals and millions of pounds of contaminated food products because of the long biological half-lives of these compounds prompted investigation of ways to enhance elimination of persistent PHAHs. Strategies reported in Fries (1985) included activated charcoal in rats and cows (Cook *et al.*, 1978; McConnell *et al.*, 1980), mineral oil in rats and monkeys (Kimbrough *et al.*, 1980; Rozman *et al.*, 1982), high fiber diets in rats (Kimbrough *et al.*, 1980), phenobarbital in cows (Cook *et al.*, 1978) and colestipol, mineral oil, propylene glycol or petroleum jelly with and without restricted feeding in chickens (Polin *et al.*, 1985, 1989). In general, none of these elimination enhancement strategies proved to be effective despite the fact that they were employed for periods of 3–6 months (Fries, 1985). More recently, studies have been conducted that have examined different strategies to increase clearance of dioxins from animals. Rats fed clenbuterol-supplemented feed for 10 days after exposure to dioxin, had 30% less fat than control rats and a 30% decrease in the dioxin body burden. In other studies, rats and mice fed dietary fiber, chlorophyll or an insoluble evacuation substance (chlorophyllin-chitosan) significantly increased excretion of PCDDs and PCDFs and reduced the TEQ body burden (Huwe, 2002).

As suggested above, once animals have been contaminated with the persistent PHAHs, there are currently no practical methods available to quickly reduce body burdens. Therefore, in a contamination incident, products are removed from the market and animals may have to be destroyed. A common strategy to reduce concentrations of contaminants in exposed animals is to provide the animal with uncontaminated feed and withhold products from the market until concentrations of the contaminant have decreased to an acceptable level. In the case of the persistent PCBs, PBBs, PCDDs, long half-lives in the animals require long withdrawal periods. Estimates of the half-lives of PCBs/PCDDs/PCDFs in milk range from 40 to190 days. In beef cattle adipose tissue, half-lives are in the range of 100–200 days. The half-lives of dioxins in adipose tissue and eggs of chickens range from 25 to 60 days. Depuration is the only way to reduce body burdens, but may be uneconomical in many situations because of the length of time required (Huwe, 2002).

At present, the best way to reduce dioxin concentrations in livestock is to minimize exposure. In general, the substitution of plant meals for animal and fish meals may prove to be an effective to lower dioxin intake in livestock and aquaculture (Huwe, 2002).

## CONCLUSION

The PHAHs, which include PCBs, PBBs, PCDDs and PCDFs are environmentally persistent, lipophilic compounds that have a tendency to bioaccumulate and biomagnify at the higher levels of the food chain. Concentrations of these chemicals have been detected in remote areas of the world and in a variety of animal species, including humans. While certain of these chemicals can pose a very serious threat to the health of animals and humans, exposure situations are generally such that risks of health effects are generally low. The most significant problem for those involved in producing a safe food supply is contamination of food products beginning at the animal. Additionally, there are areas of the environment that are heavily contaminated by these chemicals because of past industrial activities. Animals and humans residing in or near contaminated locations certainly are at risk for serious health effects. In those situations, efforts must continue to eliminate or reduce exposure to these very persistent and toxic chemicals.

## INTRODUCTION

There are about 30 orders of birds in the Aves class with approximately 2000 genera and 10,000 species. Obviously, such a large class of animals possesses a bewildering array of unique physiologic adaptations, behaviors, and ecologic niches. Thus, a discussion of a broad topic such as avian toxicology presents a daunting task. This chapter is intended to provide an overview of toxicologic hazards to three subsets of birds: pet and aviary birds, poultry and other farm-raised birds, and wild birds. Given the breadth of the topic, this chapter is not an exhaustive treatise, but will hopefully provide an overview of major avian toxicologic hazards.

### Pet and aviary birds

The popularity of birds as pets has increased substantially over the past several years. The increased popularity is due to a variety of factors including the availability of species with a diversity of sizes, colors, and temperaments, the ability to house birds in a small area and, in some cases, a long lifespan. The fact that most pet birds are confined to the home environment exposes them to toxicants that poultry and wild birds are unlikely to come into contact with such as the pyrolysis products from Teflon®-coated cookware. Alternatively, pet birds can be exposed to toxicants to which poultry and wild birds are also exposed, but which are in different forms or from different sources. For example, pet birds can be intoxicated by lead, most often in the form of lead-based paint or lead objects such as drapery weights or toys, whereas wild birds are frequently intoxicated following ingestion of lead ammunition or lead-containing fishing gear.

### Wild birds

Obviously, wild birds exist in a much less well-controlled environment than pet birds or poultry and are therefore exposed to a greater variety of potential toxicants. It is safe to say that avian toxicology had its origins in the 1950s and 1960s when the effects of organochlorine insecticides (OCs) such as dichlorodiphenyltrichloroethane (DDT) on a variety of bird species were first recognized. The rapid decline of a variety of high-profile avian species such as bald eagles, peregrine falcons, and pelicans during those years and, more recently, the declines of many songbird and waterfowl populations, has resulted in significant government funding to more fully characterize the effects of toxicants on avian wildlife. In addition, regulatory requirements to obtain premarket toxicology information for pesticides using laboratory surrogates, such as quail and mallard ducks, has generated a substantial database of toxicologic information.

One unique aspect of wild bird toxicology is the potential exposure of wild birds to toxicants via their food. Raptors and scavengers such as turkey vultures or condors are often poisoned as a result of feeding on animal carcasses contaminated with pesticides or lead. Thus, secondary or rely toxicity is a more common occurrence in wild birds than in pet birds or poultry. In addition, bioaccumulation and biomagnification of persistent environmental toxicants are much more likely to be of concern in wild birds compared to pet birds or poultry. Bioaccumulation is defined as the net accumulation of a contaminant in or on an organism from all sources including water, air, and diet (Newman and Unger, 2003). Biomagnification is defined as the increase in contaminant concentrations from one trophic level to the next due to accumulation from food (Newman and Unger, 2003). For example, fish-eating birds

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

are exposed to methyl mercury and polychlorinated biphenyls (PCBs) through ingestion of contaminated prey. Concentrations of such toxicants increase (bioaccumulate) with increasing age of the individual due to their long biologic half-lives.

Wild birds are much more likely to be maliciously poisoned than pet birds or poultry. Some avian species such as grackles, blackbirds, and pigeons are considered to be pests and are intentionally poisoned to reduce their numbers. Avicides, such as 4-aminopyridine, are specifically marketed to control pest birds.

## Poultry

Most commercial poultry are raised in well-controlled environments and are provided quality feed and water. Thus, their potential for exposure to toxicants is more limited. However, poultry can become intoxicated following exposure to common feed additives such as organic arsenicals or ionophores if feed misformulations occur. Obviously, free-ranging poultry are potentially exposed to a greater variety of hazardous chemicals.

## Physiologic differences of birds relevant to toxicology

### *Respiratory system*

The unique physiology of bird respiration makes them more susceptible to some inhaled toxicants such as carbon monoxide (CO) and pyrolysis products from overheated Teflon®. The sensitivity of birds to inhaled toxicants brings to mind the image of the canary in the coal mine. Several physiologic differences of birds increase their sensitivity to inhaled toxicants such as a higher mass specific minute ventilation, a higher mass specific ventilation of gas-exchange tissues, cross-current and counter-current gas exchange mechanisms, and a gas diffusion barrier one-half the thickness of that of mammals (Brown *et al*., 1997). Some of these physiologic adaptations are as a result of high metabolic rates of birds and the concomitant need for a high ventilatory capacity.

### *Metabolic system*

There have been a number of studies examining the metabolism of xenobiotics in a variety of avian species and comparing metabolic capabilities of birds and mammals (Pan, 1978; Watkins and Klaassen, 1986; Dalvi *et al*., 1987; Short *et al*., 1988; Coulet *et al*., 1996; Schlinger, 1997; Bailey *et al*., 1998; Gupta and Abou-Donia, 1998). Xenobiotic metabolism has been studied most extensively in chickens, pigeons, Japanese quail, and domestic ducks (Pan, 1978). As expected, there are substantial differences in metabolic pathways and capacities between birds and mammals that influence susceptibility to intoxication (Watkins and Klaassen, 1986; Short *et al*., 1988). Organophosphate (OP) insecticides are more toxic to birds than mammals and the basis for this difference is primarily due to differences in OP metabolism. Dimethoate is 20 times more toxic for pheasants than rats. Dimethoate is metabolized by pheasants to a toxic metabolite, while the toxic metabolite is detoxified by rats (Pan 1978). In addition, there are differences between bird species and between sexes and ages (Pan, 1978; Dalvi *et al*., 1987). Geese, chickens, and turkeys have similar liver aniline hydoxylase activity compared with rats, while quail and ducks had lower activities (Dalvi *et al*., 1987). Conjugating capabilities also differ. For example, glucuronidation of *p*-nitrophenol was greater in ducks than in chickens or turkeys (Short *et al*., 1988).

### *Excretion*

Birds have several unique excretory pathways for xenobiotics. Many metals are incorporated into feathers which are subsequently molted. In addition, incorporation of lipophilic toxicants into eggs provides a significant excretory pathway for female birds.

# GENERAL COMMENTS ABOUT DIAGNOSING AVIAN INTOXICATIONS

Although most diagnostic approaches for documenting intoxication in mammals are applicable to birds, there are several unique aspects that bear mentioning. Given the small size of many birds, obtaining a sufficient amount of sample for testing can sometimes present a challenge. For example, it is not unusual to be able to obtain only 100 μl (sometimes less) of whole blood or serum antemortem for lead and zinc testing, respectively. Quantities of gastrointestinal contents or tissues such as liver are sometimes limiting, especially if multiple tests are desired. The availability of less than optimal sample sizes oftentimes decreases the sensitivity of toxicologic testing, so it is possible that low toxicant concentrations are not detected. In the case of wild bird die-offs, pooling of samples from several dead birds is often required.

Investigation of wild bird die-offs is often a challenge from the standpoint that frequently birds are not discovered until significant postmortem autolysis and/or predation has occurred. Postmortem autolysis often precludes thorough pathologic, microbiologic, and virologic testing. However, for the vast majority of toxicologic tests, the condition of the tissue or fluid sample is of less concern and severely autolyzed samples may be perfectly suitable for toxicologic testing.

Antemortem, whole blood is most often requested from mammals for cholinesterase activity determinations. However, in birds, there is little cholinesterase activity that is associated with the red blood cell. Therefore, for avian species, plasma is preferred. Feathers and egg samples are sometimes useful for diagnosing either exposure to or intoxication from toxicants.

As is the case for any suspected intoxication related to feed, it is critical to obtain a representative feed sample. For example, feed-related mycotoxicoses are common concerns in poultry. However, the distribution and concentration of a mycotoxin in a feed can be quite variable. Therefore, it is important to obtain a number of samples that can then be pooled and subsampled. Other toxicants for which obtaining representative feed samples are critical include drugs, growth promotants such as ionophores, sodium chloride, and nutritionally important minerals such as copper, zinc, and selenium.

Since malicious poisonings of wild birds are common and some poisoned birds are protected by state or federal laws, the potential for litigation should always be of concern. Therefore, it may be critical to obtain and submit samples following chain-of-custody procedures.

# SPECIFIC TOXICANTS

# NATURAL TOXICANTS

## Algal toxins

### Cyanobacteria

Cyanobacteria (blue-green algae) are prokaryotic, plantlike organisms that are widely distributed in warm, nutrient-enriched waters such as eutrophic temperate lakes and reservoirs during warm weather months or in eutrophic subtropical lakes throughout the year (Zurawell *et al.*, 2005). A variety of factors contribute to the occurrence of an algal bloom such as a stable water column, warm water, high nutrient content (nitrogen, phosphorus, and organics), low N:P ratio, low $CO_2$ availability, and low grazing rates by large zooplankton (Zurawell *et al.*, 2005). One consequence of cyanobacterial blooms is the production of both neurotoxins and hepatotoxins, which are believed to be produced to reduce grazing by zooplankton and protozoa. The hepatotoxic microcystins, produced primarily by *Microcystis* spp. as well as some *Anabaena*, *Anabaenopsis*, *Aphanizomenon*, *Nostoc*, and *Planktothrix* spp., are the most commonly occurring toxins. Other hepatotoxins include nodularins and cylindrospermopsin. Cyanobacterial neurotoxins include anatoxin-a, anatoxin-a(s), and paralytic shellfish poison (PSP). Anatoxin-a is produced by *Anabaena flos-aquae*, *Aphanizomenon flos-aquae*, and *Planktothrix* spp. Anatoxin-a(s) is produced by *Anabaena flos-aquae* and *A. lemmermannii*. In fresh waters, PSPs are produced by *Aphanizomenon issatschenkoi*, *Cylindrospermopsis raciborskii*, and *Planktothrix* spp.

#### Microcystins

A variety of microcystins have been isolated and chemically characterized. They have variable toxicity based upon intraperitoneal (i.p.) injection $LD_{50}$s in mice (from ~50 to >1200 μg/kg) (Zurawell *et al.*, 2005). Microcystins are preferentially taken up by hepatocytes via bile acid transport mechanisms. They are inhibitors of protein phosphatases 1 and 2A and are potent liver tumor initiators and promotors. Protein phosphatases regulate the phosphorylation and dephosphorylation of regulatory intracellular proteins. *In vitro*, microcystins act on intermediate filaments, microtubules, and microfilaments causing altered structural integrity of the hepatocyte cytoskeleton. Apoptosis is also induced by microcystins. They cause rapid blebbing of cell membranes, cell contraction, organelle disruption, chromatin condensation, DNA fragmentation, and ladder formation (McDermott *et al.*, 1998). Following cytoskeletal disruption and subsequent separation of hepatocytes, sinusoidal endothelial cell breakdown allows severe intrahepatic hemorrhage to occur. Death results from hypovolemic shock. In an experimental study in quail, the i.p. $LD_{50}$ of microcystin RR was 256 μg/kg. Interestingly, no liver lesions were noted on necropsy, although spleens of intoxicated birds were approximately twice the size of control birds (Takahashi and Kaya, 1993).

#### Anatoxins

Anatoxin-a is a low molecular weight secondary amine that mimics acetylcholine (ACh). It binds to nicotinic ACh receptors with higher affinity than ACh and it is not susceptible to hydrolysis by acetylcholinesterase (AChE). Anatoxin-a(s) is an OP that binds to AChE preventing ACh hydrolysis.

Wild bird species are more likely to be intoxicated by cyanobacterial toxins than pet birds or poultry given their most common water sources. However, it is possible that zoo birds or production birds such as poultry, gamebirds, or waterfowl can be exposed via their water depending on its source and if conditions conducive to algal blooms are present. There are few documented instances of intoxication of birds, although cyanobacterial toxins are often found in lakes, reservoirs, and rivers used by wild birds. A recent survey of the saline Salton Sea in California detected microcystins in 85% of the samples tested (Carmichael and Li, 2006). Analyses of liver samples of eared grebe (*Podiceps nigricollis*) found microcystins at concentrations believed to be clinically significant. However, the role that microcystins play, if any, in documented large eared grebe die-offs remains to be determined. A bloom of *Microcystis*

*aeurginosa* in a pond in Japan was believed to have played a role in the death of approximately 20 spot-billed ducks (Matsunaga *et al.*, 1999). Although analysis for microcystins was not done, hepatic necrosis was noted in the one bird necropsied.

Anatoxin-a(s) was believed to have been the cause of bird mortality in several Danish lakes. *Anabaena lemmermannii* dominated the blooms and anatoxin-a(s) was detected and bloom material was shown to be toxic to mice (Henriksen *et al.*, 1997; Onodera *et al.*, 1997). Both anatoxin-a and microcystins (LR and RR) were implicated in the mass mortalities of flamingos in Kenya (Krienitz *et al.*, 2003).

#### *Avian vacuolar myelinopathy*

Avian vacuolar myelinopathy (AVM) is a disease of birds that has sporadically caused mortality of bald eagles (*Haliaeetus leucocephalus*), American coots (*Fulica americana*), and other waterbirds in several reservoirs in the southeastern Unites States. AVM is characterized by widespread, bilaterally symmetrical vacuolation of the white matter of the brain and spinal cord. Recent work has demonstrated an association between bird mortality and the presence of the invasive plant hydrilla (*Hydrilla verticillata*) (Wilde *et al.*, 2005). An unknown cyanobacterial species belonging to *Stigonematales* has been found associated with the plant. AVM was reproduced using mallard ducks exposed to *Stigonematales* blooms. It is believed that a currently uncharacterized algal neurotoxin is the cause of AVM.

## Plants

A number of plants are recognized for their toxicity. Plants contain a large variety of biologically active constituents including volatile oils, resins, alkaloids, polysaccharides, phenols, glycosides, and fixed oils. Free-flying companion birds are likely to encounter and eat household plants. Free-ranging production birds encounter plants in their outdoor environment. Both companion birds and production birds can be exposed to potentially toxic plants via their feed. Generally, wild birds are adapted to their environments and are unlikely to inadvertently ingest toxic plants.

The susceptibility of different bird species to specific toxic plants is variable. In addition, birds may be unaffected by plants that are toxic to other animals such as mammals. For example, cedar waxwings and house finches can consume fruit from the pepper tree (*Capsicum annuum*) that is toxic to mammals (Navarro, 1992).

Feeding behaviors also influence the susceptibility to intoxication. For example, it has been suggested that parrots can consume otherwise toxic plants because they remover the outer covering of fruits and seeds, which can contain high concentrations of toxins, before consumption.

There are few documented cases of bird intoxication following plant ingestion. However, there are several experimental studies of the susceptibility of small companion birds such as budgerigars and canaries along with numerous feeding studies using chickens and turkeys. Table 56.1 summarizes published information on plants poisonous to birds. There are published and anecdotal reports of fruit-eating birds being intoxicated by ethanol as a result of eating fermented fruit (Fitzgerald *et al.*, 1990).

## Zootoxins

There are few reports of bird intoxication resulting from exposure to zootoxins. Snakebite was believed to have been responsible for the deaths of two red-tailed hawks (*Buteo jamaicensis*) and a Cooper's hawk (*Accipeter cooperii*) based upon the carcasses being found in the vicinity of venomous snakes and gross findings of hemorrhages, muscle degeneration, and gangrenous necrosis of a limb (Heckel *et al.*, 1994). Chickens, turkeys, and ducks have also reportedly been killed by snakes based upon bite sites being identified on postmortem examination along with the occurrence of compatible gross organ lesions (Lawal *et al.*, 1992).

### *Bacterial toxins*

#### *Botulinum toxin*

Avian botulism results from the ingestion of botulinum toxin produced by *Clostridium botulinum*. There are eight antigenically distinct toxin types designated A, B, C alpha, C beta, D, E, F, and G); the type designations reflect their order of discovery. Type C alpha cultures produce three toxins designated C1, C2, C3, and small amounts of type *D. C. botulinum* is an anaerobic bacterium that persists in the form of dormant spores when environmental conditions are not conducive for bacterial growth. The spores are quite resistant to destruction and can remain viable for years. Spores of type C toxin are widely distributed in wetland sediments and in tissue of wetland organisms. A number of factors play a role in the occurrence of an outbreak of botulism. These include optimal environmental conditions for spore germination and bacterial growth, availability of suitable material to support bacterial replication, and a means for toxin transfer to birds (Friend and Franson, 1999). Most outbreaks occur during summer and fall months when ambient temperatures are relatively high. Bacterial replication requires substrates that are high in protein; decomposing carcasses are good bacterial substrates. Types C1 and D are produced by clostridia containing pseudolysogenic tox+ phages encoding for the respective toxin genes (Zechmeister *et al.*, 2004; Sakaguchi *et al.*, 2005). Genes encoding for C1 toxin are ubiquitous in wetlands inhabited by bird populations (Zechmeister *et al.*, 2004).

Botulinum toxin is one of the most toxic chemicals known, although for any given species toxicity varies

**TABLE 56.1 Plants reported to be toxic to birds**

| Common name | Scientific name | Toxin | Plant part demonstrated to be toxic | Mechanism of toxic action | Primary organ system affected | Species/bird type reported to be affected | References |
|---|---|---|---|---|---|---|---|
| Avocado | *Persea americana* | Persin | Fruit, leaves | Unknown | Cardiovascular system | Budgerigars (*Melopsittacus undulates*); canaries (*Serinus canaria*); cockatiels, ostriches (*Struthio camelus*) | Hargis *et al*., (1989), Shropshire *et al*. (1992), Burger *et al*. (1994), Burrows and Tyrl (2001) |
| Black locust | *Robinia pseudoacacia* | Unknown: possibly glycoprotein lectins, proteins | Leaves, bark | Unknown | Cardiovascular system and gastrointestinal tract | Budgerigars (*Melopsittacus undulates*) | Shropshire *et al*. (1992), Burrows and Tyrl (2001) |
| Bladder pod, rattlebox, coffeeweed, daubentonia, others | *Sesbania* spp. | Saponins, others | Seeds | Smooth muscle inhibition, vasodilation | Nervous system, gastrointestinal tract, kidneys | Chickens | Flory and Hebert (1984), Burrows and Tyrl (2001) |
| Cacao | *Theobroma cacao* | Theobromine, caffeine | Seeds | Adenosine receptor antagonism, increased intracellular $Ca^{++}$ concentrations | Nervous system, cardiovascular system | Chickens | Day and Dilworth (1984) |
| Canola (also referred to as rapeseed), mustards | *Brassica* spp. | Glucosinolates, other | Seeds | Accumulation of trimethylamine affects eggs (odor and taste), liver, and muscle damage due to unknown mechanism. | Eggs, liver, muscle, cardiovascular system | Chickens, Turkeys, ducks | Ratanasethkul *et al*. (1976), Wight *et al*. (1987), Burrows and Tyrl (2001) |
| Cassava | *Manihot* spp. | Cyanide | Root | See section on cyanide | | | |
| Castor bean | *Ricinus communis* | Ricin | Seeds | Protein synthesis inhibition | Gastrointestinal tract, liver | Ducks | Jensen and Allen (1981) |
| Coffee senna, sickle pod, coffeeweed, others | *Senna* spp. (previously, *Cassia* spp.) | Anthraquinones | Fruit and seeds | Irritation, mitochondrial myopathy | Gastrointestinal tract, skeletal muscle | Chickens | Cavaliere *et al*. (1997), Burrows and Tyrl (2001), Haraguchi *et al*. (2003) |
| Corn cockle | *Agrostemma githago* | Saponins | Seeds | Irritation | Gastrointestinal tract | Chickens | Heuser and Schumacher (1942), Burrows and Tyrl (2001) |

between toxin type and age (Barnes, 2003). For example, chickens, turkeys, pheasants, and peafowl are susceptible to types A, B, C, and E, but not to D or F (Gross and Smith, 1971). As broiler chickens age, they become less susceptible to type C toxin (Barnes, 2003). Most outbreaks of botulism in birds are due to exposure to type C1 toxin. Less frequently, exposure to type E has caused mortality of fish-eating birds (Friend and Franson, 1999). Domestic chickens have been intoxicated by type A. Recently, a mosaic neurotoxin (2/3 type C and 1/3 type D) was characterized that was believed to have been responsible for some forms of avian botulism (Takeda *et al*., 2005).

Avian botulism is one of the most important diseases of migratory birds (Friend and Franson, 1999). Filter feeding and dabbling waterfowl are among the species most at risk. Raptors have been intoxicated by feeding on poultry carcasses that have not been disposed of properly. Waterfowl are exposed to botulinum toxin via ingestion of contaminated substrates or via contaminated invertebrates such as maggots that feed on decaying carcasses or other organisms such as zooplankton that are inadvertently contaminated. As few as two maggots can be lethal if ingested. Outbreaks of botulism in avian wildlife result in losses that are quite variable, ranging from a few hundred birds to over one million.

Poultry and other production birds can be affected. Game farm pheasants have been intoxicated by feeding on maggots (Foreyt and Abinanti, 1980). Wound contamination by spores of *C. botulinum* was hypothesized to have contributed to the deaths of caponized chickens (Trampel *et al*., 2005).

Vultures and other carrion eaters are resistant to botulinum toxin, perhaps, in part, due to the production of antibodies to botulinum toxin which does not occur in sensitive species such as chickens and ducks (Gross and Smith, 1971; Ohishi *et al*., 1979; Friend and Franson, 1999).

Botulinum toxin blocks the release of ACh at neuromuscular junctions which results in paralysis. Blockage occurs as a result of the failure of synaptic vesicles containing ACh to fuse with the plasma membrane (Davletov *et al*., 2005). This occurs as a result of the ability of botulinum toxin to cleave and thereby inactivate cellular proteins necessary for fusion.

Clinical signs are consistent with neuromuscular paralysis. Early, affected waterfowl are unable to sustain flight (Friend and Franson, 1999). Leg paralysis in waterfowl causes birds to propel themselves using their wings. Paralysis of the nictitating membrane and neck muscles follows, resulting in an inability to hold the head erect (thus the term limberneck). In chickens, an ascending flaccid paralysis is noted (Barnes, 2003). Initially, affected birds are reluctant to walk and, when forced, appear lame. Similar to waterfowl, the wings droop and the neck becomes weak followed by eyelid paralysis. Waterfowl often drown; affected terrestrial birds die from respiratory and cardiac failure. The time between the onset of clinical signs and death can be as short as few hours. Postmortem lesions are generally not observed; in affected waterfowl, lesions may be consistent with drowning.

A presumptive diagnosis is based upon characteristic clinical signs and environmental conditions conducive to bacterial growth and toxin production. Confirmation of botulism is most often made by using the mouse bioassay to detect the presence of the toxin. Toxin specificity is determined by protecting inoculated mice with specific antitoxins. More recently, enzyme-linked immunosorbent assay (ELISA) and liquid chromatography–mass spectrometry methods have been developed to confirm the presence of toxin (Zechmesiter *et al*., 2004; Barr *et al*., 2005). The mouse bioassay is still considered to be the "gold standard" assay due to the sensitivity of the mouse to botulinum toxin. However, newer methods will likely replace the mouse bioassay in the future.

Treatment of individual affected birds with antitoxin can result in recovery, especially in waterfowl. Other affected species such as coots, shorebirds, gulls, and grebes rarely recover (Friend and Franson, 1999). Difficult logistics, limited availability of antitoxin, and cost of treatment preclude effective intervention in large outbreaks.

Prevention and control of outbreaks are critical to minimize losses. In wetlands, the amount of organic and decaying material should be limited. Prompt removal and disposal via burial or burning of animal carcasses is important during outbreaks to interrupt bacterial growth and toxin production. Immunization with inactivated bacterin-toxoids is protective but vaccination of large poultry flocks or waterfowl is expensive and, in the case of waterfowl, logistically difficult.

### *Biogenic amines*

Biogenic amines, such as gizzerosine, histamine, histidine, cadaverine, spermine, and putrescine result from the heating or bacterial spoilage of fish and animal by-products (Barnes *et al*., 2001; Brown and Julian, 2003). Poultry are potentially exposed to the amines when fish or meat meal is incorporated into their diets. Toxic concentrations vary depending on the specific amine. Dietary histamine at 0.1% is associated with reduced feed conversion and body weights in broiler chickens (Barnes *et al*., 2001). Dietary spermine is toxic to 120-week-old chicks at 0.2% (Sousadias and Smith, 1995). Putrescine is toxic at concentrations >0.05% (Chowdhury, 2001). Interestingly, a dietary concentration of putrescine of 0.05% has been associated with improved eggshell quality (Chowdhury, 2001). The improvement was hypothesized to be due to increased calcium transport.

Biogenic amines at toxic concentrations cause digestive disturbances. Gizzerosine causes gizzard erosion and hemorrhage. A dietary histamine concentration of 4 ppm results

in localized gizzard lesions and reduced growth rates in chicks (Harry and Tucker, 1976). In addition to gastrointestinal effects, toxic biogenic amine concentrations cause a malabsorption syndrome in chickens characterized by reduced feed efficiency and enlargement of the proventriculus (Barnes *et al.*, 2001).

## Feed additives

### *Arsenicals*

Arsenic exists in a variety of inorganic and organic forms and valences. Arsenic trioxide was used as an herbicide. Pentavalent and trivalent sodium, potassium, and calcium salts of arsenic have been used as insecticides, especially for ants. Trivalent organic forms of arsenic include the herbicides monosodium methanarsonate (MSMA) and disodium methanarsonate (DSMA) and thiacetarsamide, previously used for treating dogs with heartworm. Pentavalent arsenicals used as feed additives include arsanilic acid, sodium arsanilate, 3-nitro-4-hydroxyphenylarsonic acid (3-nitro, roxarsone), and 4-nitrophenylarsonic acid. Arsanilic acid and 3-nitro are the most commonly used organic arsenicals in poultry production (Feed Additive Compendium, 2005). They are used to increase feed efficiency, promote growth, improve pigmentation, and prevent coccidiosis. While exposure of birds to inorganic arsenic salts can occur, most avian arsenic intoxications involve exposure of poultry to pentavalent organic arsenicals.

Pentavalent organic arsenicals are believed to substitute for phosphate in oxidative phosphorylation. Uncoupling of oxidative phosphorylation results in cellular energy deficits (Ensley, 2004). Intoxication occurs most commonly due to feed mixing errors. Clinical signs have occurred in turkeys exposed to dietary concentrations of 3-nitro approximately twice the recommended dose. Clinical signs in affected birds include stunting, depression, apparent lameness, and ataxia. Gross lesions are typically absent, but histopathologically, Wallerian degeneration of the optic and peripheral nerves occurs. Wallerian degeneration can also occur in the spinal cord (Ensley, 2004). Ulcerative cholecystitis has been reported in turkey poults intoxicated by 3-nitro (Brown *et al.*, 1991).

Diagnosis of organic arsenical intoxication in poultry depends on detection of potentially toxic concentrations in representative feed samples and the occurrence of compatible clinical signs and postmortem lesions. Treatment consists of removing the offending feed and providing accessible feed and water.

Arsenic has been detected at relatively high concentrations in some seabirds including albatrosses and gulls (Kubota *et al.*, 2003). It is present in tissues primarily as the organic arsenical, arsenobetaine, which is relatively non-toxic.

A significant percentage of the human tolerable daily intake of arsenic can come from arsenic residues in poultry meat (Taylor, 2004). Measurable increases in soil arsenic concentrations can occur as a result of using litter from arsenic-treated poultry as fertilizer (Garbarino *et al.*, 2003; Rutherford *et al.*, 2003).

### *Sodium*

Sodium ion intoxication is a significant problem in poultry production. Intoxication can result from excessive sodium in the feed, water deprivation, or ingestion of saline waters (Brown and Julian, 2003). The most common form of sodium associated with intoxication is sodium chloride. Sodium sesquicarbonate, used as a buffering agent in ruminant feeds containing high concentrations of urea, was responsible for high mortality in broiler chickens as a result of a feed misformulation (Sander *et al.*, 1998). High dietary sodium can be well tolerated if access to water is not restricted. For example, 15-day-old turkey poults tolerated up to 10% sodium chloride in their mash for 14–16 days when drinking water was not restricted (Gitter *et al.*, 1979). However, young chicks and poults can be intoxicated from sodium in feed despite adequate water intake. Sodium concentrations in both the feed and water need to be considered in assessing sodium exposure.

A number of factors influence the toxicity of the sodium ion including bird age, bird species, dietary factors, and water quality and accessibility. Young birds are more sensitive to sodium ion toxicity, most likely due to less developed renal function. Turkeys are more susceptible to intoxication than chickens (Berger, 1993). In addition, birds have less ability to excrete salts in excess of water, so their ability to reduce high-plasma osmolality is limited (Barnes, 2003). Some waterfowl have nasal salt glands that provide an additional excretory route. In general, the addition of 1% salt (as sodium chloride) to poultry rations is safe, even for very young birds. A level of 0.25% salt in drinking water is considered to be safe (Berger, 1993).

At high sodium intakes, birds develop acute, severe diarrhea and dehydration, lose weight, and die. Renal function is often impaired, especially if sodium bicarbonate is the source for exposure (Barnes, 2003). Lower, but still toxic, sodium intakes primarily cause cardiac overload, ascites, dyspnea, and edema. Loose droppings, decreased feed intake, and poor growth are often observed. Thirteen-week-old tom turkeys affected by high dietary sodium chloride concentrations (~8%) exhibited polydipsia, diarrhea, ataxia, tremors, depression, sternal and lateral recumbency, torticollis, and death (Wages *et al.*, 1995).

Ascites, edema, fluid in the lungs, hydropericardium, cardiac hypertrophy (right-sided in chickens and bilateral in poults), and dilatory cardiomyopathy (poults) are found on postmortem examination. Most microscopic lesions are secondary to cardiac failure, although bilaterally symmetrical

areas of cerebral necrosis, vascular congestion, and edema were noted in intoxicated tom turkeys (Wages *et al*., 1995).

Sodium intoxication in waterfowl has been associated with the ingestion of hypersaline water or salt that has precipitated on feathers (Windingstand *et al*., 1987; Meteyer *et al*., 1997; Gordus *et al*., 2002; Stolley and Meteyer, 2004). Significant gross and microscopic lesions in ruddy ducks intoxicated by sodium include conjunctivitis, lens opacity, cataract formation, vascular congestion in multiple organs especially in the meninges, and myocardial and skeletal muscle degeneration (Gordus *et al*., 2002).

The use of sodium chloride as a deicing agent on roads is believed to intoxicate passerine birds. Experimentally sodium chloride was lethal to house sparrows dosed with a concentrated sodium chloride solution providing 8000 mg/kg (0.8%) (Bollinger *et al*., 2005).

A diagnosis of sodium ion intoxication relies on detection of high dietary and/or water, serum and/or brain sodium concentrations. The significance of detected dietary and water sodium concentrations needs to be assessed in conjunction with other historical, clinical, and postmortem findings. Serum sodium concentrations >150 mEq/l are elevated and brain sodium concentrations >2000 ppm wet weight are highly suggestive of intoxication (Puls, 1994).

### *Vitamin A*

Vitamin A is an essential micronutrient that plays a role in normal vision, reproduction, immunity, membrane integrity, growth, and embryogenesis. Vitamin A intoxication has been produced experimentally in poultry and cockatiels (Tang *et al*., 1985; Koutsos *et al*., 2003). Osteodystrophy occurred in broiler and leghorn chicks exposed to 330–660 IU vitamin A per day for 21 days (Tang *et al*., 1985). Skeletal development was affected in growing chickens given 200 mg retinyl acetate per kg (Baker *et al*., 1967). Anorexia, conjunctivitis, eyelid adhesions, and encrustations around the mouth were also noted by Tang. Cockatiels fed approximately 30,000 μg per kg of vitamin A (as retinol) for 269 days exhibited intensified vocalization patterns, pancreatitis, multifocal accumulation of lymphocytes in the lamina propria of the duodenum, and reduced body condition (Koutsos *et al*., 2003). Intakes of 3000 μg per kg of vitamin A also caused clinical signs, but they were less severe. A diagnosis of vitamin A intoxication can be made based upon measurement of high vitamin A concentrations in representative feed samples and in serum or liver tissue along with the occurrence of compatible clinical signs.

### *Vitamin D*

Vitamin D is required for normal calcium and phosphorus homeostasis which, in turn, is important for normal bone, beak, claw, and eggshell formation. Poultry diets are commonly supplemented with vitamin D in the form of cholecalciferol ($D_3$) (Barnes, 2003). Vitamin D stimulates the absorption of calcium from the gastrointestinal tract, influences osteoblast and osteoclast activity, and increases renal tubular reabsorption of calcium. Exposure to excessive vitamin D results in increases in calcium absorption from the gastrointestinal tract and renal tubules, and calcium mobilization from bone. High blood and tissue calcium concentrations cause metastatic tissue calcification. In broiler chicks, dietary concentrations of 30,000 IU/kg are toxic when fed during growth. Much higher doses of vitamin D can rapidly cause renal calcification and damage. Aortic and arterial calcification can also occur. Postmortem lesions include parathyroid gland atrophy, renal tubular and aortic calcification, and calcification of blood vessel walls in the brain. Older birds are less sensitive to vitamin D than younger, actively growing birds. Other forms of vitamin D are also potentially toxic. Relative toxicity is vitamin $D_2$ > vitamin $D_3$ > 25-monohydroxycholecalciferol > 1,25-dihydroxycholecalciferol (Barnes, 2003). Nephrocalcinosis was experimentally produced in chicks by feeding powdered leaves from *Cestrum diurnum* which contains an analog of 1,25-dihydroxycholecalciferol (Sarkar *et al*., 1981).

### *Drugs*

A number of chemotherapeutic agents have caused intoxications in birds, primarily in poultry and pet birds. In most cases, intoxication results from inappropriate or overuse of a drug. Table 56.2 lists chemotherapeutic agents associated with adverse effects in birds. Two drugs have been documented to intoxicate birds of prey as a result of feeding on carcasses from animals administered the drugs prior to death. Carcass residues of the non-steroidal anti-inflammatory, diclofenac, have been shown to cause renal failure, visceral gout, and death in oriental white-backed vultures (*Gyps bengalensis*) and long-billed vultures (*G. indicus*) in the Indian subcontinent (Oaks *et al*., 2004; Shultz *et al*., 2004). Diclofenac has been a widely used veterinary drug in regions with affected birds. In the United States, use of pentobarbital for euthanasia has resulted in secondary intoxication of raptors feeding on carcasses from euthanized animals (O'Rourke, 2002). Intoxication has occurred from scavenging carcasses not disposed of properly on farms or landfills.

## Pesticides

### *Insecticides*

#### *Organochlorine insecticides*

Historically, OCs were widely used from the 1940s to the 1970s in agriculture and forestry and for mosquito control. The most widely used organochlorines included the dichlorodiphenylethanes (DDT, methoxychlor, and dicofol), cyclodienes (aldrin, dieldrin, heptachlor, chlordane, and endosulfan), and hexachlorocyclohexanes (lindane

**TABLE 56.2 Drug intoxications in birds**

| Drug | Effects | Clinical signs | Pathologic lesions | References |
|---|---|---|---|---|
| Sulfonamides | Blood dyscrasias, bone marrow depression, anemia, thrombocytopenia, lymphoid depression, impaired immune function. | Depression, pallor, weight loss, decreased egg production and quality, icterus, depigmentation of brown eggs | Widespread hemorrhage, pale bone marrow, swollen, pale red or icteric liver, splenic enlargement, ulcers at proventricular-gizzard junction | Reece *et al*. (1985), Daft *et al*. (1989), Brown and Julian (2003) |
| Nitrofurans | Furazolidone causes a dose-related biventricular cardiomyopathy<br>Chronic exposure can delay sexual maturity in male broiler breeder chickens | Depression, incoordination, ruffled feathers, growth retardation, hyperexcitability, tremors, loud vocalization, opisthotonus, aimless running, seizures | Dilation of ventricles of the heart, thinning of right or left ventricular wall, passive congestion with lung edema, liver congestion, ascites | Reece *et al*. (1985), Brown and Julian (2003) |
| Aminoglycosides | Lysosomal dysfunction in renal tubular epithelial cells leading to necrosis; impaired synthesis of protective vasodilatory renal prostaglandins<br>Apoptosis in cochlear sensory hair cells | Gentamicin causes depression, edema, injection site hemorrhages, large pale nephritic kidneys; weakness, and apnea<br>Ototoxicity<br>Egg inoculation associated with embryo deaths<br>Streptomycin and dihydrostreptomycin sulfate associated with respiratory distress, paresis, and mild convulsions | Increased number of lysosomes containing myelin figures in renal tubule cells<br>Renal tubular cell necrosis<br>Degeneration of the apical portion of cochlear hair cells | Bird *et al*. (1983), Boothe (2001), Woolley *et al*. , (2001), Brown and Julian (2003) |
| Nicarbazin | Increases metabolic rate and heat production<br>Increases lipoprotein lipase activity<br>Acts as a $Ca^{++}$ ionophore | Poor eggshell pigmentation, decreased egg weight, decreased egg hatchability, growth depression, increased susceptibility to heat stress | No diagnostic lesions | Reece *et al*. (1985), Hughes *et al*. (1991) , Brown and Julian (2003), Yoder *et al*. (2006), |
| Dimetridazole (other nitroimidazoles) | Possible free radical damage to DNA and other molecules | Growth depression, decreased egg production, incoordination, inability to fly, aimless running, vocalization, tremors, seizures | No diagnostic lesions | Riddell (1984), Brown and Julian (2003) |
| 3,5-dinitro-*o*-toluamide | Purkinje cell dysfunction | Ataxia, torticollis, reduced growth | Necrosis and depletion of Purkinje cells of the cerebellar cortex | Reece and Hooper (1984), Brown *et al*. (2003) |
| Ivermectin (and other macrolide endectocides) | GABA agonist | Somnolence, listlessness, ataxia, bradypnea, mydriasis | No diagnostic lesions | Kim and Crichlow (1995), Brown and Julian (2003) |

and benzene hexachloride). While these insecticides are no longer used in the United States, Canada, and Europe, they continue to be used in developing countries. These compounds are highly lipophilic and, in general, have long environmental and body half-lives (Blus *et al.*, 1996). Because of their lipophilic and persistent nature, they biomagnify within food webs. They were banned due to their environmental persistence, concern about their impact on human health, and widespread insect resistance.

OCs can be acutely toxic and a large number of avian mortality events following exposure have been documented (Friend and Franson, 1999). Acutely, the OCs are neurotoxic as a result of their ability to prolong the opening of sodium channels (DDT) or act at presynaptic terminals (cyclodienes and lindane) (Blus *et al.*, 1996). Signs of neurotoxicity include hypersensitivity, muscle twitching and tremors, and intermittent to continuous tonic–clonic seizures (Blus *et al.*, 1996). Death is most often due to respiratory failure and hypoxia. OCs can accumulate within fat reserves to high concentrations; storage in fat prevents adverse effects from occurring within the nervous system. However, rapid mobilization of residues from fat can precipitate signs of intoxication.

Dichlorodiphenyldichloroethylene (DDE, a metabolite of DDT) was responsible for perhaps the most widely known sublethal effect of the OCs on several avian wildlife populations. Sublethal effects included failure of adults to breed, eggshell thinning, and a decrease in hatchability of eggs and survival of young birds (Blus *et al.*, 1996). DDE impairs the translocation of calcium from the mucosa cells of the shell gland to the shell gland cavity and alters the ratio of calcium bound per mole of ATP hydrolyzed during shell formation. DDE can also inhibit calmodulin. The sublethal, reproductive effects of DDE were species specific. Widespread population declines were noted in peregrine falcons, double-crested and great cormorants, ospreys, bald eagles, merlins, and brown pelicans (Blus, 2003). Interestingly, some bird species such as American kestrels, Great blue herons, and domestic chickens are resistant to the reproductive effects of DDE. OCs such as DDT, DDE, methoxychlor, and chlordecone exhibit estrogenic activity. Also, OCs induce liver microsomal enzymes which, in turn, alter sex hormone metabolism (Blus, 2003).

Although acute intoxication is rare, a diagnosis is based upon the occurrence of characteristic signs and detection and quantification of OCs in brain samples. Gross or histopathologic findings are generally absent (Friend and Franson, 1999). Occasionally, residues of OCs are a concern in poultry intended for human consumption following exposure to sublethal concentrations.

*Cholinesterase inhibitors (organophosphorus and carbamate insectisides)*

Due to their more rapid breakdown in the environment, OP and carbamate insecticides replaced the organochlorine pesticides as the later were banned for use in North America and Europe in the 1960s and 1970s. A number of different formulations are available for use either in the environment (e.g. agricultural or residential use) or on animals (e.g., livestock dips or sprays). OPs and carbamates are formulated as liquids, granules, and powders. The more toxic insecticides of each group are generally restricted to agricultural uses, whereas less toxic members are approved for use on animals or in residential environments. Although chemically distinct, the OPs and carbamates have a common mechanism of toxic action, namely, the inhibition of cholinesterase enzymes.

Possible exposure scenarios are numerous. Pet birds can be exposed via their diets, via home or premise use, or via direct application. Inhalation exposure is also possible from the use of dichlorvos-impregnated pest strips or premise spraying or fogging. Poultry and other production birds can be exposed in similar ways. There are relatively few documented reports of acute pet or production bird intoxication from the use of OPs or carbamates. However, acute OP and carbamate intoxications are common in wild birds and, while the numbers of affected birds is difficult to assess, losses are significant. For example, at the height of use of granular formulations of the carbamate insecticide, carbofuran, 17 to 91 million birds were estimated to have died annually (Mineau, 2005).

Exposure of wild birds to these insecticides can occur via ingestion of treated seeds or vegetation (accidental, intentional, or misuse of a product), poisoned insects or animals (impaired live animals or carcasses), product (especially granular formulations), or contaminated water (Friend and Franson, 1999). Inhalation or dermal exposure is also possible from spraying or spills. With avian wildlife there can be some degree of seasonality to OP or carbamate intoxications as a result of season patterns of insecticide use.

The acute oral toxicity of individual OPs and carbamates varies considerably within each of their classes. For example, within the carbamate insecticide class, the acute oral $LD_{50}$s for carbofuran and carbaryl in mallard ducks are 0.5 mg/kg b.w. (body weight) and $>2000$ mg/kg b.w., respectively (Friend and Franson, 1999). Also, acute oral toxicities of specific OP or carbamate insecticides vary considerably between species. The acute oral $LD_{50}$s of ethion range from 45 mg/kg for blackbirds to $>2000$ mg/kg for mallard ducks (Friend and Franson, 1999). A number of other factors can influence toxicity including age, sex, diet, body condition, and product formulation.

Some OPs, including insecticides such as leptophos, mipafox, and cyanofenphos and industrial chemicals such as tri-*ortho*-cresyl-phosphate (TOCP) cause a delayed neurotoxic effect referred to as OP-induced delayed neuropathy (OPIDN). OPIDN occurs as a result of inhibition of neurotoxic esterase, an enzyme found in peripheral nerves. OP insecticides are tested for their ability to cause OPIDN in adult hens as a result of their unique sensitivity to this effect. Also, pheasants and mallard ducklings are highly

susceptible to delayed neurotoxicity (Brown and Julian, 2003). Most OPIDN-inducing insecticides are no longer on the market (Hill, 2003).

As previously mentioned, OPs and carbamates inhibit cholinesterase enzymes. Inhibition of AChE is primarily responsible for the clinical signs associated with intoxication. Enzyme inhibition prevents the breakdown of ACh at the synapses and neuromuscular junctions. As a result ACh overstimulates muscarinic and nicotinic receptors in the central and peripheral nervous systems. Clinical signs include: convulsions, hyperexcitability, opisthotonus, lethargy, miosis or mydriasis, apparent blindness, ataxia, muscular weakness, tachypnea, dyspnea, emesis, defecation/diarrhea, piloerection, lacrimation, ptosis, and epistaxis (Friend and Franson, 1999). The onset of clinical signs and death can be rapid; birds are often found dead. Death is most often due to respiratory failure and hypoxia. Gross and histopathologic lesions in dead birds are usually minimal and non-specific. Gastrointestinal contents should be examined carefully, since the presence of granules or dye might suggest pesticide exposure. Often, given the rapidity of death, there is freshly ingested food in the upper gastrointestinal tract. OP inhibition of AChE activity can be irreversible, thus necessitating synthesis of new enzyme before recovery can occur. Carbamates do not irreversibly inhibit AChE and spontaneous regeneration of enzyme activity is rapid. Clinical signs can persist for days in OP intoxicated animals, whereas recovery from carbamate intoxication is generally completed within 2–3 days.

A diagnosis of intoxication is dependent on measuring reduced activity of cholinesterase along with identification of a specific insecticide in suitable antemortem or postmortem samples. In birds, plasma is suitable for cholinesterase activity determinations. Brain cholinesterase activity can be measured in dead birds. Depending on the size of the brain, either a whole brain or a right or left brain half should be submitted for analysis. It is important to point out that because carbamate inhibition of cholinesterase activity is readily reversible, even after death, care must be taken in interpreting laboratory results. In general, cholinesterase activity <50% of normal suggests significant exposure to an OP or carbamate (activity is often <20% of normal following lethal exposures) (Hill, 2003). Normal plasma/whole blood and brain cholinesterase activities are quite variable among bird species and interpretation of cholinesterase activity should be based on species specific, and when possible, laboratory specific reference ranges. Reference ranges for cholinesterase activity in plasma and brain from a variety of bird species have been published (Westlake *et al.*, 1983; Hill, 1988). Gastrointestinal contents and liver samples should be submitted for detection of a specific insecticide to confirm exposure. Urine should be submitted for detection of major metabolites of OPs (Jain, 2006).

Treatment of OP or carbamate intoxication can be effective. Atropine is used to block muscarinic receptor stimulation and its timely administration can provide rapid relief from life-threatening clinical signs. Atropine is given to effect and repeated administration is often required. Effective doses of atropine may need to be much higher in birds (25–50 mg/kg b.w. given intramuscularly (i.m.)) than generally recognized based upon experimental work in broiler chickens exposed to the OP, diazinon, or the carbamate, methomyl (Shlosberg *et al.*, 1997). Pralidoxime (2-PAM) is also given to promote AChE reactivation in OP poisoned animals. Again, effective doses in birds may need to be higher than generally recommended for mammals (up to 100 mg/kg b.w. given i.m. (Shlosberg *et al.*, 1997). Birds should be atropinized prior to administration of 2-PAM. 2-PAM is more effective when given as soon after OP exposure as possible due to the irreversible aging of AChE enzyme. 2-PAM is generally not indicated in carbamate intoxications due to the spontaneous regeneration of acetyl-cholinesterase.

Otherwise sublethal exposure to OPs or carbamates can result in mortality as a result of a variety of effects: increased vulnerability to trauma or predation, reduced ability to regulate body temperature and therefore increased susceptibility to hypothermia, and reduced activity leading to decreased feeding and weight loss (Friend and Franson, 1999; Hill, 2003). In addition, birds can be indirectly affected by reduced availability of food as a result of prey die-offs.

Fortunately, the overall adverse impact of agricultural pesticide use in general, and OPs and carbamate use more specifically, on avian wildlife has lessened over the last decade. This is due primarily to the replacement of older more toxic insecticides with newer, less toxic ones such as pyrethrins/pyrethroids and neonicotinoids (Mineau and Whiteside, 2006).

### *Pyrethrins/pyrethroids*

Naturally occurring pyrethrin (derived from chrysanthemum flowers) and synthetic pyrethroid insecticides are currently estimated to make up more than 25% of insecticide use worldwide (Volmer, 2004). Their popularity is due to their lack of environmental persistence and relatively low toxicity for birds and mammals (they are highly toxic for fish). They are used to control a variety of agricultural, home, and animal pests and are available in a large number of formulations including sprays, dusts, dips, shampoos, spot-ons, foggers, ear tags, wettable powders, granules, soluble powders, and emulsifiable concentrates. They are often combined with synergists such as piperonyl butoxide to enhance their insecticidal activity.

Pyrethrins and pyrethroids have low toxicity for birds. For example, the acute oral $LD_{50}$ of cypermethrin for mallard ducks is >4640 mg/kg and the dietary $LC_{50}$ for

mallard ducks and bobwhite quail is >20,000 ppm (Extoxnet). The 8-day $LC_{50}$ of deltamethrin for ducks and quail is >4650 mg/kg and >10,000 mg/kg, respectively. Permethrin is practically non-toxic to birds with acute oral $LD_{50}$s for one permethrin formulation (Pramex™) of >9900 mg/kg, >13,500 mg/kg, and >15,500 mg/kg for mallard ducks, pheasants, and Japanese quail, respectively (Extoxnet).

Pyrethrins and pyrethroids are neurotoxic as a result of their ability to alter sodium channels and cause repetitive nervous discharges or membrane depolarization. Clinical signs associated with acute intoxication are related to nervous system stimulation. There does not appear to be any adverse behavioral effects on avian wildlife following sublethal exposures to pyrethrins/pyrethroids, similar to those reported for OPs or carbamates, which would cause mortality due to increased predation or inability to obtain food. However, this possibility should be further investigated.

*Boric acid*

Boric acid is used in poultry litter to control darkling beetles (Brown and Julian, 2003). Recommended litter treatment concentrations are between 0.4 and 0.9 kg per 9.3 $m^2$ (Dufour *et al*., 1992). Boric acid has a relatively high acute oral $LD_{50}$ for 1-day-old chickens of 2.95 g/kg b.w. (Sander et al., 1991). Exposure of 1-day-old chicks to litter treated with up to 7.2 kg boric acid per 9.3 $m^2$ of litter for 15 days exhibited a dose-related feathering abnormality, but no effect on productivity and no lesions were noted. Exposure of poultry to litter treated with recommended amounts of boric acid is unlikely to be toxic.

*Nicotine*

Nicotine sulfate has been used to paint chicken roosts to control mites and has been given orally for internal parasites (Brown and Julian, 2003). Nicotine is a highly toxic alkaloid that stimulates nicotinic receptors at neuromuscular junctions. Initial receptor stimulation is followed by a depolarizing blockade. Death is due to hypoxia as a result of paralysis of the diaphragm and chest muscles. Currently, nicotine use as an insecticide is not common. Perhaps of more concern is the passive exposure of pet birds to cigarette, cigar, or pipe smoke. Chronic ocular, dermatologic, and respiratory diseases in pet birds have been associated with tobacco smoke exposure (Dumonceaux and Harrison, 1999).

Neonicotinoids, a new class of insecticide, are also nicotinic receptor agonists. They are considered to have low toxicity for vertebrates because of relatively low affinity for vertebrate nicotinic receptors compared to insect nicotinic receptors (Tomizawa and Casida, 2005). Neonicotinoids include acetamiprid, clothianidin, dinotefuran, imidicloprid, nitenpyram, thiacloprid, and thiamethoxam.

***Rodenticides***

*Anticoagulants*

Anticoagulant rodenticides are the most widely available and used rodenticides. They can be categorized as "first-generation" and "second-generation" anticoagulants. First-generation compounds include warfarin and indanediones such as chlorophacinone and diphacinone (Means, 2004). Because of rodent resistance to first-generation compounds, second-generation compounds such as brodifacoum, bromadiolone, difenacoum, and difethialone were developed and are now more commonly used than first-generation compounds. Products are formulated as pellets, wax blocks, and tracking powders. Warfarin products generally contain 0.025% active ingredient (AI) while second-generation compounds contain 0.05% AI (Means, 2004). Difethialone products usually contain 0.0025% AI. Second-generation anticoagulants are designed to kill rodents after one feeding and are more toxic and have much longer half-lives than warfarin.

Anticoagulant rodenticides have a common mechanism of toxic action. They block vitamin K-dependent clotting factor synthesis (factors II, VII, IX, and X) secondary to inhibition of vitamin-$K_1$ epoxide reductase. Thus, the extrinsic, intrinsic, and common coagulation pathways are affected in mammals, although in birds, affects on the extrinsic and common pathways may be more important (James *et al*., 1998). Clinical signs are often non-specific such as depression, anorexia, and weakness or are related to a coagulopathy such as subcutaneous (s.c.) hemorrhages, epistaxis, and oral petechiation (James *et al*., 1998). The onset of clinical signs is often delayed for several days after exposure to a toxic amount of anticoagulant since existing coagulation factors need to be depleted before hemorrhage occurs.

Available avian toxicity information is most often expressed as a median lethal concentration ($LC_{50}$) of anticoagulant included in feed over a defined period of time (Petterino and Paolo, 2001). A few $LD_{50}$ values are also available (see Table 56.3). There is little toxicity data available for species such as raptors which are likely to be exposed to the anticoagulants following ingestion of exposed and/or intoxicated prey.

There are almost no reported cases of anticoagulant rodenticide intoxication in poultry. There is one case report of coumafuryl toxicity in chickens <1 week of age (Munger *et al*., 1993). Exposure occurred as a result of contaminated wood-straw mats used to ship the birds. The low incidence of intoxication most likely reflects the relatively controlled environments associated with most commercial poultry production. Exposure is more likely in free-roaming poultry.

There are several documented cases of anticoagulant intoxication in captive wild birds including waterfowl, raptors, and bird-of-paradise (James *et al*., 1998; Poppenga, personal experience). Fortunately, most institutions

TABLE 56.3 Toxicity of anticoagulant rodenticides for birds

| Anticoagulant | Avian species | Acute, oral $LD_{50}$ | Dietary $LC_{50}$ |
|---|---|---|---|
| Warfarin | Japanese quail | 2000 mg/kg b.w. | |
| | Chickens | | >50 ppm b.w. – 96 h |
| Brodifacoum | Chicken | 4.5 mg/kg b.w. | |
| | Mallard duck | 0.31 mg/kg b.w. | 2.7 ppm – duration not specified |
| | Bobwhite quail | | 0.8 ppm – duration not specified |
| Bromodiolone | Mallard duck | | 110 ppm – 5 days |
| | Quail | 1600 mg/kg b.w. | |
| | Bobwhite quail | 138 mg/kg b.w. | |
| Difenacoum | Chicken | >50 mg/kg b.w. | |
| Difethialone | Mallard duck | | 1.95 ppm – 30 days |
| | Bobwhite quail | 0.264 mg/kg b.w. | 0.56 ppm – 30 days |
| Flocoumafen | Mallard duck | 24 mg/kg b.w. | 1.7 ppm – 5 days |
| | Japanese quail | >300 mg/kg b.w. | 37 ppm – 5 days |
| | Chicken | >100 mg/kg b.w. | 16.4 ppm – 5 days |
| Chlorophacinone | Mallard duck | | 204 ppm – 30 days |
| | Bobwhite quail | | 95 ppm – 30 days |
| Diphacinone | Mallard duck | 3158 mg/kg b.w. | |
| Pindone | Mallard duck | | 250 ppm – 8 days |
| | Bobwhite quail | | 1560 ppm – 8 days |

housing wild birds recognize risks associated with anticoagulant rodenticide use and either use alternative rodenticides or take precautions to avoid exposure.

Exposure of wild birds to anticoagulants either via bait ingestion or through ingestion of exposed and/or intoxicated prey is a major concern. The long half-lives of second-generation anticoagulants result in intoxication risks associated with repeated exposures to relatively low doses of the compounds. Avian species that feed primarily on small rodents are at greatest risk. Soon after the introduction of second-generation anticoagulants, the potential for secondary intoxication of raptor species such as owls was investigated (Mendenhall and Pank, 1980; Townsend *et al.*, 1981). Residues have been measured in a number of bird species (Merson and Byers, 1984; Hegdal and Colvin, 1988; Berny *et al.*, 1997; Stone *et al.*, 1999; Eason *et al.*, 2002; Stone *et al.*, 2003). Although anticoagulant intoxication has been documented in a number of individual birds, population impacts are less clear.

Diagnosis of intoxication is dependent on antemortem and/or postmortem evidence of a coagulopathy and the detection of an anticoagulant in blood, serum, or liver samples. Merely finding a residue of an anticoagulant in an animal is not sufficient for a diagnosis of intoxication since residues are often found in the absence of a coagulopathy.

Vitamin $K_1$ is antidotal treatment, although there is some delay before coagulopathy resolves. Dosing regimens have not been well defined in avian species, but vitamin $K_1$ at 0.2–2.2 mg/kg given i.m. or s.c. every 4–8 h until the bird is stabilized has been recommended (James *et al.*, 1998). Once stabilized, vitamin $K_1$ given at similar doses once daily for 2 weeks or longer is indicated.

***Avicides***

Avicides are marketed primarily to control pest bird species such as blackbirds, pigeons, and grackles, among others. They are designed to be placed on grain for baiting in such a way as to only affect a few individuals in a flock. The clinical signs exhibited by affected birds (distress cries and aerial distress displays) are such that unaffected birds are scared away. Two commonly used avicides are 4-aminopyridine and 3-chloro-*p*-toluidine hydrochloride (see Table 56.4).

A number of chemicals have been investigated for their ability to repel birds (Clark, 1998; Dolbeer *et al.*, 1998; Stevens and Clark, 1998). Repellants such as methyl anthranilate are generally not associated with lethal intoxication.

# ENVIRONMENTAL TOXICANTS

## Pentachlorophenol

Pentachlorophenol (PCP) is used primarily as a wood preservative. Poultry have been exposed to sawdust and shavings from PCP-treated wood (Brown *et al.*, 1997). Adverse effects associated with PCP include reductions in growth rates, kidney hypertrophy, and decreased humoral immune response (Stedman *et al.*, 1980; Prescott *et al.*, 1982). PCP exposure can also result in an off-taste to eggs and meat as a result of degradation of chlorophenols to chloroanisols (Frank *et al.*, 1983).

TABLE 56.4 Rodenticides, avicides, and molluscicides toxic for avian species

| Rodenticides/ avicides/ molluscicides | Uses | Formulations | Avian toxicity | Mechanism of toxic action | Clinical signs | Species affected | References |
|---|---|---|---|---|---|---|---|
| 4-aminopyridine (Avitrol®) | Control red winged blackbirds, blackbirds, grackles, pigeons, and sparrows | Powder concentrate; 0.5–3.0% grain baits; 3% cracked corn bait for agricultural use diluted to 0.03% with untreated grain; 1% whole corn diluted to 0.1% for crows; 0.5% bait for pigeons | Highly toxic for most species, including birds; $LD_{50}$s for birds range from 1.4 to 8.1 mg/kg | Blocks potassium ion channels and increases release of ACh | Distress cries, aerial distress displays, seizures, coma | Potentially all birds | Bischoff *et al*. (2001), Schell (2004a, b) |
| Bromethalin | Rodenticide | 0.01% tan or green grain-based pellets in 16–42.5 g place packs | Not determined | Uncouple oxidative phosphorylation | Not described in birds; clinical signs in mammals are dependent on ingested dose with CNS excitation noted with high doses and paralysis noted with lower doses | Potentially all birds | Dorman (2004) |
| 3-chloro-*p*-toluidine hydrochloride (Starlicide®) | Control ravens, starlings, crows, pigeons, cowbirds, grackles, magpies, and certain gull species | 98% powder used to prepare baits; 0.1% ready-to-use product | Highly toxic for most species including birds. $LD_{50}$s for birds of 1.8–3.8 mg/kg b.w. | Unknown | Decreased activity, tachypnea, dyspnea, renal failure | Potentially all birds | Schell (2004a, b) |
| Fluoroacetate (1080) | Rodenticide, coyote control | Use restricted to livestock protection collars (LPCs). LPCs for sheep and goats contain 30 ml at 1% | Oral $LD_{50}$s for magpies are 1.78–2.3 mg/kg b.w. | Blocks tricarboxylic acid cycle resulting in cell energy depletion | Vary depending on species; not well described in birds; CNS, gastrointestinal, and cardiovascular signs likely; skeletal muscle necrosis reported in mallard ducks | Potentially all birds; proper use of LPCs appears to present little to no intoxication risk to avian scavengers | Burns and Connolly (1995), Ataria *et al*. (2000), Parton (2004) |

(Continued)

TABLE 56.4 (Continued)

| Rodenticides/ avicides/ molluscicides | Uses | Formulations | Avian toxicity | Mechanism of toxic action | Clinical signs | Species affected | References |
|---|---|---|---|---|---|---|---|
| Metaldehyde | Control slugs and snails | Pelleted baits, granules, liquids, or wettable powders containing <5% metaldehyde | Minimum lethal doses for chickens and ducks are 500 and 300 mg/kg b.w., respectively | Decrease GABA in the brain alterations of other brain neurotransmitters | Restlessness, anxiety, tachypnea, seizures, hyperthermia | Potentially all birds; secondary poisoning not reported | Talcott (2004a, b) |
| Strychnine | Controlling ground squirrels, meadow, and deer mice, prairie dogs, porcupines chipmunks, rabbits and pigeons | Colored grain-based baits with 0.5–1.0% strychnine sulfate | Reported oral $LD_{50}$s for golden eagles, sage grouse, and pheasants are 5–10, 42.5 and 8.5–24.7 mg/kg, respectively | Blocks inhibitory actions of glycine of spinal cord anterior horn cells and inhibits neurotransmitter release from Renshaw cells | Nervousness, apprehension, anxiety, tachypnea, muscle spasms, stiffness, tonic extensor muscle contractions, death due to respiratory impairment Secondary toxicity reported | Potentially all birds | Redig *et al*. (1982) Wobeser and Blakley, (1987), Warnock and Schwarzbach (1995), Talcott (2004a, b) |
| Zinc phosphide | Used to control rats, mice, voles, ground squirrels, prairie dogs, nutrias, muskrats, rabbits, opossums, and gophers Aluminum phosphide is used as a fumigant | Grain-based bait, scrap bait, paste, or tracking powder; baits generally contain 0.5–2.0% zinc phosphide; paste up to 10% | Oral $LD_{50}$s for wild birds and ducks are reported to be 23.7–37.5 mg/kg; oral $LD_{50}$ in chickens reported to be 25 mg/kg | Phosphene released from zinc or aluminum phosphide blocks cytochrome oxidase | Often found dead Dullness, tachypnea, dyspnea, tremors paralysis, seizures, and death Secondary toxicity unlikely | Potentially all birds | Shivanandappa *et al*. (1979), Albretson, (2004), Poppenga *et al*., (2005), Tiwary *et al*., (2005) |

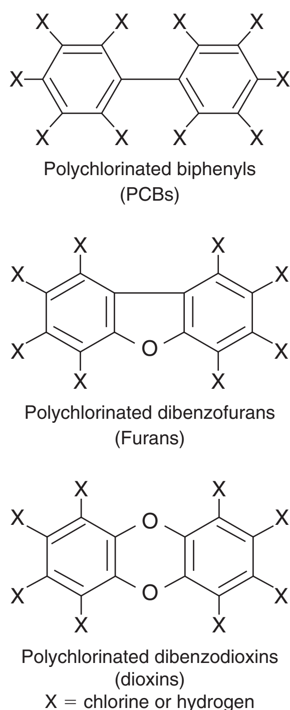

**FIGURE 56.1** Chemical structures of PCBs, PCDFs, and PCDDs.

## PCBs and dioxins

PCBs and dioxins are ubiquitous environmental contaminants. PCBs are chemicals that, historically, were used for a variety of industrial applications. They were probably best known for their use in electrical transformers.

Polychlorodibenzodioxins (PCDDs or dioxins) and related polychlorodibenzofurans (PCDFs), occur as trace contaminants in several chemical processes, primarily during the production of chlorinated phenols. They are also formed during bleaching of wood pulp and incineration of chlorine-containing waste materials (Andrews *et al*., 2001). The most well-known dioxin is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin or TCDD. The chemical structures of PCBs, dioxins, and furans are provided in Figure 56.1. Potentially, there are 209 different PCB congeners, 74 different PCDD congeners, and 134 different PCDF congeners. Not all congeners have equivalent toxicity. The most toxic PCBs are those whose phenyl rings are in a coplanar configuration and the most toxic PCDDs and PCDFs have four or more chlorine atoms. These compounds are lipophilic and environmentally stable. Like the OCs, they bioaccumulate and biomagnify within food webs. Restrictions on their production have resulted in slowly declining environmental concentrations, although they continue to cause adverse effects in wildlife. These groups of compounds are considered together given their common mechanisms of toxic action.

PCBs, PCDDs, and PCDFs are not considered to cause acute intoxication. However, chronic exposure can cause a number of adverse effects. Mechanistically, most toxic PCBs, PCDDs, and PCDFs are coplanar and bind to a cytosolic receptor called the aryl hydrocarbon or Ah receptor (AhR). The ligand–receptor complex is translocated to the nucleus where increased transcription of target genes ultimately results in a variety of responses. Adverse effects include weight loss, decreased immunocompetence, subcutaneous edema, reproductive and developmental effects, alterations in lipid metabolism and gluconeogenesis, thymic atrophy, hepatoxicity, endocrine disruption, hormone receptor modulation, and induction of liver enzymes (Bradbury, 1996; O'Hara and Rice, 1996). Non-coplanar PCBs that do not act via the AhR can alter cells in the nervous and immune systems resulting in cell death, stimulate insulin release, reduce synthesis of the neurotransmitter dopamine, and activate neutrophils to produce reactive oxygen species (Carpenter, 2006). Coplanar PCBs are anti-estrogenic, but most non-coplanar PCBs are estrogenic (Carpenter, 2006).

In avian species, perhaps the most significant impact of PCBs, PCDDs, and PCDFs is on reproduction. Avian piscivores are the most likely bird species to be affected due to bioaccumulation from dietary sources. The major effects are due to decreased egg production and embryo hatchability. The collective effects on avian embryos have been referred to as chick edema disease in chickens or Great Lakes Embryo Mortality, Edema, and Deformities Syndrome (GLEMEDS) in avian wildlife (O'Hara and Rice, 1996). Adverse effects include increased embryo and chick mortality, growth retardation, developmental abnormalities including bill deformities, club feed, missing eyes, and defective feathering, subcutaneous, pericardial, and peritoneal edema, liver enlargement and necrosis, and porphyria (Gilbertson, 1983; Gilbertson *et al*., 1991).

A diagnosis of PCB, PCDD, or PCDF intoxication can be difficult given the range of adverse effects that can be manifested. Also, clinical effects can be due to disease processes that are not a direct result of chemical exposure. For example, illness and death due to an infectious disease might occur as a result of impaired immune function. Concentrations of PCBs, PCDDs, and PCDFs in tissues such as brain and eggs have been correlated with specific adverse effects, so detection and quantification of these compounds in appropriate samples can be useful in establishing a diagnosis.

Poultry can be exposed to PCBs, PCDDs, and PCDFs via contaminated feedstuffs. Feed contaminated with PCBs and dioxin caused widespread contamination of poultry and poultry products in Belgium in 1999 (Bernard *et al*., 2002). The source was traced to recycled fat used in livestock feed production. Interestingly, diagnosis of chick edema disease in poultry receiving the contaminated feed resulted in the initial identification of the problem. Also, poultry and poultry products were found to be contaminated with TCDD as a result of inclusion of TCDD-contaminated ball clay used as a flowing agent in livestock

feed (Hayward *et al.*, 1999). No birds were clinically affected and the contamination was discovered as a result of a nationwide food survey conducted by the United States Environmental Protection Agency (USEPA).

## Ethylene glycol

Occasionally, birds are intoxicated by ethylene glycol (EG, antifreeze). There is one report of EG intoxication of ducks kept in an area used for automobile storage and repair (Stowe *et al.*, 1981). The authors has diagnosed EG intoxication in a turkey vulture; the source of exposure was not determined. A diagnosis relies on detection of EG in fluid or tissue (liver and kidney) samples and occurrence of calcium oxalate crystals in renal tubules. Another diagnostic clue in cases where EG is not suspected and kidneys are tested to assess potential exposure to metals, is a high kidney calcium concentration (often $>2000$ ppm wet weight with normal concentrations $<150$ ppm).

## Petroleum

Exposure of avian wildlife to crude oil is a significant cause of morbidity and mortality. Although oil spills involving large tanker accidents such as the grounding of the *Exxon Valdez* in Alaska receive most of the public's attention, other scenarios related to oil drilling and production, off-loading of oil from tankers, production, processing, and refining of oil, road transport, and improper disposal of waste oil and petroleum products result in considerable wildlife exposure (Jessup and Leighton, 1999). Because oil floats on the surface of water, birds that live on water or dive through water for food are more likely to be exposed in water spills. Marine birds and bird species that utilize environments near to shore are also likely to be exposed to oil if spills reach shorelines. Raptors such as peregrine falcons which feed on other birds can be exposed to oil from contaminated prey (Zuberogoitia *et al.*, 2006).

Crude oil and petroleum products are complex mixtures of chemicals, including a variety of aromatic and aliphatic compounds. The toxicity of crude oils and petroleum products varies depending on their chemical compositions. Another complicating factor in assessing the toxicity of crude oil is the fact that soon after environmental release, the process of "weathering" occurs which changes its chemical and physical properties.

Crude oil and other petroleum products affect birds in several ways. First, loss of insulating properties of the feathers results in rapid hypothermia. Oiled birds lose their ability to fly and they frequently die from starvation, exhaustion, or drowning (Friend and Franson, 1999). Second, crude oil and other petroleum products are irritating to skin, mucous membranes, and the respiratory tract. Aspiration of oil into the respiratory tract and lungs can cause aspiration pneumonia. Third, systemic absorption of chemicals found in crude oil or petroleum products causes adverse effects on several organ systems including reproductive, hematopoietic, nervous, immune, and hepatobiliary systems. Lastly, petroleum is extremely toxic to bird embryos.

Diagnosing petroleum intoxication as a cause of death can be challenging. There are no characteristic gross or histopathologic lesions specific to petroleum intoxication. A diagnosis is based upon a history or evidence of exposure and compatible clinical and postmortem findings. Exposed birds, especially those with white or light colored feathers, are easily identified because of the persistence of oil on feathers and skin. Birds are often emaciated, oil may be present in the respiratory or gastrointestinal tracts, there may be congestion along the intestines, and the salt glands may be swollen (Friend and Franson, 1999). Feathers, skin, or organs of birds which do not have external evidence of exposure can be analyzed for the presence of chemicals typically found in crude oil or petroleum products (Jessup and Leighton, 1996).

## Cyanide

Cyanide (hydrocyanic acid) is a rapidly acting cellular poison. Poisoning most often occurs following ingestion of a cyanide salt or inhalation of hydrogen cyanide gas. Avian wildlife intoxications have occurred following exposure to cyanide used in heap leach and carbon-in-pulp mill gold or silver mining processes (Friend and Franson, 1999). Birds are most often intoxicated by ingesting cyanide contaminated water. Between 1986 and 1995, 3000 cyanide-related mortalities involving 75 species of birds were reported to the National Wildlife Heath Center (Friend and Franson, 1999). Most mortality events occur in the spring and fall as migratory birds pass through mining areas. Large-scale cyanide spills have caused widespread contamination of rivers in Europe and South America (Koenig, 2000).

Cyanide binds to ferric (+3) iron of mitochondrial cytochrome oxidase. This enzyme mediates the transfer of electrons to molecular oxygen which is the last step in oxidative phosphorylation (Delaney, 2001). Cells are unable to use oxygen resulting in tissue anoxia, increased anaerobic metabolism, and rapid development of lactic acidosis.

The acute oral toxicity of sodium cyanide has been studied in several bird species. $LD_{50}$s ranged from 4.0 to 21 mg/kg b.w. (Wiemeyer *et al.*, 1986).

Cyanide is a rapidly acting toxicant; most intoxicated birds are found dead. Grossly, dead animals often have bright red blood and multi-organ congestion. A diagnosis is based upon the history of exposure and measurement of cyanide in blood, heart, liver, or brain. Samples should be stored and shipped frozen to avoid the loss of cyanide before

analysis. Denying birds access to cyanide-contaminated water is the best preventive approach.

## Disinfectants

### *Phenols*

Phenol, also known as carbolic acid, was commonly used as an antiseptic agent before the availability of other chemical antiseptics. Phenol acts as a general protoplasmic poison by causing cell wall disruption, protein denaturation, and coagulation necrosis (Sue and Delaney, 2001). Clinical signs occur as a result of local damage to the gastrointestinal tract or respiratory system. Systemic signs occur due to central nervous system (CNS), cardiac, hepatic, and renal damage.

### *Quarternary ammonium compounds*

Quarternary ammonium compounds are cationic surfactants that are used as disinfectants, detergents, and sanitizers. In general, diluted quarternary ammonium compounds have a low order of toxicity compared to other disinfectants such as phenol or formaldehyde. However, at sufficient concentrations, they are damaging to epithelial cells of the mouth, pharynx, and upper airway (Brown and Julian, 2003). Epithelial damage can progress to pseudomembrane and ulcer formation. Ulceration and epithelial thickening can occur in the upper gastrointestinal tract. There is one case report of intoxication of chickens exposed to drinking water with higher than recommended concentrations of alkyldimethylbenzyl ammonium chloride (Dhillon *et al*., 1982). The concentration in the water was not reported. Grossly, pale or white areas with focal areas of ulceration were noted on oral and pharyngeal mucosa. The same compound added experimentally to the water of turkey poults at 200 ppm did not cause an adverse effect; higher concentrations caused oral mucosal irritation and respiratory distress (Reuber *et al*., 1970).

### *Chlorine*

The toxicity of sodium hypochlorite added to drinking water for broiler chicks and laying hens has been investigated (Damron and Flunker, 1993). In chicks, 100 and 300 ppm chloride (derived from addition of sodium hypochlosite) reduced water intake and body weight, respectively. In hens, 40 ppm chloride reduced water consumption and 60 ppm reduced egg production when added to water in warm weather. Water consumption was reduced at 50 ppm, but 100 ppm had no effect on egg production or weight daily feed intake when added during cooler weather.

Seventeen of 35 psittacines housed in an aviary developed respiratory distress, depression, and anorexia after the aviary was cleaned with an undiluted solution of sodium hypochlorite (5% chlorine bleach) (Wilson *et al*., 2001). Seven birds subsequently died and were necropsied. Gross and histopathologic lesions included epithelial deciliation, ulceration, squamous metaplasia, and epithelial hyperplasia in the tracheas of the birds.

# TOXIC GASES

## Ammonia

High ambient air concentrations of ammonia (50–75 ppm) reduce feed consumption, growth rate, and egg production in poultry (Deaton *et al*., 1986). Ammonia readily dissolves in water to form ammonium hydroxide which is an alkaline irritant. Thus, contact with the moist mucous membranes of the eyes and respiratory tract results in corneal and epithelial cell damage. Toxic air concentrations cause kerato-conjunctivitis, corneal ulceration, blindness, photophobia, tracheitis, tachypnea, and dyspnea. Prolonged exposure can result in increased mucous secretion and hyperplasia of the bronchiolar and alveolar epithelium. Ambient ammonia air concentrations should be $<25$ ppm for poultry (Brown and Julian, 2003).

## Carbon monoxide

CO is an odorless, colorless, lighter-than-air gas that can reach toxic concentrations as a result of incomplete combustion of hydrocarbon-based fuels. Toxic concentrations of CO most often result from use of defective gas catalytic or open-flame brooders and furnaces or internal combustion engines in poorly or unventilated spaces. CO acts by competing with oxygen for a number of proteins, including hemoglobin. The affinity of hemoglobin for CO is approximately 250 times greater than for oxygen. Formation of carboxyhemoglobin reduces the ability of red blood cells to carry oxygen and the oxygen dissociation curve is shifted to the left resulting in tissue hypoxia. Affected birds exhibit drowsiness, labored breathing, weakness, and ataxia with seizures occurring before death (Brown and Julian, 2003). Birds may be found dead. Carboxyhemoglobin causes the blood to have a bright red appearance. Carboxyhemoglobin concentrations of 20% are associated with some motor impairment; death occurs when blood carboxyhemoglobin concentrations approach 60–70% (Osweiler *et al*., 1985). Ambient CO concentrations of 600 ppm for 30 min cause clinical signs in chickens; concentrations of 2000 ppm or greater are lethal within 1.5–2 h (Brown and Julian, 2003). Sublethal exposure to CO in poultry causes stunting.

Diagnosis of CO intoxication is based upon a history compatible with CO production, compatible clinical signs,

and measurement of ambient air CO and blood carboxyhemoglobin concentrations. Treatment is generally limited to provision of fresh air or oxygen; pet birds can be placed in oxygen cages.

Other gases such as hydrogen sulfide and carbon dioxide generally do not present significant intoxication risks for birds. Interestingly, chickens are less sensitive to hydrogen sulfide than humans or dogs (Brown *et al.*, 1997).

## Polytetrafluoroethylene: Teflon®

Polytetrafluoroethylene (PTFE) is a synthetic polymer that is widely used as a non-stick surface in cookware. It is also used in self-cleaning ovens and as a coating on heat lamp bulbs. Heated to high temperatures (⩾280°C or greater) PTFE releases toxic pyrolysis products that can cause rapid death of birds. There are no reported toxicities associated with the proper use of coated cookware since temperatures do not reach levels at which pyrolysis occurs. However, cookware without contents can reach critical temperatures within minutes.

While all birds are likely to be susceptible to intoxication, most spontaneous cases involve pet birds such as cockatiels, parrots, finches, and budgerigars (Blandford *et al.*, 1975; Wells, 1983; Stoltz *et al.*, 1992). There is one case report in which broiler chicks were intoxicated from heat lamp bulbs coated with PTFE (Boucher *et al.*, 2000) and another suspected intoxication of wild birds associated with industrial activity (Pennycott and Middleton, 1997). Quail have been exposed experimentally (Griffith *et al.*, 1973).

PTFE pyrolysis products contain particulates of respirable size (<1 μm diameter) that can penetrate to the alveoli (Wells *et al.*, 1982). The particulates are themselves toxic, but they also serve as a vehicle for other potentially damaging chemicals including hydrogen fluoride, carbonyl fluoride, and perfluoroisobutylene (Wells and Slocombe, 1982b). The fumes are acidic and cause direct damage to cell membranes of the lungs. However, it appears as though the particles are necessary for intoxication to occur since the gas phase of PTFE fumes alone does not cause damage (Seidel *et al.*, 1991). Lung damage is believed to be due to direct irritation and oxidative damage (Wells *et al.*, 1982, Johnston *et al.*, 1996).

Precise toxicity information is not available. However, experimentally, exposure of budgerigars to PTFE pyrolysis products for 9 min or longer resulted in severe clinical signs and lesions and the deaths of 31 of 32 budgerigars (Wells *et al.*, 1982). While there is little comparative toxicity information among avian species, budgerigars were more sensitive than quail in one experimental study (Griffith *et al.*, 1973).

After exposure, the onset of clinical signs is rapid. Eyelid blinking is an early sign and may be related to a direct irritant effect on the conjunctiva and cornea (Wells *et al.*, 1982). Eyelid movements could also be secondary to hypoxia-induced somnolence. Tachypnea, dyspnea, anxiety, cage wire biting, incoordination, and inability to stand may be due to hypoxia secondary to lung damage. In many cases, the bird may be found dead with no other clinical signs noted.

Grossly, the lungs are severely congested and hemorrhagic (Wells and Slocombe, 1982b). Histologically, there is extensive, severe, necrotizing, and hemorrhagic pneumonitis. Amorphous, elongate particles may also be noted (Wells and Slocombe, 1982b).

A diagnosis is generally based upon a history of exposure and characteristic postmortem lesions. Currently, there is no analytical test available to confirm exposure to the pyrolysis products. The rapidity of onset of severe signs and subsequent death most often precludes treatment. Awareness of the hazard and avoiding housing birds near PTFE coatings is the best prevention.

# Principles of ecotoxicology

*Jeffrey M. Levengood and Val R. Beasley*

## INTRODUCTION

In this chapter we offer some background information on selected issues and toxicants of importance in ecotoxicology. Because of the breadth of this subject, readers are encouraged to capitalize on other sources as well. There are numerous scientific journals that publish papers on a broad array of topics in ecotoxicology, including *Ecotoxicology*, *Environmental Toxicology and Chemistry*, *Environmental Pollution*, *Journal of Environmental Quality*, *Environmental Health Perspectives*, *Archives of Environmental Contamination and Toxicology*, and others. In addition, there are numerous texts available on this subject, including *Fundamentals of Ecotoxicology* (Newman, 1998), *Handbook of Ecotoxicology* (Hoffman *et al.*, 2003), and *Principles of Ecotoxicology* (Walker *et al.*, 2001), to name just a few. There is also a growing number of books that are focused on specific issues or taxa, e.g. *Ecotoxicology of Amphibians and Reptiles* (Sparling *et al.*, 2000), *Radiotelemetry Applications for Wildlife Toxicology Field Studies* (Brewer and Fagerstone, 1998), *Principles and Practices for Evaluating Endocrine Disruption in Wildlife* (Kendall *et al.*, 1998), *Wildlife Toxicology and Population Modeling: Integrated Studies of Agroecosystems* (Kendall and Lacher, 1994), and many others.

### Defining ecotoxicology

Ecology is defined as the science of all living organisms, and all their interactions among one another and with the environment. We define toxicology as the science of all the adverse biochemically mediated effects of all chemicals on all life forms. Newman (1998:13) defined ecotoxicology as the "science of contaminants in the biosphere and their effects on constituents of the biosphere." More recently, Hoffman *et al.* (2003:1) defined ecotoxicology as "the science of predicting effects of potentially toxic agents on natural ecosystems and on nontarget species." For the purposes of this chapter, we define ecotoxicology as the science of all the adverse biochemically mediated effects of all chemicals on all living organisms including all their interactions within organisms and among species in the environment (Beasley, 1993). As such, ecotoxicology is the most encompassing specialty within the discipline of toxicology. The breadth of ecotoxicological studies is therefore immense. It ranges from: (a) tightly controlled laboratory studies of the pathophysiological effects of single chemicals on one strain of a native or surrogate microbe, plant, or animal species, to (b) studies of the transport and fate over time of one or more contaminants in the environment, (c) studies of the pathophysiological effects of single chemicals on a suite of organisms with various inanimate factors in microcosms or mesocosms, (d) studies of toxic interactions among groups of contaminants on one or more organisms in concert with inanimate factors in microcosms or mesocosms, and (e) small- and large-scale field research on impacts of one or more chemicals on suites of abiotic and biotic components in the environment.

### Successes and challenges

The necessity of an interdisciplinary approach and a combination of field and laboratory studies was illustrated in early ecotoxicological studies of spent lead shot pellets. Although lead poisoning resulting from lead shot ingestion was known to be a mortality factor in waterfowl in the late 1800s, the scope of the problem and the nature of the syndrome were not understood until Dr Frank Bellrose began comprehensively investigating this issue in the 1940s and 1950s. Bellrose (1959) and colleagues from the Illinois Natural History Survey addressed: the geographic distribution, frequency, and magnitude of die-offs; the accessibility

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

of spent shot; ecological determinants of differential susceptibility; dose response; clinical signs in moribund individuals; lesions in exposed specimens; and the influence of diet on toxicity of lead shot. Others began examining lesions of lead poisoning in waterfowl and other species, and developing diagnostic criteria to support diagnoses of lead poisoning in birds (e.g. Longcore *et al.*, 1974a, b; Finley *et al.*, 1976a, b, c; Dieter and Finley, 1979; Friend, 1985). Their findings and others that followed eventually prompted restrictions and later a complete ban on lead shot for hunting waterfowl in the United States, Canada, and several other nations. Government regulations in these countries required the testing of potential non-toxic substitutes for lead shot. Some, such as iron (steel) (Sanderson and Irwin, 1976), bismuth (Sanderson *et al.*, 1997), and tungsten (Mitchell *et al.*, 2001), were deemed functionally non-toxic after ingestion by waterfowl and were approved for use in waterfowl hunting, whereas other candidates such as zinc were found to be toxic (Levengood *et al.*, 1999). Such restrictions soon led to decreased lead exposure (Samuel and Bowers, 2000) and reduced mortality (Anderson *et al.*, 2000) due to lead shot ingestion in some duck species.

The agricultural application of dichlorodiphenyltrichloroethane (DDT) began shortly after World War II (WWII). At that time, large amounts were sprayed on farm fields in the United States, Great Britain, and elsewhere. After noting increased incidence of raptor nests in the United Kingdom with broken eggs, Ratcliffe (1967) examined the thickness of eggshells, using the ratio of shell weight/size of eggs of three species of raptorial birds collected from 1900 through 1967. He found a precipitous decline in shell weight/size ratio from 1946 to 1950, after which shell thinning persisted. Shell thickness of eggs collected during 1900–1946 was significantly greater than of those collected during 1947–1967. Ratcliffe (1967) noted that the sharp decline in eggshell thickness coincided with beginning of widespread agricultural use of DDT (1945–1946), and Jefferies 1967 linked DDT and delayed ovulation in birds (suggesting a hormonal mechanism, i.e. endocrine disruption). This work was followed by many corroborative field and laboratory studies as discussed below, which, taken together provided an overwhelming weight of evidence as to the insidious and devastating impacts of DDT on avian reproduction. A combination of pest resistance (resulting in development of alternatives), decades of accumulated evidence on environmental effects, and publication of *Silent Spring* by Rachel Carson (1962) were necessary to drive a US ban on DDT use in 1972. Many other developed nations banned these compounds also, and pressured other, less-affluent nations to discontinue or curtail its use. Recently, the World Health Organization and Stockholm Convention on Persistent Organic Pollutants condoned the use of DDT for indoor mosquito control in tropical malaria-endemic (World Health Organization, 2005). Dichlorodiphenyldichloroethylene (DDE), the most persistent, bioactive environmental product of DDT, though declining in regions where its use was discontinued, is still widely disseminated in the environment.

The field of ecotoxicology has: helped terminate or reduce the manufacture and dissemination of some major environmental pollutants [e.g. lead, DDT, polychlorinated biphenyls (PCBs)]; prompted development of new, man-made chemicals of lower environmental risk (e.g. insect growth hormone mimics such as methoprene); helped applied ecology become problem driven; and is an important component of conservation medicine (Munson and Karesh, 2002; Tabor, 2002). In recent decades, ecotoxicology has begun to be applied in conjunction with other components of ecological restoration science to help reestablish ecological health in previously contaminated systems (Cairns, 2003; Linder *et al.*, 2003).

Despite benefits from ecotoxicology and other sciences that support rational actions to enhance ecosystem health, in many ways we have witnessed nearly 45 additional years of global mismanagement of ecological resources since the publication of *Silent Spring* in 1962. Although the general public in developed and developing nations has become more environmentally aware in recent decades, powerful economic interests e.g. mining, energy generation, chemical, construction, and agricultural and forestry industries have often hampered the application of sound ecological and ecotoxicological science to resource extraction and development.

Decisions sometimes fail to address long-term environmental needs because of misguided political pressure. Unlike progress seen recently in Europe, the United States has failed to maintain leadership in environmental stewardship with regard to contaminants. In fact, no new, major legislation in support of ecosystem health has been passed by the US Congress since 1990.

## Sources of pollution

Myriad toxic substances are released into our environment daily. Toxic agents are either deliberately manufactured (pesticides, drugs, construction chemicals, household chemicals) or accidentally produced (by-products in final formulations or in gaseous, particulate, liquid, and solid waste streams). Inappropriate siting and operation of chemical manufacturing and waste storage facilities can lead to "accidental" releases of chemicals into groundwater, surface water, soil, and air. Although it is increasingly recognized as ill-conceived, chemical and textile manufacturing plants, refineries, smelters, chemical storage facilities, and electricity generating plants were often located near waterways for ease of transportation of raw materials and finished products, because they use large

quantities of water in manufacturing, and/or to allow for dissemination of wastes. Such siting predisposes to deliberate (sometimes permitted), accidental, and even malicious releases of toxic chemicals into aquatic ecosystems.

Environmental contamination can emanate from a definable location (point-source pollution), such as atmospheric emissions from the stacks of a coal-burning power plant or liquid effluent from the discharge of a sewage treatment plant. Contamination can also be more widespread, emanating from a larger surface area (non-point source pollution), such as pesticides washed off the landscape by precipitation or airborne effluents from a host of automobiles.

## Chemical disasters

The stewardship of chemically mediated disasters ranges from responsible and efficient to neglect and indifference. Localized disasters involving a single, acutely toxic, short-lived chemical (e.g. a volatile solvent released from damaged rail tanker) can be relatively easy to address. Ecological recovery is also more likely when ecological resources (locally adapted microbes, plants, and animals) from the periphery are intact; local emergency agencies are well equipped, staffed, and responsive; funding is available from responsible parties or government to support containment, cleanup, and ecological rehabilitation; and the public is strongly engaged. Conversely, recovery is less likely when releases involve multiple long-lived chemicals (e.g. complex, halogenated, higher molecular-weight wastes) spread over a wide area when ecological resources from periphery are insufficient to support recovery, when responsible parties deny involvement, when neither the responsible parties nor the governments involved put forth needed funds, and the public is largely disengaged.

On March 24, 1989, the oil-tanker ship the *Exxon Valdez* hit a reef, spewing nearly 11,000,000 gallons of crude oil into the pristine Prince William Sound in Alaska. Exxon Corporation (now Exxon Mobil), the ship's owner, the Alyeska Pipeline Service Company, a consortium of oil companies with interests in Alaska, as well as state and federal disaster response planning, were criticized (Exxon and Alyeska were eventually sued) as being wholly unprepared to provide a quick and effective response for such a disaster, as was required by law. Containment and cleanup were to begin within 5 h, but crews and equipment did not begin arriving for 10–12 h after the incident, while oil continued to gush from the leaking tanker. Confusion, poor communications and coordination, lack of sufficient personnel, equipment and supplies for a spill of that magnitude, and the remoteness of the location hampered efforts to contain and begin effective cleanup during the first 2 days after the ship ran aground, after which rough seas created further difficulties.

Although the ecological and socioeconomic costs were tremendous, and could have been lessened, the response among the public, conservation organizations and agencies, academic institutions and media was unprecedented for an environmental disaster. Frustrated with a lack of action on the part of industry and government, local citizens began to clean up what oil they could with resources at hand. Within hours of the spill, scientists arrived to begin documenting the environmental impacts of the spill. Particularly sensitive environments were quickly identified and prioritized for protection and cleanup. Crews began to arrive from throughout the world to help clean oil-covered beaches, seabirds, and sea otters. An estimated 36,000 birds and 1000 sea otters eventually were treated for oil exposure; however, untold numbers of fish and wildlife died from direct impacts of oiling. According to the *Exxon Valdez* Oil Spill Trustee Council, the populations of only 4 of 11 bird species impacted were recovering or had recovered as of 2002. Impacts to sensitive intertidal communities may not be fully realized for many years to come.

The global news media followed many phases of the cleanup and recovery operations, focusing attention on the environmental and economic costs of this disaster, as well as on Exxon's initial response and failure to accept responsibility for the accident. The Oil Pollution Act of 1990, in response to the *Exxon Valdez* disaster, required increased spill preparedness and the phase-in of double-walled tanker ships, which greatly reduce the chances of a spill should a tanker run aground or hit an iceberg or reef. Unfortunately, the petroleum industry has found loopholes in the law and effectively delayed the deadline for new or retrofitted tankers until 2015. In the meantime, sensitive marine environments remain at high risk from oil spills. For more on the history, current activities, and future plans surrounding this disaster, see the *Exxon Valdez* Oil Spill Trustee Council's website (http://www.evostc.state.ak.us) and the US Environmental Protection Agency's *Exxon Valdez* Oil Spill Profile (http://www.epa.gov/oilspill/exxon.htm).

# ECOTOXICOLOGICAL STRESS IN CONCERT WITH OTHER MECHANISMS OF ECOSYSTEM DISEASE

Aquatic systems throughout the world are increasingly under stress from human activities. Wetlands, lakes, streams, rivers, and estuaries are being degraded due to loading with nutrients (Baird *et al*., 2004), metals, salts, synthetic organic chemicals, and combustion products, as well as a wide array of other anthropogenic stressors. For example, many of the world's coral reefs are being degraded through the use of destructive fishing and collecting methods (Hodgson, 1999; Jackson *et al*., 2001),

eutrophication (Diaz-Pulido and McCook, 2005), increasing ocean temperatures (Wolanski and De-ath, 2005), and coral diseases produced by bacteria, fungi, and cyanobacteria (Richardson, 1998). Although the role of environmental degradation in producing coral disease remains unclear, the vast majority of impacted reefs in the Caribbean were near areas of human activity (Green and Bruckner, 2000), and in the Netherlands Antilles, changes in the structure of coral reef bacterial, including cyanobacterial (blue-green algal), communities were observed in proximity to large inputs of contaminants (Klaus *et al*., 2004).

Surface runoff, coupled with stream channelization and subsurface tiling of fields, decreases groundwater recharge and increases the "flashiness" of streams, sometimes resulting in prolonged, catastrophic flooding. Rapid flow of water due to runoff from cropland, cleared forests, lawns, roofs, stockyards, roads, parking lots, demolition and construction sites, and poorly managed industrial and dump sites also carries pulses of complex pollutant mixtures to water bodies (Hyer *et al.*, 2001; Kolpin *et al.*, 2002; Gilliom *et al*., 2006). For example, precipitation events can mobilize pesticides from soils into runoff (Leu *et al.*, 2004a, b) and increase concentrations in surface waters (Stamer *et al*., 1994). Lack of water retention, due to a diminished wetland base, results in abnormally low flows during dry periods, resulting in decreased dilution and thus increased concentrations of contaminants (Kolpin *et al*., 2004). Reduced flows can also result in increased water temperatures in summer, thereby decreasing the oxygen-holding capacity of the water. Removal of tree canopies through logging, development, or other activities also increases stream temperatures to the detriment of aquatic species requiring cool, highly oxygenated water, such as trout and salmon (Kishi *et al*., 2004).

In addition to being sources of toxicants, road (Trombulak and Frissell, 2000) and bridge (Blettler and Marchese, 2005) construction, deforestation (Alin *et al.*, 2002; Klink and Machado, 2005; Silveira *et al*., 2005), agriculture (Uri, 2001), and mining (Hartman *et al*., 2005) erode soils and increase sedimentation of waterways. High suspended-sediment loads increase turbidity, shading plants so that primary productivity from photosynthesis, biomass, structure, and dissolved oxygen are reduced. Excess suspended sediments in waterways can also degrade spawning habitat (Burkhead and Jelks, 2001), produce lesions in gills (Herbert and Merkens, 1961), and modify animal behavior (Berg and Northcote, 1985), resulting in reduced fish productivity and altered fish community assemblages (Sutherland *et al*., 2002; Mol and Ouboter, 2004).

Prior to the advent of modern intensive agriculture, farms consisted of a mosaic of small fields of vegetables, grains, and forage crops, interspersed with fencerows, woodlots, pastures, and wetlands. Crop rotations offset the need for fertilization and pest control. By contrast, modern agricultural and forestry practices have produced vast monocultures of genetically similar plants that are susceptible to attack by plant pathogens such as fungi and herbivorous insects, triggering the use of toxic pesticides. Such monocultures deplete nutrients, prompting fertilization which increases the availability of free nutrients. High levels of nutrients such as nitrogen can be directly toxic (ionic forms, e.g. nitrite or nitrate) or have indirect impacts, e.g. cause harmful algal blooms that may produce toxins and usurp dissolved oxygen.

Modern agriculture and forestry, along with urbanization and suburban sprawl, have created a patchwork of habitat islands in a largely inhospitable landscape. Biota inhabiting such islands are prone to extirpation through environmental perturbations such as catastrophic weather events; competition with invasive, exotic species, habitat degradation that prompts starvation, desiccation, or predation; and mortality or reduced productivity via exposure to environmental contaminants. This loss of species from habitat patches, combined with reduced recolonization rates, can result in local or regional reductions in populations, leading to extirpation, and increasing the risks of extinction events.

Anthropogenic air pollution has been reported since 13th century London, when smog from coal fires blanketed the city; and the situation worsened with the Industrial Revolution of the 1700s. An estimated 12,000 people died in London during the Great Smog of the winter of 1952 (Wilkins, 1954). Pollutants from tall stacks of power plants may travel long distances, harming the environment far from the source. In addition to power generation, other major anthropogenic sources of atmospheric pollutants include waste incineration, oil refinement, industrial emissions, fires from slash and burn agriculture; large wildfires that follow misguided forest-fire suppression, and transportation sources. Widespread deforestation, especially in the tropics (the "lungs of the earth"), and coastal pollution that limits phytoplankton photosynthesis reduce the ability of the environment to remove $CO_2$ and clean the air.

Excessive reliance on fossil fuels (natural gas, petroleum, coal) and clearing of forests are increasing $CO_2$ and methane levels, which trigger global climate change. Small changes in average temperatures appear to be increasing the rate of glacial retreat and causing reductions in ice/snow packs, and increasing the frequency of extreme weather (e.g. drought, flooding, and hurricanes). Rising global temperatures are producing shifts in species tolerating warmer temperatures, with cold-dependent species moving nearer to the poles and into higher elevations. The United States is the leader in greenhouse emissions, according to the Oak Ridge National Laboratory (Marland *et al*., 2005). North American releases amounted to 1.73 billion tons in 2002 (approximately 92% of this generated in the United States), which was 26% of the world total. Half of the estimated 290 billion tons released due to human activities since 1751 have been since mid-1970s. Carbon dioxide emissions in the United States increased

an estimated 9-fold during 20th century. Of even greater concern at present is China, which has a much higher human population and has been rapidly industrializing, culminating in increased carbon dioxide emissions in the same time frame by 6000-fold (UKDTI, 2002).

Environmental and ecotoxicological problems related to fossil fuels go well beyond the aforementioned oil spills and global warming from carbon dioxide. Placing oilfields in sensitive arctic and marine environments, especially offshore in the Arctic, may have immense adverse impacts on marine mammal populations and indigenous human communities. Emissions during oil refining, and polycyclic aromatics produced through combustion from petroleum and coal have caused widespread pollution. Many of the polycyclic aromatic hydrocarbons are oxidized by P450 enzymes in lung, liver, and other tissues to form reactive epoxide derivatives that form adducts to DNA, resulting in mutations, with the potential to cause cancers as well as heritable defects. Among the best known polycyclic aromatic hydrocarbons is benzo(a)pyrene. Also of concern are volatile organic compounds (VOCs) such as benzene. Both benzo(a)pyrene and benzene known human carcinogens. Aluminum smelters using obsolete technologies have also polluted the environment with polycyclic aromatic hydrocarbons, and were incriminated in digestive tract cancers of beluga whales Martineau *et al*. (1991, 2002).

Through emissions of sulfur dioxide, coal-fired power plants in the United Kingdom have affected the environments of Sweden and Norway; and likewise those in the midwestern United States have impacted lakes and forests in the northeast part of that country as well as Canada. Oxidized nitrogen ($NO_x$) from burning gasoline, diesel fuel, heating oil, natural gas, and coal and oxidized sulfur from refining oil and burning coal form strong mineral acids when combined with precipitation. This can lead to changes in soil and water chemistry, including solubilization of aluminum, with adverse impacts on soil and aquatic flora and fauna. Aluminum is a ubiquitous constituent of soils, and excess concentrations in solution can precipitate out on gills of fishes and aquatic invertebrates to impair oxygen utilization (Glynn *et al*., 1992, Alexopoulos *et al*., 2003; Winter *et al*., 2005; Soucek, 2006). Highly acidic waters with excess aluminum can also reduce calcium uptake via gills, impacting growth and development in aquatic and invertebrate species (Malley and Chang, 1985).

Semi-volatile compounds such as PCBs are released into the atmosphere from soils at contaminated locations and are transported great distances before being deposited, often over cool surfaces such as large bodies of water. Thus, large lakes, seas, and oceans have become repositories for such chemicals. This process largely accounts for the comparatively high concentration of persistent organochlorines in polar ocean foodwebs. Other semi-volatile chemicals, such as halogenated dibenzodioxins and halogenated dibenzofurans, are toxic by-products of the incineration of solid wastes and manufacturing processes such as the Kraft paper bleaching process. Such compounds have multiple toxic effects including cognitive impairment, liver damage, and endocrine disruption.

Considering that milliseconds can greatly influence the likelihood of successful predation as well as avoiding becoming prey, that overall health is essential for competition to be among the breeding population in the wild, that high functioning is needed by many parents to feed and protect the next generation until it can survive on its own, it should be no surprise that biodiversity is being harmed not only by habitat loss, climate change, exotic species introduction, pathogen pollution, and noise pollution, but also by a host of chemical contaminants – both manmade and produced by anthropogenically altered populations of microbes, plankton, plants, and animals.

## ENVIRONMENTAL CONTAMINANTS

### Nutrients

Nutrients, primarily nitrogen and phosphorus, are released into the environment via chemical fertilizers, manure/sewage effluent, burning of fossil fuels, fires, and industrial processes such as pulp/paper milling and nitric acid production. Globally, the rate of transfer of atmospheric nitrogen (N) to the available nitrogen pool has doubled due to anthropogenic activities (Vitousek *et al*., 1997). Agriculture is the primary source of excess nutrients in the environment, both through soil management and livestock operations (Carpenter *et al*., 1998). World consumption of fertilizer in 2005/2006 totaled 154 million tons [International Fertilizer Industry Association, Statistics: Total fertilizer nutrient consumption = $N + P_2O_3 + K_2O$ (million tons nutrients)]. Fertilizer use in developed nations has plateaued, reaching a point where further inputs do not increase yield. The United States alone used 21 million tons of plant fertilizers in 2003, primarily as N, P, and K, which is about the same level as in 1976 (USDA Economic Research Service – US consumption of nitrogen, phosphate, and potash for 1960–2003). However, as populations and associated demand for cereal grains in developing nations grow, fertilizer use will likely increase.

Inorganic nitrogen, including ammonia, ammonium, nitrate, and nitrite, is toxic to aquatic life including fish, invertebrates, and amphibians. Ammonium nitrate fertilizer produced toxic effects in American toad (*Bufo americanus*), western chorus frog (*Pseudacris triseriata*), northern leopard frog (*Rana pipiens*), and green frog (*Rana clamitans*) tadpoles at concentrations found in the agricultural environment (Hecnar, 1995). High nitrogen concentrations contributed to lower amphibian reproductive success (Knutson *et al*., 2004) and species richness (Houlahan and Findlay, 2003; Knutson *et al*., 2004) in wetlands in agriculturalized areas. Rouse *et al*. (1999) reported that 20% of over 8000 water

samples from the Great Lakes Watershed exceeded concentrations considered toxic to amphibians. Nutrients may also interact with pesticides to produce toxic effects different than those of either alone. For example, a mixture of atrazine and nitrate had greater than expected impacts (synergistic effect) on snout-vent length of *Xenopus laevis* tadpoles (Sullivan and Spence, 2003). Conversely, the addition of higher nitrate concentrations to the same atrazine concentrations resulted in greater snout-vent lengths, an antagonistic effect. Much work remains to be done in examining the effects of complex mixtures of chemicals on amphibians and other biota.

In addition to direct toxic effects on amphibians, large inputs of nutrients into water bodies increase algal growth, which, at high levels, can result in decreased dissolved $O_2$ concentrations through algal respiration and decay, and shading, reducing light needed by submerged aquatic vegetation. Metabolism of dead vegetation further reduces dissolved oxygen concentrations, and a reduction in aquatic plants results in reduced nitrogen storage. Excess nutrient input promotes increased snail populations (Chase, 1998), due to increased algal and periphyton resources that comprise the main food source for snails. Johnson *et al*. (2002) found a positive relationship between the frequency of limb malformations and infection with *Ribeiroia* trematodes.

Trematode infections may produce limb deformities (Johnson *et al*., 1999, 2001; Schotthoefer *et al*., 2003a,b) or potentially debilitating kidney infections (Beaver, 1937; Fried *et al*., 1997; Beasley *et al*., 2005) in frogs. Infections by *Ribeiroia* and *Echinostoma* at the early stage in development can vastly reduce survival of amphibian tadpoles (Schotthoefer *et al*., 2003a,b; Beasley *et al*., 2005). Moreover, sublethal trematode infections may also make tadpoles less tolerant of other stressors. Higher snail densities coupled with increased waterbird (definitive hosts) use of a diminished wetland base and the reduced structural complexity of habits through use of herbicides and fertilizers appear to result in higher trematode infection rates and intensities. The presence and abundance of *Ribeiroia* infection were associated with the presence and abundance of snails that function as intermediate hosts for larval trematodes. These parasites undergo extremely high levels of asexual reproduction in snails. Furthermore, the presence and abundance of planorbid snails was associated with manmade wetlands (e.g. ponds) and higher orthophosphate concentrations.

Eutrophication can also promote growth of toxigenic algae such as certain blue-green algae (cyanobacteria), which produce neurotoxins, such as anatoxin-A, anatoxin-A(s), saxitoxin, and neosaxitoxin, and the yet-to-be-identified toxin believed to account for avian vacuolar myelopathy (AVM). A current theory is that acyanobacterium of the order stigonematales, a cyanobacteria that grows on the exotic invasive *Hydrilla*, which is consumed by avian species such as coots underlies AVM (Birrenkott *et al*., 2004). Eagles are exposed via the food web. In addition to producing neurotoxins, cyanobacteria may produce hepatotoxins, such as microcystins, nodularin, and cylindrospermopsin. Both neurotoxic and hepatotoxic cyanobacteria have been implicated in die-offs of lesser flamingos, an obligate algal feeder. However, additional research will be needed before the importance of cyanobacterial toxins in population trends of lesser flamingos can be deduced.

The causes of harmful marine algal blooms, which appear to be an emerging problem, increasing in frequency and distribution worldwide, are less well understood. For example, diatoms have shown to produce neurotoxic domoic acid. Other phytoplankton such as dinoflagellates have been shown to produce saxitoxins, ciguatoxins, and brevetoxins. Shellfish and finfish may accumulate these toxins and cause secondary poisoning in humans (Van Dolah, 2000), and have been implicated in mass mortalities of bottlenosed dolphins (*Tursiops truncates*) on the Atlantic coast of the United States (Flewelling *et al*., 2005). Brevetoxin exposures via aerosols and ingestion of sea grasses contaminated with toxins from dinoflagellates seem to account for a number of major death losses in manatees in Florida over the past decade.

## Organochlorine compounds

World pesticide use in 2001 totaled 2.3 billion kg. In that year, the United States alone used about 546 million kg, including herbicides (44%), insecticides (10%), fungicides (6%), and others (40%, including nematicides, fumigants, rodenticides, avicides, molluscicides, and piscicides) (US Environmental Protection Agency, 2000-2001 Pesticide Market Estimates). Agriculture accounts for the largest proportion of total pesticides applied (75-80% in United States, primarily glyphosate, atrazine, and metam sodium). The widespread use of organochlorine insecticides (OCIs), DDT, aldrin, chlordane, dieldrin, heptachlor, and others began after WWII. These compounds were initially a boon to agriculture and public health, as they were both effective and persistent. However, pests soon began to develop resistance, requiring higher application rates and the continual development of new compounds.

DDT increases sodium conductance across nerve cell membranes, increasing excitability and resulting in tremors and the potential for seizures (Hodgson *et al*., 1998). The cyclodiene pesticides such as aldrin, chlordane, dieldrin, endrin, and heptachlor, the structures of which differ markedly from DDT, exert their influence on $\gamma$-aminobutyric acid (GABA) receptors in the brain and are more acutely toxic than DDT. The slow biodegradation rate and high lipid solubility of many organochlorine compounds, which prompts accumulation in adipose tissue, causes vast increases in the net uptake as the chemical is passed from lower to higher trophic levels, resulting in biomagnification, or successively greater residue concentrations in consuming

organisms. Predatory animals thus often accumulate very high concentrations, and the nursing young of top predators feeding in contaminated aquatic food webs are often massively exposed. Among the species most at risk are marine mammals, the young of which may consume milk with extremely high fat content (e.g. up to 60% fat).

4,4′-(2,2,2-trichloroethane-1,1-diyl)bis(chlorobenzene), best known as DDT, was used extensively in agriculture and public health, at peak production in 1962, 85,000 tons were produced in the United States alone (ATSDR, 2002), and an estimated 675,000 tons were applied in that country during 1945–1972 [USEPA-DDT Regulatory History: A Brief Survey (to 1975)]. This pesticide was considered safe, as it has a low acute toxicity to most bird and mammal species. However, over time, it became apparent that DDT had insidious effects; its metabolic by-product *p,p′*-DDE inhibits prostaglandin synthetase, resulting in reduced calcium uptake by the shell gland mucosa (Lundholm, 1993, 1997) during eggshell formation. This results in thinning, so that adults crush eggs during incubation (e.g. herons and egrets – Faber *et al*., 1972; Cooke *et al.*, 1976; sparrowhawks – Burgers *et al*., 1986). Eggshell thinning resulting from DDE exposure, and subsequent impacts on productivity, has been observed in a variety of species of carnivorous birds, such as: herons and other wading birds (Henny *et al*., 1985; White *et al*., 1988); eagles (Wiemeyer *et al*., 1984, 1993; Bowerman *et al*., 1995); falcons (Newton *et al*., 1989); hawks (Burgers *et al*., 1986; Newton *et al*., 1986); gulls (Gilbertson, 1974); and others (e.g. see Grasman *et al*., 1998).

Some of the other OCIs, such as the cyclodienes aldrin and dieldrin, resulted in direct mortality in predatory birds, such as sparrowhawks and kestrels (Newton *et al*., 1992). Such mortality, when combined with sublethal effects such as starvation and accidents due to neurological deficits (Walker and Newton, 1998) and reduced productivity due to eggshell thinning caused by DDE exposure (Newton *et al*., 1986), soon led to population declines in such species (Sibly *et al*., 2000). DDE also may co-occur in egg contents with PCBs, which are embryotoxic and therefore contributed to decreased productivity in many waterbird populations (Gilbertson and Hale, 1974a, b; Bowerman *et al*., 2003). Exposure of Great Lakes fish-eating birds to organochlorine compounds including dioxins and dioxin-like compounds such as PCBs may result in embryo and chick mortality, growth retardation, and deformities associated with edema, hepatomegaly, gastroschisis, and other lesions, otherwise known as the Great Lakes Embryo Mortality, Edema, and Deformity Syndrome, or GLEMEDS (Gilbertson *et al*., 1991).

Populations of other vertebrates apart from birds may also have been negatively impacted by DDT. For example, Reeder *et al*. (2005) examined spatial and temporal patterns of intersexuality in cricket frogs collected in Illinois during 1852–2001. Compared with the preorganochlorine era (1852–1929), the percentage of intersex cricket frogs increased during the period of industrialization and initial uses of PCBs (1930–1945), was highest during the peak of manufacture and use of DDT and PCBs (1946–1959), began declining with increased public concern and environmental regulation that led restrictions and eventual ban on the use of DDT in the United States (1960–1979), and continued to decline through the period of gradual reductions in environmental residues of organochlorine pesticides and PCBs in the midwestern United States (1980–2001).

## Cholinesterase-inhibiting pesticides

Organophosphorous (OP) and carbamate insecticides such as diazinon, chlorpyrifos, malathion, and carbofuran are cholinesterase-inhibiting compounds. As such, they prevent breakdown of acetylcholine after transmission of a nerve impulse. The first OP cholinesterase inhibitors were developed as chemical weapons during WWII. After WWII, the use of OP compounds increased as pests developed resistance to OCIs and their use was restricted. The OP compounds are not persistent in the environment in comparison to OCIs, but they are highly acutely toxic and broad spectrum; human deaths from mishandling occur annually. Secondary poisoning can occur when predators consume invertebrates or vertebrate wildlife that have been poisoned by these chemicals. In one of the best-documented secondary-poisoning events, approximately 6000 wintering Swainson's hawks (*Buteo swainsoni*) were poisoned in Argentina during 1995–1996 after feeding on grasshoppers sprayed with the OP insecticide monocrotophos (Goldstein *et al*., 1999). In another incident, hundreds of laughing gulls (*Larus atricilla*) were poisoned after consuming insects killed or debilitated by application of parathion to cottonfields (White *et al*., 1979); this is especially noteworthy in that the mortality included nestlings which died after being fed contaminated prey by adult gulls. It is likely that large numbers of individual poisonings of birds and other species by OP insecticides go unnoticed, following both the intended use and misuse of licensed products. Organophosphorous insecticides have also been used illegally as avicides to protect grain crops from bird depredations (White *et al*., 1989), and in baits to kill livestock predators such as coyotes (Wobeser *et al*., 2004). Such misuse has resulted in additional mortalities from secondary poisoning of predatory birds and mammals eating carcasses of poisoned animals (Wobeser *et al*., 2004).

Two of the three previously most widely used OP insecticides, diazinon and chlorpyrifos (the third is malathion), are now severely restricted in the US. The removal of diazinon and chlorpyrifos from household products early in the 21st century led to almost immediate reduction in concentrations in umbilical cord blood and was associated with increased birth weights of babies of low-income families (Whyatt *et al*., 2004).

Granular carbofuran pellets have been consumed by birds that apparently mistook them for seeds; and one pellet of this carbamate insecticide is enough to kill a bird (Balcomb *et al*., 1984). Carbofuran was the insecticide most commonly associated with wildlife pesticide poisoning events (e.g. red-winged blackbirds (*Agelaius phoeniceus*), Augspurger *et al*., 1996; bald (*Haliaeetus leucocephalus*) and golden (*Aquila chrysaetos*) eagles, coyotes (*Canis latrans*), and red foxes (*Vulpes vulpes*), Wobeser *et al*., 2004; bald eagles and red-tailed hawks (*Buteo jamaicensis*), Elliot *et al*., 1996; buzzards (*Buteo buteo*), Dietrich *et al*., 1995; herons, Hunt *et al*., 1995), and was even implicated in declines of some species, e.g. burrowing owls (*Athene cunicularia*) (Blus, 1996). The phase-out of the granular formulation began in 1991 and registrations for most solid forms have been cancelled. In addition to direct toxic effects to avian wildlife, insecticides may reduce populations of non-target invertebrates used as food by birds (Martin *et al*., 2000; Moreby *et al*., 2001; Morris *et al*., 2005), which may require increased foraging effort (Martin *et al*., 2000; Morris *et al*., 2005) or prey switching (Martin *et al*., 2000) by adults with young to feed. Additional research in this topic area is needed.

## Other insecticides

Pyrethrins from chrysanthemums and structurally related synthetic insecticides (pyrethroids) bind to sodium channels preventing closure, or to GABA-mediated chloride channels inhibiting chloride influx at sodium channels resulting in tremors or seizures. These chemicals are generally of low toxicity to mammals and birds; however, they are highly acutely toxic to arthropods, including non-target taxa such as spiders, parasitoids, and bees. Also, they are often highly acutely toxic to tadpoles and fish. Although early formulations had a short half-life – measured in hours in direct sunlight – newer compounds are designed to be more photostable, extending their effectiveness for up to 10 days out-of-doors. Unfortunately this greater stability increases environmental risks associated with their use.

There are a variety of other classes of pesticides used for control of insects, arachnids (e.g. mites), and other "pests." Some are nerve poisons, others inhibit energy production, chitin synthesis, water balance, or growth. A number of lower-risk pesticides include microbes (e.g. the soil bacterium *Bacillus thuringiensis* (Bt) for mosquito control), microbial products (e.g. spinosyn to control caterpillars is a fermentation product of a soil actinomycete), a range of other "natural chemicals" (e.g. pheromones, florals, sulfur), and "plant-incorporated protectants" (e.g. transgenic crops that may produce toxins originally synthesized in bacteria, such as Bt). Many of these new methods of pest control are more environmentally benign alternatives to traditional insecticides. However, they are intended to disrupt normal physiological processes, and thus, each carries potential environmental risks, which are only partially understood.

## Herbicides

During 2000, herbicides represented 36% of the world pesticide market (Kiely *et al*., 2004); the agricultural sector accounted for 78% of the herbicide use in the United States in 2001. Atrazine is perhaps the world's most used agricultural herbicide, with an estimated 74–80 million pounds applied in the United States alone in 2001 (Kiely *et al*., 2004). Atrazine or its degradation products have been found in air (Kuang *et al*., 2003), rainwater (Goolsby *et al*., 1997; Kuang *et al*., 2003; Asman *et al*., 2005), surface water (Spalding and Snow, 1989; Battaglin and Goolsby, 1999; Scribner *et al*., 2000), and groundwater (Spalding *et al*., 2003; Mills *et al*., 2005).

Herbicides are often considered benign with regard to impacts on animals; however, these compounds can have toxic effects at concentrations found in the environment. Atrazine has come under increased scrutiny due to evidence that it may produce endocrine-disrupting effects in amphibians, and has been banned by several European Union countries. Reeder *et al*. (1998) associated detection of atrazine with the finding of intersex gonads in cricket frogs (*Acris crepitans*). Hayes *et al*. (2002a, b, 2003) found that concentrations of atrazine as low as 0.1 parts per billion (ppb) affected gonadal development, produced hermaphroditism, and reduced the laryngeal muscle (needed for calling to attract mates and ward off potential competing males) in larval male frogs. At a range of test concentrations that can be found in the environment, atrazine was associated with reduced survival of tadpoles (Storrs and Kiesecker, 2004), increased length of larval period (Coady *et al*., 2004), reduced size at metamorphosis (Diana *et al*., 2000), gonadal dysgenesis, and reduction of spermatogenesis (Tavera-Mendoza *et al*., 2001). However, there have been contrasting results from others studies, and authors have suggested that intersex may be found in unexposed frogs (Carr *et al*., 2003; Freeman and Rayburn, 2004; Hecker *et al*., 2005; Jooste *et al*., 2005). However, in most such reports to date, the animals in control groups or at reference sites were also exposed to low concentrations of atrazine. Additional, carefully designed studies are needed.

Glyphosate is a broad-spectrum herbicide that has become the most used herbicide in the United States. This chemical has a low toxicity to mammals; however, surfactants used in some formulations to cause glyphosate to adhere to plant surfaces greatly increases the chemical's toxicity (Goldstein *et al*., 2005). Thus, some formulations (those not intended for aquatic vegetation control) can result in direct mortality of larval and juvenile amphibians (Relyea, 2005a) and subsequent loss of biodiversity (Relyea, 2005b). Glyphosate readily adsorbs to soil or is rapidly degraded by bacteria, and therefore is not highly bioavailable to animals and has low potential for runoff (Malone *et al*., 2004). Nevertheless due to its high water solubility, glyphosate is sometimes detected in surface waters due to runoff (Battaglin *et al*., 2005). Moreover, some

formulations are intended for control of aquatic vegetation (Solomon and Thompson, 2003). Due to its effectiveness and non-specific herbicidal properties, use of glyphosate to control undesirable plant species put, non-target plants at risk (Matarczyk *et al*., 2002; Gettys and Sutton, 2004).

Studies conducted by our laboratory have revealed a complex set of interactions involving herbicides that affect the health of amphibians inhabiting agriculturalized regions. Beasley *et al.* (2005) studied impacts of herbicides on trematode infections on frogs. They found that, in herbicide-impacted farm ponds, recruitment of juvenile cricket frogs was reduced and trematode infections in the frogs were greatly increased. The reduced recruitment might have resulted from deaths due to the infection with trematode cercariae, because other species of frogs died when early stages were exposed to the parasite (Schotthoefer *et al*., 2003a,b). Sousa and Grosholz (1991) had previously suggested that a more complex habitat structure impedes parasite transmission, and Beasley *et al*. (2005) hypothesized that severe trematode infections noted in their studies were due to interacting factors related to fewer plants in the water. In such simplified ecosystems, predation would likely be facilitated so that the survivors would receive a greater infective load from trematodes in the water. Similarly, the motile cercariae would likely have less difficulty finding the tadpole intermediate host thereby facilitating infection.

Herbicide contamination of water bodies may also reduce dissolved oxygen and the algal food needed by tadpoles, which may slow the growth of tadpoles, possibly delaying metamorphosis in some species or reducing size at metamorphosis, which may reduce fitness (Diana *et al*., 2000). Both hypoxic water and reduced food may stress the tadpoles, so that they are less able to avoid cercarial infection and encystment. After a reduction in algal and macrophyte communities due to herbicide contamination, there is likely to be a subsequent rebound to produce higher than normal algal concentrations. This is because the competition for nutrients among surviving plant species is likely to be greatly reduced. Although algal food during a rebound might help later season tadpoles, it might also provide food for snails. Under conditions where snail numbers increase relative to tadpole numbers – and considering the immense amplification of infective load related to asexual reproduction of trematodes within snail intermediate hosts – it seems plausible that some wetlands impacted by herbicides may serve as sources of super-infection of tadpoles. This combination of events and nutrient loading as previously discussed may help explain a number of the outbreaks of supernumerary limbs in frogs at levels noted first in the 1990s (Helgen *et al*., 1998; Hoppe, 2000) that were previously seen only infrequently. In addition, pesticide exposure can lead to immunosuppression and increased susceptibility to trematode infections in tadpoles and frogs (Kiesecker, 2002; Linzey *et al*., 2003). Such stressors may result in prolongation of tadpole stage; longer time in the earlier tadpole stages may result in greater lethality due to trematodes, and higher body burdens of pesticides to pass to avian predators. In addition to herbicidal impacts on vegetation and periphyton, exposure to insecticides might influence trematode infections by impacting populations of benthic and plankton predators of cercariae. Members of our team (Labak and Schotthoefer, unpublished data) have demonstrated that invertebrates such as hydra, copepods, daphnids, and especially damselfly larvae and dragonfly larvae attack and consume cercariae in a controlled setting. Insecticide-mediated changes in invertebrate community structure might therefore release cercariae or other trematode life stages from this predation pressure. Whether these "micropredators" are important in determining infective loads of cercariae in natural and human-altered aquatic environments remains to be thoroughly investigated.

Herbicides typically occur in the environment along with other anthropogenic chemicals. Studies examining mixtures of herbicides and insecticides have found additive, synergistic, or even antagonistic effects on organisms, depending on the chemicals used, test organisms, and conditions (e.g. Sutton *et al*., 1971; Jin-Clark *et al*., 2001; Strachan *et al*., 2001; Anderson and Lydy, 2002; Anderson and Zhu, 2004; Green and Abdelghani, 2004). Other stress-ors may enhance the toxicity of pesticides. For example, Relyea (2005c) found that predatory stress increased the lethality of Roundup® (a popular glyphosate product) to larval amphibians. As with many chemicals, there is a need for further examination of the environmental distribution, fate and toxicity of herbicide and their transformation products, considering both direct and indirect adverse effects.

## Rodenticides

Anticoagulant rodenticides such as brodifacoum inhibit blood clotting through inhibition of vitamin K reductase, an enzyme essential to the reuse of the vitamin in producing clotting proteins. Many such compounds are highly and acutely toxic. These rodenticides may directly impact non-target small mammal populations (Brakes and Smith, 2005). Also, secondary poisonings (relay toxicoses) have had impacts on birds of prey (e.g. buzzards, Berny *et al*., 1997; barn owls (*Tyto alba*), Hegdal and Bloskiewicz, 1984; red kites (*Milvus milvus*), Ntampakis and Carter, 2005)), as well as carnivorous mammals such as mink (*Mustela vison*) (Fournier-Chambrillon *et al*., 2004), polecats (*Mustela putorius*) (Shore *et al*., 1996), and red foxes (Berny *et al*., 1997).

## Endocrine-disrupting compounds in sewage receiving waters

A variety of endocrine-disrupting compounds have been detected in sewage effluent, including steroidal hormones,

pesticides, breakdown products of surfactants and plasticizers, pharmaceuticals, and others (e.g. PCBs and dioxins). Kolpin *et al*. (2002) detected 82 compounds in 139 US streams, 34 of which are known or suspected to have estrogenic activity. In that study, 75% of the streams sampled had more than one of the organic compounds present in detectable concentrations. Non-hormonal compounds that influence estrogen receptors include those that mimic the effects of hormones (mimics) and those that interfere with normal hormonal activity (antagonists).

To our knowledge, the first study to establish a link between disruption of the endocrine system and exposure to both sewage effluent and synthetic estrogens was that of Purdom *et al*. (1994). Following reports from fishermen of hermaphroditic fish in sewage lagoons, caged rainbow trout (*Salmo gairdnari*) and carp (*Cyprinus carpio*) were placed in sewage effluent in the field, and others were exposed to an oral contraceptive formulation in the laboratory. Marked increases in plasma vitellogenin (VTG) concentrations were observed, particularly in the trout. VTG is an egg-yolk precursor protein produced in the liver under control of estrogen, and in adult fish, it is normally present in measurable amounts only in the blood or tissues of mature females. Thus, plasma VTG concentrations in males have been widely used as a marker of exposure to environmental estrogens (Hansen *et al*., 1998). Induction of VTG and increased incidence of intersexuality (presence of ova in testicular tissue) have been observed in male fish collected below sewage outfalls in numerous studies (e.g. Folmar *et al*., 1996; Harries *et al*., 1997; Jobling *et al*., 1998; Matthiessen, 1998; Larsson *et al*., 1999; Petrovic *et al*., 2002; Sole *et al*., 2002; Plesner and Christiansen, 2003). Young male roach (*Rutilus rutilus*) exposed to graded dilutions of sewage effluent experienced VTG induction and feminization of reproductive ducts, but no effects on germ cell development (Rodgers-Gray *et al*., 2001). Rodgers-Gray *et al*. (2000) found that VTG response was dose and time dependent; fish chronically exposed to low concentrations of effluent in river water had a lower threshold for VTG induction than did fish that were exposed for a shorter time period. Fish may show a sustained VTG response to estrogen exposure. High levels of plasma VTG in male fish may lead to reduced testicular growth and be accompanied by kidney and liver damage (Herman and Kincaid, 1988; Folmar *et al*., 2001). Plasma VTG concentrations in male fathead minnows remained elevated 21 days after exposure to estradiol (Panter *et al*., 2000). Also, reduced gonad mass relative to body mass (Harries *et al*., 1997; Jobling *et al*., 1998; Panter *et al*., 1998), increased relative liver mass (Harries *et al*., 1997), testicular damage (Plesner and Christiansen, 2003), reduced gonopodium length (the modified male anal fin, critical for sperm transfer in some species) (Batty and Lim, 1999), and reduced serum testosterone concentrations in males (Folmar *et al*., 1996) have been observed in fish collected downstream of wastewater treatment plants. In addition, gamete production and quality were reduced in intersex male roach collected from sites that received sewage effluent (Jobling *et al*., 2002).

Natural (e.g. 17β-estradiol, estrone) and synthetic (e.g. 17α-ethynylestradiol) steroid hormones are among the most commonly occurring and potent endocrine disrupting compounds in effluents from wastewater treatment plants handling domestic wastewater (Desbrow *et al*., 1998). However, sensitivity to estrogen exposure is species-specific (Purdom *et al*., 1994; Thompson *et al*., 2000), highlighting the need for proper selection of species for monitoring purposes.

Although mature female fish are not as responsive to estrogen exposure as are males, normal patterns of vitellogenesis in adult females may be altered by exposure to high concentrations of ethynylestradiol (e.g. Sole *et al*., 2002). Also, increased VTG production has also been documented in mussels exposed to sewage effluent, either directly (Gagne *et al*., 2001; Quinn *et al*., 2004) or in receiving streams (Gagne *et al*., 2001).

Research studies have documented a variety of endocrine-disrupting effects of steroidal hormones on fish, including reductions in gonadosomatic indices (organ weights as a proportion of body weight) and the number of males with milt and spawning tubercles (Bjerselius *et al*., 2001), reduced gonopodium (used as a phallus for sperm transfer) length (Doyle and Lim, 2002), and reduced fecundity (number of eggs) without a reduction in fertility (Oshima *et al*., 2003). Others have found changes in breeding behavior of male fish exposed to estradiol, including fewer courtship displays, chasing/following behaviors, and copulation attempts, and reduced aggressiveness toward other males (Bayley *et al*., 1999; Bell, 2001; Bjerselius *et al*., 2001; Doyle and Lim, 2002; Martinovic *et al*., 2003; Oshima *et al*., 2003). Male fathead minnows exposed to estradiol were able to acquire nests and spawn successfully in the absence of competing males (Martinovic *et al*., 2003). However, estradiol-treated males were less aggressive in encounters with control males, and subsequently acquired and held fewer nests and produced 5 times fewer offspring than controls. This decreased productivity of individual males could reduce their reproductive fitness (genes less likely to be passed to the next generation) and reduce the growth rates of exposed populations.

The long-term impacts of exposure to complex mixtures of endocrine disrupting compounds on populations of fish, frogs, and other aquatic life are not well understood. Grist *et al*. (2003) modeled the effects of ethynylestradiol exposure on populations of fathead minnows (*Pimephales promelas*) and determined that reductions in population growth rates due to reduced fertility could be anticipated. Questions such as whether males with subtle intersex characters breed successfully in the wild (impacting the reproductive fitness of affected individuals) and whether a population with fewer mature males can be sustainable long-term need to be addressed.

## Metals, metalloid and a non-metal

Metals are electropositive elements with metallic bonds that readily form cations. The heavy metals such as cadmium, lead, and mercury have high atomic weights, have no known physiological role, and can produce toxic effects at low concentrations. Others, such as the essential elements copper and zinc, are necessary for life, but they can be toxic at elevated concentrations. Metalloids are elements with properties intermediate between metals and non-metals. Some metalloids such as arsenic and non-metals such as selenium can be toxic at relatively low doses. Of course, selenium is an essential element needed in minute amounts for optimal health.

Metals are usually complexed with other elements in the environment, and the form, or species, of a metal, as well as its valence state, are important in determining its toxicity to organisms. Trivalent chromium occurs naturally, and small amounts are necessary for optimal health. In contrast, hexavalent chromium is produced and used in industry and is highly toxic.

Use of fertilizers, irrigation, and pesticides may increase the soil's toxic load of elements and salts. Early pesticides were metal salts such as lead arsenate; in some areas soils remain contaminated from early use of these compounds. Other anthropogenic activities such as processing and burning of fossil fuels, mining, smelting, and steel making have increased concentrations of metals in the biosphere.

Mercury is a highly toxic metal that is released naturally into the biosphere from volcanic eruptions, exposed bedrock, as well as through anthropogenic activities including chloralkali plants used to produce chlorine (now being phased out in much of the world), mining, reservoir development, burning fossil fuels, medical procedures and waste, metal processing, smelting, waste and incineration. Mercury is used in thermometers and barometers, electrical switches, fluorescent lights, dental amalgams and in the past was used in the making of felt hats. Mercury is also released during the burning of coal. Another important source has been use of liquid mercury metal to capture gold from stream bed deposits. Because human and wildlife populations are already experiencing the impacts of toxic exposures to methylmercury, the continued atmospheric transport and deposition of mercury are major concerns.

When mercuric salts and metallic mercury are metabolized by organisms in anaerobic sediments, they form the more toxic methylmercury. The rate of conversion of other forms of mercury to methylmercury is much faster in certain warm climates that have favorable geochemistry (e.g. parts of the Amazon and of Florida) than in areas more distant from the equator Veiga *et al*.,. Methylmercury bioaccumulates via the aquatic food chain, readily crosses the placenta and blood–brain barrier, and is highly toxic to the developing nervous system.

Cadmium is a toxic element used in Ni–Cd batteries and in certain pigments, plastics stabilizers, coatings, alloys, and electronics. It also is an impurity found in, or released during the processing of, other metals such as copper, iron, and zinc, manufacturing of steel, cement, fertilizers, and the combustion of fossil fuels. Cadmium is readily taken up by some plants (e.g. leafy vegetables, rice) and is then ingested by humans and other animals in their food. Among the principal target organs of cadmium are bone and kidneys.

Lead has been used in shotgun pellets, bullets, fishing sinkers, paint, batteries, gasoline, solder, water pipes, and other products. One of the largest sources of lead in the atmosphere is leaded gasoline; alkylated lead is added to reduce engine noises or "knocking." To help control harmful emissions, beginning in 1975 passenger cars and light trucks manufactured in the United States included catalytic converters that required lead-free gas. The US Environmental Protection Agency mandated a phase-down of lead concentrations from 2–3 to 1/10th g/gallon during 1977–1986; prohibitions on lead in paint, water pipes, and tin cans were also enacted during this period. Leaded gasoline was still available for use in passenger automobiles in some parts of the United States until 1996, and is still used in aviation, motorboat, farming, and racing vehicle gasoline. In the United States, reductions in lead use were reflected in a 37% decrease in average blood lead concentrations of human beings during 1976–1980 (Pirkle *et al.*, 1994), and 41% reduction between the periods 1988/ 1994 and 1999/2002 (Muntner *et al.*, 2005). However, lead exposures among children of some socioeconomic groups in the United States remain high due in part to contaminated dust, lead paint chips, lead dissolved from plumbing, and other sources (Muntner *et al.*, 2005). Worldwide, internal combustion engines are still a major source of environmental lead, although an increasing number of nations have banned or are beginning to restrict its usage in gasoline.

Mining of metals and minerals often carries large environmental impacts. Not only do these activities leave the land degraded and scarred, but processes to remove the product of interest often result in the release of toxic elements or other chemicals into the environment. For example, sulfides released from newly exposed rock may combine with water and oxygen to form deadly sulfuric acid, which often makes its way into soils, groundwater and streams. This acid also has the added effect of leaching or dissolution of toxic metals such as arsenic, cadmium, lead, iron, and mercury from mine tailings or "waste" rock. The legacy of the mining boom of the mid- to late-1800s in the American west are many miles of streams and rivers still contaminated with metals and sulfuric acid. In addition to devastating environmental impacts from effluents of mining in developing countries that are due to the lack, or poor enforcement, of environmental protection laws, the pursuit of the metals produced may also lead to armed conflict and human rights abuses (MMSD, 2002).

The use of chromated copper arsenic (CCA) in treating wood to prevent insect damage and rot has received much recent attention with regard to risks to children using treated playground equipment, as well as playing in areas where such equipment exists, due to leaching of the metals from wood into soil. The US Environmental Protection Agency has banned sales of CCA-treated wood for most residential uses. Nevertheless, much of the wood remains in use today, and CCA-treated wood produced before 2003 can still be sold. Of importance, animals attracted to the salty taste of the ash left from burning CCA-treated wood the pursuit of the metals produced may readily ingest a lethal dose of arsenic.

The process of removing metals from ore, or smelting, results in the deposition of aluminum, cadmium, fluoride, lead and zinc, and/or other elements that can be highly toxic to plants, soil-dwelling invertebrates, and vertebrates. Such toxicity can reduce the diversity of flora and soil fauna, leaving only more tolerate species, so that ecological function in contaminated landscapes is altered for centuries and likely millennia. An example is provided by two zinc smelters that operated near Palmerton in the mountains of eastern Pennsylvania for much of the 20th century. Approximately 485 ha of vegetation were severely impacted (Jordan, 1975), and damage extended 10 km downwind of the smelters. Drought and fire followed by erosion of as much as 30–60 cm of topsoil Oyler, 1988 exacerbated the damage to the mountainside. Areas that remained forested became dominated by species that re-sprouted from roots or stumps instead of seeds (Jordan, 1975). There was also a loss of diversity in moss (Nash, 1972) and lichen (Nash, 1975) communities. Retardation of decomposition due to greatly reduced populations of soil and litter macro- and microorganisms (Jordan and Lechevalier, 1975; Strojan, 1978a) resulted in a build-up of plant litter on top of mineral soil (Strojan, 1978b). These habitat changes, along with accumulations of toxic levels of cadmium, lead, and zinc (Beyer *et al.*, 1985, 1988), caused reductions in populations of forest birds, small mammals, and salamanders (forest floor salamanders were extirpated), especially insectivorous species. These impacts extended many kilometers downwind and beyond the area of obvious environmental impacts (Beyer and Storm, 1995). The sheer volume of contaminated soil, along with a cinder bank or "dross" pile containing an estimated 33 million tons of slag (waste ore), makes removal of contaminated material impractical. Efforts to re-vegetate the site began in the 1990s with the application of a mixture of fly ash, sewage sludge, and limestone to the barren mountainside, in an effort to control pH, prevent further erosion, and provide a medium for plant growth (Oyler, 1988). However, efforts to restore the steep, rocky, highly contaminated slopes have been largely unsuccessful to date.

Most natural soils contain low concentrations of toxic elements, although there are some areas where soils are naturally high in certain elements, e.g. seleniferous soils of the western United States. Arsenic and selenium can be present in levels of concern in ancient groundwater, and pumping from wells for drinking and irrigation makes them available at the surface. Due to the marine origins of the adjacent mountains, the soils of the San Joaquin Valley in California are high in salts and certain trace elements including selenium. Irrigation is necessary to leach salts from the soil to allow the production of vegetables and other crops away agricultural wastewater is then carried by a network of canals. In the past, the water was directed to a basin that formed 12 constructed wetlands on what became the Kesterson National Wildlife Refuge. These wetlands, located in an arid region with a diminished wetland base, were an attractive habitat to a variety of breeding waterbirds. High concentrations of selenium in wastewater became even more elevated over time in these wetlands through evaporation in the arid climate of central California, and by 1983 a high incidence of embryo mortality and deformities was noted in wetland birds such as grebes, coots, stilts, and ducks (Ohlendorf and Hothem, 1995). Because of the severely of these impacts, the ponds were closed and filled. Subsequently, 12 other water reclamation projects in the arid western United States were found to be contaminated with selenium in irrigation drainage water (Seiler *et al.*, 2003). Although this issue has received attention from planners and researchers, and some remediation has been undertaken, the underlying issues are socioeconomically, politically, and technically complex; thus, progress in finding solutions has been slow.

## Radiation/radionuclides

The nuclear age began with the discovery of X-rays in 1895. Fission was first demonstrated in 1938 by German scientists, which led to competition between Nazi Germany and the United States to develop an atomic weapon. The United States developed such a bomb in 1945, and then used two against Japan to end WWII. Nuclear weapons testing and the bombing of Hiroshima and Nagasaki, Japan, during the mid-20th century resulted in the global distribution of radioactive material.

The first reactor-produced radioisotopes for medical and industrial use were provided by the Oak Ridge National Laboratory in 1946. Since that time, nuclear medicine has been a boon for the diagnosis and treatment of many diseases.

By 1951, electricity was being produced via nuclear fission, and by July 1957 the first civilian reactor for power was on line. However, in October 1957, the first accidental release of radiation from a reactor occurred. Theoretically, nuclear energy can provide "cleaner" and cheaper electricity than burning of fossil fuels. However, in addition to small releases of radioactivity during normal operations and the transportation and storage of nuclear wastes there

have been accidental discharges of large amounts of radiation, such as the incidents at Chernobyl, Ukraine, and Three Mile Island, Pennsylvania, USA. In 1986, the explosion and fire at a poorly designed reactor at Chernobyl led to the hospitalization of 203 people and the death of 47 due to radiation poisoning. Also, as of 2004, 9 children from the area had died of thyroid cancer. Fallout containing short- and long-lived radioisotopes covered a wide area of northeastern Europe, and radiation from this incident ultimately was transported throughout the northern hemisphere. Residents of a 30 km radius were evacuated and few have returned. One source estimated that there would be an eventual 4000 additional human deaths, driven by a 2% increase in cancer rates. In spite of somatic and germ-cell mutations in birds, small mammals, and fish resulting in increased prevalence of aberrant phenotypic traits, native plants and wildlife have flourished, whereas invasive exotic species have declined, in the 30-mile exclusion zone around Chernobyl. This has been touted as "proof" that effects of radiation from this nuclear disaster were not as long-lasting as feared. However, these animals could represent the immigration of dispersing animals from surrounding areas into unoccupied habitat. Few detailed, longitudinal studies of wildlife populations and their age structures have been conducted.

Perhaps best studied in the Chernobyl area have been barn swallows, which are migratory insectivorous birds with a high degree of philopatry. Fourteen years after the incident, swallows nesting in the area around Chernobyl had high prevalence of abnormal sperm and reductions in antioxidant levels, compared to swallows from a reference area (Moller *et al*., 2004). The exposed birds also had a sustained high rate of partial albinism (Moller and Mousseau, 2001), and germline mutation rates that were 2- to 10-fold higher than distant reference sites (Ellegren *et al*., 1997). Immune suppression and reduction of carotenoid-based sexual coloration were also noted in this population (Camplani *et al*., 1999). Mutations produced phenotypic changes in secondary sexual traits (e.g. plumage coloration, feather lengths) that may influence reproductive success (Camplani *et al*., 1999; Moller and Mousseau, 2003).

Small mammal populations in some areas near Chernobyl were reduced by as much as 90% following the reactor incident. Increases in populations in the following spring were attributed to immigration from less-contaminated adjacent areas (Sokolov *et al*., 1990) and the cessation of tillage and crop harvest (Sokolov *et al*., 1993). Voles collected from the Chernobyl area had the highest radiocesium burdens and dose rates ever recorded for mammals (Baker *et al*., 2001). Researchers have reported high genetic diversity in voles from the highly contaminated zone (Matson *et al*., 2000; Baker *et al*., 2001; Wickliffe *et al*., 2006), which could be indicative of high mutation rates and/or immigration from less-contaminated areas. Cytogenetic damage was documented in voles in Belarus (Goncharova and Ryabokon, 1995) and Sweden (Cristaldi *et al*., 1991), both of which were in the direction of prevailing winds in the first few days following the disaster.

## ENVIRONMENTAL FATE OF CHEMICALS IN THE ENVIRONMENT

Our environmental contamination problems are complex but controllable, by limiting environmental contamination so that concentrations are not high enough to harm prokaryotic and eukaryotic life forms (e.g. beyond the intended target site, such as an agricultural plot selected for treatment because an exotic insect pest has been recognized). The assimilative capacity of most natural environments is tremendous; however, it is essential to ensure that pollutants are not produced and used at rates that undermine the capacity of the purposefully exposed site to detoxify itself.

Environmental contaminants are degraded, or transformed into simpler, often (though not always) less toxic forms, in several ways. Photodegradation involves transformation of chemicals often involving oxidation to reduce toxicity. Many manmade chemicals are rapidly photodegraded by sunlight. Some chemicals may become more toxic to organisms through the process of photoactivation. For example, dechlorination of hexachlordibenzo-*p*-dioxin may produce lower chlorinated but more toxic dioxin analogs.

Biotransformation involves the modification of chemicals by the physiological processes (e.g. enzymes in the liver that catalyze hydrolysis, oxidation, reduction, or conjugation) in living organisms – usually in an effort to detoxify and eliminate them. But biotransformation also occurs in soil microbes such as bacteria and fungi under aerobic or anerobic conditions. Plants and microbes within digestive tracts are also important in the biotransformation of environmental contaminants. Of course, metabolic changes can also bioactivate chemicals to produce (by definition) metabolites that are more toxic than their parent compound. For example, the organochlorine pesticide DDT is not itself highly toxic to birds. However, its metabolite *p,p'*-DDE can cause thinning of eggshells due to disruption of calcium metabolism. Also, during microbial metabolism, inorganic mercury is methylated, producing a potent neurotoxic substance responsible for cognitive, fine motor, and visual-spatial disabilities, especially in developing organisms. Efforts by organisms to detoxify exogenous compounds can sometimes produce temporary bioactivation manifested in reactive species such as singlet oxygen or hydroxy radicals. These free-radicals or oxidants can cause oxidative stress, damaging cells and may promote tumor formation. More research on fate and toxicity of metabolites and environmental degradation products is needed.

## AVAILABILITY OF CHEMICALS IN THE ENVIRONMENT

Because a contaminant is present in the environment does not mean that an organism will have contact with it. For example, surface-dwelling animals may not have direct access to a contaminant buried under of many centimeters of topsoil. However, they may gain exposure by consuming earthworms or plants that bring contaminants to the surface. Thus, contaminants and receptors (i.e. organisms of interest) must overlap in both time and space for there to be a potential for exposure. Should pollutants and receptors co-occur, there are a number of potential pathways of exposure: dermal, oral (dietary and grooming), inhalation, via gills and rarely, injection.

The bioavailability of pollutants in the environment refers to the proportion of a substance that is absorbed across the gut, skin, or other portals to enter the bloodstream and other tissues where it can cause a physiological reaction in an organism. Bioavailability can be determined by the amount of organic matter, pH, and cation-exchange capacity of soil or sediment, the presence of antagonistic elements of chemicals, and the nutritional status of an organism.

## THE FUTURE OF ECOTOXICOLOGY

The science of ecotoxicology should exist within a balanced ecological and biomedical context. In the view of the authors, ecotoxicology needs to become more of a preventive science and less of a remediative enterprise. Although diagnostic laboratories must become far more involved in forensic ecotoxicology, simply waiting on animals to come to diagnostic laboratories is insufficient to protect wildlife and ecosystems from chemically induced damage. Thus, ecotoxicology must also be pro-active, involving trips to the field for monitoring of exposures and impacts, and trips to the laboratory for exploratory and confirmatory research.

In the authors' view, there needs to be better testing of products before marketing to insure not only the health of humans, but also of pets, livestock, wildlife, plants, and the environment as a whole. For most toxicants, detailed and comprehensive ecotoxicological information exists for very few plant and animal species. Risk assessment therefore often relies upon the use of a few surrogate species, with extrapolation to a huge array of organisms that will likely be exposed when a product is used or an effluent is released.

Of concern is that much information from industry on testing of products is buried in reports to the US Environmental Protection Agency and difficult to obtain. We believe that, upon granting of patents, industry scientists should be required to publish results of toxicity testing in the scientific literature and via the Internet so that the information is fully available to scientists and the interested public. Stakeholders should share in decision-making with regard to risk management and longer-term product registration.

Finally, we are of the view that considerable effort in regulatory ecotoxicology should be devoted to removal of problematic compounds and formulations, with their replacement, when warranted, with products unlikely to present undue ecological harm.

Ecotoxicology initially was focused largely on determining chemical residues in the environment and not enough on mechanisms and effects, though this has begun to change. Ecotoxicological research typically extends beyond the health effects on individuals, to examine how these changes manifest as population-, community-, and ecosystem-level impacts. However, if environmental mismanagement places greater numbers of species at risk for extinction consideration of toxic effects on individuals will be increasingly necessary.

Far greater attention needs to be devoted to complex mixtures of chemicals, indirect effects of contaminants, fate and toxicity of chemical degradation products, development of more endpoints of exposure and their role in disease, and the validation of risk assessments.

There is a continuing need for more integrative ecotoxicology research, i.e. comprehensive, large-scale field studies examining interactions among biotic and abiotic factors, complemented by microcosm and mesocosm studies. More research incorporating reproductive toxicology including multi-generational studies is needed. More studies should examine how contaminant exposure affects animal behavior, since subtle changes in behavior can have immense negative impacts on an animal's survival and reproductive fitness. There is a need for more studies designed to identify cause and effect, including assessments of clinical signs, histological lesions, and residues over time at relevant exposures, to enhance diagnostic and forensic capabilities. Animals subjected to toxicity testing to determine $LC_{50}$ or $LD_{50}$ or minimum toxic dose or maximum tolerated dose should consistently be evaluated with clinical pathology assays, gross and histological pathology studies, and analyses to determine residues. All of these endpoints should be evaluated at doses with no impact, threshold toxic reactions, marked toxic reactions, and overt lethal toxicity.

"Veterinary ecotoxicologists" can participate in meeting critical data gaps by specializing in a variety of disciplines with regard to environmental contaminants, including: epidemiology, pathology, immunology, environmental risk assessment, environmental chemistry/fate, environmental law, ecological rehabilitation, and others. Veterinary ecotoxicologists can also specialize in a particular toxicant group (e.g. metals, hazardous wastes), animal species group (marine mammals, birds, invertebrates), given habitat type

or biome (aquatic, terrestrial, desert, forest, estuaries, coral reefs), or given region (midwestern United States, Illinois, north Africa, tropics, polar).

The future of a healthy environment for humans, domestic animals, and wild biota depends to a large extent on the degree to which we learn to use and control naturally occurring and synthetic chemicals. Although there have been successes, and some environments are cleaner now than in the recent past, the continually expanding number of chemicals released into the environment increasing free nutrients that prompt biotoxin production and the adverse impacts noted in the environment demonstrate the striking need for vigilance and accountability through research, education, environmental law and enforcement, and development of prudent science-driven environmental policy.

CHAPTER

# 58

# Aquatic toxicology

*Robert W. Coppock and P.N. Nation*

## INTRODUCTION

Aquaculture is the production of aquatic animals for human food. In aquaculture aquatic animals are grown under water in an aquatic environment. The water may be a sheltered oceanic bay containing pens of aquatic organisms, or the aquatic organisms may be raised in inland ponds or in a tank system. Chemical causes of disease in aquatic organisms are generally linked to water and food because the primary pathways of toxic substances to animals in aquaculture systems are generally feedstuffs and water. Residues of metals and persistent organic compounds can occur.

## BACKGROUND

Aquaculture is an expanding and continually developing industry. Aquatic animals are grown in a confined space, i.e. a pen, pond or tank. The aquatic animals generally are dependent on humans for all or part of their feed. Commercial feed is generally in a granular or pelleted form and contains a binding agent. Inland aquaculture generally requires at least some mechanical management of the aquatic environment. Large capital investment and high operational costs are incentives to increase stocking densities in aquaculture systems. Increased stocking densities increase the demand for water management.

## WATER

### Nitrogen cycle

The nitrogen cycle in aquatic systems is important (Boyd and Tucker, 1998; Hargreaves, 1998). An excellent review on the geobiochemistry of the nitrogen cycle has been written (Hargreaves, 1998). The nitrogen cycle transforms organic nitrogen, ammonia and other forms of nitrogen to nitrogen gas. Important sources of nitrogen in the aquatic system are feedstuff residues, feces and ammonia excreted from aquatic animals. The nitrogen cycle in an aquatic system is primarily regulated by biota. The organisms regulating the different steps in the aquatic nitrogen cycle are remarkably independent, and the products from the different steps can accumulate in the system. Species of *Nitrosomonas* oxidize ammonia to nitrite ($NO_2^{1-}$). The next step is the oxidation of $NO_2^{1-}$ to nitrate ($NO_3^{1-}$) and species of *Nitrobacter* are the primary organisms. Species of *Nitrosomonas* and *Nitrobacter* are dissimilarly affected by oxygen tension, pH, temperature, etc. and species of *Nitrobacter* are the most sensitive allowing the level of $NO_2^{1-}$ to increase. The end step in the nitrogen cycle is reduction with production of nitrogen gas ($N_2$) released into the atmosphere. The most toxic compounds in the aquatic nitrogen cycle are ammonia and $NO_2^{1-}$. Changes in the nitrogen cycle can also be seasonal, related to weather conditions. For example, nitrate poisoning (brown blood disease) in the southern USA is more common in the fall and spring (Durborow *et al.*, 1997). When the concentration of nitrite is $<1\,\mu$mol, the water is generally considered unpolluted (Jensen, 2003).

#### *Ammonia*

The economics of tank-rearing of fish requires high densities. Recirculation systems have densities as high as 0.3 kg of fish/kg of water. Estimated ammonia production by fish is 0.02 kg of ammonia nitrogen produced for each kilogram of feed fed (Masser *et al.*, 1999). Total ammonia nitrogen should be monitored in the aquatic system because ammonia is the primary nitrogen waste excreted by freshwater fish and is the most toxic form. At a given pH of the water, ammonia ($NH_3$) is in equilibrium with

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

ammonium ($NH_4^{1+}$). The unionized ammonia can radially diffuse across cell membranes. The toxicity of ammonia is dependent on the pH of water, water temperature and the species of aquatic animals.

The mechanisms of ammonia toxicity in fish have not been elucidated. Amino acid metabolism is disrupted (Arillo *et al.*, 1984; Smutna *et al.*, 2002). There appear to be metabolic dysfunctions in the liver and links to disruption of neurotransmitters and electrochemistry in skeletal muscle (Randall and Tsui, 2002). Increasing water ammonia decreases swimming ability (Wicks *et al.*, 2002). The decrease in swimming ability was linked to depolarization of white muscles, and increasing water calcium ions ameliorated ammonia toxicity. Feeding fish appears to provide some protection from ammonia toxicity (Wicks and Randall, 2002).

### Nitrite

Aquatic animals, especially freshwater fish and crustacea, are more at risk for nitrite ($NO_2^{1-}$) poisoning that are terrestrial organisms (Boyd, 1982; Boyd and Tucker, 1998). Nitrite intoxication of aquatic animals can occur when conditions exist for dyssenergy in the nitrogen cycle. Freshwater fish are more susceptible to $NO_2^{1-}$ than saltwater fish. In freshwater fish $NO_2^{1-}$ is rapidly absorbed across the gills. The generally accepted mechanism for $NO_2^{1-}$ absorption is by competing for chloride ($Cl^{1-}$) uptake across the gills. The chloride ion is exchanged for bicarbonate ($HCO_3^{1-}$) and this exchange occurs in the apical part of the gill epithelial cell. Nitrite has affinity for the chloride/$HCO_3^{1-}$ exchange protein and replaces $Cl^{1-}$ in the exchange process. Increasing the water concentration of $Cl^{1-}$ reduces the toxicity of $NO_2^{1-}$. Fish with high $Cl^{1-}$ uptake (rainbow trout, perch and pike) are more susceptible to $NO_2^{1-}$. Millimolar $NO_2^{1-}$ levels in the fish, especially if $Cl^{1-}$ in the water are low, can result from micromolar levels of $NO_2^{1-}$ exposure from water. Nitrite causes a net loss of $Cl^{1-}$ because there is a reduction in the influx of $Cl^{1-}$. Nitrite also stimulates a net loss of potassium ions from muscle and this causes an extracellular hyperkalemia and increased excretion of potassium. Nitrite also enters the red blood cells and oxidizes $Fe^{2+}$ to $Fe^{3+}$ and methemoglobin (metHb) is formed. The metHb cannot carry oxygen and oxygen tensions in blood approach the values for dissolved oxygen. The oxidation of iron changes oxygen affinity of hemoglobin. Changes in oxygen affinity and blood pH increase movement of oxygen to the swim bladder. Buoyancy problems can occur. The stress response in teleost (bony) fish is $NO_2^{1-}$-mediated disruption of the $Na^{1+}/H^{1+}$ exchange mechanism in the red blood cells. This can further decrease the affinity of hemoglobin for oxygen. Decreased oxygen tensions increase anarobic metabolism and acidosis occurs. Exposure of rainbow trout to 1 mmol $NO_2^{1-}$ causes vasodilation and an increased cardiac workload (Aggergaard and Jensen, 2001; Jensen and Agnisola, 2005). The fish died when the metHg was >70% and plasma $NO_2^{1-}$ level was 2.9 mmol at the time of death. Liver cell damage linked to mitochondrial pathology occurs and hepatic stores of glycogen are depleted. Necrosis of the retina can occur. Hepatocytes from rainbow trout have been shown to detoxify $NO_2^{1-}$ by converting $NO_2^{1-}$ to considerable less toxic nitrate ($NO_3^{1-}$) (Doblander and Lackner, 1996). Recovery from nitrite poisoning appears to take several weeks and compensatory gain may or may not occur.

Species susceptibility to $NO_2^{1-}$ is variable and is linked to $Cl^{1-}$ uptake by the gills (Durborow *et al.*, 1997; Jensen, 2003). Largemouth and smallmouth bass, bluegill and green sunfish are resistant to high concentrations of $NO_2^{1-}$ and catfish, goldfish and fathead minnows and tilapia are sensitive and coldwater fish like rainbow trout are highly sensitive to $NO_2^{1-}$.

Nitrite poisoning (brown blood disease) can be prevented by adding $Cl^{1-}$ to the water (Durborow *et al.*, 1997). The most common option is to add $Cl^{1-}$ to the water to achieve a ratio of $Cl^{1-}$ to $NO_2^{1-}$ of 10:1. Decreased feeding rates and increased throughput of non-recycled water are alternative methods of controlling $NO_2^{1-}$. Bacterial and parasitic disease increase the sensitivity of fish to $NO_2^{1-}$ poisoning. The presence of concurrent disease requires increasing the concentration of $Cl^{1-}$. Catfish producers commonly maintain 100 ppm $Cl^{1-}$ in the pond or tank water as insurance against a bump in $NO_2^{1-}$ levels or to counteract the effects of concurrent infectious disease.

## Metals

### Copper

There are many sources of copper ions including surface water that potentially can enter aquaculture systems. Copper is commonly used in aquaculture as an algicide and as a treatment for parasites. There is generally a small margin of safety for many aquatic species. Cupric ions ($Cu^{+2}$) disrupt the energy-dependent sodium/potassium pump located in the gill chloride cells. This allows increased efflux of sodium ions. Cupric ions also replace calcium ions at the tight junctions resulting in an efflux of sodium ions. The net loss of sodium ions results in cardiovascular collapse. The uptake of copper ions across the gill of fish is dependent on many parameters including water hardness (levels of calcium and magnesium ions). Copper ions are neurotoxic in fish. These are disruptive of the olfactory and mechanosensory systems (Baldwin *et al.*, 2003; Linbo *et al.*, 2006). Loss of neuromasts occurred at concentrations >20 μg/l, and peripheral olfactory function is inhibited at levels as low as 4 μg/l. Exposure to copper also decreases immune function. Copper levels can be tricky to interpret because pH, carbonate ions and dissolved organic carbon are interactive in forming unavailable forms of copper and $Mg^{+2}$ and $Ca^{+2}$

compete for copper uptake by the fish (Sciera *et al.*, 2004). Changes in these parameters can cause 60-fold difference in lethal toxicity. Decreasing the pH increases the toxicity and a 100 times increase in toxicity can occur with each unit decrease in pH. Warmwater fish are more tolerant of copper than coldwater fish. In a study in fathead minnows, increasing sodium chloride and calcium chloride levels in the water decreased copper toxicity and increasing potassium chloride increased sensitivity to copper (Erickson *et al.*, 1996).

## Non-metals

### *Chlorine*

Water is not considered safe for fish if a measurable level of chlorine ($Cl_2$) is present. Chlorine and chlorine compounds are used as disinfection agents in municipal water and in aquaculture to disinfect ponds and tanks (Boyd and Tucker, 1998). Chlorine gas added to water forms a number of compounds (hypochlorous acid, hydrochloric acid and hypochlorite) and the concentration of dissociated ion depends on the pH of the water. Chloramine is formed by the reaction of chlorine with ammonia in the water. The toxicity of chlorine residues is variable due to effects of water temperature. Residual chlorine in the water is generally oxidative and causes irritation and damage to the gills. The gill lesion can be hypertrophy and hyperplasia with necrosis occurring at higher concentrations. Gill lesions cause hypoxia.

# FEED

## Mycotoxins

### *Fumonisins and moniliformin*

Fumonisin $B_1$ ($FB_1$) or moniliformin (MON) have been shown to reduce the productivity of fish. Nile tilapia fingerlings were fed $FB_1$ or MON at 0, 10, 40, 70 and 150 ppm for 8 weeks (Tuan *et al.*, 2003). The $FB_1$ and MON were extracted from cultures of *Fusarium moniliforme* and *F. proliferatum*, respectively. Mortalities in all treatment groups were low and were not dose related. Feeding diets containing 150 ppm $FB_1$ or MON decreased hematocrit. Both mycotoxins disrupted metabolism. Feeding MON increased serum pyruvate. There was evidence that sphingolipid metabolism was disrupted in fish fed $FB_1$. For fish fed MON, decreased weight gains were observed at the 70 and 150 ppm levels, and for fish fed $FB_1$ decreased weight gains were observed at the 40, 70 and 150 ppm levels. Fish fed 10 ppm $FB_1$ had decreased weight gains for the first 2 weeks, but body weights at 4 weeks were not significantly different from controls. Histopathology linked to treatments was not observed in the fish. Studies on the combination of $FB_1$ and MON showed interactions between the two toxins (Yildirim *et al.*, 2000). Channel catfish are more sensitive to $FB_1$ and MON than tilapia and $FB_1$ is more toxic in channel catfish than MON.

### *Aflatoxins*

Aflatoxins (AF) were identified in the early 1960s as causing hepatic cancer in fish (Sinnhuber and Wales, 1978). Rainbow trout are sensitive to AF and dietary levels as low as 0.4 ppb fed for less than a year will cause hepatic cancer. Salmon are more resistant that rainbow trout to the carcinogenic effects of AF. Aflatoxin $B_1$ ($AFB_1$) is metabolized by the P450 enzyme system in the liver of fish to form the $AFB_1$-8,9-epoxide. The $AFB_1$-8,9-epoxide forms adducts with DNA, RNA and proteins. The formation of adducts is considered to be the primary mechanism of action for the carcinogenicity of $AFB_1$. *In vitro* cultures of rainbow trout peripheral blood leukocytes incubated with $AFB_1$ showed the trout leukocytes to be 1000 times more sensitive to $AFB_1$ than murine (mouse) leukocytes (Ottinger and Kaattari, 1998). Exposure of trout embryos to $AFB_1$ causes long-term immunodysfunction (Ottinger and Kaattari, 2000). $AFB_1$ has been shown to be immunosuppressive in India major carp (*Labeo rohita*) (Sahoo and Mukherjee, 2003). Feeding a diet containing 500 ppm $AFB_1$ altered immune parameters and decreased the native resistance to disease in India major carp. Dietary vitamin C was shown to provide protection against $AFB_1$. $AFB_1$ has been studied in tilapia (Nguyen Anh *et al.*, 2002). One-month-old tilapia fingerlings were fed diets containing 0, 0.25, 2.5, 10 or 100 ppm $AFB_1$ for 8 weeks. Fish fed with 10 and 100 ppm $AFB_1$ consumed less feed and expelled the feed after ingestion suggesting feed refusal occurred. At 6 weeks of feeding, the survival rate for the fish fed the 100 ppm level of $AFB_1$ was 55%. Weight gains for the fish fed the diets containing $\geqslant$2.5 ppm $AFB_1$ were decreased. Hematocrit was reduced in the fish-fed diets $\geqslant$0.25 ppm $AFB_1$. Fish fed diets containing 10 and 100 ppm $AFB_1$ had liver lesions. Pleiomorphic liver nuclei were present in 86% of the fish fed the diet containing 10 ppm $AFB_1$ and 100% of the fish fed the diet containing 100 ppm $AFB_1$. Catfish have high resistance to the carcinogenic effects of $AFB_1$ and this is linked to a low rate of formation of the $AFB_1$-8,9-epoxide (Gallagher and Eaton, 1995).

### *Ochratoxins*

Early studies of parenteral exposure of rainbow trout to ochratoxins showed that ochratoxin A (OA) was ~10 times more toxic that Ochratoxin B (OB). OA extracted from cultures of *Aspergillus ochraceus* was added to channel catfish diets at 0, 0.5, 1.0, 2.0, 4.0 or 8.0 ppm (Manning *et al.*, 2003).

The average initial weight was 6 g/fish. Decreased body weight gain was observed at 2 weeks and at 8 weeks in the catfish fed the diet containing 1.0 ppm OA. At 8 weeks, a decrease in body weight gains was observed for the catfish fed the 2, 4 and 8 ppm diets. Hematocrit was decreased in the fish fed the 8 ppm diet and white blood cell numbers were not changed. At 8 weeks, there was 80% survival in the fish fed the diet containing 8 ppm OA. Histopathology lesions were observed in fish fed the OA diets at the 1, 2, 4 and 8 ppm levels. The lesions were described as enlarged melanomacrophage centers replacing the hepatopancreatic cells and the melanomacrophage centers were present in the posterior kidney. These findings suggest the hepatopancreatic cells are the target for OA in catfish.

## Contaminants in aquaculture fish

### *Chlorinated dioxins*

Aquaculture animals are a source of polychlorinated dibenzodioxins (PCDDs), polychlorinated dibenzofurans (PCDFs) and polychlorinated biphenyl (PCBs) compounds. Each of these groups is a mixture of congeners. These groups of compounds are collectively referred to as persistent organic carbons (POCs). Health concerns exist because these compounds are bioconcentrated in body fat of animals. These compounds are also transferred to the fetus during pregnancy and excreted in breast milk during lactation. Dietary animal protein–fat and clays are the predominant source of the POCs for aquaculture animals. Catfish have been identified as an important source of PCDDs for persons consuming them, and in these individuals, this can exceed the dietary exposure from diary products (Jensen and Bolger, 2001). In a study on the transfer of PCDDs and PCDFs from diet to muscle fat, it was found that in the first 13.5 months of feeding ~30% of the dietary PCDDs and PCDFs in a diet fed to rainbow trout were transferred to fat located in muscle tissue (Karl *et al.*, 2003). At 19 months, the transfer rate increased slightly to ~34% for male trout and decreased to ~27% for egg-laying female trout. Congener-specific pattern of PCDDs and PCDFs accumulation in the fish was not identified. The concentrations of PCDDs and PCDFs in diet were directly related to the concentrations of PCDDs and PCDFs in muscle fat. The levels of PCDDs and PCDFs in muscle fat increased over the 19-month feeding period.

### *Methylmercury*

Methylmercury (meHg) is a concern for human foods from aquatic sources. The primary source of meHg in aquaculture is the use of fish by-products in feedstuffs. meHg is formed by biota in the benthic region of the aquatic system, and is biomagnified in the food web. In fish, meHg has affinity for skeletal muscle and is bioaccumulated in skeletal muscle (Berntssen *et al.*, 2004). Approximately 23% of the dietary meHg and ~6% of dietary inorganic mercury (Hg) is absorbed by fish. Fish fed diets containing 5 and 10 ppm meHg for 4 months had 1.1 and 3.1 ppm of meHg in muscle (freeze-dried), respectively. The threshold toxic level for Atlantic salmon is estimated at 0.5 ppm meHg in diet. Studies in fathead minnows showed that the threshold level of dietary meHg on spawning parameters is $<$0.88 ppp meHg (Hammerschmidt *et al.*, 2002).

# TOXICOLOGY INVESTIGATIONS

The triggers for a toxicological investigation generally are decreased performance in reproduction, feed conversion and growth, and increased mortality. It is important to document when the toxicological incident occurred. Review of records can be helpful to determine when the incident started. A complete history is important to direct the diagnostic procedures and analytical toxicology. Important questions to be asked are:

- Was the incident an acute event or did it occur over a period of time?
- What are the size, age and location of the animals that are affected?
- Were clinical signs observed?
- Can the onset be linked to changes in feed sources, a particular feed storage area?
- Are there links to changes in water handling, filtering or a rainfall event?
- Are there links to ambient and water temperature?
- Pesticide use and location of use?
- Did deaths also occur in terrestrial animals?
- Is the death of aquatic animals linked to a die-off of aquatic plants and phytoplankton?
- Previous land use in the area where the ponds have been constructed?
- Is pathology data available?

The time of day that mortalities occur is important. These can be linked to changes in water temperature and a decrease in dissolved oxygen. Sporadic mortality is more likely to be related to parasites or changes within the tank and pond system. As a general rule small fish are more resistant to low dissolved oxygen and are less resistant to chemical substances.

# CONCLUDING REMARKS AND FUTURE DIRECTIONS

Aquaculture is a growing industry. Toxicological causes of diseases in aquatic organisms are in two categories.

These are toxic substances in water and toxic substances in feedstuffs. Toxic substances in feedstuffs are generally easier to control. The manufactures and suppliers of feedstuffs to the aquaculture industry have the responsibility for quality assurance and quality control that ensure toxic substances are not present in feedstuffs. Toxic substances can bioconcentrate in aquatic organisms and present human food safety issues for the aquaculture industries. Herein animal feed safety and human food safety are linked to quality assurance, and quality control programs and due diligence in the animal feed industries.

Water safety issues are linked to chemical cause of disease in aquatic organisms. In pond- and tank-reared animals, the operator controls the aquatic environment. This requires monitoring of water for levels of toxic substances and ensuring that natural drainage of surface water does not introduce toxic substances to the aquaculture system. Multiple uses of limited water resources will continue to present challenges to water resources available to the aquaculture industry. Aquaculture also has increasing capital investment and operating costs. Water availability and economics are incentives to increase animal numbers per volume of water. Increased animal densities increase the demands on water safety for aquatic animals, and increase the need for research on water recirculation systems.

# Cyanobacterial (blue-green algae) toxins

*Birgit Puschner and Jean-François Humbert*

## INTRODUCTION

Cyanobacterial proliferations in freshwater ecosystems, also known as blooms, can have a significant impact on the health of animals and humans living in or using these systems for drinking water and/or recreational purposes. Among the 2000 species identified on morphological criteria, 40 of them are known to be toxigenic. The first scientific report of cyanotoxin poisoning in animals was made in Australia by Francis in 1878, but a much earlier indication of mammalian cyanotoxin poisoning is estimated to date back to the Pleistocene age, i.e. about 150,000 years BC (Braun and Pfeiffer, 2002). Since this first publication in 1878, numerous case reports describing animal morbidity and mortality exposed to cyanotoxins have been published (Fitzgerald and Poppenga, 1993; Naegeli *et al.*, 1997; Puschner *et al.*, 1998; Gugger *et al.*, 2005). The frequency of blue-green algae poisoning in animals is likely to be underestimated because of the lack of methods to confirm exposure. There are most likely many unreported cases. Proper diagnostic workup of suspect blue-green algae poisoning cases of humans and animals can demand extensive efforts from toxicologists and clinicians. New algal toxins are being discovered continuously and for many, toxicity data, especially after oral exposure, is unavailable. It is possible that blue-green algae poisonings are more common in animals than humans as a result of their behavior and tendency for accidental exposure.

In 1998, after several cases of major human intoxications in Australia, Europe and Brazil (Falconer and Humpage, 2005), the World Health Organization (WHO) proposed a guideline value for the concentration in water of one of the most common cyanotoxin, microcystin-LR. This guideline for drinking water has now been adopted by sanitary authorities of many countries in the European community, and North (Canada) and South America (Brazil). However, the health risks for wild and domestic terrestrial vertebrates resulting from the exposure to cyanotoxins in water are still largely ignored, despite an increasing number of reports of poisoning in the veterinary literature.

## BACKGROUND

The degradation of numerous aquatic ecosystems throughout the world, due to nutrient pollution (phosphorus and nitrogen especially), has led to significant eutrophication ($>$40% in Europe, Asia and America) (Bartram *et al.*, 1999). As a major consequence, photosynthetic microorganisms have ample nutrients available to reach very high biomasses. In addition, the diversity of the phytoplanktonic communities decreases drastically, resulting in the dominance of a very few, generally one or two, numbers of species. In such conditions, cyanobacteria are often the dominant species. Indeed, these microorganisms have developed many adaptive processes to outcompete other phytoplanktonic species and to avoid predation by zooplanktonic organisms (Mur *et al.*, 1999; Oliver and Gant, 1999).

Cyanobacteria are oxygenic photosynthetic prokaryotes that are probably among the oldest form of microorganisms found on earth, some 3 billion years ago. They can be observed as isolated cells (e.g. *Synechococcus*), organized in filaments (e.g. *Planktothrix*) or in colonies (e.g. *Microcystis*). More than 2000 species belonging to four orders are described in the botanical code based on

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

morphological and morphometrical criteria (Anagnostidis and Komarek, 1985). But cyanobacteria are also classified under the bacterial code into five sections defined on the combined use of genetic data, morphological criteria and cellular fission (Rippka *et al.*, 1979).

In aquatic ecosystems, different species can be found in the pelagic (water column) or in the benthic (e.g. on the sediments) domains. Typically, blooms of pelagic species occur in mesotrophic and eutrophic ecosystems (concentrations in phosphorus $>30\,\mu g/l$) during the summer, when the

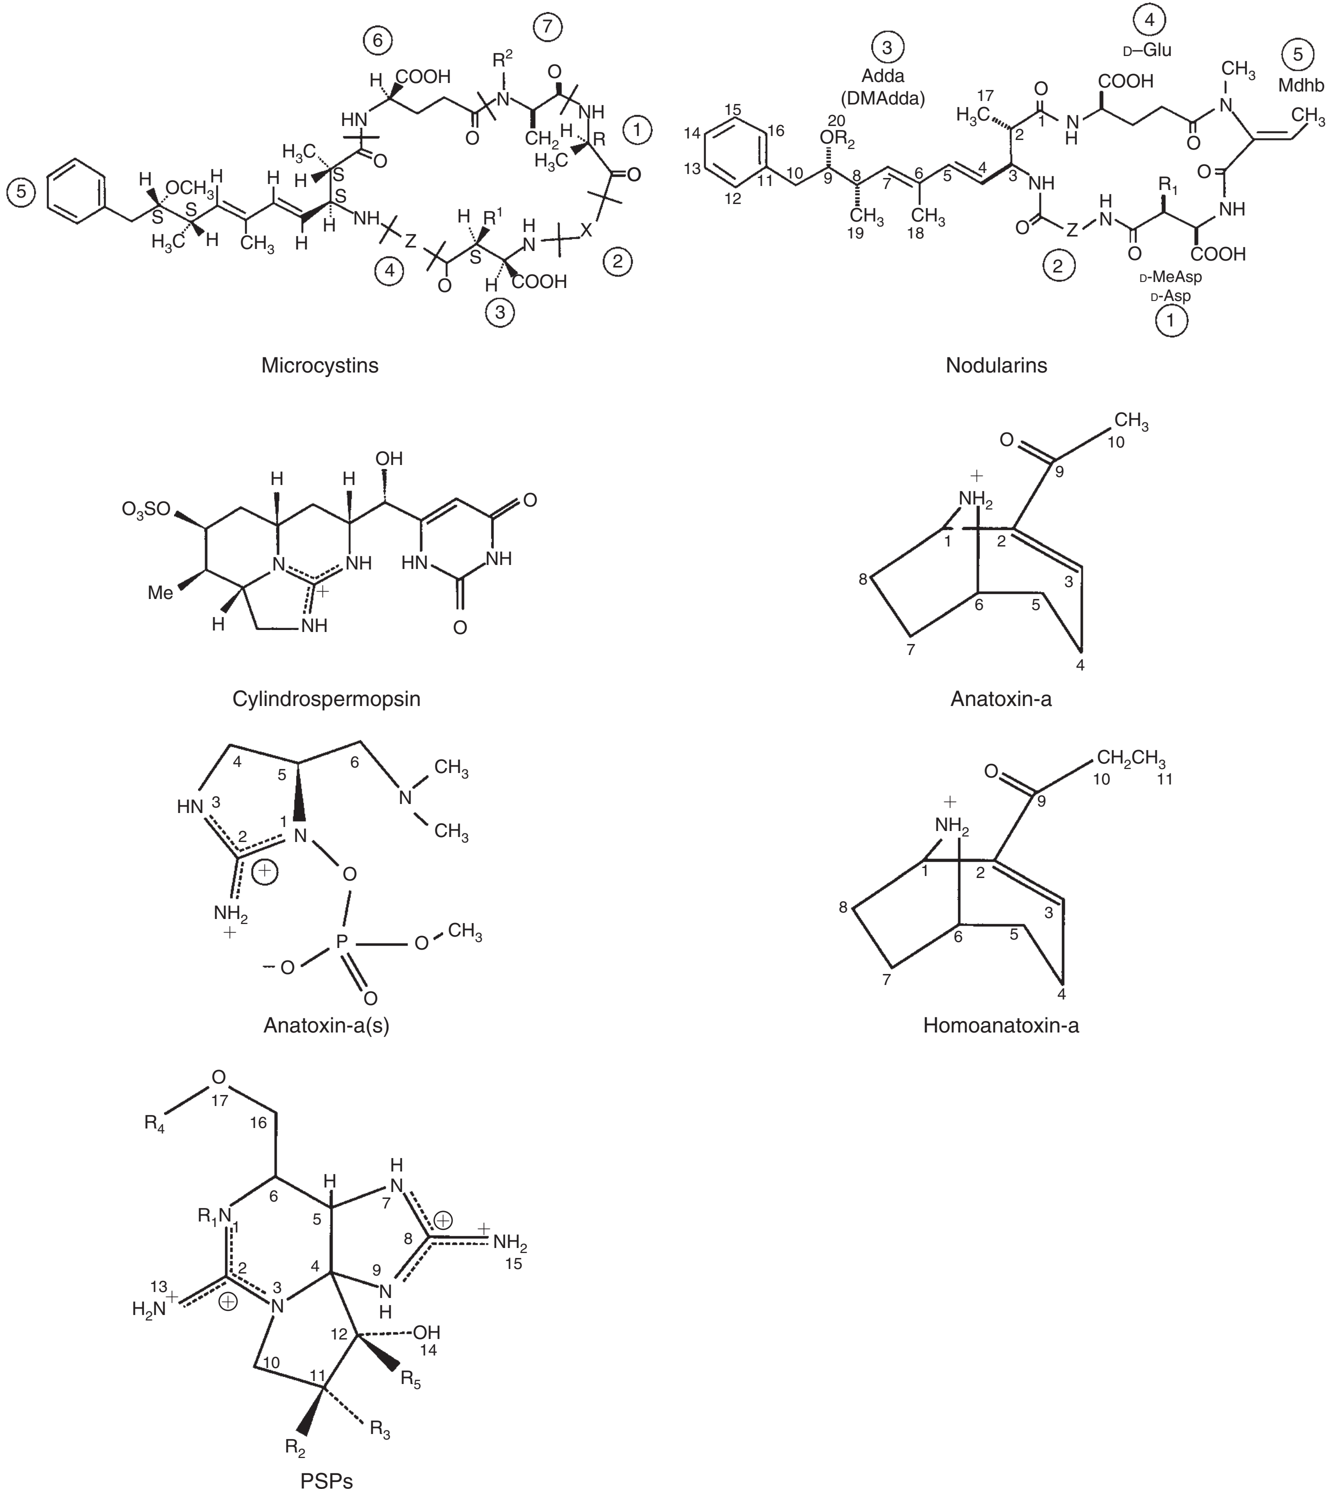

**FIGURE 59.1** Structural formulas of cyanobacterial toxins.

water temperature is warm (>20°C) and in low turbulence conditions (Reynolds and Walsby, 1975). These proliferations are usually easy to detect at the water surface of lakes or ponds, because of evident coloration of the water or the accumulation of scum. Proliferations of benthic species generally occur on the surfaces of sediment, stones or macrophytes in small oligotrophic rivers or in oligotrophic lakes (Mez *et al*., 1997) during the summer.

In the past, most cases were diagnosed by positive identification of the algae in the suspect water source along with the occurrence of consistent clinical signs and pathological findings. However, new analytical methods can now be applied to detect toxins in biological specimensof animals or humans with suspect exposure to toxic algal blooms (Figure 59.1). These capabilities will allow for in-depth diagnostic investigations and a better estimate of the true frequency of blue-green algae poisonings in livestock, pets and wildlife. Table 59.1 provides an overview of cyanobacterial species that are known to produce a large number of toxins. Some species can produce a variety of cyanotoxins and thus, it is difficult to predict the nature and the level of the toxin production during a bloom event. While not inclusive of all cyanotoxins known, this chapter is organized by the various types of toxins, providing detailed information on their toxic mechanisms, toxicokinetics, diagnostic and therapeutic approaches with a focus on veterinary medicine.

## MICROCYSTINS

Microcystins are produced by several cyanobacteria, including species within the genera *Microcystis*, *Anabaena*, *Planktothrix*, *Nostoc*, *Oscillatoria* and *Anabaenopsis* and have been found worldwide (e.g. Fromme *et al*., 2000; Hitzfeld *et al*., 2000; Ballot *et al*., 2004; Briand *et al*., 2005; Karlsson *et al*., 2005a; Ndetei and Muhandiki, 2005; Agrawal *et al*., 2006). Not all strains produce microcystins and only those that possess genes for microcystin production are considered toxicologically significant. In addition to genetic factors, the toxin production is influenced by a variety of environmental factors, such as pH, nutrient concentrations and water temperature. The production of microcystins increases with increased water temperature and elevated concentrations of phosphorus and nitrogen, and globally with the growth rate (Orr and Jones, 1998; Briand *et al*., 2005; Downing *et al*., 2005). Therefore, microcystin prevalence may be greatest in July and August when the growth of cyanobacteria is high, but the toxins may be detected any time of year. While most microcystin-producing algal blooms are most commonly found in freshwater, they have also occurred in saline ecosystems (Atkins *et al*., 2001; Carmichael and Li, 2006).

Microcystins are cyclic heptapeptides that cause hepatotoxicosis (Falconer *et al*., 1988; Falconer and Yeung, 1992). Under field conditions, the toxins are normally confined within the algal cell and are released only when the cell is damaged leading to cell lysis and death. Interestingly, the amount of microcystins may increase after a large decrease in the number of algal mats since the toxin is released after destruction of the algal cell wall (Park *et al*., 1998). After oral exposure to microcystin-containing algae, the acidic environment of the stomach can result in the release of microcystins. Recently, there has been increased concern

with the potential exposure to microcystins via blue-green algae food supplements (Schaeffer *et al.*, 1999; Dietrich and Hoeger, 2005).

Over the past years, over 80 different microcystins were isolated from various genera of cyanobacteria (Luukkainen *et al.*, 1994; Lawton *et al.*, 1995; Welker and von Döhren, 2006). The general basic structure for all microcystins is the same and involves an amino acid called ADDA (3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca-4,6-dienoic acid) and six other amino acids, of which two are variable (Figure 59.1). Microcystin-LR is the most extensively studied, has been found worldwide and has caused acute, lethal hepatotoxicoses in farm animals (Carbis *et al.*, 1994; Mez *et al.*, 1997; Puschner *et al.*, 1998) and hepatic injury in humans (Carmichael *et al.*, 2001; Rao *et al.*, 2002). This congener is also known to characterize more than 70% of the microcystins present in a sample (Lawton *et al.*, 1995).

## Pharmacokinetics/toxicokinetics

There is limited data available. Most studies have been conducted in mice after intravenous (i.v.) and intraperitoneal (i.p.) administration of cyanobacteria, their filtrates and in some instances, purified microcystins. After i.v. and i.p. administration in mice and rats, microcystins are rapidly distributed to the liver (Falconer *et al.*, 1986; Runnegar *et al.*, 1986; Robinson *et al.*, 1991). Plasma half-lives of microcystin-LR in mice after i.v. administration were 0.8 and 6.9 min for the alpha- and beta-phases of elimination (Robinson *et al.*, 1991). Interestingly, the hepatic concentration of 3H-microcystin-LR remained constant throughout the 6-day study indicating the accumulation in this target organ. This study also demonstrated that approximately 9% and 14% of the dose were excreted in urine and feces after 12 h, with 60% of it being excreted unchanged. To our knowledge, there are very few studies about the metabolism of microcystins and results are conflicting (Robinson *et al.*, 1991; Rinehart *et al.*, 1994). Glutathione and cysteine conjugation with microcystins has been confirmed and may represent major detoxification pathways (Kondo *et al.*, 1996; Pflugmacher *et al.*, 1998). In addition, other metabolites have been identified, but further work is needed.

Definite data on bioavailability for microcystins is lacking, although it has been shown that absorption takes place in the small intestine (Ito *et al.*, 2000). Therefore, the integrity of the small intestinal mucosa can significantly affect the degree of absorption. In mice, aging has shown to result in altered epithelial cell permeability of the small intestine, making aged mice much more susceptible to orally administered microcystins than young animals (Ito *et al.*, 1997). Once absorbed, microcystins are rapidly distributed to the liver (Runnegar *et al.*, 1981; Fischer *et al.*, 2000), but can also reach lung, heart and capillaries (Ito *et al.*, 2000). Recently, it was shown that there is considerable absorption of microcystin via the respiratory route (Ito *et al.*, 2001) leading to lethality in mice.

## Mechanism of action

Microcystins are specifically toxic to liver, causing liver enlargement, progressive centrilobular hepatocyte rounding, dissociation and necrosis. Breakdown of the sinusoidal endothelium and intrahepatic hemorrhage ultimately result in death (Hooser *et al.*, 1991a; Falconer and Yeung, 1992). Microcystins are unable to cross cell membranes and enter hepatocytes via the bile acid transporter mechanism (Hooser *et al.*, 1991b). Once inside the hepatocytes, microcystins are potent inhibitors of protein phosphatases 1 and 2A (Falconer and Yeung, 1992; Runnegar *et al.*, 1993). The disruption of the cytoskeletal components and the associated rearrangement of filamentous actin within hepatocytes account for the morphological changes, although other mechanisms play a role in the development of liver lesions. Recently, it was shown that microcystins can induce apoptosis of hepatocytes (McDermott *et al.*, 1998) via induction of free radical formation and mitochondrial alterations (Ding Nam Ong, 2003). In addition, microcystins are classified as tumor-promoting compounds (Humpage and Falconer, 1999). Clinical signs of microcystin poisoning have been described in a number of reports in livestock, humans and wildlife in the United States (Galey *et al.*, 1987; Kerr *et al.*, 1987; DeVries *et al.*, 1993; Fitzgerald and Poppenga, 1993; Puschner *et al.*, 1998) and other countries (Odriozola *et al.*, 1984; Done and Bain, 1993; Van Halderen *et al.*, 1995; Mez *et al.*, 1997; Naegeli *et al.*, 1997; Azevedo *et al.*, 2002; Ballot *et al.*, 2004; Ndetei and Muhandiki, 2005). While genetic and environmental conditions are important for the production of high microcystin concentrations, laboratory animals preferred water contaminated with a microcystin-producing algal bloom (Lopez Rodas and Costas, 1999) over uncontaminated water. This preference increases the risk for microcystin toxicosis in animals. Microcystin intoxication should be suspected in cases of acute hepatotoxicosis with clinical signs of diarrhea, vomiting, weakness, pale mucous membranes and shock. While most animals die within a few hours of exposure, some animals may live for several hours and develop hyperkalemia, hypoglycemia, nervousness, recumbency and convulsions. Animals that survive the acute intoxication may develop hepatogenous photosensitization. Nephrotoxic effects have been described in laboratory animals after chronic microcystin exposure (Milutinovic *et al.*, 2003). In humans, primary liver cancer as well as colorectal cancer has been associated with microcystin-contaminated drinking water (Ueno *et al.*, 1996; Zhou *et al.*, 2002). In mice, subchronic exposure by i.p. injection of microcystin-LR (20 μg/kg) causes the appearance of hepatic nodules, which is not observed after oral administration (Ito *et al.*, 1997).

## Toxicity

The lethal doses 50 ("$LD_{50}$"s) for microcystins vary between 50 and 11,000 μg/kg, depending on the microcystin analog, the species affected and the route of administration. In mice, the oral $LD_{50}$ value for microcystin-LR is 10.9 mg/kg, while the i.p. $LD_{50}$ is 50 μg/kg. Considering that most blooms contain a number of structural variants of microcystins, it is difficult to estimate the toxicity potential of a bloom. The NOAEL (no observed adverse effect level) for orally administered microcystin-LR to mice is 40 μg/kg/day (Fawell *et al.*, 1994). In pigs, the LOAEL (lowest observed adverse effect level) for microcystin-LR is 100 μg/kg/day (Falconer *et al.*, 1994) and in rat 50 μg/kg/day (Heinze, 1998). The WHO set the tolerable daily intake (TDI) for human ingestion of microcystin-LR at 0.04 μg/kg/day (Kuiper-Goodman *et al.*, 1999). The potential risk to humans by ingesting food products derived from animals exposed to microcystins was evaluated in beef (Orr *et al.*, 2003) and dairy cattle (Orr *et al.*, 2001). From these studies, it is unlikely that consumption of milk, meat or liver poses a significant health risk to humans. It might be prudent to establish specific guidelines for non-lethal, chronic microcystin exposure in livestock.

## Treatment

There is no specific antidote for microcystins. Despite the evaluation of numerous treatment options, no specific therapy has been proven to be effective. In many cases, the rapid onset of acute hepatotoxicosis does not allow for timely, therapeutic intervention and mortality rates are very high. In mice, the i.p. administration of rifampin was considered an effective treatment after exposure (i.p.) to microcystin-LR (Hermansky *et al.*, 1990b). In contrast, many of the other tested compounds, such as glutathione, silymarin and cyclosporine A, were only beneficial if administered prior to microcystin administration (Hermansky *et al.*, 1990a; Hermansky *et al.*, 1991; Rao *et al.*, 2004). This is important to consider when trying to protect against microcystin intoxication in chronic exposures. Because microcystins can enhance oxidative stress, antioxidants such as vitamin E and selenium appear to be beneficial, but best protection is likely to be achieved if given prior to microcystin exposure (Gehringer *et al.*, 2003a, b). While the adsorption of microcystins by activated charcoal is used successfully to decontaminate drinking water (Warhurst *et al.*, 1997), this decontamination procedure was not protective in mice dosed with microcystins (Mereish and Solow, 1989). Diagnosis of microcystin toxicosis is aided by identification of microcystin-containing water in the environment of the animal. Identification of algae material in water and gastric contents is an important component of the diagnostic workup, but does not confirm intoxication. As described, the toxicity of the cyanobacteria is strain specific, and morphological observations alone cannot predict the hazard level. Detection of microcystins in gastric contents is confirmatory, but these tests are not routinely available at diagnostic laboratories. In the past, the mouse bioassay was used to determine the toxicity of crude algal biomass in suspicious blue-green algae poisonings. While many assays are available to analyze water samples for microcystins (Zweigenbaum *et al.*, 2000; Maizels Budde, 2004; McElhiney and Lawton, 2005; Frias *et al.*, 2006), there are only limited methods available to reliably and accurately detect microcystins in biological specimens collected from animals suspected to have died from microcystin intoxication (Bogialli *et al.*, 2005; Karlsson *et al.*, 2005b). Recently, an ESI-LC-MS (electrospray ionization with liquid chromatography-mass spectroscopy) method was developed to determine the bound microcystin concentrations in animal tissues, which provides an estimate of the total microcystin burden in exposed animals (Ott and Carmichael, 2006).

Differential diagnoses in animals with a clinical presentation of liver failure include other toxic ingestions such as amanitins, cocklebur, cycad palm, aflatoxin, certain heavy metals and acetaminophen overdose. Careful evaluation of the history, feed and environment of the animal can help eliminate most of the toxicant differentials on the list.

# ANATOXINS

Anatoxins are mainly produced by cyanobacteria in the *Anabaena* genus (Beltran and Neilan, 2000), but also by other genera, such as *Planktothrix*, *Oscillatoria*, *Microcystis*, *Aphanizomenon*, *Cylindrospermum* and *Phormidium*. Reports of anatoxin poisoning are less frequent than microcystin toxicosis; however, poisoning has occurred worldwide (Edwards *et al.*, 1992; Gunn *et al.*, 1992; Beltran and Neilan 2000; Fromme *et al.*, 2000; Gugger *et al.*, 2005; Yang and Boyer, 2005). Anatoxins are neurotoxins and can generally be divided into anatoxin-a, homoanatoxin-a and anatoxin-a(s). Anatoxin-a is a secondary amine (Figure 59.1) and has been detected in blooms worldwide. Homoanatoxin-a is a methyl derivative of anatoxin-a (Figure 59.1) and has been identified in blooms in Japan (Namikoshi *et al.*, 2004) and Ireland (Furey *et al.*, 2003). Anatoxin-a(s) is a unique *N*-hydroxyguanidine methyl phosphate ester (Figure 59.1) that has been detected in the Americas (Matsunaga *et al.*, 1989; Monserrat *et al.*, 2001) and Europe (Henriksen *et al.*, 1997).

## Pharmacokinetics/toxicokinetics

Definite data on the toxicokinetics of anatoxin-a, homoanatoxin-a and anatoxin-a(s) have not been

established. Based on the rapid onset of clinical signs after oral exposure, rapid absorption of the toxins is suspected.

## Mechanism of action

Anatoxin-a is potent cholinergic agonist at nicotinic acetylcholine receptors in neurons and at the neuromuscular junctions (Amar *et al.*, 1993; Thomas *et al.*, 1993). Anatoxin-a has two enantiomers and the protonated (+) anatoxin-a form has higher binding affinity than the (−) form (Spivak *et al.*, 1980; Zhang and Nordberg, 1993). Compared to nicotine, anatoxin-a is approximately 20 times more potent than acetylcholine. After continuous electrical stimulation at the neuromuscular junctions, a nerve block may follow and result in death due to respiratory paralysis. Further, anatoxin-a has modulatory action at presynaptic neuronal nicotinic acetylcholine receptors, which can lead to dopamine as well as noradrenaline release (Wonnacott *et al.*, 2000; Barik and Wonnacott, 2006). Clinical signs of anatoxin-a poisoning include a rapid onset of rigidity and muscle tremors followed by paralysis, cyanosis and death. Death usually occurs within minutes to a few hours. Anatoxin-a poisonings have been reported in dogs in Europe (Edwards *et al.*, 1992; Gunn *et al.*, 1992; James *et al.*, 1997; Gugger *et al.*, 2005) and the United Staes (Puschner, personal communication). Anatoxin-a is also considered a contributing factor in the deaths of Lesser Flamingos in Kenya (Krienitz *et al.*, 2003). Homoanatoxin-a is a methyl derivate of anatoxin-a with similar pharmacological and toxicological properties (Wonnacott *et al.*, 1992). In addition to being a nicotinic agonist, homoanatoxin-a can increase the release of acetylcholine from peripheral cholinergic nerves through opening of endogenous voltage-dependent neuronal L-type $Ca^{2+}$ channels (Aas *et al.*, 1996). Poisonings caused by natural algal blooms containing homoanatoxin-a have not been reported in the veterinary literature.

Anatoxin-a(s) is different from anatoxin-a and homoanatoxin-a. This neurotoxin has a unique chemical structure and is a natural occurring irreversible acetylcholinesterase inhibitor. The increased concentrations of acetylcholine in the synapse lead to persistent stimulation, followed by a neuromuscular block (Matsunaga *et al.*, 1989; Cook *et al.*, 1990; Hyde and Carmichael, 1991). The mechanism of toxic action is similar to that of carbamate or organophosphorus insecticides/chemical warfare agents. However, one of the main differences is that anatoxin-a(s) only acts in the periphery, while the insecticides inhibit acetylcholinesterase in the brain and retina (Cook *et al.*, 1989b). Animals poisoned with anatoxin-a(s) show a rapid onset of excessive salivation ("s" stands for salivation), lacrimation, diarrhea and urination. Clinical signs of nicotinic overstimulation include tremors, incoordination, and convulsions. Recumbency and respiratory arrest are most commonly observed in cases with a lethal outcome. The survival time of animals with anatoxin-a(s) poisoning is very short and animals may die within 30 min of exposure. Animals that die from either anatoxin-a or anatoxin-a(s) toxicosis do not show specific gross or microscopic lesions. Anatoxin-a(s) poisoning has been reported in pigs, birds, dogs and calves in the United States and Europe (Mahmood *et al.*, 1988; Cook *et al.*, 1989a; Onodera *et al.*, 1997). Because of the lack of specific detection methods for anatoxin-a(s), the natural occurrence of this neurotoxin has not been fully evaluated.

## Toxicity

In mice, the i.p. $LD_{50}$ of anatoxin-a is 200 μg/kg (Stevens and Krieger, 1991), while the i.v. $LD_{50}$ is estimated at <100 μg/kg. The oral toxicity of anatoxin-a is much higher, with an oral $LD_{50}$ in mice reported as >5000 μg/kg. Several studies have shown that there are significant species differences with regards to anatoxin-a toxicity. While an anatoxin-a containing *A. flos-aquae* bloom was toxic to sheep after i.p. administration, oral administration failed to induce toxicity (Runnegar *et al.*, 1988). In contrast, calves developed toxicity after oral administration of an anatoxin-a containing *A. flos-aquae* (Carmichael *et al.*, 1977). The i.p. $LD_{50}$ of homoanatoxin-a in mice is 250 μg/kg (Skulberg *et al.*, 1992). Anatoxin-a(s) is much more toxic than anatoxin-a or homoanatoxin-a with an i.p. $LD_{50}$ in mice of 20 μg/kg (Mahmood and Carmichael, 1986; Matsunaga *et al.*, 1989; Briand *et al.*, 2003).

## Treatment

There is no specific antidote for anatoxin-a. Because of the rapid onset of clinical signs, emesis is not likely to be useful. Although there are no studies that evaluate the efficacy of specific decontamination procedures, administration of activated charcoal has been recommended. In addition, artificial respiration may be of benefit along with general supportive care. Specific measures to control seizures include benzodiazepines, phenobarbital or pentobarbital. If given, they may cause central nervous system (CNS) and respiratory depression and careful monitoring of the animal is necessary. In any seizuring animal, control of body temperature is an important part of the symptomatic care.

Treatment of animals poisoned with anatoxin-a(s) is primarily symptomatic and supportive. Decontamination procedures can be considered but have not been evaluated. It has been shown that pralidoxime (2-PAM) is not able to reactivate the inhibited acetylcholinesterase and is therefore not recommended (Hyde and Carmichael, 1991). Atropine should be given at a test dose to determine its efficacy in animals with life-threatening clinical signs. After the test dose, atropine can be given repeatedly until

cessation of salivation. It is important to carefully monitor the animal for anticholinergic effects, and to reduce or discontinue atropine should adverse effects develop.

As with other cyanobacteria toxins, toxicity is strain specific and identification of the cyanobacteria alone cannot predict the toxicity level. Therefore, detection of anatoxin-a in biological specimens is confirmatory, but these tests are not routinely available (James *et al*., 1998; Furey *et al*., 2003). Recently anatoxin-a was confirmed in the stomach contents and livers of dogs in France (Gugger *et al*., 2005) and in the stomach contents of dogs in the United States (Puschner, personal communication). Initial difficulties with the analysis for anatoxin-a have been overcome by using tandem mass spectrometry with multiple mass spectrometry experiments (Furey *et al*., 2005). In suspect cases, environmental samples should also be saved for further analysis.

Diagnosis of anatoxin-a(s) toxicosis is aided by the determination of blood acetylcholinesterase activity. However, organophosphorus and carbamate insecticides can also inhibit acetylcholinesterase and additional diagnostic workup is needed to establish a firm diagnosis. These include the determination of brain acetylcholinesterase activity assay postmortem (unchanged in cases of anatoxin-a(s) poisoning), screening of gastrointestinal contents for insecticides, morphological observation of stomach contents (possible identification of cyanobacteria) and a careful evaluation of the environment (access to freshwater, access to insecticides). Detection methods for anatoxin-a(s) are rare. Recently, a biosensor method was developed that allows the quantitation of anatoxin-a(s) in environmental samples (Devic *et al*., 2002). New analytical methods for anatoxin-a(s) are necessary to better document the distribution of this neurotoxin in freshwater worldwide.

## MISCELLANEOUS FRESHWATER CYANOBACTERIAL TOXINS

Although microcystin and anatoxin poisonings make up the majority of cases reported in animals, other cyanotoxins are of concern. Saxitoxins and derived forms (PSPs; see Figure 59.1) belong to the group of paralytic shellfish toxins and have been produced by a number of freshwater cyanobacteria, including *Aphanizomenon flos-aquae*, *Cylindrospermopsis raciborskii*, *Anabanea circinalis*, *Lyngbya wollei* and *Planktothrix* sp. (Humpage *et al*., 1994; Carmichael *et al*., 1997; Sivonen and Jones, 1999; Kaas and Henriksen, 2000; Molica *et al*., 2005). In humans, saxitoxins are associated with the development of a neurological disease after the ingestion of shellfish contaminated with saxitoxins. All saxitoxin analogs have a high toxicity in mammals and act by binding to the voltage-gated sodium channel, followed by inhibition of the influx of sodium ions. This results in a blockade of neuronal transmission leading to respiratory arrest, neuromuscular weakness and cardiovascular shock. While saxitoxin poisonings have not been documented in animals, the risk for exposure certainly exists. Another cyanotoxin of concern to animals is cylindrospermopsin. This alkaloid (Figure 59.1) has resulted in deaths in cattle (Saker *et al*., 1999) and has caused severe gastrointestinal disease in humans. Cylindrospermopsin is a potent inhibitor of protein synthesis and can lead to various degrees of injury to the liver, kidneys, adrenal gland, intestine, lung, thymus and heart (Griffiths and Saker, 2003). Furthermore, this cyanotoxin is of particular concern because of its mutagenic and possibly carcinogenic activities. As to date, cylindrospermopsin has been found in Europe, Australia, New Zealand and Asia (Hawkins *et al*., 1997; Saker and Griffiths, 2001; Fastner *et al*., 2003), but it should be considered a potential worldwide problem. Cylindrospermopsin, deoxycylindrospermopsin and 7-epicylindrospermopsin have been produced by *Cylindrospermopsis raciborskii* for the first two listed (Ohtani *et al*., 1992; Norris *et al*., 1999), and by *Aphanizomenon ovalisporum* for the third (Banker *et al*., 1997). After oral exposure, the $LD_{50}$ of cylindrospermopsin obtained with culture extracts of *C. raciborskii*, ranges from 4.4 to 6.9 mg/kg in equivalent cylindrospermopsin (Seawright *et al*., 1999; Shaw *et al*., 2000). Nodularins are cyclic pentapeptides (Figure 59.1) that lead to severe hepatotoxicosis in the same way as microcystins (Harding *et al*., 1995). In addition, nodularin is a more potent tumor promoter than microcystin (Sueoka *et al*., 1997). The only cyanobacterium species known to produce nodularin is *Nodularia spumigena*. This cyanobacterium can form extensive blooms in the Baltic Sea and in brackish waters in the summer (Francis, 1878; Sivonen *et al*., 1989; Sivonen and Jones, 1999). The risk of nodularin intoxication is 2-fold, because toxin exposure cannot only occur through recreational or drinking water, but also via contamination of seafood (Van Buynder *et al*., 2001). In cases of acute hepatotoxicity, exposure to microcystins as well as nodularins must be considered.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Worldwide, the frequency and intensity of harmful cyanobacterial bloom appears to increase in relation with the degradation of the water quality (eutrophication) in numerous freshwater ecosystems. As stated in Table 59.1, numerous cyanobacterial species are potentially able to produce a large range of toxins, but for each of these species, it is very difficult to predict, during a bloom event, the nature and the level of the toxin production. While new detection methods have allowed for better monitoring of potentially harmful blooms over the past few years, there is still a need to develop new methods

and to reliably confirm intoxications. Some of the recently developed methods have been useful in analyzing biological specimens in order to confirm a diagnosis of poisoning, but this is not routinely available or pursued in suspect cases. The lack of methods to confirm exposure is most likely responsible for the low number of reported cases in the veterinary literature over the past 20–30 years. The new analytical methods will provide insight into the true frequency of cyanotoxin poisoning in animals. For example in France, several dog intoxications due to anatoxin-a have been recently identified in different regions, in relation with the development of an analytical method using high-performance liquid chromatography (HPLC) mass spectrometry analysis (Gugger *et al.*, 2005; Mejean, personal communication). Furthermore, more information is needed on the efficacy of therapeutic measures. Until then, in the same way as for human populations, it would be prudent to take safety measures for avoiding animal intoxication, when cyanobacterial blooms occur in ponds used for their water supply.

CHAPTER

# 60

# Toxicology of marine toxins

*Aurelia Tubaro and James Hungerford*

## INTRODUCTION

Most marine toxins, tetrodotoxins being the exception, are produced by microalgae. These are the same primary producers that make up the basis of the marine food chain. Just as with many plants, bacteria and other eukaryotic organisms, many microalgae produce compounds with potent biological activity. These compounds are generally considered secondary metabolites, not essential for the basic metabolism and growth of the producing species. The role of secondary metabolites in these organisms is not yet completely clear and many functions have been hypothesized, for instance as chemical defences. This has been suggested for algal toxins, a class of secondary metabolites produced primary from three classes of unicellular algae: dinoflagellates, diatoms and cyanobacteria. Dinoflagellates are responsible for the production of the majority of these toxins, although only a few dozen species out of the several thousands of dinoflagellates identified so far are known to produce toxic metabolites. Among the diatoms, only the genus *Pseudonitzschia* produces toxic compounds. Cyanobacteria toxins are discussed elsewhere in this book.

Of the many marine algal toxins identified so far, some are responsible for human poisonings, marine mammals and birth morbidity and mortality, as well as for extensive fish kills, causing sanitary, ecological and economic problems (Van Dolah, 2000). An important distinction between envenoming and poisoning is necessary to marine poisoning. Venomous animals have a specialized gland that produces venom, generally applied or injected parenterally. Other marine animals like those described here accumulate toxic compounds from the environment, without possessing any specialized toxin producing gland. These animals can provoke human poisonings after consumption (Isbister and Kiernan, 2005).

Shellfish contamination represents a sanitary and economical problem all over the world. Although viral and bacterial infections resulting from shellfish ingestion are more common, shellfish contaminated by algal toxins can cause severe and life-threatening poisonings. These poisonings account for 7.4% of marine intoxications in the United States (Isbister and Kiernan, 2005). Human poisonings associated with marine algal toxins follow ingestion of (primarily molluscan) shellfish. These vectors accumulate the toxic compounds during their filter feeding activity.

Marine toxins are not exclusively shellfish toxins however. Fish can also be contaminated after eating toxic phytoplankton, as in the case of domoic acid (DA)-laden anchovies, or ciguatoxic herbivores inhabiting tropical reefs. The marine toxins also move through food webs, and in the process can be transformed to other more potent toxins as hypothesized for highly ciguatoxic predators that dwell near impacted reefs, eating those same herbivores. In spite of these biologically mediated changes in the natural world, the toxins are otherwise resilient. Most marine toxins are heat and gastric-acid-stable compounds.

The marine toxins represent a structurally and pharmacologically diverse group. Most, but not all of the marine toxins exert their toxic effects by disrupting the nervous system. Other toxins impact protein phosphorylation or other critical processes. Their relative toxicities also vary considerably. Among the neurotoxins, there is again considerable diversity, but those causing the greatest numbers of illnesses and some deaths, the ciguatoxins (CTXs) and the saxitoxins (STXs), have one trait in common, which is their binding and modulation of the voltage gated sodium channel (VGSC). One group enhances sodium permeability while the other blocks it. All however are of public health concern.

No matter what is the specific mechanism of toxicity, many of the marine toxins present the same limitations and challenges in both toxicological studies and in their management. Specifically, toxicological studies and other efforts addressing these and other algal toxins are limited by the reduced availability of large quantities of purified toxins and especially of certified reference materials. Often these are not commercially available. Therefore, in many of the toxicological studies a reduced number of animals are used and sometimes, to maximize the toxicological effects of the test material, parenteral routes of administration are employed. On the contrary, very few studies have examined the effects of oral administration of these toxins, the usual exposure route. In this chapter we will focus on the toxicology of the most dangerous marine toxins for humans. Specifically, the major clinical poisonings due to the consumption of fish and shellfish will be covered.

## SAXITOXINS

Saxitoxins (STXs), a family of hydrophilic toxins based on the parent STX were discovered in the last century and can contaminate seafood and drinking water. The name of this toxin group is derived from *Saxidomus giganteus*, the clam from which it was purified for the first time. The ingestion of STXs-contaminated seafood provokes a paralytic syndrome known as paralytic shellfish poisoning (PSP), one of the most common and most dangerous forms of shellfish poisoning. Although PSP cannot be classified as a major public health problem due to its relatively low incidence rate, it is of considerable concern because a fatal dose for humans can be obtained eating a single highly contaminated shellfish. There is no available antidote, although supportive treatment, if done promptly, is generally sufficient for this potent but reversibly binding group of toxins (see Treatment below). Furthermore, STX is the only marine natural product that is a declared chemical weapon (Llewellyn, 2006).

### Background

Persons suffering PSP can develop symptoms within 5–30 min after contaminated shellfish consumption. The first effect is typically paraesthesia, with burning or tingling of the tongue and lips, which spreads to the face, neck, fingers and toes. In more severe cases, this is followed by a feeling of numbness in fingertips and toes, which progresses to the arms, legs and neck within 4–6 h. Death is usually caused by respiratory paralysis and, without mechanical respiratory support, the fatality rate is 5–10%. There is a good prognosis for individuals surviving beyond 12 h, although muscular weakness can persist following recovery (Llewellyn, 2006).

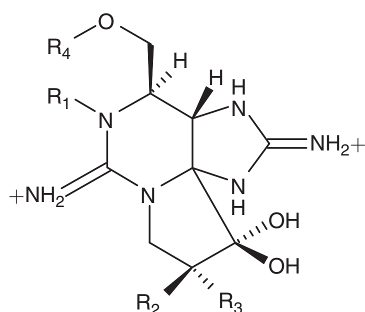
Other minor symptoms reported are: a feeling of dizziness or "floating" (owing to distortion of sensation and proprioception), generalized paraesthesia, arm and leg weakness, and ataxia. Headache, nausea and vomiting, also can occur in the initial phase of the poisoning (Isbister and Kiernan, 2005; Llewellyn, 2006). Reflexes may be normal or absent, and patients may remain conscious and alert throughout the poisoning. In patients with mild to moderate poisoning, the symptoms resolve in 2–3 days, but in more severe cases weakness may persist for a week (Isbister and Kiernan, 2005).

PSP diagnosis is based on characteristic neurological clinical signs and on a history of recent ingestion of seafood (most often bivalve shellfish, hence the term PSP). The symptoms of PSP are difficult to differentiate from those of tetrodotoxin poisoning, due to the (pharmacological) similarities of the toxins.

The toxins responsible for PSP, STX and its derivatives, including gonyautoxins (GTXs) are water soluble, heat stable, tetrahydropurine compounds that are among the most potent known neurotoxins (Isbister and Kiernan, 2005). The chemical structure of STX is represented by two guanidinium moieties joined in a stable azaketal linkage (Figure 60.1) (Rogers and Rapoport, 1980; Llewellyn, 2006; Sapse *et al.*, 2006). More than 30 natural STX analogues, that vary by different combination of hydroxyl and sulphate substitutions at four sites on the molecule, have been isolated so far. STXs can be divided into four groups based on substitution at $R_4$, the carbamate toxins, the sulphocarbamoyl toxins, the decarbamoyl toxins and the deoxydecarbamoyl toxins. The guanidinium group at positions C-7, C-8 and C-9 and the hydroxyl group at C-12 are essential for binding of STXs to $Na^+$ channels and the substitution at $R_4$ leads to substantial changes in toxicity, the carbamate toxins representing the most potent group (Ciminiello and Fattorusso, 2004).

The toxins are produced by toxic marine dinoflagellates, including *Alexandrium* ssp., *Pyrodinium bahamense* var. *compressum* and *Gymnodinium catenatum.* Shellfish accumulate the toxins by filter feeding the toxic microlagae. Paralytic toxins have been identified also in different species of freshwater blue-green algae (cyanobacteria), but no human poisoning has been reported so far (Isbister and Kiernan, 2005). Also red algae species of the genus *Jania* were reported to produce STX. Controversial is the production of STXs by a symbiotic bacteria isolated from *A. tamarense* (Llewellyn, 2006).

STX and its analogues are concentrated by bivalve shellfish such as clams, oysters, mussels and scallops, but also by crabs, puffer fish, gastropods and cephalopods. Shellfish contamination can persist for a long time after exposure to the toxic microalgae, although in most cases bivalve



| Toxin | $R_1$ | $R_2$ | $R_3$ | $R_4$ |
|---|---|---|---|---|
| STX | H | H | H | |
| neoSTX | OH | H | H | |
| GTX–1 | OH | H | $OSO_3^-$ | $H_2N$–CO |
| GTX–2 | H | H | $OSO_3^-$ | |
| GTX–3 | H | $OSO_3^-$ | H | |

| B1 (GTX–5) | H | H | H | |
| B2 (GTX–6) | OH | H | H | |
| C–3 | OH | H | $OSO_3^-$ | $^-O_3S$–NH–COO |
| C–1 | H | H | $OSO_3^-$ | |
| C–2 | H | $OSO_3^-$ | H | |
| C–4 | OH | $OSO_3^-$ | H | |

**FIGURE 60.1** Chemical structures of saxitoxin and some of its analogues (from Luckas *et al.*, 2003).

molluscs clear the toxin quickly enough to allow later reopening of harvest areas.

While Paralytic shellfish intoxication is widely distributed, crustacean-induced PSP seems to be concentrated in the tropics, where predator crabs of the Xanthidae family often are contaminated by paralytic toxins and have caused human deaths. Recently in Florida, puffer fish thought to be *Sphoeroides nephelus*, provoked the poisoning of over 12 people due to the presence of large amounts of paralytic toxins (Llewellyn, 2006). Occurrence of STX as the major toxin in another puffer fish (*Arothron firmamentum*) has also been recently reported (Nakashima *et al.*, 2004).

Shellfish contamination by STXs is a global concern, being endemic in north-western America. PSP cases also occurred in Chile, Taiwan, Japan, South Africa, Australia, India, England, Guatemala, Costa Rica, Singapore, Canada, Spain and Mexico (Gessner, 2000; Llewellyn, 2006).

## Pharmacokinetics/toxicokinetics

Although the mechanism of action of STXs is well established at the molecular level, little is known about their absorption, distribution, biotransformation and elimination. The charged nature of STXs makes these molecules poor candidates for oral availability, but their uptake from the gut occurs within minutes from ingestion, and no toxin is eliminated in the faeces of test animals (Llewellyn, 2006). Studies in animals and evidences from PSP poisonings in humans revealed that STXs are eliminated mainly through the urine (Stafford and Hines, 1995; Gessner *et al.*, 1997; Andrinolo *et al.*, 1999, 2002). The half-life of urinary elimination of a sublethal dose of STX in rats (2 μg/kg, intravenously (i.v.)) is about 90 min (Stafford and Hines, 1995). Urinary elimination of STX was demonstrated also in cats: after i.v. injection of 2.7 or 10 μg/kg STX excretion involved glomerular filtration which dropped to low levels at the highest dose of STX due to its hypotensive effect. The study also showed the presence of the toxin in liver, spleen and brain (Andrinolo *et al.*, 1999). After oral administration in cats, GTX 2/3 epimers (70 μg/kg) were completely absorbed at intestinal level and, similarly to STX, the excretion involved the glomerular filtration (Andrinolo *et al.*, 2002).

Metabolic transformation of paralytic shellfish toxins by mammals has been little studied. Serum and urine of poisoned humans revealed the occurrence of GTX2 sulphation, which is in contrast with the findings in rats, where no metabolism of STX occurs during passage in urine (Llewellyn, 2006). In another case report, STX was found mainly in the gut contents whereas the urine contained only 50% STX, with neoSTX and dcSTX becoming quite prominent (Llewellyn, 2006). The marked difference between the toxin compositions in the ingested mussels and in human sera, as well as the similar toxin profile between sera and urine samples suggest that PSP toxins are metabolized at gastrointestinal and/or hepatic levels (Gessner *et al.*, 1997). Anyway, it has to be considered that the transformations of the PSP toxins in mammals can be the consequence of both biochemical metabolism and the conditions to which the toxins are exposed, such as the gastric juice, which can convert small amounts of the less toxic sulphated PSP toxins to more potent compounds (Llewellyn, 2006). Cleareance of PSP toxins from human serum was evident within 24 h (Gessner *et al.*, 1997).

## Mechanism of action

STX is a potent neurotoxin that selectively blocks the sodium channels, preventing the entry of $Na^+$ ions into cells, preventing nerve conduction and resulting in motor and sensory nerve abnormalities. All the STX analogues bind to the same (site 1) receptor, although with different affinities (Isbister and Kiernan, 2005).

## Toxicity

### *Human toxicity*

STXs provokes potentially lethal PSP. The most common symptom of PSP, occurring in almost all affected people, is perioral paraesthesias, described as either numbness or tingling. Among people displaying more severe illness, in some cases gastrointestinal symptoms (nausea, vomiting, abdominal pain and diarrhoea) were reported. More severe intoxication leads to a variety of neurological symptoms, including weakness, dysarthria, diplopia, ataxia and vertigo or dizziness, and, in some cases, in respiratory arrest or death. It is unclear whether PSP provokes significant direct effects on the myocardium (Lagos and Andrinolo, 2000). Both diastolic and systolic hypertension have been reported in almost all the 11 PSP intoxicated patients studied by Gessner *et al.* (1997). Another previous report referred hypertension in three PSP patients from England. Experimental studies in cats and dogs emphasized a hypotensive effect after i.v. exposure to high doses of STX and an hypotensive effect at low doses (Lagos and Andrinolo, 2000). Deaths result from respiratory arrest and collapse, the terminal symptoms in patients who do not have access to medical care. No long-term clinical effects of PSP have been reported so far (Gessner, 2000).

Several PSP incidents have been recorded all over the world. The exposure to STX was estimated, examining about 20 incidents of poisoning occurred in Canada, between 1970 and 1990, and involving about 60 persons (age 3–72 years). The symptoms were classified as mild, moderately severe or extremely severe. Mild cases were generally associated with an STX exposure of 2–30 μg/kg, whereas in the more severe cases an STX exposure >10–300 mg/kg was involved. Based on these data a lowest observable adverse effect level (LOAEL) of 2 μg/kg was established (FAO/IOC/WHO, 2005).

### *Experimental toxicity*

#### *Single administration*

The mouse $LD_{50}$ (median lethal dose) values of STX by intravenous (i.v.), intraperitoneal (i.p.) and oral routes are 3.4, 10 and 263 μg/kg, respectively. Significant species differences in oral toxicity have not been observed (Andrinolo *et al.*, 1999; Llewellyn, 2006). The potency of different STXs varies widely. After i.p. administration in mice, the carbamates and the decarbamoyl derivatives are the most toxic PSP toxins, while the sulphocarbamoyls derivatives exert the lowest acute toxicity (Llewellyn, 2006).

## Treatment

The treatment for PSP is only supportive. Admission to an intensive care unit is necessary in moderate to severe cases to prevent respiratory failure: artificial respiration must be prompt and is the most vital treatment in many cases. Patients have to be carefully observed in the early stages of poisoning to immediately recognize and treat the progressing paralysis and respiratory failure.

## Concluding remarks

PSP due to the intake of toxins from the STXs group has provoked many fatalities. Since a specific antidote is not available for PSP, prevention is important and monitoring programmes are carried out in many countries. A regulatory level of 0.8 mg STX equivalents/kg shellfish meat has been set up both in North America, in European Community as well as in many other countries worldwide. The AOAC Int. validated mouse bioassay (MBA) has been widely used in monitoring programmes and has provided health protection (FAO/IOC/WHO, 2005). Three mice are intraperitoneally (i.p.) injected with the contaminated shellfish extracts, and their survival time compared to that of mice injected with different concentrations of STX. The detection limit is only 0.4 mg STX equivalents/g shellfish meat (Luckas, 1992). Various other methods have been developed to detect the paralytic toxins (such as receptor binding assay, immunoassay and instrumental methods). The recent AOAC validated Lawrence pre-column liquid chromatography (LC) fluorescence method (Lawrence *et al.*, 2005) can provide nearly full coverage of STXs and complete coverage of the most toxic forms. In Europe it was approved in 2006, with some minor restrictions, as an alternative method to the MBA in monitoring programmes.

# TETRODOTOXIN

## Background

Puffer fish are an esteemed delicacy in Japan, despite the presence of a lethal toxin, tetrodotoxin, in the gonad, liver,

viscera and skin. Tetrodotoxin poisoning is the commonest lethal marine poisoning. Its clinical effects develop rapidly: early symptoms are sensory, including perioral and distal numbness and paraesthesia. In *mild* poisoning cases, only sensory symptoms associated with minor gastrointestinal effects (mainly nausea and vomiting) occur. In *moderately severe* poisonings, patients develop distal muscle weakness and facial weakness, and later, ataxia and incoordination with normal reflexes. Dizziness can also be accompanied by sensation of floating. *Severe* poisoning provokes generalized flaccid paralysis, respiratory failure and aphonia. In *severe and life-threatening* poisoning cardiovascular effects (bradycardia, hypotension and dysrhythmias) occur together with respiratory failure and coma. Patients with severe poisoning rapidly progress to flaccid paralysis. Most moderate and severe cases generally resolve after 5 days or longer in severe poisoning. In minor cases the recovery can be complete in few hours (Isbister and Kiernan, 2005).

The symptoms are very similar to those of PSP, due to the similar mechanism of action of the involved toxins. The anamnesis (if possible) and the analysis of uneaten fish or patient's urine or serum confirms diagnosis for tetrodotoxin. Tetradotoxin (TTX) and its analogues are water soluble and heat stable heterocyclic compounds with a guanidinium group which is positively charged in the biological pH range (Figure 60.2) (Yotsu-Yamashita *et al.*, 2003) that are not produced by microalgae, but by other microorganisms. A bacterium initially classified as *Pseudomonas* sp. and later amended as *Shewanella alga* was confirmed to produce TTX (Yasumoto, 2000). A list of bacteria known to produce TTX is reported by Yu *et al.* (2004). Recently, Yu *et al.* (2004) and Wu *et al.* (2005) referred other species of TTX-producing bacteria, *Microbacterium arabinogalactanolyticum, Serratia marcescens* and the actinomycete, *Nocardiopsis dassonvillei*.

Tetrodotoxin concentrates in fish mainly of the Tetraodontidae family, which include puffer fish. TTX has also been found in xanthid crabs, horse-shoe crabs, in some frogs newts and as well as in the blue-ringed octopus (Isbister and Kiernan, 2005).

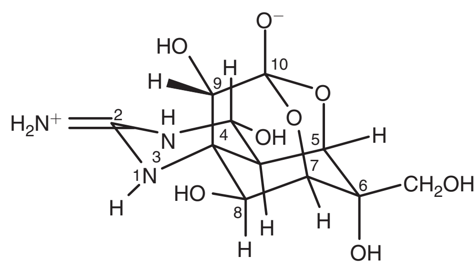

**FIGURE 60.2** Chemical structure of some tetrodotoxin (from Yasumoto, 2000).

Puffer fish poisoning mainly occurs in Asia where *fugu* is a delicacy. In the first half of the 20th century, in Japan about 100 deaths per year from ingestion of *fugu* have been reported. The mortality rate substantially decreased with improved legislation of *fugu* preparation and marketing, although TTX poisoning remains the major cause of fatal food poisoning in Japan (Isbister and Kiernan, 2005).

## Pharmacokinetics/toxicokinetics

Although the pharmacokinetics in humans is not fully understood, serum concentrations of TTX fall rapidly and may be undetectable after 12–24 h. In contrast, TTX can be detected in urine for up to 5 days after ingestion (Isbister and Kiernan, 2005).

After single subcutaneous injection in rats, TTX was detected in kidneys, heart, liver, lungs, intestine, brain and blood, reaching a peak in 20 min. The concentrations were highest in kidneys and heart, and lowest in brain and blood. A rapid appearance of high concentration of TTX in the kidneys and a slow disappearance from these organs were observed, suggesting that an appreciable amount of the toxin is excreted in the urine in unchanged form (Kao, 1966).

## Mechanism of action

Tetrodotoxin affects the nervous system by preventing the propagation of the nerve impulse. TTX blocks $Na^+$ conductance by extracellular binding at receptor-site 1 of $Na^+$ channels to occlude the outer pore and thereby prevent access of monovalent cations to the pore, blocking the membrane depolarization (Isbister and Kiernan, 2005).

## Toxicity

### *Human toxicity*

Onset of TTX poisoning generally occurs within minutes, seldom more than 6 h after consumption of contaminated fish. TTX intoxication has been divided into four stage of progression. Stage 1 includes oral paraesthesias with or without gastrointestinal symptoms. Stage 2 includes paraesthesias in other areas and motor paralysis. Stage 3 includes muscular incoordination, aphonia, dysphagia, respiratory distress, cyanosis and hypotension. Stage 4 includes respiratory paralysis and severe hypotension.

The mortality rate in TTX poisoning depends, among other things, on access to intensive care facilities. Patients, who have not died within 24 h, generally recover

completely. As with PSP, symptoms of TTX poisoning generally are completely resolved within 1–2 days (Gessner, 2000).

### *Experimental toxicity*

*Single administration*

Although the mechanism of action of TTX is well known, only outdated and limited data on its toxicity in animals are available. The effects of TTX have been tested on a variety of animal species. After i.p. injection in mice, the minimal lethal dose of TTX was 8 μg/kg, while the $LD_{50}$ was estimated to be 10 μg/kg and doses ranging from 12 to 14 μg/kg killed all the mice. After oral and subcutaneous administration in mice, the $LD_{50}$ is 332 and 16 μg/kg, respectively (Kao, 1966). Similar results were observed in a recent study, when $LD_{50}$ values after intraperitoneal, subcutaneous and oral administration in mice were determined as 10.7, 12.5 and 532 μg/kg, respectively. In rabbits, the minimal lethal doses and the lethal doses for all the animals were 5.3 and 3.1 μg/kg after intramuscular injection, or 5.8 and 3.8 μg/kg, after i.v. injection (Xu *et al.*, 2003). In almost all animal species, the observed symptoms were similar and comparable. The toxic effects involve mainly the peripheral neuromuscular system, which paralysed to different extent. Furthermore, TTX is a highly potent haemetic agent, so that vomiting was frequently observed in both cats and dogs. Moreover, a pronounced and long-lasting hypotension was observed as well as hypothermia (Kao, 1966).

## Treatment

There is no antidote available for clinical use, so far. To appropriately treat respiratory failure or cardiac effects, a careful observation of the poisoned patient is recommended. Admission to an intensive care unit is necessary in moderate to severe cases to prevent complications. In case of severe poisoning, atropine can be used to treat bradycardia. Respiratory support may be necessary for 24–72 h. Since the patient may be fully conscious during the poisoning, sedation is important when the patient is paralysed.

## Concluding remarks

Due to the severity of TTX intoxication, prevention is very important: public education is essential to reduce puffer fish poisoning (How *et al.*, 2003). In Japan, low mortality rates have been achieved after the introduction of legislation related to the preparation and marketing of *fugu* (Isbister and Kiernan, 2005). The official method to detect TTX in puffer fish in Japan is MBA, as detailed in Hungerford (2006). In United States, no regulatory limits for TTX have been established, but personal importation of puffer fish is prohibited (Gessner, 2000).

# CIGUATOXINS AND MAITOTOXINS

In tropical regions many species of fish may become toxic, provoking neurological, gastrointestinal and, sometimes, cardiovascular symptoms, when ingested. Eating these contaminated fish, humans can develop ciguatera, a marine fish poisoning that causes diverse and often long-lasting health problems. Although this poisoning is rarely fatal (0.1%), it has been estimated that more than 25,000 persons are affected every year.

# BACKGROUND

Ciguatera fish poisoning (CFP) is characterized by moderate to severe gastrointestinal symptoms (vomiting, diarrhoea and abdominal cramps), neurological signs (myalgia, paraesthesia, cold allodynia and ataxia) pruritus and, less common, cardiovascular effects (Isbister and Kiernan, 2005). Both gastrointestinal and neurological symptoms are typical of CFP, but the proportion of each type depends on the region (Isbister and Kiernan, 2005). Gastrointestinal symptoms characterize the first stage of this poisoning and are predominant in Caribbean cases of ciguatera. Generally, they appear within 2–12 h of contaminated fish ingestion and are represented mainly by nausea, vomiting, diarrhoea, but also by abdominal pain (Farstad and Chow, 2001).

Neurological symptoms predominate in the Pacific area. Neurological effects develop over 24 h, although the onset of symptoms can be very different, even in patients eating the same fish. Cold allodynia, a dysestesia that induces a burning sensation on contact with cold objects, is one of the most typical symptoms of ciguatera and is commonly incorrectly referred as “temperature reversal” (Isbister and Kiernan, 2005).

Persistent effects of ciguatera poisoning have been reported, although no prospective studies with definitive cases of ingestion have been set up. Reported chronic clinical effects include fatigue, arthralgia, myalgia, headache and pruritus. Also depression and anxiety have been associated with chronic ciguatera poisoning (Isbister and Kiernan, 2005). Cardiovascular symptoms, not very frequent, include bradycardia and hypotension (Farstad and Chow, 2001).

Initially this poisoning can present similar symptoms to those observed in Diarrhoeic Shellfish Poisoning (DSP) or in microbiological food poisoning, so the anamnesis of the patient is important. Mild ciguatera cases are often misdiagnosed as a common illness such as the flu. Whereas symptoms of cold allodynia are indicative of ciguatera poisoning, differential diagnosis of neuropathy can be necessary (Glaziou and Legrand, 1994; Isbister and Kiernan, 2005).

The toxin isolated from the ciguatera implicated fish are produced by the epiphytic benthic dinoflagellate *Gambierdiscus toxicus*. This dinoflagellate is common in coral reef waters and lives at temperature ranging from 20°C to 34°C, in conditions of low salinity and depths (3–15 m). Its growth is increased in places where there is a reef degradation by human or natural factors (Lewis and Holmes, 1993). Different strains of *G. toxicus* produce chemically distinct lipo- and water-soluble toxins, named CTXs and MTXs (maitotoxins), respectively (Lewis, 2001). Since the actual role of MTX in CFP is still unclear, the two groups of toxins will be treated separately.

The accumulation of these toxins through the food chain involves the ingestion of *G. toxicus* by herbivorous fishes which are eaten by carnivorous species (Lewis and Holmes, 1993; Lehane and Lewis, 2000). CTXs are concentrated both into viscera (such as liver, intestines and gonads) and into fish muscle (Lehane and Lewis, 2000), whereas MTXs seem to be confined only to the viscera (Yasumoto, 2001). Pacific and Caribbean reef-fish species associated with ciguatera include *Lutjanids* (red bass and snappers), *Serranids* (coral trout from the Great Barrier Reef, sea bass and groupers), *Epinephelids* (cod, including flowery cod and spotted cod), *Lethrinids* (emperors and scavengers), *Muraenids* (moray eels), *Scombrids* (mackerel, including Spanish mackerel, and tunas), *Carangids* (jacks and scads) and *Sphyraenids* (barracuda) (Lehane and Lewis, 2000; Isbister and Kiernan, 2005).

Ciguatera is endemic in subtropical and tropical regions of the western Indian and Pacific Ocean regions and in the Caribbean Sea (Lehane and Lewis, 2000). However, due to the increase in trade of these fish, CFP is not confined to the tropics. Epidemiological characterization of ciguatera has been limited by the lack of laboratory test to confirm the presence of the toxins, so far (Lewis *et al.*, 2000).

## CIGUATOXINS

Toxins responsible for CFP are mainly CTXs (Figure 60.3), lipid-soluble and heat-stable polyether compounds with a backbone composed of 10–14 rings transfused by ether linkages into a ladder-like structure that reminds the brevetoxins (PbTxs) (Dechraoui *et al.*, 1999; Lehane and Lewis, 2000).

CTXs seem to be oxidation products of their less toxic precursors, gambiertoxins, through cytochrome enzymes in the liver of fish (Lehane and Lewis, 2000; Yasumoto, 2001; Cembella, 2003). Structural differences have been found in CTXs isolated in different regions, so that Pacific (P-CTXs) and Caribbean (C-CTXs) CTXs are usually referred to separately (Danaras *et al.*, 2001; Yasumoto, 2001).

### Pharmacokinetics/toxicokinetics

Only limited data are available on absorption, distribution, metabolism and excretion of CTXs. Most of the toxicokinetic information is not obtained from actual pharmacokinetic studies, but often derives either from direct clinical observations or are indirectly hypothesized on the basis of the chemical properties of CTXs. The oral absorption of these toxins should be complete or almost complete due to their lipophilicity; it has been hypothesized that CTXs can also penetrate the skin and mucous membranes, due to the observed human effects after local exposure (Lehane and Lewis, 2000). CTXs are able to cross the placenta (Pearn *et al.*, 1982) as well as they are excreted in breast milk, although hyperaestesia of the nipples of a lactating

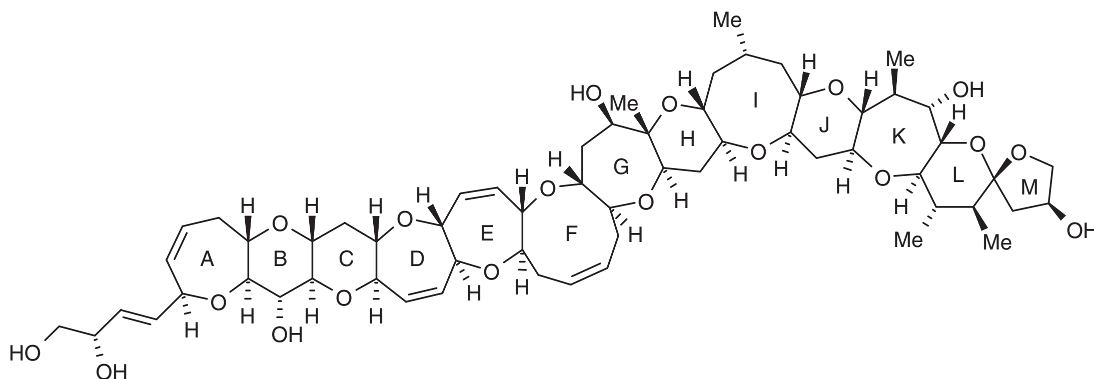

**FIGURE 60.3** Chemical structure of ciguatoxin-1 (from Lewis *et al.*, 2000).

mother may interfere with breast feeding (Bagnis and Legrand, 1987). In a recent study, the blood collected from mice exposed to a sublethal dose of C-CTX-1 was found to contain toxin concentrations ranging from 0.25 to 0.12 ng/ml, 30 min and 12 h after exposure, respectively (Bottein Dechraoui *et al.*, 2005).

## Mechanism of action

CTXs increase cell $Na^+$ permeability by binding to site 5 neuronal voltage-sensitive sodium channels which open at normal resting membrane potential. Therefore, CTXs affect various $Na^+$-dependent mechanisms to enhance membrane excitability, induce mobilization of intracellular $Ca^{2+}$, and provoke cell swelling. The effects of CTXs are most prominent in nerves (Lewis *et al.*, 2000).

It has been hypothethized that the cardiovascular effects can result from a positive inotropic effect of the toxin on the myocardium, responding to the increased intracellular $Ca^{2+}$ (Lehane and Lewis, 2000).

## Toxicity

### *Human toxicity*

Few fatal cases of CFP are reported. Postmortem analysis evidenced acute visceral congestion with eosinophilic necrotic lesions in the liver at light microscope and ultrastructural changes in the sural nerve with swelling Schwann cells, axonal compression and vesicular degeneration of myelin (Lehane and Lewis, 2000; Terao, 2000). Both P-CTX-1 and C-CTX-1 pose a health risk at concentrations above 0.1 ppb (Pearn, 2001).

In its typical form, ciguatera is characterized initially by the onset of intense vomiting, diarrhoea and abdominal pain within hours after ingestion of toxic fish, although the neurological symptoms tend to be the most distinctive and permanent ones. They include sensory disturbances such as generalized pruritus, circumoral numbness, long-lasting weakness and fatigue and the unusual and perhaps pathognomic sensory discomfort triggered by cold stimuli ("cold allodynia") (Lehane and Lewis, 2000). Patients with bradycardia and/or hypotension may require urgent care, because the infrequent cardiovascular symptoms may indicate a poor prognosis (Lewis *et al.*, 2000).

### *Experimental toxicity*

#### *Single administration*

After single administration in mice, the toxicity is similar either after oral or i.p. administration, suggesting that oral absorption is almost complete in this species. P-CTXs and C-CTXs show a different potency by i.p. injection. The i.p. $LD_{50}$ values in mice are 0.25, 2.3 and 0.9 μg/kg for P-CTX-1, P-CTX-2 and P-CTX-3, respectively, whereas $LD_{50}$ values of 3.6 and 1.0 μg/kg were recorded for C-CTX-1 and C-CTX-2 (Lehane and Lewis, 2000).

The acute i.p. injection or oral administration of P-CTX-1 or P-CTX-4C (0.7 μg/kg) in mice provokes similar toxicity, initially characterized by severe diarrhoea. Target organs were heart, medulla of adrenal glands, autonomic nerves and penis. Light microscopy examination shows marked swelling and focal necrosis of cardiac muscle cells. Degeneration of cells in the medulla of the adrenal glands was also observed. A marked lung oedema, with congestion at alveolar spaces and bronchioles, was reported in mice with severe dyspnoea. Continuous erection of the penis was observed in about 15% of the mice suffering from ciguatoxicosis (Lehane and Lewis, 2000; Terao, 2000).

#### *Repeated administration*

After repeated i.p. and oral administrations (100 ng/kg of P-CTX-1 or P-CTX-4C) for 15 days, marked swelling of cardiac cells and endothelial lining cells of blood capillaries in the heart were observed. Although single doses of the same toxins did not provoke any discernible change at macroscopic, light microscopic and at even ultrastructural level in the hearts of mice, the repeated administration of CTXs resulted in severe morphological, but reversible, cardiac changes. At the ultrastructural level, the changes induced by repeated CTXs administration were similar to those of mice receiving a CTXs single dose (700 ng/kg or more) (Terao, 2000).

## Treatment

For ciguatera poisoning there is only a supportive and symptomatic treatment such as the control of fluid and electrolyte balance, since no effective antidote for ciguatera is available, so far. The infrequent cardiovascular complications, such as symptomatic bradycardia and severe hypothension, may require treatment.

The most common treatment during the acute phase of CFP is i.v. infusion of mannitol (Lehane and Lewis, 2000; Terao, 2000), although controversial data are reported about its actual efficacy. In particular, a double-blind randomized, controlled trial found no difference between mannitol and saline treatment. Local anaesthetics and antidepressants may also be useful in some cases (Lehane and Lewis, 2000; Terao, 2000; Lewis, 2001; Isbister and Kiernan, 2005).

## Concluding remarks

Since CFP still remains a significant problem, prevention is important in endemic regions. The most widely used method for monitoring purposes is the MBA, based on

clinical signs (marked hypothermia) and death observed for up to 48 h after i.p. injection of a 20 mg ether extract from fish muscle. Due to the poor sensitivity, this assay cannot detect the presence of CTXs in low-contaminated ciguateric fish (Lehane and Lewis, 2000). Although various immunoassays, such as radioimmunoassay (RIA), enzyme-linked immunosorbent assay (ELISA), as well as binding and cytotoxicity assays have been developed, there is still a need for easy diagnostic and screening methods for ciguatera. In the United States ciguatera outbreaks are investigated using laboratory-based cytotoxicity screening and confirmatory liquid chromatography/mass spectrometry (LC-MS) methods (Hungerford, 2006).

## MAITOTOXINS

MTX, a water-soluble compound isolated together with CTXs, was considered as a biotoxin involved in CFP (Yasumoto, 2001). Anyway, its content being insignificant in the fish flesh and having low oral toxicity, MTX seems to play a limited role in CFP (Estacion, 2000; Yasumoto, 2000).

MTX, named also MTX-1 (Figure 60.4), is a polycyclic polyether and, except biopolymers, the largest natural compound isolated and structurally elucidated so far ($C_{164}H_{256}O_{68}S_2Na_2$; molecular weight (m.w.): 3422) (Yasumoto, 2001). It is produced by the epiphytic dinoflagellate *Gambierdiscus toxicus* and accumulates in the liver of fishes such as surgeonfish and parrotfish. MTX was first detected in viscera of *Ctenochaetus striatus* (*maito*), from which MTX derived its name. MTX analogues (MTX-2; m.w.: 3298 and MTX-3; m.w.: 1060) have been purified from *G. toxicus* strains (Holmes and Lewis, 1994; Bouaïcha *et al.*, 1997; Estacion, 2000; Terao, 2000).

### Pharmacokinetics/toxicokinetics

No data on MTXs absorption, distribution, biotransformation and elimination are available, so far.

### Mechanism of action

MTX is a powerful activator of $Ca^{2+}$ entry via non-selective cation channels in wide variety of cells. Thus, it causes an increase of cytosolic $Ca^{2+}$ levels which stimulate a broad spectrum of calcium-dependent processes, including cell death (Escobar *et al.*, 1998; Estacion, 2000; Morales-Tlalpan and Vaca, 2002).

### Toxicity

#### *Human toxicity*

The toxicity of MTXs in humans is unclear as its role in CFP is not completely understood (Estacion, 2000).

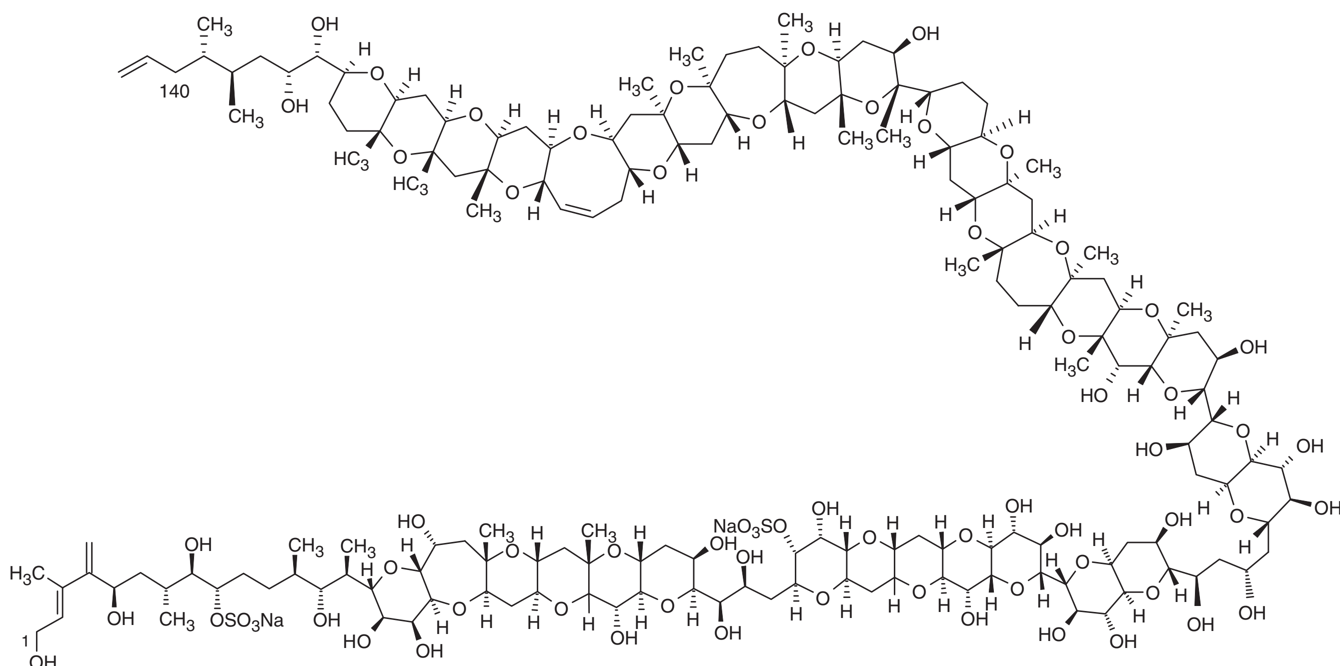

**FIGURE 60.4** Chemical structure of maitotoxin (from Yasumoto, 2001).

***Experimental toxicity***

*Single administration*

After i.p. injection in mice, the $LD_{50}$ of MTX was determined as 500 ng/kg (Yasumoto, 2000). An i.p. injection of MTX in mice (200–400 ng/kg) and rats (400 ng/kg) induced severe alterations at the gastric mucosa, cardiac muscle and lymphoid tissues, as well as an increase of plasma cortisol, which was probably involved in the lymphoid tissues involution (Terao, 2000). A hypothermic effect after i.p. injection in rats (338 ng/kg) was reported too (Gordon and Ramsdell, 2005).

*Repeated administration*

Repeated daily i.p. injection of MTX to mice (45 ng/kg, for 13 days) resulted in marked atrophy of lymphoid tissues, reduced circulating lymphocytes and serum immunoglobulin M levels, as well as increased calcium content of adrenal glands and plasma cortisol (Terao, 2000).

## Concluding remarks

Although MTX is accumulated mainly in viscera of herbivorous fishes and seems to play a marginal role in CFP, the possible contribution of MTX should not be disregarded, considering the practice of eating small fish without eliminating their viscera in some areas of the world (Yasumoto, 2000). Therefore, the possibility of MTXs detection in fish and phytoplankton is of particular importance so that biological assays and chemical methods based on high-performance liquid chromatography (HPLC) and zone electrophoresis with ultraviolet and/or mass spectrometry detection have been set up (Fessard *et al.*, 1994; Lewis *et al.*, 1994; Van Dolah *et al.*, 1994; Bouaïcha *et al.*, 1997).

# DOMOIC ACID AND ANALOGUES

## Background

Amnesic shellfish poisoning (ASP) is a toxic syndrome provoked by DA-contaminated shellfish consumption. ASP differs from most other neurotoxic marine poisonings because the main effect is on the central nervous system (CNS) (Isbister and Kiernan, 2005). It was reported for the first time in Canada in 1987 when, after consumption of contaminated mussels, people developed gastrointestinal symptoms within 24 h (vomiting, abdominal cramps and diarrhoea) and/or neurological symptoms within 48 h (headache, loss of short-term memory, disorientation, lethargy, seizures and, sometimes, convulsions and coma). Mortality was also recorded. Since the most relevant clinical effects were memory loss, the condition was termed ASP (Nijjar and Nijjar, 2000). The loss of memory in patients intoxicated with DA-contaminated mussels appeared to be similar to patients with Alzheimer's disease. However, whereas symptoms of Alzheimer's disease are generally present in older people and intensify with advancing age, loss of memory in mussel-intoxicated patients was not affected by the age of patients. Further, the findings that higher cortical functions, such as intellect, were not affected by DA poisoning distinguishes ASP from Alzheimer's disease (Nijjar and Nijjar, 2000).

The toxin responsible for ASP is DA (Figure 60.5), an amino acid belonging to the kainoid class of compounds (Wright *et al.*, 1990) and 10 DA isomers (isodomoic acids A to H and DA 5′-diastereoisomer), that are less toxic than the parent compound. DA and its isomers are water-soluble and heat-resistant tricarboxylic amino acid.

Previously DA was only known from the red macroalgae *Chondria armata*. After 1987, marine diatoms of the genus *Pseudonitzschia*, such as *P. multiseries*, *P. pseudodelicatissima* and *P. australis* were shown to produce DA. Recently, *P. navis-varingica* was found to produce isodomoic acids A and B as major toxins (Kotaki *et al.*, 2005).

DA has been shown to accumulate in blue mussels (*Mytilus edulis, Perna canaliculus* and *Mytilus galloprovincialis*) as well as in other shellfish, such as cockles (*Cerastoderma edule*), razor clams (*Siliqua patula*), scallops (*Pecten maximus*), crabs (*Cancer magister*) in furrow shell (*Scrobicularia plana*) (Jeffery *et al.*, 2004) and in anchovies.

DA contaminated shellfish and potentially toxic *Pseudonitzschia* ssp. have been detected worldwide. Although DA has caused bird (via toxic anchovies) and other animal mortalities, the only toxic episode with confirmed human illnesses is that of Canada.

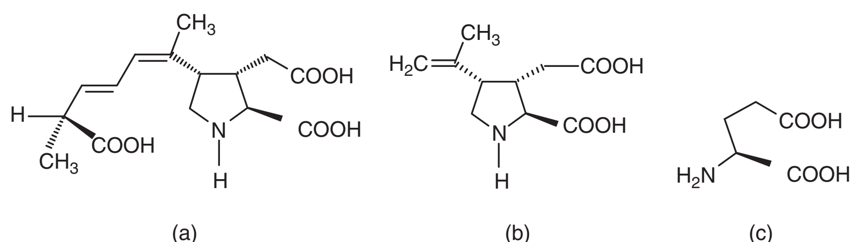

**FIGURE 60.5** Chemical structure of (a) domoic acid, (b) kainic acid and (c) glutamic acid (from Nijjar and Nijjar, 2000).

## Pharmacokinetics/toxicokinetics

Very limited data are available on the absorption, distribution, metabolism and excretion of DA, showing not appreciable differences in the effects observed after i.p. and oral administration. It has been suggested that DA is poorly absorbed after the usual exposure route (Jeffery *et al.*, 2004). Furthermore, in the two studies comparing the intraperitoneal and oral administration administration in rodents, involving a small group size ($n=1$ or 2/dose) (Iverson *et al.*, 1989), DA was almost completely excreted in the faeces supporting the hypothesis that DA is not well absorbed. Truelove *et al.* (1996) reported that only 2% of the orally administered dose of DA (5 mg/kg/day) in rats ($n=10$) was excreted in the urine. Similar results (mean DA urinary excretion of the daily dose ranged from 4% to 7%) were obtained in cynomolgus monkeys ($n=3$), treated with a subtoxic dose of DA for 32 days (Truelove *et al.*, 1997). Once absorbed, DA appears to be poorly metabolized. In fact, approximately 75% of a dose of $^{3}$H-labelled DA i.v. administered in rats ($n=8$) was excreted unchanged in the urine within 160 min, suggesting that it is not significantly metabolized before the rapid elimination. In the same study, evidences for some metabolism to compounds of greater hydrophilicity were hypothesized, due to remaining radiolabel eluted earlier during LC than DA (Suzuki and Hierlihy, 1993). In another study on the distribution and excretion of i.v. administered DA in rats (500 and 1000 μg/kg) and monkeys, half-lives of about 20 and 110 min, apparent volume of distribution of approximately 300 and 180 ml/kg and apparent clearances of approximately 10 and 1 ml/min/kg were reported. Although the limited number of animals used in the study, these data suggest that DA, after i.v. administration, is well distributed into the body fluids in both species and is rapidly eliminated (Truelove and Iverson, 1994).

After DA i.v. administration in rats, DA poorly permeates across the blood–brain barrier and appears not to cross via a specific transport carrier (Preston and Hynie, 1991). However, despite this limited transfer across the blood–brain barrier, the brain is the primary organ of DA-induced toxicity.

## Mechanism of action

The toxicity of DA in the nervous system is known to occur on excitatory amino acid receptors and on synaptic transmission. Two amino acids, L-glutamate and L-aspartate are considered to be neurotransmitters and act upon several receptor types. Three receptor subtypes have been described for excitatory amino acids, the kainic acid (KA) and the *N*-methyl-D-aspartate (NMDA) receptors being best characterized.

DA produces its action through pre- and post-synaptic receptors in a manner similar to KA opening the channel to $Ca^{++}$ and inducing cellular lethality (Wright *et al.*, 1990; Todd, 1993). Due to the structural similarity of DA to glutamic acid and, in particular, to KA (Figure 60.5), DA has a strong affinity for subclasses of kainate receptors. Kainate receptors are widely distributed in the mammalian brain and are particularly concentrated in the CA1–3 regions of the hippocampus in rodents, in the CA2 and CA3 regions in non-human primates as well as in the CA3 region in humans (Jeffery *et al.*, 2004). The high affinity of DA to kainate receptors and the apparent co-localization of these receptors at sites where DA induced damage in the brains of rodents and primates suggest that DA-kainate receptor interactions play a major role in the toxic response. This binding of DA to glutamate receptor subtypes appears to stimulate neuronal firing, eliciting an excitatory response both *in vitro* and *in vivo* (Jeffery *et al.*, 2004).

Although the exact mechanism of neuronal stimulation leading to tissue brain damage is not completely understood, and influx of $Ca^{2+}$ into cells was observed in brain tissue slices exposed to DA, as well as an increased cytosolic $Ca^{2+}$ levels in hippocampal pyramidal neurons exposed to DA were reported (Jeffery *et al.*, 2004). It seems that DA binding to glutamate receptors in specific brain regions leads to excitation of neurons, giving rise to an influx of $Ca^{2+}$ resulting in a failure to maintain intracellular ion homeostasis and in neuronal cell death (Jeffery *et al.*, 2004).

## Toxicity

### *Human toxicity*

The acute ASP outbreak occurred in 1987 in Canada after the ingestion of blue mussels (*Mytilus edulis*) was characterized by gastrointestinal and unusual neurological symptoms. Although 150 reports of this illness were recorded, only 107 individuals met the clinical definition of the poisoning (Jeffery *et al.*, 2004). The most common gastrointestinal symptoms were vomiting (76%), abdominal cramps (50%) and diarrhoea (42%); the most common neurological symptoms were headache (43%) and loss of short-term memory (25%) (Nijjar and Nijjar, 2000).

The poisoning was particularly severe in 19 people who were hospitalized: 12 individuals with particularly severe symptoms (e.g. seizures, coma, profuse respiratory secretions or unstable blood pressure) required treatment in intensive care unit. Although in most patients decreased arousal and somnolence were seen, in some cases leading to coma, in less severely affected patients, agitation was observed. Cardiovascular symptoms (tachycardia, hypotension and cardiac arrhythmias) may have been a consequence of dysfunction of the central autonomic centres, since there was no evidence of primary cardiovascular impairment (Doble, 2000).

In most patients, symptoms resolved in a few weeks, but in some of them a residual memory impairment persisted (Doble, 2000).

Three hospitalized patients died 11–24 days after consumption of mussels. A fourth patient died of myocardial infarction within 3 months of mussel consumption. Postmortem histological examination showed neuronal necrosis and astrocytosis which was most prominent in the hippocampus and amygdala nucleus (Nijjar and Nijjar, 2000).

In nine cases of poisoning, estimates of DA exposure were carried out from analysis of leftover mussels collected from households or restaurants. The amount of DA ingested ranged from 60 to 290 mg in poisoned patient. From this evaluation, it seems that 60 mg of DA/person (≈1 mg DA/kg) is sufficient to provoke gastrointestinal symptoms, whereas ingestion of 270 mg/DA/kg bw (≈4.5 mg DA/kg) provokes neurological effects (Jeffery *et al.*, 2004).

### *Experimental toxicity*

*Single administration*

After i.p. administration in mice $DL_{50}$ values of 2.4 and 3.6 mg DA/kg were reported in two different studies using DA-contaminated mussel extracts. Clinical symptoms such as scratching, tremors and seizures at both lethal and sublethal doses of the extracts were observed. $LD_{50}$ values have been recorded for newborn mice after i.p. administration at different postnatal days: the results suggest that they may be much more sensitive to DA than the adult mice (Jeffery *et al.*, 2004).

Neuropathological studies were carried out in both mice and rats: dose-related lesions in the brains (oedema in the hypothalamus and hypothalamic arcuate nucleus and neuronal degeneration in different areas of the hippocampus) of mice and rats were found after i.p. and after *per os* administration of mussel extracts containing DA (Iverson *et al.*, 1989).

Similar effects have been reported in studies of non-human primates, after i.p. and i.v. administration. Severe vomiting and scratching were reported after single i.v. DA administration (0.24, 0.5, 1.0, 1.25, 1.5, 2 and 4 mg/kg) in cynomolgus monkey, with a dose-related latency in the appearance of the symptoms. DA doses ⩾1.0 mg/kg provoked death by respiratory failure in 4/7 animals. Postmortem examination revealed lesions in the hippocampus (Scallet, 1995) and in another similar study, utilizing specialized histochemistry, also the thalamus appeared affected (Schmued *et al.*, 1995).

*Repeated administration*

After repeated (64 days) *per os* exposure to DA (0.01 or 5 mg/kg/day) of male and female rats, neither clinical abnormalities nor differences in haematology, clinical chemistry or histopathology were observed in treated animals (Jeffery *et al.*, 2004).

Neither clinical symptoms nor significant changes in body weight, haematology, clinical chemistry or brain histology were observed in cynomolgus monkey orally treated with low DA doses (0.5 mg/kg/day for 15 days and 0.75 mg/kg/day for a further 15 days) (Truelove *et al.*, 1997).

*Teratogenicity*

The effects of DA (0–2 mg/kg) i.p. daily administered to pregnant rats from gestational days 7 to 16 were studied both on mothers and their offspring at gestational day 22. Mother death was recorded only at the higher DA doses (6/12 and 6/9 at 1.75 and 2.0 mg/kg, respectively). At doses ⩾ 0.5 mg/kg/day, a reduction in the alive foetuses number at term was recorded, but the number of deaths was not increased in a dose-dependent way. A non-significant increase in the number of foetuses with visceral and skeletal anomalies was reported (Khera *et al.*, 1994).

*Genotoxicity*

Since the structure of DA contains a butadiene moiety, there is the possibility for the formation of DNA-reactive epoxides *in vivo*. Although only limited data are available about its possible genotoxicity, DA (87 or 174 μM) did not increase mutation frequency in V79 Chinese hamster lung cells *in vitro* measured by thioguanine or ouabain resistance, sister chromatid exchange or micronucleus assays, nor does it give rise to DNA-reactive metabolites (Jeffery *et al.*, 2004). *In vivo* data about carcinogenicity of DA are not available, so far.

## Treatment

The diagnosis is based on the history of ingestion of bivalve molluscs followed by characteristic symptoms. Environmental surveillance programmes of phytoplanktons in risk regions may be suggestive of a possibility of poisoning.

Due to the risk of convulsions, emesis should not be induced. Severe cases should be admitted to the intensive care unit and monitored for convulsions, CNS depression, cardiovascular collapse or gastric haemorrhages. Treatment is symptomatic and no antidote is available (Gulland *et al.*, 2002).

## Concluding remarks

After the human outbreak of ASP in 1897 a regulatory limit for shellfish flesh was introduced in Canada and

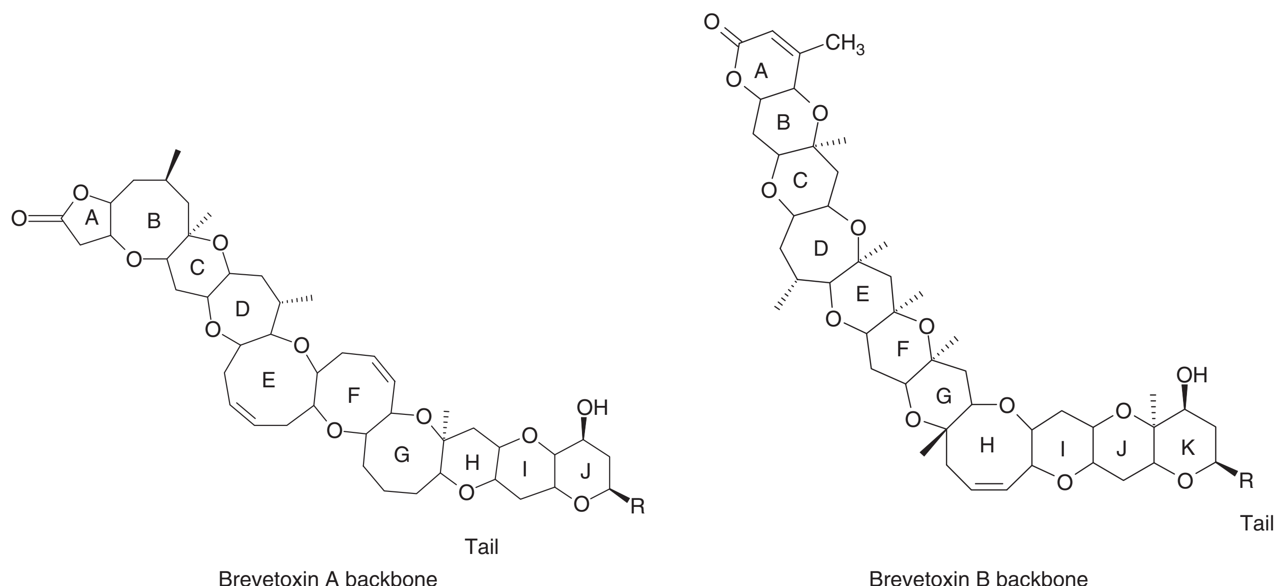

**FIGURE 60.6** Chemical structure of brevetoxins – type A and type B (from Baden and Adams, 2000).

consequently in other parts of the world. The limit, 20 mg/kg is based on a retrospective estimate of the quantity of DA in mussels that resulted in human illness in the 1987 Canadian ASP and incorporates a 10-fold safety factor. Due to the worldwide distribution of the diatoms producing DA, the action limit employed by Canada has been adopted elsewhere and is the limit enforced in the European Union, United States, New Zealand and Australia (Jeffery *et al.*, 2004). An HPLC-UV method has gained favor in various countries (FAO/IOC/WHO, 2005).

# BREVETOXINS

## Background

Brevetoxins (PbTxs) are neurotoxic polyethers produced by the dinoflagellates of *Karenia* genus (mainly *K. brevis*; formerly known as *Gymnodinium breve* or *Ptychodiscus breve*), which forms "red tide" blooms along the Florida coast and the Gulf of Mexico. These harmful blooms cause mass mortality of fish and other marine organisms, episodes of respiratory distress in humans after inhalation of the sea spray, and eyes and skin irritation also after swimming in the sea. As shellfish are resistant to PbTxs and accumulate these compounds, their ingestion may provoke an illness called neurotoxic shellfish poisoning (NSP) (Landsberg, 2002). NSP is characterized by acute gastrointestinal and neurological symptoms, including nausea, vomiting, diarrhoea, chills, sweats, headache, muscle weakness and joint pain, paraesthesia, arrhythmias, difficult breathing, mydriasis, double vision, and troubles in talking and swallowing. Recovery occurs in 2–3 days and no fatal cases from NSP have been reported (Baden and Adams, 2000; Hallegraeff, 2003; Isbister and Kiernan, 2005).

PbTxs are lipid-soluble and heat-stable polycyclic ether compounds grouped in two types (A and B), according to their backbone structures consisting of 10 (type A) or 11 (type B) transfused rings (Figure 60.6) (Baden and Adams, 2000). At least nine PbTxs are produced by *K. brevis*, while several metabolites of these compounds have been identified in shellfish (Ishida *et al.*, 2004; Plakas *et al.*, 2004; Baden *et al.*, 2005). Recently other *Karenia* species were involved in NSP, whereas some raphidophytes (*Chattonella marina, C. antiqua, Fibrocapsa japonica* and *Heterostigma akashiwo*) were reported to produce brevetoxin-like compounds, but no documented cases of NSP were caused by these species (Landsberg, 2002; Hallegraeff, 2003; Ciminiello and Fattorusso, 2004).

Blooms of *Karenia* occurred mainly in the Gulf of Mexico, where NSP has historically been limited, but occasional blooms associated with NSP were reported also along the mid- and south Atlantic coast of the United States and in New Zealand. Shellfish involved in NSP were mainly oysters, clams, cockles and mussels (Landsberg, 2002).

## Pharmacokinetics/toxicokinetics

After oral administration of $^{3}$H-labelled PbTx-3 to rats, the toxin was shown to distribute to all organs, and concentrated mainly in the liver. It was eliminated in equivalent quantities through urine and faeces: about 80% of the

dose was excreted within 7 days (during the first 48 h PbTx-3 was cleared mainly through the faeces, and afterwards mostly through urine) (Cattet and Geraci, 1993).

After i.p. injection of PbTx-3 in mice, blood concentration of the toxin was maximal between 0.5 and 4 h. After 24 h it was reduced by one-third, being still detectable after 7 days (Fairey *et al.*, 2001; Woofter *et al.*, 2003). A significant part of PbTx-3 in mouse plasma binds to high-density lipoproteins (Woofter *et al.*, 2005). In rats, after i.p. injection of PtPx-2 and PtBx-3, the toxins were detected in blood within 1 h and, for PbTx-2, a rapid metabolism to polar cysteine conjugates, eliminated in urine over 24 h, was demonstrated (Radwan *et al.*, 2005).

An i.v. administration of $^{3}$H-labelled PbTx-3 to rats showed that the toxin cleared rapidly from the blood (<10% remained after 1 min) and distributed mainly to the liver, skeletal muscle and gastrointestinal tract (18%, 70% and 8% of the dose after 30 min, respectively). Within 24 h, PbTx-3 concentration in skeletal muscle decreased to 20% of the dose, while that in liver remained constant and increased in gastrointestinal tract and faeces, probably because of biliary excretion. By day 6, about 14% of the toxin had been excreted through urine and 75% in faeces, also in the form of more polar metabolites (Poli *et al.*, 1990).

Intratracheal instillation of $^{3}$H-labelled PbTx-3 to rats revealed that over 80% of the dose was cleared within 0.5 h from the lung and distributed throughout the body, chiefly to the carcass (49%), intestine (32%) and liver (8%). Blood, brain and fat contained the lowest levels of the toxin. About 20% of the initial level in tissues was retained for 7 days. The majority of PbTx-3 was excreted within 48 h in faeces (60%) and urine (30%) (Benson *et al.*, 1999). Also in mice, after intratracheal instillation, PbTx-3 distributed rapidly to tissues, mainly in liver and gastrointestinal tract, while about 90% of excretion occurred within 4 days in urine (11%) and faeces (64%) (Tibbetts *et al.*, 2006). After repeated inhalation of PbTx-3 by rats for 5 or 22 days, small amounts of the toxins were detected in splenic and peribronchiolar lymphoid tissue as well as in liver, where no accumulation of brevetoxin occurred (Benson *et al.*, 2004, 2005).

Cutaneous application of $^{3}$H-labelled PbTx-3 on pig skin revealed a rapid penetration of the toxin to the dermis with maximal dermal accumulation at 4 h (Kemppainen *et al.*, 1991).

## Mechanism of action

PbTxs bind to site 5 on the α-subunit of voltage-sensitive sodium channels in the cell membranes. Normally, these channels open in response to membrane depolarization and subsequentially inactivate returning to closed configuration during the membrane repolarization. Binding of PbTxs opens the voltage-sensitive sodium channels, determining a sustained influx of $Na^{+}$ and a membrane depolarization, induces a shift in activation potential (towards more negative values) and alters the normal changes of the channels configuration during the depolarization/repolarization processes. These actions affect the membrane properties of excitable cells, and are the basis of the neurotoxic effects of PbTxs. A structural feature of these compounds (Figure 60.6) required for this activity is the lactone in the A ring ("head" of the molecule) as well as the conserved structure on the "tail" rings (Ciminiello and Fattorusso, 2004; Baden *et al.*, 2005).

Respiratory problems associated with the inhalation of aerosolized PbTxs are believed to be due in part to opening of sodium channels. Other actions involved in the bronchoconstriction and/or in the immunological effects at the respiratory tract seem to be related to a stimulation of neurotransmitters release and mast cells degranulation, as well as to an inhibition of the phagocytic cells lysosomal proteinases known as cathepsins (Abraham *et al.*, 2005; Baden *et al.*, 2005).

## Toxicity

### Human toxicity

Ingestion of PbTxs contaminated shellfish can cause NSP, a syndrome that include some symptoms similar to CFP, but less severe. The symptoms occur within 30 min to 3 h, last a few days and include nausea, vomiting, diarrhoea, chills, sweats, headache, muscle weakness and joint pain, paraesthesia, arrhythmias, difficulty breathing, mydriasis, double vision, and troubles in talking and swallowing. Sometimes coma, but no mortality or chronic symptoms, were reported (Baden and Adams, 2000; Hallegraeff, 2003; Isbister and Kiernan, 2005).

Due to the fragility of *Karenia* cells, PbTxs can be released in seawater and aerosolized by wind and surf with the possibility of inhalation exposure to these compounds, causing respiratory distress as well irritation of the eyes and respiratory tract mucosa. Normally, these symptoms are rapidly reversible by leaving the beach area. The main brevetoxin responsible for respiratory discomfort seems to be PbTx-3 (Benson *et al.*, 1999; Landsberg, 2002). During swimming also a direct contact with toxic blooms with consequent skin, nasal and eye irritations can occur (Landsberg, 2002).

### Experimental toxicity

#### Single administration

After i.p. injection in mice, the $LD_{50}$ of PbTx-1, -2 and -3 were calculated to be 100, 200 and 170 μg/kg, respectively. The symptoms include immediate irritability, followed by hind-quarter paralysis, dyspnoea, salivation, lachrymation, urination, defecation and death from respiratory paralysis (Landsberg, 2002; FAO/IOC/WHO, 2005).

The oral $LD_{50}$ in mice ranges from 520 μg/kg for PbTx-3 to 6600 μg/kg for PbTx-2 (FAO/IOC/WHO, 2005). PbTx-3 caused tremors followed by marked muscular contractions or fasciculations, tail elevation, laboured breathing and death (van Apeldorn *et al.*, 2001).

*Repeated administration*

Studies on repeated exposure to PbTxs were carried out in rats after inhalation of PbTx-3. Exposure to 500 μg PbTx-3/$m^3$ by nose-only inhalation for 0.5 or 2 h/day, for 5 days (corresponding to 8.3 and 33 μg/kg/day, respectively), provoked a reduction of body weight at the highest dose, but no tissue lesions or signs of cytotoxicity and inflammation in bronchoalveolar lavage fluid were observed. In contrast, the humoral-mediated immunity was suppressed (Benson *et al.*, 2004). A more prolonged inhalation exposure of rats (22 days) to PbTx-3 (corresponding to 0.9 and 5.8 μg/kg/day, respectively) showed similar results: reduced body weight in both PbTx-3 dosed groups of rats, suppression of humoral-mediated immunity, as well as minimal alveolar macrophage hyperplasia and increase of blood reticulocytes (Benson *et al.*, 2005).

***Toxicity for fish and other marine animals***

PbTxs are potent ichthyotoxins, being responsible for the deaths of billions of fish over the years. These toxins are thought to be absorbed through the gills but also by ingestion and mortality can occur in presence of about $2.5 \times 10^2$ *K. brevis* cells/ml. Signs of intoxication in fish include violent twisting and corkscrew swimming, defaecation and regurgitation, pectoral fin paralysis, caudal fin curvature, loss of equilibrium, quiescence, vasodilatation, convulsions and death due to respiratory failure. Chronically intoxicated fish show little pathology aside from slight precipitate haemolysis. Chronic haemolysis was detected via anaemia, cyanosis, viscous blood, splenomegaly, hepatic haemosiderosis and dehydration. Frequently, also birds were found moribund or dead, particularly double-crested cormorants, red-breasted mergansers and lesser scaup, and also dolphins and manatees (Landsberg, 2002).

## Treatment

The treatment of NSP is symptomatic and supportive and normally patients recovery within 2–3 days (van Apeldorn *et al.*, 2001).

## Concluding remarks

In the United States and other countries, the regulatory level of 80 μg of PbTx-3 equivalents/100 g shellfish was established. The risk assessment of NSP toxins is performed by the *in vivo* MBA, based on the observation of the survival time of mice after i.p. injection of an ether extract of shellfish. Because of the higher polarity, some of the known brevetoxin metabolites are not extracted from shellfish by the regulatory protocol for shellfish monitoring (Hungerford, 2006).

Alternatively, *in vitro* functional assays (assay on neuroblastoma cells, receptor binding assays), immunochemical methods (ELISA, RIA) and instrumental methods (spectroscopy-coupled HPLC, LC-MS) can be used for PbTxs detection. Validation studies are underway to meet all the criteria for a reference method (Hungerford, 2006).

# DIARRHOEIC TOXINS

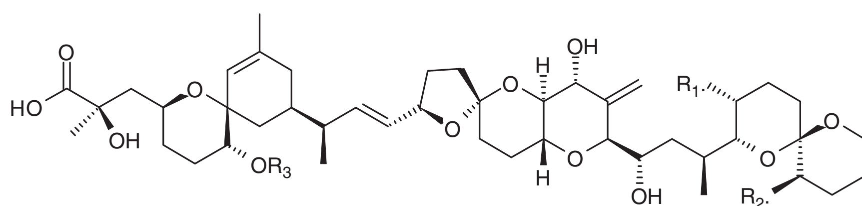
Diarrhoeic toxins induce gastrointestinal symptoms and serious diarrhoea after consumption of contaminated shellfish. They are grouped in two families of compounds: okadaic acid (OA) and its derivatives, responsible for DSP, and azaspiracids, responsible for azaspiracids shellfish poisoning (AZP).

# OA AND DERIVATIVES

## Background

Toxins from the OA group have been known to provoke human poisonings since the late 1970s. The illness was called Diarrheic Shellfish Poisoning (DSP) due to its main symptom. Symptoms of DSP are mainly gastrointestinal distress, diarrhoea, nausea, vomiting and abdominal cramps, occurring between 30 min and several hours after contaminated shellfish consumption. It is not a fatal illness and complete recovery occurs within 3 days, generally without any pharmacological treatment. Nevertheless, DSP is an important cause of morbidity worldwide, having a serious impact on the shellfish industries (Yasumoto, 1990).

The toxins responsible for DSP are lipid-soluble and heat-stable polyether compounds including OA and its derivatives dinophysistoxins (DTXs), the most frequent of which are DTX-1, DTX-2 and DTX-3 (Figure 60.7). OA, the main DSP toxin, originally isolated from the sponge *Halichondria okadai*, is produced by dinoflagellates of the genus *Dinophysis*, similar to DTX-1 and DTX-2. These compounds are produced also by cultured dinoflagellates of *Prorocentrum* genus, but these algal species were sporadically detected in marine phytoplankton during DSP



| | $R_1$ | $R_2$ | $R_3$ |
|---|---|---|---|
| Okadaic acid | $CH_3$ | H | H |
| DTX-1 | $CH_3$ | $CH_3$ | H |
| DTX-2 | H | $CH_3$ | H |
| DTX-3 | H or $CH_3$ | H or $CH_3$ | Acyl |

**FIGURE 60.7** Chemical structure of okadaic acid and dinophysystoxin-1, -2 and -3 (DTX-1, -2 and -3) (from Quilliam, 2003).

outbreaks. On the other hand, DTX-3, a mixture of OA, DTX-1 and/or DTX-2 esters containing a fatty acid generally at the 7-hydroxy group, is believed to be a metabolic product of shellfish rather than direct algal metabolites (Quilliam, 2003).

The first documented dinoflagellate species involved in DSP intoxications was *Dinophysis fortii*, in Japan (Yasumoto *et al.*, 1980), and later it was the causative organism of diarrhoeic poisoning in many other areas. Other species, such as *D. acuminata*, *D. acuta*, *D. mitra*, *D. norvegica*, *D. rotundata* and *D. tripos* were reported also as the sources of DSP toxins too (Lee *et al.*, 1989). The toxins production may vary considerably among these species and among regional and seasonal morphotypes in one species (Hallegraeff, 2003). Several bivalves, such as mussels, scallops, oysters and clams, filtering the seawater containing the toxic phytoplankton, can accumulate the toxins and cause the poisoning to humans after their ingestion.

DSP cases have been reported in many areas of the world and the global distribution of the poisoning involved mainly Japan, Europe, Chile, Thailand, Canada, Australia and New Zealand (Hallegraeff, 2003). The DSP incidences, or at least the presence of DSP, appear to be increasing, probably also because of increasing knowledge of the disease and better surveillance programmes.

## Pharmacokinetics/toxicokinetics

Few toxicokinetic studies of OA have been performed in mice. Twenty-four hours after single oral $[^3H]$OA administration (50 or 90 μg/kg), the toxin was detected in all organs and fluids, including skin, being more concentrated in urine, intestinal contents and intestine. The slow elimination of OA suggests an enterohepatic circulation of the toxin (Matias *et al.*, 1999).

After oral OA administration in mice (75–250 μg/kg), the toxin was absorbed very quickly from the small intestine, mainly from its middle part (jejunum), and reached the liver within 5 min. The distribution of the toxin, evaluated by an immunostaining method, involves the whole body, being detected in lungs, liver, heart, kidneys and intestine, where was still detected after 2 weeks (Ito *et al.*, 2002b).

After intramuscular injection of $[^3H]$OA in mice (25 μg/kg), the toxin was detected in bile and intestinal contents 1 h later and its elimination pattern showed biliary excretion and enterohepatic circulation (Matias and Creppy, 1996a). Transplacental passage of OA in pregnant mice was observed too (Matias and Creppy, 1996b).

## Mechanism of action

OA and its derivative DTX-1 are inhibitors of protein phosphatases 1 and 2A, two enzymes dephosphorylating serine/threonine residues of proteins in eukaryotic cells, through their specific binding to a receptorial site (Bialojan and Takai, 1988; Cohen, 1989). As a consequence, a rapid increase of phosphorylated proteins occurs in cells. The diarrhoea and the degenerative changes in absorptive epithelium of small intestine induced by these toxins had been attributed to accumulation of the phosphorylated proteins controlling ions secretion in intestinal cells and to inhibition of dephosphorylation of cytoskeletal or junctional elements that regulate the permeability to solutes, both phenomena resulting in a passive loss of fluids (Aune and Yndestad, 1993; Tripuraneni *et al.*, 1997). Inhibition of protein phosphatases is involved also in the tumour promoting properties of these toxins (Fujiki and Suganuma, 1993).

A free carboxyl group in the DSP molecule is essential for inhibition of protein phosphatase activity, since their

methyl and diol esters did not show inhibition (Mountfort *et al.*, 2001).

## Treatment

The treatment of the diarrhoeic poisoning is symptomatic and supportive with regards to short-term diarrhoea and accompanying fluid and electrolyte losses. In general, hospitalization is not necessary. Other diarrhoeic illnesses associated with shellfish consumption, such as bacterial or viral contamination, should be ruled out on the basis of anamnesis of the patients (Aune and Yndestad, 1993).

## Toxicity

### *Human toxicity*

Symptoms of DSP are mainly diarrhoea, nausea, vomiting and abdominal pain. Although the intoxication can be highly debilitating for some days, no human mortalities from DSP were reported, so far. Recovery is usually complete in 3 days, despite the pharmacological treatment. An LOAEL of 1.2–1.6 μg/kg was determined after human poisoning in Japan (eight persons from three families, age 10–68 years). In Norway, 38 of 70 adults were affected at levels ranging from 1.0 to 1.5 μg/kg (FAO/IOC/WHO, 2005).

### *Experimental toxicity*

*Single administration*

After single i.p. injection in mice, $LD_{50}$ values of OA were estimated in the range from 192 to 225 μg/kg (Tachibana *et al.*, 1981; Dickey *et al.*, 1990; Tubaro *et al.*, 2003).

OA or DTX-1 injection in rodents (mice and rats) induced damages at intestinal mucosa, particularly at duodenum and upper portion of jejunum, within 15 min. The injuries can be divided into three consecutive stages: increase of capillary permeability and extravasion of serum into the lamina propria of villi; degeneration of absorptive epithelium of villi; and desquamation of the degenerated epithelium from the lamina propria. At sublethal doses, these alterations are reversible and the recovery process, observed already 2 h after the toxin administration, was complete within 24 h (Terao *et al.*, 1986; Terao *et al.*, 1993; Ito and Terao, 1994). Morphological alterations induced by DTX-3 were less pronounced and consisted only in dilatation of the cysternae of Golgi apparatus and presence of vesicles in the cytoplasm of the absorptive epithelium (Terao *et al.*, 1993). An i.p. administration of OA, DTX-1 or DTX-3 to rodents induced also liver damages, with vacuolization and/or necrosis of hepatocytes (Terao *et al.*, 1993; Ito and Terao, 1994; Aune *et al.*, 1998; Tubaro *et al.*, 2003).

OA was observed to induce liver damage also after i.v. administration to rats, with congestion of blood in the liver, and dissolution of hepatic bile canalicular actin sheaths (Berven *et al.*, 2001).

OA, DTX-1 and DTX-3 are less toxic after oral administration than after i.p. injection. In particular, by oral route, the $LD_{50}$ of OA in mice ranged between 1 and 2 mg/kg (Tubaro *et al.*, 2003). Besides diarrhoea, the signs of toxicity are similar to those observed after i.p. administration. In addition, DTX-1 and DTX-3 caused also the degeneration of surface cells of the gastric mucosa (Terao *et al.*, 1993; Ito and Terao, 1994; Ito *et al.*, 2000; Berven *et al.*, 2001).

*Repeated administration*

Daily repeated oral administration of OA to mice (1 mg/kg/day, for 7 days) induced diarrhoea, body weight loss, reduced food consumption and the death of 2/5 mice. The toxic effects were observed at forestomach and liver and, at the ultrastructural level, OA induced alterations of mitochondria and fibres of myocardiocytes (Tubaro *et al.*, 2004).

*Mutagenic and genotoxic activity*

Although OA did not induce mutations in *Salmonella typhimurium* in the absence or in presence of metabolic activation, it was mutagenic in various eucaryotic cell lines *in vitro* (Aune and Yndestad, 1993; Fessard *et al.*, 1996). No genotoxicity data are available for DTX-2 and DTX-3. Genotoxic effects of OA, such as micronuclei formation, mitotic arrest and polyploidy, were observed in human Caco-2 cells (Le Hégarat *et al.*, 2006).

*Tumour promoting activity*

OA and DTX-1 are tumour promoters, as evidenced in two-stage experiments on mouse skin (Fujiki and Suganuma, 1993) and in the rat glandular stomach (Suganuma *et al.*, 1992).

## Concluding remarks

OA and DTXs are involved in DSP and possess tumour promotion activity through their inhibition of protein phosphatases. DSP risk is managed by monitoring seafood for toxicity: frequency of sampling should ensure that contamination does not rise to dangerous levels in temporal or spatial gaps between sampling times or locations. Monitoring programmes need also the assessment of the toxin-producing phytoplankton organisms in the water column in order to provide an early warning of the potential for DSP toxin contamination in shellfish.

Various methods have been developed for DSP toxins analysis. They include *in vivo* biological assays and *in vitro*

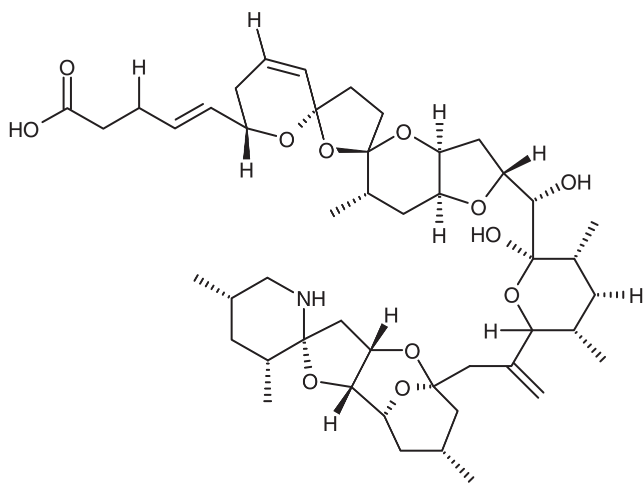


**FIGURE 60.8** Chemical structure of azaspiracid-1 (from James *et al.*, 2004).

biochemical or biological assays as well as chemical methods of analysis. The MBA is at the time of writing the accepted method for DSP toxins determination in shellfish as it can detect the presence of all DSP toxins, although other lipophilic compounds can interfere. It evaluates the survival time of mice injected i.p. with a suspension of a shellfish extract usually over a 24 h observation period (Fernández *et al.*, 2003). *In vitro* assays include enzyme or radioactivity-based immunoassays, mainly for OA and DTX-1 determination. Protein phosphatase 2A inhibition assay is a particularly sensitive *in vitro* functional assay, being based on the mechanism of action of OA (Cembella *et al.*, 2003). Chemical methods of analysis include high-performance liquid chromatography (HPLC), capillary electrophoresis (CE) and liquid chromatography-mass spectrometry (LC-MS) techniques (Quilliam, 2003). For functional, ELISA and instrumental methods, the results should include the toxins release by hydrolysis of their ester forms.

Regarding the control of DSP toxins, the regulation in most countries is based on the negative results of shellfish samples at the MBA. In the European Union, besides the MBA, alternative detection methods can be used for the assessment of DSP risk and the maximum tolerated level of diarrhoeic toxins in shellfish was set at 160 μg of OA equivalents/kg of edible part (EC, 2002).

## AZASPIRACIDS

### Background

AZP is the most recently discovered toxic syndrome from algal contaminated shellfish consumption. The illness was reported for the first time in 1995 in the Netherlands, when eight people, after ingestion of blue mussels from Ireland, developed symptoms very similar to those of DSP, even though the concentration of OA and derivatives was low. Subsequently, the azaspiracid toxin group was discovered. The structural elucidation of the first toxin of this group, Azaspiracid1 (AZA1), showed that it had a polyether backbone with a unique spiral ring assembly, a cyclic amine and a carboxylic acid (Figure 60.8). Two analogues of AZA1 (AZA2 and AZA3) were discovered in mussels by liquid chromatography-tandem electrospray mass spectrometry (Ofuji *et al.*, 1999). Others analogues are AZA4 and AZA5, these structures were elucidated by electrospray ionization-mass spectrometry (Ofuji *et al.*, 2001). Recently, five hydroxylated analogues were discovered in mussels (*Mytilus edulis*) using multiple tandem mass spectrometry (James *et al.*, 2003b).

AZAs, first detected in blue mussels (*Mytilus edulis*), have been found in other bivalves, including oysters (*Crassostrea gigas*, *Ostrea edulis*), scallops (*Pecten maximus*), clams (*Tapes phillipinarium*), cockles (*Cardium edule*) and razor clams (*Ensis siliqua*) (Furey *et al.*, 2003). Reports of AZA poisonings and/or contaminated shellfish have been documented from several European Countries, including Ireland, United Kingdom, Norway, the Netherlands, France and Spain. The source of AZAs is considered to be the heterotropic dinoflagellate *Protoperidinium crassipes*. Although AZAs have not been identified outside of Western Europe so far, *Protoperidinium* species occur throughout the world's oceans. Therefore, the AZP syndrome is probably widespread, but generally unreported because its gastrointestinal symptoms are similar to those of DSP or of bacterial enterotoxin poisoning (James *et al.*, 2003a).

### Pharmacokinetics/toxicokinetics

No data are available, so far, about absorption, distribution, metabolism and excretion of AZAs.

### Mechanism of action

Studies on neuroblastoma cells demonstrated that AZA1 disrupts the cytoskeletal structure decreasing F-actin pools (Román *et al.*, 2002). AZA1 was also found to affect the arrangement of F-actin in Jurkat cells, with the concurrent loss of pseudopodia (Twiner *et al.*, 2005). It has been suggested that the actin-disrupting effect of OA in cultured cells could be associated with its diarrhogenic activity, reflecting the loosening of tight junctions *in vivo* (Fiorentini *et al.*, 1996). Although the AZAs effect on F-actin is lower than that of OA, this link between F-actin changes and diarrhogenic activity could be relevant to

explain the AZAs gastrointestinal toxicity, very similar to that of DSP. AZA1 causes also a significant increase in intracellular calcium ions levels ($[Ca^{2+}]_i$) in lymphocytes (Román *et al.*, 2002), whereas AZA4 appears to inhibit $Ca^{2+}$ entry in human T lymphocytes (Alfonso *et al.*, 2005).

## Toxicity

### *Human toxicity*

The human symptoms included nausea, vomiting, severe diarrhoea and stomach cramps (Magdalena *et al.*, 2003).

### *Experimental toxicity*

Due to the lack of commercially available toxins, only few *in vivo* toxicological studies are available for AZAs, so far.

#### *Single administration*

After i.p. administration, the lethal dose of AZA1 in mice has been shown to be 200 μg/kg, whereas AZA2 and AZA3 are more toxic (140 μg/kg). AZA4 and AZA5 are less toxic (James *et al.*, 2004). Although diarrhoea is the main symptom in humans, AZAs did not cause diarrhoea after i.p. injection: mice showed progressive paralysis of the limbs, dyspnoea, and convulsions before death.

After *per os* administration of sublethal doses of AZA1 in mice, necrosis in the lamina propria of the small intestine and in lymphoid tissues (thymus, spleen and Peyer's patches) was observed. Both T and B lymphocytes were injured. Fatty changes in the liver were also observed (Ito *et al.*, 2000). The authors hypothesized that the oral toxicity is 2.5 times higher than that after i.p., but no data on $LD_{50}$ are available. No data about oral toxicity are available for AZA analogues.

#### *Repeated administration*

After repeated oral intake of sublethal doses of AZA1 (250–450 μg/kg) in ICR mice, death in some mice was observed as well as serious gastrointestinal, pulmonary and hepatic effects that persisted for a prolonged period in surviving mice. Repeated oral administration of AZA1 once or twice a week (20–50 μg/kg, for 10–20 weeks) caused interstitial pneumonia, shortening of intestinal villi as well as death of some mice. Lung tumours were developed by 4 out of 20 mice treated with 20 or 50 μg AZA1/kg but further studies are needed to confirm the carcinogenicity of this toxin (Ito *et al.*, 2002a). No genotoxicity data are available and no definitive conclusions regarding relevance to humans can be drawn, so far (FAO/IOC/WHO, 2005).

## Treatment

As for DSP, a specific antidote is not available for AZP: therefore, the treatment is only symptomatic and supportive.

## Concluding remarks

The maximum overall level of azaspiracid was set by the European Union at 160 μg of AZAs equivalents/kg of edible mollusc part (EC, 2002). Mouse or rat bioassay can detect AZAs with a limit of detection of about 160 μg/kg, but other lipophilic toxins can potentially interfere in this assay. Analytical methods like LC-MS (MS) are preferred for accuracy in measuring the concentration of AZAs in contaminated shellfish.

# OTHER TOXINS

# YESSOTOXINS

## Background

Yessotoxin (YTX) (Figure 60.9) is a ladder-shaped polycyclic ether toxin, named for the scallop *Patinopecten yessoensis*, from which it was isolated (Murata *et al.*, 1987). YTX and its analogues were initially included in the DSP toxins because they were found together with OA and other lipophilic toxins during the shellfish extraction procedure for DSP MBA. Recently, YTXs have been classified and regulated separately from the DSP toxins, since they do not induce diarrhoea (Ogino *et al.*, 1997). More than 30 YTX analogues have been isolated both from scallops and microlagae, so far. Nevertheless, no human toxicity has been reported for YTXs, although many of these compounds are highly toxic to mice, after i.p. administration (Bowden, 2006).

YTXs were initially found to be produced by dinoflagellates, such as *Protoceratium reticulatum* (=*Gonyaulax grindley*) (Satake *et al.*, 1997) and *Lingulodinium polyedrum* (=*Gonyaulax polyedra*) (Paz *et al.*, 2004). Because both algal species are common in coastal waters of many regions. The YTXs have widespread occurrence (Yasumoto and Satake, 1998). Recently, in New Zealand also *Gonyaulax spinifera* was identified as a YTX producer (Rhodes *et al.*, 2006).

During their filter-feeding activity, YTXs are concentrated in bivalve shellfish.YTXs-contaminated shellfish are found mainly in Japan, Chile, Italy, Norway and New Zealand (Ciminiello and Fattorusso, 2004; Aasen *et al.*, 2005a; Koike *et al.*,2006).

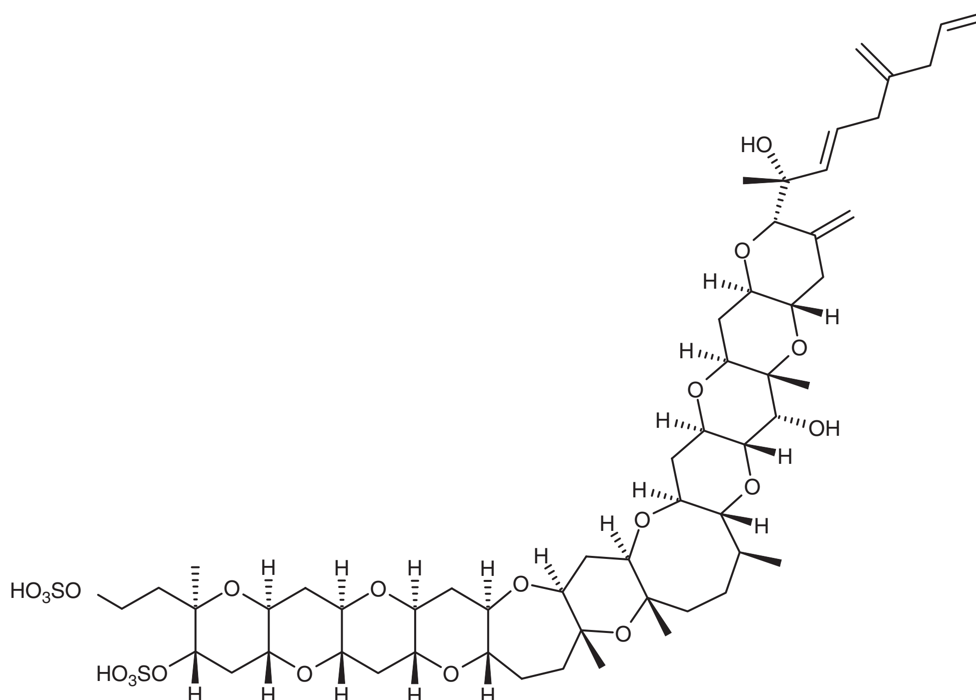

**FIGURE 60.9** Chemical structure of yessotoxin (from Quilliam, 2003).

## Pharmacokinetics/toxicokinetics

No data are available for about absorption, distribution, metabolism and excretion of YTXs, although toxicity data in mice suggest a poor absorption after oral intake.

## Mechanism of action

Based on available data, very low concentrations of YTX appear to affect many systems *in vitro*, but some of these effects are not confirmed *in vivo* after *per os* exposure (Bowden, 2006). Bianchi *et al.* (2004) demonstrated that YTX opens the permeability transition pore of the inner mitochondrial membrane at nanomolar concentrations. YTX is cytotoxic against several cell lines (Glioma C6, HeLa $S_3$, BE(2)-M17, L6 rat myoblast and BC3H1 mouse myoblast) and induces apoptotic effects (Ogino *et al.*, 1997; Leira *et al.*, 2002a; Malaguti *et al.*, 2002; Suarez-Korsnes *et al.*, 2006). Furthermore, YTX disrupt cell adhesion and causes E-cadherin fragmentation at concentrations ranging from $10^{-8}$ to $10^{-10}$ M (Ronzitti *et al.*, 2004). Furthermore, YTX seems to modulate intracellular calcium movements and cyclic AMP (cAMP) levels at higher concentration (ranging from $10^{-7}$ to $10^{-5}$ M) (de la Rosa *et al.*, 2001).

## Toxicity

### *Human toxicity*

There are no reports of human poisoning induced by YTXs, so far (FAO/IOC/WHO, 2005).

### *Experimental toxicity*

Although more than 30 YTXs were isolated, only YTX, desulpho-YTX, homo-YTX and 45-OH-homoYTX were submitted to actual toxicological studies.

#### *Single administration*

After i.p. injection in mice, $LD_{50}$ values ranging from 100 to 750 μg/kg are reported for YTX and homoYTX, while 45-OH-homoYTX did not induced lethality at 750 μg/kg (Terao *et al.*, 1990; Ogino *et al.*, 1997; Aune *et al.*, 2002, Tubaro *et al.*, 2003). Light microscopy revealed only slight intracellular oedema in the heart of animals treated with 750 and 1000 μg/kg (Aune *et al.*, 2002). Electron microscopy analysis revealed swelling of cardiomyocytes and rounded mitochondria in some areas of these cells closed to capillaries (Terao *et al.*, 1990; Aune *et al.*, 2002; Tubaro *et al.*, 2003). Damages to cerebellar Purkinje cells after i.p. injection of YTX (420 μg/kg) were also observed, but not confirmed after *per os* administration (Hungerford, 2006).

After oral administration (the usual human exposure route), YTXs are much less toxic. No lethality or changes in mice behaviour was observed after acute administration of YTX (0.5–10 mg/kg). Only ultrastructural changes were observed at myocardium level, similar to that described after i.p. administration (Terao *et al.*, 1990; Aune *et al.*, 2002; Tubaro *et al.*, 2003). Although YTX induces apoptosis *in vitro* in various cell lines, no apoptotic changes were observed in the myocardium of treated animals using *in situ* TUNEL staining (Tubaro *et al.*, 2003).

*Repeated administration*

After repeated *oral administration* no deaths, notable changes in behaviour or growth, macroscopic abnormalities were observed after daily treatment for 7 days with YTX (1 and 2 mg/kg), homoYTX and 45-OH-homoYTX (1 mg/kg). Only ultrastructural changes at cardiac level (cardiomyocytes swelling, protrusion of cardiac cells into pericapillary space with rounding mitochondria) were observed (Tubaro *et al.*, 2004).

## Concluding remarks

Due to the lack of evidence of adverse effects in humans and the significant reduction in potency after oral administration compared to i.p. injection in mice, so far a regulatory level of 1 mg YTX equivalents/kg shellfish has been fixed in some countries. For regulatory purposes, MBA for lipophilic toxins is used in European countries (EC, 2002), but LC-MS methods, suitable for screening and confirmation, have been developed for YTXs (FAO/ IOC/WHO, 2005).

Since, *in vitro* very low concentration of YTX provokes disruption of the tumour suppressor E-cadherin, a possible risk that YTX may favour tumour spreading and metastasis formation *in vivo* has been hypothesized (Ronzitti *et al.*, 2004). However, further *in vivo* experiments are necessary to verify this hypothesis.

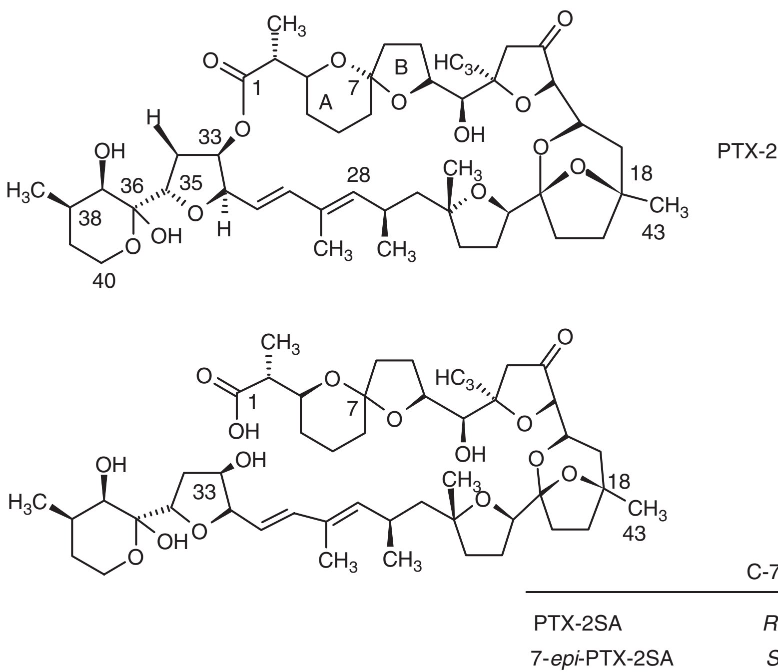
# PECTENOTOXINS

## Background

Pectenotoxins (PTXs) are hepatotoxic compounds, initially classified as DSP toxins, being often detected in shellfish and phytoplankton together with these compounds. Nevertheless, although a PTX derivative was associated with severe diarrhoeic illnesses in Australia, the actual diarrhogenic potential of PTXs is still unclear as is their actual health threat to consumers of contaminated mussels (Burgess and Shaw, 2001; FAO/IOC/ WHO, 2005).

PTXs are polyether macrolides containing a spiroacetal, three substituted tetrahydrofurans and 19 (20 in the case of PTX-11) stereocentres within a 40-carbon chain. To date, more than 10 PTXs and two PTX-2 derivatives (PTX-2 seco-acid and 7-epi-PTX-2 seco acid) (Figure 60.10) have been isolated from phytoplankton or shellfish. Recently, fatty acid esters of PTX-2 seco acids were detected in shellfish too (Miles *et al.*, 2006; Wilkins *et al.*, 2006).

PTX-2, produced by the dinoflagellate species *Dinophysis acuta* and *D. fortii*, is thought to be the precursor of the other PTXs, formed through biotransformation reactions in shellfish (Draisci *et al.*, 2000; Leira *et al.*, 2002b). Only PTX-11, -12 and -13 were identified as biosynthetic compounds in algae (*D. acuta*), besides PTX-2 (Miles *et al.*, 2004, 2006; Suzuki *et al.*, 2006). PTXs are accumulated in the digestive glands of filter-feeding bivalves, such as



| | C-7 |
|---|---|
| PTX-2SA | *R* |
| 7-*epi*-PTX-2SA | *S* |

**FIGURE 60.10** Chemical structure of pectenotoxin-2 (PTX-2) and of its seco acids (from Draisci *et al.*, 2000).

scallops (*Patin-opecten yessoensis*), green-shell mussels (*Perna canaliculus*), blue mussels (*Mytilus galloprovincialis* and *Mytilus edulis*), cockles (*Cerastoderma edule*) and pipis (*Donax delatoides*), after filtration of *Dinophysis* cells (Yasumoto *et al.*, 1985; Draisci *et al.*, 2000; Suzuki *et al.*, 2001; Vale and de Sampayo, 2002). These organisms can transfer the toxins to humans after their consumption.

PTXs were detected in shellfish and/or phytoplankton from Japan, New Zealand and Europe (Sasaki *et al.*, 1999; Draisci *et al.*, 2000; Burgess and Shaw, 2001; Pavela-Vrančič *et al.*, 2001; Leira *et al.*, 2002b; Miles *et al.*, 2004; Suzuki *et al.*, 2006).

## Pharmacokinetics/toxicokinetics

No data on absorption, distribution, metabolism and excretion of PTXs are available.

## Mechanism of action

The mechanism of hepatotoxic action of PTXs requires clarification. PTXs are cytotoxic against several cancer cell lines and PTX-1 and PTX-2 were shown to induce apoptotic effects (Draisci *et al.*, 2000; Chae *et al.*, 2005). *In vitro* studies revealed a depolymerizing action of F-actin by PTX-6 (Leira *et al.*, 2002b). Furthermore, PTX-6 modified cAMP levels in human lymphocytes (Leira *et al.*, 2002b).

## Toxicity

### *Human toxicity*

PTXs had been associated with severe diarrhoeic illness in Australia, resulting in hospitalization. However, although the shellfish responsible for the poisoning contained PTX-2 seco acid, the gastrointestinal effects were later attributed to OA esters. Consequently, no evidence of gastrointestinal or other adverse effects in humans for PTXs is available (FAO/IOC/WHO, 2005).

### *Experimental toxicity*

*Single administration*

After i.p. injection in mice, $LD_{50}$ values of PTXs were determined to be 250 μg/kg (PTX-1), 219–260 μg/kg (PTX-2), 350 μg/kg (PTX-3), 770 μg/kg (PTX-4) and 500 μg/kg (PTX-6), whereas $LD_{50}$ of PTX-7, PTX-8, PTX-9, PTX-2 seco acid and 7-epi-PTX-2 seco acid was higher than 5 mg/kg. Thus, it seems that the oxidation of substituent at C18, occurring in the digestive glands of shellfish, reduces the toxicity of PTXs (Draisci *et al.*, 2000; Miles *et al.*, 2004, 2006).

A hepatotoxic effect was observed in suckling mice for PTX-1 as well as for PTX-1 and PTX-2 in adult mice and rats. None of the two toxins caused diarrhoea and no damage at the intestinal level was observed in suckling mice after i.p. injection of up to 1 mg PTX-1/kg. On the other hand, PTX-1 and -2 induced an increased permeability of capillaries in the digestive tract, ascites and fluid accumulation in the thorax and pericardium of adult mice and rats at the dose level of 375 μg/kg (Terao *et al.*, 1986, 1993).

Although some literature data on PTXs toxicity after oral administration are controversial, Terao *et al.* (1993) observed that PTX-1 and PTX-2 (750 μg/kg) did not induce changes at intestinal level of mice and rats. Recently, no lethality and no diarrhogenic effects were evidenced for PTX-2 and PTX-2 seco acid in mice, at the dose of 5 mg/kg (Miles *et al.*, 2004).

## Concluding remarks

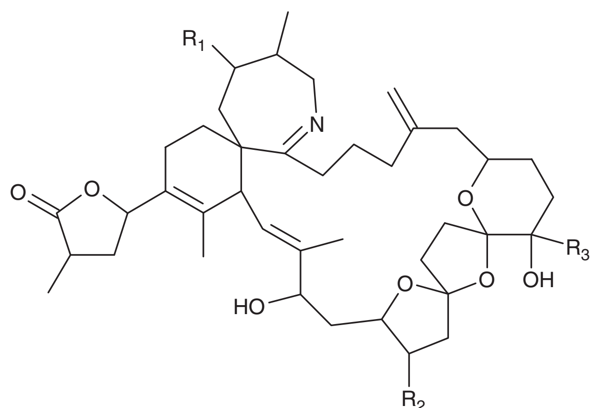
The European Union did not set a maximum overall level for PTXs alone in shellfish since the established level of 160 μg/ kg of edible part of shellfish is referred to the sum of PTXs and diarrhoeic toxins of the OA group (EC, 2002). MBA can detect PTXs, but not the seco acids, the presence of other lipophilic toxins, such as azaspiracids, OA and its derivatives can be detected by the MBA. Since PTXs are synthesized by the same microalgae producing OA and its derivatives, it is important to distinguish the two toxin groups. Immunochemical and LC-MS methods are preferred for their sensitivity and accuracy in detecting PTXs in shellfish (FAO/IOC/WHO, 2005).

# CYCLIC IMINE TOXINS

## Background

In recent years, a variety of seafood toxins with a cyclic imine function and macrocyclic structure had been discovered through their fast lethality in mice using the MBA for lipophilic shellfish toxins detection. These toxins include spirolides, gymnodimines, prorocentrolides and pinnatoxins, which harmful potential for humans is unclear (Quilliam, 2003; FAO/IOC/WHO, 2005).

Several spirolides, characterized by a spiro-linked tricyclic ether structure and an imine or amine function, had been identified in shellfish and phytoplankton: spirolides A–G and their derivates, among which spirolides E and F are non-toxic metabolites formed in shellfish (Hu *et al.*, 1996; Falk *et al.*, 2001; Aasen *et al.*, 2005b) (Figure 60.11). Spirolides, produced by the dinoflagellate *Alexandrium ostenfeldii*, are accumulated in filter-feeding bivalves, such as mussels and oysters (Cembella *et al.*, 2001). They occur



| Spirolide | $R_1$ | $R_2$ | $R_3$ |
|---|---|---|---|
| A | H | $CH_3$ | $CH_3$ |
| B | H | $CH_3$ | $CH_3$ |
| C | $CH_3$ | $CH_3$ | $CH_3$ |
| D | $CH_3$ | $CH_3$ | $CH_3$ |

**FIGURE 60.11** Chemical structure of spirolides A–D (from Ciminiello and Fattorusso, 2004).

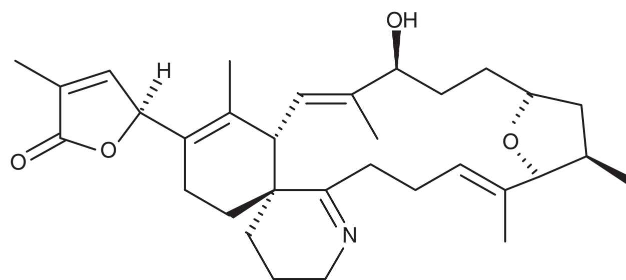


**FIGURE 60.12** Chemical structure of gymnodimine (from Quilliam, 2003).

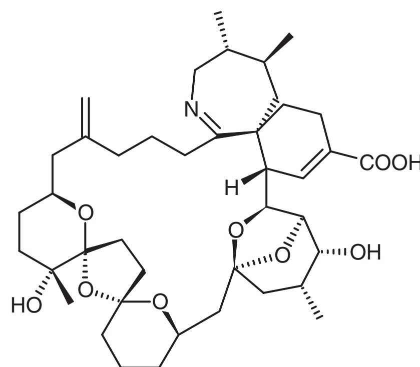

**FIGURE 60.13** Chemical structure of pinnatoxin A (from Quilliam, 2003).

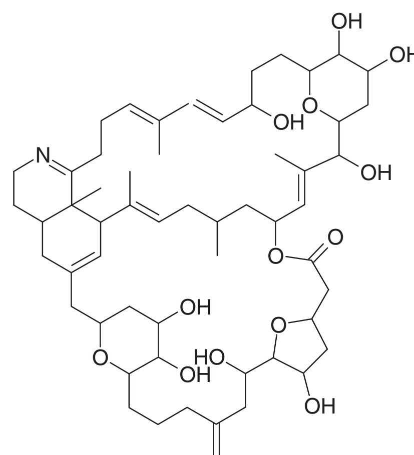

**FIGURE 60.14** Chemical structure of prorocentrolide (from Torigoe *et al.*, 1988).

in different areas of the world, being detected in the United States, Canada, Norway, Denmark and Scotland (Aasen *et al.*, 2003; Cembella, 2003, Gribble *et al.*, 2005).

Gymnodimines (Figure 60.12) containing a spiro centre and an imine function, are structurally related to spirolides. They are produced by dinoflagellates of *Gymnodinium* (*Karenia*) genus and accumulated in bivalves, such as oysters species (*Crassostrea gigas*, *Tiostrea chilensis*), greenshell (*Perna canaliculus*), scallops (*Pecten novaezelandiae*), also in tissues outside the digestive gland. These toxins were detected in New Zealand and other parts of the world, as for instance Tunisia (Seki *et al.*, 1995; Stewart *et al.*, 1997; Miles *et al.*, 2000; Stirling, 2001; MacKenzie *et al.*, 2002; FAO/IOC/WHO, 2005).

Pinnatoxins (Figure 60.13) consist of a 20-membered ring with 5,6-bicyclo, 6,7-azaspiro and 6,5,6-triketal moieties in their structure. They are accumulated in shellfish of the genus *Pinna*, common seafood in Japan and China, where their consumption caused human intoxications initially attributed to pinnatoxins (Kuramoto *et al.*, 2004). However, it was later shown that the poisoning was due to contamination by *Vibrio* species (FAO/IOC/WHO, 2005).

Other cyclic imines of algal origin are the cyclic polyethers prorocentrolide (Figure 60.14) and its analogue prorocentrolide B produced by dinoflagellates of the genus *Prorocentrum* (Torigoe *et al.*, 1988; Hu *et al.*, 1996).

## Pharmacokinetics/toxicokinetics

No data on absorption, metabolism, distribution and elimination of these cyclic imines are available.

## Mechanism of action

The mechanism of action of the cyclic imines is not completely known. Biological studies on spirolides suggest hippocampus and brain stem as their main toxicity targets with an action as muscarinic acetylcholine receptor antagonists and weak L-type transmembrane calcium channel activators (Gill *et al.*, 2003; Sleno *et al.*, 2004). The active pharmacophore of these compounds seems to be the cyclic imine moiety, since spirolides E and F, lacking of this structure, are inactive (Luckas *et al.*, 2005).

Gymnodimine seems to block nicotinic receptors at the neuromuscular junction (Munday *et al.*, 2004).

## Toxicity

### Human toxicity

No human poisoning syndrome due to cyclic imines was documented, so far. In Japan and China, seafood poisonings initially attributed to pinnatoxins were later shown to be caused by *Vibrio* species (FAO/IOC/WHO, 2005).

### Experimental toxicity

*Single administration*

After i.p. injection in mice, spirolides cause the death of animals within some minutes, preceded by neurotoxic symptoms as piloerection, abdominal spasms, hyperextension of the back and arching of the tail (Gill *et al.*, 2003; Ciminiello and Fattorusso, 2004). $LD_{50}$ in mice by i.p. was calculated to be about 40 μg/kg, the lethality being about 25 times higher than that after oral administration ($LD_{50}$ = 1 mg/kg) (Cembella *et al.*, 2002).

After i.p. injection of gymnodimine in mice, an $LD_{50}$ value of 96 μg/kg was determined for gymnodimine, which induced paralysis and respiratory distress (Munday *et al.*, 2004). After oral administration in mice by gavage, an $LD_{50}$ of 755 μg/kg was calculated, but no toxicity was seen if the toxin was ingested with food at a level corresponding to a dose of about 7500 μg/kg (Munday *et al.*, 2004).

The $LD_{50}$ of prorocentrolide by i.p. injection in mice was calculated to be 400 μg/kg (Torigoe *et al.*, 1988).

## Concluding remarks

Although cyclic imines are lethal in mice and contaminate shellfish in several parts of the world, no cases of adverse effects in humans due to these toxins were reported. Only pinnatoxins were associated to seafood poisonings, subsequently attributed to a contamination by *Vibrio* species (FAO/IOC/WHO, 2005). Therefore, no maximum tolerated level for these toxins was established, although their actual toxicity needs to be clarified.

The high i.p. toxicity of cyclic imines interferes with the MBA for the lipophilic toxins detection, giving positive results. Therefore, other methods are needed to quantify these toxins, such as the LC-MS methods, already set up for spirolides and gymnodimines analysis (FAO/IOC/WHO, 2005).

## Bacterial Toxins

CHAPTER

# 61

# Botulinum neurotoxin

*Julie A. Coffield and Dorothy D. Whelchel*

## INTRODUCTION

Botulism, or "sausage poisoning", was reportedly first recognized in Germany around the late 1700s. However, it was not until the 1820s that Justinus Kerner systematically studied and described the fatal paralytic disease (*aka*, "Kerner's disease") associated with the ingestion of spoiled sausage (Jankovic and Brin, 1997; Ergbuth and Naumann, 1999). Kerner recognized that a poisonous substance isolated from the spoiled sausage was responsible for the clinical signs associated with botulism; however, he was unable to identify the origin of the deadly poison. With the subsequent introduction of anaerobic microbiological techniques in the late 1800s, the source of the poison was finally determined. In 1897, van Ermengem (1979) was able to identify the offending etiological agent as a bacterium, now known as *Clostridium botulinum* (*C. botulinum*), in spoiled ham. The deadly poison produced by the bacteria is now known as botulinum neurotoxin (BoNT), the most potent biological toxin ever encountered, with lethal doses as low as 0.03 ng/kg body weight depending on both toxin type and animal species (Gill, 1982). This chapter describes the toxicology of BoNT in relation to various animal species.

## BACKGROUND

BoNT is produced under anaerobic conditions by primarily, *C. botulinum*, a rod-shaped, spore-forming (subterminal) bacterium; however, other clostridial species such as *C. barati* and *C. butyricum* are also capable of producing the neurotoxin (Cato *et al.*, 1986; Hatheway, 1989; Schiavo *et al.*, 2000). Although often referred to collectively as a single toxin, there are actually seven immunologically distinct serotypes of BoNT, and they are designated alphabetically, A–G (Simpson, 1981). Serotypes A, B, C1, and D have been associated with outbreaks of botulism in our domestic animals, livestock, poultry, and wildlife; while serotypes A, B, E, and, rarely F, are known to cause disease in humans. When isolated from the bacterium, native BoNTs are found in complex with hemagglutinins and other non-hemagglutinin, non-toxic proteins (DasGupta and Sugiyama, 1972). These accessory proteins are thought to protect the toxin from harsh environmental conditions such as those found in the gut following ingestion of toxin-contaminated food products (Sharma and Singh, 1998). The molecular masses of these toxin complexes range between 300 and 500 kDa, depending on the toxin serotype. Although serologically distinct, the seven toxin serotypes share both structural and functional similarities (DasGupta and Sugiyama, 1972). When not complexed with other proteins, the active neurotoxin has a molecular mass of 150 kDa and exists as a polypeptide di-chain molecule. The di-chain consists of a heavy chain linked by a single disulfide bond to a light chain. The 100 kDa heavy chain is responsible for membrane targeting and cellular uptake, while the 50 kDa light chain mediates its intracellular action. The neurotoxin molecule can be further divided both structurally and functionally into three domains. The heavy chain contains both a binding domain and a translocation domain, while the smaller light chain contains a catalytically active domain.

## MECHANISM OF ACTION

BoNTs are potent zinc-dependent metalloproteases that exquisitely target acetylcholine (ACh) containing nerve terminals (Schiavo *et al.*, 1992b). Since BoNTs are too

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

large to cross the intact blood brain barrier, their selective action on cholinergic terminals is generally limited to peripheral cholinergic systems (Ambache, 1949). The primary target site is the neuromuscular junction (NMJ), where they act within the motor nerve terminal to prevent the release of ACh, the primary neurotransmitter at this major synapse (Burgen *et al.*, 1949; Kao *et al.*, 1976). Intoxication by BoNT has been described as a multistage process (Simpson, 1980, 1989). In the first stage of intoxication, the toxins must bind selectively, via their heavy chains, to protein receptors (and gangliosides) located on the plasma membrane of the motor nerve terminal (Montecucco, 1986). The binding of the toxins to the nerve terminal membrane initiates the second stage of the intoxication process which is characterized by receptor-mediated uptake of the toxins into endosomes (e.g. endocytosis). The third stage of intoxication occurs within the endosome, where the disulfide linkage between the toxin heavy and light chains is reduced, and a subsequent drop in endosomal pH promotes a conformational change in the toxin molecule, allowing the light chain to escape across the endosomal membrane into the cytosol, possibly mediated by the translocation domain of the toxin (e.g. translocation). Following this translocation to the cytosol, the toxin light chain is free to act upon its intracellular target during the final stage of intoxication. During this last stage of the process, the neurotoxins enzymatically cleave one of three specific proteins found within the presynaptic terminal (Schiavo *et al.*, 1992a, b). These three proteins, SNAP-25, synaptobrevin, and syntaxin, known collectively as SNARE (soluble *n*-ethylmaleimide sensitive factor attachment protein receptor) proteins, are necessary for neurotransmitter release (Söllner *et al.*, 1993). Synaptobrevin, an integral membrane protein, is found on the synaptic vesicle, while SNAP-25, a membrane associated protein and syntaxin, another integral membrane protein, are both localized to the presynaptic terminal membrane. Under normal circumstances, these SNARE proteins interact to form a four helical "fusion" or "SNARE" complex that brings the ACh containing synaptic vesicles into close apposition with the terminal membrane. Fusion of the vesicular and terminal membranes and the subsequent release of ACh into the synaptic cleft are triggered by fast $Ca^{2+}$ signaling. The enzymatic cleavage of any one of the SNARE proteins by BoNT either destabilizes or prevents the formation of functional SNARE complexes, inhibiting vesicular fusion and neurotransmitter release (Schiavo *et al.*, 1992b). The catalytic active sites of the different BoNT serotypes vary slightly, giving each serotype both substrate and cleavage site specificity. Toxin serotypes A, C, and E cleave SNAP-25; serotypes B, D, F, and G cleave synaptobrevin, and serotype C cleaves syntaxin (Schiavo *et al.*, 1992a, 1993a, b, 1994; Blasi *et al.*, 1993a, b; Kalandakanond and Coffield, 2001).

## CLINICAL DIAGNOSIS AND TREATMENT

Clinically, botulism is recognized as a lower motor neuron disease resulting in progressive flaccid paralysis. Although deficits in somatic neuromuscular transmission are the most prominent effects, motor deficits in cranial nerve function, as well as the autonomic nervous system have also been reported (Sugiyama, 1980). With the exception of impaired vision (most likely related to disruption in autonomic function), neither altered sensation nor mentation has been specifically reported in botulism (Caya, 2001). In animals, paresis begins in the hind limbs and progresses cranially, often resulting in quadriplegia and recumbency. As in humans, death may result from respiratory muscle paralysis. The onset of clinical signs may be within hours or days of exposure, and is dependent on exposure conditions (dose and duration), as well as individual sensitivity. Susceptibility to the different serotypes varies across species. Botulism in large animals (herbivores) is commonly, but not exclusively, due to serotype B; while botulism in small animals (carnivores) and avian species is most commonly due to serotype C1. With the exception of serotype C1, the different toxin serotypes produce similar clinical disease. Serotype C1 toxin producing strains of *C. botulinum* bacteria may produce multiple exotoxins, including the C1 neurotoxin, and the C2 and C3 cytotoxins (Ohishi and Sakaguchi, 1982; Rubin *et al.*, 1988; Hauser *et al.*, 1993). The concurrent presence of these cytotoxins with C1 neurotoxin may account for the different clinical scenarios that have been reported in botulism associated with serotype C1 intoxication, including dysautonomias in horses and cats.

Botulism is most often acquired from the ingestion of preformed toxin in either spoiled vegetation or carrion-contaminated foodstuffs, although this may vary among species. In addition, two other forms of botulism are well recognized in veterinary medicine and include wound contamination with *C. botulinum*, or gastrointestinal (GI) colonization by *C. botulinum* (toxico-infection). The mainstay of therapy for all animal species with botulism is supportive care, although the specifications of this therapy may differ slightly between species. Antitoxin (equine origin) may be administered in certain instances; however, since the antitoxin is only protective against toxin in the general circulation, it must be given early in the disease course to be effective. Once the patient displays symptoms, antitoxin administration may be ineffective. Further, antitoxin administration can cause adverse effects. Antibiotic administration may be indicated to reduce the risk of secondary infections; however, aminoglycosides, tetracycline, and procaine penicillin should be avoided as these drugs potentiate neuromuscular weakness (L'Hommedieu *et al.*, 1979; Wang *et al.*, 1984). *C. botulinum*

is not sensitive to metronidazole, an antimicrobial used to treat anaerobic infections. Further, metronidazole has been associated with an increased risk of botulism in laboratory animals and workers exposed to the bacterium, possibly due to alterations in GI flora that permit clostridial growth (Wang and Sugiyama, 1984; Sweeney *et al.*, 1986; Whitlock, 2002).

## LABORATORY DIAGNOSIS

The diagnostic gold standard for botulism is the mouse bioassay (MBA). Although the MBA may have limited sensitivity, especially in horses, the test is highly specific. Samples of serum, vomitus, gastric contents, feces, wound tissues, and suspect food can be submitted to specific diagnostic laboratories for MBA analysis. All samples, with the exception of wound samples, should be kept at 4°C immediately following collection. Blood samples should be collected in red top tubes or serum separating tubes. Serum volumes between 10 and 15 ml should be collected as soon as clinical signs are detected; volumes less than 3 ml may yield inconclusive results. Whole blood should not be submitted as hemolysis may occur during shipment. For fecal samples, 20–50 g should be submitted. For constipated patients, 20 ml of rectal contents post-enema can be submitted; however, it is important to use as little fluid as possible in the enema to avoid over-dilution of samples. Suspect food should be left in its original container, and placed inside a sterile, unbreakable and well-labeled container. Empty food containers can also be submitted for testing. Environmental samples can also be tested with the MBA; submission of 50–100 g of soil and approximately 100 ml of water is recommended. All specimens should be placed in leak-proof containers marked "Medical Emergency, Biological Hazard, Refrigerate on Arrival." Specimens should be shipped with ice packs in order to maintain a temperature of 4°C. In cases of wound botulism, debrided tissues, exudates, and/or tissue swabs may be submitted. Wound specimens should be placed in anaerobic transport devices and shipped without refrigeration. For specific details on packaging and shipping, refer to the American Society of Microbiology Procedures for Transportation and Transfer of Biological Agents (www.asm.org). If samples cannot be shipped for several days, specimens should be frozen and then subsequently shipped on dry ice. Freezing samples may compromise the detection of *C. botulinum* bacteria; however, freezing will not affect toxin detection (CDC, 1998; ASM, 2006).

Only qualified diagnostic laboratories can perform both the MBA and neutralization tests to determine the presence, as well as the serotype of BoNT in submitted samples. During these tests, mice (20–30 g IRC strain) are injected IP with prepared samples of serum and/or other sample extracts. For the MBA, a group of mice is injected with sample only to determine the presence of the toxin. For the neutralization assay, a separate group of mice is injected with the sample combined with a serotype-specific antitoxin. In both cases, mice are observed for clinical signs of botulism including ruffled coats, abdominal breathing patterns, dyspnea, weakness, ataxia, respiratory failure, and ultimately death (CDC, 1998). *C. botulinum* bacteria can be isolated from anaerobic enrichment cultures of submitted samples. Following enrichment, culture supernatants are collected and tested similarly for the presence and serotype of toxin using the MBA and neutralization tests. In the former case, a positive MBA test is suggestive of the presence of *C. botulinum* bacteria in the sample (CDC, 1998). It should be emphasized that humans are extremely sensitive to certain serotypes of BoNT; therefore, both toxin and clostridial bacterial isolation should only be attempted by qualified immunized personnel in diagnostic laboratories approved by the Centers for Disease Control and Prevention (CDC).

Although the MBA is still the most widely utilized test for botulism, alternative diagnostic avenues are being explored in an effort to minimize the use of animals in toxicity testing. For example, enzyme-linked immunoabsorption (ELISA) techniques have been used to identify BoNT in both avian and bovine specimens (Sakaguchi *et al.*, 1987; Thomas, 1991; Rocke *et al.*, 1998; Trampel *et al.*, 2005). In one study comparing the capabilities of the ELISA and the MBA to detect BoNT/C and D in bovine serum and tissue samples, Thomas (1991) determined that the ELISA was not sensitive enough to replace the MBA. Further, a cross-reaction with *C. novyi* serotype A was reported. Similarly, Rocke *et al.* (1998) found that the MBA was more sensitive than the ELISA (immunostick method) in detecting BoNT/C in small serum volumes from wild birds with botulism. However, when larger sample volumes were tested, the sensitivity of the ELISA improved, and actually surpassed that of the MBA. When comparing these two methods, it should be noted that only the MBA detects biologically active toxin, while the ELISA detects both active and inactive forms as well as subunits of the toxin (Rocke *et al.*, 1998). The use of polyvalent antibodies to capture toxin antigen and the slight antigenic heterogenicity within serotypes may further complicate ELISA results. More recently, polymerase chain reaction (PCR) methods have also been used to detect the genes encoding BoNT. Trampel *et al.* (2005) used PCR to identify BoNT/C genes from cecal samples in caponized chickens. Further, Szabo *et al.* (1994) determined that PCR detection of the genes encoding BoNT/B following culture enrichment of equine serum, tissues, and fecal samples were comparable to results obtained by the MBA.

## SPECIES-SPECIFIC DISEASE

### Equine botulism

#### *Background*

Horses are thought to be among the most susceptible of species to intoxication by BoNT. The serotype most commonly reported to cause equine botulism in North America (greater than 80% of equine cases) is serotype B; however, serotypes A and C1 have also been associated with clinical disease in the horse (Whitlock *et al.*, 1989). Serotype B producing strains of *C. botulinum* are found ubiquitously in the soils of the northeastern and central United States, particularly in regions extending from Kentucky to the mid-Atlantic states. Conversely, serotype A producing strains are more prominent in the western states (California, Utah, Idaho, Oregon) and have also been reported in Ohio (Whitlock and Williams, 1999). Although intoxication with BoNT/C1 occurs with less frequency, cases have been reported in California, Florida, the New England States, and Canada (MacKay and Berkhoff, 1982; Kinde *et al.*, 1991; Whitlock, 1996).

Horses acquire botulism in one of three ways: (1) from the ingestion of preformed toxin in contaminated foodstuffs, (2) from the contamination of wounds with *C. botulinum*, and (3) from the colonization of the intestinal tract with *C. botulinum* bacteria (toxico-infection). The ingestion of preformed toxin, in either spoiled vegetation or carrion-contaminated foodstuffs, is the most common scenario for equine botulism. Contaminated feed sources such as alfalfa cubes, alfalfa hay, baled hay, wheat, oats, potatoes, bale silage, rye silage, grass clippings, oat chaff, and brewer's grains have all been purported sources of botulism in large animals (Whitlock and Buckley, 1997). Serotype B is more commonly associated with contamination of spoiled foodstuffs or moldy hay. Interestingly, the feeding of silage or hay stored in large plastic bags has been implicated as an increased risk factor for botulism. The damp, alkaline conditions of spoiled vegetation provide an optimal environment for clostridial growth, sporulation, and toxin production (Ricketts *et al.*, 1984; Broughton and Parsons, 1985; Haagsma *et al.*, 1990; Wichtel and Whitlock, 1991). For these reasons it is recommended that silage with a $pH > 4.5$ should not be fed to horses (Whitlock and Buckley, 1997; Galey, 2001).

Cases of equine botulism associated with the ingestion of carrion-laden foodstuffs are more often the result of intoxication with BoNT serotype C1 (Galey, 2001). A herd outbreak of BoNT/C1 intoxication in California was determined to be the result of the ingestion of preformed toxin in alfalfa cubes contaminated with rodent carcasses (Kinde *et al.*, 1991). Interestingly, another report of an outbreak of BoNT/C1 intoxication in horses revealed that birds may act as mechanical vectors, transporting toxin or bacterial spores from a rotting carcass to nearby horse farms (Schoenbaum *et al.*, 2000).

Wound botulism occurs from the contamination of a wound with the *Clostridium* bacteria. The anaerobic environment of the wound provides optimal conditions for *C. botulinum* growth and toxin production. The neurotoxin (most commonly serotype B) is produced within the wound and enters the peripheral circulation where it is distributed to the toxin's site of action, the NMJ. Distal limb wounds, castration sites, umbilical hernias, and injection site abscesses have all been associated with wound botulism (Swerczek, 1980a; Bernard *et al.*, 1987; Mitten *et al.*, 1994; Whitlock and Buckley, 1997).

"Shaker foal syndrome" is a form of toxico-infectious botulism that occurs in foals usually between 2 and 5 weeks of age (Rooney and Prickett, 1967; Vaala, 1991; Whitlock, 2002). The infection occurs most commonly in fast growing foals on high planes of nutrition. GI ulcerations and liver abscesses have been documented post-mortem in foals that succumbed to botulism (Swerzcek, 1980a, b). Thus, exposure to stress, high nutrient diets, or corticosteriod use may all play a role in the foal's susceptibility to toxico-infection. Such underlying conditions may lead to gastric ulcers, which then serve as a nidus for *C. botulinum* colonization. Further, as in human neonatal toxico-infection, the immature GI tract of foals may be more permissible to overgrowth by *C. botulinum*. Shaker foal syndrome is commonly associated with the production of toxin serotype B; however, a case of serotype C1 intoxication was documented in a foal in Florida (MacKay and Berkhoff, 1982). Serotype C1 producing clostridial strains have been identified in Florida soils, and in this particular case, it was concluded that the foal developed a toxico-infection after ingesting bacterial spores from the soil. Additionally, this foal was also diagnosed with sand colitis; an irritated GI mucosa likely increased this foal's susceptibility to toxico-infection.

Toxico-infection with BoNT serotype C1 has also been implicated as a causative agent of equine dysautonomia, also known as equine grass sickness (EGS). EGS is frequently diagnosed in Great Britain, and its occurrence correlates with the grazing season. EGS presents as an acute or subacute illness resulting in death (or euthanasia) within days of onset; however, classic neuromuscular symptoms of botulism are not observed in EGS. Rather, the primary symptoms associated with this syndrome include dysphagia, ileus, and weight loss. If the horse survives the subacute phase, a chronic form may persist. In addition, histological examination revealed neuronal degeneration in autonomic ganglia, the myenteric plexus, and the submucosal plexus (McGorum *et al.*, 2003). Such histological findings are not reported with classic botulism. Increased BoNT/C1 has been detected in ileal and fecal contents of horses diagnosed with EGS; however, it should be noted that in this same study, BoNT/C1 was also isolated from a small number of

control animals (Hunter *et al.*, 1999). Conversely, Garrett *et al.* (2002) demonstrated an increased number of bacterial colonies with a prominent number of clostridial species in the GI tract of horses with EGS, compared with healthy control horses. The possibility, however, that the increased colonization of the gut by clostridia was secondary to the ileus produced in EGS cannot be ruled out. McGorum *et al.* (2003) recently documented the occurrence of clinical and pathological signs associated with both EGS and toxico-infectious botulism in the same foal. One theory proposes that in addition to the blockade of acetylcholine release at cholinergic nerve terminals, the C1 neurotoxin also causes nerve cell degeneration. However, it is worth noting that serotype C1 producing clostridial strains may also produce the ADP-ribosylating cytotoxic toxins, C2 and C3. Interestingly, the C2 toxin has been associated with an increase in vascular permeability leading to the development of edema, congestion, and hemorrhage in *in vivo* models (Ohishi *et al.*, 1981; Ohishi and Sakaguchi, 1982; Simpson, 1982). It is plausible then these exotoxins may play a role in producing the clinical symptoms of EGS that deviate from those of classic botulism (Williamson and Neale, 1998; Cottrell *et al.*, 1999; Hunter *et al.*, 1999; Garrett *et al.*, 2002). To date, however, the exact cause of EGS and the potential role of a *C. botulinum* toxico-infection in its manifestation remain elusive.

### *Clinical signs*

The onset of clinical signs associated with equine botulism is variable and can occur anywhere between 12 h and 10 days post-exposure. The clinical presentation of poisoned horses may be gradual, acute, or peracute depending on exposure dose and duration, as well as on individual sensitivity to the toxin (Whitlock and Buckley, 1997). Adult horses that ingest low doses of toxin may show only mild dysphagia, and recover with minimal treatment; whereas, ingestion of large doses is associated with peracute illness and a grave prognosis. In peracute illness, muscle paralysis progresses rapidly and the animal is recumbent within 8–12 h; ultimately, paralysis of the respiratory muscles results in death.

With the exception of serotype C1 and EGS, clinical symptoms of equine botulism vary little between the different botulinum toxin serotypes (Whitlock, 1996; Whitlock and Buckley, 1997). Myasthenia and dysphagia are usually the first symptoms observed. Astute horse owners may first notice mild signs such as depression, exercise intolerance, and difficulty with grain consumption. Ataxia, gait stiffness, and muscle tremors (particularly in the triceps muscles) may be noted early in the course of disease. In addition, mydriasis, ptosis, and decreased pupillary light responses, as well as decreased palpebral reflexes are characteristic of early botulism. As the disease progresses, pupillary light responses diminish further. Periods of exercise may worsen paresis due to the reduction of acetylcholine release at the NMJ. As dysphagia and pharyngeal weakness progress, the swallowing of food becomes more difficult and secondary aspiration pneumonia may ensue. Horses may also have difficulty drinking as they tend to stand with their muzzles submerged in water troughs without swallowing (Whitlock, 1996; Galey, 2001; Whitlock, 2002). In horses infected experimentally with serotype C, there was a more pronounced mydriasis and an inability to lift the head; facial edema and inspiratory stridor resulted from low head carriage (Whitlock, 1996).

Initially, vital signs such as heart rate, respiration rate, body temperature, and capillary refill time are within normal limits. However, decreased borborygmi, ileus, colic, and constipation develop as botulism progresses. Diarrhea is often associated with serotype C, possibly in association with C2 toxin (Whitlock, 1996; Galey, 2001). Urine retention with resultant bladder distention often occurs, thereby increasing the risk of urinary tract infection. As the disease progresses, horses spend more time in sternal recumbency, and ultimately become laterally recumbent. Heart and respiratory rates may increase as recumbent horses struggle to stand. In late stages, dyspnea and other signs of respiratory distress may be observed. With serotype C intoxication, an exaggerated expiration and "prolonged abdominal lift" may be noted (Whitlock, 1996). In the final stages of botulism, horses are laterally recumbent, demonstrate significant respiratory difficulty and develop anoxia. As the anoxia progresses, horses may exhibit agonal paddling. At this point, the patient either dies due to respiratory failure or is euthanized (Whitlock and Buckley, 1997; Galey, 2001).

In the foal, botulism most commonly occurs between 2 and 5 weeks of age (Vaala, 1991). The first clinical signs usually observed are increased periods of recumbency and muscle tremors. Shortly after the foal rises, muscle tremors are evident and after brief periods of standing, the foal collapses from weakness. Recumbent foals appear to be bright and alert. Foals may dribble milk from their muzzles shortly following nursing due to dysphagia and pharyngeal muscle paresis. Thus, aspiration pneumonia is a common sequela in the foal. Constipation and ileus are also frequently observed. Other symptoms are similar to those observed in the adult horse (Whitlock, 2002).

### *Diagnosis*

A tentative diagnosis of botulism can be made following a comprehensive neurological assessment. Typically, abnormalities in palpebral reflexes, pupillary light responses, tail tone, tongue tone, prehension of food, dysphagia, and gate are detected with botulism. Both the tongue stress test and grain test are sensitive measures for botulism. In the tongue test, the examiner pulls the tongue laterally

through the interdental space. As the horse attempts to retract the tongue, muscular tone is assessed. Although this test is both subjective and variable, a flaccid tongue or weak retraction effort is suggestive of botulism. In the grain test, the consumption of 8 oz of grain is timed; typically, a healthy horse consumes 8 oz of grain in 2 min (Whitlock and Buckley, 1997). Difficulty in prehension, slow consumption, and a characteristic grain/saliva mixture hanging from the lips are indicative of botulism (Whitlock, 1996; Whitlock and Buckley, 1997). These examination findings may also be useful in the assessment of disease progression and treatment efficacy.

Abnormalities in routine diagnostic indicators (complete blood cell (CBC) count, blood chemistry, cerebral spinal fluid (CSF) analysis, and urinalysis) are not typically detected in early botulism, but do usually accompany other neurological diseases. Therefore, normal laboratory values in light of neurological deficits support the diagnosis of botulism. Differential diagnoses for botulism include infectious diseases such as equine protozoal myeloencephalitis, equine herpes virus-1, eastern and western equine encephalitis, rabies, guttural pouch mycosis, listeriosis; other toxicoses such as leukoencephalomalacia (moldy corn poisoning), ionophore poisoning (monesin, salinomycin, and narasin), yellow star thistle poisoning, yew poisoning, white snake root poisoning, and organochlorine poisoning; metabolic disorders such as equine motor neuron disease, azoturia, eclampsia, hypocalcemia, hyperkalemic periodic paralysis, white muscle disease; and pharyngeal ulceration (Whitlock and Buckley, 1997; Whitlock, 2002).

A tentative diagnosis of equine botulism may be confirmed by: (1) MBA detection of formed toxin in horse sera, GI contents, viscera, or wounds, (2) detection of *C. botulinum* spores or toxin in suspect foodstuffs in association with clinical signs, and (3) ELISA detection of serum antitoxin antibodies in unvaccinated horses with clinical signs (Whitlock, 1996). However, a definitive diagnosis of botulism is often difficult to achieve in the horse. There are no gross or pathognomonic histological lesions associated with botulism, and serum toxin levels in the horse are often too low to be detected by the MBA. Because the horse is more sensitive to BoNT than the mouse, the MBA is most valuable in early, peracute equine botulism, when higher concentrations of toxin may be present in the bloodstream (Kinde *et al.*, 1991; Whitlock and Buckley, 1997). In addition to serum, GI contents and liver samples can also be submitted for the MBA, although greater diagnostic success may be achieved through detection of BoNT in the foodstuff rather than within the patient (Galey, 2001). Fecal or tissue culture enrichment can be used to enhance bacterial spore numbers and toxin levels for greater detection. However, since spores may be present in the feces of healthy horses, direct detection of BoNT within the animal is a more reliable finding (Swerczek, 1980b; Whitlock, 1996; Whitlock and Buckley, 1997). Following a positive result from the MBA, the serotype can be identified using the mouse neutralization test.

### *Treatment*

Once botulism is suspected, the patient should be confined to the stall to prevent exertion. Polyvalent antiserum (antitoxin) should be given as soon as possible; the recommended dose for an adult horse is 70,000 IU (500 ml) and 30,000 IU (200 ml) for the foal. One dose usually provides passive immunity for approximately 60 days (Sprayberry and Carlson, 1997; Whitlock and Buckley, 1997). The use of parasympathomimetics should be avoided as these agents deplete acetylcholine stores and exacerbate paresis/paralysis (Galey, 2001). Antibiotic therapy is indicated in cases of wound botulism or secondary infections; however, as previously stated aminoglycosides, tetracycline, procaine penicillin, and metronidazole are contraindicated. Aminoglycosides block neurotransmission at the NMJ and will exacerbate muscle weakness and paralysis (Barsanti, 1990). Although Gram-positive anaerobes are sensitive to penicillin and metronidazole, administration of these drugs is controversial. These antimicrobials may cause more bacterial lysis, thus increasing the release of toxin (in the case of a toxico-infection) or they may promote *C. botulinum* colonization by altering the normal intestinal flora (Barsanti, 1990). Drugs such as the aminopyridines and guanidines should also be avoided as they will further deplete acetylcholine stores (Critchley, 1991).

Second only to antitoxin administration, supportive care is the mainstay of therapy for botulism. $H_2$ blockers and proton pump inhibitors may be indicated, especially for foals. Topical ophthalmic ointments should be used to prevent corneal abrasions and ulceration. Adult horses may need to be sedated with xylazine or diazepam to reduce anxiety and exertion. Patients should be muzzled between feedings to prevent aspiration pneumonia. Nutritional support should be provided to dysphagic patients. Alfalfa slurries with adequate amounts of water may be administered through a nasogastric tube to adult horses. Foals should receive milk replacer through a nasogastric tube, or parenteral nutrition if ileus is present. Patients should be maintained in sternal recumbency to prevent aspiration pneumonia and checked periodically for gastric reflux as ileus may lead to the accumulation of ingesta/fluid in the stomach. If gastric reflux is not present, some authors recommend that mineral oil be administered via a nasogastric tube to alleviate ileus and constipation; however, this should be done under close supervision due to the increased risk of aspiration in these patients. Recumbent patients should be turned frequently or suspended periodically by full body slings to prevent decubital ulcer formation, myopathies, and other complications of prolonged recumbency. Recumbent stallions

and geldings should be catheterized twice daily to empty the bladder and prevent pressure necrosis or cystitis (Whitlock and Buckley, 1997).

A tracheostomy should be performed in cases of botulism where horses show signs of upper airway obstruction as a result of paralysis of the nares or larynx. In more complicated cases, patients may require intravenous (IV) fluids to correct respiratory acidosis resulting from decreased ventilation. For foals in particular, arterial blood gases should be monitored frequently to determine the need for artificial ventilation. Intranasal oxygen insufflation and mechanical ventilation can be instituted in foals with poor arterial blood gas values and/or metabolic acidosis (Wilkins and Palmer, 2002, 2003). Unfortunately, mechanical ventilation is not practical in the adult horse.

The overall prognosis is favorable for horses that are exposed to low doses of the toxin, exhibit a slow disease progression (3–7 days), or display mild symptoms. Likewise, a grave prognosis is given to patients exposed to high doses of toxin, manifest a rapid onset of clinical disease, or become recumbent within 8–12 h (Whitlock and Buckley, 1997). Patients responsive to antitoxin therapy should be able to eat within 7–10 days post-treatment and regain full strength within a month. Recumbent foals are often able to stand within 7–10 days post-antitoxin administration. Although the prognosis for recumbent adult horses is poor, if the patient does not become distressed or show severe respiratory compromise, recovery may be achieved with extensive supportive care (Whitlock and Buckley, 1997). The most common complications associated with botulism are decubital ulcers and aspiration pneumonia; these problems can be resolved with supportive care and antimicrobial therapy.

### *Prevention*

Following recommended vaccination protocols, along with sound husbandry methods, reduces the occurrence of equine botulism. Forages should be examined for carrion, while pastures should be cleared of decaying vegetation and rotting animal carcasses. Appropriate wound management is also an important preventative measure (Galey *et al.*, 2000). To date, only serotype B toxoid vaccine is marketed for horses in the United States (Whitlock, 1996). The American Association for Equine Practitioners (2005) recommends vaccination only for horses in endemic areas. Adult horses in endemic areas should be vaccinated annually. Mares should be boostered 4–6 weeks prior to parturition to achieve adequate antitoxin immunoglobulin (Ig) levels in colostrum. Foals born to vaccinated mares should receive a series of three vaccinations, each 1 month apart, starting at 2–3 months of age. Foals born to unvaccinated mares should be vaccinated at 2, 4, and 8 weeks of age (Whitlock and Buckley, 1997; Galey, 2001).

## Avian botulism

### *Background*

Avian botulism, otherwise known as "limberneck" or "western bird disease", has been a significant problem worldwide in both domestic and wild fowl. The occurrence of avian botulism has been globally widespread, having been documented in as many as 17 countries and on every continent except Antarctica (Jensen and Price, 1987). The majority of the natural outbreaks of avian botulism have occurred in fowl (Lamana, 1987). Carnivorous, omnivorous, carrion-scavengers, and insectivorous birds, as well as aquatic bottom-feeding birds are all susceptible to botulism. In 1984, 117 avian species were determined to have been affected by the disease (Jensen and Price, 1987). Specifically, botulism has been reported in chickens, ducks, turkeys, pheasants, and ostriches (Jensen and Price, 1987; Allwright *et al.*, 1994). Although broiler outbreaks are not uncommon, botulism is a more significant problem for waterfowl, resulting in millions of deaths worldwide (Gross, 1984; Jensen and Price, 1987). Avian species are sensitive to serotypes A, B, C1, and E, although serotype C1 is most commonly associated with outbreaks (Smith, 1975; Gross, 1984; Dohms, 2003). Outbreaks of serotype C1 intoxication have been reported worldwide, while outbreaks of serotype A botulism have only been reported in western regions of North and South America; serotype B in the eastern United States, England, Europe, and China; and serotype E in the Great Lakes and North Sea (Gross, 1984). Interestingly, serotype A was found to be more toxic than serotype C1 when administered IV to chickens; however, when given orally, serotype C1 demonstrated greater toxicity.

The etiology of botulism among wild avian species and waterfowl differs from that observed in other animals. The process is a complex cycle involving environmental contamination, toxico-infection, bird die offs, bacterial proliferation in bird carcasses, and invertebrate vectors. *C. botulinum* often colonizes the intestinal tract and cecum of clinically normal birds, increasing the potential for toxico-infection in avian species (Dohms, 2003). Since these birds are already seeded with the bacteria, upon death, avian carcasses provide an excellent substrate for *C. botulinum* growth. The proliferating bacteria spread from the GI tract to other tissues, the carcass becomes flyblown and toxin accumulates in the fly larvae. Invertebrates concentrate the bacterium or toxin after feeding on contaminated carcasses; however, due to their neurophysiological differences, BoNT does not affect insects and aquatic invertebrates. Subsequently, birds ingest these animals and accumulate lethal amounts of BoNT. One gram of fly larvae may contain $1.8 \times 10^5$ mouse $LD_{50}$s, and ingestion of as little as eight fly larvae was sufficient to kill a pheasant (Gross, 1984). Bird and invertebrate die offs perpetuate botulism outbreaks by increasing the levels of

*C. botulinum* in soils, lakes, rivers, and estuaries (Gross, 1984; Lamana, 1987). Environmental factors such as shallow alkaline waters, warm seasons/summer months, and flooding of mudflats or dried out lakes may promote invertebrate die offs, further enhancing environmental levels of *C. botulinum* (Gross, 1984; Jensen and Price, 1987; Wobeser, 1987). As *C. botulinum* levels increase in the environment, the intestinal tracts of wild birds and waterfowl become seeded with the bacteria, and any cause of bird deaths can trigger an outbreak of botulism (Gross, 1984).

Contaminated feed, water, litter, carcasses, and insects may be associated with botulism in broilers. Often the source of BoNT cannot be identified and toxico-infection has been hypothesized to be the perpetuating factor (Dohms, 1987). *C. botulinum* has been isolated from the intestinal tract and cecum of healthy birds; further, the chicken body temperature (41°C) and cecal pH (7.4) are optimum for *C. botulinum* growth (Miyazaki and Sakaguchi, 1978; Trampel *et al.*, 2005). Most broiler outbreaks have occurred in chickens between 2 and 3 weeks of age; however, an outbreak in post-caponized chickens was documented in birds as old as 14 weeks (Page and Fletcher, 1974; Dohms *et al.*, 1981; Trampel *et al.*, 2005). Coprophagy has also been implicated as a causative factor in poultry outbreaks since both BoNT/C1 and *C. botulinum* are secreted in cecal droppings (Hyun and Sakaguchi, 1989). Broiler outbreaks are also more likely to occur in hot weather (Dohms, 1987).

Morbidity and mortality of avian botulism increase with the dose of BoNT ingested. The onset of clinical symptoms may be anywhere from a few hours to 2 days post-exposure (Gross, 1984; Dohms, 2003). The mortality rate in broilers has been reported to be as high as 27%, whereas thousands to millions of birds may have been lost as a result of outbreaks in waterfowl (Page and Fletcher, 1974; Dohms *et al.*, 1981; Jensen and Price, 1987). In fact, it had been suggested that botulism may have been the limiting factor of waterfowl population growth in predisposed areas of the United States (Jensen and Price, 1987).

### *Clinical signs*

As in other species, avian botulism is characterized by lower motor neuron deficits resulting in flaccid muscle paralysis. Paresis begins in the legs and progresses cranially to involve the wings, neck, and eyelids. Mildly affected birds may appear ataxic, reluctant to move, have a ruffled coat, and easily epilated feathers. The wings may droop and the neck become flaccid, hence the name "limberneck". Diarrhea is often noted in broilers. As the disease progresses, birds become recumbent. Neck muscles become paralyzed and birds eventually lie down with necks extended out, resting on the ground. Birds may appear comatose due to eyelid paralysis. Dyspnea may develop as paralysis progresses. Birds usually die from respiratory failure and dehydration. Broilers may succumb to hyperthermia as sick birds are smothered by others and the respiratory mucosal cooling mechanism is compromised (Page and Fletcher, 1974; Gross, 1984; Dohms, 1987).

### *Diagnosis*

The diagnosis of avian botulism is based on clinical signs, a lack of specific pathological changes, and the isolation of toxin from serum/tissues of clinically ill birds. Although no pathognomonic changes have been described, post-mortem hepatic and renal congestion along with signs of dehydration may be found (Page and Fletcher, 1974). The most definitive diagnosis of botulism is the isolation of BoNT from the sick bird. Ten milliliters of blood is the suggested minimum amount for the MBA; however, if necessary, equal aliquots of blood from individual sick birds may be pooled to accommodate volume requirements of the assay (Dohms, 1987). Following a positive result from the MBA, the serotype can be identified using the mouse neutralization test. Most outbreaks of avian botulism are due to BoNT/C1; therefore, antiserum for serotype C1 is usually tested first. One IU of antiserum/mouse typically neutralizes BoNT/C1 levels found in chickens suffering from botulism. BoNT/C1 and other serotypes can also be detected in bird serum using ELISA technology (Sakaguchi *et al.*, 1987; Rocke *et al.*, 1998; Trampel *et al.*, 2005). For small sample volumes, the MBA appears to be more sensitive; however, for larger serum samples, the ELISA sensitivity may be comparable to the MBA (Rocke *et al.*, 1998). Isolation of BoNT or *C. botulinum* from the bird intestines, cecum, or other tissues may aid in a diagnosis; however, these tests are less valuable as the bacterium can be isolated from the intestinal tract of healthy birds. Further, isolation of BoNT or the bacterium from carcass tissues is not definitive since *C. botulinum* may proliferate and spread from the intestinal tract to surrounding tissues of the carcass (Gross, 1984; Dohms, 2003). The MBA can be performed on intestinal, cecal, and crop flushes, or samples can be assayed for toxin or bacterium after culture enrichment (Dohms, 1987; Trampel *et al.*, 2005). PCR methods have been used to identify genes encoding BoNT/C light chain in cecal contents (Trampel *et al.*, 2005). In order to identify the source of contamination, feed, water, litter, carcasses, and insects should be assayed for toxin, or cultured to isolate the bacterium (Dohms, 1987). Both ELISA and the passive hemagglutination test can be performed to identify serum antibodies to BoNT. However, the levels of toxin that produce illness are usually insufficient to stimulate an immune response in chickens and ducks (Dohms, 1987; Dohms, 2003). Interestingly, antibody titers to several BoNT serotypes have been identified in healthy carrion-eating birds such as vultures and crows (Ohishi *et al.*, 1979).

Differential diagnoses for avian botulism in poultry include transient brain paralysis, coccidiostat toxicity, pesticide or other chemical toxicity, New Castle disease, Marek's disease, avian encephalomyelitis, avian reovirus, and musculoskeletal problems. Fowl cholera and chemical toxicity, lead poisoning in particular, are the common differentials for botulism in waterfowl (Rosen, 1971; Dohms, 1987, 2003; Smith, 1987). However, eyelid paresis and the lack of postmortem lesions are supportive of botulism as the diagnosis (Dohms, 2003).

### Treatment

When possible, clinically ill birds should be isolated and provided fresh water; once these measures are taken, birds often recover fully within a few days. Waterfowl should be herded to uncontaminated shores, and carcasses should be removed daily in poultry operations. Antitoxin therapy may be administered for valuable birds or zoo animals, but it is impractical for most production operations or wildlife (Dohms, 2003). Furthermore, antitoxin protection is transient and birds may again become susceptible to BoNT (Gross, 1984). In broiler outbreaks, antimicrobial therapy may be instituted through watering systems or feed. Administration of bacterin (100 g/ton of feed) or streptomycin (500–1000 g/ton of feed or 1 g/l of water for 3 days) was shown to decrease mortality rates in chickens (Schettler, 1979; Sato, 1987). Penicillin may also be administered, but a mixed efficacy has been reported with this treatment (Roberts and Aitken, 1973; Page and Fletcher, 1975; Dohms, 2003). Periodic use of chlortetracycline was reported to reduce botulism outbreaks on one poultry farm (Yamambe and Koga, 1982). Additives such as sodium selenite (6 g/1000 l of water for 5 days) and vitamins A, D3, and E may also reduce mortality (Schettler, 1979). Conversely, elevated iron levels in water or feed may promote the intestinal proliferation of *C. botulinum*; therefore, citric acid, an iron chelator, may be added to water as a preventative (Pecelunas *et al.*, 1999; Trampel *et al.*, 2005). Further, citric acid may lower the pH of the GI tract, inhibiting the growth of *C. botulinum* and promoting the growth of normal flora (Graham and Lund, 1986).

### Prevention

Immunization with the toxoid vaccine has been explored in broilers, pheasants, and ducks with mixed results (Shimizu and Kondo, 1978; Dohms *et al.*, 1981; Gross, 1984). Protection in broilers between 3 and 8 weeks of age was variable after vaccination at 1 and 14 days of age. Chickens are most susceptible to botulism between 2 and 8 weeks of age, and vaccinations to protect this group may be less efficacious due to interference from maternal antibody and immaturity of the immune system. Routine vaccination further increases production costs, and the toxoid may not provide adequate protection against the high doses of toxin obtained from maggot ingestion. Toxoid immunizations are also impractical for waterfowl (Gross, 1984; Dohms, 2003). Therefore, preventative measures to minimize outbreaks of avian botulism should be aimed at flock and environmental management in both production birds and waterfowl.

In broiler outbreaks, the goals are to limit further exposure and eliminate *C. botulinum* or BoNT from the environment. Unaffected birds should be moved to uncontaminated houses. Carcasses should either be incinerated or buried in a deep hole. Rodents should be eliminated from broiler houses as rodent carcasses may harbor *C. botulinum* (Yamambe and Koga, 1982). Chicken houses associated with outbreaks should be emptied and cleaned. All litter should be removed. Houses should be washed with high-pressure steam and cleaned with a detergent agent. A surface-active solution should be sprayed on the interior walls. The walls should then be disinfected with an organic iodine solution or an organic iodine and calcium hypochlorite solution. Twenty-four hours later, the interior walls should be sprayed with 10% formalin. Soil in contaminated areas may also be treated with calcium hypochlorite. Houses should also be sprayed with pesticides to limit flies (Schettler, 1979; Sato, 1987). Iron levels in feed and water sources should be monitored (Pecelunas *et al.*, 1999).

Prevention of waterfowl outbreaks is best achieved by reducing the potential for environmental contamination associated with the proliferation of *C. botulinum* in the carcasses of dead vertebrate and invertebrate animals. Carcasses should be collected and flocks should be herded away from shores associated with outbreaks. Pond management should maintain deep waters, steep banks, and smooth bottoms to prevent deaths of invertebrates and vertebrates. Routine flooding, which may lead to the death of terrestrial invertebrates, should be avoided in areas utilized by waterfowl. Water in wetland areas should be maintained as fresh as possible as oxygen depletion in shallow, stagnant waters leads to aquatic animal die offs. Any factors that may increase deaths in susceptible wetlands, such as overhead power lines, should be removed or avoided (Wobeser, 1987).

The possibility for transmission of botulism from birds to their predators may exist. Coincidence of avian outbreaks with botulism in omnivorous animals have been documented. For instance, Weiss *et al.* (1982) reported botulism in a fox and a weasel in association with a waterfowl outbreak. In addition, there have been several reports of canine botulism in hunting breeds (Barsanti *et al.*, 1978; Richmond *et al.*, 1978; Jensen and Price, 1987). Farrow *et al.* (1983) reported the occurrence of botulism in three dogs after the consumption of a rotten duck carcass. Outbreaks of botulism (BoNT/C and D) in cattle and sheep have been associated with the feeding of contaminated poultry litter in silage (Egyed, 1987; McLoughin *et al.*, 1988). No cases of human botulism resulting from the consumption or

handling of contaminated birds have been reported although both scenarios have likely occurred. The risk for the human acquisition of botulism from avian species appears to be limited. Although Smart *et al.* (1980) reported an outbreak of BoNT/C in non-human primates, humans do not appear susceptible to BoNT/C or D following oral exposure (Jensen and Price, 1987). Further, proper cooking of poultry should denature any toxin protein and eliminate the possibility of transmission through consumption.

## Bovine botulism

### *Background*

Cattle are susceptible to BoNT serotypes B, C1, and D, and acquire botulism most commonly from the ingestion of preformed toxin in spoiled silage, carrion-laden silage, or silage contaminated with poultry litter. As with horses, toxico-infectious and wound botulism are also potential routes of intoxication in cattle. All three toxin serotypes (B, C1, D) have been associated with clinical disease caused by the ingestion of spoiled or carrion-laden feedstuffs. Intoxication with BoNT/B is associated with the ingestion of poorly ensiled or spoiled silage, while BoNT/C1 is associated with the ingestion of carrion- or poultry-litter-laden feedstuffs. Although less frequent, BoNT/D has also been implicated with the ingestion of contaminated silage (Rings, 1987; Critchley, 1991). Interestingly, intoxication with BoNT/D has also been associated with the ingestion of bones by phosphorus-deficient cattle or cattle with pica. There are numerous studies documenting the association between outbreaks of bovine botulism and the ingestion of improperly ensiled silage or spoiled haylage contaminated with BoNT/B (Divers *et al.*, 1986; Yeruham *et al.*, 2003; Braun *et al.*, 2005). Wet hay or soil-contaminated hay, wrapped in plastic bags for storage, can provide the ideal moist anaerobic environment for *C. botulinum* growth (Braun *et al.*, 2005). Contamination of a total mixed ration (TMR) with a cat carcass was determined to be the source of a BoNT/C1 outbreak in a herd of adult Holstein dairy cattle in California (Galey *et al.*, 2000). The practice of feeding ensiled poultry litter to cattle has also been associated with outbreaks of serotype C1 botulism as documented in an Irish beef herd by McLoughin *et al.* (1988). Although serotype D is less commonly associated with food-borne botulism, an outbreak occurred on a Canadian feedlot following the feeding of a TMR containing spoiled bakery waste (Heider *et al.*, 2001). A separate outbreak of BoNT/D in a Holstein dairy herd occurred where the source was suspected, but not proven, to be contaminated haylage (Martin, 2003).

### *Clinical signs*

Bovine botulism usually occurs in the context of a herd outbreak. The classical signs of bovine botulism are similar to those observed in horses; however, cattle exhibit a more gradual progression of clinical signs, improving the prognosis and probability of recovery in cattle (Whitlock, 2002). Further, at least one study has reported that ruminal microbes degrade BoNT, decreasing the absorption of active toxin in cattle compared to horses (Allison *et al.*, 1976). The clinical course ranges anywhere from 2 to 30 days, depending on exposure dose and duration, and the administration of treatment. Early botulism may be confused with milk fever as generalized muscle weakness, increased ataxia, and muscle tremors may occur in both conditions. Cattle with botulism also exhibit depression, dysphagia, decreased tongue and jaw tone, hypersalivation, dehydration, decreased tail tone, decreased pupillary light responses, and mydriasis. Rumen contractions decrease and constipation may develop. Diarrhea and/or putrid smelling feces may also be noted. Cattle with botulism tend to spend significant amounts of time in sternal recumbency. At terminal stages of botulism, cattle are laterally recumbent, exhibit abdominal breathing patterns, and finally succumb from respiratory failure (Galey *et al.*, 2000; Braun *et al.*, 2005). Vital signs are often normal in early stages of botulism; however, as the disease progresses, increased heart and respiratory rates may be noted, while body temperature may decrease (Divers *et al.*, 1986; Galey *et al.*, 2000; Braun *et al.*, 2005).

Recently, a syndrome resembling equine dysautonomia has been described in German cattle and a link to BoNT has been proposed. These cattle may present with a subclinical to chronic "visceral" disease. Non-specific symptoms such as weight loss, decreased milk production, depression, alternating constipation and diarrhea, edema, laminitis, ataxia, retracted abdomen, emaciation, tachypnea, and unexpected death are associated with this syndrome (Böhnel *et al.*, 2001). In cattle exhibiting these symptoms, Böhnel and associates demonstrated the presence of both *C. botulinum* and BoNT in lower GI tract contents. Further, neither BoNT nor *C. botulinum* was isolated from asymptomatic herds. This study hypothesized that small levels of *C. botulinum* colonized the lower intestinal tract and created a low level, chronic exposure of BoNT. This low level of toxin may not reach the systemic circulation, and thus toxin may only disrupt nearby parasympathetic ganglionic innervation of the GI tract, altering intestinal function (Böhnel *et al.*, 2001).

In cases of bovine botulism, clinical pathology may reveal signs of dehydration such as increases in packed-cell volume and total plasma protein. Bicarbonate loss from excessive ptyalism may lead to a metabolic acidosis. Increases in muscle enzymes such as aspartate transaminase (AST) and creatinine kinase may be present due to muscle atrophy or trauma resulting from prolonged lateral recumbency. Electrolyte abnormalities and hyperglycemia may also be detected. One study documented indicators of renal failure in a herd poisoned by BoNT/B; increased

γ-glutamyl transpeptidase (GGT), urea, creatinine, and phosphorus were also detected (Heider *et al.*, 2001; Cobb *et al.*, 2002; Martin, 2003; Braun *et al.*, 2005).

As with other species, there are no definitive gross pathological or pathognomonic histological signs of botulism (Galey *et al.*, 2000). Aspiration pneumonia and pulmonary emphysema are the most frequent sequelae of botulism in cattle (Galey *et al.*, 2000; Heider *et al.*, 2001; Braun *et al.*, 2005). Other lesions such as gastric ulcerations, thickened intestinal mucosa, hepatic lipidosis, suppurative rumenitis, and renal failure have been documented in concurrence with botulism; however, these findings are not consistent in all cases of bovine botulism (Galey *et al.*, 2000; Yeruham *et al.*, 2003).

### *Diagnosis*

Botulism in cattle is usually a presumptive field diagnosis made on the basis of clinical signs and the ruling out of other diseases. Differential diagnoses include hypocalcemia, hypomagnesia, hypokalemia, hypophosphotemia, listeriosis, lead poisoning, polio-encephalomalacia, ionophore toxicity, nutritional or plant toxin induced myopathies, molds, organophosphate poisoning, and tick paralysis (Divers *et al.*, 1986; Heider *et al.*, 2001; Moeller *et al.*, 2003). Clinical diagnosis is usually made through the detection of neurological deficiencies in light of relatively unremarkable laboratory diagnostic findings. The neurological examination should assess cranial nerve responses, gait, posture, and attitude. Specifically, a tongue tone test, tongue stress test, and a jaw tone test should be performed. The tongue stress test is performed by placing a hand at the base of the cow's tongue and putting pressure on the tongue followed by an assessment of muscular tone. The tongue tone test is performed as in the horse. Cattle with botulism will exhibit weak tongue strength. The jaw test is performed by grasping the mandible near the symphysis and attempting to move the mandible laterally. This test assesses the strength of the masseter muscles. A "loose" jaw is suggestive of botulism (Whitlock, 2002).

A definitive diagnosis is made by identifying toxin in the patient's serum, ruminal fluid, or tissues. Identification of BoNT or *C. botulinum* in suspect feedstuffs previously consumed by clinically ill animals may further support a diagnosis. Isolation of BoNT from the rumen may prove difficult because the toxin is often diluted by rumen contents and/or degraded by ruminal microbes (Whitlock and Williams, 1999). Similar to botulism in other species, the MBA is the gold standard for a definitive diagnosis in cattle; however, as in horses, the MBA is often not sensitive enough to detect the low levels of toxin in the general circulation (Sakaguchi, 1983; Rocke, 1993; Galey *et al.*, 2000). The MBA may also be used to detect toxin in rumen contents, the liver and other organ tissues, milk, or feedstuffs. Due to the relatively slower progression of clinical signs in cattle, diagnostic samples are often obtained long after ingestion of toxin. Thus, the level of toxin in these samples may have fallen below the level of detection (Divers *et al.*, 1986). Specimens may also be cultured to isolate *C. botulinum*. An ELISA test has been developed to detect BoNT/C and D in cattle; however, this test is considered less sensitive than the MBA (Thomas, 1991). ELISA tests for the detection of antibodies to BoNT/C and D in cattle have also been developed (Gregory *et al.*, 1996).

### *Treatment*

Supportive care is the core of therapy for bovine botulism, and treatment should only be pursued in standing cattle. Affected cattle should be kept in confinement to minimize movement and exertion. Dehydration, electrolyte deficiencies, acid/base abnormalities, and glucose deficiencies should be managed with fluid therapy. Fluids can be administered orally (via an orogastric tube) or IV. Mineral oil or sodium sulfate can be administered with care as cathartics to treat ileus; however, magnesium sulfate should be avoided as it may potentiate muscle weakness (Divers *et al.*, 1986). Rumen transfaunation may also be performed. Alfalfa gruels may be administered via an orogastric tube to maintain caloric intake. Equine origin polyvalent antiserum may be administered to cattle. However, anti-toxin therapy may be less efficacious in cattle since most of the toxin will have been internalized into the neuron or degraded by the time the diagnosis is made. Antibiotics may be administered for secondary complications such as aspiration pneumonia; as in horses, those that produce muscle weakness should be avoided. Although toxoid vaccinations for serotypes B, C, and D are administered to cattle in other countries, there are no FDA approved vaccinations for cattle in the United States (www.vmtrc.ucdavis.edu).

### *Public health*

The Food Safety Act of the United States (1990) requires that meat or milk products be withheld from market for a minimum of 14 days after the onset of the last clinical case of botulism in an affected herd (Cobb *et al.*, 2002). However, the public health concern for transmission of BoNT through milk appears to be minimal. No cases of human botulism acquired from the consumption of meat or milk from botulism affected cattle have been reported; further, it does not appear that calves acquire botulism through nursing from affected cows. Only a single report to date has been able to detect BoNT in milk from a dairy cow affected with botulism (Böhnel *et al.*, 2005). In this report, BoNT/B was isolated in milk collected from one udder quarter that was simultaneously affected with mastitis. The toxin concentration in the milk was determined to be approximately $10^4$ mouse $LD_{50}$s. However, the milk did not test positive for *C. botulinum* bacteria. It is likely that the concurrent mastitis

infection enhanced the passage of the rather large toxin protein (150 kDa) across the normally protective blood:milk barrier by altering its permeability. This is supported by a much earlier report from Moberg and Sugiyama (1980), who isolated BoNT in milk using an infected rat model. Other studies have not been able to detect BoNT in milk from affected cows using either ELISA or MBA techniques (Galey *et al.*, 2000; Cobb *et al.*, 2002; Moeller *et al.*, 2003). Regardless, the pasteurization process would likely denature any toxin protein that was able to pass into milk, reducing the risk to the consumer. It should be noted, however, that the potential for BoNT contamination of milk may be more relevant in regions where unpasteurized milk is available for public consumption (Böhnel *et al.*, 2005).

## Canine and feline botulism

### *Background*

Although carnivores are thought to be more resistant to the development of botulism, cases of canine botulism have been documented in the United States, Great Britain, continental Europe, and Australia. Most reported cases of botulism in dogs result from the ingestion of BoNT/C1-contaminated carrion; however, a few cases of serotype D have been documented in Senegal (Barsanti, 1990, 2006). Barsanti *et al.* (1978) described an outbreak of type C1 botulism in a hunting colony of American foxhounds; however, the source of the toxin was not identified. Farrow *et al.* (1983) described type C1 botulism in three young Australian Cattle Dogs following the ingestion of rotting duck carcasses found around a local Sydney park. Canine botulism has also been associated with the ingestion of contaminated raw meat (Darke *et al.*, 1976).

Until recently, the only documented cases of feline botulism were experimentally induced; however, Elad *et al.* (2004) have described a natural outbreak of botulism in eight cats who ingested parts of a pelican carcass contaminated with BoNT/C1. Interestingly, BoNT/C1 botulism has also been reported in lions (Critchley, 1991).

### *Clinical signs*

The onset of canine botulism can occur within hours or as late as 6 days post-exposure. Severe cases are associated with an earlier onset of clinical signs. The course of the disease usually ranges from 12 to 24 days. In the clinical report of an outbreak of feline botulism, clinical symptoms were first noted 3 days post-ingestion of contaminated pelican muscle (Elad *et al.*, 2004). Although 50% of the exposed cats died, those that survived recovered significantly by 6 days post-intoxication.

Lower motor neuron dysfunction as well as to a lesser extent, cranial nerve, and autonomic nervous system deficits are observed in canine botulism. Paresis begins in the hind limbs and progresses cranially, ultimately resulting in flaccid muscle paralysis and quadriplegia. Interestingly, dogs with botulism maintain the ability to wag their tail. Tremors of the masseter and temporal muscles may be noticed. Muscle atrophy is variable throughout the course of the disease. Mydriasis, decreased pupillary light response, decreased palpebral reflexes, and decreased or weak vocalizations may occur. Hyperemic conjunctiva and decreased Shirmer tear tests may be noted. Heart rates and respiratory patterns are variable; however, as abdominal muscle tone diminishes, diaphragmatic breathing may be noted. Regurgitation, megaesophagus, urinary retention, and constipation are also observed. Secondary complications include aspiration pneumonia, bilateral keratoconjunctivitis sicca, and urinary tract infections. If paralysis progresses to the respiratory muscles, death may occur from respiratory failure; however, death may also result from progressive secondary pneumonia or urinary tract infections (Barsanti, 2006). If secondary complications do not arise, the prognosis for canine botulism is good. Recovery occurs in the reverse order from that of the onset of paralysis; cranial nerve function and motor function of the neck and limbs return first (Barsanti, 2006). In the one case study of natural botulism in cats, clinical signs were similar to those of dogs. Motor deficits and paresis were noted; however, cranial nerve reflexes were normal (Elad *et al.*, 2004). Depression, anorexia, mild dehydration, tachycardia, and urinary retention were also noted.

As with EGS in the horse, there has also been speculation of an association between feline dysautonomia ("Key–Gaskell's disease") and BoNT/C. Clinical signs for feline dysautonomia include depression, anorexia, vomiting, regurgitation, mydriasis, constipation, and urinary retention; however, the somatic lower motor neuron paralysis characteristic of classical botulism is not observed. Histological evidence of neuronal degeneration in autonomic ganglia confirms the diagnosis of dysautonomia. Interestingly, BoNT/C was detected in feces, ileal contents, and foodstuffs of cats displaying symptoms of dysautonomia (Nunn *et al.*, 2004). Further, affected cats had higher levels of anti-BoNT/C and *C. botulinum* surface antigen IgA in their feces when compared to control cats. Additional studies are warranted to determine the potential role of BoNT/C in feline dysautonomia.

### *Diagnosis*

With the exception of dehydration or secondary infection, the CBC count, blood chemistry, urinalysis and CSF analysis are usually within normal limits in canine and feline botulism. Thoracic radiographs may reveal a megaesophagus and aspiration pneumonia. Electromyographic (EMG) findings may indicate lower motor neuron disease in clinically ill animals. Decreases in the amplitudes of compound

muscle action potentials and motor unit potentials are often detected. Furthermore, fibrillation potentials and decreases in nerve conduction velocity may also be detected (Barsanti *et al.*, 1978; van Nes *et al.*, 1986; Braund, 1994; Barsanti, 2006). In order to make a definitive diagnosis, toxin must be identified in serum, vomitus or gastric contents, feces, or food samples from animals showing clinical signs. The gold standard MBA appears to have adequate sensitivity for the detection of toxin in canine and feline biological samples or in carrion (Barsanti, 1978, 2006; Elad *et al.*, 2004). It should be noted that the isolation of *C. botulinum* bacteria through cultures of feces, GI contents, or viscera is not a definitive diagnosis, as this bacterium can be isolated from the GI tract and viscera of healthy dogs.

Differential diagnoses for canine botulism should include tick paralysis, polyradiculoneuritis (coonhound paralysis), myasthenia gravis, coral snake envenomization, and the dumb form of rabies (Chrisman, 1991). Both the lower motor neuron deficits and EMG findings are similar to those of tick paralysis and polyradiculoneuritis; however, due to its action on cholinergic terminals, botulism also causes cranial nerve and autonomic deficits (Oliver *et al.*, 1997; Coleman, 1998; Barsanti, 2006). The nature of botulism outbreaks to affect multiple animals further differentiates the disease from other causes of lower motor neuron dysfunction.

### *Treatment*

Treatment of canine botulism mainly consists of supportive care (Barsanti, 1990; Critchley, 1991). If the ingestion of toxin-contaminated food has been recent, gastric lavage, cathartics, and enemas may be used to decrease toxin absorption from the GI tract. However, as in other species, magnesium sulfate should be avoided. Supplemental fluids should be administered as needed to maintain hydration. Nutritional support via orogastric or parenteral administration may also be needed. Animals should be monitored for aspiration pneumonia due to megaesophagus and decreased gag reflexes. If constipation develops, enemas and stool softeners may be administered. Manual expression of the bladder may be required to decrease the occurrence of urinary tract infections. Topical ophthalmic ointments should be used to prevent corneal ulcers, which may result from diminished palpebral tone and tear production. Adequate bedding and frequent repositioning are necessary to prevent the development of decubital ulcers. In cases where respiration is compromised, mechanical ventilation may be necessary. Antimicrobial therapy may be needed for secondary infections; however, as in other species aminoglycosides, tetracycline, procaine penicillin, metronidazole, aminopyridines, and guanidines should be avoided.

Administration of the equine antitoxin in small animals is controversial. By the time clinical signs are noted, antitoxin is likely to be ineffective as most of the toxin is already bound to the nerve cell or has translocated into the neuron. Only the trivalent antitoxin vaccine for serotypes A, B, and E is available in the United States; this antitoxin is less useful for dogs and cats, which are usually affected by serotype C (Barsanti, 2006). However, the heptavalent antitoxin is available in other countries (Byrne and Smith, 2000; Arnon *et al.*, 2001). Since adverse reactions to antitoxin may occur, and patients with mild disease often recover with supportive care alone, antitoxin administration is usually reserved for severe cases (Chrisman, 1991).

### *Prevention*

Limiting exposure of small animals to carrion, and fully cooking all meat products to be fed to companion animals are simple measures to prevent botulism in these species. Heating foodstuffs to 80°C for 30 min or 100°C for 10 min denatures the toxin protein. Although a toxoid vaccine is available for other species, no such vaccine exists for dogs or cats.

## ACKNOWLEDGMENTS

We wish to offer our sincerest appreciation to Drs. Susan White and Jeanne Barsanti for their careful review of and comments on this chapter.

# Enterotoxins

*Larry J. Thompson*

## INTRODUCTION

The term food poisoning can be used to describe the result of eating pathogenic organisms or toxins in contaminated food. The list of causative agents for food-borne illness can be quite lengthy including infectious agents (e.g. bacteria, viruses and parasites), natural toxins (e.g. bacterial toxins, mycotoxins, shellfish poisons and plant poisons) and other contaminants (Mead *et al.*, 1999). Veterinarians and owners often use the term garbage intoxication or garbage poisoning to describe the situation where animals, especially dogs, eat discarded or otherwise poorly preserved foodstuffs and subsequently develop a syndrome composed mainly of severe vomiting and diarrhea. This chapter is focused on the effects of enterotoxins, which are defined as those bacterial exotoxins that are specific for the intestinal tract causing vomiting, diarrhea and abdominal pain. Although many organisms produce enterotoxins (Vaishnavi, 1996; Fasano, 2002) those produced by *Staphylococcus aureus* and *Bacillus cereus* will be stressed in this chapter. Botulism is covered separately in the previous chapter. In contrast to enterotoxin, the term endotoxin is used to describe a cell-associated bacterial toxin, usually a lipopolysaccharide complex that is found on the outer membrane of Gram-negative bacteria. Endotoxins essentially remain associated with the cell wall until the destruction of the bacteria by autolysis, external lysis or phagocytic digestion. While all animals can be affected by endotoxin, the horse is especially prone to disease complications due to endotoxemia (Werners *et al.*, 2005).

## BACKGROUND

This chapter is focused on the most common situations associated with enterotoxin exposures in veterinary medicine, namely dogs ingesting garbage, carrion or other spoiled foodstuffs. Dogs readily consume a wide variety of such material and owners often are unaware when their animal has had access to or has consumed foodstuffs of doubtful origin. Many owners have the mistaken opinion that dogs (and other animals) are not susceptible to food poisoning and thus may feed their pets foods that humans would rather not ingest. Discarded foodstuffs are often high in proteins and carbohydrates and serve as excellent substrates for the rapid growth of bacterial, often with enterotoxin release. Instances of garbage intoxication increase in warm weather and around major holidays when increased food is prepared and discarded. Under conditions of warm temperatures and adequate moisture, these discarded foodstuffs can have an almost explosive growth of bacteria, especially *S. aureus* and *B. cereus*, which are the most common causes of enterotoxin related food poisonings in the human. While a great deal of time and energy has been expended by public health officials in the pursuit of the origin and control of food poisonings in humans, there is a paucity of specific information concerning animals.

## PHARMACOKINETICS AND MECHANISM OF ACTION

*S. aureus* is a facultative anaerobic Gram-positive coccus that may be single, paired or in a grape-like cluster. *S. aureus* does not form spores and thus contamination may be avoided by proper heat treatment of food to kill the bacteria. *S. aureus* is able to grow in a wide range of temperatures (7–48.5°C) with an optimum range from 30°C to 37°C. *S. aureus* can also grow over a wide pH range (4.2–9.3) and can tolerate sodium chloride concentrations of up to 15%. These characteristics allow it to grow in a wide variety of foodstuffs and in situations of discarded food. *S. aureus* is an important infective pathogen as well and can easily be found in the nostrils and on the skin of most mammals (Le Loir *et al.*, 2003). At least 14 different staphylococcal

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

enterotoxin (SE) types have been found and they are best described as short proteins secreted by the cell into the growth matrix (Balaban and Rasooly, 2000). All SE types are water soluble, very heat resistant and resist most proteolytic enzymes, such as trypsin and pepsin, which make it possible for them to travel through the digestive tract to their site of action. Thus all SE types resist the conditions that could easily destroy the bacteria that produced them. SEs are thought to have a direct effect on the intestinal epithelium as well as on the vagus nerve to cause stimulation of the emetic center as well as increasing peristalsis. Foods that are frequently associated with staphylococcal food poisoning include meat and meat products; poultry and egg products; salads such as egg, tuna, chicken, potato and macaroni; bakery products such as cream-filled pastries; and milk and other dairy products. An illustration of a proverbial high-risk food would be the potato salad at the summer picnic left out for several hours without refrigeration.

*B. cereus* is in the family Bacillaceae which are all Gram-positive rod-shaped bacteria which form endospores. The family has two main divisions: the anaerobic spore-forming bacteria of the genus *Clostridium* and the aerobic or facultatively anaerobic spore-forming bacteria of the genus *Bacillus*. *B. cereus* is a primary inhabitant of soils and contaminates almost all agricultural products and is routinely involved in the contamination and spoilage of food products. *B. cereus* can also be involved in wound, eye or systemic infections. *B. cereus* food poisoning is generally described as having two types of illness caused by different metabolites. The diarrheal type of illness is caused by one or several heat-labile high molecular weight proteins, while the vomiting (emetic) type of illness is believed to be caused by a low molecular weight, heat-stable peptide which has been named cereulide (Schoeni and Wong, 2005). In the human, the diarrheal syndrome is thought to be the consequence of a food-borne infection with enterotoxic *B. cereus* following the observation that the diarrheal enterotoxins are produced during the vegetative growth of *B. cereus* in the small intestine. *B. cereus* food poisoning has been classically associated with fried rice and other cooked rice dishes because the bacteria is frequently present in uncooked rice and heat-resistant spores may survive cooking. If cooked rice is subsequently held at room temperature, vegetative forms multiply, and a heat-stable toxin is produced that can survive brief heating, such as stir frying. *B. cereus* food poisoning can also be associated with meat- or vegetable-containing foods after cooking where the food was held above room temperature for a prolonged period of time.

## TOXICITY

The symptoms of staphylococcal food poisoning occur in humans when as little as 100 ng of enterotoxin is ingested (Bennett, 2005). There is a paucity of information on the dose of individual enterotoxins which will cause clinical signs in common domestic animals. The first and most common clinical sign in dogs is vomiting, which usually occurs within 2–3 h following ingestion. This can often suffice to remove enough contaminated food from the gastrointestinal tract to prevent the development of more severe clinical signs. However, vomiting can be protracted and lead to fluid and electrolyte abnormalities. Diarrhea can often develop within 2–48 h following ingestion of contaminated food and can be severe, sometimes bloody. The combination of both vomiting and diarrhea in the affected animal can quickly lead to profound fluid and electrolyte abnormalities. The animal may exhibit tenderness to the abdomen or the stomach and intestinal tract can be distended with gas (Coppock and Mostrom, 1986).

The emetic form of *B. cereus* food poisoning is characterized in the human by an acute attack of nausea and vomiting. This occurs within 1–5 h after consumption of contaminated food and diarrhea is not a common feature in this type of illness. In the human, the diarrheal syndrome is characterized by abdominal pain, abdominal cramping and diarrhea that often can be very watery. There is an incubation period of 4–16 h and clinical signs can persist for 12–24 h. Nausea may accompany the diarrhea but vomiting rarely occurs.

## TREATMENT

It is important to remember three factors when a food-borne problem is included in the differential diagnosis. These factors include the presenting clinical signs, the possible exposure to foodstuffs not normally included in the animal's diet, and the interval between exposure and onset of clinical problems. Many of these may not be known at the time of initial presentation but should be explored as the case is developed.

In general, treatment of garbage intoxication in animals should be directed at correcting the fluid and electrolyte abnormalities along with considerations of acid/base balance. As mentioned above, non-complicated cases will often resolve within hours of presentation with only supportive care. However, because the clinical signs can be similar to more serious conditions, a more thorough diagnostic workup (e.g. survey abdominal radiographs) and close observation should always be considered. Since cases most often present following several vomiting episodes, the use of emetics is usually not indicated. In the case of protracted vomiting, the judicious use of antiemetics should be considered. Administration of activated charcoal is not required for known garbage intoxications but many clinicians will use it as part of a general approach to these

cases. Activated charcoal should not be given to dehydrated animals unless fluid administration is also initiated. Antibiotics are not indicated in uncomplicated cases of garbage intoxication.

## CONCLUDING REMARKS

This chapter has reviewed garbage intoxication with emphasis on preformed enterotoxins as the causative agents. The great number of other types of food-borne illnesses, including infectious agents and toxins, will require other diagnostic and treatment considerations.

# Caterpillars and mare reproductive loss syndrome

*Manu M. Sebastian, William Bernard, and Lenn R. Harrison*

## INTRODUCTION

During the spring of 2001, horse farms in and around Central Kentucky experienced an epidemic of early fetal and late fetal loss (EFL/LFL) which, together with smaller numbers of fibrinous pericarditis (FP) and unilateral uveitis (UU), are now known as the mare reproductive loss syndrome (MRLS). The EFL and LFL were identified during the last week of April, peaked on May 5th and declined rapidly thereafter. FP and UU were identified during the same time period (Kane and Kilby, 2001; Harrison, 2001; Powell, 2001). The same pattern of abortion, but in lesser numbers, was observed in 2002.

Four epidemiological investigations were conducted to identify risk factors associated with MRLS (Cohen *et al*., 2003a, b; Dwyer *et al*., 2003; Seahorn *et al*., 2003). Risk factors identified included exposure to moderate to high concentrations of eastern tent caterpillars (*Malacosoma americanum*, ETCs) (Figure 63.1) in the pastures, the presence of cherry trees, ⩾50 broodmares/farm, feeding hay in pasture, greater than usual amounts of white clover in pastures, abortion during a previous pregnancy, being fed on pastures exclusively during the 4-week period prior to abortion, access to pasture after midnight during the 4-week period prior to abortion, drinking from a water trough, or not, access to water buckets or automatic water taps, etc. Risk factors associated with FP included being from a farm with mares and foals affected by MRLS, exposure to ETC in or around the pastures, younger age, shorter duration of residence in Kentucky, being fed hay grown outside Kentucky, lack of access to pond water and a lack of direct contact with cattle.

**FIGURE 63.1** Late instar ETCs in nest. This figure is reproduced in color in the color plate section.

Approximately 14,980 foals of all breeds were lost due to MRLS in 2001. Smaller numbers of clinically similar fetal losses, abortions and still births were reported from Southern Ohio, West Virginia and Tennessee during the same time period, indicating that MRLS was not limited to Kentucky. A lesser incidence of MRLS was recorded in Central Kentucky in 2002, and few cases were reported in 2003. At least 17 breeds of horses were affected. The abortions were heavily concentrated in Central Kentucky but aborted equine fetuses from 32 counties in Kentucky were submitted to the University of Kentucky diagnostic laboratory for necropsy. The specific number of LFL and EFL abortions in the field was not recorded.

The economic loss due to MRLS in 2001 was estimated at $336 million. The combined losses from MRLS in 2001 and 2002 were estimated at approximately $500 million. MRLS was therefore one of the most economically devastating

acute diseases to strike livestock industry. The syndrome of foal deaths drew substantial media attention, resulting in national and international news reports (Paulick, 2001).

## CLINICAL FINDINGS

### Early fetal loss

Mares undergoing EFL showed few systemic clinical signs. Some mares were presented with a sero-sanguineous or purulent vulvar discharge, and some with fetal membranes protruding from their vulva with fetuses located either in the vagina or vulva. A proportion of mares (approximately <15%) reportedly exhibited mild colic signs, abdominal straining or low-grade fevers (101.0–101.5°F) 1–3 days before EFL.

In most EFL cases rectal palpation was apparently normal. The typical ultrasound presentation of an EFL/MRLS loss was a dead fetus (i.e. no heartbeat), surrounded by echogenic allantoic fluid and a more echogenic amniotic fluid. In cases where the fetus was not dead, ultrasound examination generally showed a fetus with slow heart rate and slow movements, suspended in an amniotic fluid which was echogenic, either "cloudy" or "flocculent". Some mares aborted markedly autolyzed fetuses, while some retained the fetus in the vaginal canal. Most mares which had EFL pregnancies as identified by ultrasound expelled the fetus within 2 days to 2 weeks. Majority of EFL cases occurred between days 40 and 80 of gestation, with few cases up to 140 days. It was also noted that mares less than 30 days pregnancy were apparently less susceptible to MRLS.

Culture of aspirates of allantoic fluid collected from three EFL mares in 2001 grew alpha *Streptococcus* bacteria in two cases and *Escherichia coli* in one case. Complete blood counts and blood chemistry panel evaluation from these mares did not show any significant abnormalities. Microscopic examination of uterine biopsies from EFL mares within 7 days of abortion showed moderate to severe inflammation (Riddle and LeBlanc, 2003).

### Late fetal loss

LFL losses were those observed in the last trimester of gestation. The majority of LFL mares exhibited few signs of impending foaling or abortion. Clinical features associated with LFL included explosive parturition, dystocia, foaling while standing, premature placental separation ("red bag delivery") stillbirth, foals born weak and agalactic mares. Clinical signs associated with foals born weak were consistent with asphyxia and many required resuscitation. Many of the weak foals were admitted to local equine veterinary hospitals and survived for up to 4 days. Blood cultures were rarely positive for bacteria. The most frequently isolated bacteria were alpha *Streptococcus* and *Actinobacillus* spp. These foals were dehydrated, hypothermic, and tachycardic with irregular respiration. Leukopenia, hypoglycemia and acidosis were also consistent findings. Bilateral hyphema was observed in many of these foals at birth (Byars and Seahorn, 2002).

## FIBRINOUS PERICARDITIS

Thirty-eight cases of FP were admitted to two large Central Kentucky referral veterinary clinics. The pericarditis cases occurred in horses of all ages, breeds and sexes, and were not restricted to pregnant mares. The clinical presentation of the pericarditis cases included ultrasonographic evidence of effusive FP, tachycardia, muffled heart sounds, hyperfibrinogenemia, lethargy, tachypnea, jugular pulse distention and pleural effusion and/or ascitis. Analysis of fluid removed from the pericardial sac of most cases demonstrated a low white cell count and high protein content. This fluid was mostly sterile exudates, but in cases where bacteria grew, they were similar to those observed in EFL/LFL abortions. Less than 15 confirmed cases of pericarditis were recorded in 2002 and two cases were reported associated with MRLS in 2003 (Bolin *et al.*, 2004).

## UNILATERAL UVEITIS

During MRLS in 2001, 40 UU cases were observed in foals, yearlings and adult horses of all breeds, ages and sexes. The condition was unilateral in all cases. The onset of clinical signs was peracute, with profound exudative opthalmitis occurring within the first 12-h period. Consistent changes included corneal edema and exudates in the anterior and posterior chambers. The anterior chamber exudates were tan yellow, presumably proteinaceous and often accompanied by hemorrhage from the surface of the iris. A markedly turbid yellow vitreous was visible through a mid-range pupil, and this was confirmed by ultrasound. Affected eyes appeared refractive to treatment and blindness ensued, followed by various degrees of global atrophy. No eyes were enucleated for histopathological examination. The culture and cytology results were negative ($n = 1$). Fewer cases were reported in 2002. One colt affected by MRLS in 2001 UU won the Illinois Derby and raced in the 2004 Kentucky Derby (Latimer, 2002).

Three cases of *Actinobacillus* meningoencephalitis (age >4 years), caused by the same organism associated with the EFL/LFFL/FP cases, were diagnosed on necropsy during

MRLS in 2001. No cases of *Actinobacillus* meningoencephalitis were observed during MRLS in 2002 in Central Kentucky (Sebastian *et al.*, 2002a).

## PATHOLOGICAL FINDINGS

The EFL fetoplacental units were moderately to markedly autolyzed at the time of submission, which limited pathological evaluation and related testing. Most fetoplacental units showed moderate neutrophilic infiltrates in the placental membranes, and the amniotic and allantoic fluids. The overall finding of EFL was a bacterial placentitis. Severe autolysis precluded location of the inflammation to specific anatomical regions of the placenta, in contrast to the LFL histopathological findings. The same organism isolated from LFL was isolated from the EFL aborted fetuses and no funisitis was observed in these.

The majority of LFL fetuses were between 10 months of gestation and term. Gross lesions included pale brown placenta, in sharp contrast to its normal dark reddish brown color, with a thick, dull, edematous yellowish umbilical cord, hemorrhage in the eyes, marked placental thickening, placental edema and intact cervical star ("red bag"). In some fetuses the lungs were edematous with fluid oozing from cut sections.

Characteristic histopathological changes associated with LFL included placentitis, funisitis and perinatal pneumonia. The alveoli contained free bacterial colonies with and without inflammatory response and numerous free squamous epithelial cells. Funisitis (inflammation of umbilical cord) was a characteristic lesion of LFL/MRLS and was mostly confined to the amniotic segment of the umbilical cord. Umbilical cord lesions were generally confined to the surface and consisted of mild to dense infiltration of inflammatory cells, mostly neutrophils admixed with bacterial colonies. Microscopic lesions observed in the placenta were largely confined to the celomic space in the subchorionic stroma, and they were mostly perivascular. The MRLS placentitis was distinguishable from the ascending placentitis by the pattern of distribution of inflammatory cells. No single lesion was pathognomonic for MRLS/LFL. The diagnosis depended on overall evaluation of the case and consideration of its history (Williams *et al.*, 2002; Cohen *et al.*, 2003c).

Standard bacteriological isolation procedure yielded up to 10 different bacterial species from lung, stomach fluid, allantochorion and placental fluid of LFL 2001 cases. Nonbeta hemolytic streptococci (51%) and/or *Actinobacillus* spp. (13 %) comprised the majority of the isolates fetuses (Donahue *et al.*, 2002).

The gross findings of FP cases included enlarged heart with large quantities of sero-fibrinous fluid in the pericardial cavity, in some cases up to 3 l of fluid. Histopathological findings consisted of the visceral pericardium covered with fibrin, admixed with neutrophils and lesser numbers of lymphocytes. In many cases the inflammation extended beneath the epicardium into the myocardium forming a thick uniform layer of fibrinous/fibrinopurulent exudate made up of neutrophils and lymphocytes admixed with proliferating fibroblasts and large quantities of fibrin. While *Actinobacillus* spp. was isolated from 31% of these cases, all other attempts showed no bacterial growth, suggesting that an unidentified factor, not simply a bacterial infection, was responsible for the condition. A number of pericarditis patients failed to survive in spite of treatment and were submitted for necropsy examination. *Actinobacillus* spp. was isolated from a total of 10 nontreated horses of 32 cases submitted for necropsy during MRLS in 2001 (Bolin *et al.*, 2004).

No eye tissue from uveitis cases was submitted for histopathological examination and hence the histopathological findings in this condition are unknown. In the three cases of encephalitis that occurred during the same period, *Actinobacillus* spp. were isolated from the brain and other organs and the isolates were similar to the EFL/LFL cases. Detailed virological and serological examinations were conducted on the fetal and placental samples and no viral agents were identified, thus ruling out a primary infectious cause.

## INVESTIGATION OF ETIOLOGICAL AGENTS

A variety of possible causes were considered as etiological agents. A primary infectious cause was ruled out based on the absence of specific clinical symptoms in aborting mares. The point source onset of the syndrome suggested a noninfectious cause and investigations were directed toward an environmental toxin.

Fetal fluid samples were negative for nitrate/nitrite which ruled out its toxicity. Pasture samples collected during this period showed less than toxic levels of nitrate/nitrite. The aborting mares did not show prolonged gestations and the placentas from MRLS mares showed marked inflammation. These findings and preliminary testing conducted in the University of Kentucky ruled out ergot alkaloid/fescue toxicosis. Detailed examinations for phytoestrogens and other mycotoxins were conducted during the first few weeks of the outbreak and were ruled out.

Epidemiological investigations identified both spatial and temporal association between the presence of ETC and MRLS abortions. Preliminary field investigations confirmed these time and place associations between dispersing ETC and MRLS. These findings led to a search for an

ETC or its habitat associated toxin. Cyanide associated with the black cherry tree ETC biological system was the only significant toxin identified. This investigation was supported by positive tests for low concentrations (about 500 ppb) of cyanide in some aborted fetal heart tissue. Extensive studies were conducted in pregnant mares by exposing them with variable cyanide doses which were not lethal to mares and none of the studies could induce abortion. The blood cyanide concentration in MRLS aborted mares was not different from the concentration in control mares used in experimental studies further supporting the fact that cyanide may not be directly involved in MRLS.

Prunasin is the primary organic cyanide in cherry tree leaves, the principal food of ETC and it is digested/metabolized to mandelonitrile. Mandelonitrile, which spontaneously hydrolyzes to yield cyanide, is also present in the regurgitated materials of ETC and is used by the ETC as a defensive chemical against predators (Fitzgerald, 2002). Based on this scientific evidence, pregnant mares were challenged with mandelonitrile. Mandelonitrile was administered at a dose of 2 mg/kg/horse in feed, BID, for 14 days to six late-term pregnant mares. Each administration yielded a sharp increase in the plasma concentration of cyanide, peaking at about 600 ng/ml, followed by an 8–12 h increase in plasma thiocyanate. Mild diarrhea was observed in the treated mares. No abortions were observed in any treated mare. No pathological changes suggestive of EFL/LFL were observed, and the role of free cyanide or its precursors in MRLS was eventually discounted (Harkins *et al.*, 2002).

The possibility that MRLS could be due to inhalation of mandelonitrile/cyanide was also investigated. Four early-term pregnant mares were exposed to mandelonitrile vapor for 6 h for 3 consecutive days. Two mares were administered 2–50 mg mandelonitrile/day and another two were administered 2–500 mg mandelonitrile/day. Two hours after the last challenge, fetal pulse rates increased by 25% above pre-challenge values in three of the four exposed mares. The control mares remained normal. Forty-eight hours after the first observation, fetal pulse rates returned to normal, while the amniotic turbidity scores increased by one grade. The control mare values remained unchanged. Total serum progestagens and ECG values remained within normal limits. Fetal heartbeat and amniotic turbidity scores returned to baseline values and no fetal losses were observed. These experiments indicated that mandelonitrile by itself is not a toxic compound responsible for MRLS.

## EXPERIMENTAL STUDIES WITH CATERPILLARS

Experiments specifically designed to replicate the natural exposure of mares to ETC were carried out in spring of 2002. Pregnant mares were kept in experimental plots and exposed to live ETC or their frass (feces). Mares were exposed to ETC for 6 h each day for a maximum of 10 days or until they aborted. Pregnant mares exposed to ETC and frass aborted, however no abortions occurred in the frass-only group. The fetoplacental units recovered showed no significant gross findings, but bacteria similar to natural cases of MRLS were cultured from most of the fetal/placental tissues. Based on estimates of caterpillar concentrations in the treatment fields it was estimated that an average caterpillar concentration of 11.3–27.5 larvae/25 $cm^2$ was likely sufficient to cause MRLS abortion. This experiment established that ETC exposure will cause EFL/MRLS abortions (Webb *et al.*, 2004).

In another experiment mares (<102 days of pregnancy) were challenged with ETC and frass. This experiment comprised five control mares (administered saline), five mares administered 2.5 g/day of frass (by gastric tube) that had been stored at −80ºC and five mares administered 50 g/day homogenized ETC, by nasogastric tube. All three groups were treated for 10 days. All mares were confined in stalls and fed with hay from Nevada and treated for a period of 10 days. Four of the five mares treated with ETCs aborted during days 8–13 of the experiment. This study confirmed the relationship of ETC exposure to fetal losses in early stages of gestation, consistent with MRLS and ruled out involvement of Kentucky hay or pastures (Bernard *et al.*, 2004).

The LFL was reproduced by administration of homogenized ETC from Michigan to late-term pregnant mares. Six mares were administered 50 g/day of ETCs by nasogastric intubation for 9 days, the ETC having been fed fresh Kentucky Black cherry leaves. All mares exposed to ETC aborted and none of the control mares aborted. All placentas had intact cervical stars. No abnormal clinical signs, blood chemistry panel changes or blood cultures were recorded throughout the entire experiment. This experiment confirmed that ETC is abortigenic for mares in the late term of pregnancy and also demonstrated that ETCs from a region other than Central Kentucky are capable of causing MRLS (Sebastian *et al.*, 2002b).

Later on, the potency of different ETC body components to induce abortion was investigated. The integument of 100 g of ETC was separated from their digestive tracts and administered each separated fraction to six mares (early- to mid-gestation stage) each for 5 days. Two of the five mares administered the ETC integument fraction aborted, while the five mares administered the digestive tract contents did not abort. The results of this experiment suggested that the ETC abortifacient property is associated with the ETC integument, and not the digestive tract fraction. This experiment did not identify the factors/structures of the ETC integument that is abortigenic.

In an experiment to determine the abortifacient potential in different body components of ETC, pregnant mares were exposed to selected anatomical components/fractions

and filtrates of ETC. This experiment consisted of seven groups of five early pregnant mares, and the ETC used in the experiments was preserved at −80ºC. Group 1, the positive controls, was fed 50 g ETC homogenate mixed in sweet feed. Group 2, the negative controls, was fed saline mixed sweet feed. Groups 3–6 were fed specific parts, extracts, filtrates and retentates of ETC. For this experiment, ETC was dissected into three distinct body parts, exoskeleton, gut and internal contents. All the three components were fed to pregnant mares in early stages of gestation. Another group of early-term mares were fed filtrates of a phosphate buffered saline homogenate of ETC that had been filtered (<45 μm) and the retentate from this preparation was fed to two groups of mares in early stages of gestation. A positive and a negative control groups were also maintained in the experiment. All five mares in the positive control group aborted. Three of five mares in the group fed with exoskeleton aborted and one mare in the group fed the retentate aborted. No other groups were affected. This experiment confirmed that the abortifacient potential is associated with ETC exoskeleton. Filtration of the homogenate appears to have removed the abortifacient component, and it is worth noting that the homogenization/filtration process virtually completely, but not quite completely, inactivated the abortigenic factor (Webb *et al.*, 2004).

The ability of frozen ETCs, autoclaved ETC and gypsy moth caterpillars (GMC), a hairy caterpillar, to induce MRLS was investigated in detail. Three of five mares fed frozen ETCs (maintained at −80ºC) aborted; none of the five mares administered ETC that were autoclaved before administration aborted. One of the four GMC treated mares aborted; however, the abortion was considered atypical for MRLS and as such excluded from the analysis. This experiment showed that the abortifacient is not lost by freezing, being stable for at least 4 months at −80 ºC, but that the abortigenic factor is inactivated by autoclaving. The failure of GMC to cause MRLS abortion indicates that GMC which have many hairs (setae) similar to ETC do not have abortigenic factor or potential to induce abortion in mares (Webb *et al.*, 2004).

Investigations were undertaken to determine if the closely related forest tent caterpillars (*Malacosoma distria*, FTC) would produce MRLS. A group of early-term mares were challenged with 100 g of FTC homogenate/mare for 5 days (the FTC was raised/hatched out in laboratory), by stomach tube. A second group of early-term mares served as controls. There were no abortions in the FTC challenge group or the controls. This experiment suggests that the abortifacient responsible for MRLS is not uniformly present in all *Malacosoma* or tent caterpillar species. FTC also have setae/hairs of caterpillar and hence it indicate that setae as such may not induce abortions.

Experiments were conducted to rule out the role of bacteria associated with ETC. The ETCs were sterilized with alcohol by blending with 95% ethanol in a mechanical blender for 5 min and allowed to sit at room temperature for 2 h. This homogenate was cultured to assure the absence of viable bacteria A 50 g dose was administered to each mare for 10 consecutive days via a nasogastric tube. In Group 2 mares, saline replaced the ethanol, while the negative control mares received 200 ml of 10% ethanol. Two of the five mares that received the ethanol/ETC homogenate aborted. These abortions were considered typical of MRLS. No abortions were observed in the ethanol sham control groups. This experiment suggested that the causative agent is not an ETC associated bacteria. Although the ethanol treatment was bactericidal, it may not have been potent enough to destroy viruses and the possibility of a viral agent as the cause of MRLS was not excluded. In another experiment to rule out the role of virus and bacteria associated with ETC, homogenate of ETC prepared in normal saline was exposed to 30 kGy cobalt irradiation, a level demonstrated to destroy/inactivate marker bacteria and viruses while not significantly altering the activity of enzymatic or chemical markers. All six mares administered 100 g fresh frozen ETCs by stomach tube aborted within 32–120 h after the onset of treatment. Three of the six mares administered with 100 g irradiated ETCs aborted. These fetuses had gross and histopathological changes similar to those observed in the natural MRLS cases. *Actinobacillus* spp. and *Streptococcus* spp. were isolated from these fetoplacental units. This was the first experiment in which the typical MRLS funisitis has been demonstrated in experiment, funisitis being a typical and to some extent defining lesion in many field MRLS cases. The results of this experiment demonstrated that frozen ETC from 2003 preserved at −80ºC will induce abortion in late gestation mares. This experiment ruled out the role of naturally occurring virus or bacteria in ETC. The abortions that occurred as a result of exposure to the irradiated ETCs were remarkably similar to the experiments of 2001 and 2002. Irradiation markedly reduced the abortifacient capabilities of the 2003 ETC but did not eliminate all together their capability to induce abortion (Sebastian *et al.*, 2003a).

## ANIMAL MODELS

Attempts to produce a laboratory model of MRLS using mice were not successful. Various preparations of fresh and frozen ETC, ETC homogenates, ETC frass and ETC setal (hair) fragments were evaluated using 5–12 day pregnant mice. No significant number of abortions was observed in the mouse studies (Sebastian *et al.*, 2002c). The overall findings of the experiments suggest that there may be a species susceptibility for ETC abortifacient property. Experimental trials in rats by feeding finely chopped ETC mixed in feed to 4 days pregnant rats through the end of gestation did

not result in statistically significant number of abortions, but setal granulomas (granulomas with hair/setae cross sections in the center) were observed in the gastrointestinal tract of some animals. The abortifacient capability of ETC was investigated in pregnant pigs. Two of five gilts fed ETCs aborted their litters, while none of the controls aborted. This experiment showed that species other than equines can be affected by the ETC-related abortifacient, although this experiment was not repeated. A study was conducted in pregnant goats (>100 days gestation) with a dose of 50 g/ETC/day (same dose as in horse experiment) for 10 days by oral dosing and none of the goats aborted, but setal granulomas were observed in the gastrointestinal tract of all animals in the test group. Hence the studies in goats and rats suggest that setae as itself may not induce abortions in multiple species of animals and abortifacient property of ETC is species specific.

## UNIQUE FEATURES

The unique features of MRLS were the absence of premonitory clinical signs, limited distribution pattern of lesions, pathological lesions confined to pericardium, eye and fetoplacental unit and the bacteriological findings. Consistent with the absence of clinical signs, no abnormalities in clinical chemistry panels or complete blood counts were documented in the natural or experimental cases. Also blood cultures did not demonstrate a bacteremia in field or experimental cases of MRLS.

The histopathological studies conducted on LFL fetuses and placenta show no indications suggestive of the two well-characterized routes of entry of pathogenic organisms into the fetal membranes, either ascending via the cervix or hematogenous. Ascending infection via the cervix is considered unlikely by virtue of the lack of inflammation where the placenta contacts the cervix. The intact cervical star of placentas of aborted fetuses in late-term experimental studies supports this argument. The hematogenous route of infection also does not fit the inflammatory pattern as there is minimal inflammation on the chorionic surface of allantochorion. In LFL MRLS, the microscopic lesions observed in the allantochorion are generally confined to the celomic space in the subchorionic stroma and very closely associated with blood vessels suggesting a primary vascular involvement (Sebastian and Harrison, 2005). In the LFL fetuses submitted to the LDDC no single pathological finding was identified as being specific for MRLS, although a characteristic finding was funisitis. Funisitis, inflammation of the umbilical cord, has not previously been reported in the veterinary literature as a primary lesion, although inflammatory cell infiltrates of the umbilical cord have been reported. The specific pathogenesis of the characteristic funisitis of MRLS is unknown.

Prior to the identification of MRLS, it was very rare for the bacterial species *Actinobacillus* spp. and *Streptococcus* spp. to be associated with an abortion or placentitis. Recently it was discovered the MRLS-like *Streptococcus* spp. were found in the alimentary tract of mares with a greater concentration in the upper part of the tract, the tongue, tonsillar area and esophagus. Comparison of isolates from different mares demonstrates differences suggesting that the source of fetal and placental infection in each mare is derived from its own bacterial population.

One case of pericarditis was observed in a mare which aborted as part of EFL. Pericarditis and uveitis together have not been identified in any mares which aborted during the MRLS period. Prior to 2001, pericarditis had been an uncommon diagnosis in the equine population of Central Kentucky. The incidence of pericarditis during MRLS in 2001 was 30-fold (an average of seven cases per year in years before 2001) above the mean local prevalence, therefore warranting the inclusion of this condition in the case definition of MRLS.

The occurrence of UU was not reported prior to MRLS in any species of animals as an outbreak. UU was not diagnosed in any individual mare affected by EFL or LFL. Additionally, neither pericarditis nor UU was reproduced in any of the ETC exposure/administration experiments. It is a unique condition and the pathogenesis is unknown.

## OTHER OBSERVATIONS AND PATHOGENESIS

The EFL/MRLS affected short-term fertility but not long-term fertility. The LFL/MRLS did not affect either short- or long-term fertility. MRLS did not have a chronic or negative impact on fertility. Furthermore, it has been reported that the 2001 MRLS affected mares bred in 2002 conceived and maintained their pregnancies at rates consistent with prior years. There is no substantial evidence that MRLS had a long-term effect on fertility.

Blood samples collected before and 7 days after oral administration of irradiated and non-irradiated ETC were tested for lymphocyte subpopulation distribution, lymphocyte proliferation, phagocytosis and oxidative burst capacity, opsonic capacity of serum, and serum immunoglobulin isotype levels. No definitive evidence of an immunosuppressive condition was observed in experimental studies (Flaminio *et al.*, 2005).

In a retrospective study conducted to evaluate the EFL on four equine farms in Central Kentucky, one farm had

fewer fetal losses suggesting that management or environmental factors may have an effect. The study also ruled out the association of any specific sire used for mating in the stud farm (Morehead *et al.*, 2002).

The time course of the abortions observed after administration of different doses of ETC to late-term mares well fitted in an unusual statistical model called accelerated failure time analysis. Review of the experimental data and the statistical analysis showed that ETC induced abortions are characterized by a dose-dependent lag time, followed by initiation of the abortions, which occur at a rate that is also dose dependent. Based on this study, it was estimated that during MRLS in 2001 mares had an initial exposure to about 5 g ETC/day, increasing to about 30 g/day at the peak of the outbreak (Sebastian *et al.*, 2003b).

An abortion storm similar to MRLS is believed to have occurred previously in Kentucky during the spring of 1981 and 1982, and there was anecdotal evidence of an ETC population explosion during the same period in Central Kentucky. No detailed epidemiological studies were conducted during that episode and hence the risk factors were not recorded. Recently MRLS was reported from Florida in spring of 2006 and many ETC were observed in the pasture where aborted mares were maintained which strongly supports the role of ETC in MRLS.

The intact cervical stars and the light brown/yellow appearance of the allantochorions in the late-term pregnancy mare experiments suggest that placental detachment happened *in utero*. It is well known that placental detachment leads to hypoxia, resulting in fetal death and abortion. So this experiment suggests that the abortifacient component of ETC may be acting on the uteroplacental interface leading to placental detachment, which may be the probable pathogenesis or at least a component of the mechanism of the disease.

Currently two hypotheses are being investigated: (1) A breach in the gastrointestinal mucosal barrier allows the entry of bacteria (isolated from the MRLS cases) into the bloodstream, crosses the uterus and reaches the fetus and its membranes resulting in the death of the fetus. The specific mechanism by which the bacteria can induce abortion is unknown. (2) The second hypothesis is that MRLS is caused by an unidentified toxin carried and/or deposited in the environment by the ETC that is either toxic to the placenta or the fetus. The results of experiments with irradiated ETC support the toxin hypothesis, as the abortions in irradiation ETC exposed group could culture the same bacterial organisms from the fetuses as well as reproduce the funisitis which has not been reproduced in experimental settings. The statistical analysis of the results of experiments defining the correlation between abortion time and dose supports the hypothesis that MRLS is caused by a toxin (Sebastian *et al.*, 2003b; 2006).

## TREATMENT AND PREVENTION

Many therapeutic approaches to EFL were attempted. Sulfonamide–trimethoprim combinations and other broad-spectrum antibiotics were administered to combat the bacterial infections. In EFL abortions, mares were lavaged (uterine) and treated with antibiotics based on culture and sensitivity. In the subsequent heat most of the mares had normal uterine cytological findings. No bacteria were grown from the uterus. No significant pathological changes were observed in the uterine biopsies performed on 10 mares, 1–2 months after their 2001 abortions. Therapy in foals born with MRLS included supportive care with fluids, resuscitation, and antibiotics, but the majority of these foals did not survive.

In FP cases the pericardial fluid was removed/drained and antibiotic treatments (Ceftiofur sodium, Ampicillin) were administered to horses admitted to hospitals. Some horses recovered after treatment with antibiotics. Several pericarditis cases were reported during the same time period in 2002; however, the numbers admitted to veterinary hospitals were markedly fewer. Attempted treatments in UU included systemic and topical antibiotics, non-steroidal anti-inflammatory drugs (NSAID and corticosteroid), atropine, tissue plasminogen activator, mycotoxin binders and cyclosporine.

Domperidone was administered to treat possible ergotoxin involvement, mycotoxin binders were administered to eliminate possible mycotoxins, non-steroidal anti-inflammatory agent such as Flunixin meglumine to reduce inflammatory responses and Pentoxifylline to improve the blood supply to the fetus, all with no obvious therapeutic effect. Prevention of ETC included cutting down cherry trees, spraying of ETC nests with insecticides and muzzling of mares when out in pasture. These preventive measures reduced the incidence of MRLS in subsequent year, in farms which adopted the ETC control measures (Riddle and LeBlanc, 2003).

## CONCLUSION

The epidemiological findings identified exposure to ETC as a risk factor for MRLS. The experiments with ETC came up with the following findings: exposure of live ETC to pregnant mares can induce abortion, administration of ETC homogenate to early- and late-term pregnant mares can induce abortion, ETCs but not the frass cause MRLS although the dose administered was not similar, integument/skin of ETC may be the anatomical component with the abortifacient property, hairy caterpillar and gypsy moth which have hairs similar to ETC do not induce MRLS abortions, laboratory raised FTC do not induce abortions,

autoclaving destroys abortifacient property in ETC but is conserved at −80°C, irradiation partially reduces the abortifacient potential of ETC and MRLS is not caused by the direct effect of virus or bacteria in ETC. In the studies using irradiated ETC, the bacteria isolated from the aborted fetuses and their membranes did not originate from the ETC. Results of that experiment strongly suggest that an ETC-resident virus is not the cause of MRLS and the abortifacient appears to be a factor other than bacteria and virus in the ETC. The placentitis observed in LFL/MRLS appears to be different from typical ascending placentitis. The specific pathogenesis of MRLS is still unknown. Elimination of ETC in horse pastures and avoiding direct exposure to ETC appear to prevent MRLS.

## INTRODUCTION

The Animal Kingdom is populated by a vast variety of creatures whose main focus in life is to live to see tomorrow. To this end, many animals have developed chemical means of defense and/or food procurement. Every phylum within the Animal Kingdom contains species that produce poisons or venoms. *Poisons* are compounds produced in non-specialized tissues as secondary products of metabolism that accumulate in the host animal or that accumulate in predators following ingestion of prey. *Poisonous* animals, therefore, lack means of actively delivering these chemical compounds to others – exposure generally requires oral contact (rarely dermal) in order for another animal to become poisoned. In contrast, *venoms* are produced in specialized tissues or glands, and *venomous* animals have developed a variety of *venom apparatuses* (stingers, teeth, etc.) to deliver their venom to target animals, a process termed *envenomation*.

Most venoms and poisons are not composed of a single chemical substance, but are mixtures of a variety of chemical compounds that often act synergistically to produce their toxic effect. Typical constituents might include peptides, amines, serotonin, quinones, polypeptides, and enzymes (Russell, 2001). These compounds are collectively termed *toxins* (the science of study of toxins is termed *toxinology*), and toxins produced by members of the Animal Kingdom are collectively termed *zootoxins*.

Not every exposure to a poisonous or venomous animal will necessarily result in a toxicosis (Meier, 1995). Variations in size, age, sex, season, toxin composition, and geographic location can result in zootoxins with relatively more or less toxicity. Similarly, the animal exposed to the zootoxin may be more or less susceptible to toxicosis based on its age, weight, sex, and degree of exposure.

Compared to other means of injury or illness in animals, envenomation or poisoning from zootoxins are relatively rare causes for presentation of domestic animals to their veterinarians, due largely to the protection afforded by animal owners. Wildlife, on the other hand, probably face potential exposure to zootoxins on a nearly daily basis. Bites and stings from arthropods and snakes certainly can occur in any species, and the potential for oral exposure to animals such as poisonous toads, snakes, or insects will vary with the region and environment.

In managing known or suspected zootoxicoses, veterinarians should be mindful to "treat the patient, not the poison." Patient assessment and stabilization, along with supportive care, are critical in managing these patients. Although antivenins are available for treatment of some types of envenomation, financial and availability issues may limit their use in many instances.

## ARTHROPODA

## ARANEAE: SPIDERS

### Introduction

There are at least 30,000 species of spiders distributed throughout the world (Goddard, 2003). Spiders are characterized by a two-segmented body: a head/thorax (prosoma or cephalothorax) and the abdomen (opisthosoma). They have eight segmented legs (Lucas and Meier, 1995b). Venom is stored in two glands located in the cephalothorax and empties through fangs (chelicerae) located at the rostral end of the prosoma (Lucas and Meier, 1995b). With the exception of spiders in the family Ulobiridae (found

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

in Australia), all spiders are capable of inflicting an envenomating bite via fangs. Most spider envenomations, however, are likely to cause few signs other than local swelling and pain. Anaphylaxis and other allergic reactions to venom components are possible (Goddard, 2003). While there is disagreement in literature, it appears that fewer than 100 spider species can inflict a bite of medical significance (Lucas and Meier, 1995b).

## WIDOW SPIDERS (*LATRODECTUS* SPP.)

### Background

Spiders of this genus are found throughout the world. The spiders are identified by a red, yellow, or orange hourglass-shaped marking on the ventral abdomen of the female. Males and immature females are brown; the immature females do not have the hourglass marking. The fangs of the male are considered too short to inflict an envenomating bite to humans or other mammals (Lucas and Meier, 1995b). In the United States, there are five major species of widow spiders (Goddard, 2003):

1. *L. mactans* (black widow spider): These spiders are found throughout the United States but especially in the Southern United States. They prefer dark places, especially under debris such as leaf litter or cardboard.
2. *L. hesperus* (Western black widow spider): Common black widow of the Western United States.
3. *L. variolus* (Northern widow spider): Common in Northern United States; the hourglass mark is not joined.
4. *L. bishopi* (red widow spider, red-legged widow spider): Found in palmetto fronds of sandy, scrub-pine region of Central and Southern Florida. They are brightly colored.
5. *L. geometricus* (brown widow spider): The hourglass is orange in this species. They are an introduced species to the United States found mainly in Florida.

Widow spiders are found mostly outside of living spaces, preferring dark secluded area such as piles of debris, and densely growing plants. Inside houses, they prefer dark, rarely disturbed spaces, and will often settle under appliances and cabinets. Adult spiders are most active in the warm months and will die during the colder months if not in a heated space. They build webs to ensnare prey. In general, widow spiders are shy and do not bite larger animals unless provoked (Goddard, 2003).

### Mechanism of action

Widow-spider venom is a complex mixture of about six neuroactive proteins; there are also some proteolytic enzymes. The principle toxin for mammals is $\alpha$-latrotoxin, a polypeptide that causes a large release and then depletion of acetylcholine and norepinephrine at postganglionic sympathetic synapses (Lucas and Meier, 1995b).

### Toxicity

The venom of widow spiders is extremely potent. For instance, the $LD_{50}$ for whole venom of *L. mactans tredecimguttas* (European black widow) in guinea pigs is 0.0075 mg/kg and for mice is 0.9 mg/kg (White *et al.*, 1995).

The syndrome caused by widow venom is called lactrodectism. Following a widow-spider bite, the venom is taken up by lymphatics and then enters the bloodstream (White *et al.*, 1995). Clinically, there may be short-lived, localized pain at the bite site. Then, in about 30–120 min, myalgia and muscle cramps near the site of envenomation will begin. The pain begins to spread to the large muscles groups of the legs, thorax, back, and abdomen, peaking in about 2–3 h. Mild to moderate hypertension and tachycardia are common. In most cases, signs resolve in 48–72 h but signs such as weakness, fatigue, and insomnia may persist for weeks to months (White *et al.*, 1995; Goddard, 2003).

Cats are very sensitive to the effects of widow venom. In one study, 20 of 22 cats died after widow-spider bites with average survival time of 115 h. Paralysis occurs early in the course; severe pain is evidenced by howling and other vocalizations. Hypersalivation, restlessness, vomiting, and diarrhea were common. Muscle tremors, cramping, ataxia, and inability to stand may precede an atonic paralysis. Cheyne–Stokes respiratory pattern may develop prior to death (Peterson and McNalley, 2006a).

### Treatment

Treatment is largely symptomatic with control of pain by opioids and use of muscle relaxants such as diazepam and methocarbamol to control the muscle rigidity. Calcium gluconate, which was once used for treatment of widow envenomation, is no longer recommended as it was found to be less effective at controlling pain than opioids and muscle relaxants (Clarke *et al.*, 1992; Peterson and McNalley, 2006a). An equine-origin antivenin (Lycovac®, available in the United States from Merck and Co.) has been used in humans. It is generally administered to high-risk patients (the very young or old) or in those whose signs are progressing despite other medical care. The antivenin is extremely effective; in one study, all 58 patients receiving the agent had resolution of signs within 30 min (Clarke *et al.*, 1992). In one case report (Twedt *et al.*, 1999), a cat with suspected lactrodectism was treated with antivenom about 26 h after signs began. The cat rapidly recovered neurologic function.

## RECLUSE OR VIOLIN SPIDERS (*LOXESCELES* SPP.)

### Background

While there are at least 50 species of *Loxesceles*, few are capable of inflicting a medically significant envenomation known as loxoscelism. In the United States, where several *Loxesceles* species occur, the brown recluse spider (*L. reclusa*) is considered the only one of medical importance. *L. reclusa* is found principally in Missouri, Arkansas, Oklahoma, Kansas, and Tennessee, but its range extends from the Southern Gulf states and Southern Atlantic states through Indiana and Illinois. Other species of *Loxesceles* are found principally in the Southwest US and California. In South America, *L. laeta* and *L. gaucho* have been associated with severe loxoscelism in Brazil, Chile, Argentina, Peru, and Uruguay (White *et al.*, 1995). (*L. laeta* now appears to have been introduced into the Los Angeles, California area (Goddard, 2003).) While species of *Loxesceles* may occur in other regions of the world, significant morbidity and mortality has not been associated with these spiders (White *et al.*, 1995). Brown recluse spiders (*L. reclusa*) are nocturnal, non-aggressive spiders. They are recognizable by the "fiddle"-shaped marking on the dorsal surface of the cephalothorax.

### Mechanism of action

The venom of the recluse spider contains several necrotizing enzymes including hyaluronidase, esterases, and alkaline phosphatases. Sphingomyelinase D, a phospholipase, appears to be the most important component; it binds to cell membranes and causes migration and activation of neutrophils in the area of the envenomation. Additionally, the venom inactivates serum hemolytic complement leading to intravascular coagulation, occlusion of small capillaries, and tissue necrosis; systemic depletion of clotting factors (VII, IX, XI, and XII) can also occur (White *et al.*, 1995; Goddard, 2003; Peterson and McNalley, 2006b). Platelet activation can also be seen (Peterson and McNalley, 2006b). Additionally, in the presence of calcium and C-reactive protein, sphingomyelinase D can cause hemolysis. Platelet activation can be seen. Finally, lipases can cause free lipids in the blood which may act as inflammatory mediators and/or cause embolization (Peterson and McNalley, 2006b).

### Toxicity

In one study (Denny *et al.*, 1964), dogs injected with brown recluse venom intravenously developed thrombocytopenia, absence of reticulocytes, and evidence of hemolysis with decreased hematocrit. Necropsy showed widespread petechial and ecchymotic hemorrhage, dehydration, and hypocellular bone marrow with depression of the erythroid and platelet cell lines. Another study (Futrell *et al.*, 1979) of *in vitro* hemolysis found that human and pig erythrocytes were far more susceptible to lysis from brown recluse venom than those of dogs.

Initially, the bite may produce little pain or local reaction. Approximately 3–8 hours after envenomation, the site becomes red, swollen, and tender; this is a so-called "bull's-eye" lesion. A vesicle may form and be replaced by a black scab or eschar. Tissue around the bite may slough leaving a 1–25 cm ulcer. Distribution may occur in areas dependent to the bite due to gravity. Healing is slow and may take months, often leaving a large scar (Goddard, 2003). Diagnosing a brown recluse bite may be difficult if the bite is not witnessed. In many cases, a brown recluse bite is "blamed" for necrotic lesions due to other causes (Mullen, 2002b). Systemic signs, though uncommon, can be seen with a brown recluse bite; they may develop 48–72 h after exposure. Hemolysis with anemia and hematuria, tachycardia, pyrexia, myalgia, vomiting, dyspnea, DIC, and coma have been reported but are rare (Goddard, 2003).

### Treatment

For the necrotic lesion, local wound care including chemical debridment with Burrows solution (aluminum acetate) or hydrogen peroxide and bandaging should be performed. Pruritus may be controlled with diphenhydramine (2.2 mg/kg q8h). Antibiotics, especially if infection is evident, should be administered. Analgesics for pain (NSAIDs for mild, opioids for severe) may be required. Surgical excision, used in the past, is no longer recommended (Peterson and McNalley, 2006b).

Dapsone (4,4'-diaminodiphenylsulfone) may be helpful in limiting the severity of the necrotic lesion as it inhibits neutrophil migration. In dogs, a dose of 1 mg/kg/day for 14 days has been used experimentally. Dapsone can cause methemoglobinemia as well as hemolysis in individuals with G6PD deficiency (Peterson and McNalley, 2006b).

Antivenins are available for South American *Loxesceles* species. Experimental antivenins for *L. reclusa* have been developed. It has shown to be effective if given within 4 h of envenomation. However, this antivenin is not commercially available at this time (Mullen, 2002b).

## HOBO SPIDERS (*TEGENARIA AGRETIS*)

### Background

Hobo spiders are native to Europe but were introduced in the Pacific Northwest in the 1930s. They occur mainly in

Washington, Oregon, and Idaho but their range includes Central Utah through Western Canada to the Alaskan Panhandle. In the 1980s, the appearance of necrotic spider bites in the Pacific Northwest was initially blamed on *L. reclusa* but later the bites were correctly attributed *T. agretis* (Goddard, 2003).

Hobo spiders are poor climbers and build a funnel web at ground levels or in basements. Males will leave their web at night in search of females and may enter houses while doing so. Males are more venomous than females and are more likely to bite (Mullen, 2002a, b; Goddard, 2003).

### Toxicity

In most cases, the bite is initially painless. Within 30 min, a localized expanding area of erythema may occur; the lesion may eventually reach 15 cm in diameter. Then, in about 15–35 h, the area ruptures and there is a serous discharge from the wound. The wound may require 3 years to heal especially if it is in fatty tissue (Goddard, 2003).

In humans, systemic signs may occur in about 45% of bites and about one-third of these may require hospitalization. Signs may include headache (which can last for days), nausea, weakness, and vision changes. The signs may progress to vomiting (often intractable), watery diarrhea, and bone marrow destruction resulting in anemia, pancytopenia, and thrombocytopenia. Fatalities are rare (Mullen, 2002b).

### Treatment

Treatment of the Hobo spider bite is supportive and symptomatic.

## FUNNEL WEB SPIDERS (*ATRAX* AND *HADRONYCHE* SPP.)

### Background

There are approximately 35 species of funnel web spiders. They are all found in Australia, principally distributed along the Southeast coastal region. While all may potentially dangerous to mammals, the Sydney funnel web spider (*A. robustus*) is considered the most dangerous as this is the only species in which human fatalities have been recorded (White *et al.*, 1995). *A. robustus* is found within a 160 km (100 miles) from the center of Sydney. They are large aggressive black spiders (Sutherland and Tibballs, 2001).

### Mechanism of action

The toxic component of the funnel web spider's venom is the neurotoxin, robustoxin, a 42 amino acid protein. The toxin binds to the pre-synaptic neuron and both inhibit central nervous system (CNS) mediated neurotransmitter release while increasing spontaneous release of neurotransmitters; the toxin affects both the autonomic nervous system and skeletal muscles. Other species of funnel web spiders contains structurally similar neurotoxins which are less potent than robustoxin (White *et al.*, 1995).

### Toxicity

There is a wide variation of reaction in different species of animals; the sex of the spider also effects toxicity of the bite. For instance, rats, rabbits, and cats are unaffected by the bite of a female spider while 20% of mice and guinea pigs died after the bite of a female. When mice or guinea pigs are bitten by a male spider, most die. The male funnel web spider's venom appears to be six times more potent than the females based on minimum lethal dose determinations. However, in dogs and cats, male funnel web spider bites cause mild transient effects. Humans and other primates appear to be extremely sensitive to the venom of this spider (Sutherland and Tibballs, 2001).

## TARANTULAS

Tarantulas are large, ground dwelling spiders. During mating season, males wander in search of females and may be more aggressive at these times. In most cases, the bite of the tarantula causes little more than localized pain that develops slowly but usually resolves within 30 min. There are about a dozen genera of tarantulas that may deliver a potentially life-threatening bite. These spiders occur in the tropical regions of South America, Africa, and Australia. Their venom contains a neurotoxin; there may also be a necrotoxin and hemolytic toxin. Following envenomation, muscle spasms, edema, hemoglobinuria, jaundice, and circulatory shock may develop (Mullen, 2002b).

Tarantulas of the family Theraphosidae (bird-eating or whistling spiders) are often kept as pets in Australia and Asia. In one Australian study (Isbister *et al.*, 2003), the bite of these spiders was found to cause only local effects in humans. However, seven dogs bitten by spiders of the genera *Phlogiellus* and *Selenocosmia* died rapidly, often within 2 h of the envenomation. (In two cases, the dog and their owners were bitten by the same spider.) The spiders are also considered highly poisonous for cats. The exact cause of death was not discussed but, based on experimental data, apnea and cardiac arrhythmias may occur.

Species of tarantula living in the United States are not capable of delivering serious envenomation. However, many of these species possess urticating hairs on their abdomen; the hairs possess spines and barbs which can penetrate skin. When threatened, these tarantulas can stroke

their abdomen and flick the urticating hairs at their attacker. The hairs can cause severe inflammation of the skin, eyes, mouth, and respiratory tract. The effect is purely mechanical as there is no toxin associated with the hairs. Urticaria, edema, and vasodilation may occur in the skin. In the eyes, swelling of the lids and corneal abrasions are common (Mullen, 2002b). Dogs or cats attempting to ingest tarantulas may gag or vomit.

## SCORPIONES: SCORPIONS

### Background

Scorpions are arachnids with two body divisions: the combined head and thorax referred to as the prosoma or cephalothorax and the abdomen or opisthosoma. They possess large paired claws or pincers known as pedipalps and four pairs of legs. At the caudal portion of the abdomen, scorpions have a tail that terminates in the telson – a barbed appendage that houses two venom glands that exit via a stinger at the end of the telson. Scorpions are nocturnal hunters; they may spend the day in burrows or hiding under rocks or vegetation. They may also hide in blankets, shoes, and clothing; this a common way for humans to exposed to them (Keegan, 1980).

There are about 1400 species of scorpions occurring on all continents except Antarctica (Goddard, 2003). Most occur in tropical or temperate regions (Lucas and Meier, 1995a). Table 64.1 lists locations and species of scorpions capable of inflicting life-threatening envenomations in humans. The main genera of scorpions found in North America are the bark scorpions (*Centruroides* spp.). They are found primarily in Central America, Mexico, Southern through Southwest United States (Mullen and Stockwell, 2002). In the United States, only *Centruroides exilicauda* (Arizona bark scorpion) is considered capable of inflicting a life-threatening sting (Goddard, 2003).

**TABLE 64.1 Scorpions of medical importance: species and location**

| Location | Species |
|---|---|
| India | *Buthotus tamulus* |
| Mexico and Central America | *Centruroides* spp. |
| Middle East | *Androctonus* spp.<br>*Buthus* spp.<br>*Hemiscorpion lepturus*<br>*Leiurus quinquestriatus*<br>*Mesobuthus gibbosus* |
| South Africa | *Parabuthus* spp.<br>*Buthus minax* |
| South America | *Tityus* spp.<br>*Centruroides gracilis* |
| United States | *Centruroides sculpturatus* |
| West Indies (Trinidad) | *Tityus trinitatis* |

Adapted from Lucas and Meier (1995a) and Keegan (1980).

### Mechanism of action

All scorpions can deliver an envenomating sting (Keegan, 1980). Scorpion venom components vary greatly between genera and may even differ based on geographic location within species (Mullen and Stockwell, 2002). The venom consists of a mixture of low molecular weight polypeptides. At least two potent neurotoxins have been identified: $\alpha$-scorpion toxin found in *Androctonus*, *Leiurus*, and *Buthus* spp. and $\beta$-scorpion toxin found in *Centruroides* spp. Both toxins can be found in the venom of *Tityus* spp. These venoms block the voltage-sensitive sodium and potassium channels in nerves (Mullen and Stockwell, 2002).

### Toxicity

Scorpion stings cause instant, sharp pain at the site of envenomation. Some stings will cause localized pain that resolves over hours. Localized edema and pruritus are common. Regional lymph nodes may enlarge, there may be an allergic reaction characterized by swelling of the eyelids, tongue, and vomiting. Sloughing of the skin at the site of envenomation can also occur (Mullen and Stockwell, 2002). Signs usually resolve within 24 h (Keegan, 1980). Systemically, signs can vary but generally include numbness of face, myalgia, tachycardia or bradycardia, respiratory depression, and seizures; however, there is a lack of evidence that scorpion envenomation in dogs and cats is a serious concern (Mullen and Stockwell, 2002).

### Treatment

The treatment of scorpion stings, in most cases, consists of analgesics and local wound care. Systemic signs are treated symptomatically with control of hypertension, heart rate changes, and neurologic signs. Some antivenoms in the United States are produced locally; however, since these are not FDA approved they cannot legally be transported to another state (Goddard, 2003). In addition, their use in veterinary patients is considered controversial (Dalefield and Oehme, 2006).

## IXODIDA: TICKS

### Background

Ticks are well known as being vectors for a large number of human and animal diseases, with the first reports of tick

paralysis originating in Australia in 1890 and British Columbia in 1912 (Sonenshine *et al.*, 2002). Worldwide, 43 species of ticks from nine different genera have been associated with tick paralysis: *Amblyomma*, *Argas*, *Dermacentor*, *Haemaphysalis*, *Hyalomma*, *Ixodes*, *Ornithodoros*, *Otobius*, and *Rhipicephalus* (Dipeolu, 1976; Fowler, 1993). Tick paralysis has been reported in North America, Europe, Africa, Australia, and the former Soviet Union.

### Mechanism of action

The exact mechanism(s) of action of tick toxins is(are) not well known, but in most tick species it is suspected that the toxin interferes with the synthesis and/or release of acetylcholine at the neuromuscular junctions, resulting in lower motor neuron paresis and paralysis very similar to that produced by botulinum toxin (Fowler, 1993; Grattan-Smith *et al.*, 1997). The Australian tick, *Ixodes holocyclus*, toxin may differ, as it appears to have more of an effect on central nerve centers rather than peripheral (Fowler, 1993).

### Toxicity

Tick paralysis has been reported in a large variety of animal species, including dogs, cats, cattle, sheep, goats, llamas, poultry, wild antelope, bison, foxes, wolves, mice, ground hogs, black-tailed deer, and several species of wild birds (Fowler, 1993; Beyer and Grossman, 1997; Sonenshine *et al.*, 2002). In the North America, most cases of tick paralysis in livestock occur in the Pacific Northwest due to *Dermacentor andersoni*, while most cases in dogs are due to *D. variabilis* (Fowler, 1993; Sonenshine *et al.*, 2002). *D. occidentalis* occasionally causes tick paralysis in cattle, ponies, and deer but not dogs (Sonenshine *et al.*, 2002). In the Southeastern United States, *Ixodes brunneus* has been associated with tick paralysis in wild passerine birds (Luttrell *et al.*, 1996). In Australia, tick paralysis is caused by *I. hyolocyclus*, while *I. rubicundus* and *Rhipecephalus evertsi* are the primary species responsible for tick paralysis in Africa (Sonenshine *et al.*, 2002). Tick paralysis in Europe and Asia has been reported due to bites from *Hyalomma punctata* and *I. ricinus.*

Tick paralysis has occurred following the bite of as few as one tick and heavily infested animals may succumb quickly (Fowler, 1993). Clinical signs include an ascending ataxia that progresses to paresis and flaccid paralysis. Early in the intoxication, animals remain bright, alert, and able to eat and drink if properly supported. Eventually, paralysis of the respiratory muscles leads to respiratory failure and death. Paralysis produced by *I. holocyclus*, the Australian tick, generally occurs more rapidly and tends to persist following removal of the tick.

### Treatment

The main goal of treatment is to remove the ticks and provide supportive care (especially respiratory support) until recovery occurs. Recovery can occur quite rapidly following complete removal of the ticks, or it may take a few days (Fowler, 1993). The use of topical insecticides may aid in the removal of ticks, and can be especially helpful in cases where numerous ticks are embedded. Heavily coated animals may need to be shaved in order to ensure that all embedded ticks are found and removed. Removal of embedded ticks should be performed carefully to avoid expressing additional toxin into the wound or leaving the head embedded in the skin. Forceps may be used to grasp the tick as close to the skin as possible and gentle traction should be used to remove the tick. In most cases where ticks are removed before bulbar paralysis has occurred, the prognosis for full recovery is very good. A short-term immunity develops following recovery from tick paralysis. In Australia, a polyclonal dog antiserum has been developed to treat tick paralysis, but it is only effective early in the stages of paralysis (Masina and Broady, 1999).

## MYRIAPODA: CENTIPEDES AND MILLIPEDES

Centipedes and millipedes are distantly related to lobsters, crayfish, and shrimp. These arthropods are widely distributed throughout the world and vary, and are characterized by a long, flat, multi-segmented body with one (centipede) or two (millipede) legs emerging from each body segment. Although most centipedes and millipedes are less than 1.5 in. long, centipedes from the genus *Scolopendra* may grow to be 4–6 in. long. All centipedes have a pair of modified front legs (forcipules) that serve as fangs and that are connected to venomous glands directly under the head (Norris, 2004). Larger centipedes have the ability to inflict painful bites resulting in local swelling, erythema and lymphangitis (Stewart, 1985). Additionally the legs of *Scolopendra* spp. are tipped with sharp claws that are capable of penetrating skin, and toxin produced at the attachment point of each leg may drop into these wounds, causing inflammation and irritation.

Centipede venom has been poorly studied but components identified in various centipedes include serotonin, a cytolysin, a hemolysin, and a vesicating agent (Deng *et al.*, 1997; Norris, 2004). In most cases systemic toxicosis is not expected, although local necrosis may occur (Russell, 1996); a single case report exists of a human fatality from the bite of *Scolopendra subspinipes* (Norris, 2004). Signs generally subside within 48 h and rarely require more than symptomatic care (e.g. analgesics). Millipedes do not bite, but can emit irritating and foul-smelling secretions from repugnatorial glands; some species can spray these fluids over

distances of several inches. These secretions are irritating to mucosal surfaces, particularly the eyes, and corticosteroids have been recommended to decrease the inflammatory response (Russell, 1996).

# INSECTS

## Introduction

Insect and insect-related problems are common in domestic and wild animals. Insects such as lice, fleas, deer flies, horse flies, sand flies, mosquitoes, black flies, biting midges, and sand flies may cause severe annoyance to animals because of biting behavior. Members of several groups of insects can inject venom when they bite or sting, most notably bees, wasps, and ants. Bites or stings from insects such as lice, fleas, bees, ants, wasps, mosquitoes, and chiggers may cause direct effects from the venoms or may result in allergic host reactions resulting from over-responsive host immune systems. Contact allergies may occur when certain beetles or caterpillars touch the skin. Other insects, such as blister beetles and certain caterpillars, produce toxins that can cause adverse reactions when they are touched or ingested (Durden and Mullen, 2002). Respiratory allergies can result from inhaling allergic air-borne particles from cockroaches, fleas, or other arthropods (Durden and Mullen, 2002). Some insects invade the body tissues of their host. Various degrees of invasion may occur, ranging from subcutaneous infestations to invasion of organs such as the lungs and intestine (Durden and Mullen, 2002). Table 64.2 provides a list of nine orders of insects that are of particular interest to veterinary entomologists.

# COLEOPTERA: MELOIDAE (BLISTER BEETLES)

## Background

More than 300,000 species of beetles have been described, representing 30–40% of all known insects. About 25,000 species of beetles occur in the United States and Canada (Krinsky, 2002). Fewer than 100 species of beetles worldwide are known to be of public health or veterinary importance. Most of these are in the suborder Polyphaga. The species that have the greatest impact on the health of human and domestic animals are in the following families: Melidae (blister beetles), Oedemeridae (false blister beetles), Staphylinidae (rove beetles), Tenebrionidae (darkling beetles), Dermestidae (larder beetles), and Scarabaeidae (scarab or dung beetles) (Krinsky, 2002).

Most blister beetles are in the family Melidae, although some are in the Staphylinidae family. Blister beetles are elongate, soft-bodied specimens in which the pronotum (section between head and wings) is narrower than the head or wings. Two of the common blister beetle species are potato beetles, one with orange and black longitudinal stripes and one black with gray wing margins (Goddard, 2003). Members of the genus *Mele* are called oil beetles because they exude an oily substance from their legs when disturbed. Oil beetles are approximately 20–25 mm long and black, with no hind wings, giving the appearance that their wings are too short (Goddard, 2003).

Species that pose problems in the United States include the striped blister beetle (*Epicauta vittata*), the black blister beetle (*E. pennsylvanica*) (Figure 64.1), the margined blister beetle (*E. pestifera*), and the three-striped blister beetle (*E. lemniscata*), as well as *E. fabricii*, *E. occidentalis*, and *E. temexa*. Of these the most common species associated with

**TABLE 64.2 Insects of veterinary importance**

| Order | Common names | Clinical significance |
|---|---|---|
| Coleoptera | Beetles | Toxic beetles (e.g. blister beetle); vectors for pathogenic organisms; intermediate host for nematodes, flukes, cestodes, acanthocephalans |
| Dictyoptera | Cockroaches | Intermediate hosts nematodes, flukes, cestodes, acanthocephalans; vectors for pathogenic organisms |
| Diptera | Flies, mosquitoes | Vectors for pathogenic organisms; myiasis; decreased production due to annoyance or anemia from biting/sucking insects |
| Hemiptera | True bugs | Transmission of infectious agents (e.g. trypanosomiasis); decreased production due to anemia from blood-sucking bugs |
| Hymenoptera | Wasps, hornets, ants, and bees | Envenomation, allergy from bites or stings; poisonous insects (e.g. sawfly larvae) |
| Lepidoptera | Moths and butterflies | Urticaria, irritation, ulceration from urticating hairs; poisonous insects (e.g. monarch butterfly) |
| Phasmida | Stick insects and leaf insects | Irritation from secretions of walkingsticks |
| Phthiraptera | Lice | Decreased production due to annoyance or anemia; vector for pathogenic organisms |
| Siphonaptera | Fleas | Decreased production due to annoyance or anemia; vector for pathogenic organisms |

**FIGURE 64.2** An adult blister beetle (*Epicauta*), with hemolymph droplets containing cantharidin. This figure is reproduced in color in the color plate section. (Photo courtesy of Dr. Maria Eisner, Cornell University.)

toxicosis are *E. occidentalis* and *E. temexa* (Stair and Plumlee, 2004).

## Mechanism of action

The toxic principle in melioid beetles, cantharidin, has the formula $C_{10}H_{12}O_4$ and is a bicyclic terpenoid (Goddard, 2003; Stair and Plumlee, 2004). The concentration of cantharidin present in beetles varies from 1% to 5% of the dry weight of the beetle. Males always have a higher concentration because the male produces the cantharidin and transfers a quantity to the female during copulation (Krinsky, 2002). Cantharidin is present in the hemolymph as well as in the clear, yellow secretion that is exuded at the joints of the legs of these beetles by reflex bleeding (Figure 64.2).

The mechanism of action of cantharidin may involve interference with enzyme systems responsible for active transport across mitochondrial membranes, resulting in membrane disruption and permeability changes. Mitochondrial damage results in cellular disruption, acantholysis and vesicle formation. Cantharidin also has been shown to inhibit protein phosphatase 2A, resulting in disruption of signal transduction and cell metabolism (Stair and Plumlee, 2004).

Purified, crystalline cantharidin is a potent vesicating agent that is readily absorbed through the gastrointestinal mucosa and, to a lesser degree, the skin, and is eliminated unchanged through the kidneys (Krinsky, 2002).

## Toxicity

Adult blister beetles feed on flowering foliage, especially blooming alfalfa (*Medicago sativa*). Blister beetles in alfalfa fields contain enough cantharidin to provide lethal doses to livestock that feed on forage when it is used as hay. Modern methods of hay harvesting, especially crimping, decrease the opportunity of blister beetles to vacate the foliage before it is incorporated into hay, thereby increasing the likelihood of blister beetles being trapped in the hay (Stair and Plumlee, 2004). Cantharidin released from crushed adult blister beetles may contaminate hay without visual evidence of insect parts. Cantharidin is very stable and may persist in hay for long periods of time. Because in the United States alfalfa is most widely grown in the South, cantharidin toxicosis is most commonly found in the Southern states; however, due to interstate transport of alfalfa hay across the country, cantharidin toxicosis could potentially occur in any state.

Horses are the species in which cantharidin toxicosis is most commonly reported. However, the following hosts have also been poisoned in natural or experimental situations: cattle, sheep, goats, rabbits, rats, hedgehogs, dogs, and emus. Poisoning in human beings has been noted for decades and is usually the result of either improper medicinal use of cantharides or malicious poisoning (Krinsky, 2002). Horses are considered to be particularly susceptible to the effects of cantharidin (Stair and Plumlee, 2004). The estimated lethal dosage of cantharidin for the horse is approximately 0.5–1 mg/kg, and as little as 4 g of dried beetles may be lethal to a horse (Krinsky, 2002). The oral experimental lethal dosage of crystalline cantharidin for dogs and cats was 1.0–1.5 mg/kg and 20 mg/kg for rabbits. It is estimated that the lethal dosage for a human being is less than 1.0 mg/kg.

Cantharidin produces an intense, direct irritant effect on the skin and mucous membranes of the esophagus, stomach, and intestines. Once absorbed, the toxin may affect many different organs. Excretion is via the kidneys, resulting in transfer of the irritant effect to the urinary tract, particularly the bladder and urethra (Krinsky, 2002).

Clinical signs will vary with the dose ingested. Massive doses may cause shock and death within 4 h (Krinsky, 2002). Smaller doses may cause gastroenteritis, nephrosis, cystitis, and/or urethritis; thus, signs may include anorexia, soft feces, mucoid to bloody feces, intestinal atony, colic, dysuria (frequent, painful urination, or oliguria to anuria), and hematuria. The body temperature may elevate to 106°F (41.1°C). Other signs observed include depression, weakness, muscle rigidity, collapse, prostration, dehydration, and sweating (Krinsky, 2002). Animals frequently become dyspneic and rales may be detected on auscultation due to pulmonary edema. Myocarditis may initiate cardiovascular signs including tachycardia, congested mucous membranes, and decreased capillary refill time. Synchronous diaphragmatic flutter and muscle fasciculations have been reported in horses and are thought to be a result of hypocalcemia (Stair and Plumlee, 2004). Ulceration of the oral mucosa membranes may be observed and animals may be seen dipping their muzzles into water without drinking (Krinsky, 2002). Diarrhea may be observed in animals that live for a few days. The course of the disease may be as short as 4 h, with massive dose ingestion, to 5 days in lethal poisoning. In horses, the mortality rate is approximately 50%, with horses surviving more than 1 week having a favorable prognosis (Krinsky, 2002).

In both field cases and experimental cantharidin poisoning, there are elevations in serum protein and packed cell volume caused by dehydration and shock. The damaged gastrointestinal mucosa allows rapid invasion of enteric bacteria, resulting in bacteremia and leukocytosis. There may be mild elevation in serum urea nitrogen. Profound hypocalcemia (5.9 mg/dl, normal 12.8 $\pm$ 1.2) and hypomagnesemia (0.7–1.8 mg/dl, normal 2.5 $\pm$ 0.3) have been reported. Specific gravity of urine is low in the early stages of the disease, and erythrocytes are usually present in the urine, yielding a positive occult blood reaction.

Gross lesions may be minimal with massive dose ingestion. In more protracted cases, oral ulcers, vesication, and desquamation of patches of the distal esophagus, erosions, and ulceration of the gastrointestinal tract, mucus in the renal pelvis, and renal cortical hemorrhages may be seen. Hyperemia and hemorrhages are seen in the urethra and bladder mucosa. Ventricular myocarditis, pulmonary edema, petechial hemorrhages of serosal surfaces, hepatomegaly, and splenomegaly may also be present.

The initial microscopic lesion is acantholysis of mucosa of the gastrointestinal tract, epithelium of the urinary tract, and endothelium of vessels (Krinsky, 2002). Other microscopic lesions include myocarditis, renal tubular nephrosis, and degenerative changes in the kidneys and digestive tract.

Cantharidin may be detected in urine, tissue (kidney and blood), gastrointestinal contents, and the dried beetles themselves by high-pressure liquid chromatography (HPLC), or gas chromatography/mass spectrometry (GC–MS). Cantharidin is excreted rapidly and may not be present in detectable amounts after 4–5 days following ingestion (Krinsky, 2002).

### Treatment

There is no specific treatment. The administration of either activated charcoal or mineral oil (but not together) via a gastric tube may aid animals that have consumed a small dose or are in the early stages of poisoning. General supportive therapy should include correction of fluid loss and electrolyte imbalances, particularly hypocalcemia and hypomagnesemia (Krinsky, 2002).

Broad-spectrum antimicrobial therapy may be necessary to counter secondary bacterial invasion from the gastrointestinal tract. Aminoglycoside antibiotics and others that are potentially nephrotoxic or that are excreted via the kidney should be avoided, as nephrosis is a potential effect of cantharidin.

## COLEOPTERA: FIREFLIES

### Background

Fireflies of the genus *Photinus* have been reported to cause death when fed to captive reptiles and amphibians (Knight *et al.*, 1999).

### Mechanism of action

Lucibufagins, steroidal pyrones structurally related to cardiotoxic bufodienolides of toads, have been isolated from the bodies of *Photinus*. It is suspected that lucibufagins have cardiotoxic effects similar to bufodienolides, i.e. they inhibit sodium–potassium ATPase activity in the myocardial cell membrane in a mechanism similar to digitalis (Brubacher *et al.*, 1999).

### Toxicity

It is likely that the lucibufagins protect the fireflies from predation from birds and spiders (Knight *et al.*, 1999). Reported cases of firefly toxicosis have occurred when captive reptiles and amphibians were fed the fireflies by their owners. As few as one firefly has caused death in lizards. Toxicosis has been reported in bearded dragons (*Pogona* spp.), an African chameleon (*Chamaleleo* spp.), White's tree frogs (*Litoria caerulea*), and a *Lacerta derjugini* lizard.

Within 5–90 min of being fed fireflies, affected lizards displayed head shaking, oral gaping, dyspnea, skin color change to black, and regurgitation, with death occurring as rapidly as 15 min postingestion (Knight *et al.*, 1999).

No gross lesions were reported in animals presented for postmortem.

### Treatment

Because of the rapid onset of signs and rapid progression to death, no veterinary care could be instituted in the reported cases (Knight *et al.*, 1999). Treatment for affected animals would include management of any cardiac arrhythmias and general supportive care. As the lucibufagins are similar in structure to bufodienolides, in theory one would expect that digoxin-specific Fab fragments (e.g. Digibind®) might be of benefit in treating animals with firefly toxicosis (Brubacher *et al.*, 1999). However, given the rapid development and progression of clinical signs following ingestion of fireflies, the prognosis in most cases will be poor.

## COLEOPTERA: OTHER TOXIC BEETLES

Ingestion of rove beetles, *Paederus fuscipes* (Staphylinidae), has resulted in toxicosis in horses and cattle in Southeast Asia (Krinsky, 2002). Pederin, a toxin more potent than *Latrodectus* spider venom, can cause severe vesicular damage to the mucosa of the alimentary tract. Ingestion of the rose chafer (*Macrodactylus subspinosus*), a member of the Scarabaeidae, has been associated with deaths in chickens, ducklings, goslings, and young turkeys in North America, although modern confinement poultry production operations have largely reduced the risk of toxicosis.

In Michigan, a dog that ingested large numbers of Asian ladybeetles (*Harmonia axyridis*) developed severe shock, cyanosis, rapid pulses, and lateral recumbency (Hoenerhoff *et al.*, 2002). The dog subsequently died, and on postmortem, large numbers of partially digested and intact Asian ladybeetles were detected in the small and large intestines associated with severe hemorrhage, thickening and ulceration of the jejunum and ascending colon. There was a pungent odor to the gastrointestinal contents that mirrored the foul-smelling fluid that Asian ladybeetles can produce when disturbed. Asian ladybeetles were introduced as a biologic control agent and are spreading rapidly throughout the United States.

## HYMENOPTERA: BEES, WASPS, AND HORNETS

### Background

Bee and wasp stings caused approximately 23 human deaths per year in the United States during the 1950s (Akre and Reed, 2002). During that same period, approximately 13 individuals per year died of snakebite. No statistics are available for fatal bee or wasp stings in animals. Over 20,000 species of bees are distributed throughout the world (Fowler, 1993). The honeybee, *Apis mellifera*, is one of two domesticated insect species (the other is the silk worm, *Bombyx mori*). Native honeybees in tropical Southeast Asia were the source of the domestic honeybee. When early American colonists imported European strains of the honeybee to the Virginia Colonies, the bees became known as European honeybees. Africanized honeybees (*A. mellifera scutellata*) are a subspecies of the common honeybee native to Africa that has spread from South and Central America up into South Texas, New Mexico, Arizona, Nevada, California, and Puerto Rico (Akre and Reed, 2002).

### Mechanism of action

There are numerous variations in the venom apparatus of members of Hymenoptera (Fowler, 1993). The stinger is a modification of the ovipositor apparatus and is found only in female bees and wasps. Venom secreted from specialized cells in the acid glands is transported to the venom sac reservoir via small tubules. One-way valves in the bulb of the venom apparatus control the flow of venom during envenomation. At the time of venom injection, the alkaline gland contributes a secretion that enhances the toxicity of the venom. The stinger of the honeybee is covered with retrograde barbs that cause the stinger to remain impaled in thick-skinned victims. When this occurs and the bee attempts to withdraw, the entire stinger apparatus is pulled from the bee, resulting in death of the honeybee.

Honeybee venoms are complex mixtures of proteins, peptides, and small organic molecules (Akre and Reed, 2002). Phospholipases and hyalouronidases present in the venom account for the majority allergic responses to bee venoms in humans and likely other animals as well. Phospholipase A2 is one of the most lethal peptides in honeybee venom (Schmidt, 1995). Mellitin is a membrane disruptive compound that increases the susceptibility of cell membranes to the damage caused by phospholipases within the venom (Akre and Reed, 2002). Mellitin also can cause pain, trigger hemolysis, increase capillary blood flow, increase cell permeability, and enhance spread of venom constituents within tissue. Mellitin, in combination with phospholipase and a mast cell degranulating peptide, triggers the release of histamine and serotonin. In mice, mellitin was found to be the primary lethal component of honeybee venom (Schmidt, 1995). Apamin is a neurotoxin that blocks calcium-activated potassium channels and has been associated with transient peripheral nerve effects in humans after bee stings (Saravanan *et al.*, 2004). In cats, bee venom can cause contraction of bronchiolar muscles.

Like honeybees, vespid wasps (including yellow jackets and hornets) produce venoms containing peptides, enzymes and amines designed to trigger pain (Akre and Reed, 2002). The primary pain-inducing substances are kinins; however, other compounds present in vespid venom, such as serotonin, histamine, tyramine, catecholamines, and acetylcholine, can contribute to the pain as well as local vasoactivity. Several of the constituents of vespid venom can act as allergens and trigger allergic reactions. Some vespid venoms contain neurotoxins or alarm pheromones that alert the swarm to an intruder.

## Toxicity

Honeybees can inflict only a single sting, but an animal attacked by a swarm or hive of bees may sustain multiple stings and the cumulative envenomation may be lethal. The Africanized honeybee (*A. mellifera scutellata*) presents a special case. Although its venom is no more toxic than that of the domestic honeybee, the aggressive behavior of the African honeybee increases the likelihood of multiple stings occurring by swarms of these bees (Akre and Reed, 2002). Wasps and hornets either lack a barbed stinger or the barbs are small and do not prevent withdrawal of the stinger. Therefore, a single wasp may inflict multiple stings. Also, because many wasps are highly social, multiple stings are commonplace.

A sting by a single bee or vespid rarely causes more than a transient, painful prick in animals, in contrast to humans, where sensitive individuals may die peracutely from a single sting. However, death following a single bee sting has been reported in a dog (Fowler, 1993). Deaths following attacks on livestock by Africanized bees have been reported, although the majority of interactions between livestock and bees or wasps result in only local reactions. Yellow jacket envenomation leading to skin lesions and death has been reported in a group of pigs (Fowler, 1993).

Local reactions to single bee, hornet, or wasp stings consist of swollen, edematous, and erythematous plaques at the site of the sting (Fowler, 1993). Most small animal patients present with facial, periorbital, and/or aural edema. Honeybee stingers will occasionally be located embedded in the area, and a small abscess may form at the site. In the Middle East, the German wasp, *Vespula germanica*, has been observed to injure the teats and udders of dairy cattle, causing lesions which can lead to mastitis. Apparently the wasps served as a vector in spreading *S. dysgalactiae* infection in the herds (Yeruham *et al.*, 1998).

Multiple stings may produce numerous wheals, urticaria, and in severe cases may cause severe systemic responses as direct toxic effects of the venom. Systemic effects reported in dogs following multiple stings from bees or vespids include prostration, convulsions, CNS depression, shock, hyperthermia, bloody diarrhea, bloody vomiting, leukocytosis, intravascular hemolysis, disseminated intravascular coagulopathy, and elevations of blood urea nitrogen (BUN), and alanine transaminase (ALT), suggesting renal and hepatic involvement (Wysoke *et al.*, 1990; Cowell *et al.*, 1991; Fowler, 1993). Hepatic injury in cats has also been reported following exposure to hornet venom. Acute lung injury similar to the human acute respiratory distress syndrome (ARDS) developed in a dog following envenomation by over 100 bees (Walker *et al.*, 2005).

The classic anaphylactoid response to bee and vespid venoms that is not uncommon in humans has not been documented in livestock, but anaphylaxis in dogs due to bee stings has been reported (Akre and Reed, 2002). Immune-mediated hemolytic anemia secondary to bee envenomation developed in two dogs (Noble and Armstrong, 1999). Clinical signs included lethargy, hematuria, ataxia, and seizures, and one dog died. Clinicopathologic data included non-regenerative anemia, spherocytosis, and positive results for Coomb's test, and occult hematuria. Treatment included oral administration of corticosteroids at immunosuppressive dosages and supportive care. The surviving dog initially responded to corticosteroids, but hemolysis recurred as the dosage was tapered. Hemolysis resolved with prolonged administration of corticosteroids.

## Treatment

Ideally, when an insect has stung an animal, identification of the insect should be attempted. Most often, stings occur in areas that are free of hair or have short hair. For bee stings, the site should be examined to determine if any part of the stinger remains. Retained stingers should be scraped away from the injection site; grasping the stinger with forceps may result in more venom being expressed into the injection site. Cold compresses may be used as first aid to relieve pain and swelling. Antihistamines and corticosteroids are thought to have questionable value once lesions have developed, but are not contraindicated (Fowler, 1993). Patients should be monitored for development of systemic or anaphylactic reactions, which need to be treated promptly and aggressively. Epinephrine may be used in cases where anaphylaxis is suspected. In cases of true systemic toxicosis, aggressive intravenous fluid therapy is recommended using balanced fluid solutions. Other treatments that have been recommended include corticosteroids, antihistamines, oxygen for dyspnea, and diazepam as needed for convulsions (Fowler, 1993). Renal and hepatic function should be monitored in animals that develop systemic reactions. In most cases exposure to single stings from bees and vespids is rarely fatal.

# HYMENOPTERA: ANTS

## Background

There are more than 10,000 species of ants, some of which bite, some of which sting, and others that both bite and sting. Some ants that lack a sting have the ability to spray formic acid, which can cause local irritation to the victim if it gets in the eyes or wounds produced by the ant's mandibles.

Multiple stings from venomous ants have resulted in the death of pets, livestock, and wild animals in North, Central, and South America (Fowler, 1993). The red imported fire ant, *Solenopsis invicta*, is the most important species in terms of envenomation of animals. This ant was native to Brazil but entered the United States in the 1940s, where it has become a serious pest in the Southeast as far West as Texas.

## Mechanism of action

Ant venoms, like bee venoms, are complex mixtures of compounds that can induce a variety of adverse effects in animals. Fire ant venoms consist largely of alkaloids with less than 1% proteinaceous component (Akre and Reed, 2002). The alkaloids consist of solenopsins (methyl-*n*-alkylpiperidines) and a piperidine which cause dermal necrosis when injected in skin. These alkaloids have cytotoxic, hemolytic, fungicidal, insecticidal, and bactericidal properties.

## Toxicity

Animals most likely to be severely affected by fire ants tend to be those that are unable to move away from a colony and would include those that are neonatal, juvenile, or disabled. Attacks of fire ants resulting in deaths of newborn game animals such as rabbits and deer have been reported (Akre and Reed, 2002). Nesting bird chicks and newly hatched quail and poultry have been killed (and often eaten) by fire ants (Fowler, 1993).

Clinical effects of fire ant envenomation include intense pain at the site of the sting. In humans, within minutes of a sting there is formation of an urticarial wheal, which progresses to a vesicle then a pustule within 24 h (Fowler, 1993). Within a few days, the pustule will rupture, resulting in a crusting lesion. Dogs do not appear to develop the pustules described in humans, instead they develop erythematous pruritic papules that generally resolve within 24 h (Rakich *et al*., 1993). There are no reports of anaphylaxis in animals secondary to fire ant stings (Akre and Reed, 2002). Multiple stings may result in systemic signs similar to those of multiple bee or wasp stings.

## Treatment

Single bites from fire ants generally require no treatment. Multiple envenomations resulting in severe systemic reactions or anaphylaxis should be managed similarly to systemic reactions to bee stings (i.e. fluids, corticosteroids, supportive care).

# HYMENOPTERA: SAWFLIES

## Background

Sawflies are primitive hymenopterans belonging to the suborder Symphyta and are widely distributed around the world. Sawfly poisoning has been reported in livestock in Denmark by *Arge pullata*, in Australia by *Lophotoma* spp., and in Uruguay by *Perreyia flavipes* (Fowler, 1993; Thamsborg *et al*., 1996; Dutra *et al*., 1997).

## Mechanism of action

Sawfly larvae harbor D-amino acid containing peptides that are considered the toxic principle in sawfly larvae poisoning, which results in hepatic, and occasionally renal, degeneration, and necrosis (Oelrichs *et al*., 1977). Lophyrotomin, an octapeptide structurally similar to cyclic peptide hepatotoxins from *Amanita* mushrooms (Thamsborg *et al*., 1996), is the major toxin found in the Australian and Danish sawfly larvae (Oelrichs *et al*., 1977). The bile acid transport system is important in the hepatocellular uptake of lophyrotomin, which causes a periportal hemorrhagic necrosis of the liver (Oelrichs *et al*., 2001; Chong *et al*., 2002). Pergidin, a heptapeptide containing a phosphoseryl residue, is the major toxin found in the South American sawfly. In contrast to lophyrotomin, pergidin causes a periacinar coagulative necrosis in the liver (Oelrichs *et al*., 2001).

## Toxicity

In natural outbreaks, deaths have occurred in livestock, primarily sheep and cattle, when large numbers of sawfly larvae have been ingested. In Australia, outbreaks have occurred in Queensland, where large forests of silver-leaf iron bark trees (*Eucalyptus melanophloia*) provide sustenance for *Lophorotoma interrupta* (Dutra *et al*., 1997). Large piles of larvae accumulate on the ground under the trees and are ingested by cattle and sheep. In Denmark, a similar outbreak in sheep and goats involving the sawfly *Arge pullata* occurred associated with birch trees (*Betula pendula*) heavily infested with larvae. Outbreaks of sawfly

poisoning of cattle, sheep, and pigs in Uruguay were associated with masses of *Perreyia flavipes* crawling through grass in orderly columns. In Uruguay, sheep were reported to be less frequently affected than cattle. Mortality rates on affected farms have been reported to range from 1.3% to 28% (Dutra *et al.*, 1997).

Minimum lethal dosages of lophyrotomin and pergidin when dosed intraperitoneally in C57/B16 male mice were 8 and 32 mg/kg, respectively (Oelrichs *et al.*, 2001). Administration of intact *P. flavipes* larvae to pigs, calves, and lambs resulted in mortality (Dutra *et al.*, 1997). Deaths occurred in pigs and calves at dosages of 40 g of larvae per kilogram body weight. Sheep administered 10, 20, and 40 g of larvae per kilogram body weight died at 68, 43, and 14 h, respectively. One calf administered 9 g of larvae per kilogram body weight developed diarrhea and became depressed, anorexic, and ataxic, but recovered 10 days following dosing. The toxicity of live and dead larvae is equivalent.

Livestock ingesting sawfly larvae may be simply found dead without prodromal signs (Dutra *et al.*, 1997). Clinically, affected cattle may develop weakness, muscle tremors, depression, agitation, aggression, stupor, and death within 2–7 days. Icterus and mild photosensitization were reported in some cattle that survived. In sheep and goats, clinical signs included depression, anorexia, ataxia, recumbency, and death (Thamsborg *et al.*, 1987).

Clinical laboratory abnormalities associated with sawfly larvae poisoning include elevations in liver enzymes aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, and gamma glutamyltransferase (Thamsborg *et al.*, 1996).

Massive hepatic necrosis was the primary postmortem lesion found in cattle and sheep, while renal tubular degeneration was occasionally identified in sheep (Thamsborg *et al.*, 1987; Dutra *et al*. 1997). Lesions secondary to hepatic failure included widespread hemorrhage, icterus, and photosensitization (Dutra *et al.*, 1997).

### Treatment

Management of sawfly larvae poisoning would include removing animals from the source of the larvae and providing symptomatic and supportive care. Administration of silymarin (44–58 mg/kg IV) in combination with penicillin (200,000 IU/kg IV) and glucose (20 g/lamb) at 7 and 24 h following dosing with sawfly larvae prevented clinical signs of toxicosis and significant liver enzyme changes in experimental lambs (Thamsborg *et al.*, 1996). Lambs receiving larvae along with glucose and penicillin without silymarin developed a milder course of clinical illness and lower liver enzyme changes than untreated control lambs administered sawfly larvae.

## LEPIDOPTERA: BUTTERFLIES AND MOTHS

Caterpillars of many species of moths and butterflies may possess hairs and spines on their surfaces that can trigger urticarial reactions in humans and animals (Mullen, 2002a). Necrosis and partial sloughing of the tongue was reported in three dogs in Israel following exposure to the pine processionary moth (*Thaumetopoea wilkinsoni*); early signs included vomiting, swelling of the tongue, dyspnea, hyperthermia, tachypnea, cyanosis, lingual edema, labial angioedema, ptyalism, bilateral submandibular lymphadenopathy, and conjunctivitis (Bruchim, 2005). All dogs survived following symptomatic care. Caterpillars of monarch butterflies that feed on milkweed plants may accumulate the cardiotoxic glycosides from the plant into their bodies (Fowler, 1993). Upon metamorphosis into monarch butterflies, the glycosides are localized to the wings, and predatory animals such as birds, lizards, and small mammals may be poisoned if they ingest the monarchs.

## PHASMATODEA: WALKINGSTICKS

Ulcerative keratitis has been reported when dogs encountered the two-striped walkingstick (*Anisomorpha buprestoides*). These insects are distributed through Florida and the Gulf coastal plain west to Texas and possess defensive glands that produce a lachrymogenic and irritation substance. When annoyed, the walkingstick will spray this secretion at its harasser (Dziezyc, 1992).

# AMPHIBIA: TOADS

### Introduction

Poisonous amphibians include frogs, salamanders, and toads, but only toads have been associated with toxicosis in domestic animals. Poisonous frogs belong to the Dendrobatidae family and are popular aquarium pets due to their vivid, gem-like coloration. Poisonous frogs have been found to have nearly 500 different bioactive alkaloids in their skin secretions, some of which have been used for food procurement by Central and South American aboriginals who live in areas that these frogs inhabit (Daly, 1980; Daly *et al.*, 2002; Takada *et al.*, 2005). Most of these alkaloids are not thought to be synthesized *de novo* by the frog, but originate from insects that make up the frogs' diets; the alkaloids are absorbed from the insects and sequestered in the glands produce the skin secretions (Daly, 1995a, b; Donnelly, 2002; Saporito *et al.*, 2004). Captive dendrobatids tend to lack these toxic alkaloids in their skin

secretions, most likely due to the difference in diets. The remaining discussion will focus on poisonous toads.

## Background

Members of the genus *Bufo* are found all over the world and all are considered to produce zootoxins capable of causing clinical effects in animals. However, only the larger toads, specifically *B. marinus*, *B. alvarius*, *B. regularis*, and *B. blombergi*, are considered to produce sufficient poison to cause serious toxicosis (Fowler, 1993). *B. marinus* is found in Florida, Texas, Hawaii, the Caribbean, Central and South America, Fiji, Australia, the Philippines, and the Marianas. *B. alvarius* is found in the Imperial Valley of California and the Colorado River basin between Arizona and California. *B. blombergi* is found only in Colombia and *B. regularis* is found in Ethiopia (Fowler, 1993).

Toads possess mucous glands, which are widely distributed over the skin and produce a slimy secretion which keeps the skin moist and lubricated. The mucus secretions may aid in defense through their objectionable odor and/or taste to predators. Toads produce their toxic secretions from granular glands, modified mucous glands, throughout the head, shoulders, and dorsolateral areas of their skin. The more toxic toad species possess a parotid gland, which is an aggregation of granular glands located caudal and lateral to the ear (Fowler, 1993).

## Toxicokinetics

Dogs are the species most commonly involved in toad toxicosis. Mouthing of toads stimulates release of toxins from the parotid gland into the mouth, with absorption occurring across the mucous membranes in the mouth (Roder, 2004). Toad secretions contain a variety of compounds including bufogenins, bufotoxins, and bufotenines.

## Mechanism of action

Bufogenins inhibit sodium–potassium ATPase activity in a manner similar to cardiac glycosides such as digitalis, ultimately causing increased intracellular calcium in myocardial cells which results in cardiac arrhythmias (Eubig, 2001). Bufotoxins are bufogenins conjugated with suberyl arginine, and they have a similar mechanism of action as bufogenins. Bufotenines are indolalkylamines such as serotonin and 5-hydroxytryptophan; in combination with catecholamines present in *Bufo* toxin, these agents may be responsible for many of the neurologic and gastrointestinal effects of *Bufo* toxins (Eubig, 2001).

## Toxicity

The relative potency of *Bufo* toxins varies with species of toad, geographic location, and size of the toad (Fowler, 1993). Smaller patients may show more severe signs when exposed to toad secretions (Eubig, 2001). *Bufo* toads in Florida appear to be more toxic than those in Hawaii and Texas, based on mortality rates of dogs exposed to the toads (Roder, 2004). One hundred milligrams of crude *Bufo* toxin is said to be toxic for dogs weighing 9–14 kg.

Clinical effects of toad poisoning include hypersalivation, anxiety, vomiting, which can occur almost immediately following exposure, and death may occur as rapidly as 15 min following exposure (Eubig, 2001). Other signs including hyperemic mucous membranes, recumbency, collapse, and tachypnea may also be present. Neurologic effects are common and include convulsions, ataxia, nystagmus, stupor, or coma (Fowler, 1993; Roder, 2004). A variety of cardiac arrhythmias have been reported, including bradycardia, sinus tachycardia, and sinus arrhythmias (Eubig, 2001). Pulmonary edema, hyperthermia, and hyperkalemia have also been reported (Fowler, 1993).

## Treatment

On-the-spot decontamination of the oral cavity by copious water lavage is recommended in cases where no signs beyond ptyalism and gagging have occurred (Eubig, 2001). Patients displaying more severe signs should be transported to a veterinary facility for stabilization prior to oral lavage. If an entire toad has been ingested, emesis under veterinary supervision is indicated for dogs where no signs beyond hypersalivation have occurred. Endoscopic or surgical removal of the toad from the stomach may be required in cases where signs have developed, but it is important to stabilize the patient prior to attempts to remove the toad. Alternatively, multiple doses of activated charcoal with a cathartic may be used when entire toads are ingested (Eubig, 2001).

Patients displaying severe signs of toxicosis should be treated symptomatically and aggressively. Seizures may be managed with diazepam or a barbiturate. Intravenous fluid therapy is essential to aid in cardiovascular support. Arrhythmias should be managed as they develop. Bradycardia may be treated using atropine, while propranolol or esmolol may be used to treat tachycardia (Eubig, 2001). Correction of potassium imbalances should be performed as needed. Animals experiencing severe hyperkalemia, severe neurologic signs, or severe arrhythmias unresponsive to therapy may be treated with digoxin-specific antigen-binding fragments (digoxin immune Fab), however the high cost of this product often makes its use in veterinary medicine unfeasible (Eubig, 2001).

The prognosis for patients exposed to small toads and/or showing mild clinical signs is good. Animals developing advanced neurologic or cardiac signs have a more guarded prognosis.

# REPTILIA

Venomous reptiles come from the order *Squamata*, which includes the lizards and the snakes. Outbreaks of poisonings from consumption of the flesh of certain turtles and tortoises have occasionally been reported in humans, but the incidence is fairly low; reports in the veterinary literature of chelonitoxism are lacking.

## SNAKES

### Introduction

Of the 3500+ species of snakes in the world, approximately 400 are venomous (Russell, 2001). Venomous snakes are widely distributed around the world, with the exception of certain islands, such as Hawaii, Ireland, and New Zealand (Fowler, 1993). Venomous snakes come from the families Colubridae, Crotalidae, Elapidae, Hydrophiidae, Laticaudidae, and Viperidae; only members of the Crotalidae and Elapidae are represented in the Western hemisphere.

## CROTALIDS

### Background

The crotalids are also known as pit vipers, so named for the indented, heat-sensing pits located between the nostrils and eyes. Other features of this family include elliptical pupils, triangular-shaped heads, retractable and hollow front fangs, and a single row of subcaudal scales distal to the anal plate (Peterson, 2004). Rattlesnakes have special keratin "rattles" on the ends of their tails and are members of the genera *Crotalus* and *Sistrus*. Other crotalids native to North America include water moccasins, also known as cottonmouths (*Agkistrodon picivorus*) and copperheads (*A. contortrix*).

At least 29 subspecies of rattlesnakes are found throughout the United States, while copperheads and water moccasins are distributed through Eastern and Central United States. The approximate distributions of some of the more common species are illustrated in Figure 64.3. Because of their tendency to associate near areas of human habituation, copperheads are responsible for the majority of human (and likely animal) snakebites in the United States. However, the majority of animal and human deaths in the United States are attributed to rattlesnakes, due to their more potent venoms. It is estimated that anywhere from 150,000 to 300,000 animals are bitten every year by pit vipers within the United States (Peterson, 2004; Wallis, 2005).

### Toxicokinetics

Pit vipers inject their venom by rotating their retractable fangs downward and forward in a stabbing motion (Peterson, 2004). Contraction of muscles in the venom glands then forces the venom through the hollow fangs and into the tissues of the victim. Snakes can control the amount of venom delivered to the victim by regulating the muscular contraction of the venom glands.

### Mechanism of action

Crotalid venoms are complex combinations of enzymes, cytotoxins, neurotoxins, cardiotoxins, hemolysins, coagulants/anticoagulants, lipids, nucleosides, nucleotides, organic acids, and cations such as zinc (Fowler, 1993; Peterson, 2004). Most venoms contain a minimum of 10 of these different components. In North American rattlesnakes, three general venom types have been defined (Peterson, 2004). "Classic" diamondback venom causes marked tissue destruction, coagulopathy, and hypotension. Mojave A venom causes little tissue destruction or coagulopathy but causes severe neurotoxicosis. The third venom class contains components of both classic and neurotoxic venoms.

Hyaluronidase ("spreading factor") and other enzymes break down collagen and other connective tissues, allowing for rapid penetration of venom components throughout the victim's tissues. Low molecular weight myotoxins open sodium channels in the muscle cell membrane, leading to myocyte necrosis. Phospholipase A stimulates hypercontraction of myocyte membranes, resulting in myofibril rupture (Peterson, 2004). Alteration of blood coagulation may lead to either hyper- or hypocoagulation through either direct effects on clotting factors or induction of hyperfibrinolysis, resulting in dissolution of clots as they are forming. Some diamondback rattlesnake venoms contain cardiotoxic agents (myocardial depressant factors) that cause profound hypotension unresponsive to fluid therapy. Neurotoxic components bind the pre-synaptic nerve membrane, inhibiting neurotransmitter release, and causing paralysis (Fowler, 1993).

### Toxicity

Dogs are the species most commonly bitten by pit vipers. In a study of prairie rattlesnake bites in dogs, most bites

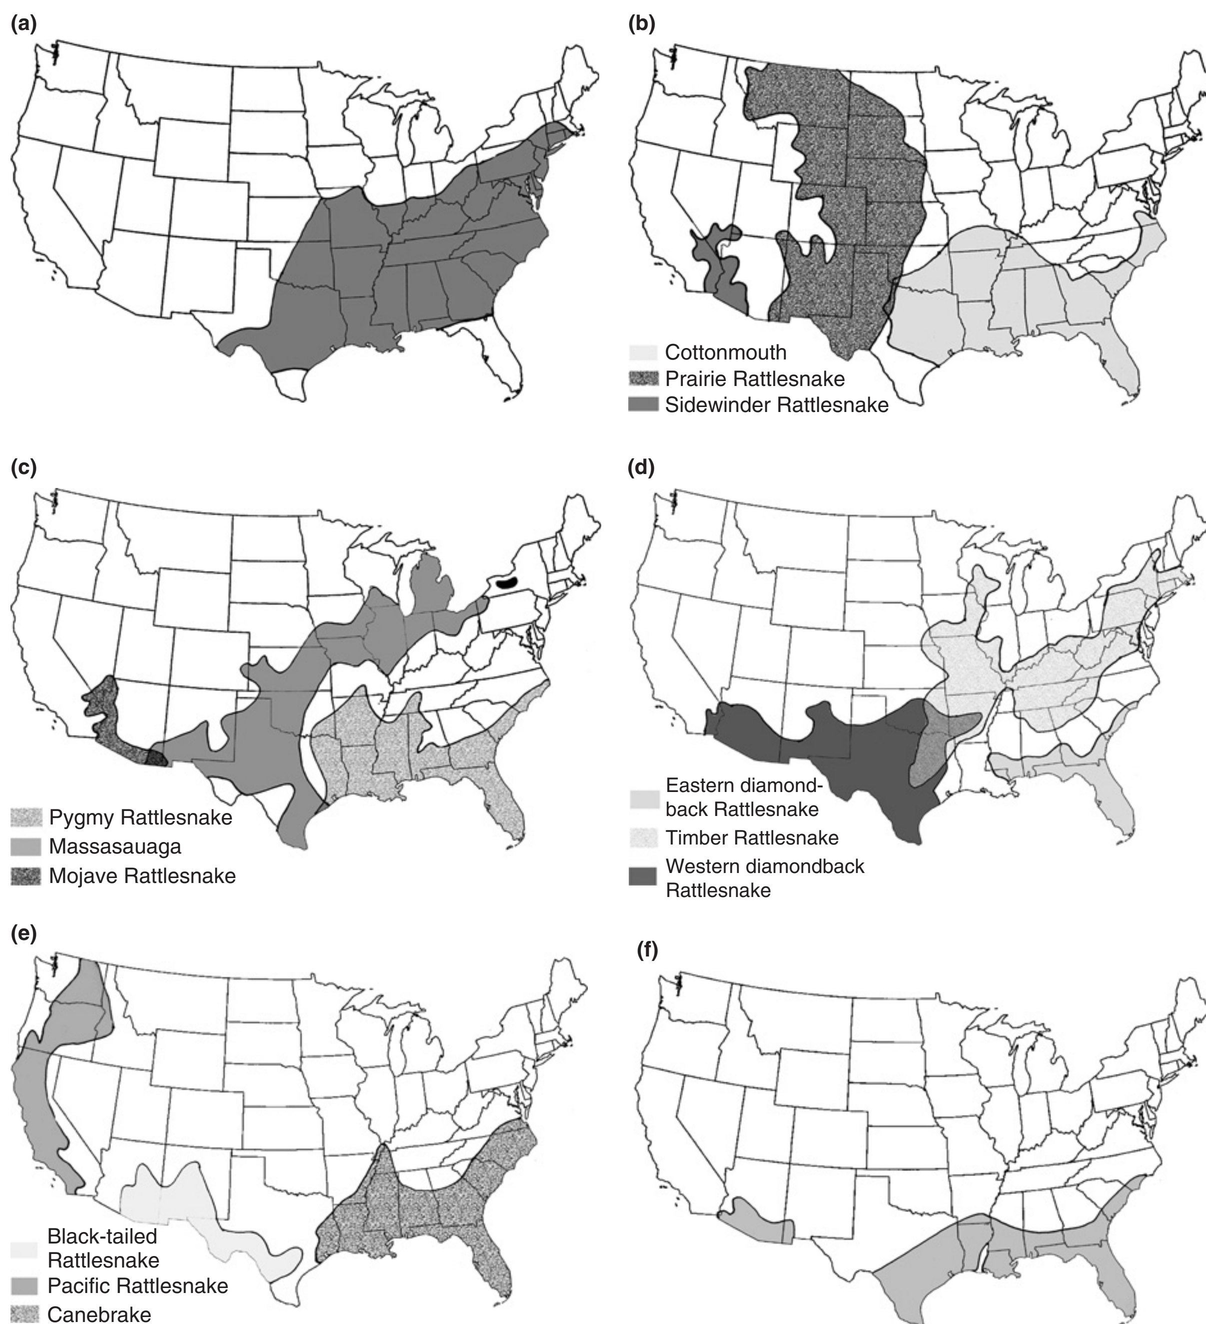

**FIGURE 64.3** Distribution of venomous snakes in the United States. (a) Distribution of copperheads (*Agkistrodon contortrix*). (b) Distribution of cottonmouths (*Agkistrodon picivorus*), prairie rattlesnakes (*Crotalus viridis*), and sidewinder rattlesnakes (*Crotalus cerastes*). (c) Distribution of pygmy rattlesnakes (*Sistrurus miliarius*), massasauga rattlesnake (*Sistrurus catenatus*), and Mojave rattlesnake (*Crotalus scutulatus*). (d) Distribution of the Eastern diamondback rattlesnake (*Crotalus adamanteus*), timber rattlesnake (*Crotalus horridus*), and Western diamondback rattlesnake (*Crotalus atrox*). (e) Distribution of the black-tailed rattlesnake (*Crotalus molossus*), Pacific rattlesnake (*Crotalus atrox*), and canebrake rattlesnake (*Crotalus horridus atricaudatus*). (f) Distribution of coral snakes (*Micruroides euryoxanthus*, *Micrurus fulvius*). (Adapted from Fowler, *Veterinary Zootoxicology*, CRC Press, and Professional Pest Control Products website, http://www.pestproducts.com/snakeinfo.htm)

occurred between May and September during the late afternoon (Hackett *et al.*, 2002). Most bites involved young dogs (median age 3.7 years) and were located on the head.

Dogs are most commonly bitten on the front legs and head, horses are most commonly bitten on the muzzle, and cattle are more commonly bitten on the tongue or muzzle (Peterson, 2004). Cats are considered more resistant to

pit viper venom, but cats are often presented in more severe clinical conditions due to their small body size, tendency to be struck on the torso, and, often, delay in obtaining veterinary care when they run and hide following a bite. Bites to the thoracic wall allow for more rapid and complete venom absorption, while bites to the tongue are essentially equivalent to intravenous envenomations.

The toxicity of any given crotalid bite will depend on both victim and snake factors. The species of the victim is an important factor as some species of animals have a degree of natural immunity to snake venoms. Additionally, the victim's size, pre-existing health, interval until medical care is obtained, and site of the bite are victim-related factors that can influence the severity of the snakebite. Snake factors that affect toxicity include species, size and age of the snake, as well as the time of year, time since the snake's last bite, and whether the bite was defensive or offensive. "Dry" bites, those in which no venom is injected, may occur in up to 25% of snakebites (Peterson, 2004). Snakes that have recently fed may be depleted of venom, and inject less (Fowler, 1993). Older snakes may have more potent venom, and larger snakes may harbor larger volumes of venom to deliver.

Analysis of venoms from a variety of North American pit vipers indicates that the ranking of relative toxicity of venoms, from highest to lowest is Mojave A rattlesnake (*Crotalus scutulatus*), Eastern diamondback (*C. adamanteus*), Western diamonback (*C. atrox*), timber rattlesnake (*C. horridus*), cottonmouth (*Agkistrodon picivorus*), and copperhead (*A. contortrix*).

## Clinical effects

In most cases of snakebite, the initial signs are usually local pain and swelling, followed by petechiation, ecchymosis, and discoloration of the skin in the region of the bite. Swelling and/or the haircoat of the victim may mask bite wounds. Bites from snake species that possess only neurotoxic venom may show little local swelling. Several hours may elapse before more significant clinical signs develop. Hypotension, shock, tachycardia or other arrhythmia, vomiting, diarrhea, shallow respiration, lethargy, nausea, obtundation, muscle fasciculations, ptyalism, and pain and enlargement of regional lymph nodes may occur (Peterson, 2004). Local tissue necrosis may be severe, especially in areas with minimal muscle mass. Local swelling from bites to the head or front legs in dogs may result in regional circulatory alterations that reduce venom uptake (Peterson, 2004). Horses or llamas bitten on the muzzle may succumb to asphyxiation due to occlusion of the nares due to tissue swelling. Horses develop pitting edema that frequently progresses to involve the entire head and neck or limb, but tissue necrosis is uncommon (Fowler, 1993). Hemolysis, rhabdomyolysis, thrombocytopenia, and coagulopathy may occur.

## Treatment

Historically, a variety of first aid measures have been described for managing snakebites in humans and animals, including suction, electric shock, ice packs, and tourniquets (Bush, 2004; Peterson, 2004). However, most of these measures are of questionable value, and they waste precious time that could be used to transport the patient to a veterinary medical facility. Initial first aid should be focused on keeping the animal quiet (exertion will hasten the spread of venom factors into the tissues) and attempting to keep the bitten area below heart level.

The haircoat around the bite area should be clipped in order to fully visualize the bite. Use of a magic marker to delineate the margins of local edema and/or circumferential measurements above, at and below the bite site will allow objective evaluation of the progression of local tissue involvement (Fowler, 1993; Peterson, 2004). Vital signs, including blood pressure should be monitored closely for the first several hours; all patients should be monitored for a minimum of 24 h before being released (Fowler, 1993). Tracheostomy may be required in cases where severe swelling in the head or neck region results in respiratory compromise or in cases of obligate nasal breathers (e.g. horses, llamas) that are bitten on the muzzle. Intravenous crystalloid therapy is recommended to manage hypotension or hypovolemia. Coagulopathy and hemolysis should be managed using blood or platelet transfusions. Conditions such as muscle tremors, seizures, cardiac arrhythmias, and pulmonary edema should be managed as they develop using standard medical therapies. Corticosteroid use is controversial in snakebites, with some indicating that corticosteroids have no place in management of snakebite (Peterson, 2004), while others suggest that judicious use of corticosteroids may be of benefit (Fowler, 1993). In horses, topical application of dimethyl sulfoxide to the bite site should be avoided as it enhances systemic absorption of venom (Peterson, 2004). Diphenhydramine may be useful for its sedative effect. Broad-spectrum antibiotics are advocated by some to aid in prevention of infection (Peterson, 2004), and horses should receive tetanus antitoxin or toxoid (Fowler, 1993).

The use of intravenous antivenin in crotalid snakebites can result in the reversal of potentially life-threatening problems such as coagulopathy, thrombocytopenia, and paralysis (Peterson, 2004). Antivenin cannot reverse tissue necrosis or secondary effects such as renal damage. One study on prairie rattlesnake bites in dogs suggested that antivenin administration was not significantly associated with clinical outcome, and the value of its use in

prairie rattlesnake envenomation was questioned (Hackett *et al.*, 2002).

Equine-origin polyvalent antivenin has historically been used to manage snakebites in animals. More recently, polyvalent immune Fab fragments (CroFab, Protherics) have become available to treat snakebites in humans and animals. Advantages of the crotalid Fab antivenin over the equine-origin antivenin include decreased antigenicity (and therefore decreased potential for allergic reaction), more rapid elimination, increased stability, and more rapid reconstitution (Gwaltney-Brant and Rumbeiha, 2002). The crotalid Fab antivenin has been shown to be effective in management of canine snakebite (Peterson, 2004). Administration of either antivenin should be begun as early as possible and patients should be closely monitored for signs of anaphylaxis during antivenin administration. Studies in dogs have shown that single vial doses of crotalid Fab antivenin were sufficient to manage most cases of canine snakebite envenomation. Coagulation parameters should be monitored, and additional vials of antivenin should be administered if deterioration is noted.

The prognosis for recovery from snake envenomation is dependent on the type of snake involved, the severity of the envenomation, and the rapidity and aggressiveness of veterinary intervention.

Recently a rattlesnake vaccine (Crotalus Atrox Toxoid, Red Rock Biologics) has been developed and marketed with the aim of reducing the morbidity and mortality of dogs due to crotalid snakebites (Wallis, 2005). The vaccine is designed to elicit an immune response to the major protein fractions of *Crotalus atrox* (Western diamondback rattlesnake) that may also cross-react to the major protein fractions of some other rattlesnake venoms. The vaccine does not induce neutralizing antibodies against Mojave neurotoxin. The vaccine is administered as two injections (three for dogs exceeding 100 pounds of body weight) spaced 4 weeks apart. Titers peak in 4–6 weeks and decline after about 6 months, and twice-yearly vaccination is recommended for dogs that have potential to be exposed to rattlesnakes year round. The manufacturer emphasizes that the vaccine does not eliminate the need to seek veterinary care in the event that a venomous snake bites a vaccinated dog. In clinical trials, vaccinated dogs experiencing mild envenomations from subsequent snakebites frequently had their swelling receding within hours of the bite, compared to unvaccinated dogs, which may have swelling progress and persist for 1–2 days following a mild envenomation. Vaccinated dogs that are severely envenomated may still require treatment with antivenom, although the amount of antivenom required may be reduced in vaccinated dogs (Wallis, 2005). The vaccine has only recently been on the market and additional time and study will be required to determine its overall efficacy and value.

## ELAPIDS

### Background

In North America, there are two species of venomous elapid snakes: the Sonoran coral snake (*Micruroides euryoxanthus*) and several subspecies of *Micrurus fulvius*, including the Texas coral snake (*M. f. tenere*), the Eastern coral snake (*M. f. fulvius*) and the South Florida coral snake (*M. f. barbouri*) (Peterson, 2004). The Sonoran coral snake is found in Central and Southeastern Arizona and Southwestern New Mexico. The Texas coral snake is found from Eastern and South-central Texas north into Louisiana and Southern Arkansas. The Eastern coral snake is present from Eastern North Carolina south to Central Florida and west through Alabama and Mississippi. The South Florida coral snake is located in Southern Florida.

North American coral snakes tend to be shy, nonaggressive, and nocturnal, making interactions between them and domestic animals less common than pit vipers (Peterson, 2004). These snakes are brightly colored, with alternating bands of black, red and yellow, and they have small heads and round pupils. The venom delivery apparatus of coral snakes includes short, fixed (non-hinged) front fangs that are partially covered by a membrane (Fowler, 1993). During the bite, the membrane is pushed away and the venom duct empties at the base of the fang, bathing the fang with venom that runs down grooves in the fang. During the bite, coral snakes hold onto the victim and chew, delivering additional venom to the wound.

### Toxicokinetics

Like crotalid venom, coral snake venom is composed of a variety to compounds, mostly small polypeptides and enzymes. Neurologic signs following envenomation may be delayed in onset for up to 12 h, and the duration of effects is prolonged (Peterson, 2004). Total clearance of venom from the body may take up to 14 days.

### Mechanism of action

Neurotoxic peptides in coral snake venom cause a nondepolarizing postsynaptic neuromuscular blockade similar to the effects of curare (Peterson, 2004). Binding of neurotoxins to postsynaptic receptors appears to be irreversible. Enzymes within the venom can cause local tissue necrosis, myoglobinemia in cats, and hemolysis in dogs.

### Toxicity

As with crotalid envenomations, the severity of the bite is related to the size of the victim and the amount of venom

delivered. The amount of venom injected is related to the duration of the bite, intensity of chewing and reason for the bite (offensive versus defensive). Clinical signs vary with the species of the victim. In cats, the signs are primarily neurologic including progressive ascending flaccid paralysis, decreased nociperception, CNS depression, and diminished spinal reflexes (Peterson, 2004). Hypotension, respiratory depression, anisocoria, myoglobinemia, and hypothermia may have also been described in cats. In dogs, depression of the CNS, decreased spinal reflexes, muscle weakness, and respiratory depression may occur. Vomiting, hypersalivation, hypotension, dyspnea, dysphagia, muscle fasciculation, tachycardia, and hemolysis have also been reported in dogs. Potential complications include dysphagia leading to aspiration pneumonia. Death is due to respiratory paralysis.

### Treatment

Management of coral snake envenomations in animals should entail immediate transport for veterinary care. Because onset of clinical signs may be delayed up to 12 h, patients that have been bitten should be closely monitored for a minimum of 24 h. Baseline serum chemistry and complete blood count values should be obtained, and respiratory function should be closely monitored. Ventilatory support may be required if clinical signs progress to the point where respiration is compromised; ventilation may be required for 72 h or more (Peterson, 2004). Administration of specific *Micrurus* antivenin should be considered if neurologic signs begin to develop; early administration is recommended as the antivenin is considered poorly effective at displacing venom components bound to receptor sites (Peterson, 2004). As with crotalid antivenin, anaphylaxis is a potential complication of *Micrurus* antivenin administration. Broad-spectrum antibiotics and symptomatic wound care may be indicated. Recovery periods of 7–10 days have been reported in cats envenomated by coral snakes (Chrisman *et al.*, 1996).

The prognosis for coal snake envenomations in animals is generally good provided prompt and aggressive veterinary care is obtained.

## LIZARDS

### Background

Venomous lizards are only found in North and Central America and are members of the genus *Heloderma*. *H. suspectum* and *H. cinctum* are commonly referred to as Gila monsters, while *H. horridum* is known as the Mexican beaded lizard. The Gila monsters are found in Arizona and parts of Utah, New Mexico, Nevada, and Southern California, while the Mexican beaded lizard is found in Mexico, from Sonora down the Pacific Coast into Guatemala (Cantrell, 2003; Peterson, 2004).

Venomous lizards are large and heavily bodied, with blunt, rounded tails, powerful jaws, and short legs with clawed, hand-like feet. The colorful, bead-like scales form a reticular pattern of dark brown to black on a yellow, orange, pink, and/or cream background. Gila monsters, which can reach 55 cm in length, are smaller than Mexican beaded lizards, which can grow up to 1 m in length and weigh up to 2 kg (Cantrell, 2003; Peterson, 2004).

*Heloderma* spp. possess venom glands in the lower jaw at the base of the teeth, and venom is delivered through grooves in the teeth via capillary action as the lizard masticates. These lizards are generally considered to be docile, but when provoked can be aggressive biters that can hang on tenaciously to their victim, often requiring prying the jaws open to release the victim (Cantrell, 2003). The teeth are loosely attached and brittle, and may break off into the wound. The venom is considered a defensive weapon rather than one for procuring food (Peterson, 2004).

### Mechanism of action

*Heloderma* venom is composed of a complex mixture of proteins and enzymes, many of which are similar to those found in snake venoms, including hyaluronidase, phospholipase $A_2$, serotonin, and a variety of enzymes (Cantrell, 2003). Hyaluronidase ("spreading factor") catalyzes the cleavage of internal glycoside bonds of acid mucoglycosides, resulting in decreased viscosity of hyaluronic acid, which in turn increases tissue permeability and allows deeper penetration of venom into tissue. Phospholipase $A_2$ uncouples oxidative phosphorylation which inhibits cellular respiration, causes cell membrane destruction, and inhibits platelet aggregation (Huang and Chiang, 1994; Peterson, 2004). Various proteolytic enzymes result in local tissue damage as well as aid in the spread of venom through the tissue. In addition, *Heloderma* venoms contain several unique components that have a variety of clinical effects; these are summarized in Table 64.3. Gilatoxin is considered to be the major lethal factor in *Heloderma* venom (Fowler, 1993).

### Toxicity

The toxicity of *Heloderma* venoms is dependent on the amount of venom delivered to tissues, which in turn is dependent on the duration and severity of the bite. Dogs are the species most likely to have a significant encounter *Heloderma* spp. due to their inquisitive nature and tendency

**TABLE 64.3 Contents and effects of various *Heloderma* spp. venom components**

| Component | Effects | Reference |
|---|---|---|
| Gilatoxin | "Lethal factor", kallikrein-like activity, pain, hypotension | Fowler (1993); Utaisincharoen *et al.* (1993) |
| Helodermin | Vasodilation, hypotension | Grundemar and Hogestatt (1990) |
| Helospectin I and II | Vasodilation, hypotension | Grundemar and Hogestatt (1990) |
| Helothermine | Lethargy, paresis, hypothermia | Peterson (2004) |
| Hyaluronidase | "Spreading factor," degrades connective tissue | Peterson (2004) |
| Phospholipase $A_2$ | Inhibition of platelet aggregations | Huang and Chiang (1994) |

to harass wildlife that they encounter. Although rare, *Heloderma* bites to dogs and cats have occurred, and death in at least one dog has been reported (Fowler, 1993; Peterson, 2004).

The clinical effects of *Heloderma* envenomation include intense local pain, edema, and hemorrhage at the site of the wound (which may contain fractured teeth). Regional lymphangitis and local ecchymoses may occur, although tissue necrosis is not common. Systemic signs described in humans include weakness, dizziness, tinnitus, muscle fasciculations, hypotension, and tachycardia. In dogs and cats, signs may include tachypnea, vomiting, polyuria, salivation, and lacrimation. Aphonia has been reported in cats (Peterson, 2004). Hypotension, tachycardia, and respiratory distress have been reported in dogs and cats injected with boluses of *Heloderma* venom, although reports of these conditions in natural exposures are lacking.

### Treatment

Management of *Heloderma* bites in small animals includes initial first aid followed by assessment and monitoring. The first course of action is often disengaging a lizard that is still attached to the victim, as these lizards may hold on tenaciously once they bite. Removal should be attempted as quickly as possible because the amount of venom delivered is proportional to the duration of the bite. Suggested means of removal of the lizard include applying a flame from a match or cigarette lighter to the underjaw of the lizard, prying the jaws open with metal bar, or killing the lizard by incising the jugular vein with a knife. Attempts to pull the lizard off the victim or to strike the lizard in the head may enlarge or deepen the wounds at the site of the bite (Fowler, 1993). Once the lizard is removed, a veterinarian should evaluate the patient. The bite site should be irrigated with 2% lidocaine and the wound probed with a 25-gauge needle to detect any embedded tooth fragments (Peterson, 2006). Diazepam, 0.1–0.5 mg/kg IM may be helpful in sedating agitated or highly painful animals. Analgesics should be administered as needed, and the animal should be monitored for several hours for the development of hypotension or shock; if either develops, appropriate medical treatment including intravenous fluid therapy is indicated. Broad-spectrum antibiotics should be administered to prevent infection from the myriad of potentially pathogenic bacteria that have been reported to frequent the mouth of reptiles (Peterson, 2006). General wound care should be instituted and the wound should be examined daily for evidence of infection. Envenomation of pets by *Heloderma* spp. is rare, and in most cases a favorable outcome can be expected provided prompt and appropriate veterinary care is obtained.

## AVES

Two genera of passerine birds native to New Guinea, *Pitohui* and *Ifrita*, have poisonous secretions on their feathers, most likely as means of defense against predators (Dumbacher *et al.*, 1992; Weldon, 2000; Dumbacher and Fleischer, 2001). The toxins are present in highest concentrations in the contour feathers of the belly, breast, and legs, with lesser amounts on the head, back, tail, and wing feathers (Weldon, 2000). Several steroidal alkaloids have been isolated from the feathers of these birds, including batrachotoxin and homobatrachotoxin as well as derivatives of these compounds; similar compounds are present on the skin of poison dart frogs (Dendrobatidae) from Central and South America (Daly, 1995b).

The origin of the toxins found in *Pitohui* ("rubbish bird") and *Ifrita* ("bitter bird") is thought to be through accumulation from insects ingested by the birds, rather than by *de novo* synthesis (Dumbacher *et al.*, 2004). High levels of batrachotoxins have been found in beetles of the genus *Choresine* (family Melyridae) that serve as part of the diet of *Pitohui* species. The beetles themselves are unable to synthesize steroidal skeletons and likely accumulate the base steroids from plant phytosterols that they ingest. The beetles then convert the steroids to the steroidal alkaloids and accumulate them within their bodies.

Batrachotoxins act through the opening of sodium channels in nerve and muscle cells, resulting in depolarization and paralysis (Dumbacher *et al.*, 2004). However, exposure of humans to the feathers of *Pitohui* and *Ifrita* species primarily result in respiratory irritation, allergic-type responses, burning sensations of the eyes, skin, and oral mucosa (Dumbacher *et al.*, 2000).

## MAMMALIA

Only a handful of mammals are poisonous or venomous, and toxicosis from exposure to these animals is uncommon. Poisonous mammals include certain carnivores (e.g. polar bears) and pinnipeds (e.g. walruses, seals), whose livers contain high levels of vitamin A; ingestion of these livers may result in acute or chronic hypervitaminosis A (Cleland and Southcott, 1969; Fishman, 2002). Additionally, the meat of marine mammals such as whales may accumulate high levels of organotins, mercury, and other agents that can pose a toxicologic hazard if ingested in sufficient quantity (Endo *et al.*, 2005). Impairment in cell-mediated immunity was found in sled dogs from Greenland that were fed the blubber of minke whales (*Balaenoptera acutorostrata*) (Sonne *et al.*, 2006).

Venomous mammals belong to the orders Monotremata and Insectivora (Fowler, 1993). Venomous Monotremes are the platypus and echidna, of which only the platypus is considered to be of toxicologic significance, as the venom gland in the echidna is non-functional. The male platypus possesses a curved, grooved, conical, sharp spur on the medial aspect of the tarsus. The spur is normally kept retracted against the leg, but when stimulated, muscles cause the spur to project perpendicularly to the leg. The venom gland is kidney shaped and located on the medial aspect of the thigh, and venom is first transported to a reservoir near the spur then is moved through a duct to the spur. Envenomation occurs when the platypus kicks the spur into the victim. Although poorly studied, components identified in platypus venom include a protein similar to natiuretic peptide, a defensin-like peptide, a hyaluronidase, 5-hydroxytryptophan, and histamine (Hodgson, 1997; Torres *et al.*, 2006). Based on reports of human envenomation by platypus, expected signs include intense pain and numbness at the site of the wound and local swelling that may progress proximally (Fowler, 1993). Regional lymph nodes may become enlarged and painful. Humans have reported a feeling of faintness. No reports of human or animal fatality from platypus exist. There are infrequent anecdotal reports of dogs being envenomated by platypus.

Venomous insectivores include various shrews and solenodons, and possibly some moles and hedgehogs (Dufton, 1992). The European hedgehog (*Erinaceus europaes*) has been noted to mix its frothy saliva with toad toxins and smear this mixture over their forward spines. Some moles will store "paralyzed" worms and slugs away, the paralysis thought to be due to paralytic toxins within the mole's saliva. Studying the American short-tailed shrew (*Blarina brevicauda*), the Haitian solenodon (*Solenodon paradoxus*), the European water shrew (*Neomys fodiens*), and the Mediterranean shrew (*N. anomalous*) have obtained more definitive evidence of presence of venoms. These mammals possess three pairs of salivary glands: parotid, retrolingual, and submaxillary. The submaxillary glands are thought to contribute to the bulk of the venom in these species. The Haitian solenodon has grooved incisors that direct the venom to the wound, while the shrews have teeth with concave inner surfaces that may play a similar role as grooves.

Envenomation is achieved by biting and chewing the victim, accompanied by copious salivation. Insectivore venoms contain a variety of peptides and enzymes, and recently a compound isolated from *Blarina* venom has been shown to have kallikrein-like activity (Kita *et al.*, 2005). The venom of *Blarina* appears to be the most toxic, with that of *N. fodiens*, *N. anamalous*, and *Solenodon* being 1/3, 1/6, and 1/20 as toxic, respectively (Dufton, 1992). There is considerable species variation in sensitivity to the venom in shrew and solenodon venom, with voles and rabbits being most sensitive to the effects, and mice, cats, and humans being relatively more resistant (Dufton, 1992). In most natural exposures, the primary effects of shrew and solenodon venoms are related to neurotoxicity. Mice bitten by *Blarina* rapidly develop depression and immobility. When submaxillary gland extracts are injected into experimental animals, depression, irregular respiration, dyspnea, ptosis, rear limb paralysis, convulsions, and death occur. Intravenous injection of 7 mg/kg of *Blarina* toxin extract in a cat resulted at decreases in respiratory and heart rates with concomitant decrease in blood pressure. These effects resolved within 15 min but returned with subsequent doses of 2.5 and 7 mg/kg. Apparent recovery following the final dose was followed by acute respiratory depression and cardiac arrhythmia, and the cat subsequently died. In humans, symptoms of bites from shrews or solenodons result in localized burning sensation surrounding the lower jaw tooth puncture sites and localized swelling. The burning sensation may persist for several days. Systemic toxicosis has not been reported in natural exposures to the bites of shrews or solenodons in humans or domestic animals.

## CONCLUSION

Every phylum of the Animal Kingdom contains animals capable of producing toxic effects, either through envenomation or poisoning. However, only a small number of these animals are sufficiently toxic to be of importance to veterinary clinicians. Arachnids, insects, toads, and snakes cause the most clinically significant problems for domestic and wild animals. Although in some cases specific antidotes (i.e. antivenins) exist for exposures to venomous animals, availability and cost of these antidotes often make their use in veterinary medicine unfeasible. Therefore,

most cases of zootoxicosis in animals will be managed with symptomatic and supportive care.

## Estrogenic Toxicants

C H A P T E R

# 65

# Chemical-induced estrogenicity

*Stephen H. Safe, Shaheen Khan, Fei Wu, and Xiangrong Li*

## INTRODUCTION

17β-estradiol (E2) and related steroidal hormones play an important role in multiple physiological processes. However, these hormones are risk factors for hormone-dependent diseases including breast and endometrial cancer. Inappropriate exposures (high or low) to estrogens can also lead to adverse health effects. The identification of estrogenic compounds in the environment, coupled with human exposures to these compounds has generated public, regulatory and scientific concern regarding their potential hormonal toxicity to humans and wildlife. This chapter is focused on chemical-induced estrogenicity and the potential toxicological impacts of these compounds.

## ESTROGENS PLAY A ROLE IN NORMAL PHYSIOLOGICAL FUNCTION AND DISEASE

### Background

Estrogens regulate the development and function of the female reproductive system and their effects are mediated through estrogen receptor $\alpha$ (ER$\alpha$) and ER$\beta$. However, estrogens are by no means only female hormones. In both males and females, estrogens play crucial physiological roles, including sex differentiation, bone development and maintenance, central nervous system and cardiovascular function (Martinez-Vargas *et al.*, 1975; Ansar Ahmed *et al.*, 1989; Maggi *et al.*, 1989; Smith *et al.*, 1994; Brosnihan *et al.*, 1997; McEwen and Alves, 1999). The ER is important for mammary gland development and ER$\alpha$ knockout ($\alpha$ERKO) mice are viable but sterile and are estrogen-insensitive in several estrogen target organs, including mammary glands, reproductive tracts and gonads. The well-recognized estrogenic responses, such as uterine weight increase and vaginal cornification, are all absent in $\alpha$ERKO mice (Lubahn *et al.*, 1993; Korach, 1994). In $\alpha$ERKO mice, mammary glands undergo normal development in the prenatal period, but fail to develop terminal end buds and are severely undertropic during adulthood (Lubahn *et al.*, 1993; Korach, 1994). No significant ovarian abnormalities were detected in neonatal $\alpha$ERKO mice, but ovaries in the mature $\alpha$ERKO mice have disrupted ovulation and luteinization and develop multiple hemorrhagic cysts (Schomberg *et al.*, 1999). Surprisingly, adult male $\alpha$ERKO mice are also infertile because of impaired spermatogenesis (Eddy *et al.*, 1996). Similar results were observed in male mice with disrupted aromatase, an enzyme essential for estrogen synthesis (Robertson *et al.*, 1999). In contrast to the extensive reproductive tract abnormalities in $\alpha$ERKO mice, ER$\beta$ knockout ($\beta$ERKO) mice are fertile and have no significant abnormalities except reduced fertility (Korach, 1994; Krege *et al.*, 1998).

### Estrogens and women's health

Women have significantly lower risk of cardiovascular disease than men and this has been putatively attributed to the beneficial effects of estrogen on cardiovascular function (Nathan and Chaudhuri, 1997). Estrogen decreases low-density lipoprotein (LDL) level and increases high-density lipoprotein (HDL) levels (Bush, 1990; Knopp *et al.*, 1996). Estrogen exhibits vasodilatory effects and protects against vascular injury (Pare *et al.*, 2002) and also induces COX-2-dependent upregulation of atheroprotective prostacyclin $PGI_2$ (Egan *et al.*, 2004). In epidemiological studies, estrogen has been linked with improved cardiovascular functions (Grodstein *et al.*, 1996). Bilateral ovariectomy before

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

menopause elevates the risk for coronary heart disease (CHD) and the increased risk is eliminated by estrogen-replacement therapy (Colditz *et al.*, 1987). However, a large clinical trial conducted by Women's Health Initiative has reported contradictory results on the effects of estrogens since women taking hormone replacement therapies (HRT) have an increased risk for heart diseases and stroke (Rossouw *et al.*, 2002). The relationships between estrogen and cardiovascular diseases require further assessment.

Estrogen is also important for bone development and maintenance. Before and during puberty, estrogen stimulates bone growth in both males and females and may be the major driving force of pubertal growth spurt (Cutler, 1997). In adulthood, estrogen is crucial for maintaining bone density. A young adult male with homozygous disrupted ER$\alpha$ gene has normal masculinization, but incomplete epiphyseal closure, tall stature and decreased bone density (Sudhir *et al.*, 1997). In premenopausal women, estrogen exposure is strongly associated with bone mass (Armamento-Villareal *et al.*, 1992). The deficiency of estrogen in postmenopausal women leads to an increased risk of osteoporosis and increased estrogen intake can alleviate bone loss (Ettinger *et al.*, 1985). The Women's Health Initiative also confirmed that HRT protect against hip fracture in postmenopausal women (Rossouw *et al.*, 2002).

Estrogen also plays important roles in sexual differentiation in the brain and reproductive behavior (Breedlove, 1992; Bakker *et al.*, 2003) and sustained estrogen treatment improves learning ability, memory and fine motor skills in animal models (O'Neal *et al.*, 1996; Lacreuse and Herndon, 2003). However, results of the Women's Health Initiative show that the use of HRT can lead to increased risks for heart disease and stroke. There is concern that these estrogens may induce some adverse neurological responses (Rossouw *et al.*, 2002; Shumaker *et al.*, 2003; Espeland *et al.*, 2004). The most well-characterized adverse responses of endogenous and exogenous estrogens is associated with their effects on both breast and endometrial cancer in women (Bernstein, 2002; Hilakivi-Clarke, 2002). The potential effects of synthetic estrogenic compounds on breast cancer risk stems for extensive research and epidemiological studies on this disease. In addition there is also concern that fetal or early postnatal exposure of males to estrogens will affect the male reproductive tract functions in adults (Skakkebaek *et al.*, 2001).

## ESTROGENS AS A RISK FACTOR FOR BREAST CANCER

### Genetic factors

There are several different risk factors for breast cancer and there is a strong interplay of genetic and environmental factors in the initiation and progression of this disease (Martin and Weber, 2000). Breast cancer risk increases with age and 77% of women diagnosed with breast cancer are older than 50. Risk factors can be broadly classified as genetic, hormonal, environmental and other lifestyle factors. Five to ten percent of all breast cancers are associated with the inheritance of mutations in one of the two major breast cancer susceptibility genes, BRCA1 and BRCA2 (Struewing *et al.*, 1996; Peto *et al.*, 1999). There is an 80% chance of developing breast cancer during a lifetime in women with an inherited BRCA1 or BRCA2 mutation (Rebbeck *et al.*, 1996; Nathanson *et al.*, 2001). BRCA1 and BRCA2 are tumor suppressor genes and their proteins have been implicated in a multitude of different processes including DNA repair and recombination, cell cycle control and transcription (Venkitaraman, 2002). Several other genetic mutation also contribute to the risk in breast cancer and these include genes such as p53 which also enhance risk for multiple cancers.

### Hormonal factors

Several studies have shown that prolonged exposure to the hormone estrogen increases the risk of breast cancer. Epidemiological studies have established a strong link between higher risk of breast cancer and reproductive factors that increase the overall number of menstrual cycles such as early menarche (before age 12), late menopause (after age 55), age of women at first birth (over 30–35) and nulliparity (Russo *et al.*, 1992; Talamini *et al.*, 1996). Breast cancer risk is lower in women with multiple pregnancies and women with a pregnancy prior to age 24 (Lambe *et al.*, 1996; Meeske *et al.*, 2004). Women who are above 30–35 years of age at first birth are at higher risk compared to nulliparous women (Albrektsen *et al.*, 1994; Rosner *et al.*, 1994). The protective effects of pregnancy against breast cancer is explained by the induction of complete differentiation of the breast that may markedly reduce the carcinogen susceptibility of the fully differentiated mammary gland to due, at least in part, to the decreased proliferative activity of parous epithelium (Russo *et al.*, 2000). Another hypothesis is that the decreased risk may also be due to the altered hormonal environment during pregnancy, and these include specific molecular changes induced by estrogen and progesterone and decreased circulating growth hormone (Sivaraman and Medina, 2002; Russo *et al.*, 2005). Breastfeeding is also protective against breast cancer and this may be due to the reduction of total number of ovulatory menstrual cycles and consequently cumulative ovarian hormone exposure (Enger *et al.*, 1997; Lipworth *et al.*, 2000; Russo *et al.*, 2000; Lee *et al.*, 2003). Recent studies have shown that the use of HRT and oral contraceptives for long time periods can also increase the risk of developing breast cancer (Althuis *et al.*, 2003; Ewertz *et al.*, 2005).

In some studies women exposed to diethylstilbestrol (DES) were also found to be at slightly increased breast cancer risk (Titus-Ernstoff *et al.*, 2001; Sasco *et al.*, 2003).

### Lifestyle and dietary risk factors

Ionizing radiation is the most well-characterized environmental risk factor for breast cancer. Radiation-induced breast cancer risk depends on the various factors including age at exposure (highest before age 30 years), the status of hormone levels, parity and other genetic disorders (Coyle, 2004). A number of reports showed that patients who received radiation therapy for Hodgkin's disease, breast cancer and other illnesses, had an increased risk of breast cancer and women in Japan exposed to atomic bomb radiation also have a high rate of breast cancer (Hancock *et al.*, 1993; Goodman *et al.*, 1997; Land *et al.*, 2003). Other risk factors include solar radiation, light and chemicals. Solar radiation creates an active form of vitamin D that may lower the risk of breast cancer and studies show that women who work at nights are at higher breast cancer risk. This may be due to decreased vitamin D synthesis and suppression of normal nocturnal production of melatonin by the pineal gland, increases the estrogen release by the ovaries thereby disrupting circadian patterns (Garland *et al.*, 1990; Davis *et al.*, 2001; Schernhammer *et al.*, 2001; Grant, 2002).

Various lifestyle factors such as diet, exercise, smoking and alcohol consumption are related to an increased risk of developing breast cancer (Key *et al.*, 2003). Confirmation of the risk of dietary fat intake and breast cancer has not been substantiated in large epidemiology studies (Velie *et al.*, 2000; Smith-Warner *et al.*, 2001), however a dietary pattern of high fiber and low fat intakes is associated with a lower risk of breast cancer in postmenopausal women (Baghurst and Rohan, 1994; Mattisson *et al.*, 2004; Saadatian-Elahi *et al.*, 2004). In some studies protective effects of some vegetable fats, vitamin E, selenium and other antioxidants have been observed (Gerber *et al.*, 2003; Gaudet *et al.*, 2004). Decreased ovarian hormone levels decreased the risk of breast cancer in populations in Asia and is related to their high consumption of soya products containing significant amount of the isoflavones, daidzein and genistein, that act as weak estrogens (Mezzetti *et al.*, 1998; Lu *et al.*, 2000).

## ESTROGENS AS RISK FACTORS FOR MALE REPRODUCTIVE TRACT PROBLEMS

Although estrogens are female steroid hormones and influence normal physiology and disease in women, there has been increasing concern on the potential adverse effect of estrogenic compounds on development of the male reproductive tract (Sharpe and Skakkebaek, 1993). Support for the hypothesis that "environmental estrogens" (xenoestrogens) and other endocrine disrupting compounds are responsible for an increase in male reproductive tract problems is derived from laboratory animal, wildlife and human studies. For example, there are numerous reports of feminized fish in river systems, particularly those in the United Kingdom and this has been linked to their exposures to endogenous estrogens (17$\beta$-estradiol/estrone), synthetic contraceptives (17-ethinylestradiol) and industrial by-products such as alkylphenols (Desbrow *et al.*, 1998; Routledge *et al.*, 1998). There is some evidence that nonylphenol and alkylphenols may contribute to estrogenization of fish near sewage outflows.

It has also been suggested that the major concern regarding environmental/dietary estrogens is *in utero* or early postnatal exposures during the important initial periods of male reproductive tract development (Skakkebaek *et al.*, 2001). The potent estrogenic drug DES was extensively used by pregnant women with disastrous consequences for their male and female offspring (Giusti *et al.*, 1995). Females exposed *in utero* develop a high incidence of a rare vaginal adenocarcinoma whereas male offsprings developed a range of responses including deformed genitalia. The effects by DES form one of the bases of the endocrine disruption hypothesis and the opinion that a testicular dysgenesis syndrome which includes low sperm counts, increased hypospadias and cryptorchidism and testicular cancer my be linked to *in utero* exposure to estrogenic compounds and other endocrine disrupting compounds (Skakkeback *et al.*, 2001). This opinion and hypothesis have been challenged (Safe, 2000; Handelsman, 2001). However, it has become increasingly clear that humans are exposed to a wide range of xenoestrogens and phytoestrogens which constitute the major subclass of endocrine disruptors of concern. The following section describes several different structural classes of synthetic estrogenic compounds, phytoestrogens and estrogens/antiestrogens such as DES and tamoxifen that have been used as pharmaceutical agents. In addition the mechanism of estrogen action and implications for risk assessment of these compounds will also be discussed.

## ESTROGENIC CHEMICALS OF CONCERN

The hypothesis that environmental/dietary estrogens may play a role in male reproductive tract problems and the increased incidence of breast cancer is controversial and the significance of these compounds on human health is not

resolved. Nevertheless this resulted in legislation in the United States requiring the Environmental Protection Agency to develop testing procedures for examining industrial compounds for their activity as estrogens/antiestrogens, androgens/antiandrogens and thyroid hormone mimics. Initial screening studies for estrogens used the MCF-7 cell proliferation assay (E-screen) (Sonnenschein and Soto, 1998) and this was complemented by development of receptor binding and transactivation studies in various cell lines. All of these assays have advantages and disadvantages and for the most part give complementary results on the estrogenic activity of individual compounds.

Steroidal and non-steroidal estrogens and antiestrogens have been developed as pharmacologic agents and Figure 65.1 illustrates the structures of 17$\beta$-estradiol, the endogenous hormone, DES and three clinically used antiestrogens, tamoxifen, ICI 182780 (fulvestrant) and raloxifene (Jordan, 2003a, b). It is well known that phytoestrogenic compounds in the diet also constitute a major source of exposure to estrogens and these compounds are present in fruits, nuts and vegetables and are particularly high in many soya products which are enriched in isoflavonoids (Havsteen, 2002). Figure 65.2 shows the structures of genistein, a major isoflavonoid in soy, equol a genistein metabolite and naringenin a flavonoid which is found in grapefruit. Genistein and equol can be detected in human serum and urine along with the estrogenic lignans enterodiol and enterolactone and these compounds are used as biomarkers of exposure to dietary phytoestrogenic compounds. Resveratrol is an estrogenic polyphenolic stilbene analog found in grapes and wine.

The list of synthetic estrogenic compounds continues to grow as testing of current and new synthetic industrial chemicals progresses and expands. A major class of xenoestrogens of concern are the alkyl phenols such as nonylphenol which are widely used in industry as ethoxylates (Soto *et al.*, 1991). These compounds are surfactants and

are used in detergents, paints, herbicide/pesticide formulation and plastics. Alkyl hydroxybenzoates (parabens) (Figure 65.3) used as preservative agents and cosmetic UV filters such as 4-methylbenzylidene camphor that are used in homecare products also exhibit estrogenic activity (Schlumpf *et al.*, 2004; Schreurs *et al.*, 2005). Bisphenol A (BPA) is perhaps one of the most controversial xenoestrogens since it is extensively used in plastic production and plastic lines in which trace levels of BPA have leached directly into food products (Krishnan *et al.*, 1993). This estrogenic compound has also been identified in the environment. Other estrogens of concern include polychlorinated biphenyls (PCBs) and hydroxy-PCBs which have been identified in the environment and in humans; the pesticide metabolite 1,1-bis(*p*-chlorophenyl)-2,2-dichloroethylene (DDE) and kepone (Kutz *et al.*, 1991; Bergman *et al.*, 1994). These compounds are persistent environmental contaminants and kepone-induced estrogenic poisoning in a group of exposed production workers. The compounds illustrated in Figure 65.4 exhibit relatively weak binding to the ER and induce reporter gene expression in transactivation assays in cell culture systems and some of these compounds exhibit uterotrophic effects in female rodents. The important toxicological question concerning these chemical estrogens is whether they differ only in potency which is governed by their intrinsic estrogenicity and bioavailability based on their metabolism and pharmacokinetics. On the other hand, since the estrogenic activity of these compounds is receptor dependent (ER), is the estrogenic activity of structurally diverse xenoestrogens more unique and not necessarily governed by intrinsic ER binding affinities and pharmacodynamic factors?

# MECHANISMS OF ESTROGEN-INDUCED TRANSACTIVATION

## ER$\alpha$ and ER$\beta$ domain structure

The ER is a member of the nuclear receptor superfamily of transcription factors which exhibit modular structures and similar mechanisms of action. For example, the transactivation function of ER is mediated by two separate but not mutually exclusive transactivation domains namely, ligand-independent activation function (AF) 1 (within the A/B) and ligand-dependent AF-2 (within the ligand binding domain, LBD) (Tora *et al.*, 1989) (Figure 65.5). The A/B domain is the least conserved region between ER$\alpha$ and ER$\beta$ with only 30% similarity at the amino acid level. The activity of AF-1 in ER$\beta$ is negligible on estrogen-responsive element (ERE) reporter constructs compared to the AF-1 of ER$\alpha$ in several different cell lines (Cowley and Parker, 1999).

ER$\alpha$ and ER$\beta$ also exhibit distinctive responses to the synthetic antiestrogens such as tamoxifen and raloxifene which act as partial ER agonists for ER$\alpha$ and as pure ER antagonists for ER$\beta$ (Barkhem *et al.*, 1998). The functional differences between the respective A/B regions of ER$\alpha$ and ER$\beta$ may explain their differences in ligand-dependent activation (Matthews and Gustafsson, 2003). The AF-1 region of ER$\alpha$ interacts with different transcriptional regulators and co-activators that affect ligand-independent transactivation. The activity of AF-1 is also regulated through kinase-dependent phosphorylation and the individual pathways involved vary with cell and promoter context (Tzukerman *et al.*, 1994). In most cell lines, both AFs act synergistically to attain maximum transcriptional activity while in other cells only one AF may be activated (Benecke *et al.*, 2000).

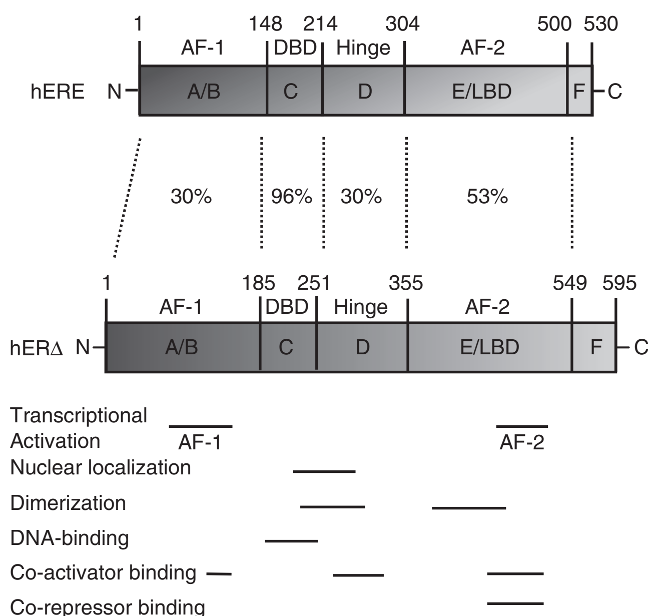

**FIGURE 65.5** Structural domains of human ER$\alpha$ and ER$\beta$. The percent identity between the individual domains at the amino acid level is indicated (modified from Pearce and Jordan (2004) and Koehler *et al.* (2005)).

The DNA binding domain (DBD) (region C) is highly conserved between ER$\alpha$ and ER$\beta$ and exhibits 96% identity. This domain contains two zinc finger (CI and CII) as observed for other nuclear receptors. The DBD of both ER$\alpha$ and ER$\beta$ bind with high affinity to EREs (Mosselman *et al.*, 1996; Pettersson *et al.*, 1997). The minimal consensus ERE sequence is a palindromic inverted repeat (IR): 5′-GGTCAnnnTGACC-3′. Extension of the length of the ERE palindrome, e.g. 5′-CAGGTCAnnnTGACCTG-3′, forming a 17-bp palindromic IR, and the sequences immediately flanking the ERE are important for determining ER binding affinities for this motif (Klinge, 2001). The hinge region or D domain is a 40–50 aa sequence separating the DBD and LBD and is not well conserved between the two receptors. The C-terminal E/F region encompasses the LBD, a co-regulator binding surface, a dimerization domain, another nuclear localization signal and AF-2 (Nilsson *et al.*, 2001). Significant homology between the two receptors exists in the E/F region and both proteins display essentially the same binding affinity for E2 and many other estrogenic compounds (Kuiper *et al.*, 1997). However, the two receptors differ in their binding affinities for only a few ligands including antiestrogens and phytoestrogens. For example, the phytoestrogen geneistein binds with approximately a 30-fold higher affinity for ER$\beta$ than ER$\alpha$ (Barkhem *et al.*, 1998).

## X-ray crystallographic studies

Crystallographic studies with the LBDs of ER$\alpha$ and ER$\beta$ revealed that both ER$\alpha$ and ER$\beta$ share a similar overall architecture. The AF-2 interaction surface is composed of amino acids in helix 3, 4, 5 and 12 and the position of helix 12 is altered upon ligand binding. Amino acids within helices 3, 5 and 11 are important for ligand binding since mutation of these residues significantly decrease the binding affinity for E2 (Wurtz *et al.*, 1998). Deletion and mutation analysis have revealed that ER dimerization is mediated through helices 7–10 (Fawell *et al.*, 1990; Lees *et al.*, 1990). Crystal structures of the ER-LBD complexed with E2, DES, the antiestrogens raloxifene and tamoxifen, and the pure antiestrogen ICI 164,384, an analog of fulvestrant (ICI 182,780), have been determined (Brzozowski *et al.*, 1997; Shiau *et al.*, 1998; Pike *et al.*, 1999; Pike *et al.*, 2001). These structures reveal critical information regarding the agonist and antagonist activity of various ligands and showed that the structure of helix 12 with AF-2 is sensitive to ligand binding. For example, when the ER$\alpha$ LBD is complexed

with agonists such as E2, helix 12 is repositioned over the ligand binding pocket and it generates a functional AF-2 that interacts with LXXL motifs of co-activators. In contrast, binding of antagonists such as raloxifene or tamoxifen with ERα-LBD results in displacement of helix 12 from its agonist positioning and this helix is repositioned into the hydrophobic groove formed by helices 3, 4 and 5. This disrupts formation of the co-activator interaction surface (Shiau *et al.*, 1998; Pike *et al.*, 1999) and the ligand-dependent effects of helix 12 positioning is dependent on the agonistic or antagonistic activity of various ER ligands (Brzozowski *et al.*, 1997; Pike *et al.*, 2001).

# XENOESTROGENS AND PHYTOESTROGENS AS SELECTIVE ER MODULATORS

## Complexity of estrogenic activity
