Results of X-ray crystallographic analysis clearly demonstrates that both ER agonists differentially bind the ER and induce compound-specific changes in the bound complex. Although tamoxifen and E2 induce distinct conformations of the ER and exhibit antiestrogenic and estrogenic activity in breast cancer, these compounds both induce ER-dependent activity in the uterus and prolonged treatment with tamoxifen increases the risk for endometrial cancer (Bernstein *et al.*, 2002). Tamoxifen is also an ER agonist in the bone and vascular system and there are tissue- and species-specific ER agonist or antagonist activities in animal models where tamoxifen is an ER antagonist in chicks, a partial ER agonist/antagonist in rats and an ER agonist in several short-term assays in mice (MacGregor and Jordan, 1998). Studies on tamoxifen and other ER agonists has led to the development of the acronym selective ER modulators (SERMs) which exhibit a complex pharmacology and induce tissue-specific ER agonist or antagonist activities. These structure-dependent differences are related to differential activation of estrogen-responsive genes/pathways and due to several factors (Katzenellenbogen *et al.*, 1996; Smith and O'Malley, 2004), including:

a the structure of the estrogenic compound;
b tissue-specific expression of ER subtype (ERα and ERβ) or variant;
c tissue-specific expression of critical co-activators and other co-regulatory proteins
d promoter context and chromatin state which is dependent on histone methylation or acetylation, promoter methylation, and expression of critical modulating *trans*-acting factors.

## Development of bioassays for clinically relevant SERMs

SERMs were primarily developed for treatment of hormone-dependent diseases or conditions and define the increasing complexity of ER action. If xenoestrogens and phytoestrogens are SERMs, then their estrogenic and antiestrogenic activities will also be tissue-specific and their role in causation or protection from hormone-dependent problems will depend on the structure of the individual compound, the amount of exposure (assuming a threshold) and the time of exposure where critical modifications of hormone-responsiveness are induced. The structurally diverse SERMs, E2, tamoxifen, raloxifene and ICI 164,384 have unique *in vivo* biologies and were used as model compounds to develop an *in vitro* bioassay that would distinguish between these compounds (Tzukerman *et al.*, 1994; McDonnell *et al.*, 1995). This bioassay utilizes the modular structure of ERα and ERβ in which the various domains (E–F) exhibit both separable and overlapping functions which govern their interactions with other co-regulatory proteins and promoter DNA. AF-1 and AF-2 are located in the A/B and E domains, respectively, and are particularly important for this assay system. Results in Table 65.1 show that these four compounds differentially induce transactivation in human hepatoma HepG2 cells transfected with the E2-responsive pC3 construct (human complement C3 promoter linked to the luciferase gene) and expression plasmids for wild-type ERα, ERα-AF-2 in which the AF-1 domain has been deleted, or ERα-AF-1 in which the critical amino acids in AF-2 have been mutated (aa D538N, E542Q and D545N). E2 induces transactivation in HepG2 cells transfected with wild-type/variant ERα; in contrast raloxifene activates ERα-AF-1, tamoxifen activates ERα and ERα-AF-1, and ICI 164,384 does not induce or inhibits transactivation.

## Xenoestrogens and phytoestrogens as SERMs

This assay has been used for distinguishing between different structural classes of xenoestrogens and phytoestrogens including BPA (2′,4′,6′-tricholo-4-biphenylol ($Cl_3$–PCB–OH), 2′,3′,4′,5′-tetrachloro-4-biphenylol ($Cl_4$–PCB–OH), *p*-*t*-octylphenol (OP), *o*-nonylphenol (NP), naringenin, kepone, resveratrol and 2,2-bis(*p*-hydroxyphenyl)-1,1,1-trichloroethane (HPTE). E2, ICI 182,780 and 4-hydroxytamoxifen were used as positive controls (Gould *et al.*, 1998; Yoon *et al.*, 2000, 2001). Results obtained in several cell lines using the E2-responsive complement pC3-luc construct or a construct ($pERE_3$) containing three estrogen-responsive elements (EREs) linked to luciferase demonstrate that xenoestrogens/phytoestrogens also differentially induce transactivation.

**TABLE 65.1 The SERMs tamoxifen, raloxifene, ICI 164384 and E2 differentially activate ERα and also exhibit unique *in vivo* biologies (Tzukerman *et al.*, 1994)**

| SERM | ERα | | | | ERα-AF-1 | | | | ERα-AF-2 | | | *In vivo* ER activity | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | A/B | C/D | E | F | A/B | C/D | E*** | F | C/D | E | F | Bone | Breast | Uterus |
| E2 | | +++[a] | | | | +++ | | | | +++ | | Ag[b] | Ag | Ag |
| Tamoxifen | | + | | | | + | | | | ND | | Ag | Ant | Ag |
| Raloxifene | | ND | | | | + | | | | ND | | Ag | Ant | – |
| ICI 164,384 | | ND | | | | ND | | | | ND | | – | Ant | Ant |

[a]E2 induced maximal responses in all assays (+++), and responses >40% (++) or <40%(+) of that observed for E2 are indicated. ND indicates no significant induction or inhibition of activity.
[b]Ag and Ant indicate ER agonist and antagonist, respectively; – indicates no agonist activity.

**TABLE 65.2 Different structural classes of xenoestrogens, phytoestrogens, E2 and 4-hydroxytamoxifen differentially induce transactivation in HepG2 and U2 cells transfected with $pERE_3$, wild-type and variant forms of ERα (Yoon *et al.*, 2001)**

| | ERα | | ERα-AF-1 | | ERα-AF-2 | |
|---|---|---|---|---|---|---|
| | A/B C/D | E F | A/B C/D | E*** F | C/D E | F |
| | HepG2 | U2 | HepG2 | U2 | HepG2 | U2 |
| 17β-estradiol | +++* | +++ | +++ | +++ | +++ | +++ |
| 4-Hydroxytamoxifen | + | ND | ND | ND | ND | ND |
| NP | + | + | ++ | ND | ++ | ND |
| OP | + | + | + | + | ND | ND |
| $HO–PCB–Cl_4$ | ++ | ++ | + | ND | ++ | +++ |
| $HO–PCB–Cl_3$ | ++ | ++ | + | ++ | +++ | +++ |
| HPTE | +++ | + | + | ND | +++ | ++ |
| BPA | ++ | ++ | + | ++ | ++ | +++ |
| Kepone | ND | ND | + | ND | + | ND |
| Naringenin | ND | ND | ND | ND | ND | ND |
| Resveratrol | ND | ND | ND | ND | ND | ND |

* E2 induced a maximal response (+++) in all assays. A significant induction response of >40% (++) or <40% (+) of that observed for E2, and no significant induction (ND) are indicated. ICI 182,780 gave an ND for all responses. The doses used were 10 nM and 1 μM for E2 and 4′-hydroxytamoxifen, respectively, 100 μM for BPA, and 10 μM for the remaining compounds.

Results summarized in Table 65.2 compare the maximal induced responses observed for these compounds using human hepatoma HepG2 and human U2 osteogenic cancer cell lines transfected with $pERE_3$ and ERα, ERα-AF-1 or ERα-AF-2 (Yoon *et al.*, 2001). Even among structurally related compounds such as the hydroxy-PCBs, alkylphenols and bisphenolics HPTE and BPA, there were some significant differences in their induction of transactivation. Moreover, using a similar approach in HepG2, U2 and MDA-MB-231 cancer cell lines transfected with a pC3-luc construct similar differences were observed (Yoon *et al.*, 2000). For example, the two bisphenolic compounds HPTE and BPA exhibit a similar pattern of transactivation in many assays except that in U2 cells BPA but not HPTE induces transactivation in cells transfected with ERα-AF-1. It was also apparent from other *in vivo* and *in vitro* studies that BPA and HPTE exhibit difference in their estrogenic activities. For example, HPTE was a more potent estrogen than BPA in the female rat uterus; however in combination with E2, lower doses of BPA inhibited E2-induced uterine progesterone receptor (PR) binding and peroxidase activity (Gould *et al.*, 1998). HPTE versus BPA also exhibited other differences in HepG2 cells where both HPTE and BPA are ERα agonists, whereas HPTE is an ERβ and androgen receptor (AR) antagonist and BPA is an ERβ agonist and did not affect AR in this cell line (Gaido *et al.*, 1999). These activities can also vary in other cell contexts but clearly demonstrate significant *in vitro* and *in vivo* biological differences between HPTE and BPA, suggesting that structurally diverse estrogenic compounds are SERMs.

Several other *in vitro* studies have demonstrated significant differences among different structural classes of estrogenic compounds and the planar phytoestrogens coumestrol and genistein. For example, an ERα mutant (D351G) is activated by E2 and DES but not by 4′-hydroxytamoxifen or the non-planar HPTE and related compound (Jordan *et al.*, 2001). It was also reported that isoflavones, daidzein, biochanin and genistein are ERβ-selective and this is due to their preferential induction of co-activator interactions with AF-2 of ERβ compared to AF-2 of ERα (An *et al.*, 2001). Other reports also show that activation of gene expression in *in vitro* assays by structurally diverse xenoestrogens/phytoestrogens depends on the promoter context

(i.e. different consensus versus non-consensus EREs) and on co-activator interactions (Hall *et al.*, 2002; Mueller *et al.*, 2004). Recent studies in the laboratory have also demonstrated structure-dependent activation of non-genomic kinase pathways by xenoestrogens/phytoestrogens (Li and Safe, 2006). Moreover it has also been shown that some estrogenic compounds activate kinases via ER-independent pathways by directly binding to a G-protein coupled receptor (GPR30) (Thomas *et al.*, 2005; Revankar *et al.*, 2005). The structure dependence on this ER-dependent pathway has yet to be determined. These results clearly imply that xenoestrogens/phytoestrogens are SERMs.

## XENOESTROGENS AND PHYTOESTROGENS AS SERMS AND IMPLICATIONS FOR RISK ASSESSMENT

Xenoestrogens and phytoestrogens differentially activate wild-type and variant ER$\alpha$ *in vitro* suggesting that these compounds are SERMs. This implies that their estrogenic activity and potency cannot be determined by simple ER binding or gene expression assays. Thus, in order to fully understand the estrogenic or antiestrogenic activities of phytoestrogens and xenoestrogens studies will have to focus on their tissue-specific impacts at various critical periods of exposure. Risk assessment of these compounds will be complex and dependent on all the variables indicated in a previous section. Moreover, since individual SERMs exhibit unique biologies, the overall impact of mixtures of these compounds may not be additive. These factors highlight the challenges faced by scientists and regulators in addressing the health risks and benefits of estrogenic compounds.

## ACKNOWLEDGMENTS

Financial support for preparation of this chapter has been provided by the National Institutes of Health (R01-ES004917 and P30-ES09106) and the Texas Agricultural Experiment Station.

## INTRODUCTION

Poisonous plants and the secondary compounds they produce cause large economic losses to the livestock industries throughout the world. Using 1989 figures, it was determined that poisonous plants cause losses of over $340 million annually to the livestock industry in the 17 western states of the United States (Nielsen *et al.*, 1988; Nielsen and James, 1992). This cost only considered death losses and specific reproductive losses in cattle and sheep and only the 17 western states were included. Less obvious costs such as lost grazing opportunities, additional feed costs, increased health care costs, management changes, increased culling costs, lost weight gains, delayed or failed reproduction, and the emotional stress accompanying many poisonous plant cases were not included in the Nielsen and James analysis. When one considers these other costs, inflation, current animal values and when all pastures and ranges in the United States are factored in, the economic cost of poisonous plants to the livestock industry is very large. Additionally, an often ignored cost is the lost biodiversity frequently resulting from invasive species, many of which are poisonous. These invasive and poisonous species are often aggressive invaders and reduce optimum utilization of private, federal and state managed forest, range and pasture lands. This aspect alone has far reaching implications, not only for livestock producers, but also for many other segments of society.

A frequently asked question is, why do animals consume plants which may harm them or their offsprings? In some cases it is a matter of survival. For example, in the arid livestock-producing regions of the world, such as the western United States, regions of South Africa, Australia, China, and others, browsing or grazing animals may have limited access to high-quality forage at certain times of the year and are forced to survive by grazing some poisonous species. In other instances, hay or forages harvested in areas where poisonous plants are abundant may be contaminated with a high percentage of poisonous plants and when animals are fed contaminated hay, they may be poisoned. Poisonous plant problems are often exacerbated during periods of below normal rainfall when the abundance of grasses is reduced. Frequently, the animal's diet shifts during the season as grasses and palatable forbs mature and senesce, e.g. the consumption of some poisonous plants such as lupines, locoweeds, or larkspurs, which stay green longer into the season, may increase as the season progresses. In other instances poisoning occurs early in the season before grasses begin to grow but poisonous plants have emerged and are usually very toxic. Poisoning by plants only occurs when animals eat too much too fast or graze it over a prolonged period of time. Therefore, management strategies to control these factors can minimize losses from poisonous plants.

At the Poisonous Plant Research Laboratory, poisonous plant problems are attacked using a multi-disciplinary approach. Veterinary medicine, chemistry, toxicology, pathology, animal and plant physiology, and range management are all key in the approach to reduce losses to the livestock industry. The plants in this chapter are some of the most important poisonous plants in the United States and considerable research has been conducted to reduce their incidence of poisoning.

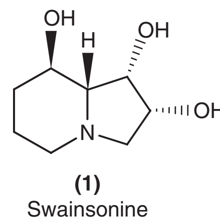
This chapter is not intended to be all inclusive but focuses on some of the most economically important and geographically widespread poisonous plants to livestock producers in the United States. There are excellent comprehensive texts available with a more general and broad coverage of specific poisonous plants (Kingsbury, 1964; Keeler *et al*., 1978 (ISOPP1); Seawright *et al*., 1985 (ISOPP2); James *et al*., 1992 (ISOPP3); Colegate and Dorling, 1994 (ISOPP4); Cheeke, 1998; Garland and Barr, 1998 (ISOPP5); Burrows and Tyrl, 2001; Knight and Walter, 2001; Acamovic *et al*., 2004 (ISOPP6); Panter *et al*., 2007 (ISOPP7)). The ISOPP series, 1–7, 1978–2006 (*Proceedings of the International Symposium on Poisonous Plants*) provides a worldwide view of poisonous plant research and is currently in its seventh publication in 2006.

## *ASTRAGALUS* AND *OXYTROPIS* SPECIES (LOCOWEEDS, NITRO AND SELENIUM SPECIES)

### Locoweeds

Of all the poisonous plants in the United States the *Astragalus* and *Oxytropis* genera cause the most losses to the livestock industry in the Western States (James *et al*., 1981). The locoweeds are those species of the *Astragalus* and *Oxytropis* genera that contain the "loco" toxin (swainsonine) and induce the classic neurological and pathological signs of "locoism." Swainsonine is also present in other *Astragalus* species not usually considered locoweeds such as some selenium and nitro-containing *Astragalus*. There are three toxic syndromes associated with these species: (1) locoism, caused by the indolizidine alkaloid swainsonine **(1)** (24 species); (2) nitrotoxins (356 taxa); and (3) species that accumulate selenium at high levels (22 species).



#### *Description and ecology*

These species are members of the Fabaceae (Leguminosae) or pea family. This family is distinguished by its distinct papilionaceous flower (butterfly-like) having a single large banner petal, two side petals or wings, and two lower petals fused together to form a keel. Flowers are leguminous (pea-like), few to many, in axillary racemes, may be blue, purple, yellow, or white in color; fruit is a legume pod of various shapes, sizes and surfaces among the species containing one to many kidney-shaped seeds. The distinguishing feature in *Oxytropis* is the porrect beak on the keel petal, *Astragalus* have a blunt keel petal (Figure 66.1). Some *Astragalus* species have extensions of the keel forming points, but they are not turned upward as in *Oxytropis*. In addition, *Oxytropis* species are acaulescent (without a stem, all leaves basal) with leafless flowering stalks originating from the crown, whereas leaflets of *Astragalus* species grow from the multi-branched stems with the flowering head on top (Figure 66.1). Leaflets are opposite pinnately compound. Pod shape, size, and chambers are very diverse, and are a principal means of distinguishing species (Figure 66.1).

*Astragalus* is a very large and complex genus, with 354 species and 198 varieties of *Astragalus* (552 taxa) in the

**FIGURE 66.1** Comparison of *Astragalus* and *Oxytropis*. *Astragalus mollissimus* (purple loco) is on the left and *Oxytropis lambertii* is on the right.

United States and Canada (Welsh *et al*., 2007). *Oxytropis* is much smaller with 22 species and 35 varieties (57 taxa).

Barneby (1952, 1964) earlier described and classified 368 species and 184 varieties of *Astragalus* and 35 species of *Oxytropis* in North America. Irregardless, the *Astragalus* genera is the largest of the Leguminosae family. Species and variety identification are difficult even for trained botanists. Because of obvious similarities between *Oxytropis* and *Astragalus* some botanists treat them together as *Astragalus*. Certainly, from a toxicology perspective, both contain swainsonine and induce the same condition in livestock, therefore both genera will be treated the same in this discussion.

### *Distribution and ecology*

The *Astragalus* and *Oxytropis* are worldwide in their distribution and toxic effects on livestock. Table 66. 1 lists those species in the western United States suspected of field cases of poisoning or which have been shown by chemical analysis to contain swainsonine (Marsh, 1909, 1924; Barneby, 1952, 1964; Molyneux and James, 1991; Molyneux *et al*., 1991).

Species of *Astragalus* and *Oxytropis* occur in every major plant community. However, livestock poisoning is erratic, due to the cyclic nature of the locoweed populations. Locoweeds have different survival strategies which allows perpetuation of the species through long-term climatic cycles and short-term weather conditions (Ralphs *et al*., 2003). Climate controls the establishment and growth of these plants by the amount and timing of precipitation. The three main survival strategies include the following:

1 Annual plants avoid drought by seed-dormancy through dry cycles, and germinate in years when sufficient moisture is available (winter annuals such as *A. wootonii* and *A. emoryanus*).
2 Biennial or short-lived perennial plants exhibit opportunistic survival strategies by relying on both timely and adequate moisture for germination, growth, flowering, and seed set. Seeds germinate in fall following autumn rains, persist over winter and flower in spring. If sufficient moisture is available, they will remain for 2–3 years until the next drought occurs (*A. mollissimus, A. lentiginosus, A. pubentissimus*).

**TABLE 66.1 Locoweeds (*Astragalus* and *Oxytropis*) species, habitat, and distribution (Ralphs *et al*., 2003) and *Astragalus* species containing nitrotoxins or accumulating selenium (Welsh *et al*., 2007)**

| Species | Common name | Habitat | Distribution |
|---|---|---|---|
| *A. allochrous* | Rattleweed | Desert grassland | AZ, NM |
| *A. asymmertricus* | Horse loco | Annual grasslands | CA |
| *A.* bisulcatus[a] | Two-grooved milkvetch | Limestone, shale, high in Se | MT, ND, WY, CO, NM, Ut |
| *A. didymocarpus* | | Creosote deserts | CA, AZ, NV |
| *A. drummondii*[a] | Drummond milkvetch | Prairies, sage, oak, P/J | MT, WY, CO, NM, UT |
| *A. emoryanus*[b] | Red stem peavine | Creosote, Mesquite, P/J | NM, TX |
| *A. humistratus* | Ground cover milkvetch | P/J woodlands | AZ, NM |
| *A. lentiginosus* | Spotted locoweed | Salt-desert shrub, sage, P/J | AZ, UT, NV, ID |
| *A. lonchocarpus* | Great rushy milkvetch | P/J woodlands | CO, UT, AZ, NV |
| *A. missouriensis* | Missouri milkvetch | Short-grass prairies | Canada to TX |
| *A. mollissimus* | Woolly loco | Short-grass prairies | CO, KA, OK, TX, NM |
| *A. nothoxys* | Beaked milkvetch | Oakbrush, P/J woodlands | AZ |
| *A. oxyphysus* | Diablo loco | Desert grasslands | CA |
| *A. praelongus*[a] | Stinking milkvetch | Sandstone, shale high in Se | UT, NM, AZ |
| *A. pubentissimus* | Green River milkvetch | Salt-desert shrub | CO, WY, UT |
| *A. purshii* | Pursh loco | Sagebrush, P/J woodlands | WY, MT, ID, NV |
| *A. pycnostachyus* | Brine milkvetch | Salt marshes and beaches | CA |
| *A. tephrodes* | Ashen milkvetch | Oakbrush, P/J woodlands | AZ, NM |
| *A. thurberi* | Thurber milkvetch | Creosote, Oak, P/J woodlands | AZ, NM |
| *A. wootonii* | Garbancillo | Creosote desert | AZ, NM, TX |
| *O. besseyi* | Red loco | Gravely hill tops | MT, WY |
| *O. campestris* | Yellow loco | Prairies, mountains meadows | MT, Canada |
| *O. lambertii* | Lambert locoweed | Short and mid-grass prairies | MT, ND, SD, WY, CO, NM |
| *O. sericea* | White locoweed | Rocky soils, foothills and mountains | MT. SD, WY, CO, NM, UT |
| **Nitrotoxins** | | | |
| *A. atropubescens* | Kelsey milkvetch | Gravelly benches | ID, MT |
| *A. canadensis* | Canada milkvetch | Introduced | Throughout US |
| *A. convallarius* | Rushy milkvetch | Sagebrush | ID, NV, UT, WY |
| *A. emoryanus* | Red-stem peavine | Short-grass prairies | AZ, NM, TX |

(*Continued*)

**TABLE 66.1 (Continued)**

| Species | Common name | Habitat | Distribution |
|---|---|---|---|
| *A. falcatus* | | Introduced species | |
| *A. miser* | Timber milkvetch | | |
| var *serotinus* | Columbia milkvetch | Rough fescue grasslands | BC Canada |
| var *hylophilus* | Yellowstone milkvetch | Sagebrush/timber | WY, MT |
| var *oblongifolius* | Wasatch milkvetch | Mountains sagebrush | UT, CO |
| *A. pterocarpus* | Winged milkvetch | Sagebrush | CA, NV |
| *A. tetrapterus* | Four-winged milkvetch | Sagebrush | CA, NV |
| *A. toanus*[c] | Toano milkvetch | Salt-desert shrub | Great Basin |
| *A. whitneyi* | | Sierra Mountains | CA, NV |
| **Selenium accumulators** | | | |
| *A. albulus*[c] | Cibola milkvetch | Salt-desert shrub | Northwestern NM, AZ |
| *A. beathiii*[c] | Beath milkvetch | Badlands | AZ, NV, UT |
| *A. bisulcatus* | Two-grooved milkvetch | Sagebrush | MT, WY, ND, SD, CO,UT, NM |
| *A. crotalariae*[c] | Rattle box milkvetch | Desert | AZ, CA |
| *A. cutleri*[c] | | | |
| *A. debequaeus*[c] | | | |
| *A. eastwoodiae*[c] | Eastwood milkvetch | Badlands | Four Corners |
| *A. flavus* | Yellow milkvetch | Alkaline soils | Colorado plateau |
| *A. grayii*[c] | Grays milkvetch | Badlands | WY, MT |
| *A. moencoppenis* | Moenkopi milkvetch | Badlands | UT, AZ |
| *A. nelsonianus*[c] | | Alkaline flats | WY |
| *A. oocalycis*[c] | | Sagebrush | CO, NM |
| *A. osterhouti* | Osterhout milkvetch | Clay hills | Grand Company, CO |
| *A. pattersoni* | Patterson milkvetch | Oakbrush | Rocky Mountains |
| *A pectinatus* | Tiny-leaved milkvetch | Northern prairies | MT, ND, WY, CO, KA |
| *A. praelongus* | Stinking milkvetch | Badlands | Four Corners |
| *A. racemosus* | Alkali milkvetch | Badlands | Plains states |
| *A. sabolosus* | Cisco milkvetch | Badlands | Eastern UT |
| *A.* saurinus[c] | Dinosaur milkvetch | Badlands | Eastern UT |
| *A. sophoroides*[c] | Painted desert milkvetch | | AZ |
| A. *toanus*[c] | Toano milkvetch | Salt-desert shrub | Great Basin |

There are many varieties, especially of *A. lentiginosus, A. mollissimus*, and *O. sericea*, that have been referred to as separate species in the past.
Species taken from Marsh (1909), Molyneux *et al*. (1991), Smith *et al*. (1992), and Fox *et al*. (1998).
[a]Also contains selenium.
[b]Also contains nitrotoxins.
[c]Minor species.

3 Long-lived perennial plants exhibit a stress-tolerant survival strategy. They have deep taproots that can access deep-stored water. They grow where moisture is more abundant and more regularly available. The plants flower and produce seeds for many years following initial establishment, although they too may die out during extended droughts (*O. sericea, O. lambertii*).

The seed bank in the soil supports these cycles. The seeds have hard coats and remain viable for many years, thus providing an ecological advantage to exploit environmental conditions and maintain the "boom and bust" population cycles (Ralphs and Cronin, 1987). Livestock poisonings follow these cycles, often in catastrophic proportions.

### *Toxicology*

Locoweed poisoning was one of the first poisonous plant problems recognized by stockmen and reported as early as 1873 (Vasey, in Marsh, 1909). Extensive stock losses in the western United States eventually led to the establishment of a field station in Hugo, Colorado in 1905 to study the problem. Research from 1905 to 1907 determined that certain species of the *Astragalus* and *Oxytropis* genera were responsible and this research was published in 1909 as a USDA bulletin titled "The locoweed disease of the plains" by C.D. Marsh.

There are numerous effects of locoweed on animals but the classic syndrome from which the term "locoism" came is one of neurological dysfunction. The disease is a chronic one developing after weeks of ingesting locoweeds and beginning with depression, dull appearing eyes, incoordination progressing to aberrant behavior including aggression, staggering, solitary behavior, emaciation, and ending in death if continued consumption is allowed. Other problems associated with locoweed ingestion include reproductive failure, abortion, birth defects, weight loss, and enhanced susceptibility to brisket disease at high elevations (James *et al*., 1981).

Locoweed poisoning affects all animals but because of the transient nature of the poisoning, animals removed from the locoweed early in the toxicosis will recover most of their function and may be productive animals. In the final stages of locoism, central nervous system tissue shows swelling of axonal hillocks (meganeurites) and growth of new dendrites and synapses (Walkley and Siegel, 1989). This altered synaptic formation in nervous tissue in severely affected animals is permanent and may be the cause of some irreversible neurological signs. Because of neurological dysfunction and apparent permanence of some lesions in the nervous system, horses are believed to be unpredictable and therefore unsafe to use for riding yet may remain reproductively sound once they have recovered from the poisoning (James *et al.*, 1969).

### Toxin

The toxin in locoweeds is the indolizidine alkaloid swainsonine **(1)**. First isolated from the Australian plant *Swainsona canescens* (Colegate *et al.*, 1979), swainsonine and its *N*-oxide were isolated and identified soon thereafter from the locoweeds (Molyneux and James, 1982).

Remarkably, C.D. Marsh (1909) made the connection between the clinical and pathological syndrome of locoweed poisoning and a similar condition reported in Australian livestock called "peastruck." Confirmation feeding trials in New South Wales with Darling pea (*Swainsona* spp.) were reported a few years before Marsh reported the details of locoweed poisoning (Martin, 1897, in Marsh, 1909). Ironically, the toxin (swainsonine) was isolated and characterized from *Swainsona canescens* and reported in Australia in 1979 (Colegate *et al.*, 1979), and subsequently identified and isolated from locoweeds (*Astragalus* and *Oxytropis*) in the United States and reported in 1982 (Molyneux and James, 1982).

The isolation and characterization of swainsonine from *Swainsona canescens* resulted from investigations by a multidisciplinary research team in Australia whose members were experienced in various aspects of lysosomal storage disease in domestic animals (Dorling *et al.*, 1989). This investigation concentrated on the details of the pathogenesis of the toxicosis enabling the research team to elucidate the mechanism of action which provided the bioassay method for toxin isolation and identification. A review of the historical aspects can be found in Dorling *et al.* (1989). In essence the locoism syndrome is a lysosomal storage disease in which $\alpha$-mannosidase is inhibited resulting in prevention of hydrolysis of mannose-rich oligosaccharides in cells and accumulation of these oligosaccharides resulting in cellular dysfunction. Most organ systems are affected but some are more susceptible such as glandular and neurological tissues.

Recent research has shown that inhibition of $\alpha$-mannosidase is relatively transient and quickly reversible once animals stop eating locoweed (Stegelmeier *et al.*, 1994). Blood serum clearance of swainsonine is rapid (half-life 20 h) thus the effects of locoweed should be reversible if tissue damage has not become extensive and permanent. This would suggest that intermittent grazing of locoweed should be an effective means of reducing locoweed poisoning. There is also an apparent threshold dosage where severity of cell damage is more time dependent than dosage dependent. Once the threshold dosage is reached, which appears to be relatively low (0.35 mg/kg in the rat), eating more locoweed does not accelerate the toxicosis (Stegelmeier *et al.*, 1995). Therefore, increasing animal numbers on loco pastures and reducing time of grazing is a logical method to reduce adverse effects.

Many locoweeds are biennials or perennials that flourish periodically under optimum environmental conditions. Historically, losses are regional and sporadic, with large regional economic impact. Individual cases of significant losses are frequent and reported in James and Nielsen (1988). Recently, 25% of over 500 mother cows of a University Foundation herd either aborted or apparently resorbed their fetuses after grazing pastures with *Oxytropis sericea*. Necropsy of aborted fetuses showed pathological lesions characteristic of locoweed poisoning and 50 calves born alive showed outward signs of toxicity (personal communication, 1994). Followup communication indicated that locoed calves were immunologically compromised and 3–4% of these calves died after weaning. The remainder of the loco calves remained about 200 lb behind calves not exposed to loco even though after the first 28 days in the feedlot the rate of gain was about the same.

### Conditions of grazing

The early literature suggested locoweeds were distasteful and animals were forced to start eating them because of hunger (Kingsbury, 1964). However, once started, animals seemed to become addicted to locoweeds. Recent research showed that locoweeds are not addicting, but are relatively more palatable than associated forages during various seasons of the year (Ralphs *et al.*, 1991b).

Preference for locoweed is relative to what other forage is available. Many locoweeds are cool-season species that green-up and start growth early in the spring, flower, set seed, and go dormant in summer, then resume growth in fall. Livestock generally prefer the green, growing locoweeds to dormant grass. Sheep preferred the regrowth foliage of Green River milkvetch to dormant grasses during late fall and early winter on desert range in eastern Utah (James *et al.*, 1968). Horses selected green-spotted locoweed to dormant grasses in spring in Arizona (Pfister *et al.*, 2003). Cattle readily grazed Wahweap milkvetch in proportion to its availability on desert winter range in southeastern Utah (Ralphs and Bagley, 1988). In a series of grazing studies in northeast New Mexico, cattle readily grazed white locoweed in March, April,

and May, but stopped grazing it in June as warm-season grasses became abundant and white locoweed matured and became coarse and rank (Ralphs *et al*., 1993, 2000). Stocker cattle grazed white locoweed on short-grass prairies in May and early June (Ralphs, 1987), but the weight loss continued throughout the summer, even though they were not eating locoweed (Ralphs *et al*., 2000; Torell *et al*., 2000). On mixed-grass prairies on the eastern foothills of the Rocky Mountains in northern Colorado, cattle ceased grazing white locoweed when it matured following flowering in mid June, and became rank and unpalatable in 1998. However, they continued to graze it throughout the summer in 1999 when abundant summer precipitation caused locoweed leaves to remain succulent (Ralphs *et al*., 2001).

### *Prevention of poisoning and management recommendations*

Prevention of poisoning remains a matter of management strategy adapted to individual grazing programs to minimize grazing of locoweed plants. Currently no broad management schemes or methods of treatment are known to generally prevent locoweed poisoning. Management strategies for individual operations have been developed once the grazing practices and options are identified, allowing utilization of the particular range and yet minimizing losses (Ralphs *et al*., 1984, 1993). It was determined that cattle generally rejected woolly loco even under extreme grazing conditions, but once they were forced to start eating it they continued to graze it and became intoxicated. Ranchers should watch for these "loco eaters" and remove them to clean pastures. Shortage of feed with high grazing pressure, social facilitation "loco eaters" teaching non-loco eaters to eat loco, or supplementing with alfalfa hay or cubes may compel cattle to start grazing woolly locoweed (Ralphs *et al*., 1993). White locoweed is more palatable than woolly locoweed and is green before spring grasses begin to grow in northeastern New Mexico. Therefore, cattle readily graze white loco in early spring while grasses are dormant and once green grass starts to grow cattle switch-off of loco. Recommendations include creating loco-free pastures through spraying, fencing, or selection of low loco-infested pastures for early spring grazing and also to provide a place to move the identified loco-eaters too. This practice appears to reduce the impact of locoweed on these ranges (Ralphs *et al*., 1993).

Many minerals, feed additives, and clay minerals have been investigated to prevent poisoning, but none have been effective. The poisonous plant literature is filled with statements that native livestock are less likely to be poisoned than new, inexperienced livestock. Locoweed poisoning does not follow this general trend. Cattle that are familiar with locoweed will likely select it first (Ralphs *et al*., 1987). Early observations by Marsh (1909) suggested that black cattle and black-faced sheep were more inclined to be poisoned by locoweed than white-faced cattle and sheep. In a recent grazing study comparing breeds, Brangus steers consumed more locoweed than Hereford and Charolais steers (Duff *et al*., 2001). The gregarious nature of Brangus cattle may have facilitated the social acceptance of locoweed among the steers.

Livestock should be denied access to locoweeds during critical periods when they are relatively more palatable than associated forages. On short-grass prairies of northeastern New Mexico, stocker cattle should not be turned onto locoweed-infested rangelands until warm-season grasses start growth in late May or early June. Cattle on rangeland year-round should be removed from locoweed-infested areas in the spring when it is green and growing, and warm-season grasses remain dormant. They can be returned to locoweed-infested pastures in summer when warm-season grasses are abundant.

Most locoweed species are endemic, growing only in certain habitats or on specific soils. Fences could be constructed on soil or vegetation boundaries to provide seasonal control of grazing. Reserving locoweed-free pastures for grazing during critical periods in spring and fall can prevent locoweed poisoning.

Locoweed-free areas can be created by strategic herbicide use (Ralphs and Ueckert, 1988; McDaniel, 1999). White locoweed is most susceptible to Clopyralid, but Picloram and Escort are also effective. However, natural population cycles should be considered to determine the practicality of spraying large areas and the potential lifetime of control. With the abundant seed bank in the soil, locoweeds are sure to germinate and reestablish when environmental conditions are favorable.

Animals that start eating locoweed may influence others to start. Social facilitation or peer pressure is a very strong influence inducing others to start eating locoweed (Ralphs *et al*., 1994b). Graham developed the "eat and pull" management strategy, whereby livestock should be watched closely and removed if they start eating locoweed to prevent poisoning and prevent them from influencing others to start (Torell *et al*., 2000).

Grazing pressure can also force cattle to begin grazing locoweed when they run short of desirable forage (Ralphs, 1987; Ralphs *et al*., 1994a). Ranchers should not overstock locoweed-infested ranges, but rather should ensure adequate forage is always available. Improper use of some grazing systems can cause livestock to graze locoweed. Rest-rotation grazing systems are designed to force livestock to uniformly graze all forage in a pasture. This caused cattle and horses to start grazing spotted locoweed in western Utah (James *et al*., 1969). Changing to a three-herd, four-pasture deferred rotation grazing system stopped locoweed poisoning by reducing the grazing pressure and allowing the cattle to select alternative forages in preference to white locoweed (Ralphs *et al*., 1984a). The

heavy grazing pressure associated with short-duration grazing systems may also induce poisoning problems.

Conditioned food aversion can be used as a management tool to train animals to avoid grazing locoweed (Ralphs *et al.*, 1997a). In the conditioning protocol, animals are brought into a pen and fed fresh-picked locoweed, and then lithium chloride (an emetic that causes gastrointestinal (GI) distress) is administered by stomach tube. The animals associate the induced illness with the taste of the plant and subsequently avoid eating it. Naive animals that are unfamiliar with the target plant form strong and lasting (>3 years) aversions following a single dose. Averted animals must be kept separate from non-averted animals on locoweed areas to prevent social facilitation from extinguishing the aversions. Aversion conditioning may be feasible where losses are heavy and persist year after year.

#### Summary

Locoweed is the most widespread poisonous plant problem in the western United States. Knowledge of sites where locoweeds grow and environmental conditions when they cause problems is necessary to manage livestock and prevent poisoning. Locoweeds are relatively palatable. Many locoweeds are the first plants to start growing in the spring and they may also regrow in the fall. Livestock generally prefer the green-growing locoweeds to other forage that is dormant in the fall, winter, and spring. The most effective management strategy is to deny livestock access to locoweeds during critical periods when they are more palatable than associated forage. Reserving locoweed-free pastures or controlling existing locoweed populations with herbicides can provide "safe" pastures for critical periods. Watching animals closely and removing those that begin eating locoweed can prevent further intoxication and prevent them from influencing others to start. Finally, conditioned food aversion is an effective practice to train animals to avoid eating locoweeds, and may be economical where losses are large and persistent. Good range management and wise grazing strategies can provide adequate forage for livestock and avoid critical periods of the year when locoweed is relatively more palatable than associated forages.

## Nitro-containing *Astragalus* (milkvetches)

There are over 260 species and varieties (356 taxa) of nitro-containing *Astragalus* in North America (Barneby, 1964; Williams and Barneby, 1977; Welsh *et al.*, 2007). They are frequently referred to as milkvetches as are some of the other *Astragalus* species. Nitrotoxins are, therefore, the most common toxin in the *Astragalus* followed by swainsonine (loco) and selenium (as discussed later). Major livestock losses occur in many regions of the western United States. These plants are very diverse and concentrated on the deserts, foothills, and mountains of the west.

#### Description

The description of these plants is the same as the locoweeds as discussed earlier. The milkvetches emerge from late April to June depending on elevation and snow cover. After seed dispersal in July or August the stems and leaves become dry and less dangerous as toxicity and palatability is reduced.

#### Distribution

The aliphatic nitro-containing *Astragalus* are distributed throughout North America with substantial livestock losses occurring in the 17 western states where cattle or sheep are concentrated in areas of milkvetch infestation (Table 66.1). There are examples of a number of *Astragalus* spp. such as *A. cicer* that are good forages and apparently contain low levels of the toxins discussed. Because of the extent of this group of *Astragalus* only a few of those implicated in poisonings will be mentioned here. For a more comprehensive review of the nitro-containing *Astragalus* the reader is referred to Williams and Barneby (1977). Examples of these include *A. emoryanus* (emory milkvetch) in New Mexico, Texas, and Arizona (*A. emoryanus* also contains swainsonine; Molyneux and James, 1991); *A. tetrapterus* (four-winged milkvetch) in Oregon, Utah, Nevada, and Arizona; *A. pterocarpus* (winged milkvetch) in Nevada; and *A. miser* var. *serotinus* var. *oblongifolius* and var. *hylophyilus* (collectively referred to as timber milkvetch) in western Canada, Montana, Idaho, Utah, Colorado, and Wyoming (James *et al.*, 1981).

#### Toxicology

The nitro-containing *Astragalus* cause an acute and chronic type of poisoning in sheep and cattle. The acute form results in weakness, increased heart rate, respiratory distress, coma, and death. Even though blood methemoglobin is high (induced from nitrotoxin metabolism to nitrites) and is a contributing factor to the respiratory difficulties, administration of methylene blue in cattle does not prevent death. Therefore, the methemoglobinemia is apparently not the primary cause of death (James *et al.*, 1981). The chronic form is the most frequent form of poisoning observed and follows a course of general weakness, incoordination, central nervous system involvement resulting in knuckling of the fetlocks, goose-stepping, clicking of the hooves, "cracker heels" progressing to paralysis, and death. A respiratory syndrome is also present in the chronic and acute signs with emphysema-like signs causing the animals to force respiration: "roaring disease." Sheep manifest the respiratory syndrome more than the central nervous syndrome and are more resistant to poisoning compared to cattle.

The toxic principles are β-D-glycosides of 3-nitro-1-propanol (3-NPOH) or 3-nitropropionic acid (3-NPA). The glycoside conversion occurs more readily in the ruminant because of the microflora and is apparently the reason for increased toxicity in ruminants. The glycoside (miserotoxin) is metabolized to the highly toxic 3-NPOH in the GI tract of ruminants (Williams *et al.*, 1970). Thus NPOH is absorbed in the gut and apparently converted to NPA by the liver (Majak *et al.*, 1985). Further metabolism yields inorganic nitrite and an unidentified metabolite which may be involved in toxicity (Majak *et al.*, 1985). It appears that NPOH is more rapidly absorbed from the gut than is NPA therefore forage containing the alcohol form is the most toxic (Williams and James, 1975).

### Prevention and treatment

There is no preferred treatment for milkvetch poisoning, although treatment with methylene blue appears to reverse the methemoglobinemia but does not prevent death in cattle (James *et al.*, 1981). Oxidation of NPOH to NPA was prevented if alcohol dehydrogenase was saturated with ethanol or inhibited with 4-methylpyrazole before NPOH was given (Majak *et al.*, 1985). This suggests that NPOH is a good substrate for the enzyme alcohol dehydrogenase. This information could be useful in acute cases, however, its value in treatment of poisoning in the field is unknown.

Livestock losses can be reduced by decreasing the density of the *Astragalus* species with herbicides or avoid grazing livestock on infested areas when the plant is most poisonous. Wasatch milkvetch contains the highest concentration of miserotoxin from bloom to immature pod stage of growth (Williams and Norris, 1969). Nitro compounds are found in all parts of the plant, but the leaves contain the highest concentration. Once the leaves begin to dry and lose their green color, the nitro levels drop very rapidly and the plant is relatively non-toxic (Williams and Binns, 1967). However, the toxins in plants pressed green and preserved in herbaria appear to remain stable for years (Williams and Barneby, 1977). Herbicide treatment decreases the density of plants and also decreases the toxicity of the plants once they start to dry, therefore spraying milkvetch appears to be the best method to reduce losses and still utilize infested ranges.

## Seleniferous *Astragalus*

About 22–24 species of *Astragalus* known to accumulate selenium have been identified (Rosenfeld and Beath, 1964; Welsh *et al.*, 2007). These are less numerous and more geographically restricted than the nitro-containing species. Many of these species are referred to as indicator plants because they only grow on soils high in selenium, therefore they are helpful in locating and identifying areas or soils high in selenium. The *Astragalus* are generally deep-rooted plants and may bring selenium from deeper soil profiles in a form unavailable to other plants and convert it to an available form subsequently taken up by grasses and other forbs (Olson, 1978). It is these secondary absorbers that create most of the subacute or chronic toxicity problems for livestock.

### Description

These *Astragalus* appear similar to those of locoweed and nitro-containing species as discussed earlier. One identifying feature of the selenium *Astragalus* species is an unpleasant garlic-like odor especially if picked and allowed to sit in a warm car or window. They are generally distasteful to livestock. Many selenium *Astragalus* may contain other toxins; e.g. *A. praelongus* and *A. bisulcatus* which contain selenium and swainsonine (the loco toxin) (Molyneux *et al.*, 1991) and *A. toanus* which contains all three: the nitrotoxins, selenium, and swainsonine (Williams and Parker, 1974).

### Distribution

The selenium *Astragalus* are limited in their distribution to geographical locations and soil sites of high selenium (Table 66.1). Major seleniferous areas of the west are in North and South Dakota, Montana, Wyoming, Colorado, and Utah with minor isolated pockets of seleniferous soils in most of the other western states.

The *Astragalus* species mostly associated with selenium poisoning include *A. bisulcatus* (two-grooved milkvetch), *A. praelongus* (stinking milkvetch), *A. pattersonii* (Patterson milkvetch), *A. pectinatus* (tiny-leaved milkvetch), and *A. racemosus* (alkali milkvetch).

### Toxicity

The syndromes of selenium poisoning are acute and chronic. Acute cases of selenium poisoning are rare and usually involve animals forced to graze indicator plants which are very disagreeable or animals accidentally eating chemical selenium preparations. Acute poisoning by overdosing with O-se or Bo-se in the treatment of white muscle disease may occur if label directions are not carefully followed. The signs of acute selenium poisoning include diarrhea, unusual postures, increased temperature and heart rate, dyspnea, tachypnea, respiratory distress, prostration, and death (James *et al.*, 1981; Tiwary *et al.*, 2005, 2006). Gross pathological findings are usually limited to pulmonary congestion and hemorrhage and pulmonary edema (James *et al.*, 1981). Histologically, multi-focal myocardial necrosis and pulmonary alveolar vasculitis is common (Tiwary *et al.*, 2006).

Chronic selenium poisoning is common and referred to as alkali disease because in most areas where selenium

is found there are alkali flats. This form of intoxication occurs from prolonged ingestion of forage containing 5–40 ppm selenium. Clinical signs include rough coat, hair or wool loss, poor growth, emaciation, abnormal hoof growth and lameness, dermatitis, and depressed reproduction (James *et al*., 1981). In swine a condition of paralysis (poliomyelomalacia or polioencephalomalacia) often occurs with cervical or lumbar involvement (Panter *et al*., 1996b). The description of a second chronic syndrome in cattle called "blind staggers" has been redefined and is now believed to be polioencephalomalacia induced by high-sulfate water or high-sulfate forage sources (James *et al*., 1989a).

Selenium is found in the inorganic and organic forms. The organic forms are found in plants and are more bioavailable than the inorganic forms resulting in higher tissues levels when administered at equivalent doses (Tiwary *et al*., 2006). While a dramatic difference in tissue selenium uptake between organic (seleno-methionine) and plant (*A. bisulcatus*) forms and inorganic (sodium selenate) forms occurs, the clinical and pathological syndromes are similar, i.e., poliomyelomalacia in pigs (Panter *et al*., 1996b), and pulmonary edema and hemorrhage in sheep (Tiwary *et al*., 2006).

Recent research demonstrated that a significant amount of selenium is eliminated in respired air especially when high doses are administered (Tiwary *et al*., 2006). Respiratory elimination kinetics were much different between sheep administered Se-methionine compared to sodium selenite. Significantly higher levels of Se were eliminated and for significantly longer periods of time after Se-methionine administration compared to sodium selenite. Grasses, forbs, and certain vegetables assimilate selenium from the soils at levels high enough to induce chronic selenium poisoning in animals and occasionally in man and this is of the organic form.

#### *Prevention of poisoning*

There is no treatment for selenium poisoning except the removal of the source allowing spontaneous recovery in the chronic cases. Monitoring soils in a particular area and understanding the plant communities can provide the management information to avoid poisoning. In areas where selenium is a problem many ranchers have switched to grazing steers because of the reproductive problems in cows. Sheep seem to be more resistant to selenium compared to cattle and are better adapted for some of these ranges; however, acute selenium poisoning in sheep after brief grazing on mine reclamation sites where high soil selenium occurred was recently reported (personal communications, 2004). Monitoring of soil selenium, vegetation, and animal selenium levels will help avoid poisoning. Likewise, deficiency problems can be rapidly resolved with frequent monitoring.

## LARKSPURS (*DELPHINIUM* SPP.)

There are over 80 wild species of larkspurs in North America (Kingsbury, 1964) and there are a larger number of domestic horticultural varieties. Wild larkspurs are divided into three general categories based primarily on mature plant height and distribution: low, tall, and plains larkspurs (Figure 66.2). The dominant larkspur species in the western United States are shown in Table 66.2. The larkspurs are a major cause of cattle losses on western ranges. In 1913, Marsh *et al*. (1916) stated that more cattle deaths on western ranges are caused by *Delphinium* spp. than any other poisonous plant except locoweed.

### Description

Most of the wild larkspurs have flowers of blue or purple, bilaterally symmetrical, in erect terminal racemes or panicles: five sepals, the upper prolonged backwards in a prominent spur; petals smaller and variable among species, usually four and sometimes two, the upper pair projecting back inside the spur; carpels one to five, sometimes fused, ripening into many-seeded follicles (Kingsbury, 1964).

The tall larkspurs (Figure 66.2) are 1–2 m tall or more, flower in summer and set seed in late summer subsequently senescing in the fall. In the west the tall larkspurs typically inhabit higher mountain elevations in the more open moist areas of canyons, draws, and meadows. *Delphiniums* are frequently confused with *Aconitum* but certain features distinguish them. As implied by the common names *Delphiniums* have a distinct spur (hence larkspur)

**FIGURE 66.2** Low larkspur (*Delphinium bicolor*) is on the left and tall larkspur (*D. barbeyi*) is on the right.

whereas *Aconitum* has no spur but a hood (hence monkshood). Tall larkspurs have hollow stems and their leaves are relatively long petioled whereas monkshood has stems that are solid and pithy and leaves are short petioled.

Low larkspurs (Figure 66.2) appear similar to tall except they grow in different habitats and locations, i.e. lower elevations in drier habitats, on the foothills and flats. They appear first as a rosette-like clump in early spring, soon producing an erect flowering stem, usually not more than 1 m in height, then die back in early summer.

Plains larkspur falls between the low and tall larkspur classifications. Plants range from 0.3 to 2 m tall. It grows on the short-grass plains of Wyoming into Nebraska and in the sagebrush and juniper woodlands of the Colorado Plateau.

## Distribution and habitat (Table 66.2; Kingsbury, 1964; Nielsen and Ralphs, 1988)

### *Low larkspur*

*D. nelsonii*: Idaho, South Dakota, Wyoming, Colorado, and Utah

*D. bicolor*: North Dakota, Montana, Wyoming, Oregon, and Washington

*D. andersonii*: Oregon, California, Nevada, Utah, and Idaho

*D. tricorne*: Nebraska and Oklahoma eastward

*D. virescens*: Great plains, east of the Rockies

### *Intermediate larkspur*

*D. geyeri*: Colorado, Wyoming, Nebraska, and Utah

### *Tall larkspur*

*D. barbeyi*: Utah, Wyoming, Colorado, and New Mexico

*D. occidentale*: Washington, Idaho, Wyoming, Nevada, Utah, and Colorado

*D. glaucescens*: Idaho and Montana

*D. glaucum*: Washington, Oregon, California, Nevada, Idaho, and Montana

*D. trolliifolium*: Washington, Oregon, and California

*D. robustum*: Colorado and New Mexico

## Toxicology

Larkspurs (*Delphinium* spp.) are a serious toxicity problem for cattle on foothill and mountain rangelands in western North America. Larkspurs contain numerous norditerpenoid alkaloids that vary greatly in toxicity. Three alkaloids are of primary concern (Manners *et al.*, 1995): methyllycaconitine (MLA **(2)**), 14-deacetylnudicauline (DAN), and nudicauline (NUD). MLA and DAN occur to some extent in all classes of larkspurs, whereas NUD occurs only in low and plains larkspurs (Majak and Engelsjord, 1988). The $LD_{50}$ for NUD, MLA, and DAN in mice is 2.7, 4.8, and 4.0 mg/kg i.v., respectively (Table 66.3; Panter

**TABLE 66.2 Characteristics of the dominant larkspur species in western North America**

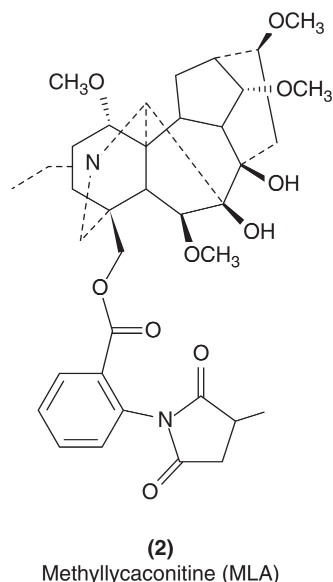
| Class/species | Height at maturity | Elevation | Associated plant communities | Toxicity ranking[a] | Typical risk of losses[b] |
|---|---|---|---|---|---|
| **Tall larkspurs** | | | | | |
| *D. glaucum*[c] | 90–200 | >2000 | Aspen, conifers, alpine meadows | 1 | Low |
| *D. barbeyi* | 90–180 | >2200 | Aspen, conifers, alpine meadow, mountain brush, alpine tundra | 2 | Moderate to severe |
| *D. glaucescens* | 76–90 | >2000 | Mountain meadows, sagebrush | 3 | Low to moderate |
| *D. occidentale* | 90–180 | >2000 | Mountain brush, sagebrush, conifer, aspen | 4 | Low to severe |
| **Low larkspurs** | | | | | |
| *D. nuttallianum* | 20–60 | >1200 | Mountain brush, sagebrush, aspen, conifer, mountain and foothill meadows | 2 | – |
| *D. bicolor* | 20–40 | >800 | Mountain brush, sagebrush | – | – |
| *D. andersonii* | 10–60 | >1200 | Desert shrub, mountain brush, sagebrush, pinyon-juniper | 1 | – |
| **Plains larkspur** | | | | | |
| *D. geyeri* | 40–80 | >1500 | Desert shrub, mountain brush, sagebrush, short-grass prairie | – | – |

[a] Tall larkspur and low larkspur species each ranked according to concentration of toxic alkaloids, from greatest (1) to least (4).

[b] The risk of losing cattle to tall larkspur species is a subjective evaluation based on plant toxicity, numbers of grazing cattle threatened during the growing season, and the geographical distribution of the larkspur species. *D. glaucescens* is relatively more toxic late in the growing season compared to mature plants of the other tall larkspur species. Spatial and temporal variability in plant density and toxicity preclude making such a risk assessment ranking for low larkspurs and plains larkspur.

[c] *D. glaucum* = *D. brownii* in Canada; livestock losses to *D. brownii* in Canada may greatly exceed those of *D. glaucum* in the United States (Majak and McDiarmid, 2000).

*et al.*, 2002). The toxic alkaloid concentration of the tall larkspur (*D. barbeyi*) dosed to cattle in the lethality study of Olsen (1978) was not determined. Assuming that the plant material (vegetative and early flowering tall larkspur) contained ~12 mg/g of toxic alkaloid, the $LD_{50}$ of MLA + DAN in cattle is approximately 30 mg/kg. The lethal dose is undoubtedly lower when tall larkspur is ingested repeatedly over 2–4 days, as often happens in field cases of intoxication (Pfister *et al.*, 1997).



**(2)**
Methyllycaconitine (MLA)

There are two primary structural features necessary for toxicity: (1) an *N*-ethyl bicyclo tertiary alkaloid nitrogen atom; and (2) a C-18 anthranilic acid ester (Kukel and Jennings, 1994). Other studies have also shown that MLA's **(2)** aromatic ester function is a significant haptophore (Coates *et al.*, 1994), and that the succinimide group imparts significant toxicity to alkaloids (Blagbrough *et al.*, 1994; Hardick *et al.*, 1996). Two other structural features also enhance toxicity: (1) functionality at the anthranilic acid amine nitrogen and (2) functionality at C-14 (Manners *et al.*, 1995).

Tall larkspur species vary substantially in toxicity, with a relative ranking (most to least toxic) of *D. glaucum* (*D. brownii* in Canada), *D. barbeyi*, *D. glaucescens*, and *D. occidentale* (Ralphs *et al.*, 1997b). Generally in tall larkspurs, the concentration of MLA and DAN is highest in immature plant tissues. MLA concentrations in immature tall larkspurs may exceed 20 mg/g. Before shattering, tall larkspur pods are relatively high in toxicity (MLA + DAN = 7–12 mg/g). Toxicity declines rapidly in tall larkspurs once pods begin to shatter. Measuring plant toxicity early in the growing season may allow prediction of season-long toxicity and risk (Ralphs *et al.*, 2002).

**TABLE 66.3 Relative toxicity of individual larkspur alkaloids: in the order of toxicity according to alkaloid class and determined by mouse bioassay (Manners *et al.*, 1993)**

| **MSAL[a] class alkaloid; $LD_{50}$ mg/kg** | **Lycoctonine class alkaloid; $LD_{50}$ mg/kg** | **MDL[b] class alkaloid; $LD_{50}$ mg/kg** |
|---|---|---|
| Nudicauline; 2.5 i.v.[c] | Anthronyllycoctonine; <365 sc[d] | Deltaline; 720 sc, 133 i.v. |
| 14-deacetylnudicauline; 4.5 i.v. | Lycoctonine; <450 sc | 14-*o*-acetyldictyocarpine; >765 sc |
| Methyllycaconitine; 7.5 i.v. | 14-dehydrobrownine; >254 sc | Dictyocarpine; >2000 sc |
| Barbinine; >115.5 i.v. | Brownine; >720 sc | |

[a]MSAL = methylsuccinimido anthranoyllycoctonine (most toxic).
[b]7,8-methylene dioxyllycoctonine (least toxic).
[c]i.v. = intravenous.
[d]*>sc = subcutaneous.

MLA and NUD are the dominant toxic alkaloids in low larkspurs with concentration ranges from 0.8 to 4.5 mg/g and 1 to 4 mg/g, respectively, for MLA and NUD in low larkspur populations (*D. nuttallianum* and *D. andersonii*) in Utah, Colorado, and Arizona (Gardner, unpublished data). Majak (1993) reported very high concentrations of MLA (up to 8.7 mg/g) in vegetative low larkspur (*D. nuttallianum*) from Canada, contrasted to 2 mg/g in flowering plants (Bai *et al.*, 1994). Unlike tall larkspurs, concentrations of toxic alkaloids in low larkspurs do not decline precipitously after senescence (Majak, 1993; Gardner, unpublished data). MLA is the major toxic alkaloid in plains larkspur (*D. geyeri*), with concentrations ranging from 1 to 4 mg/g in Wyoming and Colorado (Pfister *et al.*, 2002a). We emphasize that NUD is more toxic than MLA, and both alkaloids are frequently found together in low larkspurs (Gardner, unpublished data). Thus, the potential lethality of low larkspurs can be highly variable depending on alkaloid concentrations and plant density.

The primary result of larkspur toxicosis is neuromuscular paralysis from blockage at the post-synaptic neuromuscular junction (Aiyar *et al.*, 1979; Benn and Jacyno, 1983). MLA also elicits central effects in mice and rats (Alkondon *et al.*, 1992; Stegelmeier *et al.*, 1998). Larkspur alkaloids compete as post-synaptic inhibitors of acetylcholine particularly at $\alpha$-1-nicotinic sites (Dobelis *et al.*, 1999). MLA strongly competes with $\alpha$-bungarotoxin at nicotinic ACh (nACh) receptors (Kukel and Jennings, 1994). Larkspur alkaloid binding to nAch receptors appears to be correlated to toxicity in various tissues (Kukel and Jennings, 1994), and may explain sheep tolerance to larkspur if larkspur toxins bind less avidly to nAch receptors in sheep (Ward *et al.*, 1990; Stegelmeier *et al.*, 1998).

Clinical signs of intoxication include muscular weakness and trembling, straddled stance, periodic collapse into sternal recumbency, respiratory difficulty, and finally death while in lateral recumbency. An effective dose of larkspur causes labored breathing, rapid and irregular heartbeat and collapse, but not death. The effective i.v. dose for purified MLA is 2 mg/kg b.w. in calves versus 10 mg/kg in sheep given a single injection (Panter, unpublished data). Nation *et al.* (1982) reported that an effective dose of MLA in cattle receiving two i.v. injections was 1.1 mg/kg. Conversely, the effective i.v. dose for deltaline in both calves and sheep is 50 mg/kg (Panter, unpublished data). Cattle typically show clinical signs (i.e. tremors and periodic collapse) when given an MLA + DAN dose (i.e. via ground plant) of 20 + 3 mg/kg b.w. (Pfister *et al.*, 1994a, b). Stress and/or exertion will reduce the effective dose. Assuming an MLA + DAN concentration of 5 mg/g (dry weight (d.w.)), a 450 kg cow may show clinical signs after rapidly eating 1.8 kg (d.w.) of tall larkspur ($\approx$7.2 kg wet weight (w.w.)).

Key factors in larkspur intoxication are the amount eaten and the rate of ingestion. Studies utilizing direct observations of grazing animals have provided a number of insights into the amount and timing of tall larkspur ingestion (Pfister *et al.*, 1988). Over 10 such studies have been conducted since 1986 and have led to two major conclusions: (1) cattle eat little or no tall larkspur before the plant has elongated flowering racemes (Pfister *et al.*, 1997) and (2) weather patterns are very important determinants of larkspur consumption (Ralphs *et al.*, 1994c; Pfister *et al.*, 1999). Cattle often eat more tall larkspur during summer storms, and reduce larkspur consumption during drought for reasons that are not clear.

Cattle generally begin consuming tall larkspur after flowering racemes are elongated, and consumption increases as larkspur matures. Consumption usually peaks during the pod stage of growth in late summer, when cattle may eat large quantities (25–30% of diet as herd average; >60% on some days by individual animals).

Because larkspur toxicity generally declines throughout the growing season and cattle tend to eat more larkspur after flowering, we have termed the period of greatest danger a "toxic window" (Pfister *et al.*, 2002b). This "toxic window" extends from the flower stage into the pod stage, or about 5 weeks depending on temperature and elevation (Figure 66.3). Many ranchers typically defer grazing on tall larkspur-infested ranges until the flower stage to avoid death losses. This approach wastes much valuable forage, and often places cattle into larkspur-infested pastures when risk of losses is high. An additional 4–6 weeks of grazing may be obtained by grazing these ranges early, before larkspur elongates flowering racemes (Pfister *et al.*,

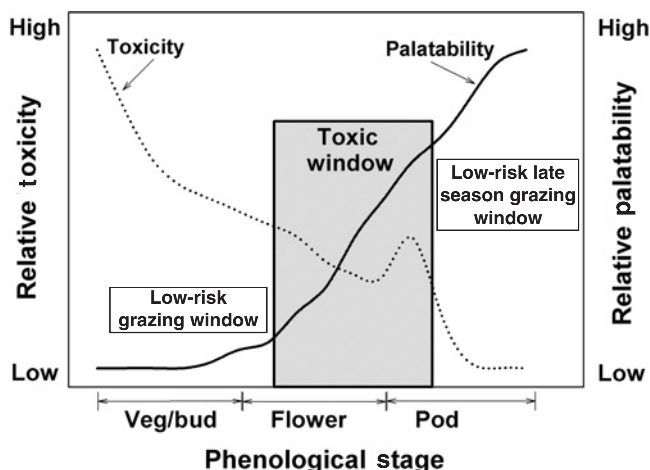


**FIGURE 66.3** Relationship between toxicity and palatability in tall larkspurs. Most cattle deaths are predicted to occur during the toxic window when concentration of toxic alkaloids is relatively high, and consumption by cattle begins to increase after flowering racemes elongate. There is a low-risk grazing window early in the season before flowering when larkspur is generally very toxic but risk is low because cattle typically eat little tall larkspur during this phenological stage. There is also a low-risk grazing window in late summer after pods shatter.

1997). The risk of losing cattle is low when grazing before flowering even though larkspur is very toxic, because larkspur consumption is typically very low. Once pods are mature and begin to shatter, larkspur ranges can usually be grazed with impunity because pod toxicity declines rapidly, and leaf toxicity is low. Based on limited study, cattle increase consumption of low larkspur after flowering, and increases in grazing pressure increase amounts of low larkspur eaten by cattle (Pfister and Gardner, 1999). No consistent consumption patterns of plains larkspur (*D. geyeri*) by cattle were found, thus management recommendations need to be tailored to each specific year and location (Pfister *et al.*, 2002a, b).

## Prevention and management of poisoning

### *Grazing management*

A simple and low-risk grazing management scheme can often be used based simply on tall larkspur growth and phenology: (1) graze during early summer when sufficient forage is available until larkspur elongates flowering racemes (4–6 weeks depending on elevation and weather); (2) remove livestock, or contend with potentially high risk from flowering to early pod stages of growth (4–5 weeks); and (3) graze with low risk during the late season when larkspur pods begin to shatter (4–6 weeks). This scheme can be refined substantially if livestock producers obtain an estimate periodically of the toxicity of tall larkspur, and if ranchers spend time to periodically observe and document larkspur consumption by grazing cattle (Pfister *et al.*, 1999).

Management to reduce losses to low larkspur begins with recognition of the plant during spring. Vegetative low larkspur plants will typically begin growth before the major forage grasses. Low larkspur populations fluctuate with environmental conditions (Pfister, unpublished data). Risk of losing cattle is much higher during years with dense populations. During those years, recognizing the plant, and finding alternative pasture or waiting to graze infested pastures for 4–6 weeks, until the low larkspur has dried up, will reduce losses.

### *Graze sheep before cattle*

Sheep can be herded into or bedded on the patches to reduce larkspur availability or acceptability to cattle on tall larkspur-infested ranges where larkspur grows as discrete patches (Ralphs *et al.*, 1991a; Ralphs and Olsen, 1992). In those areas where larkspur is uniformly spaced over a pasture, sheep must eat immature larkspur and leave sufficient feed for subsequent grazing by cattle. This can be problematic, since early growth tall larkspur may not be palatable to sheep. Marsh *et al*. (1916) also noted that sheep grazing may reduce cattle losses to low larkspur. Our observations (Pfister, unpublished data) indicate that sheep eat little low larkspur (*D. nuttallianum*) unless a high stock density is used.

### *Drug intervention*

A variety of remedies have been applied in the field when ranchers find intoxicated animals (e.g. bleeding by cutting the tail), but most are without a solid scientific rationale. Any imagined success with these treatments was probably related to the dose. If less than a lethal dose were ingested, the animal would likely recover in spite of any treatment, unless bloat or aspiration pneumonia occurred during recumbency. Drugs that increase ACh effectiveness at the neuromuscular junction have potential for reversing larkspur toxicity or reducing susceptibility. The cholinergic drug, physostigmine (0.08 mg/kg i.v.), has been successfully used under field and pen conditions to reverse clinical larkspur intoxication (Nation *et al.*, 1982; Pfister *et al.*, 1994b). This reversal lasts about 2 h, and repeated injections of physostigmine are sometimes required. Under field conditions, physostigmine temporarily abates clinical signs and animals quickly (~15 min) become ambulatory. Depending on the larkspur dose, the intoxication may recur. The use of physostigmine-based treatments may aggravate losses in the absence of further treatment if suddenly ambulatory animals later develop increased muscular fatigue, dyspnea, and death.

### *Herbicidal control*

Larkspur losses can be reduced greatly if dense larkspur populations are reduced by herbicides. Picloram, metsulfuron, and glyphosate have proven to be effective in killing tall larkspurs when applied at specific growth stages (Mickelsen *et al.*, 1990; Ralphs *et al.*, 1992). These herbicides do not reduce toxic alkaloid concentrations in treated larkspur plants, and metsulfuron may increase toxicity. Therefore, sprayed areas should not be grazed until the following growing season.

# LUPINES (*LUPINUS* SPP.)

The *Lupinus* genus contains more than 150 species of annual, perennial, or soft woody shrub lupines (Cronquist *et al.*, 1989). Over 95 species occur in California alone (Riggins and Sholars, 1993). The lupines are rich in alkaloids, responsible for most of the toxic and teratogenic properties. There are domestic lupines that through plant breeding are low in alkaloid content and have been selected for ornamental purposes or for animal and human food. Only those range lupines known to cause poisoning or birth defects will be discussed here.

Stockman have long recognized the toxicity of lupines when livestock, particularly sheep, were poisoned in the fall by the pods and seeds of lupine (Chesnut and Wilcox, 1901). Sampson (1952) and Stoddart and Smith (1955) reported that lupine was a major cause of sheep losses in the west and indeed single flock losses of hundreds and even thousands were reported (Chesnut and Wilcox, 1901). Lupines are poisonous to other livestock also and field cases of poisoning in cattle, horses, and goats have been reported. However, the most recognized condition of lupine ingestion is the "crooked calf syndrome," a congenital condition in calves resulting in skeletal contracture-type malformations and cleft palate after their mothers have grazed lupines during sensitive periods of pregnancy (Panter *et al*., 1999). The condition was first reported by Palotay (1959) and Wagnon (1960) and experimentally confirmed after large outbreaks in Oregon and Montana (Shupe *et al*., 1967a, b).

## Description

Lupines belong to the Leguminosae family, with alternate palmately compound leaves with 5–17 oblong to lanceolate leaflets (Figure 66.4). Flowers are terminal legume-like and can be blue, purple, white, yellow, or reddish. The seeds are flattened in legume-like pods. Range lupines are generally low, perennial, or annual forbs and species and varieties are taxonomically difficult because extensive hybridization occurs and literature may be somewhat confusing in this regard. Chemical profiles (chemo-taxonomy) can support or contradict taxonomic identification and this is a valuable resource if included in a voucher specimen, especially if the identified species is implicated in toxicoses or teratogenicity. The plant grows early in spring, flowering in early to mid-summer and forms pods in late summer or early fall. Seedlings may germinate in fall if temperature and moisture are conducive for seed germination. Some lupines are annuals and others are woody and shrub-like, however, these have not been reported in livestock poisoning. The reader is referred to Cronquist *et al*. (1989) or Riggins and Sholars (1993) for detailed descriptions of species and varieties.

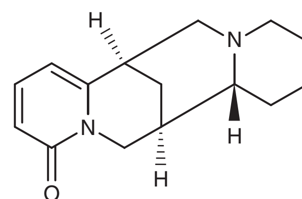
## Distribution

Most species of lupines grow in states and provinces from the rocky mountains, westward. They are classified as increaser species, i.e., they increase in abundance following disturbance from overgrazing or fire, to the point they may dominate the plant community at times. Their populations also cycle, increasing in wet years and dying back during drought. Table 66.4 lists species involved in toxicity, their common names, habitats, and geographical distribution.

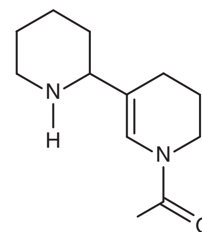
**FIGURE 66.4** *Lupinus leucophyllus*

## Toxicology

Most lupine species contain quinolizidine alkaloids, a few contain piperidine alkaloids and some contain both. The specific alkaloids responsible for "crooked calf disease"



**(3)**
Anagyrine



**(4)**
Ammodendrine

are anagyrine **(3)**, ammodendrine **(4)**, and *N*-methyl ammodendrine. Hence, risk is based on chemical profile and presence and concentration of these teratogenic alkaloids. We know that chemical profile and concentration differs, resulting in changing levels of toxicity within and between species and populations (Davis and Stout, 1986). The chemical phenology has been studied in *L. caudatus* (Keeler, 1976)

**TABLE 66.4 Lupine species known to be toxic or teratogenic**

| Scientific name | Common name | Habitat | Distribution |
|---|---|---|---|
| *L. alpestris* | Mountain silvery lupine | Dry rocky soils | CA to MT, CO and AZ |
| *L. arcticus* | | | AK, BC |
| *L. andersonii* | Anderson's lupine | Mountain meadows and clearings | Sierra Nevada, CA to 2900 m |
| *L. arbustus* | Spur lupine | Dry open hillsides | NV, CA to CO; western MT |
| *L. argenteus* | Silvery lupine | 1200–1500 m elevation; dry flats, slopes, woods, open hillsides | CA to MT, NM, OR, ID, UT, NV |
| *L. caudatus* | Tail cup lupine | | CA, OR, ID to UT, NV |
| *L. cyaneus* | | | MT |
| *L. formosus* | Lunara lupine | Dry flats | CA |
| *L. greenei* | | Plains and hills | WY, NV, CO, AZ |
| *L. latifolius* | Broad-leaved lupine | Mountain meadows and stream banks | Pacific states |
| *L. laxiflorus* | Spurred lupine | Hillsides, dry soils | WA, OR, ID |
| *L. leucophyllus* | White-leaved lupine, poison lupine | Dry soils | WA, MT, UT, CA |
| *L. nootkatensis* | Nootka lupine | | AK |
| *L. onustus* | Plumes lupine | Open pine wood | CA |
| *L. polyphyllus* (five varieties) | Meadow lupine | Mountain meadows, banks | WA, BC |
| *L. pusillus* | Rusty lupine, small lupine | Dry plains | BC to KS, NM, AZ |
| *L. sericeus* | Silky lupine | Dry hills, valleys | UT, WY to MT, BC |
| *L. sulphureus* | Yellow lupine | Open hillsides | OR |

and *L. leucophyllus* (Lee *et al*., 2006). Total alkaloid concentration is high in the new early growth but diluted as the plant biomass increases. Pools of total alkaloids increase during the phenological growth stages and peak at the pod stage. The teratogenic alkaloid anagyrine appears to be an end product in the biosynthetic pathway and accumulates in the floral parts and is stored in the seed. Following seed shatter both concentration and pools of all alkaloids decline precipitously, leaving the senescent plant relatively non-toxic.

Stockmen recognized the toxicity of lupines in the fall when the pods and seeds are ripe. Historically, lupines were responsible for more sheep deaths than any other single plant in Montana, Idaho, and Utah (Kingsbury, 1964). Most losses occurred from hungry sheep grazing seedpods. Poisoning occurred following trucking or trailing bands in late summer or fall, or getting caught in early snowstorms that covered herbaceous vegetation. Hungry sheep non-selectively grazed lupine pods, which are highest in alkaloids, and were poisoned. Large losses have also occurred when lupine hay harvested in the seedpod stage was fed in winter. Seeds alone can be toxic to sheep at 0.25–1.5% of their body weight depending on alkaloid composition. A few cases of poisoning occurred on young plants. Recent losses of 80–100 sheep in multiple bands have been reported the last 5 years in Idaho and Wyoming (Panter, personal communication, 2005).

Poisoning by lupine plants should not be confused with lupinosis reported in Australia. This condition is entirely different and is a mycotoxicosis of livestock caused by toxins produced by the fungus *Phomopsis leptostromiformis* which colonizes domestic lupine stubble. It affects livestock which graze lupin stubble and limits the use of this animal feed in Australia (Allen and Cowling, 1992).

The lupine-induced "crooked calf disease" was first reported in 1959 (Palotay) and 1960 (Wagnon) and experimentally confirmed in 1967 (Shupe *et al*., 1967a, b). Crooked calf disease includes various skeletal contracture-type birth defects and occasionally cleft palate (Shupe *et al*., 1967a, b; 1968). The skeletal defects are similar to an inherited genetic condition reported in Charolais cattle (Nawrot *et al*., 1980). Through epidemiological evidence and chemical comparison of teratogenic and non-teratogenic lupines the quinolizidine alkaloid anagyrine was determined to be the teratogen (Keeler, 1973). A second teratogen, a piperidine alkaloid called ammodendrine found in *Lupinus formosus*, was also demonstrated to cause the condition (Keeler and Panter, 1989). Further research determined that the anagyrine-containing lupines only caused birth defects in cattle and did not affect sheep or goats, however, the piperidine-containing lupine *L. formosus* induced similar birth defects in cattle and goats (Keeler and Panter, 1989; Panter *et al*., 1998). This led to interesting speculation about possible metabolism or absorption differences between cattle and small ruminants. Keeler and Panter (1989) hypothesized that perhaps the cow was metabolizing the anagyrine to a complex piperidine, meeting the structural characteristics determined for a teratogenic piperidine (Keeler and Balls, 1978). This was supported by feeding trials with other piperidine-containing plants, extracts, and pure compounds. Coniine **(5)**, a simple piperidine from poison-hemlock, and anabasine **(6)**, a simple piperidine from tree tobacco (*N. glauca*), induced the same defects in cattle, sheep, and goats. Even though comparative studies support the hypothesis that the cow may metabolize the quinolizidine anagyrine to a complex piperidine, recent evidence reporting the absorption and elimination patterns

of many of the quinolizidine alkaloids, including anagyrine, in cattle, sheep, and goats, did not support the metabolism theory (Gardner and Panter, 1993). This research is currently ongoing at the Poisonous Plant Research Laboratory in Logan, Utah.

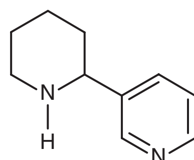
Coniine



**(6)**
Anabasine

Different lupines produce varying toxic syndromes in a given species of livestock, apparently because the alkaloid profile varies remarkably among species. Season and environment influenced alkaloid concentration in a given species of lupine. Generally alkaloid content is highest in young plants and in mature seeds and alkaloids are not lost upon drying, so wild hay may be highly toxic if young lupine plants or especially seedpods are present. For many lupines, the time and degree of seeding varies from year to year. Most losses occur under conditions in which animals consume large amounts of pods in a brief period, such as when they are being driven through an area of heavy lupine growth, unloaded into such an area, trailed through an area where the grass is covered by snow, but the lupine is not, or when feeding podded lupine hay, which is apparently palatable. Most serious poisonings may occur in the late summer or early fall because lupine remains green after other forage has dried and seedpods are present. Once the poisonings were understood the practice of harvesting lupine hay for winter sheep feed was discontinued.

### *Cattle grazing*

Lupine is not very palatable to cattle, although it has been considered fair feed on some ranges that are heavily utilized. Its palatability or acceptability depends on availability and maturity of other forage. In a grazing study of velvet lupine (*L. leucophyllus*) on annual cheatgrass ranges in eastern Washington (Ralphs *et al.*, 2006), cows selected lupine only in July and August after cheatgrass dried and other forbs were depleted or matured and became rank. The deep-rooted lupine remained green and succulent

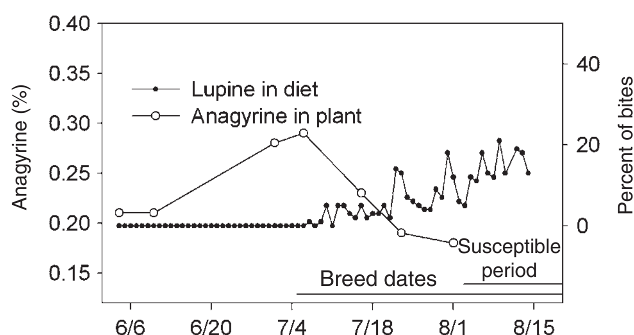


**FIGURE 66.5** The relationship between the concentration of the teratogen anagyrine in the plant and the amount of lupine in the diets of cattle during breeding and susceptible gestational stages.

longer into the summer than the other forage. Lupine was higher in crude protein (CP) and lower in fiber (neutral detergent fiber (NDF)) than the other forages throughout the season (CP level in foliage was 15% and in seeds 36%). However, the thick velvety pubescence was believed to be partially responsible for its lack of palatability. The high alkaloid concentration in the floral parts and seedpods may also have contributed to its lack of palatability. Once the seeds shattered in early July, the alkaloid concentration declined, and the cows began selecting lupine. Figure 66.5 shows the overlap of lupine consumption with the susceptible period of gestation, in relation to the anagyrine concentration in the lupine plants. Lopez-Ortiz *et al.* (2006) also confirmed that cattle selected velvet lupine in July after cheatgrass and other forbs matured.

The abundance of lupine is another factor influencing the amount of lupine consumed. Lupine population cycles are influenced by weather patterns. Catastrophic losses from lupine-induced crooked calves occurred in the Channel Scabland region of eastern Washington in 1997 (Warnock, 1997). Annual precipitation from 1995 to 1997 was 33% above average, initiating an outbreak of lupine throughout the region. Density of velvet lupine plants has declined since then (Ralphs, unpublished data) and incidence of crooked calves has been minimal.

Clinical signs of poisoning are those of muscular weakness (neuromuscular blockade) beginning with nervousness, frequent urination and defecation, depression, frothing at the mouth, relaxation of the nictitating membrane, ataxia, muscular fasciculations, weakness, lethargy, collapse, sternal recumbency followed by lateral recumbency, respiratory failure, and death. Signs may appear within 15 min to an hour after ingestion or as late as 24 h depending on amount and rate of ingestion. Death usually results from respiratory paralysis.

Incidence of crooked calves is variable geographically and from year to year within a given herd. Up to 100% of a given calf crop may be affected and individuals may be more severely affected than others. Affected calves are generally born alive at full term. Dystocia may occur when

calves are severely deformed and assistance is required, often by cross-section.

Arthrogryposis is the most common malformation observed often accompanied by one or more of the following: scoliosis, torticollis, kyphosis, or cleft palate (Shupe *et al.*, 1967a). Elbow joints are often immobile because of malalignment of the ulna with the articular surfaces of the distal extremity of the humerus. The part of the limb distal to the elbow joint is often rotated laterally. In crooked calf disease the osseous changes observed are permanent and generally become progressively worse as the calf grows and its limbs are subjected to greater load-bearing stress. Frequently, minor contractions such as "buck knees" often attributed to lupine will resolve on their own and the calf will appear relatively normal.

No breed predilection or genetic susceptibility to the lupine-induced condition has been determined. However, body condition was shown to affect the absorption and elimination half-life of anagyrine in sheep (Lopez-Ortiz *et al.*, 2004). Research to compare alkaloid disposition in cattle based on body condition is ongoing at the Poisonous Plant Research Laboratory. Preliminary data would suggest that body condition may have a significant impact on absorption, distribution, and elimination of toxins and therefore could impact teratogenic outcome of lupines. The fetal disposition of teratogenic alkaloids is unknown at this time.

The dangerous gestational period in the pregnant cow for exposure is 40–70 days with suspicious periods extending to day 100 (Panter *et al.*, 1997). The condition has been experimentally induced with dried ground lupine at 1 g/kg b.w. and with semi-purified preparations of anagyrine (the apparent teratogen) at 30 mg anagyrine/kg b.w. fed daily from 30 to 70 days gestation (Keeler, 1976; Keeler *et al.*, 1976). The dose range of anagyrine to cause crooked calves is 6.5–11.9 mg/kg b.w./day for 3–4 weeks during gestation day 40–70 (Keeler, 1976). Crooked calf disease has also been induced by feeding the piperidine alkaloid-containing lupine, *L. formosus* (Keeler and Panter, 1989). The teratogenic piperidines, ammodendrine, *N*-acetylhystrine, and *N*-methyl ammodendrine are absorbed quickly after ingestion and can be detected in blood plasma by 0.5 h and peak levels maintained for over 24 h (Gardner and Panter, 1993, 1994; Panter and Gardner, 1994). The mechanism of action has been determined to be an alkaloid-induced reduction in fetal movement by a neuromuscular blocking effect during the critical stages of gestation (Panter *et al.*, 1990a). This inhibited fetal activity is responsible for the skeletal malformations and cleft palates (Panter and Keeler, 1992).

## Prevention, management, and treatment

Keeler *et al.* (1977) proposed a simple management solution to prevent crooked calves: stagger grazing of lupine infested pastures so that the susceptible period of gestation (40–70 days) does not overlap the flower and pod stage of growth when anagyrine is highest. Ralphs *et al.* (2006) refined Keeler's recommendations to restrict access during the susceptible period of gestation, when anagyrine concentration is still high in the flower and pod stage, only when cattle are likely to eat lupine, and in years when it is abundant. Panter (unpublished data) has suggested that intermittent grazing between lupine pastures and clean pastures would allow the fetus to regain normal movement for a few days during the sensitive stage of gestation. It has been hypothesized that inhibited fetal movement over a prolonged period of time is required for severe malformations to occur (Panter *et al.*, 1999).

Lupines are easily controlled with 2,4-D-type broad-leaf herbicides (Ralphs *et al.*, 1991c), however, herbicide treatment alone rarely provides long-term solutions to poisonous plant problems. Seed reserves in the soil will rapidly reestablish the stands if grazing management practices are not implemented.

Death losses in sheep can be reduced by recognizing the variability in lupine toxicity with stage of growth and the conditions under which animals graze the plant. Providing a choice of other quality forages usually prevents excess lupine grazing. The dangerous period of plant growth for sheep exists mainly with podded plants. The hazard increases if sheep are hungry as often exists with crowding, hauling, driving, or overgrazed conditions. The hazard is reduced or eliminated when lupine is in post-seed stage.

Treatment for overt poisoning is usually symptomatic and recovery is often spontaneous if animals are not stressed further by driving. Once the animal is observed showing muscular tremors it should be allowed to drop back and proceed at its own pace. Never force poisoned animals to continue moving as this will exacerbate the clinical effects and can result in death. The elimination of the toxic alkaloids in the urine is quite rapid ($t_{1/2}$ = 6.32 – 6.88 h) and begins within hours of ingestion (Lopez-Ortiz *et al.*, 2004). Therefore, allowing the animal to rest and move slowly will often result in full recovery within 24 h. There is no treatment for the malformations and euthanasia is recommended for the serious skeletal defects and cleft palate. However, less severe contracture defects, particularly of the front legs (buck knees), will often resolve if the knee joint can be locked within a week after birth. If not, the defect generally becomes worse with growth and size and while the animal will continue to grow, the front legs will break down and the animal will not be adequate for the feedlot.

## Summary

A reduction in incidence can be expected and has been achieved by using one or more of the following: (1) coordinating grazing periods according to plant growth stage;

(2) changing time of breeding by either advancing or delaying or changing from spring to fall calving; and (3) reducing lupine populations through herbicide treatment; and (4) intermittent grazing between clean pastures and lupine pastures to break the cycle of lupine ingestion.

## POISON-HEMLOCK (*CONIUM MACULATUM*)

Poison-hemlock was introduced into the United States as an ornamental herb and grows throughout the United States. Generally, poison-hemlock grows in waste areas where adequate moisture will sustain the biennial stands. Four species are recognized worldwide but only one (*Conium maculatum*) is found in the United States. Historically, poison-hemlock has been associated with human poisoning more than livestock and is believed to be the tea used to execute Socrates (Daugherty, 1995; Reynolds, 2005).

### Description

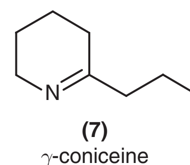
Unlike the lupines, locoweeds, etc., multiple *Conium* species are few worldwide and only one species is described in the United States, that being *C. maculatum*. *Conium maculatum* is a biennial plant 1–2.5 m tall (Figure 66.6). The stems are stout, rigid, smooth, and hollow except at the nodes. A distinguishing characteristic of the plant is the purple spots found up and down the main stem and a single carrot-like taproot. The leaves are large, triangular, fern like, and alternate on the erect stem. The stem grows the 2nd year from a rosette and taproot established from seed. Frequently, seed will germinate in the fall before winter then complete its reproductive cycle the following year. The flowers are small, white or cream–colored, and in umbellate clusters. The fruits are grayish-brown with conspicuous wavy, knotted ridges. The plant has a fleshy, usually unbranched, white taproot which looks like parsnips. Roots have been mistaken for parsnip, seeds for anise and leaves for parsley (Kingsbury, 1964).

**FIGURE 66.6** The hemlocks, poison-hemlock (*Conium maculatum*) on the left and water hemlock (*Cicuta douglasii*) on the right. Note the tubers and partitioned stalk on water hemlock versus the single taproot on poison-hemlock. Leaf structure is different and poison-hemlock has purple spots on the stems.

The geographical distribution of poison-hemlock is throughout the United States, restricted only by cultivation and adequate moisture to sustain stands of the plant from year to year. The plant usually grows in waste places where moisture may accumulate and protected from cultivation.

### Toxicology

Eight piperidine alkaloids are known in poison-hemlock, five of which are commonly discussed in the literature (Roberts and Brown, 1981). Two alkaloids (coniine **(5)** and $\gamma$-coniceine **(7)**) are prevalent and likely responsible for toxicity and teratogenicity of the plant. $\gamma$-coniceine **(7)** is the predominant alkaloid in the early vegetative stage of plant growth and is a biochemical precursor to the other *Conium* alkaloids (Panter *et al.*, 1988a; Panter and Keeler, 1989). Coniine **(5)** predominates in late growth and is found mainly in the seeds. $\gamma$-coniceine **(7)** is 7–8 times more toxic than coniine in mice (Bowman and Sanghvi, 1963). This makes the early growth plant most dangerous in the early spring and the seedlings and regrowth again in the fall. This is also the time when green feed is limited to livestock and may impact their propensity to graze this plant. Seeds, which are very toxic, can contaminate poultry and swine cereal grains (Panter and Keeler, 1989). Plants often lose their toxicity upon drying but seeds remain toxic as long as the seed coat is intact.



A recent analysis of a single plant of *Conium*, second year rosette, revealed $\gamma$-coniceine levels of 387, 326, 198, 176, and 850 mg/g fresh plant for whole plant, root crown, stem, leaf, and green seed, respectively. Coniine was only

detected in the leaf at 12 mg/g fresh plant (Panter and Gardner, unpublished data, 1994).

The clinical signs of toxicity are the same in all species and include initial stimulation (nervousness) resulting in frequent urination and defecation (no diarrhea), rapid pulse, temporarily impaired vision from the nictitating membrane covering the eyes, muscular weakness, muscle fasciculations, ataxia, incoordination followed by depression, recumbency, collapse, and death from respiratory failure (Panter *et al.*, 1988b).

*Conium* plant and seed are teratogenic, causing contracture-type skeletal defects and cleft palate like those of lupine. Field cases of teratogenesis have been reported in cattle and swine and experimentally induced in cattle, swine, sheep, and goats (Panter *et al.*, 1999). The birth defects include arthrogryposis (twisting of front legs), scoliosis (deviation of spine), torticollis (twisted neck), and cleft palate. Field cases of skeletal defects and cleft palate in swine and cattle have been confirmed experimentally (Keeler, 1978).

In cattle, the susceptible period for *Conium* induced terata is the same as that described for lupine and is between the 40th and 70th day of gestation. The defects, susceptible period of pregnancy and probable mechanism of action is the same as "crooked calf disease" induced by lupines (Panter *et al.*, 1999). In swine, sheep, and goats the susceptible period of gestation is 30–60 days. Cleft palate only has been induced in goats when plant or toxins were fed from 35 to 41 days gestation (Panter and Keeler, 1992).

Field cases of poisoning have been reported in cattle, swine, horses, goats, elk, turkeys, quail, and chickens (Copithorne, 1937; MacDonald, 1937; Widmer, 1984; Jessup *et al.*, 1986; Frank and Reed, 1987, 1990; Galey *et al.*, 1992; Frank *et al.*, 1995). Poisoning in wild geese eating small seedlings in early spring was recently reported (Panter, personal communication). Human cases of poisoning are frequently reported in the literature and recently a case of a child and his father mistakenly ingesting the plant was reported (Frank *et al.*, 1995). Field cases of teratogenesis have been reported in cattle and swine and experimentally induced in cattle, sheep, goats, and swine (Keeler and Balls, 1978; Panter *et al.*, 1990a). Pigs become habituated to poison-hemlock and if access to the plant is not limited they will eat lethal amounts within a short time (Panter, 1983).

There are no diagnostic lesions in poisoned animals and diagnosis is based on clinical history of exposure and/or alkaloid detection in liver, urine, or blood. At necropsy, presence of plant in stomach and a characteristic pungent odor in contents with chemical confirmation of the alkaloids may be diagnostic.

## Prevention and treatment

Prevention of poisoning is based on recognizing the plant and its toxicity and avoidance of livestock exposure when hungry. If a lethal dose has not been ingested, the clinical signs will pass spontaneously and a full recovery can be expected. Avoidance of stressing animals poisoned on *Conium* is recommended. However, if lethal doses have been ingested, supporting respiration, gastric lavage, and activated charcoal are recommended. Control of plants is easily accomplished using broad-leaf herbicides, however persistent control measures are recommended as seed reserves in the soil will quickly reestablish a population.

The mechanism of action of the *Conium* alkaloids is twofold. The most serious effect occurs at the neuromuscular junction where they act as non-depolarizing blockers like curare (Bowman and Sanghvi, 1963). Systemically, the toxins cause biphasic nicotinic effects, including salivation, mydriasis, and tachycardia followed by bradycardia as a result of their action at the autonomic ganglia. The teratogenic effects are undoubtedly related to the neuromuscular effects on the fetus and have been shown to be related to reduction in fetal movement (Panter *et al.*, 1990a). Likewise, cleft palate is caused by the tongue interfering in palate closure during the reduced fetal movement and occurs during 30–40 days of gestation in swine and 32–41 days in goats and 40–50 days in cattle (Panter and Keeler, 1992; Panter *et al.*, 1998).

# WATER HEMLOCK (*CICUTA* SPP.)

Water hemlock (*Cicuta* spp.) is among the most violently poisonous plants known to man. It is often confused with poison-hemlock because of its name, growth patterns, and appearance. There are distinct differences in appearance as shown in Figure 66.6.

## Distribution

There are about 20 species of *Cicuta* throughout the world and all are poisonous (Shishkin, 1973). Most of these species are found in North America; 9 are common in the United States, and 7 are found in the western United States (Table 66.5).

## Description

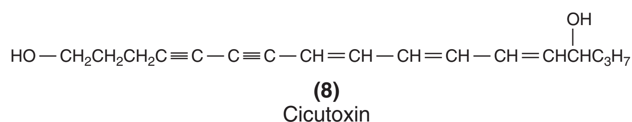
Water hemlock is often confused with poison-hemlock and, in fact, there are similar plant characteristics and both belong to the Umbelliferae family (Figure 66.6). However, their toxic effects are dramatically different and when toxicoses occur differentiation between the two genera is important.

Water hemlock (*Cicuta*) is a biennial, 1–2 m tall, with thickened tubers possessing long slender parsnip-like

**TABLE 66.5 Water hemlock species and geographical distribution**

| Species | Geographical distribution |
|---|---|
| *C. bulbifera* | Northern US, southern Canada |
| *C. bolanderi* | Central to western CA |
| *C. californica* | Central to western CA |
| *C. douglasii* | Throughout US |
| *C. machenziana* | Southeastern AK north to the Brooks Range |
| *C. occidentalis* | Rocky Mountains, Black Hills, and WA; south into NV and NM |
| *C. vagans* | Pacific northwest US and Canada |

roots radiating out from the main tuber. Water hemlock frequently grows directly in streambeds or water sources and is limited to wet habitats. The tubers are bulbous and exhibit several chambers or cavities separated by cross-partitions as seen in a vertical cut through the tuber at the base of the stem. The cut surface of the stem or tuber exudes a yellowish, thick, oily liquid believed to be predominantly cicutoxin **(8)**. This oily substance has a parsnip-like odor. The chambered tuber is a distinguishing feature of this plant (Figure 66.6). The roots extending from the tuber may be solid, white, and fleshy, closely resembling a parsnip. The stems are hollow except at the nodes, hairless, and occasionally have purple stripes up the stem. Leaf stalks alternate up the stem and leaves 2–3 pinnately divided and may be 30–60 cm long. Flowers are small, white, or cream colored and in terminal umbrella-shaped clusters. The fruits are small, with prominent ribs, and encased in a hard brownish shell very similar to poison-hemlock. The primary distinguishing feature separating water and poison-hemlock is the tuberous roots with the very distinct partitions in water hemlock (Figure 66.6). Poison-hemlock lacks the large tubers, although occasionally there are very small partitions observed in the area where the root and stem connect if the plant is cut vertically. The parsnip-like root is a single taproot in poison-hemlock whereas there are often multiple white parsnip-like roots radiating off the main tubers in water hemlock (Figure 66.6).



**(8)**
Cicutoxin

## Toxicology

The toxic principle in water hemlock is a long chain, highly unsaturated alcohol called cicutoxin **(8)**. Water hemlock acts on the central nervous system as a stimulant, inducing violent grand mal seizures and death from respiratory failure.

Tubers are the most toxic part of the plant especially in early spring. The parsnip-like roots extending from the tuber are 2–4 times less toxic and as the vegetative parts of the plant grow and mature they become less toxic. Preliminary studies suggest that mature leaves and stems are much less toxic and after drying are non-toxic (Panter *et al.*, 1988b). Historically, water hemlock was believed to be most dangerous in early spring, and poisoning usually occurred when animals milled around in streambeds or sloughs and exposed tubers which were then ingested. While this is true, a recent case of poisoning and death in cattle after ingesting flower and green-seed heads implicates this phenological stage as dangerous also (Panter *et al.*, 2007a, b). Chemical comparison of green seed and tubers and mouse bioassay studies showed that green seed was equally as toxic as tubers. Like tubers, the more mature vegetation including leaves, flowers, and green-seed heads were very palatable. Free choice exposure of hamsters to the white parsnip-like roots suggest they are quite palatable and are less toxic than is the tuber itself. Observations of cattle grazing early in spring suggest the young shoots of water hemlock are very palatable as young plants growing in streambeds were frequently and extensively grazed (Panter, personal observation).

Clinical signs of poisoning appear within 10–15 min after ingestion and progress from nervousness, frothing, ataxia, dyspnea, muscular tremors and weakness to involuntary, spastic head and neck movements accompanied by rapid eye blinking and partial occlusion of the eyes from the nictitating membranes. This is quickly followed by collapse and intermittent grand mal seizures lasting 1–2 min each followed by relaxation periods of 8–10 min. Depending on the dosage, recovery may occur or seizures continue until death from exhaustion or respiratory failure. There appears to be a threshold response in which very small increases in dosage will induce an apparently normal animal into grand mal seizures (Panter *et al.*, 1996a).

Upon necropsy, gross lesions are confined to pale areas in heart muscle and skeletal muscles, particularly the long digital extensor muscle groups (Panter *et al.*, 1996a). Microscopic lesions include multifocal, subacute to chronic myocardial degeneration characterized by granular degeneration of myofiber cytoplasm necrosis and replacement fibrosis in the heart. These areas correspond to the pale areas observed grossly. There is bilateral symmetrical, subacute to chronic, myofiber degeneration and necrosis of the long digital extensor muscle groups. Clinical serum chemistry changes of elevated lactic dehydrogenase (LDH), aspartate aminotransferase (AST), and creatine kinase (CK) occur in relation to severity of seizures. The extent of gross and microscopic lesions and clinical chemistries are a result of the severity of the seizures. Experimentally, barbiturates prevented seizures, death and lesions in sheep and a 3 × lethal dose of water hemlock could be reversed with pentobarbital and no death occurred (Panter *et al.*, 1996a). In animals in which seizures were prevented by barbiturates there were no lesions observed

even though doses of 2 and 3 times a lethal dose were administered.

## Prevention and treatment

Prevention of poisoning is accomplished by recognizing the plant and avoiding exposing animals to them early in the spring or when in flower/seed stage. Water hemlock is easily controlled with herbicides (2,4-D per manufacturers specification) however herbicide use is often restricted near natural water sources. If few plants are present hand pulling may be accomplished using caution to discard tubers away from possible exposure to animals or humans.

Successful treatment with barbiturates or perhaps tranquilizers prevents death and the lesions and serum chemistry changes, however treatment must be prompt (Panter *et al.*, 1996a). This treatment has been successful in humans, but in animals has never been demonstrated in the field and would require a veterinarian to be on sight quickly after the ingestion of this plant.

# PONDEROSA PINE NEEDLES (*PINUS SPP.*)

The needles of ponderosa pine have been known for years to induce abortion in pregnant cows when grazed, particularly during the last trimester of pregnancy (James *et al.*, 1989b). Occasional toxicity in pregnant cows occurs (Panter *et al.*, 1990b), however cases of toxicity in non-pregnant cows, steers, or bulls are not reported.

## Description

Ponderosa pine (*Pinus ponderosa*) is one of the most prevalent species of *Pinus* in the western United States. Under ideal conditions it grows to heights of over 60 m and 1.5–2.5 m in diameter. It is extensively harvested for lumber. During early growth the bark is dark brown to black, hence the name "black jack" pine. Older trees have a bark of cinnamon brown to yellow hence the name "yellow pine." Ponderosa pine is a three-needled pine although groups of two and three can be found on the same tree. The needles are about 8–20 cm long growing in clusters. They are soft and quite palatable especially in the winter when green feed is limited. The cones are brown, 7–15 cm long, and frequently grow in clusters. Two varieties of ponderosa pine have been identified including var. *ponderosa*, var. *scopulorum*, and a separate five-needled species *Pinus arizonica* (Conkle and Critchfield, 1987).

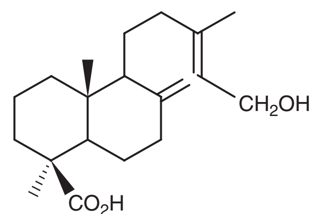
## Distribution

Ponderosa pine grows in every state west of the Great Plains and western Canada. It has a total stand greater than any native tree in the western United States except Douglas fir. It grows at elevations between 1500 and 2500 m although populations in California do extend almost to sea level. Ponderosa pine is drought resistant and is extensively harvested for lumber. Gardner and James (1999) surveyed numerous other *Pinus, Juniperus, Abies* spp., etc. for isocupressic acid (ICA) content and Table 66.6 lists common names, location, and ICA concentration of many species of trees or shrubs.

*Pinus ponderosa* var. *ponderosa* (western variety) extends from the mountains of southern California, northward on the western and eastern sides of the Sierra Nevada–Cascade crest to Canada. The eastern variety *P. ponderosa* var. *scopulorum* meets the western variety near the Continental Divide in west-central Montana and extends southward throughout mountains, plains, and basins to scattered stands in the Sierra Madre Occidental and Sierra Madre Oriental of Northern Mexico. *Pinus arizonica* (once considered a third variety) has scattered populations in southern Arizona and New Mexico (Conkle and Critchfield, 1987).

## Toxicology

The toxin in ponderosa pine that induces abortion in cattle is the labdane resin acid ICA **(9)** (Gardner *et al.*, 1994). Two related derivatives (succinyl ICA and acetyl ICA) also contribute to the induction of abortion after hydrolytic conversion to ICA in the rumen (Gardner *et al.*, 1996). Other related labdane acids (imbricataloic acid and dihydroagathic acid) that are found in ponderosa pine needles (PN) at low levels may also contain abortifacient properties based on their similar chemical structure to ICA. Other genera and species have also been implicated in abortions such as Monterey cypress (Parton *et al.*, 1996), Korean pine (Kim *et al.*, 2003), California juniper, and lodgepole pine (Panter, personal communications).



**(9)**
Isocupressic acid

The primary toxicological effects of ponderosa PN in cattle are abortion and complications associated with the abortion, such as retained fetal membranes (RFM), metritis and

occasional overt toxicity, and death (James *et al*., 1989b; Panter *et al*., 1990b, 1992b; Gardner *et al*., 1999). The abortions generally occur in the last trimester of pregnancy in the late fall, winter, or early spring. Abortions have been induced as early as 3 months gestation and have been reported by ranchers to occur anytime; however, the closer to the time of normal parturition that ingestion of PN occurs the higher the risk of abortion. Abortions may occur following a single exposure to the needles but results from controlled experiments indicate the highest incidence of abortion is in cows eating the needles over a period of days. Abortions have been associated with grazing of green needles from trees, slash from the lumber industry, and dead, dry needles from the ground.

Abortions are generally characterized by weak uterine contractions, uterine bleeding, incomplete cervical dilation, dystocia, birth of weak but viable calves, agalactia and RFM. Two syndromes seem to occur depending on the amount of PN eaten. Either abortion occurs relatively quickly (3–6 days) in which no signs of pending abortion such as udder filling, vulvar swelling, or pelvic relaxation occur but a small weak calf is quickly delivered or the second syndrome in which abortion occurs after 6–14 days and all the before-mentioned signs occur before the calf is born. Unless complications occur, most calves are born alive and the closer to normal parturition the higher the survival rate. Calves born after 255 days gestation will often survive with extra care but need to be supplemented with colostrum and milk from other sources until the dam begins to lactate. Cows with RFM may need antibiotic therapy to avoid uterine infections.

The PN will induce abortion in buffalo (Short *et al*., 1992) but sheep and goats do not abort. The PN, pine bark, and new growth tips of branches are all abortifacient and new growth tips were toxic also (Panter *et al*., 1990b).

A separate toxic syndrome has been described in addition to the abortion in which the abietane-type diterpene resin acids cause depression, feed refusal, weakness, neurological problems, and eventually death. Specific compounds include abietic acid, dehydro abietic acid, and other related compounds (Stegelmeier *et al*., 1996). At 15–30% of the diet PN have been shown to alter rumen microflora and affect the rumen fermentation (Pfister *et al*., 1992; Pfister and Adams, 1993). Rumen stasis is part of the toxic syndrome (Stegelmeier *et al*., 1996).

PN-induced abortion appears to mimic normal parturition except premature. The mechanism of action appears to be a reduction in blood flow to the caruncular vascular bed stimulating the fetal parturition mechanism (Christensen *et al*., 1992a, b; Ford *et al*., 1992). ICA has not been found to be directly vasoactive (Short *et al*., 1996) and it is unclear if ICA metabolites are vasoactive or if the vasoconstriction is a secondary response to ICA or ICA metabolites. Further research is needed to determine the cellular or biochemical mechanism and if metabolic alteration of the ICA occurs.

Extensive vasoconstriction of the caruncular vascular bed with accompanying necrosis and hemorrhage have been the only reported pathological changes in maternal tissues (Stuart *et al*., 1989). This was supported by Christensen *et al*. (1992 a, b), when serum from pregnant cows fed PN showed vaso (vasoconstriction) activity *in vitro*.

## Prevention and treatment

Currently the only recommendation to prevent PN abortion is to avoid grazing pregnant cows in pine trees especially in the third trimester. There is no known treatment for cattle once ingestion of PN has occurred. Open cows,

steers, or bulls are apparently unaffected by PN and likewise sheep, goats (pregnant or not), and horses can graze PN with impunity and experience no adverse effects. Supportive therapy (antibiotic treatment or uterine infusion for RFM) is recommended for cows that have aborted and intensive care of the calf may save the life of the calf. Grazing of PN intensifies during cold inclement weather (Pfister and Adams, 1993) and if other forage is in short supply. In spring before green grass is available cows will leave feeding grounds in search of new green grass and frequently graze old dry needles from surrounding trees where the snow has melted. These cows are at risk and should be kept away from the pines. Anecdotal information suggests that pregnant llamas may be at risk from PN but no experimental support has been done (Panter, personal communications).

## BROOM SNAKEWEED (*GUTIERREZIA* SPP.)

Broom snakeweed causes significant losses to cattle, sheep, and goat producers in Texas and New Mexico from abortions and toxicoses. There are some similarities with that of ponderosa PN except PN apparently only affect cattle.

### Description and distribution

There are two major species of broom snakeweed, G*utierrezia sarothrae* (perennial snakeweed or turpentine weed) and *G. microcephala* (threadleaf broomweed). Snakeweeds are short-lived perennial half shrubs ranging from 15 to 60 cm tall (Parker, 1982). Many unbranched erect stems originate from a woody base and die back when the plant enters dormancy. They have a suffrutescent growth form with new stems originating from the crown each year without becoming woody. The stems originate from the crown and are unbranched, giving rise to the common name of broom snakeweed, with the stems resembling the straight straws of a broom. Leaves are narrow and linear and alternately arranged on stems. These species are of the Composite family, thus they have two types of flowers. Disk flowers are tightly clustered in the center of the head, while long yellow petal ray flowers radiate out from the head (Lane, 1985; McDaniel and Loomis, 1985).

#### *Broom snakeweed (Gutierrezia sarothrae (Pursh) Britt. & Rusby)*

It has more than three florets (usually seven) per involucre or flowering cluster. Broom snakeweed is one of the most ubiquitous range plants and widely distributed throughout North America, ranging from the cold temperate climate of Canada to subtropical areas of Mexico; from the subhumid Great Plains, up to the montane Rocky Mountains and Sierras, to the arid Great Basin. It ranges in elevation from 50 to 2900 m, rainfall from 20 to 50 cm, and temperatures from 4°C to 21°C (McDaniel and Sosebee, 1987). It is a principal component of the following plant communities: desert creosote, desert grassland, short-grass prairie, salt-desert shrub, sagebrush, pinyon-juniper, and mountain brush. Its wide tolerance limits allow it to inhabit a broad range of environments, and can dominate and cause significant problems as both a noxious and poisonous weed in the short-grass prairies and sagebrush plant communities.

#### *Threadleaf snakeweed (G. microcephala (DC) Gray)*

It has one floret per flowering cluster. Threadleaf snakeweed is restricted to the Mojave, Sonoran, and Chihuahuan deserts of the southwestern United States and northern Mexico. It grows in dry, desert habitat and favors sandy soils and has a greater tolerance for arid climates than broom snakeweed.

### Ecology

Broom snakeweed is a native plant and was a minor component of pristine plant communities (5–10%; Campbell and Bamberger, 1934). It was restricted to rocky ridges, gravely slopes and immature or infertile soils (Parker, 1982). However, it aggressively invades disturbed areas. The early literature associated it with overgrazing, which reduced desirable vegetation and allowed broom snakeweed to increase where it already existed, and invade deeper soils and more productive sites (reviewed by McDaniel, and Torell, 1987). Other disturbances such as fire, drought, and chaining can also cause it to increase (USFS, 1937; Parker, 1939; Arnold *et al.*, 1964). It is very competitive with desirable grasses and greatly suppresses forage production (Ueckert, 1979; McDaniel *et al.*, 1982).

A two-tier root system allows the deep taproot to extract deep-stored water, and the extensive adventitious roots near the surface take advantage of the light sporadic rain showers. It has little leaf stomatal control (Depuit and Caldwell, 1975), thus is a luxuriant water user for maximum growth. It grows early in the spring and depletes moisture from the entire soil profile before warm-season grasses break dormancy. Platt (1959) ranked it one of the most undesirable plants in the various regions of the West. On many localized rangelands of the southwest, it is the most significant problem limiting forage and livestock production.

Broom snakeweed is short-lived and experiences dramatic population cycles, which appear to be related to climatic patterns. Although it is very competitive for soil

moisture, it is not particularly drought tolerant. Its populations die-off in drought and from insect depredation, but is one of the first plants to germinate and establish when rains resume, forming widespread monospecific stands (McDaniel and Ross, 2002; Ralphs and Sanders, 2002).

## Toxicology

The snakeweeds are toxic and abortifacient to cattle, sheep, and goats. Abortions and RFM in cattle are among the most serious problems in livestock. In 1985, McGinty estimated losses in excess of $15 million annually to the cattle industry in Texas alone and over $30 million when losses in New Mexico and Arizona were included. This does not account for indirect losses such as loss of useable forage, management changes, increased calving intervals, or added veterinary care.

Snakeweed contains toxic and abortifacient compounds. Dollahite *et al*. (1962) extracted what they called a saponin fraction from threadleaf snakeweed which caused abortions in rabbits, goats and cattle at low doses, and caused death at high doses. Molyneux *et al*. (1980) identified some major monoterpenes and sesquiterpenes in the essential oil fraction of snakeweed and these included α-pinene, myrcene, linalool, *cis*-verbenol, *trans*-verbenol, verbenone, geraniol, caryophyllene, and γ-humulene. Roitman *et al*. (1994) extracted several furano-diterpene acids and flavones from the resinous exudate in trichomes on leaves of broom snakeweed. These diterpene acids were structurally similar to ICA, the abortifacient compound in ponderosa pine (*Pinus ponderosa* Laws) needles (Gardner *et al*., 1994). Gardner *et al*. (1999) speculated that some of the furano-diterpene acids may be abortifacient, while others may be toxic, and the relative concentrations determine whether animals are poisoned or abort. The crude resin content of broom snakeweed, which includes the diterpene acids along with other monoterpenes, increased from 5% in early growth up to 13% at flowering in August (Ralphs and Wiedmeier, 2004, 2007).

Snakeweeds are both abortifacient and toxic. In West Texas in the 1930s, 10–60% of cattle ranches experienced abortions, and cows retained placentas which led to infection and death of the cows. Many calves were born small and weak. Mathews (1936) fed threadleaf snakeweed to cattle, sheep, and goats and reported it damaged the liver and kidneys, but no abortions were produced. Dollahite and Anthony (1957) and others found threadleaf snakeweed did cause abortions, retained placenta and weak calves, and was more toxic on sandy soils (Shaver *et al*., 1964). Low levels of snakeweed caused abortions and high levels are toxic. Clinical signs of poisoning include anorexia, mucopurulent nasal discharge, loss of appetite and listlessness, diarrhea, then constipation and rumen stasis, which may lead to death.

There appears to be a relationship between nutrition and fertility problems caused by broom snakeweed (Flores-Rodriguez *et al*., 1989; Strickland *et al*., 1998). Smith *et al*. (1991) summarized research in rats at New Mexico State University and concluded that increasing amounts of snakeweed in rat diets reduced intake, which led to malnutrition and contributed to diminished fertility and increased fetal mortality. Edrington *et al*. (1993a, b) confirmed that increasing amounts of snakeweed in rat diets reduced intake and contributed to problems of malnutrition and toxicity. However, they determined the overriding factor in reducing fertility and reproduction was the impaired hormone balance and disruption of blood flow to the uterus and developing embryos. Ewes on a high-quality alfalfa diet (18% CP) consumed snakeweed for up to 25% of the ration with no adverse effects on estrus; while ewes fed blue grama hay (11% CP) would not consume rations containing more than 10% snakeweed, and 43% of these ewes did not show estrus and did not breed (Oetting *et al*., 1990). Heifers fed snakeweed as 15% of a balanced diet before breeding and during early gestation had no effect on progesterone levels or conception rates (Williams *et al*., 1993). During the last trimester of gestation, snakeweed added up to 30% of this same diet did not cause abortion or lower calf birth weight (Martinez *et al*., 1993). In a grazing trial on snakeweed-infested crested wheatgrass, cows in the last trimester of gestation were forced to graze snakeweed as a biological control. Snakeweed consumption averaged 10% of bites over the day and peaked at 20% of bites in the evening grazing periods. There were no signs of toxicity or abortions, even though their feed intake was severely restricted (Ralphs and Wiedmeier, 2007).

## Management and treatment

Broom snakeweed is not palatable to most large ungulates (Pieper, 1989). Cattle will not graze snakeweed unless all other vegetation is depleted (Ralphs and Wiedmeier, 2007).Thus the management strategy is simple – ensure adequate feed is available. This can be accomplished by maintaining range in good condition and moving animals when proper utilization is reached.

Broom snakeweed can be controlled by the common rangeland herbicides: Tordon (0.25–0.5 lb/ac) is most consistent; Escort (3–6 oz/ac) is a new and promising herbicide; and 2,4-D (1–2 lb/ac) can be applied for two successive years when soil moisture is not limiting growth (McDaniel *et al*., 1982; McDaniel and Duncan, 1987; Whitson and Freeburn, 1990). Better control is obtained in fall after flowering, when the carbohydrate stream is going down and carries the herbicide to the roots (Sosebee *et al*., 1982).

Snakeweed is readily killed by fire. McDaniel and Ross (2002) suggested prescribed burning is an effective control

in the early stages of the population cycle while there was sufficient grass to carry a fire and respond to the released resources. In the latter part of the population cycle, grasses will be crowded out and spraying with herbicides may be the only alternative. In this case, spraying must be followed by seeding, to ensure a weed-resistant plant community is established that will resist reinvasion of snakeweed.

Insects may play a role in snakeweed population die-off. There are many insects that are associated with snakeweed: defoliators (leaf tyers, grasshoppers, weevils), sap suckers (scale insects and mealy bugs), root boring weevils, and gall formers (Wangberg, 1982). Individually and collectively, they contribute to the demise of mature snakeweed populations. However, it is unlikely that they will contribute to preventing a population buildup because of the time lag of their populations in relation to that of snakeweed.

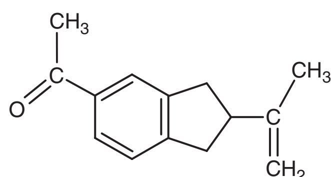
Treatment of sick animals is only symptomatic providing supplementation to weak calves and antibiotic therapy to cows with RFM to avoid infection.

# RAYLESS GOLDENROD (*HAPLOPAPPUS HETEROPHYLLUS*)

Rayless goldenrod (*Haplopappus heterophyllus*) is a toxic range plant of the southwestern United States. The disease associated with toxicity has been referred to as "alkali disease" because originally it was associated with drinking of alkali water (Kingsbury, 1964). Currently, it is referred to as "milk sickness" or "trembles" (the same as white snakeroot in the Midwest) because the toxin tremetone **(10)** is excreted in the milk and subsequently results in poisoning of humans and nursing offspring. *Haplopappus acradenius* was most recently implicated in poisoning in cattle in southern California (Galey *et al.*, 1991).

## Description

Rayless goldenrod is an erect, bushy, unbranched perennial shrub growing 0.5–1.5 m tall. The base is woody and leaves alternate linearly up the stem. Heads are numerous, small, and clustered at the top of the stem with 7–15 yellow flowers on each head.



**(10)**
Tremetone

## Distribution

Rayless goldenrod grows in the desert rangelands of the southwestern United States from southern Colorado into Texas, New Mexico, Arizona, and California into Mexico. The plant grows abundantly on alkaline and gypsic soils in western texas and the Pecos River Valley (Ueckert, 1984).

## Toxicology

The toxic constituent of rayless goldenrod is the same as that of white snakeroot and was originally termed tremetol (a mixture of ketones and alcohols) in white snakeroot (Panter *et al.*, 1992a). Tremetone **(10)** (5-acetyl-2,3-dihydro-2-isopropenyl-benzofuran) was determined to be the principal toxic factor (Zalkow *et al.*, 1962; Beier *et al.*, 1993).

The toxicity of rayless goldenrod mimics that of white snakeroot. Clinical signs of poisoning may occur after ingestion of 1–15% body weight over a 1–3 week period (Schuster and James, 1988). Signs begin with depression or inactivity, followed by noticeable trembling of the fine muscles of the nose and legs. Most cases of poisoning reported constipation, nausea, vomition, rapid labored respiration, progressive muscular weakness, stiff gait, standing in a humped-up position, dribbling urine, inability to stand, coma, and death. Signs are similar in cattle, sheep, and goats (Beier and Norman, 1990). The disease is often more acute and severe in horses than cattle and horses may die of heart failure after subacute ingestion of white snakeroot and presumably rayless goldenrod (Smetzer *et al.*, 1983). Cattle have also been poisoned on a related plant (*Haplopappus acradenius*) in southern California (Galey *et al.*, 1991). In this case 21 of 60 cattle died and 15 of 60 were affected but recovered. Creatine phosphokinase and ketones were elevated and severe myonecrosis was described in the dead animals.

## Prevention and treatment

Rayless goldenrod is not readily palatable and toxicity results from animals being forced to graze the plant due to lack of good quality forage. Avoiding overgrazing will usually minimize poisoning in livestock.

Control of rayless goldenrod can be accomplished with herbicide applications (Ueckert, 1984). Late summer and early fall application of picloram or 2, 4-D ester are successful in reducing plant populations.

Treatment is generally symptomatic and supportive providing dry bedding, good shelter, and fresh feed and water (Beasley *et al.*, 1997). Activated charcoal and saline cathartic may be beneficial. Treatment may include fluids, B-vitamins, ketosis therapy, and tube feeding. Hay and water should be placed within reach if the animal is recumbent. In lactating cows, frequent milking may facilitate a more rapid

elimination of the toxins. In horses, monitoring of cardiac arrhythmias and EKG will provide information concerning heart damage and associated circulatory dysfunction. Treatment is the same for rayless goldenrod and white snakeroot as the toxins are the same.

## HALOGETON (HALOGETON GLOMERATUS)

Halogeton is an alien, invasive, noxious, and poisonous weed introduced from central Asia in the early part of the 20th century. It was first collected along a railroad spur near Wells, Nevada in 1934, and rapidly invaded 11.2 million acres of the cold deserts of the western United States (Young, 1999). There has been no appreciable spread since the 1980s, because halogeton has filled all the suitable niches within its tolerance limits. It currently infests disturbed areas within the salt-desert shrub and sagebrush plant communities in the Great Basin, Colorado Plateau, and Wyoming's Red Desert physiographic provinces, which range from 3 to 15 in. annual precipitation (Pemberton, 1986).

Halogeton's infamy began in the 1940s and 1950s by causing large, catastrophic sheep losses. There were many instances of large dramatic losses; sometimes entire bands of sheep died over night from halogeton poisoning. *Life Magazine* ran a cover story "Stock Killing Weed" which focused national attention on halogeton. Congress passed the Halogeton Act in 1952 with the intent to:

1 Detect the presence of halogeton.
2 Determine its effects on livestock.
3 Control, suppress, and eradicate this stock killing weed.

Federal research was reallocated from the Forest Service Experiment Stations to the Bureau of Plant Industries, creating the Range Research unit devoted specifically to "solving" the halogeton problem. It was realized that halogeton was not the problem but a symptom of a larger problem; that of degradation of desert rangelands (Young, 1999). It invaded disturbed sites where sheep congregated: around railroad loading sites, trailheads, stock drive ways, and around water holes. When hungry sheep were turned loose to graze, halogeton was the only feed available, and they consumed too much, too rapidly, and were poisoned.

### Description and ecology

Halogeton is an annual plant germinating from seed each year. Its stems are branched from the base and tinged with red and purple. Its leaves are fleshy and "hot-dog" shaped, with the distinguishing feature of a single spine on its tip. It can be distinguished from Russian thistle and pigweed (with which it grows) by the tubular, spine tipped leaf. It does not have flowers, but bracteoles formed in the axils of leaves from which seed clusters develop. These seed clusters occur throughout the length of its stems. A robust plant may have 1500 linear inches of stem, with 75 seeds/in., producing 200–400 lb seed/ac (Cronin and Williams, 1966). The seeds are winged, and are spread by wind and rodents.

Its seeds are dimorphic (Williams, 1960), which is key to its successful survival strategy. The majority of its seeds are black, and readily germinate anytime temperature and soil moisture are favorable. However, the black seeds are viable for less than a year. A small percentage of the seeds are hard and brown with low germination rates but they survive for long periods in the soil, and germinate when favorable conditions returned. The dimorphic seed provided abundant seed for germination each year, but also a reserve if drought killed its populations over successive years.

Although halogeton will germinate whenever conditions are favorable, it remains as a seedling until May, at which time lateral branches develop and ascend. It reaches its reproductive stage by mid summer, or when soil moisture becomes limiting. When mature, the winged fruits are blown by wind or carried and deposited by rodents (Cronin, 1965).

Halogeton is not competitive with perennial shrubs and grasses. It will not invade healthy desert plant communities. Only when a site is disturbed will halogeton invade and establish. It is also allelopathic (Eckert and Kinsinger, 1960). It takes up sodium and potassium from saline soils forming the respective oxalates. These oxalates provide an important metabolic function to maintain high cell sap osmotic potential to allow the plant to take up saline water (Kinsinger and Eckert, 1961). Oxalates accumulate over the growing season, reaching peak concentration in the fall (20–36% of plant dry weight). Soluble oxalates leach out of the senescent foliage over the winter and accumulate on the soil surface, thus increasing its salinity. Thus halogeton modifies its environment, making it more saline to meet its requirements, while exceeding the tolerance limits of associated species.

### Toxicology

The toxins are sodium and potassium oxalates (Cook and Stoddart, 1953). The plants are high in these oxalates in the fall and early winter when sheep enter the desert winter ranges. Poisoning occurs when sheep consume more oxalates than the body can detoxify (James, 1972 1999a). Rumen microbes can detoxify the oxalates, and their populations can be induced to accommodate increasing levels of oxalates (James *et al.*, 1967). Furthermore, calcium in the native plants or Ca supplements will rapidly combine with the oxalates in the rumen to form Ca oxalates that cannot

be absorbed and are excreted in feces. If the Na oxalates are absorbed, they can be flushed out in urine (James and Johnson, 1970). If they reach the bloodstream, they precipitate the Ca from the blood, creating Ca oxalate crystals, causing hypocalcemia and shock (James, 1968). The Ca oxalate crystals physically damage the tubules of the kidney (Van Kampen and James, 1969). The Na oxalates interfere with two key enzymes (succinic dehydrogenase and lactic dehydrogenase) in the Krebs cycle, disrupting energy metabolism (James, 1968). Combined, they cause rapid and acute death.

Clinical signs of poisoning include depression, anorexia, weakness, incoordination, recumbency, blood-tinged nasal discharge, coma, and rapid death (Cook and Stoddart, 1953). Gross pathological changes include hemorrhage and edema of the rumen wall, hyperemia of the abomasal wall and intestinal mucosa and ascites (Shupe and James, 1968). Morphological changes include hemorrhage and calcium oxalate crystal formation in the rumen wall and oxalate crystals with accompanying cellular damage in the renal tubules of the kidney (Van Kampen and James, 1969).

## Treatment of poisoned animals

Animals can be drenched with water to flush oxalates out in the urine (James and Johnson, 1970). They can be drenched with dicalcium phosphate (Cook and Stoddart, 1953); the Ca will combine with oxalates in the rumen and can be excreted. An i.v. injection of calcium gluconate can maintain blood Ca levels, but the forming Ca oxalate crystals will continue to damage kidneys. However, it is generally impractical to treat a severely poisoned animal. Prevention is the key to avoid poisoning. Only hungry sheep are poisoned. Research demonstrated that as little as 1 oz of soluble oxalates can be lethal to fasted, hungry sheep. Well-fed sheep grazing nutritious forage throughout the day can tolerate more than 4 oz of soluble oxalate (Cook and Stoddart, 1953). Sheep grazed in a desert plant community infested with halogeton consumed it from 5% to 25% of their diets without ill effect. If other forage is available, they will likely not get a lethal dose.

## Management to prevent poisoning

Never turn hungry sheep onto dense halogeton-infested sites. Provide good feed following trucking or trailing. Ensure there is good feed available following watering. Introduce sheep gradually to halogeton to allow rumen microbes to adjust. Some sheep producers graze their sheep on shadscale ranges (which contains low oxalate levels) before going into halogeton areas. Do not overgraze; maintain desert range in good condition. This prevents halogeton invasion, as well as provides an alternative food source (James and Cronin, 1974).

Herbicide control is not recommended (Cronin, 1965) as the waxy surface of its leaves hinders absorption of most herbicides. But more importantly, desirable desert shrubs are killed, leaving the site open for further invasion and degradation by halogeton and other invasive weeds.

# OAK POISONING

Toxicoses in cattle from ingestion of oak buds, leaves, and acorns occur in many parts of the United States and Europe (Cheeke and Shull, 1985). Poisoning is usually seasonal with ingestion of buds and leaves in spring and acorns in fall.

All oaks should be considered potentially toxic (Table 66.7). Oaks are perennial trees or woody shrubs. They grow in all parts of the United States especially in the southwestern states of Texas, Arizona, and Utah and in Europe and New Zealand.

## Conditions of poisoning

The most dangerous period for oak poisoning is during March and April when new foliage is sprouting. Poisoning of cattle and less frequently sheep and goats occurs on ranges of the southwest and especially during drought years when the forage is limited. Supplemental feeding so that oak ingestion is below 50% of their diet will usually prevent poisoning. Acorn poisoning occurs in the fall, particularly when an acorn crop is heavy. Cattle, sheep, horses, and swine have been involved and craving for acorns has been observed in which animals appear to seek them out (Kingsbury, 1964).

Swine seem to be somewhat resistant and goats apparently utilize oak browse and are used to control oak brush. Feeding high levels of immature gambel oak to goats did not induce any toxicosis (Nastis and Malechek, 1981).

The toxins in oak are tannins, particularly tannic acid and the phenolic acid (gallic acid), and these are highest

**TABLE 66.7 Oak species believed to contribute to poisoning**

| Species | Common name |
|---|---|
| *Quercus gambelii* | Gambel's oak |
| *Q. harvardii* | Shin or shinnery oak |
| *Q. marilandica* | Jack oak |
| *Q. stellata* | Post oak |
| *Q. breviloba* or *durandii* | |
| *Q. coccinea* | Scarlet oak |
| *Q. pedunculata* or *robur* | European oak |
| *Q. prinus* | Chestnut oak |
| *Q. xubra* | Northern red oak |
| *Q. velutina* | Yellow-barked oak |

in new spring growth. Clinical signs of poisoning begin with depression, nasal discharge, abdominal pain, constipation, thirst, frequent urination, rapid pulse, progressing over 1–3 days to rumen atony, anorexia, emaciation, weakness, prostration, rough coat, dry muzzle, subnormal temperature, bloody diarrhea, and death. Diagnosis is based on history of ingestion, clinical signs, elevated SGOT (serum glutamic oxaloacetic transaminase) and BUN (blood urea nitrogen), creatinine, serum potassium, and lower urine specific gravity. Death may occur within 24 h of the onset of clinical signs.

Gross and microscopic lesions include gastritis, nephritis, increased peritoneal and pleural fluids, perirenal edema and hemorrhages with pale swollen kidneys. The proximal convoluted tubules of the kidneys may be damaged and abundant hyline or granular casts may be evident. Mucous and blood are common in voided feces.

## Prevention and treatment

Prevention is the best policy by providing adequate feed to reduce oak ingestion to less than 50% of the diet. Supplemental high-energy feed at 0.5–1 kg/head/day of a 54% cottonseed or soybean meal with 30% alfalfa meal, 6% vegetable oil, and 10% calcium hydroxide may be beneficial.

Treatment includes blood transfusions if anemic, fluid therapy, rumenotomy if warranted, activated charcoal, plenty of fresh water, and avoid stressing animals as much as possible.

# PYRROLIZIDINE ALKALOID-CONTAINING PLANTS

Pyrrolizidine alkaloid (PA) containing plants are numerous and worldwide in distribution and in toxic significance (Cheeke, 1998). Three plant families predominate in PA producing genera and species: Compositae (*Senecio* spp.), Leguminosae (*Crotalaria* spp.) and Boraginaceae (*Heliotropium, Cynoglossum, Amsinckia, Echium*, and *Symphytum* spp.). All of these do not occur in the western United States. For plant descriptions readers are referred to those species causing losses in the western United States and are listed in Table 66.8 with common names and distribution.

## Toxicology

Over 150 PAs have been identified and structural characteristics elucidated (Mattocks, 1986). The PAs contain the pyrrolizidine nucleus and can be represented by the basic structures of senecionine and heliotrine. The toxic effects of all PAs are somewhat similar although their potency varies and are due to their bioactivation in the liver to toxic metabolites called pyrroles (Figure 66.7). These pyrroles are powerful alkylating agents that react with cellular proteins and cross-link DNA resulting in cellular dysfunction, abnormal mitosis and tissue necrosis. The primary effect is hepatic damage, however, many alkaloid and species-specific extra hepatic lesions have been described

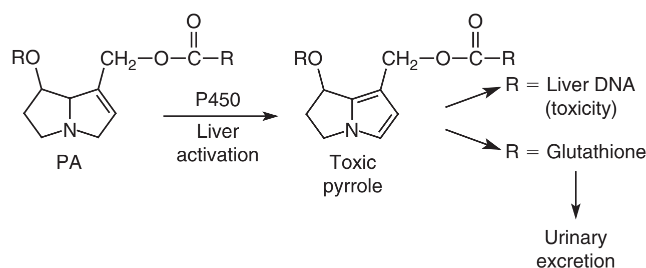


**FIGURE 66.7** Metabolic pathway of PAs showing the toxic pyrrole pathway and glutathione conjugate pathway for excretion.

**TABLE 66.8 PA-containing plants in the western United States, common names, habitat, and distribution**

| Scientific name | Common name | Habitat | Distribution |
|---|---|---|---|
| *Amsinckia intermedia* | Tarweed, fiddleneck | Dry, open cultivated fields | Pacific Coast; CA, WA, OR, ID |
| *Cynoglossum officinale* | Houndstongue | Dry, open areas; cultivated fields | Throughout West |
| *Echium vulgare* | Vipers bugloss | | CA |
| *Symphytum officinale* | Comfrey | | |
| *Senecio brasiliensis* | | | |
| *Senecio cineraria* | Dusty miller | | Ornamental |
| *Senecio glabellus* | Bitterweed | Wet soils | TX and East |
| *Senecio integerrimus* | | | MT; Rocky Mountains, CA |
| *Senecio jacobaea* | Stinking willy, Tansy ragwort | Open fields and woods | Pacific Northwest |
| *Senecio longilobus* | Woody or groundleaf groundsel | Deserts | WY to NE, south to AZ and TX |
| *Senecio spartioides* | Broom groundsel | | CO, UT south to TX, AZ, NM |
| *Senecio riddellii* | Riddell groundsel | Deserts | CO, UT south to TX, AZ, NM |
| *Senecio vulgaris* | Common groundsel | | CA, OR |
| *Crotalaria sagittalis* | | | Pacific Northwest |

(Hooper, 1978). Small amounts of pyrrole may enter the blood and be transported to other tissues, but there is some debate on this issue as most pyrroles are super reactive and not likely to even make it into the circulation (Stegelmeier *et al.*, 1999). When PA metabolites circulate, they are probably protein adducts that may be recycled. Some alkaloids (monocrotaline) may come off their carrier blood proteins and damage other tissues such as lung (Lame *et al.*, 2004). Pigs seem more prone to develop extra hepatic lesions.

Toxicity of *Senecio, Heliotropium*, and *Echium* is largely confined to the liver while *Crotalaria* will cause significant lung damage also (Hooper, 1978; Lame *et al.*, 2004). Typical histological lesions are swelling of hepatocytes, hepatocyte necrosis, periportal necrosis, megalocytosis (enlarged parenchymal cells), karyomegaly (enlarged nuclei) fibrosis, bile duct proliferation, and vascular fibrosis and occlusion. Hepatic cells may be 10–30 times normal size and DNA content may be 200 times normal.

In most species affected by PA poisoning, the liver becomes hard, fibrotic, and smaller. Because of decreased bile secretion, bilirubin levels in the blood rise, causing jaundice. Common clinical signs include ill thrift, depression, diarrhea, prolapsed rectum, ascites edema in the GI tract, photosensitization, and aberrant behavior. In horses, "head pressing" or walking in straight lines regardless of obstacles in the path may occur. These neurological signs in horses are due to elevated blood ammonia from reduced liver function (Knight *et al.*, 1984). PA poisoning may cause elevated blood ammonia resulting in spongy degeneration of the central nervous system.

Elevated levels of serum enzymes such as alanine aminotransferase, AST, $\gamma$-glutamyl transferase, and alkaline phosphatase are reported (Craig *et al.*, 1991; Stegelmeier *et al.*, 1999). Use of these tests for diagnosis is supportive but should not be relied upon exclusively as they vary with animal species and other conditions. They may also be in the normal range even though liver damage had occurred and they tend to be transient. Liver function tests such as bilirubin, bile acids, or sulfobromophthalein (BSP) clearance may be useful estimates of the extent of liver damage.

There are marked differences in susceptibility of livestock and laboratory animals to PA toxicosis. Cows are most sensitive followed by the horse, goat, and sheep, respectively. In small laboratory animals, rats are most sensitive followed by rabbits, hamster, guinea pig, and gerbil, respectively. Among avian species chickens and turkeys are highly susceptible while Japanese quail are resistant (Shull *et al.*, 1976).

Detoxification mechanisms of PAs generally involve the liver and GI tract. Evidence of ruminal detoxification in sheep suggests this contributes to the reduced toxicity in that species. There are also substantial species-specific differences in rate of PA metabolism. Both probably contribute to species susceptibility. For example, *Echium* and *Heliotropium* PAs are easily degraded by certain rumen microflora, but there is little evidence of ruminal degradation of *Senecio* PAs. The PAs in *Senecio* are macrocyclic-closed esters of retronecine as opposed to the open esters found in heliotridine (Kim *et al.*, 1993). Therefore, it is unlikely to be the rumen detoxification but more likely differences in species-specific enzymatic activation of *Senecio* PAs that is the reason for the difference in *Senecio* toxicity between sheep and cattle (Cheeke, 1998). For example, *in vitro* studies of retrorsine metabolism have been shown to be high in those species that are most susceptible and lowest in animals of least susceptibility. Additionally, using *in vivo* studies, Shull *et al.* (1976) demonstrated a higher pyrrole production rate in cattle than sheep. Simple induction of liver microsomal enzymes by phenobarbitone increases pyrrole production and increased PA toxicity ($LD_{50}$ in guinea pigs from >800 to 216 mg/kg). PA toxicity may disrupt other hepatic functions. Abnormal copper metabolism coagulation, $NH_3$ metabolism, protein metabolism, etc. may be affected in PA poisoning.

## Prevention and treatment

As there are no proven effective methods of prevention or treatment, avoidance of the plant and controlling plant populations with herbicides or biological control are essential. Resistance to PA toxicosis in some species suggests that possibilities may exist to increase resistance to PAs. Dietary factors, such as increased protein particularly those high in sulfur amino acids, had small protective effects in some species. Antioxidants such as butylated hydroxytoluene (BHT) and ethoxyquin-induced increased detoxifying enzymes such as glutathione *S*-transferase and epoxide hydrolase. Zinc salts have been shown to provide some protection against hepatotoxicosis from sporidesmin or lupinosis in New Zealand and Australia and zinc supplementation reduced toxicity in rats from *Senecio* alkaloids (Cheeke, 1998; Burrows and Tyrl, 2001; Knight and Walter, 2001).

Many of these plants were introduced either inadvertently or intentionally. Without natural predators to keep populations in check they experienced explosive growth and distribution followed by epidemic proportions of toxicity. Introduction of biological controls and natural population controls have reduced many of the plant populations and thus toxicoses have declined. Sheep, a resistant species, have been used to graze plants particularly *S. jacobaea* (Cheeke, 1998).

# PHOTOSENSITIZING PLANTS

There are numerous plants that cause photosensitization resulting in losses to the livestock industry. Photosensitization is the development of abnormally high reactivity

to ultraviolet radiation or natural sunlight in the skin or mucous membranes. Primarily induced in livestock by various poisonous plants, the syndrome in livestock has been defined as primary and secondary photosensitization.

## Description and distribution

Photosensitizing plants are too numerous to describe individually and readers are referred to taxonomic texts for plant description. Photosensitizing plants occur throughout the world and are common in the diets of livestock and people. Their distribution in the western United States, common names, and toxins are listed in Table 66.9.

## Toxicology

### *Primary*

In primary photosensitization, the photoreactive agent is absorbed directly from the plant and reaches the peripheral circulation and skin where it reacts with the ultraviolet rays of the sun and results in sunburn, particularly of the unprotected areas of the body (Rowe and Norman, 1989). Hypericin and fagopyrin are polyphenolic derivatives from St. John's wort and buckwheat, respectively, and are primary photodynamic agents (Cheeke and Shull, 1985). By definition, primary photosensitization does not induce hepatic damage. Most agents are ingested, but some may induce lesions through skin contact. Several of these plants are weedy in nature and can contaminate pastures and feed. Exposure to some plants is increasing as they are becoming widely used as herbal remedies and holistic medicines. In most cases the photodynamic agent is absorbed from the digestive tract unchanged and reaches the skin in its "native" form (Stegelmeier, 2002)

There are drugs and other toxins known to cause primary photosensitization and should be considered in the differential diagnosis. Phenothiazine-induced photosensitization is most common in ruminants because the photodynamic agent is phenothiazine sulfoxide, a rumen metabolite. Clinical signs in addition to photosensitivity include corneal edema and kerato conjunctivitis from the phenothiazine sulfoxide excreted in tears and the aqueous humor. Other toxins associated with primary photosensitivity include thiazides, acriflavins, sulfonamides, tertracyclines, methylene blue, coal-tar derivatives, furosemide, promazine, chlorpromazine, quinindine, and some antimicrobial soaps (Stegelmeier, 2002).

### *Secondary*

In secondary or hepatogenous photosensitization, the photoreactive agent is phylloerythrin, a degradation product of chlorophyll. Phylloerythrin is produced in the stomach of the animals especially in ruminants and absorbed into the bloodstream. In normal animals, the hepatocytes conjugate phylloerythrin and excrete it in the bile. However, if the liver is damaged or bile secretion is impaired, phylloerythrin accumulates in the liver, the blood, and subsequently the skin, causing photosensitivity. This is the most common

**TABLE 66.9 Photosensitizing plants of the western United States, listed as primary and secondary photosensitizers (Kingsbury, 1964; Johnson, 1982; Cheeke and Shull, 1985)**

| Scientific name | Common name | Distribution | Toxin |
|---|---|---|---|
| **Primary photosensitizers** | | | |
| *Hypericum perforatum* | St. John's wort, Klamath weed | Pacific Coast states | Hypericin |
| *Fagopyrum sagittatum* | Buckwheat | Northwestern US | Fagopyrin |
| *Cymopterus watsoni* | Spring parsley | Southwestern US | Furocoumarins |
| *Ammi majus* | Bishop's weed | Southwestern US | Furocoumarins |
| **Secondary photosensitizers** | | | |
| *Artemesia* | Sagebrush | Western US | |
| *Tetradymia glabrata* | Spineless horsebrush | Western US | |
| *Tetradymia canescens* | Gray horsebrush | Western US | |
| *Agave lecheguilla* | Lechuguilla | Southwest | Saponins |
| *Nolina texana* | Sacahuiste | Southwest | Saponins |
| *Tribulus terrestris* | Puncture vine | Southwest | Saponins |
| *Trifolium hybridum* | Alsike clover | North, Midwest | |
| *Lantana* spp. | Lantana | Southwest | Saponins |
| *Panicum* spp. | Panic grass, Kleingrass | Western US | |
| *Brassica napus* | Rape | Western US | |
| *Senecio* spp. | Senecios | Western US | PAs |
| *Cynoglossum officinale* | Houndstongue | Western US | PAs |
| *Cooperia pedunculata* | Amaryllis family | Southwest US | |
| *Thamnosma texana* | Dutchmans breeches | Southwest US | Psoralens |
| *Kohia scoparia* | Kochia, Burning bush | | Saponins |
| *Descurania pinnata* | Tansymustard | | Unknown |

cause of photosensitization in livestock and horses (Knight and Walter, 2001). Since chlorophyll is almost always present in the diet of livestock the etiological agent of secondary photosensitization is the hepatotoxic agent.

The dermatological signs of photosensitization in livestock are similar regardless of the plant or toxicant involved. Degree or severity varies, depending on the amount of toxin or reactive phylloerythrin in the skin, degree of exposure to sunlight, and amount of normal physical photo protection (hair and pigmentation). First signs in most animals are restlessness or discomfort from irritated skin followed by photophobia, squinting, tearing, erythema, itching, and sloughing of skin in exposed areas, i.e. lips, ears, eyelids, udder, external genitalia, or white pigmented areas (Burrows and Tyrl, 2001). Swelling in the head and ears (edema) of sheep after ingestion of *Tetradymia* has been referred to as bighead. It was determined that sheep grazing black sagebrush (*Artemesia nova*) before *Tetradymia* were 3 times more likely to develop this photosensitization (Johnson, 1974). Tissue sloughing and serum leakage may occur where tissue damage is extensive. Primary photosensitization rarely results in death. However, in secondary or hepatogenic photosensitization the severity of liver damage and secondary metabolic and neurological changes of hepatic failure may ultimately result in death. Recovery may leave sunburned animals debilitated from scar tissue formation and wool or hair loss.

#### *Prevention and treatment*

Prevention of poisoning lies in controlling plants with photosensitizing potential and providing adequate quality forage to animals. Treatment after poisoning involves removing animals from sun exposure, treating areas of necrosis and sunburn, antibiotic therapy and supplementing young animals when access to sunburned udders is prevented because of nursing discomfort to dams. Identifying chronic hepatic disease is complicated because many of the serum markers for hepatic disease have returned to normal. As normal hepatocytes become replaced with fibrous connective tissue there are fewer damaged cells to elevate serum enzymes. Percutaneous liver biopsies are invaluable in identifying and diagnosing these cases (Stegelmeier *et al*., 1999).

Plant-induced hepatopathy generally results in characteristic histological lesions. For example, PAs generally cause bridging portal fibrosis with hepatocellular necrosis, biliary proliferation, and megalocytosis. *Panicum* and *Tribulus* species generally produce a crystalline cholangiohepatitis. Liver biopsy also provides prognostic information. The degree of damage is correlated directly with the animal's ability to compensate, recover, and provide useful production. Keep in mind that the liver reacts to insult in a limited number of ways, and most histological changes are not pathognomonic. Hepatic cirrhosis (necrosis, fibrosis, and biliary proliferation) involves non-specific changes that can be initiated by a variety of toxic and infectious agents (Stegelmeier *et al*., 1999).

## DEATH CAMAS

All death camas species are assumed to be toxic; however, variation in toxicity exists between species and even within species depending on season, climate, soils, and geographical locations. Poisoning in sheep, cattle, horses, pigs, fowl, and humans has been reported (Kingsbury, 1964; Wagstaff and Case, 1987). The largest losses generally occur in sheep. Sheep are primarily affected because of their tendency to select forbs, particularly in early spring when they are turned onto range before grasses have emerged.

Death camas is generally not palatable to livestock but is one of the earliest species to emerge in the spring. Poisoning most frequently occurs in spring when other more palatable forage is not available, or on over-grazed ranges where there is a lack of more desirable forage. Poisonings have resulted due to management errors in which hungry animals were placed in death camas-infested areas (Panter *et al*., 1987).

### Description, habitat, and geographical distribution

Foothill death camas is typical of the 15–20 species of *Zigadenus* in North America and Asia (Figure 66.8). A list of death camas species, habitat, distribution, and growth period is given in Table 66.10. It is difficult to distinguish between species because they are taxonomically similar. A member of the lily family, death camas is a perennial, glabrous herb with basal V-shaped grass-like leaves growing from an onion-like bulb with a dark-colored outer coat. Stems produced at flowering are single, unbranched, sparingly leafed, and terminated by a terminal raceme of greenish-white, cream-colored, or pink inflorescence. The perianth is six-membered, consisting of three lanceolate or ovate sepals and three petals separate or united below, with one or two glands just above the base; stamens six; styles three; floral parts are persistent but winter as the fruits develop. The seed is a three-cavitied capsule, separating into three members and opening inwardly at maturity (Kingsbury, 1964; Muenscher, 1975). Death camas is easily confused with wild onion, mariposa lily, or common camas particularly before flowering. Wild onions are distinguished by tubular leaves and their onion-like odor. Mariposa lilies have leaves more U-shaped in cross-section and common camas has a blue flower.

**FIGURE 66.8** Foothill death camas with leaf structure, flower head, and bulb.

Death camas is prevalent in the western part of North America and is native to the open plains and foothills of the United States. Table 66.10 lists species of death camas with available information about common names, geographical distribution, growth period, and habitat.

## Toxicity of death camas to livestock

The toxins in death camas are of the cevanine steroidal alkaloid type, i.e., zigacine **(11)**. Clinical signs of toxicity are similar in all livestock poisoned by *Zigadenus*, irrespective of the species of plant involved (Kingsbury, 1964). Excessive salivation is noted first, with foamy froth around the nose and muzzle which persists, followed by nausea and occasionally vomiting in ruminants (Kingsbury, 1964; Panter *et al*., 1987). Intestinal peristalsis is dramatically increased, accompanied by frequent defecation and urination. Muscular weakness with accompanying ataxia, muscular fasciculations, prostration, and eventual death may follow. The pulse becomes rapid and weak, and the respiration rate increases but the amplitude is reduced. Some animals become cyanotic and the spasmodic struggling for

**TABLE 66.10** ***Zigadenus* spp.: common names, distribution, habitat, and growth periods**

| Species | Common name | Distribution | Habitat | Growth period |

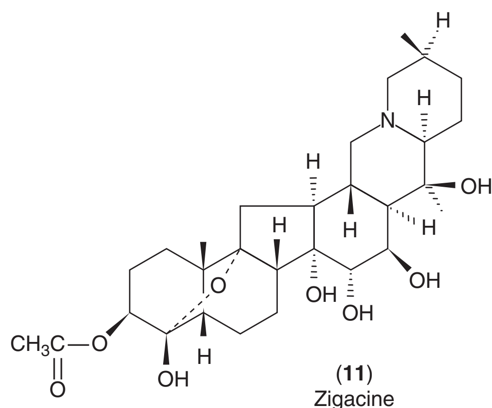
breath may be confused with convulsions. The heart fails before respiration, and at necropsy the heart is usually found in diastole. A comatose period may range from a few hours to a few days before death.

Pathological lesions are those of pulmonary congestion. Gross lesions of sheep include severe pulmonary congestion, hemorrhage, edema, and subcutaneous hemorrhage in the thoracic regions. Microscopic lesions include severe pulmonary congestion with infiltration of red blood cells in the alveolar spaces and edema. Diagnosis of poisoning may be established by clinical signs of toxicity, evidence of death camas being grazed, histopathological analysis of tissues from necropsied animals, and identification of death camas in the rumen or stomach contents (Panter *et al*., 1987).



(**11**)
Zigacine

Similarity in clinical signs of toxicity between certain species of these plants suggests the same alkaloids are present; however, differences in concentrations can explain the differences in relative toxicity of different species (Table 66.11).

## Management and prevention

Conditions conducive to poisoning by death camas include driving animals through death camas-infested ranges; not allowing animals to graze selectively; unloading hungry animals in infested areas; lambing, bedding, watering or salting livestock in death camas-infested areas; or placing animals on range where little forage is available. Poisoning generally occurs in the early spring when death camas is the first green forage available and the young immature foliage is the most toxic. Single losses of 300–500 sheep have been reported (Kingsbury, 1964; Panter *et al*., 1987). In the 1987 case 80% of the dead sheep were 80–90 lb lambs. Three key factors contributed to the losses: (1) ewes with lambs were driven through a heavily infested area of death camas when the sheep were hungry; (2) the sheep were bedded down for the night near the death camas area providing immediate access to death camas the following morning; and (3) the herder panicked and rapidly forced the sheep out of the area contributing to the stress and probably exacerbating the toxic effects and increasing the losses.

# *VERATRUM* SPP.

*Veratrum* belongs to the Liliaceae (Lily) family and is comprised of at least five species in North America. During the mid- 20th century, up to 25% of pregnant ewes that grazed on pastures infested with *Veratrum californicum* in the mountains of central Idaho gave birth to lambs with serious craniofacial malformations (James, 1999b). These malformations ranged from the gross anomaly of cyclops to less severe deformities of the upper and lower jaws. The Basque shepherds called the cyclopic defect "chatto" which translated as "monkey-faced" lamb disease. While losses from *Veratrum* have long been reduced or eliminated on these ranges because of the research and recommended management strategies, biomedical research using the alkaloids, isolated and identified at the Poisonous Plant Research Laboratory, as molecular probes have opened a new frontier for human medical research (Gaffield and Keeler, 1996; James *et al*., 2004).

## Distribution

*Veratrum californicum* grows primarily in the high mountain ranges of the western United States (Kingsbury, 1964; Knight and Walter, 2001). *Veratrum viride* is the most widespread species and grows in the northwestern United States north through western Canada into Alaska and is also widespread in the northeastern United States; *V. insolitum* grows in a relatively small region of northwestern California and southwestern Oregon; *V. parviflorum* grows in the central southeastern states; and *V. woodii* grows from Ohio to Missouri, Oklahoma, and Arkansas. Two other species have been reported to cause poisoning in other countries, *V. japonicum* in Korea and *V. album* in Europe.

Common names include western false hellebore, hellebore, skunk cabbage, corn lily, Indian poke, wolfsbane, etc. Caution should be used with common names as they may be used interchangeably within this genus but also in unrelated genera. For example, the name hellebore is also used for the genus *Helleborus* in the buttercup family.

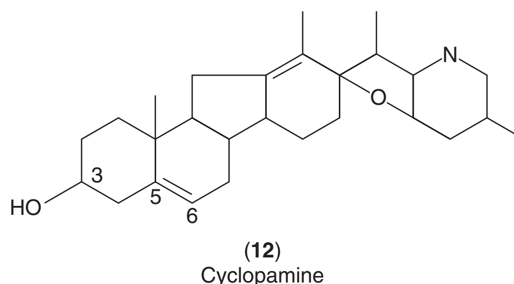
## Habitat and description

Most *Veratrum* spp. are found in similar habitats of moist, open alpine meadows or open woodlands, marshes, along waterways, in swamps or bogs, and along lake edges in high mountain ranges (Kingsbury, 1964). Most species grow at higher elevations. All species are similar with coarse, erect plants about 1–2.5 m tall with short perennial rootstalks. The leaves are smooth, alternate, parallel veined, broadly oval to lanceolate, up to 30 cm long, 15 cm wide, in three ranks and sheathed at the base. The inflorescence is panicle flowers, the lower ones often staminate and the upper ones perfect. The flowers of *V. viride* are distinctly green and the fruit is three-chambered with several seeds.

## Toxicology

Over 50 complex steroidal alkaloids have been identified from the *Veratrum* spp. Five classes of steroidal alkaloids have been characterized: veratrines, cevanines, jervanines, solanidines, and cholestanes. The veratrines and cevanines are of considerable interest in toxicology as they are neurological toxins and hypotensive agents that bind to sodium channels delaying closure and causing cardiotoxic and respiratory effects. The cevanine alkaloids, like zigacine **(11)** are also found in *Zigadenus* spp., also members of the Lily family. The jervanines are most significant for their teratogenic effects; the most notable alkaloids were named cyclopamine **(12)** and jervine, both potent inducers of the congenital cyclopia "monkey-faced" lamb syndrome reported in many flocks of sheep in the late 1950s in central Idaho (Binns *et al.*, 1965). This cyclopic defect is induced in the sheep embryo during the blastocyst stage of development when the pregnant mother ingests the plant during the 14th day of gestation. Early embryonic death up to the 19th day of gestation and other defects such as limb defects and tracheal stenosis occur when maternal ingestion includes days 28–33 of gestation (Keeler *et al.*, 1985; Keeler and Stuart, 1987; Keeler, 1990). The solanidine alkaloids are also found in many *Solanum* spp. and are toxic and teratogenic. The cholestanes have been used as hypotensive drugs but are much less likely to induce the birth defects (Gaffield and Keeler, 1994). Structure activity relationship is very important in potency to produce birth defects. It is now known that this structure activity relationship is key in the mechanism of action which is the inhibition of the sonic hedgehog signaling pathway (Gaffield and Keeler, 1996). This sonic hedgehog gene pathway and the subsequent down stream regulation of other gene's expression have now been implicated in numerous cancers, birth defects and other anomalies. The toxin, cyclopamine, has become a significant tool in the study of this very complex sonic hedgehog pathway. Clinical trials have been proposed and studies are ongoing to further identify the hedgehog complex of genes and to understand its mechanism and function in formation and growth of numerous cancers, childhood birth defects, and manipulation of regulatory pathways.

Clinical signs of poisoning are most likely caused by the neurotoxic cevanine alkaloids present in most species of *Veratrum*. Typical signs begin with excess salivation with froth around the mouth, slobbering and vomiting progressing to ataxia, collapse, and death.



(**12**)
Cyclopamine

## Prevention and treatment

Control of *Veratrum* is relatively easy with herbicides such as broad-leaf herbicides and long-term control has been demonstrated (Williams, 1991). The teratogenic effects of *Veratrum* can be avoided by keeping sheep and other livestock species off pastures containing the plants during the first trimester of pregnancy. Observation of toxicoses in the field is rare unless herders move the animals shortly after exposure. The neurological signs, which are likely produced by the cevanine alkaloids (both *Veratrum* and *Zigadenus* spp.) can be treated with atropine to improve the cardiovascular output. Activated charcoal to adsorb toxins and administration of picrotoxin to improve respiration have been recommended (Burrows and Tyrl, 2001).

# BRACKEN FERN (*PTERIDIUM AQUILINUM*)

## Distribution and habitat

The bracken fern family is worldwide in distribution and include about 20 genera and over 400 species. While most species described are found in the tropics, there are 4 genera

and 6 species described in North America (Burrows and Tyrl, 2001). The bracken fern most associated with toxicoses in the United States is *Pteridium aquilinum* (Kuhn) and is distributed throughout North America. It is reported to be one of the most widespread species of vascular plants only exceeded in geographical range by a few annual weeds. Four varieties of *P. aquilinum* have been described including var. *pubescens* (western bracken fern) found throughout the western United States; var. *caudatum* (lacy bracken) restricted to southern Florida; var. *latiusculum* (eastern bracken) distributed throughout the eastern United States; and var. *pseudocaudatum* (tailed bracken) mostly located in the southeastern quarter of the United States.

Western bracken grows best in rocky, gravelly, well-drained soils in dry open woodlands to semi-shaded habitats. Extensive stands frequently grow along pasture edges, in logged areas or where fires have opened up the canopy. Moisture needs are modest in comparison with many of the ferns and good soil drainage is important.

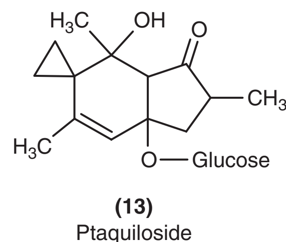
## Description

Bracken plants are deciduous and grow from brown to black woody rhizomes, forming large often dense patches. The leaves emerge from erect fronds and are pinnately compound, scattered, erect, coarse, narrowly or broadly triangular, to 2 m in height. Fronds (leaves) are pinnules (ultimate segments) oblong, entire in the apices of the pinnae, lobed toward the stalk. Reproduction is by spores produced in sporangia lining the under surface margins of the photosynthetic fronds when reproductive, covered by the narrow recurved edge of the leaf (Kingsbury, 1964; Burrows and Tyrl, 2001).

## Toxicology

Toxicity of bracken fern was first recognized in the 1800s and described in horses as a neurological condition. Contaminated hay was believed to be the cause and the condition was described in the United Kingdom and Pacific Coast states of the United States (Taylor, 1990; Burrows and Tyrl, 2001). Early research determined that 20–25% bracken for 3 or 4 weeks would induce a neurological disease followed soon after by death. While the neurological condition is mostly described in horses, low hematocrits and reddish-brown urine has also been described in suspected cases of bracken poisoning (Kelleway and Geovjian, 1978).

Bracken causes a wide range of syndromes that have been described in livestock including thiamine deficiency in monogastrics, acute hemorrhagic disease associated with bone marrow aplasia and ulceration of the upper GI tract, "bright blindness" progressive retinal degeneration, and neoplasia of the urinary bladder and upper digestive tract (Smith, 2004). The major toxin is the sesquiterpene glucoside, ptaquiloside **(13)**. Other toxins, carcinogens and mutagens may be implicated in the disease conditions also.



**(13)**
Ptaquiloside

People have consumed the rhizomes or croziers of bracken fern as a traditional food or out of necessity, and the toxin is transferred through milk of cows grazing the plant. Epidemiological evidence suggests that some cancers in man probably result from primary or secondary consumption of the carcinogens. Ptaquilosides form adducts with DNA, binding to certain base sequences, especially those associated with adenine. Ptaquiloside mutates codons associated with known oncogenes and this hypothesis has been proposed in the pathogenesis of the disease (Smith, 2004).

Syndromes of bracken poisoning are well recognized in livestock. Many factors must be considered in the genesis of the disease such as quantity consumed, phenological stage of the plant, time of year, consumption rate and length of time consumption occurs, animal species, age, sex of the animal and other factors. The disease conditions described include thiamine deficiency in monogastrics, acute hemorrhagic disease, bright blindness, enzootic hematuria, and small intestine carcinoma (Smith, 2004). These conditions have been experimentally produced by feeding bracken fern and ptaquiloside to livestock species and rodent models. Bracken fern feeding studies in rodents have produced neoplasms in the ileum, urinary bladder, mammary glands, and lungs of rodents.

The toxin ptaquiloside **(13)** was isolated, characterized and the structure published in the early 1980s (Niwa *et al.*, 1983; Hirono *et al.*, 1984). Different species and varieties of *Pteridium* have been compared for ptaquiloside concentration and all examined to date contained ptaquiloside. Large variations in concentration were demonstrated between locations, altitude, season, etc., suggesting a genetic component or another factor such as endophyte-produced compounds. These differences were maintained when bracken fern rhizomes were transferred to a greenhouse and soils were changed, thus the ptaquiloside differences were still evident for the next 3 years. Ptaquiloside concentrations are highest in young growing parts, i.e. the tips of the croziers and immature fronds while the concentration diminishes as the plant matures and as samples are taken from more mature pinnae and towards the base of the lamina. All

samples of rhizome, the apices of the fronds or primordia taken from below the soil surface had no ptaquiloside; however, very immature croziers only a few centimeters above the surface showed the presence of the toxin (Smith, 2004). The emergence of the crozier apices and exposure to light apparently influence the biosynthesis of the toxin. The spores have not been shown to contain ptaquiloside but they have caused cancer and formed DNA adducts suggesting carcinogenic or mutagenic derivatives are present. Ptaquiloside and other ptaquiloside-like compounds with carcinogenic activity have been isolated from other ferns from the genera *Histiopteris, Cheilanthes, Cibotium, Dennstadtia, Hypolepis, Pteris*, and *Pityrogramma* (Saito *et al*., 1990).

While bracken fern poisoning occurs in the United States the most serious risk is in countries such as Australia, New Zealand, Japan, and the United Kingdom where bracken is more prevalent and utilized for human food or animal feed. Epidemiology studies have associated increased esophageal and gastric cancers with direct ingestion, secondary ingestion (i.e. milk from cows grazing bracken) or just living in bracken fern-infested areas. Bracken fronds steeped in water or treated with wood ash or sodium bicarbonate have reduced toxicity but this process only reduces the concentration and does not eliminate the toxins (Hirono *et al*., 1972).

Lesions in horses poisoned by bracken fern are indicative of thiamine deficiency and include congestion of the brain, a swollen and edematous cerebrum grossly and necrosis of some neurons microscopically. Acute hemorrhagic disease in cattle is characterized by extensive hemorrhage of the mucous membranes and subcutaneous hemorrhage and edema.

Pathology of the bracken-induced enzootic hematuria include desquamated and proliferative bladder epithelium and areas of vascularized epithelial proliferation appear as polyploid, papillary, or fungoid reddened foci. Microscopically, columns of transitional epithelium infiltrate into the lamina propria along with mononuclear cells. Neoplasia, when it occurs, is most commonly the non-invasive papillomatous type, but other papillary types of transitional cell carcinoma, squamous cell carcinoma, adenocarcinoma, or hemangiomas may also develop (Burrows and Tyrl, 2001).

## Treatment

Bracken-induced thiamine deficiency in horses is treatable with administration of thiamine parenterally at 0.5–1 g followed by decreasing doses over the next few days. Symptomatic care with good feed and fresh water accompanied by administration of a laxative but *not* mineral oil is helpful. In ruminants, the bone marrow suppression and deficiency of blood platelets and neutrophils is best treated with antimicrobials to counteract any bacterial infection that might occur because of diminished immune function. Good veterinary care, symptomatic treatment, clean water and quality feed in a quiet clean environment is recommended.

# MILKWEEDS: *ASCLEPIAS* SPP.

## Description

Milkweeds are divided into two broad groups: narrow-leaved with narrow, linear, lanceolate leaves; and broad-leaved with leaves about 4 cm wide throughout much of their length (Figure 66.9). There are over 150 species of *Asclepias* of which 108 occur in North America (Woodson, 1954). Milkweeds are perennial, summer or early autumn flowering-herbs with a milky latex-like cream in the stems. Of the many species found in North America several are important toxicologically and represented in Table 66.12. The stems of the plants are erect and range from 4 to 150 cm tall, leaves opposite or whorled. Flowers are of various colors, umbellate clusters or solitary, and terminal or extra-axillary. Numerous seeds are contained in an inflated milkweed-type pod and are flat, large and each bearing a tuft of long, silk-like hairs for wind distribution.

**FIGURE 66.9** Narrow-leaf (left) and broad-leaf (right) milkweeds (*Asclepias* spp.) represented.

**TABLE 66.12 Milkweeds: *Asclepias* spp., common names, distribution, habitat and toxin**

| Species | Common name | Distribution | Habitat | Toxin; content* |
|---|---|---|---|---|
| **Narrow-leaved milkweeds** | | | | |
| *A. labriformis* Jones | Labriform milkweed | Southeastern UT | Along old stream beds in sandy soils | Cardiac glycosides, digitoxin; very high |
| *A. verticillata* L. | Eastern whorled milkweed, spider milkweed | From TX to MI, east to FL and MA | Dry open areas | Cardenolides; very low |
| *A. subverticillata* Vail | Western whorled milkweed, horsetail milkweed | Western KS and OK, UT, AZ, TX and into Mexico | Dry plains and foothills, spreads rapidly along waterways and canals | Cardenolides; very low |
| *A. pumila* Vail | Low whorled milkweed, plains whorled milkweed | East of the Rockies from TX and NM north to southeast MT and southwest ND | Small patches in draws and ravines | Cardenolides; very low |
| *A. mexicana* Cav. | Mexican whorled milkweed | Southern TX to central Mexico | Open areas and dry soils | Cardenolides; unknown |
| *A. asperula* Woodson | Antelope horn milkweed | KS, AR to NV and AZ | Open areas and dry soils | Cardenolides; very high |
| *A. fascicularis* Decne. | Mexican milkweed | CA, western OR through eastern WA, ID and NV | | Cardenolides; very low |
| *A. brachystephana* Engelm. | Short-crown milkweed | West central TX, southern AZ into NM and Mexico | | Cardenolides; very high |
| *A. subulata* Decne. | Desert milkweed, yamate, ajamete | Southern CA, AZ, west coastal region of Mexico | | Cardenolides; very high |
| **Broad-leaved milkweeds** | | | | |
| *A. eriocarpa* Benth. | Woolly-pod milkweed | CA | Dry soils | Cardenolides; very high |
| *A. latifolia* Brit. | Broad-leaf milkweed | KS, CO to TX and AZ | Dry plains | Cardenolides; high |
| *A. speciosa* Torr. | Showy milkweed | MN south to MI and TX; west to CA | Prairies and open spaces | Cardenolides; intermediate |
| *A. syriaca* L. | Common milkweed | Widely distributed in central and eastern US | Open areas and along roadsides | Cardenolides; intermediate |
| *A. incarnata* L. | Swamp milkweed | IN | Cool damp soils | Cardenolides; very low |
| *A. vestita* Hook and Am. | Woolly milkweed | Central and southwestern CA | | Cardenolides; very high |
| *A. virdis* Walter | Green milkweed, spider milkweed | Southcentral states, FL | | Cardenolides; high |

*Cardenolide content mg/g plant from <0.25 (very low) to >4 (very high).

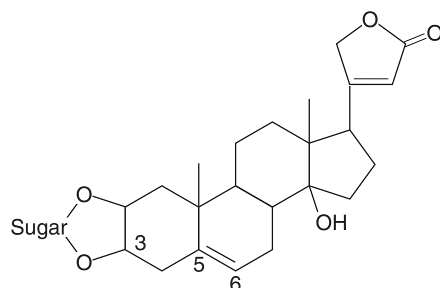
## Distribution and habitat

Milkweeds are adapted to a broad range of habitats and environmental conditions and are found in most plant communities. Occupied habitats include prairies, woodlands, open areas, rocky plains, sand dunes, swamps, marshes, seeps, canyon bottoms, dry washes, desert lands, and wastelands. Most species are weedy and form small to large patches often along roadsides, in disturbed areas or in overgrazed pastures.

## Toxicology

Some species of milkweeds have been used as medicines, food or a source of poison. Most species contain a mixture of steroidal glycosidic cardenolides **(14)** that are toxic and induce two syndromes: GI/cardiotoxic effects and the other neurological (Radeleff, 1970). Earlier literature suggested that the broad-leaved group was cardiotoxic while the narrow leave-type was neurotoxic. However, most narrow-leaved species have now been shown to contain cardiotoxins also (Ogden *et al.*, 1992).

Historically, naturalists observed as early as the mid 1800s that birds avoided eating certain butterflies, such as the monarchs whose larvae fed on milkweeds. It was later learned that the feeding larvae were able to concentrate some of the cardenolides that were potent emetics and thus created an effective defense against herbivory. Interestingly, other butterfly species mimicked the color configuration of the monarch as an effective defense mechanism against herbivory by birds. As of the late 1980s, 27 species of milkweed



(**14**)
Cardenolide

were recognized as common feed for butterfly larvae, and the most toxic species were often preferred (Malcolm *et al.*, 1989). The milkweeds are host to many other insect species also.

The basic structure of the series of identified cardenolides **(14)** is a 23-C steroidal backbone with a five-membered, singly unsaturated lactone ring at the C-17 position, a hydroxyl group at C-14, and methyl groups at C-10 and C-13. Glycosidic linkage usually occurs at the C-3 or C-2 positions and may include glucose, rhamnose or thevetose as the sugars. Additional functionalities attached to the backbone further influence solubility, and binding thus increasing or decreasing toxicity. The cardenolides inhibit $Na^+$, $K^+$-ATPase, and the structure activity relationship is believed to reside in the unsaturated lactone ring at C-17 and the hydroxyl group at C-14 (Joubert, 1989).

Sheep, goats, cattle, horses, and domestic fowl have been poisoned with milkweeds (Kingsbury, 1964). Clinical signs usually begin with depression, weakness and labored breathing accompanied by ataxia and loss of balance, progressing to recumbency, seizures and death. The order of clinical signs is dependent on the type of animal affected, toxicity of the plant, time of ingestion and amount of the toxin consumed. Clinical effects appear within a few hours of ingestion and death may follow within one to a few days later in fatal cases.

## Treatment and control

There are two syndromes of milkweed poisoning, a neurological one and a cardiac one. Treatment for the cardiotoxic signs is approached similar to that of digitalis glycoside toxicity, i.e. activated charcoal, atropine for atrioventricular (AV) block, and/or antiarrhythmic drugs. There is no specific treatment for the neurological syndrome except symptomatic treatment to control seizures and supportive therapy. A field test with a detection threshold of 0.057% is available for detecting cardenolides in the latex of milkweeds (Sady and Seiber, 1991). Knowledge of the milkweed species in the pasture, stage of plant growth when consumed and history of grazing and clinical effects are all important in developing a diagnosis and eliminating other causes.

In most cases, knowledge that the plant exists in your pasture and prevention of ingestion is the best way to avoid poisoning. Purchase of weed-free hay to avoid poisoning via contamination is also important. Know where the hay comes from and always be alert as to the content of the hay. Control of milkweeds can be accomplished with herbicides such as 2,4-D, picloram, amitrole or glyphosate depending on the other forage it has infested and the circumstances. Always follow the manufacturer's recommendation.

# NIGHTSHADES

The nightshade family comprises over 80 or 90 genera and more than 2300 species worldwide. Some of the more common poisonous genera include *Brugmansia, Brunfelsia, Capsicum, Cestrum, Datura, Hyoscyamus, Lycium, Lycopersicon* (tomato), *Nicotiana* (tobacco), *Solandra, Solanum, Nicandra*, and *Physalis*. Some common nightshade species are listed in Table 66.13. In the United States and Canada the nightshades can be annual, perennial or shrubs with alternate, simple or compound leaves, axillary inflorescences, radially symmetrical flowers composed of five free sepals, five free petals, usually five stamens with anthers grouped conically about the stigma and berry-like fruits of variable colors.

## Toxins

The nightshades have a variety of toxins known to affect people and animals and include the tropane alkaloids, affecting the autonomic nervous system by blocking the action of cholinesterase (Knight and Walter, 2001). This results in accumulation of acetylcholine and subsequent inhibition of the parasympathetic nervous system, causing dry mouth, decreased intestinal motility, dilated pupils, and tachycardia. The tropane alkaloids also affect the GI tract causing colic in horses, constipation and/or hemorrhagic diarrhea. The *Nicotiana* spp. contain neurological toxins including the pyridine and piperidine alkaloids responsible for toxicoses and teratogenesis. Some species of *Solanum* cause a neurological disease in cattle, sheep, and goats characterized by loss of equilibrium, tremors, ataxia, collapse, opisthotonus, seizures, and death. *Solanum malacoxylon* and *Cestrum* spp. contain vitamin D-like compounds that cause abnormal calcium absorption and metabolism resulting in calcified tissues, lameness, and weight loss. Green potatoes, sprouts, and vines contain steroidal glycoalkaloids that are both toxic and teratogenic. Table 66.13 provides a limited

**TABLE 66.13 Nightshade species with known links to toxicosis in humans or animals: common names, distribution, and toxins**

| Species | Common name | Distribution | Toxins |
|---|---|---|---|
| *Solanum elaeagnifolium* | Silverleaf nightshade | Southern US | Solanine and solanidine |
| *S. nigrum* | Black nightshade | Throughout North America | Tropane and glycoalkaloids |
| *S. dulcamara* | Bittersweet; climbing nightshade | Eastern half of US; parts of OR, WA, NV, CA, UT and WY | Glycoalkaloids |
| *S. rostratum* | Buffalo bur | Central US to north and south borders | Glycoalkaloids |
| *S. triflorum* | Cutleaf nightshade | Central US to north border | Glycoalkaloids |
| *S. americanum* | Huckleberry; wonderberry | Southern US | Glycoalkaloids |
| *S. physalifolium* | Tropical soda apple | Throughout US | Glycoalkaloids |
| *S. sarrachoides* | Hairy nightshade | | Glycoalkaloids |
| *S. carolinense* | Horse or bull nettle | Eastern half of US; west coast | Tropane alkaloid solanine |
| *S. tuberosum* | White or Irish potato | Worldwide | Glycoalkaloids |
| *Datura wrightii* | Sacred datura | Southwestern US | Tropane alkaloids |
| *D. stramonium* | Jimson weed; thornapple | Southeastern half of US; west coast | Tropane alkaloids |
| *Nicotiana tabacum* | Cultivated or burley tobacco | Southern US | Pyridine alkaloids (nicotine) |
| *N. glauca* | Tree tobacco | Southern US | Piperidine alkaloids |
| *Capsicum annum* | Green or chile pepper | Cultivated in US | Capsaicinoids |
| *Cestrum parqui* | Willow-leaved jessamine | Southern Gulf states | Glycoside of vitamin D |
| *Atropa belladonna* | Deadly nightshade; belladonna | Cultivated as an ornamental | Tropane alkaloids |
| *Hyoscyamus niger* | Black henbane | Northern US | Tropane alkaloids, calystegins |
| *Physalis virginiana* | Ground cherry | Plains states and eastern US | Glycoalkaloids, calystegins |
| *P. lobota* | Chinese lantern | Southern regions; cultivated throughout US | Glycoalkaloids |
| *Lycopersicon esculentum* | Tomato | Worldwide | Glycoalkaloids |

Adapted from Kingsbury (1964), Burrows and Tyrl (2001), and Knight and Walter (2001).

overview of selected species, their distribution, and toxin (Burrows and Tyrl, 2001; Knight and Walter, 2001).

## Clinical signs

The toxins in the Solanaceae family contribute to various clinical effects depending on the amount of plant/toxin ingested, the plant species eaten and the animal species consuming the plant. Signs range from mild digestive upset to severe colic in horses when contaminated hay is fed, to neurological dysfunction, seizures and death in sheep and cattle, to "big head" and calcification of the blood vessels to teratogenesis.

## Treatment

Animals showing severe neurological signs such as tremors, ataxia, dilated pupils, etc. may be treated with physostigmine. Oral activated charcoal as an adsorbent may be effective if administered in a timely fashion. However, most animals will recover if treated symptomatically and if the animals are not overly stressed.

# KNAPWEEDS: *CENTAUREA* SPP.

The knapweeds are a large group with primarily noxious, invasive characteristics. While this genus is not a great risk for livestock producers, a serious disease of horses called nigropallidal encephalomalacia warrants its inclusion in this chapter. There are 450–500 species of *Centaurea* and 29 have been described in North America (Burrows and Tyrl, 2001). Most of these have been introduced and have made a huge negative impact on rangelands in the western United States. While most species are opportunists and will aggressively invade rangelands, especially those that have been overgrazed, burned or disturbed, only two are of any toxicological significance, *Centaurea repens* (Russian knapweed) and *C. solstitialis* (yellow star thistle).

## Habitat and distribution

Yellow star thistle is most abundant in the western United States from central California north through Oregon, Washington, and Idaho. Smaller invasions are reported in many states east of the Intermountain Region and while these have not received the attention of the larger invasions in the west, they have the potential to rapidly spread under the right environmental conditions (Panter, 1991; Burrows and Tyrl, 2001; Knight and Walter, 2001). Russian knapweed has invaded very large areas of the Intermountain Region of the western United States and the Great Plains. Again, smaller populations have invaded areas of the Midwest and northeastern United States and have the potential to expand rapidly. While the aggressive nature of these species threatens rangelands and prohibits optimum utilization, a greater threat is the risk to sensitive or threatened native plant species and the balance of plant biodiversity.

## Toxicology

The compounds isolated from knapweeds include a large class called sesquiterpene lactones. While the putative toxin causing the neurological disease in horses has not been specifically identified, six of these compounds have been screened for cytotoxicity in an *in vitro* neuronal cell bioassay (Riopelle *et al*., 1992). The rank order of activity is repen > subluteolidejanerin > cynaropicrin > acroptilin > solstitial in (Riopelle and Stevens, 1993). Toxicity of solstitialin A 13-acetate and cynaropicrin has been demonstrated to primary cultures of fetal rat substantia nigra cells (Cheng *et al*., 1992). These sesquiterpene lactones are quite unstable and it has been hypothesized that they are precursors to the ultimate neurotoxin. Also, there are aspartic and glutamic acids present in these plants and they possess neuroexcitatory properties (Roy *et al*., 1995).

## Clinical signs

Thus far, only yellow star thistle and Russian knapweed have been implicated in toxicoses in the United States and only in horses. Ruminants are apparently not affected and the *Centaurea* spp. may be useful forage for sheep and goats. However, in other countries toxicoses in ruminants have been reported. For example, in South Africa, *C. repens* fed to sheep at 600 g dosages for 2 days caused an acute digestive upset and pulmonary edema and acsites (Steyn, 1933). In Azerbaijan, *C. repens* is reported to cause a neurological disease in buffalo similar to what has been described in horses (Dil'bazi, 1974). However, no neuropathology similar to what was seen in horses was observed in the buffalo.

Toxicity generally occurs in summer and fall when forage is depleted and horses are forced to graze less palatable species. Ingestion often occurs for several months or more before an abrupt onset of neurological dysfunction is observed. Impaired eating and drinking are often the first observable signs. Depression and hypertonicity of the lips and tongue follow and a constant chewing may be observed hence the name "chewing disease." Abnormal tongue and lip postures may be observed and other neurological signs including locomotor difficulties such as aimless walking, drowsy appearance, and inactivity with the head held low. The neurological disease is considered permanent and while some improvement may be seen, difficulty eating and drinking may preclude long-term recovery. Often the disease progresses to dehydration, starvation, bizarre behavior including submergence of the head in water to allow water to flow into the esophagus or lapping water like a dog. *C. repens* appears to be more toxic than *C. solstitialis* but prolonged ingestion is required by both before disease appears. Amounts of plant ingested to induce the clinical effects is reported to be 60% or more of body weight for *C. repens* and 100% or more of body weight of *C. solstitialis*. Intermittent grazing can prevent disease suggesting there is not a cumulative effect but rather a threshold must be exceeded before neurological signs are observed (Cordy, 1954, 1978). Once neurological signs are observed in horses, prognosis for recovery is poor and euthansia should be considered.

## Pathology

The lesions are very specific and limited to the globus pallidus and the substantia nigra (nigropallidal encephalomalacia), where distinct pale yellowish to buff-colored foci or softening and cavitation are seen (Cordy, 1954, 1978). The lesions are typically bilateral and symmetrical. This specificity of the lesions for the basal ganglia has prompted more investigations into unraveling the mysteries of human diseases associated with dopaminergic pathways, such as Parkinson's or Huntington's disease, and tardive dyskinesia. This disease in horses is often called equine Parkinsonism. This unusual disease is manifest by an almost immediate onset after prolonged ingestion suggesting an all or none type of acute neurological crisis. The lesions develop quickly and completely and progressive stages of degeneration rarely occur except for some changes in the adjoining neurons adjacent to the necrotic foci in the globus pallidus and the pars reticularis of the substantia nigra (Cordy, 1954). Microscopically there is extensive necrosis of neurons, glia and capillaries within sharply defined margins of the involved brain centers. Occasionally, lesions may be observed in the gray and white matter of the brain.

## Prevention and treatment

Good veterinary care and supportive therapy including good feed, easy access to water, supplemental vitamins, and good nursing care is essential for survival. Treatment of the disease once it is manifest is not generally successful. However, in Argentina affected horses have been treated with glutamine synthetase and a bovine brain ganglioside extract given daily i.m. for a month with some success (Selfero *et al*., 1989). When animals are first observed grazing *Centaurea* spp. they should be immediately removed to better pastures. Prevention of the disease is easily accomplished by knowing the plants that exist in your pastures, by providing good quality and adequate amounts of forages and feed and by frequent observation of your animal's grazing patterns and behavior.

Control of plant invasion by good range/pasture management to prevent overgrazing and loss of other competitive grasses and forbs is important. Herbicide control is quite easily accomplished with broad-leaf products including 2,4-D, dicamba, picloram, etc. applied according to

label. These plants are prolific seed producers and follow-up treatment will be required to eliminate the populations. Seeds are often distributed through contaminated hay or other feed sources and initial populations often start near feed bunks and spread from there. Because of their morphology, size and parachute-like structures, seeds are easily spread by wind and water. Understanding your weeds and close monitoring of populations will help in control of these highly invasive species.

# CONCLUSION

Even with our ever increasing knowledge about poisonous plants and their toxins, poisonings continue to occur, some catastrophic, on livestock operations. Poisoning in humans and companion animals from toxic plants also continues to be a significant risk, especially to pets and children. As the influx of small acreage farmers onto native rangelands increases and ranchettes become more common, the potential risk for poisonous plant problems increases. Lack of understanding and increased grazing pressure on these small acreages often contribute to the consumption of toxic plants by animals. In some cases, novel or unusual animal species are exposed to unfamiliar forages further contributing to potential poisonings. Plant poisonings will undoubtedly increase in wildlife populations also, as humans continue to encroach on their native ranges and interrupt their migratory pathways.

There are a few basic concepts that can help reduce risk of poisoning:

1. Understand and recognize the plants on your range or pastures and know the potential hazards of grazing where poisonous plants grow. Know the conditions under which poisoning may occur.
2. Do not introduce unfamiliar animals onto ranges where poisonous plants may present a hazard.
3. Avoid introducing animals to poisonous plant-infested ranges when adequate, good quality forage is not available.
4. Do not throw grass, shrub, or tree clippings into paddocks where animals reside (yew clippings are a common cause of poisoning in many animals).
5. Provide free access to fresh water and minerals/salt.
6. Do not overstock the range or pastures.
7. Avoid bedding, lambing/calving, watering, salting, or unloading hungry animals near poisonous plant populations.
8. Avoid excess stress to those animals showing clinical signs of poisoning and contact your veterinarian.
9. Control poisonous plants if economically feasible, either through hand grubbing, mechanical clipping or herbicide treatment.

# ACKNOWLEDGMENTS

The authors thank Ms. Terrie Wierenga for technical assistance in preparing this manuscript and Holly Broome Hyer for artistic representation of selected poisonous plants.

CHAPTER

# 67

# Cyanogenic plants

*Steven S. Nicholson*

## INTRODUCTION

Cyanide, hydrocyanic acid, hydrogen cyanide (HCN) and prussic acid are all terms relating to the same toxic principle. Cyanide is used as a fumigant and in chemical synthesis; 50–60 ppm in air, as in fumigants, may cause poisoning. Cyanide salts are used in metal cleaning, hardening, refining and in the recovery of gold from ores. Burning nitrogen-based polymers used in plastics, fabrics and seat covers releases HCN. Cyanide blocks molecular oxygen transfer in cytochrome oxidase systems in mitochondria causing tissue anoxia. The process is reversible. Various cyanogenic glycosides, which can hydrolyze to form HCN, are present in a number of plant species. These compounds probably developed as a defense against excessive grazing by herbivores. Only a few of these plants are a significant risk to livestock. Some are grasses cultivated as forage for livestock and horses and others are ornamentals, commercial fruit trees, shrubs, weeds and range plants. All animal species are susceptible to cyanide poisoning. The ability of rumen microbial flora to rapidly hydrolyze cyanogenic glycosides makes ruminants particularly at risk of cyanide intoxication from plant sources. A recent review of the risks and effects of cyanogenic plants in animals was published by Burrows and Tyrl (2001).

## BACKGROUND

In general, the location of cyanogenic glycoside in plants is the epidermis, with highest levels in seeds, leaves, bark and twigs, to lowest in fruit. Seeds of grain sorghum and other grasses do not contain these glycosides. Seeds of members of the Rosaceae family including apple, cherry, peach and apricot do contain cyanogenic glycosides. Laboratory test results of plant tissues for presence of cyanide are reported as cyanide potential since free cyanide is not present in plants but is generated from glycoside during testing.

HCN potential of cyanogenic plants ranges from a few parts per million to 8000 ppm dry weight from the glycoside dhurrin in foliage of a grain sorghum (Burrows and Tyrl, 2001). Similar levels may occur in *Sorghum halapense* (Johnsongrass), considered a weed but also utilized for grazing and hay. Related sorghum hybrids and Sudangrass forages were developed which have less cyanide potential but most could be a hazard under certain conditions. Nitrogen fertilization increases glycoside content. Cyanide potential in these forages is greatest during early growth. Concentrations of the glycoside prunasin in leaves of *Prunus virginiana* may be as high as 6% dry weight (Majak *et al.*, 1981). Within a growing season glycoside levels in plants are generally highest in early growth and decline as maturity approaches. Fluctuations in glycoside levels during a growing season occur associated with climatic changes such as periods of drought.

Physical damage to plant tissue (freezing, crushing, macerating, cutting and drying) allows plant enzyme $\beta$-glycosidase and hydroxynitrile lyase to come in contact with and hydrolyze the glycoside to hydroxynitrile and free, volatile HCN. The first step in this process yields a sugar and an aliphatic or aromatic $\alpha$-hydroxynitrile aglycone (cyanohydrin), then formation of an aldehyde or a ketone, e.g. benzaldehyde, and HCN (Conn, 1979). Generally, hay loses most of the HCN prior to feeding. In some situations toxic levels may remain in large bales of *Sorghum* spp. where the cut forage dries rapidly and is immediately

baled. Properly ensiled silage loses cyanide potential. Green chopping immature sorghum forage and feeding it the same day to ruminants is a serious potential hazard.

## PHARMACOKINETICS/ TOXICOKINETICS AND MECHANISM OF ACTION

Rumen microflora rapidly hydrolyze cyanogenic glycosides releasing HCN which is quickly absorbed and distributed to the tissues. Lower ruminal pH in cattle fed high-grain diets reduces the action of microbial enzymatic activity and release of HCN (Majak *et al*., 1990). Acid stomach contents in monogastrics limit hydrolysis and release of HCN. HCN is rapidly absorbed from the gastrointestinal tract, lungs and slowly through the skin.

Cyanide ion combines with ferric (trivalent) iron in the cytochrome oxidase system, blocking electron transport and molecular oxygen transfer from oxyhemoglobin to tissues. The effect is cellular hypoxia or histotoxic anoxia. This is a reversible action.

Arterial blood is normally bright red because of the presence of oxyhemoglobin. In cyanide toxicosis oxygen is not released from oxyhemoglobin to the tissues and the bright red color remains in venous blood. This process, from ingestion of a toxic dose of plant material, release of cyanide in the rumen and onset of clinical signs, can occur within a few minutes.

Some cyanide is detoxified by an endogenous thiosulfate limiting process. Thiosulfate combines with cyanide to form thiocyanate which is excreted in the urine. The reaction is catalyzed by the enzyme rhodanese. The ability to detoxify cyanide allows animals to safely metabolize small amounts of cyanide.

## TOXICITY

Ruminants are more likely to be poisoned by plant origin cyanide than other animals because rumen microorganisms readily release cyanide from the glycoside. An active microbial flora in the gut allows considerable but somewhat delayed and slower hydrolysis of cyanogenic glycosides in humans and hamsters, and lesser amounts in mice, rats, guinea pigs and monkeys (Stavric and Klassen, 1980; Adewusi and Oke, 1985; Frakes *et al*., 1986). Although uncommon there are reports of cyanide toxicosis in horses, pigs and dogs. Eating raw plant material containing $\beta$-glycosidase along with crushed apricot or apple seeds has proved fatal in humans. Generally speaking, monogastric animals including horses are poisoned by 1–3 mg/kg b.w. of preformed HCN or cyanide salts. The lethal dose of sodium cyanide, 3–4 mg/kg b.w. to ruminants (Burrows and Way, 1977), is quite similar to the lethal dose of cyanide from the glycoside prunasin in plant material, 5 mg/kg b.w. in cattle (Majak *et al*., 1990). Plant material containing more than 20 mg/100 g (200 ppm) cyanide potential is considered hazardous. A level of 500 ppm has been used more specifically for the sorghums (Burrows and Tyrl, 2001).

The effects are not cumulative. One-half the lethal dose can be given repeatedly during the course of a day such that a total dose of 4–5 times the single lethal dose can be tolerated (Burrows and Tyrl, 2001). Tolerance does not develop.

Death may occur within minutes after ingestion of a toxic amount of a plant containing high cyanide potential. An exception may occur if ruminants grazing arid rangelands ingest a toxic amount of chokecherry or arrow grass while rumen contents are quite dry, with release of HCN by rumen flora delayed until the animal drinks water later in the day. Affected animals may be found dead in or near the water source.

Ruminants may exhibit signs within minutes to less an hour after commencing ingestion of toxic plant material. Cattle may become apprehensive and excitable at the sight of herdmates that are suddenly affected and collapsing. Onset of clinical signs is peracute and includes apprehension, pronounced polypnea then dyspnea because initially there is stimulation of chemoreceptors in the carotid body and respiratory centers. The pupils dilate and mucous membranes may be pink and venous blood a bright cherry red. Weakness, voiding of urine, collapse, paddling and death follow within a few minutes. Sublethal cases may recover within the hour.

Lesions are few. Mucous membranes may be pink, venous blood bright red and clot slowly. Subendocardial and subepicardial petecchial and ecchymotic hemorrhages typical of an agonal death may be present. A bitter almond or "cherry coke" odor from stomach contents is detectable in some cases. Venous blood may not be bright red in animals dead several hours. At necropsy, blood of animals that died of some other cause may develop bright red color when exposed to the air for several minutes.

Differential diagnosis of cyanide toxicosis in ruminants may include acute toxicoses caused by nitrate–nitrites, urea–ammonia, ipomeanol, perilla ketone, 3-methylindole, bluegreen algae and electrical shock or lightning strike.

When cyanide toxicosis is suspected submit to the laboratory, along with the usual specimens, refrigerated heart or skeletal muscle and rumen contents for cyanide ion detection. In blood, concentrations of 1 ppm or more are consistent with severe intoxication in mammals and birds (Burrows and Tyr, 2001). Blood should be kept in air-tight containers at 4°C (Egekeze and Oehme, 1979). Continued hydrolysis of glycoside and loss of HCN may make necropsy samples less useful for confirming the diagnosis.

Specimens can be immersed in mercuric chloride to prevent hydrolysis from continuing. Rumen or stomach contents can be examined for presence of material from cyanogenic plants. A sensitive field test using alkaline picrate treated filter paper strips can be prepared (Burrows and Tyrl, 2001) for testing plant materials and fresh rumen contents.

Chronic cyanide poisoning (or a nitrile compound) may be involved in equine ataxia–urinary incontinence seen in horses, grazing sorghum hybrid pastures (Van Kampen, 1970; Wheeler and Mulcahy, 1989). There are reports of a similar condition in cattle and sheep (Bourke, 1995). After grazing forage sorghum and grain sorghum regrowth, 54 of 330 breeding cows became ataxic and developed urinary incontinence. Wallerian degeneration of the white matter of the spinal cord, cerebellar peduncles and cerebellum was seen histologically (McKenzie and McMicking, 1977). In humans, long-term consumption of the cyanide containing plants tropical lima beans and cassava root are associated with well-documented conditions involving the spinal cord, optic nerves and other lesions. A study of children in Mosambique evaluated the possible association of high cyanide and low sulfur intake in cassava-induced spastic paraparesis. The study results supported the hypothesis that the epidemic was due to the combined effects of high dietary cyanide exposure and sulfur deficiency (Cliff *et al.*, 1985). Teratogenic effects of cyanide were demonstrated in hamsters (Frakes *et al.*, 1986).

## TREATMENT

Rapid response to intravenous antidote solution can be striking although the opportunity to treat is rare because of the peracute nature of the poisoning. The antidote of choice in humans, dogs and probably most other animals is 10–20 mg/kg b.w. of sodium nitrate in combination with 250–500 mg/kg b.w. of sodium thiosulfate (Baskin *et al.*, 1992; Burrows and Tyrl, 2001). Ruminants can be treated with thiosulfate alone using a 30–40% solution intravenous at a dose of 25–50 g/100 kg b.w.

## CONCLUDING REMARKS AND FUTURE DIRECTION

Cyanide poisoning is an uncommon event in livestock production but the potential for sudden economic loss to individual farmers and ranchers is significant. Veterinarians, agricultural educators and consultants should continue to remind clientele of the risks to ruminant species associated with forages, shrubs and trees of known cyanide potential.

# Nitrate and nitrite accumulating plants

*Steven S. Nicholson*

## INTRODUCTION

Ruminants are particularly at risk of acute, fatal nitrate–nitrite poisoning. Microorganisms in the rumen reduce nitrates to nitrites then ammonia for microbial growth. Excess intake of nitrates may cause toxic levels of nitrite to accumulate and be absorbed into the blood. Cattle graze a variety of grasses and weeds which, under certain conditions, especially excessive fertilization, can accumulate levels of nitrate in the stems that may prove toxic to animals that eat a sufficient dose. Excess levels of nitrate may be present in grazed forages and weeds, in hay or fresh cut forage brought to the animals as greenchop. Ensiling may reduce nitrate levels by 30% or more. Sheep and rabbits can convert nitrate to toxic levels of nitrite. Goats browse leafy portions of plants and may not ingest toxic levels of nitrates in stalks and stems of forages. In horses some bacterial reduction of nitrate to nitrite does occur in the large bowel (Bruning-Fann and Kaneene, 1993). Nitrate toxicosis in horses is rarely reported as a clinical entity (Hintz and Thompson, 1998).

Monogastric species are susceptible to the toxic effects of nitrites ingested as nitrites from non plant sources. Nitrates and nitrites are water soluble and may contaminate water sources. Forages and weeds growing in soil rich in manure waste or in holding pens are a potential source of poisoning. Nitrate fertilizers are commonly found on farms and ranches and accidental ingestion or feed contamination does occasionally occur.

## BACKGROUND

Plants take up nitrogen from the soil primarily in the form of nitrate. Nitrate accumulation in the stems and leaves of plants may be associated with high levels of nitrates, or ammonia, in the soil. Plants growing in soil where livestock manure and urine were applied as fertilizer or where accumulations occur in holding pens may accumulate nitrates. Hungry cattle and sheep introduced to stockyards containing a dominant or pure growth of button grass (*Dactyloctenium radulans*) suffered acute nitrate–nitrite toxicity in four incidents in inland Queensland between 1993 and 2001 (McKenzie *et al.*, 2004). The nitrate content of the button grass from within the stockyards ranged from 4.0% to 12.9% as $KNO_3$ in dry matter and from outside the stockyards ranged from <0.2% to 0.4%. After harvesting corn in Nebraska cornstalks remaining in fields had an average decrease in potassium nitrate content of only 30% in 90 days (Johnson *et al.*, 1992). Young plants are more likely to have high nitrate levels than are more mature plants. Nitrate concentrations decline considerably in all parts of Sudangrasses following heading (Mizukami *et al.*, 1997).

Plant growth may be slowed, and nitrate accumulation increased, when growing in soil that contains nutrient deficiencies or excesses. For example, molybdenum is a component in enzymatic reactions of nitrate reductase in plants. Nitrate accumulation in stalks and stems may follow herbicide damage to plants or loss of leaves due to hail.

A major reason plants accumulate nitrates is drought. During periods of drought the growth of forages and weeds is reduced but the roots may continue to collect and store nitrate in the stems. This is particularly true of well-fertilized sorghum hybrid (*Sorghum* spp.) and millet (*Pennisetum* spp.) forages grown for temporary summer grazing and for hay production (Clay *et al.*, 1976). Plants may accumulate nitrates during periods of reduced sunlight. Sunlight is needed to drive photosynthesis and the energy-dependent nitrate reductase system in the plant. Forage or weeds growing in the shade of trees in an orchard may be subject to nitrate accumulation. Nitrate poisoning is occasionally a problem in areas of the United States where

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

winter grazing for cattle consists of fertilized pastures of ryegrass (*Lolium multiflorum*), oats (*Avena* spp.), turnips (*Brassica rapa*) or wheat (*Triticum* spp.). During extended periods, perhaps several days, of overcast weather the nitrate content of the forage may increase to potentially toxic levels. Accumulation is more likely when temperatures are mild (>55°F) and the root systems are actively taking up nitrates. Growth slows or stops but the roots continue uptake of nitrate which is stored in the stems until there is adequate sunlight and growth resumes. Generally, a day or two of sunlight with temperatures above 55°F allows plant growth to continue, converting excess stored nitrate to plant protein.

To reduce trampling of forage farm management may employ limited grazing periods allowing hungry cattle to consume a large amount of green forage for 2 h or so each day. This increases the risk because of the time–dose relationship that exists when excess nitrate is present and conversion of nitrate to nitrite exceeds the ability of the rumen flora to convert nitrite to ammonia. Total dietary intake of nitrate should be considered. Supplemental feeding of hay that has increased nitrate levels to cattle grazing forages with elevated nitrate levels increases the risk of toxicosis in this situation. Nitrate in drinking water adds to dietary intake. Nitrate concentrations in water in excess of 1000 ppm may cause nitrate poisoning in livestock.

Nitrate levels are not reduced by drying and baling as hay. High nitrate hay (>1.5% $KNO_3$; 1.0% nitrate) fed to cattle months after baling can cause multiple deaths and possibly abortions. Mortality can be striking as in a case in Nebraska where *Amaranthus*/*Kochia* hay with 4.9% $KNO_3$ and Sudangrass with 8% $KNO_3$ were fed to 390 cattle resulting in death of 226 and 42 abortions (Hibbs *et al.*, 1978). High nitrate summer hay fed during the winter of 1977–1978 killed cattle in Oklahoma (Haliburton and Edwards, 1978).

Determining the nitrate status of bales of stored hay can be a challenge because only the forage growing in a portion of a hay field may have been affected. Bales must be labeled, sampled and tested for nitrate content. Obtaining a representative sample requires using a hollow hand-held commercial tool which cuts through to the center of the bale and recovers a core sample of an ounce or so of hay. At least two samples from each bale should be collected. Investigation might reveal that one-third of the bales have nitrate levels, say <0.5%, a third perhaps 0.5–1.0%, and the remaining portion >1%.

Rumen microorganisms can adapt to and utilize increasing levels of nitrate in the diet. The period of maximum acclimation occurs within 6 days (Allison and Reddy, 1984). Adaptation can be lost within a few days. The ability of rumen microorganisms to safely reduce nitrate and nitrite can be increased by feeding corn-based supplements to cattle (Burrows *et al.*, 1987). Nitrate content in properly ensiled forage may be reduced by 30% or more during the ensilage process. The silage should be tested before feeding. Silage juices draining from the silo may be high in nitrates. Nitrogen dioxide ($NO_2$) and nitrogen tetroxide ($NO_4$) gases may be formed from oxides of nitrogen generated during anaerobic fermentation of high nitrate forages. These pulmonary toxicants are heavy yellow–brown gases.

## PHARMACOKINETICS/ TOXICOKINETICS

Action of the rumen flora reduces nitrate to the much more toxic nitrite which normally is converted to ammonia and further utilized by the microorganisms. Nitrite is absorbed into the blood when the intake of nitrates and the production of nitrite exceed the capacity of the rumen flora to further reduce nitrite. In some cases preformed nitrite in hay may shorten the period from ingestion to onset of signs. Nitrates are absorbed into the blood as well but are much less toxic than nitrite. In adult cattle the half-life of nitrate is estimated to be 9 h and in the bovine fetus more than 24 h (Johnson *et al.*, 1992). The half-lives of nitrate and nitrite in the blood of sheep are 4.2 and 0.5 h (Schneider and Yeary, 1975).

## MECHANISM OF ACTION

The nitrite anion causes vasodilation and oxidizes ferrous iron in hemoglobin to the ferric (trivalent) state forming methemoglobin which cannot accept molecular oxygen. As the percentage of methemoglobinemia rises oxygen starvation to tissues increases and blood becomes chocolate brown in color. In sheep the half-life of methemoglobinemia is about 1.5 h (Schneider and Yeary, 1975). Clinical signs such as exercise intolerance appear at 30–40% methemoglobinemia with death from hypoxia likely when concentrations exceed 80% (Burrows, 1980). In non-fatal cases a red blood cell intrinsic NADH-dependent diaphorase or reductase system gradually reduces methemoglobin to hemoglobin.

## TOXICITY

Nitrate level in edible stalks and stems of plants generally accepted as safe for all classes of cattle is <0.5%. It is recommended that pregnant animals not be fed forage or hay with nitrate content between 0.2% and 1.0% nitrate levels. Forage nitrate above 1% (1.5% $KNO_3$) is considered dangerous. The rate of conversion of nitrate to nitrite then

to ammonia is a limiting factor in safe utilization of nitrates by ruminants. Hungry cattle are at greater risk and intake of dry matter from hay may be faster than from grazing. The additive effect of nitrates in water and other feed sources must be considered when evaluating total dietary nitrate.

The rumen flora can safely utilize higher amounts of nitrate if sufficient dietary energy is present to promote reductive activity. Feeding corn-based supplements to cattle reduced nitrite accumulation (Burrows *et al.*, 1987). In this study feeding of 3.2 kg of corn protected against nitrate poisoning by reducing intraruminal nitrite and blood methemoglobin ($p > 0.05$).

Clinical signs of nitrate–nitrite toxicosis in cattle include weakness, cyanosis of mucous membranes, ataxia, collapse and death. Increased respiratory rate may be noted in some animals. Affected animals may remain standing then collapse and die within minutes. Dead animals may be found in sternal recumbancy or lying on their side. Blood is dark and may have an obvious brown color when drawn into a syringe or spread on a white cloth. At necropsy of animals dead several hours this color may not be as apparent.

In cattle abortions may occur in the herd 3–7 days after the acute toxicosis episode. Less oxygen is available to the fetus because of methemoglobinemia in the cow and nitrite induces methemoglobinemia in fetal blood (Bruning-Fann and Kaneene, 1993). Bovine abortion has been reported to occur with forages containing 0.61–1% nitrate (van't Klooster *et al.*, 1990). Differential diagnoses to consider include acute toxicoses caused by insecticides, carbohydrate overload, hypomagnesemia in lactating cattle, cyanide, bluegreen algae, urea (ammonia) and potent oxidizing agents such as sodium chlorate herbicide and aniline dyes. Lesions are not diagnostic. Blood and tissues may appear brown at time of death but this becomes less obvious as autolysis proceeds. Dark blood may suggest septicemia. Agonal hemorrhages in the epicardium may be present.

Ocular fluid is an excellent body fluid for nitrate analysis. Plasma and serum are acceptable. Ocular fluid nitrate levels are 35% lower than serum levels (Boermans, 1990). The diphenylamine blue test is widely used for testing fluids and plant tissues (Burrows, 1980; Bhikane and Singh, 1990). Another test that has been used is the diazotization test (Bhikane and Singh, 1991). Nitrate concentrations in ocular fluid of 10 ppm are indicative of excessive nitrate exposure and $> 20$ ppm are considered positive diagnosis of poisoning (Burrows and Tyrl, 2001). In abortion and stillbirth situations interpreting bovine fetal ocular fluid nitrate levels is more problematic because normal levels may approach 20 ppm in weak or stillborn calves (Johnson *et al.*, 1994). Level of 30 ppm or more and additional diagnostic information such as elevated forage nitrates may be needed to confirm nitrate-induced abortion (Casteel and Evans, 2004). The clinical history may suggest nitrates as a possible cause. All sources of forages, weeds, water, feed supplements and fertilizers to which the animals had access should be determined and sampled for analysis.

## TREATMENT

Treatment is with intravenous methylene blue in a 1% or 2% aqueous solution at a rate of 1–2 mg/kg b.w (Bhikane *et al.*, 1990). Up to 10 mg/kg b.w. can be administered in severe cases. The response to intravenous treatment of a 2% solution of methylene blue at a dosage of 20 ml/100 kg b.w. is rapid with reversal of the clinical signs within several minutes (Burrows and Tyrl, 2001). In severe cases treatment at a lower dose can be repeated. Methylene blue serves as an electron carrier for an NADPH-dependent system to reduce methemoglobin to hemoglobin. Methylene blue is most effective in humans and ruminants (Burrows and Tyrl, 2001). Tissues in the treated animals are stained and the urine becomes dark green. Treated animals should not be sold for slaughter for 180 days. Other dyes such as tolonium chloride (tolonium blue) are effective in reducing methemoglobin to hemoglobin but have a narrow therapeutic index (Gupta *et al.*, 1992; Cudd *et al.*, 1996).

## CONCLUDING REMARKS

Safe use and storage of nitrate fertilizers is essential if accidental poisoning of livestock, especially cattle, is to be avoided. Use of liquid fertilizer tanks to deliver water to livestock is a documented hazard for nitrate or urea toxicosis. The potential for nitrate accumulation in weeds and forages intended for feeding or grazing and the risks this poses to ruminants, especially cattle, should be pointed out to farmers and ranchers by university extension and farm industry personnel. Cutter blades can be raised to reduce the amount of edible stalk in harvested forages if conditions warrant. Pre-feeding testing of potentially high nitrate forages is especially important when environmental conditions affect growth. Feeding cattle an energy source like corn or providing oral product containing *Proprionibacterium* can increase the rate of nitrite reduction by rumen flora.

# Oxalates-containing plants

*Theuns W. Naudé and V. Naidoo*

## TREATMENT

Oxalates are of importance in veterinary toxicology for two reasons.

The first and most important reason is that absorbed *soluble oxalates* cause serious primary nephropathy and kidney shut down by severely damaging the renal tubular epithelium. They form insoluble complexes with calcium and magnesium and cause hypocalcaemia and hypomagnesaemia and form crystalline deposits in especially the kidneys. They also contribute to the formation of urinary calculi.

The second reason is that highly irritating *insoluble calcium oxalate raphides* form in certain plants as protection against herbivory and may cause alarming signs if the plants are eaten, or in the case of those with a "nettle action", touched.

These two syndromes are discussed in this chapter separately.

## PART I: SOLUBLE OXALATE POISONING

## BACKGROUND

Oxalates (Figure 69.1) occur in many plants and formation is via the glyoxylate cycle or from ascorbic acid (*vide infra*). The toxic levels of soluble oxalates in plants are given as 0.5% for *Osteodystrophia fibrosa* in the horse and 10% for nephropathy (Cheeke, 1998). The latter level is supported by other authors (Seawright, 1989 cited by Kellerman *et al.*, 2005).

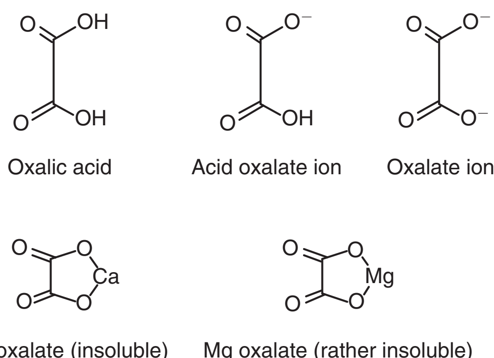

**FIGURE 69.1** Oxalic acid and its salt.

The families and genera which are of toxicological significance differ from country to country but any plant high in oxalates eaten by animals in quantity could potentially be toxic. What appears to be the generally important families and genera involved are listed in Table 69.1.

In addition to plants, a variety of saprophytic fungi may produce oxalates and render hay toxic even without any obvious moldy appearance (Wilson and Wilson, 1961; Cheeke, 1995).

All species, including man, are susceptible to intoxication but it is generally sheep and cattle that succumb from nephropathy and horses that develop *osteodystrophia fibrosa.*

In all cases of soluble oxalate toxicity unadapted animals (*vide infra*) have to be rather abruptly exposed to large quantities of oxalate-containing plants these often being the only, or largely, the plants eaten. It is often a problem in low rainfall areas that some of these are the dominant plants that animals have to browse. During feed shortage the cut-up leaves of agave and cathodes of prickly pear (*Opuntia ficus indica*), particularly the thornless variety,

**TABLE 69.1 Significant plants involved in oxalate poisoning**

| Family | Genus | Common name |
|---|---|---|
| Agavaceae | *Agave* | Agave |
| Amaranthaceae | *Amaranthus* | Pigweed |
| Araceae* | For example *Dieffenbachia** | Dumb cane* |
| Cactaceae | *Opuntia* | Prickly pear |
| Chenopodiaceae | *Beta* | Beetroot, mangold, sugar beet |
| | *Bassia* | Bassia |
| | *Chenopodium* | White goosefoot |
| | *Spinacia* | Spinach |
| | *Halogeton* | Halogeton |
| | *Sarcobatus* | Greasewood |
| Euphorbiaceae* | *Tragia** | Noseburn* |
| Mesebryanthemaceae | *Mesembryanthemum* | Mesems |
| Oxalidaceaea | *Oxalis* | Sorrel |
| Poaceae | *Cenchrus* | Blue buffelgrass |
| | *Setaria* | Bristlegrass |
| | *Digitaria* | Pangolagrass |
| | *Pennisetum* | Kikuyu |
| Polygonaceae | *Rumex* | Sorrel, dock |
| | *Rheum* | Rhubarb |
| Fungi | Especially *Aspergillus* and *Pennicillium* (also *Botrytis, Rhizopus, Pithomyces, and Mucor*) | Moldy hay and silage |

*Insoluble raphides.

two species specially cultivated for this purpose, are fed to stock and in excessive quantities, may result in oxalate toxicosis.

## STRUCTURAL FORMULAE

Those of the acid and its two salts and of insoluble calcium and magnesium oxalate are given in Figure 69.1. Note that in the plants having oxalic acid and the acid oxalate ion occur if the plant sap has a pH of *ca.* 2 (e.g. *Oxalis* and *Rumex*), whereas if the plant sap's pH is *ca.* 6 the oxalate ion is found (e.g. *Halogeton* and *Mesembryanthemum*). With acid oxalate both acute and chronic toxicity occur but with oxalate only acute toxicity (Cheeke, 1998).

## BIOSYNTHESIS OF OXALATES IN PLANTS

This complex synthesis is summarized by Franceschi and Nakata (2005). Oxalic acid can be formed through the oxidation of glycolate and glyoxylate by the activity of glycolate oxidase or by the activity of isocitrate lyase on isocitrate. By C2/C3 cleavage, ascorbate is also a substrate for synthesis (Libert and Franceschi, 1987).

## TOXICOKINETICS

At present the toxicokinetics of oxalates have only been studied in any detail in people. Since the oral bioavailability of chemicals in people may be used as a model for monogastric physiology, the toxicokinetics of oxalates may be applicable to the veterinary situation for all non-ruminants. The bioavailability of oxalates in people is dependent on the person, oxalate content in the plant and most likely the method of cooking. Depending on the plant, studies have shown the bioavailability from grilled spinach is $0.75 \pm 0.48\%$ and for *Oxalis tuberosa*, $1.44 \pm 1.31\%$ after the first 6 h of ingestion (Albihn and Savage, 2001; Brogren and Savage, 2003). Furthermore they are absorbed from the gastric mucosa.

The reason for preferential gastric absorption is linked to the specific conditions required for the reaction of calcium with oxalic acid. For the insoluble calcium oxalate to form, an alkaline environment in required. Therefore the acidic environment favors the absorption of oxalic acid before the formation of the insoluble salts as in ruminants (Zhiqiang *et al.*, 2003).

In the normal healthy rumen, a portion of the oxalic acid and soluble oxalates can combine with calcium and become insoluble thereby reducing the chance of toxicity, the pH of *ca.* 5–7 of the rumen appears to favor the formation of Ca oxalate. This is in contrast to non-ruminants with a gastric pH of 1–2 (Phillis, 1976).

Ruminants have, however, developed an additional protective mechanism via a variety their rumen microorganisms. If the rumen is adapted by gradual exposure to oxalic acid and oxalates, these microorganisms (such as *Oxalobacter formigenes*) can use oxalic acid as an energy source and produce the by-products carbon dioxide and formate. It is only when the microbes are unable to break down oxalic acid that toxicity results (Rekhis, 1994).

In studies using guinea pigs previously adapted to a diet high in oxalates (2%), as a model for hindgut fermenters, it has been shown that the caecal bacteria played an important role in adaptation. This adaptation could be negated by treating animals with gut active antibiotics and certain secondary bile salts associated with ileal diseases (Argenzio *et al.*, 1988).

With ruminants being able to adapt to a higher concentration of oxalates in their diets, it has been questioned why a similar degree of protection fails to occur in horses. By combining the predominant gastric absorption of the soluble oxalates and the level of adaptation in hindgut fermenters, it may be concluded that if tolerance did develop

it would occur too low down the gastrointestinal tract (GIT) to allow for sufficient protection from absorption.

In humans oxalates are eliminated mainly by urinary excretion. Excretion is biphasic and peaked at 40 min and 3 h after the consumption of a warmed, commercially bought frozen spinach meal in normal healthy patient. The initial peak was however absent in patients that had undergone gastrotomy due to cancer. This once again indicated the importance of the stomach in initial absorption, i.e. the first major peak. The second peak would as such be related to delayed absorption from the intestines. When comparing oral bioavailability between the two groups, it was seen that area under the curve (AUC) was 50% greater in the patients with a functional stomach. At the 3.5 h post-feeding period these patients still had a greater extent of absorption with a difference of 20%. The excretion of oxalates was determined to be 0.0732 ± 0.0294 mg/min (Zhiqiang *et al.*, 2003).

# MECHANISM OF TOXICITY

There are four ways in which soluble oxalate-containing plants may cause toxicity or have adverse effects.

## Cellular toxicity

The organ systems most commonly affected are the kidneys, GIT and neural tissue and generally it was assumed that it resulted from the precipitation of calcium oxalate crystals in these specific organs (Andrews, 1971). Van Kampen and James (1969), however, in an experiment with sheep poisoned with a lethal dose of *Halogeton* (containing mainly the oxalate ion) and slaughtered sequentially every 2 h up to 8 h, that Ca oxalate crystal deposition is secondary to vascular and renal cellular damage. Their postulation is that a deficiency in intracellular Ca and Mg (due to its removal as insoluble oxalates, *vide infra*) results in inactivation of vitally essential Ca- and Mg-dependent enzymes and consequent cell damage. In a review in 1972, James summarizes literature that oxalate competitively inhibits oxidation of lactate and non-competitively interferes with pyruvate reduction. This is further supported by Absan (1997) who states that *ca.* half the Mg in the body is intracellular and that it is an essential co-factor to catalyze some 300 enzymatic reactions, particularly those involving ATP production.

The exact cellular pathophysiology for cellular toxicity, hereafter, has not been further elucidated despite the importance of ethylene glycol toxicity in people and dogs. At present the pathophysiology of nephrotoxicity is believed to be related to the following mechanism.

Once the absorbed, soluble oxalate is freely available to filter out through the glomerulus, where in the tubuli it binds to calcium to precipitate out as crystals on the damaged cells. Although the physical injury to the tubules may account for the nephrotoxicity, it at this stage believed unlikely to be the only mechanism, as the rapid transit time of 3–4 min in the tubules hardly seems long enough for the crystals to grow, in sufficient size to block tubules (Corley *et al.*, 2005; Jonassen *et al.*, 2005). James *et al.* (1971), however, pointed out that the original site where the crystals actually form is in the filtered fluid in the lumens of the tubules and not necessarily those associated with the oxalate-damaged cells. These crystals may, however, grow to such sizes that secondary mechanical damage is caused.

Apart from the kidney, high oxalate levels also occur in the blood vessels of the rumen and here extensive deposition of crystals in the walls of small arteries of the submucosa with thrombosis results in severe diphtheritic inflammation and invasion with secondary microorganisms. The vasculature damage, again, precedes the crystal deposition (Van Kampen and James, 1969).

In tissue culture, it has been shown that certain chemical changes occur in the renal tubular cells once exposed to the oxalates. One of these is to produce phosphatidylserine which would normally recruit macrophages to remove damaged cells. However, in cases of toxicity, the latter appears to promote the attachment of oxalates to the cell membrane. Other changes induced in the cell, include the activation of phospholipase $A_2$ that eventually lead to the release of bioactive lipids that alter mitochondrial function, activate caspases and result in apoptosis (Kohjimoto *et al.*, 1999; Cao *et al.*, 2004; Jonassen *et al.*, 2005).

A third pathway may also be present as calcium oxalate induces lipid peroxidation in both renal cell cultures and rodents (Maroni *et al.*, 2005). The latter was deduced from an increase in malondialdehyde (Malini *et al.*, 2000; Thamilselvan *et al.*, 2003) and changes in the redox index (Farooq *et al.*, 2006) following the exposure of the renal tubules to oxalates. It has been deduced that the compromised cells, undergo apoptosis or necrosis as a result and subsequently slough off into the mucosa to form the nidus over which further crystals may precipitate (Jonassen *et al.*, 2005).

# INFLUENCE ON SERUM ELECTROLYTES

## Hypocalcaemia

This occurs in all species exposed to intake of plants containing high soluble oxalates. With oxalic acid and acid oxalate ion (Figure 69.1) poisoning, it is responsive to

treatment with calcium borogluconate but with oxalate ions not (James, 1972a; Cheeke, 1998). The soluble oxalates, including oxalic acid, are free to enter into the circulation and combine with calcium to result in hypocalcaemia similar to that seen with eclampsia in the bitch (Rekhis, 1994). In a review article, James (1972b), points out that it is unlikely that hypocalcaemia is the principal cause of death as there is proof that hypocalcaemia due to EDTA infusion or dialysis, does not result in mortality.

In foals the exposure to *Rumex* spp. resulted in signs of hypocalcaemia (Laan *et al.*, 2000). In people and animals the exposure to oxalates has been associated with muscle paralysis which may be related to the decrease in serum calcium (Benitez *et al.*, 1991).

In addition, hypocalcaemia may also result in a decreased blood-clotting time, as calcium is vitally important in the blood-clotting cascade (Steyn, 1934; Kingsbury, 1964).

## Hypomagnesaemia

Wilson and Wilson (1961) suggest that oxalates from a series of oxalate-producing fungi (Table 69.1) in spoiled hay, may produce frank hypomagnesaemia ("grass tetany") in cattle. An alarming fact is that such hay may not even appear obviously moldy. This is certainly an aspect to consider.

Hypomagnesaemia would imply low intracellular Mg too (*vide supra*).

## Nutrient deficiency

Nutrient deficiencies ascribed to oxalates have long been known in people (von Unruh *et al.*, 2004). This occurs from the ability of the oxalates to bind to various minerals such as calcium, iron and magnesium. By binding to these minerals in the plants, their bioavailability is decreased (Quinteros *et al.*, 2003). James *et al*. (1968) found that low levels of *Halogeton glomeratus* had a deleterious influence on nutrient balance in sheep. Additionally oxalates can also decrease the absorption of calcium from other dietary sources such as milk. In one study in ponies fed on a diet rich in oxalate it was shown that calcium absorption is decreased in animals as well. This increase in calcium excretion occurs only from dietary sources. For this trial the radio-tagged $Ca^{2+}$ circulating in the blood, following intravenous (IV) administration, did not end up in the faeces and was excreted by the kidneys. It was also noted that magnesium reten-tion by the animals was decreased while overall the plasma calcium and phosphorous levels were unchanged (Swartzman et al., 1978). With long-term exposure to plants with oxalates (such as various grasses, *vide* Table 69.1) horses will mobilize large amounts of calcium from the bony appetite and this will eventually precipitate O*steodystrophia fibrosa* (*vide infra*) (Walthall and McKenzie, 1976).

## Kidney and bladder stones

Together with silicates, calcium oxalate plays a major role in the formation of kidney and bladder stones of livestock, 75% of such stones consisting of calcium oxalate (Libert and Franceschi, 1987; Chai and Liebman, 2005).

# TOXICITY SYNDROMES

Two *acute syndromes* occur: death in 8–12 h due to *oxalate ion* poisoning (as in *Halogeton* intoxication) or death due to, arguably, *hypocalcaemia* in *acid oxalate* and *oxalic acid* poisoning (as in *Oxalis* and *Rumex* intoxication).

Subacute to chronic poisoning occurs only with the latter.

## Oxalate ion toxicity

Distinction between the two ion-dependent syndromes is not always specified in the literature as the specific ion involved and the pH of the plant sap are not specified, for example that of *Halogeton* in the Chenopodiaceae is specified but that of beet and white goosefoot (of the same family *vide* Table 69.1) is not. The position in, or example, Amaranthaceae, Agavaceae and Cactaceae (Table 69.1) is not known.

In the case of *Mesembryanthemum nodiflorum* of Western Australia the pH of the plant sap is also 6, and the active ion there would thus be oxalate. The same acute syndrome as with *Halogeton* is experienced and poisoning with *Mesembryanthemum crystallinum* in Australia (J.G. Allen, Perth, personal communication, 2006).

In South Africa mesems of the Aizoaceae are widely distributed in our western, semi-desert areas and although they are known to contain toxic quantities of oxalates (Steyn, 1934) they are so widely occurring that stock (especially sheep and goats) just consume it in small quantities as part of their daily diet and frank toxicity like in Western Australia is not seen (D.J. Schneider, S.A. Stellenbosch, personal communication, 2006).

*Setaria sphacelata*, with an acidic sap, on the contrary, is believed to contain ammonium oxalate (Douglas and Birch, 1967, cited by James *et al.*, 1971). In Australia it causes the typical acute syndrome in sheep due to the oxalate ion (James *et al.*, 1971).

According to Burrows and Tyrl (2001) the Chenopodiaceae contain both the oxalate and the acid oxalate ions as toxic principles and they point out that there are

subtle differences in the syndromes caused by *Halogeton glomeratus* and other soluble oxalate-containing plants.

### Sheep

Under circumstances where sheep have grazed *Halogeton* extensively, up to 1200 have been poisoned at a time and under many conditions 100–800 sheep have died (James, 1972a). *Halogeton*, as summarized by Burrows and Tyrl (2001), affects mainly sheep and to a lesser extent cattle. They summarize the literature with the following: ". . . sheep within a few hours (exhibit) dullness, head held low, anorexia, white froth from mouth; shortly, weakness, stiffness (and) rapid respiration sets in (as well as) ataxia (animals becoming) comatose with extensive jerky extensor rigidity".

### Cattle

Burrows and Tyrl (2001) describe that the clinical signs in cattle are similar to those of sheep but more subacute: incoordination, apprehension, belligerence, excess salivation, recumbency, coma, bloat, cyanosis and death. Subacute locomotor disturbances are mainly evident when animals are forced to move and start with the forelimbs. In calves, however, more severe signs of hypersensitivity to stimulation and seizures are possible.

These signs are typically associated with hypocalcaemia (as low as 1.4 mg/dl) during which time blood magnesium and phosphorus may double.

In one incident in South Africa cited in Kellerman *et al.* (2005) 4 out of 40 nursing beef cows developed acute flaccid paralysis 24 h after introduction to a harvested wheat land heavily infested with the chenopodiaeceous *Chenopodium album* (white goosefoot). The paralysis was so marked that the investigating veterinarian (E. Albertyn, S.A. Winburg, personal communication, 2006) suspected botulism and sent the owner to Onderstepoort for antitoxin. Fortunately, he also sent the heavily grazed weed with. After identification and advice to use calcium borogluconate IV, he used MFC ("Merial", calcium borogluconate: magnesium hypophosphite (20%:4%) (Swan, 2005/2006) to which he had added 15 g $MgSO_4$/500 ml IV (a practice he had been using for years with recalcitrant "milk fever" with total recovery). Despite the warning that the four cows should preferably be slaughtered as eventual kidney lesions were still a probability, he specifically kept track of the four animals and informs that they had experienced total recover. The plant contained 16% oxalate (total) on dry matter basis.

According to Shupe and James (1967) *Halogeton* is a highly toxic to sheep and produces an acute syndrome where animals die within 8–12 h of exposure, rarely any longer and no chronic syndrome is seen. The clinical signs are dullness, lowered heads, anorexia and ruminal stasis, blood-tinged frothing from the mouth, weakness, stiffness, polypnea, ataxia with jerky extensor rigidity and coma and death with sheep lying dead where they had grazed.

At necropsy marked edema and hemorrhages are encountered in the rumen which is caused by severe rumenitis with vascular damage. Kidneys are pale edematous and enlarged and histopathology reveals hyalinization of the glomeruli and marked tubular dilation. Calcium oxalate crystals are encountered in both the ruminal wall around the damaged vasculature as well as in the kidneys.

Van Kampen and James (1969) determined the pathogenesis by dosing a group of 12 sheep with a known lethal dose of *Halogeton*, sacrificing two animals every 2 h and studying the sequential development of the lesion in relation to the deposition of calcium (and magnesium oxalate?) crystals. It is clear that the deposition of crystals is secondary to cellular damage and not *vice versa*, although secondary mechanical damage also occurs. Some sheep died peracutely with insignificant morphologic kidney lesions and even in sheep with severe kidney damage, death occurred too rapidly to be attributed to renal dysfunction. They state that sheep with a bilateral nephrectomy live longer than those with acute oxalate intoxication.

They maintain that in *Halogeton* poisoning the serum calcium is within the range where tetany should occur but it does not. Signs preceding death are in fact extreme weakness and flaccidity of all skeletal muscles. Calcium borogluconate is the standard treatment for most oxalate plant intoxications but in *Halogeton* in sheep it may delay death but not necessarily result in survival. Van Kampen and James (1969) postulate that intracellular inactivation of Ca- and Mg-dependent enzyme systems may be significant in causing death (*vide supra*).

An interesting, aberrant syndrome is reported by James (1972a, b) with *Bassia actinophylla* of the Chenopodiaceae where on an oxalate basis the lethal dose for sheep is about one-half of that of *Halogeton*. The signs resembled those of *Halogeton* but there was a greater tendency to develop tetany and incoordination and less than half the lethal amount fed per day resulted in a cumulative effect and mortality. Compared to *Halogeton* this plant was higher in potassium and lower in sodium suggesting a difference due to cations.

The effect of acutely toxic doses of the different cations of oxalate fed daily by rumen fistula to unadapted sheep was reported by James (1972a, b). In a preliminary experiment prior to testing the adaptation of sheep to *Halogeton* he stated that sodium oxalate at *ca.* 25–45 g oxalic acid equivalent on the first day and 40–74 g on the last day, killed three sheeps in 3–6 days after they had been off feed all the time. Diarrhea and severe edema and hyperemia of the rumen wall were evident. Two sheep dosed with potassium oxalate at *ca.* 25 and 42 g on the first day and 56 and 67 g oxalic acid equivalent on the last day took

6 days to die and they were only slightly off feed for the last 3 days. There was less diarrhea and the effect on the rumen wall was less severe.

Magnesium oxalate, on the contrary, at 70.6 g oxalic acid equivalent dosed to one sheep for 1 day caused only diarrhea.

If the oxalate ion is in fact the toxic substance, these differences in cations are difficult to explain.

## Oxalic acid and acid oxalates

The nephrotoxic syndrome occurring here is basically the same as with predominantly the oxalate ion (*vide supra*) but seems to be delayed: it develops slower, is subacute with mortalities and signs more typically a day or more after exposure. Chronic toxicity also occurs.

### Species-specific toxicity

#### *Sheep*

According to Panciera *et al.* (1990), acute exposure to *Rumex crispus* may result through calcium deficiency in sudden death or in animals showing severe clinical signs such as depression, salivation, coarse head tremors and stilted, ataxic gait and recumbency. When excited some animals become severely ataxic, fall and struggled to arise. Generally, clinical signs observed in sheep are polypnea, dyspnea, anorexia, dullness and depression and sometimes muscle fasciculation, tremor, loss of coordination, teeth grinding, pulmonary edema, tetany, seizures, recumbency, prostration and death (Panciera *et al.*, 1990). In animals affected with the more chronic form of the disease may show signs of azotemia and hypocalcaemia on clinical pathology.

Littledike *et al.* (1976) describe virtually the same changes in acute *Halogeton* poisoning of sheep.

On necropsy animals show acute renal tubular necrosis. The kidneys are pale swollen and moist. On histopathology the predominant lesion is nephrosis and is characterized by the widespread dilation of the convoluted and collecting tubules in the cortex. Although necrosis of the tubular epithelium is rarely seen, the tubular epithelium is generally flat and appears degenerate, particularly where the crystals impact the tubular walls. Birefringent crystals are also observed in the mucosa of the abomasums (Panciera *et al.*, 1990).

Chronic toxicity has also been reported to occur in sheep. Animals demonstrated clinical signs over 2–12 months, the principal clinical signs being anemia and loss of condition and appetite. On postmortem the kidneys were half the normal size and weight and were pale and mottled. In animals that were anemic, the hearts were enlarged (McIntosh, 1972).

#### *Cattle*

In cattle clinical sings reported included catarrhal abomasitis, enteritis, pale edematous kidneys and congested lungs (Dickie *et al.*, 1978). According to Walthall and McKenzie (1976), affected cattle on oxalate-containing pasture grasses (probably ammonium oxalate), much like sheep, tend to show signs of depression, anorexia and diarrhea. On pathology the kidneys are pale and firm. On cut surface the renal medulla is thin and the calyces dilated (confirmed histopathologically). Cortical and medullary tubules distended with crystalline casts. The crystals were typical in appearance of birefringence under polarized light. The crystals were specifically stained with Pizzolato's technique (peroxide–silver staining) with which they appeared brown to black.

Although the origin of the oxalates was not known, Gopal *et al.* (1978) were of the opinion that it may also play a role in abortions and possibly teratogenicity. In one random survey on pre- and perinatal mortalities of cattle, 56 of 142 dead calves had oxalate crystals on kidney sections. Although the presence of the crystals might have been incidental, the occurrence was higher in the calves showing a variety of congenital disorders. The fetal presence of crystals was believed to originate from the cow and therefore suggested that oxalate can cross the placenta. It was also believed that exposure to higher concentrations may have caused the teratogenicity seen in some of the calves.

In their sequential sacrificing experiments (*vide supra*) Shupe and James (1967), however, found no crystalline deposits in the tissues of fetuses of ewes that had been pregnant during exposure to *Halogeton*.

#### *Congenital primary hyperoxaluria in Beefmasters*

It needs to be mentioned that the presence of oxalate crystals in cattle may not be due to oxalates from plants only. Rhyan *et al.* (1992) describes this condition in the above breed in the United States in the absence of oxalates of plant origin. The general term is used for an inherited metabolic disorder that results in early death by renal failure due to a recessive inherited metabolic disorder.

#### *Horses*

Both acute and chronic toxicity can occur in horses. For experimental acute toxicity to occur, animals need to be exposed to a high dose of 454 g of either Na-, K- or ammonium oxalate. This toxicity is characterized by hypocalcaemia and will result in muscle rigidity and a stiff gait (Laan *et al.*, 2000). Non-fatal toxicity occurs when animals are exposed to 200 g of oxalic acid/day for 8 days (Andrews, 1971).

Chronic poisoning, following 2–8 months of exposure, to oxalate-containing grasses resulted in nutritional secondary hyperparathyroidism (NSHP) or *osteodystrophia fibrosa.* Clinical signs observed in these animals were lameness, ill thrift (harsh coats, loss of condition) and in some animals, swelling of the osseous structure of the head. Mildly affected horses showed a decreased ability to work while the more severely affected animals became cachectic and even died. The swelling to the head was bilateral and involved the nasal bones or the maxillae. At necropsy there was swelling of the maxillae and mandibular rami. Fibrous proliferation occurred and extended from the original cortices of the bone. Histopathologically a decrease in osseous tissue could be confirmed. Fibrous tissue surrounded small fragments of old bone in which sites of osteoclastic activity were detected (Walthall and McKenzie, 1976).

Nephrotoxicity has also been reported. The clinical signs are anorexia and gradual weight loss. Although the kidney appeared normal, on histopathology the renal cortex contained dilated tubules lined with flattened or degenerated epithelial cells. Tubular structures were displaced by fibrous tissue while the glomeruli had undergone various degrees of degeneration. Crystals were present in the tubules, particularly the proximal convoluted tubule (PCT) and were yellowish brown and aggregated into rosettes having radial symmetry. The crystals were anisotropic under polarized light (Andrews, 1971).

### *Pigs*

This species has a strongly acidic gastric pH (like the horse) but only one incident of oxalate poisoning in 1932 is on record where acute poisoning was reported in pigs following the consumption of beet. There is, however, uncertainty of the correct diagnosis as beet also contains nitrates and a "brown discoloration of the blood" is also mentioned (Rupprecht, 1932). Baxter (1956) describes fodder beet poisoning in pigs but the signs were not those of oxalosis but he cites that Gregor (1953) found oxalic acid in toxic amounts in sugar-beet tops.

Although Beasley (1999) states that convulsions may also occur with this in pigs, one would have expected more reports of intoxication in this exceptionally widely farmed commodity and species (especially where they are farmed free range) if oxalosis was indeed a problem in swine.

### *Dogs*

The predominant form of oxalate poisoning in dogs is due to consumption of ethylene glycol (antifreeze). Although no confirmed instance of poisoning due to plant oxalates were found, it must be considered as a possibility (Stowe and Fangmann, 1975).

### *Fowls*

It is hardly likely that chickens, as other farm stock, will be as exposed to oxalate poisoning as other farm stock. However, Williams and Olsen (1992), during an investigation into the contribution of each of a mixture of miserotoxin, nitrates and oxalate involved in a particular syndrome, established the $LD_{50}$ of sodium oxalate for 1-week-old chicks to be 984 mg/kg.

### *Humans*

This fatal nephrotoxic syndrome also occurs in people. Cooked rhubarb stems owe their pleasant, acrid taste to its oxalic acid content. During World War I, shortage of greens in Britain lead to rhubarb leaves (where the concentration of soluble oxalates is much higher than the stems) being widely advocated as a substitute for spinach and other greens until several deaths due to renal damage were attributed to it (Ellenhorn and Barceloux, 1988).

Acute fatalities due to soup containing 500 g of *Rumex crispus* in an adult man within 4 h and that of a 4-year-old child who had eaten an unspecified quantity of rhubarb leaves within 1½ h, are recorded (Tallqvist and Vaananen, 1960 and Farre *et al.*, 1989 cited by Ellenhorn *et al.*, 1997).

## TREATMENT

In Animals suffering from a decrease in calcium and showing signs of eclampsia or of muscle stiffness may be treated with IV calcium (Laan *et al.*, 2000; Kellerman *et al.*, 2005). Following the development of acute clinical signs, oral dosing with lime water/milk or calcium lactate followed later by an emetic (in appropriate species) may be helpful. The rationale is to bind the unabsorbed oxalates to calcium in the GIT and remove it from the system. Activated charcoal may also be used. In animals already convulsing, the use of emetics (where applicable) is not recommended. In these animals, the plasma calcium levels should be monitored and treatment with calcium borogluconate instituted.

Although this is not practicable in the veterinary situation it must be noted that heat treatment diminishes the oxalate content of green vegetables considerably. In one study using beans, chickpeas and lentils it was shown that standard cooking on a hot plate could reduce oxalate content by 0–40%, while microwave cooking reduced oxalate content from 60% to 85% and industrial cooking reduced oxalate content from 80% to 92% (Quinteros *et al.*, 2003). The fatalities in humans after consuming rhubarb

leaves (*vide supra*) was most probably due to insufficient heat treatment.

## ADAPTATION

It has been shown that the constant exposure of rumen microorganism, i.e. *Oxalobacter formigenes*, can handle the large concentration of oxalates. In one study goats were adapted to a concentration of 0.6 mmol oxalic acid by exposing the animals to equal increases over a 5-day period, and maintenance over 2 days prior to receiving a ration high in oxalate concentrations. Exposure was obtained by dosing the animals with gelatin capsules filled with oxalic acid. This study indicated that artificial exposure of ruminants to oxalates can create adequate microorganism adaptation to allow an animal to cope on high oxalate-containing plants. Alternatively, the same may be achieved by gradually exposing animals artificially to the plants that contain oxalates (Frutos *et al.*, 1998). With *Halogeton* James (1972a, b) experimentally determined that sheep were 5–10 times more resistant after 8–25 days' feeding and they advise an adaptation period of 10 days prior to known field exposure which would increase the lethal dose by some 30%.

## PROPHYLAXIS

Dicalcium phosphate has been recommended to reduce the likelihood of *Halogeton* toxicity when mixed into the ration at a ratio of 1:3 with salt. Alternatively, 5% dicalcium phosphate-containing alfalfa pellets should be fed at a rate of 100 g to 2 kg (3–5 lb) per sheep per day (Beasley, 1999). The purpose of this is to have all the soluble oxalates precipitated in the rumen.

## CONCLUSION

Fatal soluble oxalate poisoning is caused by exposure of unadapted ruminants to a large intake of plants high in oxalates. Due to occasional shortage of feed or other unforeseen circumstances it may be difficult to avoid such incidents. The fact that apparently good quality hay may be contaminated with oxalate-producing fungi may also be discovered too late.

When horses graze pastures containing grass species high in oxalates precautionary measures should be taken to prevent *osteodystrophia fibrosa*.

## POSSIBLE FUTURE RESEARCH DIRECTIONS

### The role of Ca and Mg at cellular level on enzyme activity and the pathogenesis of the oxalate syndrome

Practically all authors on oxalates, *vide supra*, refer to tetany as a result of hypocalcaemia in ruminants. In addition the serum Mg levels reported are also exceptionally variable between authors.

Radostits *et al.* (1999) refer to the production of tetany in cows infused with Ca-EDTA and regard this as a suitable model for experimental production of hypocalcaemia. It must, however, be pointed out that EDTA complexes both Ca and Mg (although the latter less strongly) and, therefore, the tetany may have been produced by a combination of both hypocalcaemia and hypomagnesaemia.

In contrast, Findlay (1998) describes uncomplicated hypocalcaemia ("milk fever") in the cow and ewe as a flaccid paralytic condition and that tetany (signs of "grass staggers") may be seen briefly only if concurrent hypomagnesaemia is present. This is in stark contrast to non-ruminants where eclampsia in the bitch and the queen results in excitement and tetanic muscular activity. In would indeed be interesting to know how often the magnesium status has been assessed in small animal "eclampsia".

In contrast to calcium, magnesium homeostasis is not regulated by a hormonal feedback system and is simply dependent on inflow and outflow across membranes (Martens and Schweigel, 2000). The analytical techniques of determining serum magnesium levels are often reported to be unreliable with only the referenced atomic absorption method atomic absorption and the enzymatic methods giving consistently reliable results. However, this is cumbersome and difficult to set up and calibrate. Photometric or colorimetric techniques are unreliable as they are influenced by a number of factors, including the calcium level and bilirubin (Saur *et al.*, 1994; Prof (Emeritus) Reyers, Specialist Clinical Pathologist, Pretoria: personal communication, 2006).

### Triterpenes

In one study it has been shown that rodents treated with triterpenes had reduced formation of urinary calculi. With the plants' diuretic effect, it causes a decrease in the accumulation of calcium in the renal tubular environment decrease the super-saturation typical in cases of stone formation. Since the triterpenes are also known to be anti-oxidant in nature, they have the ability to decrease

the peroxidative injury seen with calcium oxalate stone formation (Malini *et al.*, 2000). This must, however, be weighed up against their potential toxicity.

### Thiazide diuretics

In dogs suffering from calcium oxalate urolithiasis, surgical and medical treatment has been used to treat animals. Although surgery is in most cases required, the thiazide diuretics have been beneficial as they decrease the overall calcium excretion by the kidneys thereby reduces the calcium available to bind the oxalic acid. Added benefits arise from treating the animal with potassium citrate. In addition to alkalinizing the urine and rendering oxalic acid more soluble, calcium shows an increased tendency to bind to citrate and thereby forms a more soluble complex than with oxalic acid. As such in very valuable animals showing early signs of renal pathology, it may be possible to initiate clinical therapy to modulate the degree of nephrotoxicity (Booth, 2001).

### Speciation of oxalates

The exact speciation of soluble oxalate ions in the various plants involved in toxicosis seems to be directly related to the pH of the plant sap. This could be of assistance in explaining or even predicting the outcome of intoxication.

### Inclusion of Mg with Ca borogluconate as standard treatment of oxalosis

In view of the fact that magnesium (*vide supra*) is also complexed with oxalate and is unavailable at cellular level as a co-factor for essential enzyme activity, surely indicates experimental investigation of supplementation in intoxicated individuals.

### Role of Mg in Ca oxalate crystals

There does not appear to be any analyses of the contribution of magnesium (although slightly more soluble) to the well-known calcium oxalate crystals characteristic of this syndrome. These crystals can be readily collected as described by James *et al.* (1971).

### Pathogenesis of oxalic acid and acid oxalate poisoning

As the mechanism of intoxication with the oxalate ion, e.g. *Halogeton,* has been determined and it was proved by Van Kampen and James (1969) that cellular damage precedes calcium oxalate deposition, it should be determined if this is indeed the case with oxalic acid and the acid oxalate ion too.

### Greater toxicity of the oxalate ion

The reason why the oxalate ion appears to be more toxic than the acid oxalate ion and oxalic acid (Figure 69.1) to at least ruminants is intriguing. The intracellular body pH is around 7 and for oxalic acid the $pK_1 = 1.27$ and the $pK_2 = 4.28$ (Budavari, 1996) exists that the double negative ion (of which a 0.1 M solution in water has a neutral pH) will bind with $Mg^{2+}$ and $Ca^{2+}$ more readily and forthwith than the acid oxalate ion (0.1 M solution in water pH 2.7) and oxalic acid (0.1 M solution in water, pH 1.3 (Budavari, 1996)). In the rumen (pH 6.5) both these should, however, be rapidly be changed to the oxalate ion. The fact that the cations ($Na^+$, $K^+$ and $NH_4^+$) of the soluble oxalates may differ, should not be a factor either as they will be fully ionized in the rumen.

### The role of cations of oxalates

At present there are scientific apparent inexplicable differences in toxicity whether oxalate is bound to $Na^+$, $K^+$ or $NH_4^+$ (James, 1972a, b). This should be followed up. In addition as far as could be ascertained, potassium acid oxalate has not yet been used to simulate *Rumex* and *Oxalis* poisoning. It is interesting that the Merck Index lists the potassium salt (potassium binoxalate or "sal acetosella" [salt of *Rumex acetosella*]) but not the sodium acid oxalate (Budavari, 1996).

## CONCLUSION

In conclusion, we would like to echo the 30-year-old words of James (1972a,b), a scientist who has published most extensively in this field: "Oxalate poisoning remains a complex and poorly understood phenomenon". There is apparently as much dissimilarity as similarity among the effects of the different types of oxalates on the different species of animals.

# PART II: POISONING BY INSOLUBLE CALCIUM OXALATE RAPHIDES

## BACKGROUND

Calcium oxalate is a common substance found in some 250 species of plants. Since the calcium oxalate crystals

accounts for the majority of calcium in the plant it is possible that it is found in all plants (Franceschi and Nakata, 2005). Its exact function within the plant is at present unknown. It has been speculated that these substances may play a role in protection from chemicals produced by other plants, protection from herbivores/insects and perhaps it is the plant's natural calcium sink (Jauregui-Zuniga *et al.*, 2005; Korth *et al.*, 2006; Weir *et al.*, 2006).

Insoluble calcium oxalate is formed in plants by the simple combination of calcium and oxalic acid in the endogenous environment. The crystals can form in a number of different shapes which range from prismatic crystals (rhomboid), large elongate rectangular styloids, bundles of needle (acicular) raphide crystals, druse crystals or small angular crystals known as crystal sand (Webb, 1999; Nakata, 2002; Franceschi and Nakata, 2005). Of these only the raphide crystals (presumably formed as an antiherbivor maneuver) are of toxicological significance. At present the exact formation of the crystals in raphides is unknown (Volk *et al.*, 2004; Franceschi and Nakata, 2005; Xu *et al.*, 2006).

Members of the family Araceae are widely grown for either their flowers or for their particularly attractive foliage, e.g. *Diefenbachia* spp. (dumb cane), *Colocasia* spp. (elephant's ear), *Phillodendron* spp. (sweetheart vine) and *Monstera* spp. (delicious monster). They are also widely cultivated for culinary purposes of the starch-rich tuberous rhizomes or as green vegetables, e.g. *Colocasia esculenta* (cocojam, taro) and *Xanthosoma* (new cocojam, okumo). The whole family is known to have irritant properties on the buccal mucous membrane when the fresh plants are eaten or even just chewed and the syndrome is a common occurrence in humans and occasionally in animals (Frohne and Pfänder, 1983). Plants intended for eating, must, therefore, be cooked or baked beforehand to render them non-irritant (Purseglove, 1972).

The irritant properties are due to insoluble calcium oxalate raphides (needle-sharp crystals, 250 μm). They are formed and located in special vacuoles in microscopic lemon-shaped ideoblasts, (explosive ejector cells with an operculum) in the epidermis of these plants. The exact complex mechanism by which they are formed is not known (Franceschi and Nakata, 2005). The raphides are packed together lengthwise in a gelatinous mass and if the plant is damaged the operculum of the ideoblast is dislodged, sap of the plant or saliva causes the gelatinous mass to swell and the needles are expelled under the pressure (Frohne and Pfänder, 1983). Cheeke (1998) describes it: "They ... (the crystals) ... emerge like bullets one at a time, with sufficient force to cause the cell to recoil like a gun and (this) goes on for many minutes".

If the plant is chewed, prior to being swallowed, masses of these raphides penetrate the mucous membrane of the mouth causing alarming, severe (but usually transient) local irritation and clinical signs such as excessive salivation in people (Gardner, 1994; Chiou *et al.*, 1997; Salinas *et al.*, 2001) and even laryngospasm. Salivation, gagging, colic, bloody diarrhoea, depression, prostration and sometimes death are known to occur in animals (Knight and Walter, 2003) but the latter is rare.

This phenomenon can be experienced by taking a single experimental bite of the stem or leaf of one of these plants: after a latent period of *ca.* 30 s it results in this transient, somewhat uncomfortable sensation which may last up to 30 min.

Occasional intoxication in sheep kept in paddocks with no grazing and force-fed only, or mainly, these plants pruned in gardens, is seen (Kellerman *et al.*, 2005).

An extraordinary incident in a black rhino is reported by Wood *et al.* (1997). In a game reserve in Zimbabwe, an orphan black rhino (*Diceros bicornis*) calf of 12 months started chewing half a leaf of an ornamental araceous *Xanthosoma mafaffa* (elephant's ear, new cocoyam) in the conservation officer's garden but promptly spat it out. Irritation was manifested by severe salivation, flicking her tongue and rubbing her mouth for an extended period in mud. She tried to browse after a while but spat out the food. These signs lasted for 3–4 h and then she made an uneventful recovery.

The black rhino eats various *Euphorbia* spp. with impunity (Loutit *et al.*, 1987). The latter has severely caustic, ingenol- and phorbol-containing latex which results in serious blistering of the mouth and even skin in humans (Watt and Breyer-Brandwijk, 1962) and domestic stock (Kellerman *et al.*, 2005). It is amazing that the relatively mild calcium oxalate raphide irritation described above, caused such marked clinical signs in a rhino.

Burrows and Tyrl (2001) described that in *Tragia* spp. (noseburns) of the Euphorbiaceae, the stinging hair of this unobtrusive creeper contains a calcium oxalate raphide up to 4 mm long which on contact, penetrates the skin allowing the highly irritant proteinaceous contents to enter the small wound causing a transient pruritis very similar to but less severe than that caused by the well-known stinging nettles of the Urticaceae.

In summary, in the veterinary situation, Ca-oxalate raphide intoxication is rare but it is prudent to be aware of it in coming to a diagnosis of sudden acute mouth irritation in humans and diverse species of animals.

## ACKNOWLEDGMENTS

We would like to express our sincere thanks to the following individuals and organizations as the completion of this chapter was greatly attributed to them.

Prof. (Emeritus) Fred Reyers, Specialist Clinical Pathologist, Pretoria, for unstinting assistance, lateral

thinking, essential scientific input and criticism of aspects of the manuscript; Mr. Faan Naude, Merensky Branch and Ms. Antoinette Lourens of the Onderstepoort Branch of the University of Pretoria (UP) Libraries for outstanding services. Dr. Moira Bode, Organic Chemist, CSIR, South Africa & Prof Z Apostolides, Biochemist, Department of Wild Life and Agricultural Sciences, UP; colleagues of various Departments at the Faculty of Veterinary Science, Onderstepoort, but in particular those of the Department of Paraclinical Sciences where we were able to work from.

# *Datura* spp. and other related plants

*Theuns W. Naudé*

## INTRODUCTION

*Datura* appears to be the main (species) genus involved in poisoning by tropane alkaloids (hyoscyamine, scopolamine and atropine). Although *Datura* poisoning is possible in most animal species, it is particularly a practical problem in equines. The reason for this is that equines are particularly sensitive to atropine and related tropane alkaloids. Being hindgut fermenters, the alkaloids are absorbed as the contaminated feed passes through the stomach. A paralytic ileus results with consequent death (from acute complications like torsion, strangulation or tympany) or recalcitrant impaction colic may develop. Swines appear to be also rather susceptible.

Being annuals, *Datura* weeds, particularly *D. stramonium* and *D. ferox*, invade and contaminate especially annual crops like corn (maize), sorghum, soybeans and linseed. The weeds ripen with the crop and the weed seed contaminates the finally harvested grain. With annual grass crops, such as tef, the equally toxic immature weeds are cut and dried with the hay. Other plants that contain tropane alkaloids usually only cause incidental poisoning in livestock.

## BACKGROUND

The family Solanaceae contains several genera that are toxic due to the tropane alkaloids atropine and scopolamine. The genera *Atropa* (belladonna), *Hyoscymus* (henbane), *Brugmansia* (angel's trumpet) and *Datura* (jimsonweed) are all of toxicological importance (Burrows and Tyrl, 2001). They can all cause incidental poisoning but only the genus *Datura* appears to be of veterinary significance.

**FIGURE 70.1** *Datura stramonium* L. (jimsonweed, common thorn apple) (courtesy South African National Biodiversity Research Institute (SANBRI), Pretoria, South Africa).

*Datura stramonium* L. (jimsonweed, common thorn apple) (Figure 70.1) and *D. ferox* L. (large thorn apple) (Figure 70.2) probably originate from the Tropical Americas (Henderson, 2001). Although the latter occurs in the United States

**FIGURE 70.2** *Datura ferox* L. (large thorn apple) (courtesy SANBRI, Pretoria, South Africa).

**FIGURE 70.3** *Datura subspecies innoxia* C Mill. subspecies *innoxia* (*D. meteloides* Dunal) (downy thorn apple) (courtesy SANBRI, Pretoria, South Africa).

(Burrows and Tyrl, 2001) no distribution map for this species and the extent to which it occurs there is given. Both these spp. now have a cosmopolitan distribution and are annual pioneer weeds on wasteland and are particularly troublesome, serious invaders on fertilized soil with annual crops (Henderson, 2001) all over the world, thus their significance concerning livestock.

These plants have malodorous leaves (common name "stink leaf") and spiny fruit capsules by which the two species can be readily identified. *D. ferox* and *D. stramonium* both have erect, ovoid capsules with the longest spines in the former. They have erect, funnel shaped flowers, white in *D. ferox* and white, mauve or purplish ones in *D. stramonium*. The stems are green except that a purple-stemmed variety occurs with the latter (this, on drying e.g. in hay, turns brownish). The seeds of the two species are black, kidney shaped and flat with a characteristically pitted exterior (Henderson and Anderson, 1966) and the seed of the two species cannot be differentiated morphologically from each other. The seeds of *D. ferox* are, however, larger (average weight 14.1 mg ($n = 6 \times 1$ g)) than those of *D. stramonium* (average weight 6.6 mg (also $n = 6 \times 1$ g)) (SS de Kock, L Jonker, National Horse Racing Authority of South Africa) and TW Naudé (Veterinary Faculty at Onderstepoort, unpublished data, 2004).

A third species *D. innoxia* C Mill. subspecies *innoxia* [=*D. meteloides* Dunal] (downy thorn apple) (Figure 70.3), is primarily an invader of waste areas and sandy river banks and beds but may also occur in cultivated areas. It produces large, tubular, white flowers but in contrast to the glabrous previous two species this species is softly, grey-velvety on all parts. Furthermore it is differentiated by a pendulous, globose fruit capsule densely covered with small spines. Its seeds are of similar shape and size as those of *D. ferox* but are brown (Henderson, 2001). As it is quoted in literature on *Datura* spp., it is included here.

The problem with the seed of *D. ferox* and *D. stramonium* (no mention in the literature about the seed of *D. innoxia* was found) is that as the plants grow more rapidly than the crops they invade and, therefore, cannot be effectively controlled by mechanical means, the fruit ripen concurrently with those of the planted crop, e.g. corn (or maize) and are harvested at the same time. The seeds, therefore, occur admixed in the threshed corn seed. Their specific gravity is approximately the same as the corn and unless sifting is done in single layers it is not separated from the corn. It is, therefore, often a contaminant of

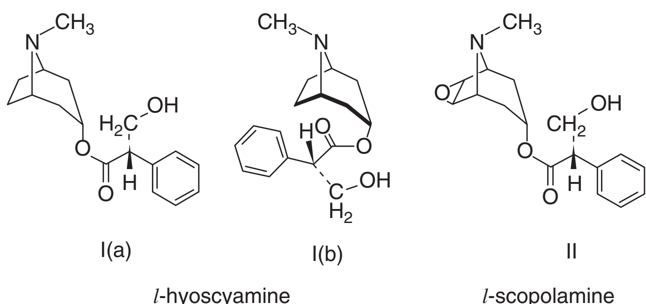

**FIGURE 70.4.1** (I) structures of hyoscyamine (conventional, (a) and stereo-specific (b) and (II) scopolamine (conventional).

grains such as corn, sorghum, soybeans and linseed. All counties have strict legislation about the number of *Datura* seeds allowable in grain for human consumption. Grain rejected for this reason usually finds its way into stock feed and further sifting to clear such seed for human consumption often results in the heavily contaminated siftings being used as stock feed (Kellerman *et al*., 2005).

## STRUCTURE OF TROPANE ALKALOID MUSCARINIC RECEPTOR ANTAGONISTS

These alkaloids basically consist of a bicyclic seven member tropane alkaloidal ring esterified through its hydroxyl group at C3 with the carboxyl group of L-tropic acid. (Figures 70.4.1 and 70.4.2).

The best known drug in this group in veterinary practice is atropine (a racemate of *d,l*-hyoscyamine) of which practically only the one isomer, l-hyoscyamine (Figures 70.4.1 and 70.4.2), is anti-muscarinic (Adams, 2001; Brown and Taylor, 2001).This is an ester of tropine and *l*-tropic acid (Figure 70.4.2). In the plant it occurs as this active isomer, *l*-hyoscyamine, but during commercial extraction it partially racemizes and is then further chemically converted to the stable racemate, atropine (Budavari, 1996). Most atropine is currently synthesized and, consequently, is the racemate (R. Smith, Phytex, Australia, personal communication, 2006). In this chapter the *l*-isomer will be referred to as hyoscine in contrast to atropine (which is *d,l*-hyoscyamine), which has only half the antimuslarinic potency of *l*-hyoscyamine. Its pharmacological potency in plant material is thus double that of atropine as used therapeutically.

Scopolamine (hyoscine) is similarly an ester of scopine and *l*-tropic acid (Figures 70.4.1 and 70.4.2). It is hardly, if ever, used in veterinary medicine but is well known in medical circles as a pre-anesthetic. Due to its potency as a hallucinogen, it has even been used at 1.5 mg/70 kg man as

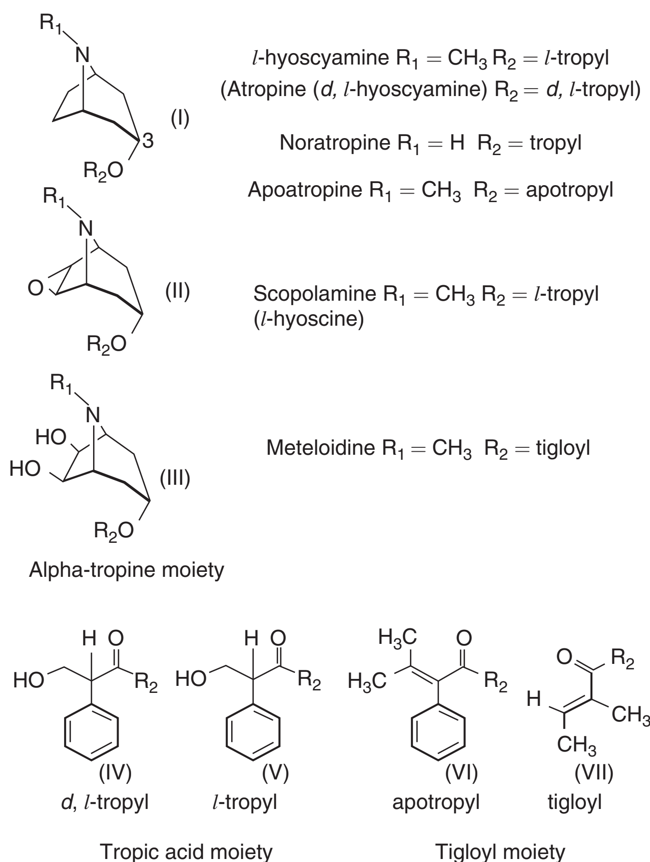

**FIGURE 70.4.2** Relationship between relevant tropane alkaloids.

an incapacitating agent in chemical warfare. It has now been replaced by an extremely potent, structurally related compound, 3-quinuclidinyl benzilate (BZ or QNB) which is 3-fold more potent than scopolamine (Ketchum and Sidell, 1997).

Hyoscyamine and scopolamine are the major toxic components of *D. stramonium* (Watt and Breyer-Brandwijk, 1962) and predominantly scopolamine that of *D. ferox* (Springhall and Seawright, 1972; cited by Everist, 1974). Also refer to Table 70.1.

## STRUCTURE–ACTIVITY RELATIONSHIP

The pharmacological anti-muscarinic action of atropine and scopolamine are both dependent on the presence and optical configuration of the levorotatory tropic acid moiety. The intact ester bond free hydroxyl group on the acyl portion is essential (Brown and Taylor, 2001). Furthermore the tropic acid moiety must be attached alpha to, and thus below, the plane of the tropane ring (Figure 70.4.1b).

**TABLE 70.1 Hyoscyamine and scopolamine determinations on South African weed – *Datura* spp.**

| *Datura* spp. and part | Alkaloid concentrations (μg/g) | | | | Ratio |
|---|---|---|---|---|---|
| | Hyoscyamine | | Scopolamine | | Scopolamine/ hyoscyamine. |
| | Average | Range | Average | Range | |
| *Datura stramonium* | | | | | |
| Young plants | | | | | |
| Purple stem | 1046 | 531–2291 | 1063 | 296–2844 | 1.01 |
| Green stem | 587 | 491–742 | 525 | 249–1155 | 0.89 |
| Seed | 557 | 273–908 | 587 | 254–800 | 1.1 |
| *Datura ferox* | | | | | |
| Young plants | 68 | 0–149 | 1048 | 82–2541 | 15.4 |
| Seed | 7.5 | 2–19 | 766 | 218–956 | 102 |
| *Datura innoxia* | | | | | |
| Young plants | 360 | 175–462 | 790 | 692–869 | 2.2 |
| Seed | 297 | 127–524 | 454 | 104–815 | 1.85 |

Apoatropine (Figure 70.4.2) differs from atropine only in having an apotropyl acid moiety at C3. Its acute toxicity to mice is, however, 180 times that of atropine by intraperitoneal injection and it is convulsive (Krantz *et al.*, 1954). Kobert (1905, cited by Krantz *et al.*, 1954) found it only mildly mydriatic and the latter confirmed mydriasis and vagal block at as little as 2 mg/kg i.v. in dogs. In addition, severe cardiac depression was observed. However, it has about the same potency as atropine in relaxing barium-induced spasm of rabbit intestine but was 40 times less effective in reducing intestinal motility in the rat (Krantz *et al.*, 1954).

In summary the replacement of the optically active tropyl group of atropine with an inactive apotropyl group does not abolish but definitely diminishes the anti-muscarinic potency of atropine.

No pharmacological or toxicological data could be obtained on meteloidine, found at significant concentration, and the other related tropane alkaloids (Figure 70.4.2) found at low concentrations in plant material (*vide infra*).

## BIOSYNTHESIS IN PLANTS AND METABOLISM IN MAMMALS

The biosynthesis of tropane alkaloids by plants is succinctly summarized by Dräger (2004). An ubiquitous 4-carbon diamine (putrescine) is methylated and enzymatically transformed into the bicyclic, seven-membered alkaloid, tropinone. The latter is enzymatically converted to either alpha tropine, the precursor of the tropane alkaloids under discussion (Figure 70.4.2) or into its stereo-isomer, beta pseudotropine, from which the polyhydroxylated glycosidase inhibitors, the calystegines, originate.

The intact esters of the tropane alkaloids (Figure 70.4.2) are essential for anti-muscarinic activity. Atropine esterases occur to varying extent in the livers of different animals and detoxify it by hydrolysis. It is interesting that the resistance to tropane alkaloid poisoning by guinea pigs and certain strains of the rabbit, where metabolic polymorphism occurs, is ascribed to high enzyme liver activity in these species. In addition, the enzyme detoxifies exclusively the *l*-isomers and has no activity in relation to scopolamine (Bernheim and Bernheim, 1938). In contrast, Wada *et al.* (1991), however, found in *in vivo* experiments that scopolamine is indeed hydrolyzed by this esterase in the guinea pig and certain strains of the rabbit but not in the rat and only to a minor extent in the mouse. According to Brown and Taylor (2001) hepatic metabolism accounts for the elimination of about half the dose of atropine in man and the remainder is excreted unchanged in the urine. No metabolism data are available for livestock (Adams, 2001).

## MECHANISM OF ACTION

Muscarinic receptor antagonists compete with acetylcholine (ACh) for a common binding site on the muscarinic receptors and thus block the action of ACh at muscarinic neuroeffector sites on smooth and cardiac muscle, gland cells, in peripheral ganglia and in the central nervous system (CNS). In general they cause little blockade at nicotinic receptor sites (Brown and Taylor, 2001).

## SIGNS OF INTOXICATION

In man, atropine at therapeutic doses has virtually no detectable effect on the CNS whereas scopolamine, which more readily crosses the blood–brain barrier, causes CNS

depression manifested as drowsiness, amnesia and fatigue. Euphoria is also encountered. The acute toxic effects commonly seen with atropine are mydriasis and cycloplegia, dry mucous membranes and tachycardia. At higher doses central nervous excitation becomes more prominent resulting in restlessness, irritability, disorientation, hallucination and delirium. At still larger doses, stimulation is followed by depression leading to circulatory and respiratory failure after a period of paralysis and coma (Brown and Taylor, 2001). Although humans are very susceptible to poisoning, atropine has an exceptionally wide therapeutic index in man, fatalities being rare even in instances of gross over dosage or poisoning. *Datura* poisoning, especially following ingestion of the seed, is often seen in man (Watt and Breyer-Brandwijk, 1962; Brown and Taylor, 2001).

In the horse, additionally, the motility of the large intestine is seriously affected and either an acute paralytic ileus results with consequent death from acute complications like torsion, strangulation or tympany, or in more chronic cases recalcitrant impaction colic develops (Naudé *et al.*, 2005).

## EXTRACTION, ISOLATION AND QUANTIFICATION OF TROPANE ALKALOIDS: SURVEY ON SOUTH AFRICAN WEED–*DATURA* SPECIES

As no such survey data seem to be available and as the procedure used may be universally applicable (or can be adapted), the basic technique employed by SS de Kock, L Jonker (National Horse Racing Authority) and TW Naudé (Faculty of Veterinary Science, Onderstepoort) (unpublished data, 2002), for this purpose, is given.

The standard procedure was used: after extracting the alkaloids in the dry, finely milled plant material into an aqueous acid medium, the latter was alkalinized and the alkaloids back-extracted in methylene chloride. Gas chromatography (GC) isolation was found to be less sensitive, less compound- specific and produced artifacts, thus high pressure liquid chromatography (HPLC) isolation was used in preference. This isolation entailed the use of a gradient of water and methanol both containing 10 mM ammonium formate and a C18 reverse phase column. LC/MS/MS was undertaken on a Thermo Finnigan LCQ ion trap instrument operated in positive ion mode with atmospheric pressure chemical ionization (APCI). Full scan LC/MS was undertaken for alkaloid presence and target MS/MS analyses were on the $[M + H]^+$ (protonated molecular ion) entities observed with this mild ionization technique. For hyoscyamine this corresponds to $m/z$ 290 and for scopolamine to $m/z$ 304.

The one standard used was analytically pure atropine sulphate (racemic *d,l*-hyoscyamine). These two diastereoisomers cannot be differentiated unless a chyral column is used. In the plant only the antimuscarinic *l*-hyoscyamine is produced. Atropine, if dosed or injected, thus has only half the potency of the plant's alkaloid.

The other standard was *l*-scopolamine.

## RESULTS OF *DATURA* SURVEY IN SOUTH AFRICA

The results of tropane alkaloid analyses on vegetative material and the seed of various species of *Datura* are summarized in Table 70.1.

Note the great variations in alkaloid concentrations between individual plants of the same species as reflected by the highest and lowest values found for that particular species. Note further that the vegetative parts of the purple-stemmed variety of *D. stramonium* had approximately twice the alkaloid content of the botanically identical green-stemmed variety. Selected plants were also investigated by LC/MS/MS for the presence of tropane alkaloids other than hyoscyamine and scopolamine. These included the compounds meteloidine, noratropine and apoatropine (Fig. 70.4.2).

Meteloidine was the most significant of these alkaloids, in many cases exceeding the levels of atropine and scopolamine. Noratropine and apoatropine levels were generally very similar at about 5% that observed for hyoscyamine.

## TOXICITY TO LIVESTOCK

### Equines

*Datura* poisoning, especially following ingestion of the seed, is often seen in man (Brown and Taylor, 2001). In animals it is rare and the only cases of significance have been reported in the horse although the pig is regarded as rather susceptible to tropane alkaloid poisoning. The serious consequences of gastrointestinal complications are, however, only mentioned in equines (Adams, 1995). Three field outbreaks occurred after ingestion of grain heavily contaminated with *Datura* seed (Barney and Wilson, 1963; Williams and Scott, 1984; Schulman and Bolton, 1998). The clinical signs and course of intoxication varied rather widely.

In the first case, 15 animals from a group of 34 were affected and 11 died, 2 as long as 6 days after withdrawal of the incriminated feed, cracked maize containing "an unusually large number" of jimsonweed seeds. The signs recorded were anorexia, hyper excitability, staggers, muscular spasms, frequent urination and mydriasis with

impaired vision progressing to convulsive seizures, rigor and coma preceding death. There is no mention of gastrointestinal complications. In the case reported by Williams and Scott (1984) two horses were fed a meal containing 0.5% *D. stramonium* seed. They exhibited depression, mydriasis, anorexia, tachycardia, polydipsia and polyuria, fever and brown, fetid diarrhea. Both recovered after supportive treatment. In the last case (Schulman and Bolton, 1998) one horse died from acute gastric dilation and rupture whereas the second had to be euthanized due to unresponsive paralytic ileus. As this had occurred in South Africa, it is assumed that the seed involved was probably a mixture of that of *D. stramonium* and *D. ferox*.

Only two cases of experimentally produced *Datura* intoxication were found. Barney and Wilson (1963), *vide supra*, also fed a Shetland pony two quarts (*ca.* 2.2 litres) of the cracked maize containing "an unusually large number of jimsonweed seeds" on a daily basis for an unspecified number of days. Inappetence, hyper excitability and mydriasis appeared on the 8th day. On the 10th day staggering and muscle spasms were exhibited and the animal died on the 10th day. Again the authors do not refer to any clinical signs associated with colic.

Following the discovery of scopolamine in the urine of horses post racing by Galey *et al*. (1996), it emerged that they had been on bedding containing *Datura*. Galey *et al*. (1996) dosed four adult mares with air-dried *D. meteloides* (*D. innoxia*) vegetative plant material containing *ca.* 550 mg scopolamine and 740 mg as atropine, thus (*vide supra*) 740 mg *l*-hyoscyamine/kg at 0.0125, 0.025, 0.1 and 0.5 g/kg. Clinical signs consisting of severe gastrointestinal atony, tachycardia, sweating and colic were seen at only the highest dose of 0.5 g/kg, equivalent to 0.275 mg scopolamine and 0.185 mg hyoscyamine/kg (in addition to the other unquantified related tropane alkaloids in the plant). Clinical signs were evident 2 h after dosing and had not resolved by 72 h after dosing. Urine alkaloid concentrations peaked within 1–2 h after dosing reaching the mg/ml range according to the graphs and at low dosages were mostly absent after 12–24 h. The $t_{1/2}$ of scopolamine and atropine (=hyoscyamine) were 1.7 and 2.3 h, respectively at the lowest dose.

Recently, two cases of *Datura* intoxication where the poisoning is attributed to dried vegetative plants in tef hay were described (Naudé *et al*., 2005; Gerber *et al*., 2006). The vegetative material was found to be as toxic as seed.

Atropine is widely used in veterinary practice especially for the treatment of poisoning by organophosphorus and carbamate cholinesterase inhibitors (Adams, 2001). However, even when used as a pre-anesthetic or mydriatic in the horse, the potential detrimental effects on intestinal activity should be considered (Roberts and Argenzio, 1986; Adams, 1995).

In the horse it is also used for the treatment of chronic obstructive pulmonary disease but with the proviso that it must be used with care as it may produce ileus and abdominal pain (Pearson and Rierbold, 1989). Similarly, Ducharme and Fubini (1983) found that the horse was especially sensitive to gastrointestinal atony on administration of atropine and concluded that it was contraindicated for the relief of intestinal spasm and may in fact lead to severe gastrointestinal complications. After experimental atropine i.v. injection of clinically normal ponies ($n = 5$) at 0.044 (=0.022 hyoscyamine) mg/kg and 2 weeks later again at 0.176 (=0.08 hyoscyamine) mg/kg, intestinal motility was decreased after 30 min and the horses had stopped eating, exhibited abdominal pain and were quiet and depressed at both dose levels. With the low dose they resumed eating after 1–2 h but after the higher dose, which also caused cecal distention, they only resumed eating 2–7.5 h later and intestinal motility had only gradually returned to normal by 12 h.

In an equine study on myoelectrical and mechanical intestinal activity in clinically normal ponies ($n = 4$), atropine at 0.044 (=0.022 hyoscyamine) mg/kg caused a marked decrease in jejunal and pelvic flexure motility for longer than 2 h and had increased pelvic flexure sphincter tone possibly indirectly by decreasing parasympathetic tone (Adams *et al*., 1984).

In man the gastrointestinal tract is, in contrast to the horse, rather insensitive to the effect of atropine. Only one report of paralytic ileus was traced and was due to protracted, excessively high, constant infusion of atropine (2600 mg over a 30-day period) to control excessive bronchial secretion after an organophosphorus suicide attempt (Beards *et al*., 1994). In contrast to man, scopolamine is hardly ever used in veterinary medicine (Adams, 2001) and in older textbooks is mentioned mainly as a soporific in man and the dog. It is stated that its use in horses appears to produce hallucination and excitability (Milks, 1949). Galey *et al*. (1996) administered scopolamine s.c. at 0.008 mg/kg to a horse. It caused transient sweating and tachycardia but not colic. No data are available on the dose of scopolamine which may result in colic. Its role and that of the other minor tropanes in *Datura* spp. can only be surmised to be additive and aggravating.

Apart from atropine, xylazine also decreases the myoelectrical and mechanical activity of the distal portion of the equine jejunum and the pelvic flexure of the colon (Adams *et al*., 1984) and fatal drug induced, refractory impaction colic in the equine can be related to the use of amitraz. These should be considered in the differential diagnoses of suspected tropane alkaloid poisoning.

### *A brief account of two recent outbreaks of* Datura *poisoning due to dry, young plants in hay is given below*

*Outbreak No. 1 (Naudé et al., 2005)*

Eighty-three riding horses were kept at an established, well-managed riding school. A spate of impaction colic, a

condition which had not been diagnosed there previously, suddenly occurred. Over a 6-week period 18 horses were affected of which 1 died. A new consignment of hay, received from the usual supplier had been fed to the horses. Impaction colic occurred in a total of 18 horses during the following 7 weeks several having up to three attacks. The attending veterinarian referred a number of affected animals to the Equine Clinic of the Faculty of Veterinary Science, Onderstepoort where a tentative diagnosis of atropine intoxication was made as some *Datura* plants were found in the hay submitted with the animals. Following an *in loco* inspection the suspect hay was withdrawn after it had been fed for 7 weeks. During the week following the withdrawal there were, however, still 11 cases of impaction colic. The withdrawal terminated the outbreak of colic. One horse, however, exhibited an abnormal *habitus* 6 days before withdrawal of the hay and was hospitalized for suspected colic but was discharged the following day. The same animal had to be readmitted 3 days after withdrawal of the suspect hay with severe, recalcitrant impaction colic and eventually had to be euthanized after 8 days, i.e. 11 days after the last possible exposure to toxic plant material. All other probable sources of *Datura,* except the hay were excluded.

**Physical examination of hay:** The two last consignments were examined for contaminating plants, six bales of each irrespective of whether it was *Eragrostis curvula* or tef were picked at random and the stable hands requested to collect all material other than grass for further inspection.

The second last batch was of poorer quality than the last. The following dried foreign plant material was identified: several maize stalks; stems of a large, hard grass and even tufts and roots of various veld grasses; numerous pieces of nut sedge and several broad-leafed weeds. Additionally *Datura* spp. were present and comprised some 30 small to large pieces of young, brownish stems (diameter 0.5–1 cm), which could initially not be identified as such. Fortunately, two of these stems with young fruit were present and were positively identified as *D. stramonium* by a botanist thus enabling probable identification of the remaining stems by comparison (Figure 70.5b).

The contamination was traced to the tef hay which was of inferior quality. On a second visit two bales were very carefully examined by gently taking it apart, separating layer by layer. This enabled recovery of three *Datura* plants. The young, extremely brittle, dried, pressed plants were intact and entire with leaves, of which one could, due to the presence of the typical young fruit, be positively identified as *D. ferox* (Figure 70.5a).

From the positive identification of *D. stramonium* from the previously inspected bales, the other two young botanically sterile plants appeared to be possibly *D. stramonium* (Figure 70.5c). Both the positively identified *D. stramonium* and *D. ferox* plants as well as the botanically

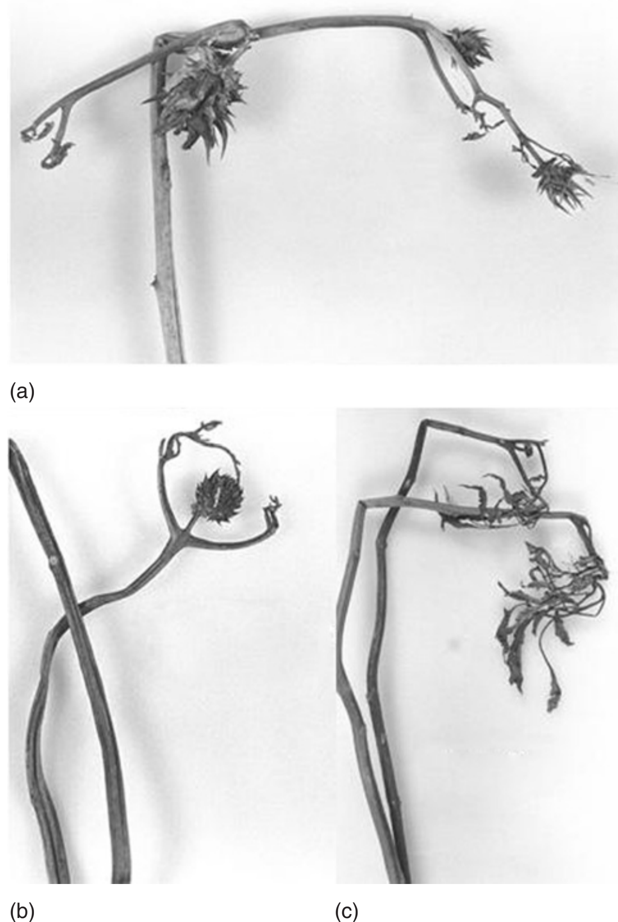

**FIGURE 70.5** Young plants from hay: botanically identifiable (a) *D. ferox*, (b) *D. stramonium* and (c) botanically sterile *Datura* spp.

sterile suspect entire plants taken from the hay were milled and chemically analyzed for tropane alkaloid content. In order to compare these analyses with that of the well-known toxic seed, material collected from waste areas as well as fertilized lands in the Onderstepoort vicinity were also subjected to chemical analysis for tropanes in Australia.

**Colic management and treatment:** Sixteen horses were referred to the Onderstepoort Equine Clinic over a period of 18 days. The standard tests for and treatment of impaction colic in horses (*vide infra)* were implemented. Apart from the impaction colic, and despite a tentative diagnosis of *Datura* poisoning, no other characteristic signs of parasympathetic blockade were observed. Treatment was symptomatic and administered according to the severity and extent of the signs of colic and rectal findings (*vide infra*). Neostigmine at 0.005 mg/kg s.c. was also given occasionally but with no dramatic effect. Treatment was continued until all signs of discomfort were absent and rectal examination revealed resolution of the impaction. Most of the animals needed repeated treatment over several days until all signs of discomfort were absent. Then tef and alfalfa

(lucerne) were reintroduced in small amounts several times a day and gradually increased. All responded well to treatment except for one which had undergone surgery for severe large colon impaction which was unresponsive to conservative treatment. Five days later it had to be euthanized due to recurrence of the same problem.

**Tropane alkaloid analysis:** This was done in Australia and the extraction and chromatographic procedure were more or less on the same lines as described (*vide supra*). The botanically identified vegetative *D. stramonium* from the hay contained respectively 1500 μg hyoscyamine and 1600 μg scopolamine/g. The identified *D. ferox* contained no hyoscyamine and 1100 μg scopolamine/g. The unknown vegetative young *Datura* plants contained 1400 μg hyoscyamine and 1200 μg scopolamine/g.

*Outbreak No. 2 (Gerber et al., 2006)*

A group of eight mares kept for student training at the Department of Theriogenology at the Veterinary Faculty of Onderstepoort had been kept on artificial pasture and were brought into a concrete paddock for a few days. Here they were fed cubed concentrate and tef hay and they had been in this paddock for 4 days when one developed acute, colic due to paralytic ileus. She exhibited severe, continuous pain and severe bilateral abdominal distention confirmed by rectal examination which revealed severe gas distention of the cecum and moderate distention of the large colon. She was unresponsive to treatment with xylazine and butorphanol and had to be euthanized for humane reasons. At necropsy the stomach was greatly distended with feed, the small intestine mildly fluid-distended and the cecum moderately and colon severely distended with gas and ingesta. A diagnosis of generalized gut atony was made. Eight days later (day 0) a mare from the same paddock and eating the same feed was admitted to the clinic after exhibiting moderate colic for a few hours. She only exhibited mild, bilateral abdominal distension, all other parameters being within normal limits. On rectal examination moderate gas distention of the cecum was evident. This mare, however, had severe bilateral mydriasis. She was treated symptomatically with flunixin and recovered from the colic without any further treatment. Mydriasis was, however, still very obvious the next day (day 1) and a moderate degree of mydriasis could be detected for the next 5 days. Urine was collected from her on days 1–3 and kept frozen until analyzed.

**Examination of the hay:** The hay being fed to the horses in the paddock was inspected on day 1. A piece of dried *Datura ferox,* identified by its characteristic, long-spined fruit capsule (Henderson, 2001), was found at the bottom of the metal trough in which the morning's tef hay had been eaten. The tef hay was immediately withdrawn and no further cases of colic developed in this group. Five bales of the tef hay from this particular consignment were subsequently carefully examined for any foreign material (*vide supra*) which revealed that this too was of poor quality with three containing *Datura* spp. One had one specimen of *D. ferox* with almost mature fruit, another contained a stem which could have been either *D. ferox* or *D. stramonium* and the last contained three specimens of *D. ferox* with fruit and numerous sterile specimens that could have been either species Specimens of the dried plant material identified as, or resembling *D. ferox*, were collected and analyzed for tropane alkaloids.

**Extraction, identification and quantification of tropane alkaloids:** Following overnight incubation of urine with β-glucuronidase to free the glucuronylated alkaloids, the acidified urine was once extracted with ethyl acetate and further like the plant extraction as described (*vide supra*). Extraction of plant material was done as described *(vide supra).* In the plant material the average concentrations of hyoscyamine and scopolamine were 18.5 and 1 553 μg/g, respectively. In the urine hyoscyamine was present at 0.4 ng/ml on Day 1 and barely detectable on day 2 whereas the scopolamine levels were 68, 5 and 0.4 ng/ml on respectively days 1–3.

## DISCUSSION ON BOTH CASES AND ON EQUINES IN GENERAL

Both incidents of intoxication were attributed to consignments of exceptionally poor quality *Datura* contaminated tef hay. Horses being fastidious feeders would normally avoid fresh *Datura* plants because of their offensive smell. However, when the plants are dry and contained in baled hay the smell largely dissipates. Additionally the dried young plants are brittle and disintegrate when the bales are opened and become so intermingled that the animals cannot avoid eating it. The young plants have, consequently, not been discovered in South Africa in contaminated hay in the past and the diagnosis not been confirmed despite strong evidence of suspected *Datura* poisoning.

The clinical signs encountered during the first outbreak were characterized by only gastrointestinal colic manifested as retarded motility. The usually expected signs of muscarinic receptor blockage, *inter alia* mydriasis, tachycardia, sweating and dry mucous membranes (Adams, 2001; Brown and Taylor, 2001) were not recorded at all. Furthermore, stimulatory CNS signs, e.g. what could be expected from hallucination, were absent and animals were, in fact, very docile. Repeated attacks on the farm were initially probably due to re-exposure to the contaminated hay. One horse, however, developed severe, recalcitrant

impaction colic 3 days after withdrawal of the hay and eventually had to be euthanized 11 days after the last possible exposure to *Datura.*

The spate of impaction colic of the first outbreak was, nevertheless, attributed to *Datura* intoxication as withdrawal of the contaminated hay, resulted in complete termination of its incidence. The case of serious colic that necessitated euthanasia 11 days after the last possible exposure to *Datura* contaminated hay was remarkable. A certain way to have confirmed the diagnosis in this outbreak would have been the determination of tropane alkaloid levels in the urine of affected horses. However, there was no access to this facility at that time.

In the second outbreak, apart from unresponsive gut atony, no other specific anti-muscarinic signs were noted in the first horse of this group that had to be euthanized due to unresponsive impaction colic. However, indications are that this mare had suffered from per acute *Datura* intoxication. Except for transient impaction colic, which responded well to conservative treatment, anti-muscarinic signs were indeed present in the second mare. The signs were, however, limited to a slight tachycardia, marked mydriasis for the first 2 days and mild mydriasis for 7 further days, a remarkably long period. In contrast to the first incident where colic kept on recurring even after the contaminated hay had been withdrawn, this mare's colic attack was very transient. This could possibly be linked to the fact that mainly scopolamine from predominantly *D. ferox*, as opposed to hyoscyamine and scopolamine from predominantly *D. stramonium* in the previous case could have been involved. The analytical method was so sensitive that hyoscyamine and scopolamine could be observed in urine specimens at even ng/ml concentrations. Using this methodology none of the other minor tropane alkaloids meteloidine, noratropine and apoatropine (Table 70.2) could be detected in the urine or in the *D. ferox* plant specimens. The tropane alkaloid analysis of this horse's urine as well as of the suspect plant material indicate that only (or mainly) *Datura ferox* might have been the cause of intoxication.

The fact that hyoscyamine was only detected in the urine of the horse at a very low concentration and ratio in comparison to scopolamine is in accordance with the ratio of these two alkaloids present in the leaves (arguably the main vegetative component ingested) of the plant. These levels and ratios are also in accordance with that data of the survey (Table 70.1) on *Datura ferox* occurring in South Africa.

The metabolism of anti-muscarinic tropanes varies greatly in different laboratory animals (*vide supra*) and comprehensive studies in various livestock species (*inter alia* the horse) do not appear to be available.

However, the administration to horses of *Datura innoxia* (*D. meteloides*) with a hyoscyamine:scopolamine ratio of *ca.* 1.5:1, resulted in urine concentration ratios of only *ca.* 1:10. Therefore, upon ingestion very little non-metabolized atropine (hyoscyamine?) is excreted in urine in comparison with comparable administration of scopolamine. Furthermore, Galey *et al*. (1996) found that both atropine (hyoscyamine?) ($t_{1/2} = 1.7\,\text{h}$) and scopolamine ($t_{1/2} = 2.3\,\text{h}$) were not present in the urine after 24 h in spite of the fact that one of the horses (administered the plant at 0.5 g/kg) had developed severe gastrointestinal atony, sweating and colic. This is in contrast to the present findings where, in this clinical case of *Datura* poisoning, scopolamine was present in the horse's urine at a level of 68 ng/ml 24 h after showing signs of intoxication and was still detectable (0.4 ng/ml) at 72 h. The fact that the mare still continued exhibiting mydriasis at a stage where the scopolamine was presumably depleted could indicate exceptional potency of these alkaloids due to very strong and long-acting receptor binding with the activity persisting even after the majority of the alkaloids had cleared the urine.

Galey and his associates (1996) are of opinion that tropanes behave erratically in the horse and any substantial exposure should be treated with extreme care. Despite the short half-life following low doses it seems that the residence time at higher levels may be prolonged and it is surmised that once atony sets in it seems to be intractable. This could explain why the one horse in the first incident had to be euthanized 11 days after the last possible exposure. It is, therefore, postulated that the horses during the first outbreak under discussion might have had just transient signs of mydriasis, etc., or that this was missed and that only the long-term effects on the gastrointestinal tract were noticed. In this incident both hyoscyamine

**TABLE 70.2 Tropane alkaloid profiles of selected *Datura* spp. plants and seed detected by LC/MS/MS**

| | Range of related tropane alkaloids (μg/g) detected in plants and seed | | | | |
|---|---|---|---|---|---|
| **Species** | **Hyoscyamine** | **Scopolamine** | **Meteloidine** | **Noratropine** | **Apoatropine** |
| *D. stramonium* | 336–800 | 226–1036 | 11–560 | ND–44 | 6–33 |
| *D. ferox* | 2–20 | 338–1800 | 1.4–321 | 0.8–31 | ND |

ND: not detected.

and scopolamine were involved whereas in the second incident it was presumably mainly scopolamine from *D. ferox*.

During routine screening for drugs in thoroughbreds post racing (implying that they had been deemed fit for racing) by the laboratory of the South African National Horse Racing Authority (SS de Kock, personal observations, 2002) confirmed the observations by Galey *et al*. (1996). It was interesting that scopolamine had been detected in up to eight urine specimens annually for the past few years. In these specimens scopolamine was prominent at levels sometimes exceeding 100 ng/ml, most often with hyoscyamine also present, but at much lower concentrations. The presence of tropane alkaloids in apparently healthy thoroughbreds' urine suggests that feed or bedding (Galey *et al*., 1996) contamination with *Datura* may be more widespread than realized up to now. The etiology of many incidents of impaction colic are never ascertained and the possibly that it might be due to grain contamination with *Datura* seed or hay contamination with the plants, should be considered.

In the first outbreak (Naudé *et al*., 2005) affected animals were depressed and docile which is in contrast to the hyperexitability, muscular spasms, rigor and convulsive seizures described by Barney and Wilson (1963), but in accord with the signs described by Williams and Scott (1984) and Ducharme and Fubini (1983). Colic is the dominant sign described by other authors (Galey *et al*., 1996; Schulman and Bolton, 1998) and it is possible that the nervous signs mentioned by Barney and Wilson (1963) could have been due to per acute colic or even hallucination.

Galey *et al.* (1996) refer to atropine (*d,l*-hyoscyamine) and scopolamine found in *Datura innoxia*. As this alkaloid occurs as the levorotatory isomer in the plant, it may be assumed that they actually refer to *l*-hyoscyamine. The tropane alkaloid content (determined by GC/MS as the trimethylsilyl derivatives) of the plants dosed to horses in a paste was 370 mg atropine (probably as *l*-hyoscyamine) and 550 mg scopolamine/kg. They determined that only at 0.05% *Datura innoxia* plant material, colic was induced: "That horse developed gastrointestinal atonia, tachycardia, sweating and colic beginning within 2 h after dosing. Signs had not resolved by 72 h". This represents a dose of 0.185 mg atropine (probably *l*-hyoscyamine) and 0.225 mg scopolamine/kg. At 0.01% (equivalent to respectively 0.037 mg/kg L-hyoscyamine (atropine?) and 0.04 mg/kg scopolamine) there were no clinical signs of intoxication. However, scopolamine was detected in the urine of even the horse that had even received a dose as low as 0.00125% at more than 100 ng/ml after 1 h but it had disappeared all together at 10 h.

Ducharme and Fubini (1983) found atropine sulfate to cause colic at 0.044 mg/kg (equivalent to only 0.022 mg/kg of *l*-hyoscyamine) and marked atony lasting 12 h at a dose of 0.176 mg/kg. The latter would be equivalent to only 0.088 or *ca.* 0.1 mg *l*-hyoscyamine/kg. The toxic oral dose of hyoscyamine affecting gastrointestinal motility in the horse (not taking the possible additive effect of additional scopolamine into consideration), therefore, seems to be in the order of about 0.01–0.1 mg/kg (or 0.02–0.2 mg atropine/kg) if taken repeatedly.

In the first incident under discussion the dried *Datura* plants ingested by the horses contained an average of 1450 mg *l*-hyoscyamine and 1300 mg scopolamine/kg (*vide supra*). In terms of just *l*-hyoscyamine, the equivalent dose of plant material containing 0.1 mg of *l*-hyoscyamine/kg on a repeated basis could thus have resulted in intractable impaction colic would have been only 69 mg/kg (ca 70 mg/kg) or ca 0.007% body mass.

From a pharmacological viewpoint neostigmine appeared to be the drug of choice in hyoscyamine poisoning but it did not have any dramatic beneficial effect on the intestinal atony in the first outbreak. Mild cases receiving the drug recovered as well as those not receiving it. As the dose of neostigmine used in this case was slightly higher than that usually employed, the treated horses were walked after injection to obviate possible side effects. There were none and thus higher doses of neostigmine could possibly have been used (*vide infra*).

The *Datura* contamination was limited to the dry tef, hay in these two outbreaks. Tef is sown annually and *D. stramonium* and *D. ferox* are annual weeds and it must, consequently, be expected that tef (and any other annual grasses or first stands of perennial grasses or even alfalfa) would easily be contaminated with poisonous weeds. Tef should routinely be sprayed with broad-leaf herbicides a couple of weeks before the hay is cut in order to ensure freedom from noxious weeds (A. Lawrence, tef farmer, Greylingstad, South Africa – personal communication, 2002).

It is most difficult once *Datura* has been found in a few bales of hay of a particular consignment, to attempt to exactly quantify the extent of contamination. It is impractical to do a detailed, layer-by-layer examination of every bale. Problems may either be due to only one or two bales or most of the bales may be contaminated. Manual removal of all toxic plants in order to render contaminated bales safe is impractical. This procedure is both very labor intensive and, due to the brittle nature of the fragile dried young plants, impossible. Such hay should certainly not be used for equines. Provided the contamination is not gross there, however, appears to be only minor danger to ruminants fed such contaminated hay (Kellerman *et al*., 2005).

The danger of *Datura* seed to particularly equines (Kellerman *et al*., 2005) and man (Adams, 2001; Brown and Taylor, 2001) has always been recognized. References to the toxicity of vegetative parts of *Datura* to man is well-known (Steyn, 1934; Watt and Breyer-Brandwijk, 1962; Brown and Taylor, 2001) but have up to now, been largely ignored in relation to livestock as intoxication from it was not diagnosed.

# RUMINANTS

## Cattle

Fresh *Datura* is frequently grazed by ruminants in South Africa as part of their overall diet under grazing conditions (TW Naudé and TS Kellerman, Onderstepoort, personal observations past three decades). The vegetative part of the plant as such has, consequently, to date been regarded as of relatively minor toxicological importance (Kellerman *et al*., 2005). During the survey conducted in South Africa (Tale 70.1) single lush-growing specimens of both *D. ferox* and *D. stramonium* were collected in an overgrazed, well-fertilized area on a specific beef cattle farm. The plants contained, respectively, 149 and 260 μg/g hyoscyamine and 988 and 260 μg/g scopolamine. A few weeks later these 1–2 m high plants had been mowed down by the herd with no apparent deleterious effect (TW Naudé, personal observation, 2000).

An early report on jimsonweed toxicity in cattle is by Case (1956). A group of 7 hungry spring beef calves "mowed down" a patch of *D. stramonium* plants in a few hours: "They were dead within a week from . . . a textbook picture of poisoning by the Jimsonweed group . . . ". No data are, unfortunately, given on which to validate this statement. Burrows and Tyrl (2001) cites a Czechoslovakian incident reported by Ofukany *et al*. (1983) where mass intoxication of cows occurred on *D. stramonium* where out of 510 cows at risk, 44 died and 22 more had to be destroyed.

Nelson *et al*. (1982) exposed a control and 3 test groups ($n = 3$) of dairy type heifers to diets containing 0, 8.8, 880 and 4410 *D. stramonium* seeds/kg for 14 days. Only at the highest dose repeated cycles of marked anorexia, which abated after 2–3 days only to be repeated, occurred. During these spells bloat, dry muzzles, miosis (mydriasis?) and tenesmus were observed in two of the three heifers. It was deducted that the poisoning was self-limiting in that the anorexia allowed the heifers to metabolize the absorbed alkaloids to a level where they could start eating again. The seed contained 0.26% atropine (probably as *l*-hyoscyamine) and 0.55% scopolamine but the diets were not analyzed. Although the seed had not been milled and some seed might not have been digested, it was estimated that the toxic dose of alkaloids was 2.49 mg atropine (probably hyoscyamine thus actually 5 mg of atropine) plus 0.5 mg scopolamine/kg/day.

This is in accordance with the unpublished pilot experiment by TW Naudé and NPJ Kriek, Onderstepoort Veterinary Research Institute (1969) as cited by Kellerman *et al*. (2005), where a single dose 5 mg atropine sulfate/kg *per os* produced mild anti-muscarinic signs in a bovine. Cattle are probably susceptible to acute tropane alkaloid intoxication but it seems to be very dose specific and no cumulative effects are evident.

## Sheep and goats

In the pilot experiment by Naudé and Kriek (unpublished data, 1969) as cited by Kellerman *et al*. (2005), they could not produce acute toxicity in sheep with excessive doses of *Datura* seed with an alkaloid concentration of *ca*. 0.2% by rumen fistula at up to 50 g/kg. The susceptibility of a merino type sheep weighing approximately 30 kg to atropine was then tested by giving it an intravenous bolus injection of 1 g atropine sulfate (*ca*. 33 mg/kg, thus 16 mg hyoscyamine/kg). Its pupils dilated maximally, its heart rate shot up to a steady ca 100 per min and the next day it was clinically normal. An oral dose of atropine sulfate at 50 mg/kg evicted only mild, transient signs of muscarinic blockade.

El Dirdiri *et al*. (1981) dosed groups of male desert sheep and Nubian goats daily until death or disposal with fresh, green *D. stramonium* leaves or fruit. The sheep ($n = 2$) were dosed with both fruit or leaves at 10 g/kg/day and with leaves only at 1 g/kg/day. Signs set in after 2–6 days and continued up to death at 12–38 days at the higher dose whereas signs set in and at 35 and 45 days and the sheep were disposed of at 45 and 61 days at the lower dose. The goats ($n = 4$) were similarly dosed with both leaves or fruit at 10 g/kg/day and with fruit only at 2.5 g/kg/day. Signs set in after 2–101 days and continued up to death or disposal at 30–136 days at the higher dose, whereas at the lower dose signs set in at 36–110 days and the animal died or were disposed of at 30–136 days.

The signs noted in both species included reduced water intake, ataxia, intermittent hyperesthesia, tremors, drowsiness and recumbence. No anti-muscarinic signs were reported. Histopathological examination revealed focal necrosis and fatty vacuolation of centrilobular hepatocytes and renal tubular degeneration.

## Springbok

Lindeque and Scheepers (1992) reported that a group of these antelopes, *Antidorcas marsupialis*, in the northern Namibian desert area were forced to graze reasonably exclusively on dense stands of the alien invader, *D. innoxia.* Two adult male animals from this group exhibited abnormal behavior in having an unsteady, jerky gait and a delayed response to visual and auditory stimuli allowing the observers' vehicle to approach to a quarter the distance at which these antelope usually fled. They ascribed this to possible tropane alkaloid toxicity.

In ruminants microbial degradation of some hyoscyamine, scopolamine and related tropanes (most probably by hydrolysis of the ester bond) presumably takes place in the rumen. The toxic dose of hyoscyamine *per os* for cattle appears to be about 2.5 mg/kg in *Datura stramonium* seed. The poisoning was also self-limiting as anorexia

prevented further intake until the levels of alkaloids were reduced to allow normal intestinal function. The signs of intoxication were, however, that of mild muscarinic receptor blockade. Naudé and Kriek (1969), cited by Kellerman *et al*. (2005), also observed mild anti-muscarinic signs with orally administered atropine sulfate at 5 mg/kg. The subcutaneous therapeutic dose of atropine for ruminants (0.05 mg/kg) is, however, the same as for equines. In contrast the toxic oral dose for the horse (a hindgut fermenter) is, *vide supra*, 0.2 mg atropine/kg (equal to 0.1 mg/kg of hyoscyamine). The signs of mainly ataxia and the extended course of intoxication over weeks and even months of goats and sheep produced by El Dirdiri *et al*. (1981) are also not at all reminiscent of muscarinic receptor blockade. Massive doses of both *D. stramonium* leaves or green fruit were needed daily over a period of 12–61 days in sheep and 30–134 days in goats to cause death at an average of 32 days in sheep and 68 days in goats.

*Datura* spp. also contain calystegines (glycosidase inhibitors, *vide supra*) and its possible involvement with *Datura* spp. is mentioned by Burrows and Tyrl (2001). Calystegine $B_2$ was isolated from *D. wrightii* (Nash *et al*., 1993). Although only low levels were found in *D. stramonium* by Dräger *et al*. (1995), it is known that their concentration varies from time to time in the same species (Molyneux R, APHIS, USDA, California, personal communication, 2006). The possibility is thus real that the sheep and goats with the aberrant nervous signs in the chronic experiment reported by El Dirdiri *et al*. (1981), might have succumbed from lysosomal storage disease rather than from chronic muscarinic blockade.

Recently, it was observed that tropane alkaloid levels in the purple-stemmed and green-stemmed varieties of *D. stramonium* (Table 70.1) varied by almost 100% and it is thus possible that the same may apply to the calystegine polyhydroxylated pseudotropine alkaloids. The observation on the abnormal behavior of springbok that were forced to graze *D. innoxia* (Lindeque and Scheepers, 1992) could possibly also be due to this syndrome.

## Pigs

As a hindgut fermenter it is to be expected that this species would be susceptible to tropane alkaloid intoxication. Very little data on this could, however, be obtained. According to Adams (1995), swine are not resistant to ingested material and poisoning occurs more often than in other spp. from eating belladonna, the deadly nightshade plant. The only positive intoxication with signs of typical muscarinic blockade in pigs is reported by Keeler (1984). Subsequent to the speculative linking of arthrogryposis in pigs to *Datura* by Leipold *et al*. (1973), Keeler disproved the speculation by feeding dried *D. stramonium* vegetative material at levels causing typical muscarinic blockade signs to pregnant sows at the two most critical periods of organogenesis. Two groups of animals ($n$ = 4–5 and 5) received for respectively 40 and 10 days at levels of 1.2–1.7 g/kg/day. One animal died at 1.7 g/kg and all showed ataxia, lethargy, docility and drowsiness and pupil dilatation during the treatment period. No arthrogryposis was detected in any of the offspring.

The alkaloid levels of the plant material is not given but calculated from South African data (Table 70.1) the combined levels of hyoscyamine and scopolamine (which are about equal in this species) the toxic dose of alkaloids for the pigs was at an alkaloid level of between 1.8 and 2.6 mg/kg. Worthington *et al*. (1981) on the contrary, fed two groups of pigs ($n$ = 4) with ground *D. stramonium* seed in a ration at alkaloid levels of respectively 1.4 and 2.2 mg/kg/day for 4 days without any signs of intoxication. The pigs, however, found the mixture rather unpalatable. In this publication they, however, refer to litigation where it was claimed that *Datura* seed contamination in corn dust and grits was responsible for 803 deaths in fattening pigs and severe retardation in growth of many more. Similarly, Janssens and de Wilde (1989) fed two groups of pigs ($n$ = 4) for 12 weeks with linseed oil cake contaminated with *Datura stramonium/ferox* seed at a scopolamine level of 2 mg/kg mixed into their grower/finisher ration. The final intake of alkaloid was calculated to have been between 0.05 and 0.06 mg/kg/day. No signs of intoxication were seen but a statistically significant lower intake and weight gain compared to the control group occurred and it took 10 days longer for the test groups to attain slaughter weight. It was concluded that unpalatability at even this rather low alkaloid level contributed greatly to these differences. As no atropine and only scopolamine was detected in this meal, it can be deduced that the seed contamination was probably only that of *D. ferox* (*vide supra*, Table 70.1).

In their publication on the effects of a mixture (92:2) of scopolamine/hyoscyamine in broilers, Kovatsis *et al*. (1993), cite an ILBO report, TNO Nutrition and Food Research, Wageningen (1992) entitled *Toxicity of Datura Alkaloids in Pigs.* It is cited that "pigs fed this mixture at as low as 1.5 mg/kg feed, exhibited marked pupil dilatation and abdominal gas accumulation". An interesting South African case of "head bashing" of the foreheads against the bars above the feeding troughs, in especially adult sows and boars, is described by Spencer *et al*. (2000). The feed was made with maize (corn) contaminated with "*Datura stramonium*" seed. On withdrawal of the contaminated corn the syndrome, suspected to have been due to tropane alkaloid hallucination, ceased. Unfortunately, other typical signs of muscarinic blockade, e.g. mydriasis, were not checked. As the seeds of *D. stramonium* and *D. ferox* look identical (*vide supra*) both could have been involved and it is possible that the pigs had consumed a

diet especially high in scopolamine known to be especially hallucinogenic in man (*vide supra*). The toxic dose of tropane alkaloids for swine is not known but circumstantial evidence indicates that poisoning may certainly be a problem. In addition, milled *Datura* seed in a ration affects its palatability.

## Chickens

The chicken seems to be rather resistant to poisoning. In a well planned and executed trial, Kovatsis *et al*. (1993), investigated the effect of pure scopolamine and hyoscine at a ratio of 98:2 (the ratio at which it occurs in *D. ferox* seed) on broiler chicks. Five groups ($n = 20$, 16 females and 4 males) were exposed over 90 days at levels of 0, 1.5, 15, 75 and 150 mg/kg of feed. Weights were determined weekly, clinical signs were checked daily, clinical chemistry on serum enzymes was done twice. No signs of muscaric receptor blockade or changes of practical significance in these parameters were found except for a significant reduction in weight gain up to day 52 at the higher two doses but not after that. At the highest dose this occurred only during the first 4 weeks. The effect on final weight is, unfortunately, not given.

In a much smaller and shorter-term trial on day-old male chick groups ($n = 5$), Day and Dilworth (1984) fed milled *D. stramonium* seed with an unspecified alkaloid level at 0%, 1%, 3% and 6% admixed in their rations. At 3 weeks there was also a significant drop in weight gain at the two high doses. Similarly, Flunker *et al*. (1987) fed milled *D. stramonium* seed of unknown alkaloid level in their normal rations for 3 weeks at between 0.5% and 3% to six groups ($n = 24$) of day-old chicks and for 14 days at 1%, 2% and 3% to adult White Leghorn hens ($n = 5$). No deleterious effect growth in the chicks and egg production in the hens occurred except that the intake in the latter was decreased at the 3% level. Indications of early embryonic death and malformed embryos in chicken eggs inoculated into the yolk sac with a 92:2 mixture of scopolamine and hyoscyamine at 10 μg or more (Magras *et al*., 1993) does not appear to be of any practical significance. Steyn (1934) cites Sinclair (1898) that ostrich poults are susceptible to *Datura stramonium* seed poisoning. They became sleepy, staggered about before coma set in. This phenomenon has never been reported again during the past century. In practice, poultry will most probably only be exposed to feed contaminated with *Datura* seed. Chickens do not appear to be susceptible to acute tropane alkaloid poisoning. However, the negative effect on weight gain in broilers and possibly egg production in hens and perhaps unpalatability ascribed to milled *Datura* seed as also observed in pigs, might well be of significance in the poultry industry.

# TREATMENT

Impaction colic in equines due to ileus, must be treated symptomatically and according to rectal findings, the extent and severity of the usual signs of colic (pawing, sweating and rolling), reduced or absence of borborygmi, whether nasogastric intubation reveals reflux, if clinicopathological findings are within normal limits and fluid obtained by abdominocentesis reveal any abnormalities (Naudé *et al*., 2005; Gerber *et al*., 2006).

Therapy should include water by nasogastric tube, laxatives *per os* ($MgSO_4$ or technical oil), cisapride *per os*, polyionic fluid by intravenous infusion at a rapid rate (4 ml/kg/h) and an analgesic such as flunixin when required. This should be continued until all signs of discomfort are absent and rectal examination reveals resolution of the impaction.

The use of reversible AChE inhibitors as specific pharmacological antagonists to overcome the muscarinic blockade is of paramount importance in the horse. Neostigmine is generally used in veterinary medicine for this purpose. However according to Brown and Taylor (2001) physostigmine (eserine), a tertiary natural alkaloid is regarded as the drug of choice to treat tropane alkaloid intoxication in man. It rapidly abolishes delirium and coma and should seriously be considered as a cholinergic in especially the horse. It is, in contrast to neostigmine (a quaternary alkaloid), not ionized and consequently readily passes the blood–brain barrier (Brown and Taylor, 2001). It might also just overcome the recalcitrant, perceived gut receptor blockage. As it is rapidly metabolized in man, repeated doses at short intervals (1–2 h) are necessary. It is, however, a very potent drug with a narrow therapeutic index and should be used with circumspection. Adams *et al*. (1984) found in their study on the effect of drugs on the myoelectrical and mechanical activity of the jejunum and pelvic flexure of the equine colon, that whilst neostigmine increased the propulsive activity of the pelvic flexure and regularly resulted in defecation, it had no effect on the motility of the jejunum.

Of the natural cholinomimetic alkaloids, only arecoline and pilocarpine are not ionized and as arecoline also acts at nicotinic sites (Brown and Taylor, 2001) pilocarpine could also be considered as a pharmacological antagonist that might also cross these barriers.

# FUTURE RESEARCH DIRECTIONS

## Horses

Reasonable data are available on the effects of atropine (and thus *l*-hyoscyamine) in this species. However, no

data are available on pure scopolamine and its contribution to the impaction colic syndrome seen with *Datura* spp. As this intoxication possibly occurs more frequently than expected with contaminated hay, the use of pharmacological antagonist drugs that cross tissue barriers, e.g. physostigmine and other tertiary cholinomimetic alkaloids should be thoroughly investigated in the treatment of the resultant intractable, and frequently fatal, impaction colic. It would appear from the work of Galey *et al*. (1996) that with early acute intoxication the tropane residues in urine will be in the mg/ml range. This should be followed up as a matter of priority for diagnosis.

### Cattle

There is a lack of data in relation to the acute oral toxic doses of both atropine (thus hyoscyamine) and of scopolamine in bovines. This species appears to be susceptible. Being continuously exposed to grain contamination with *Datura* seed, the chronic effect of sub-toxic doses on feed intake, growth and production of both beef and dairy animals should be explored. The possibility of adaptation of ruminal microorganism to detoxify tropane alkaloids should be further investigated.

### Sheep and Goats

These two species are very different in reaction to many drugs and the actual acute oral toxic doses of both atropine and scopolamine should be determined. They both, however, appear to be rather refractory to acute anti-muscarinic tropane intoxication. The possibility that calystegines had been the cause of peculiar chronic syndrome described by El Dirdiri *et al*. (1981), should be followed up.

### Swine

There are definite indications that this hindgut fermenter of fiber (like the horse) is probably rather susceptible to acute intoxication. As another species very frequently being fed grain contaminated with *Datura* seed, the oral acute toxic dose of both atropine and scopolamine should also be determined here as well as the effect of chronic exposure at sub-toxic levels on feed intake, growth and production.

### General

The non-tropanyl alkaloid meteloidine (Figure 70.4.2) occurs haphazardly in various *Datura* spp. at levels sometimes comparable with hyoscyamine and/or scopolamine. No toxicity or pharmacological data on it appears to be available and its possible contributory role in tropane alkaloid poisoning should be determined.

## ACKNOWLEDGMENTS

The outstanding services of both the Onderstepoort Veterinary Library and the Merensky Library Branch of the University of Pretoria, particular Mr. Faan Naudé, in obtaining relevant literature at short notice, is most sincerely appreciated. The unstinting support of the organic chemist, Dr. Moira Bode (CSIR, South Africa), Reg Smith of Phytex Australia and my veterinary and other colleagues at the Faculty and particularly of the Section of Pharmacology and Toxicology of the Department of Paraclinical Sciences at the Veterinary Faculty at Onderstepoort, University of Pretoria, is gratefully acknowledged.

CHAPTER

# 71

# Fescue toxicosis

*Dennis J. Blodgett*

## INTRODUCTION

A hardy tall fescue grass (*Festuca arundinacea* Schreber) was obtained from a Kentucky farm in 1931 and was first marketed commercially in 1943 (Ball, 1984). Today, this variety of tall fescue, Kentucky 31, occupies more than 20 million hectares in the United States, primarily in the southeastern region of the United States (Stuedemann and Seman, 2005). It is a cool season grass that grows well in the fall producing substantial forage for the winter months. By 1948, fescue foot problems had been described in New Zealand and in 1950, the same syndrome was reported in the United Sates (Bacon, 1995). In 1973, it was noticed that cattle on a Kentucky 31 pasture were very unthrifty compared to cattle on an adjoining non-fescue pasture (Schmidt and Osborn, 1993). This observation initiated an investigation that revealed a fungus growing within the plant (endo = within; phyte = plant) (Bacon *et al.*, 1977). Today, it is believed that >95% of tall fescue pastures containing mostly the Kentucky 31 variety are infected by the endophyte (Yates and Powell, 1988). Endophyte-infected (E+) fescue is estimated to cause more than 1 billion dollars of loss yearly in livestock production in the United States (Oliver, 1997).

## BACKGROUND

### Endophyte name

Bacon *et al.* (1977) initially discovered the endophyte and based on earlier morphologic research classified it as *Epichloe typhina*. As is common for many microbial organisms, it was later renamed as *Acremonium coenophialum* (Morgan-Jones & Gams) (Morgan-Jones and Gams, 1982). Further molecular phylogenetic evaluation has generated the latest name of *Neotyphodium coenophialum* (Morgan-Jones & Gams) Glenn, Bacon & Hanlin comb. nov. (Glenn *et al.*, 1996). A similar endophyte, *Neotyphodium lolii*, is found in perennial ryegrass. Endophytes are not uncommon in a number of forage grasses.

### Mutualism

The tall fescue plant and the endophyte enjoy a mutualistic relationship (Thompson *et al.*, 2001). Each benefits the other. The plant supplies a comforting and safe internal environment for the endophyte along with all the required nutrients. In return, the endophyte lives in intercellular spaces in the plant without disrupting cells of the plant. The endophyte generates multiple toxins that are distributed throughout the plant. The toxins make the plant more resistant to drought, insects, parasitic nematodes, fungi and herbivores. The endophyte invades seed heads of the plant and is able to continue its relationship with the next generation of fescue through its contamination of the seed. Endophyte infections cannot be transferred naturally to a non-endophyte-infected variety of tall fescue. However, E+ varieties of fescue are more hardy and persistent than non-endophyte fescue plants and thereby, may eventually take over a pasture. Endophyte-infected plants produce more forage and seeds than do non-infected plants.

### Toxins secreted

Multiple classes of toxins are produced by *N. coenophialum* including ergot alkaloids, peramine and loline alkaloids (Porter, 1995). Peramine and loline alkaloids are primarily

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

insect deterrents. Loline alkaloids belong to an aminopyrrolizidine group of alkaloids, but are not known to cause hepatic problems similar to pyrrolizidine alkaloids in other plant species. The loline alkaloids found in fescue include loline, *n*-acetylloline, *n*-formylloline, *n*-acetylnorloline and *n*-methylloline (Porter, 1994).

## Ergovaline

### *General toxicity*

Among the ergot alkaloids found in tall fescue, ergovaline is by far the most prevalent ergopeptide (Porter, 1995). It accounts for approximately 90% of the ergopeptide alkaloid content of tall fescue (Lyons *et al*., 1986). Estimates of the minimum threshold toxic concentrations of ergovaline in fescue to cause clinical problems range from 50 to 500 ppb (Moubarak *et al*., 1993; Tor-Agbidye *et al*., 2001; Aldrich-Markham *et al*., 2003). Minimal concentrations depend somewhat on the type of syndrome being considered, the species affected and environmental temperatures. Species susceptibility from most to least susceptible would be: horses (i.e. pregnant mares) > cattle > sheep (Aldrich-Markham *et al*., 2003). In general, ergovaline concentrations greater than 200 ppb dry weight are toxic for cattle and horses (Rottinghaus *et al*., 1991; Blodgett, 2001). Ergovaline is a peptide (i.e. peptine) alkaloid with a lysergic acid structure combined with three amino acids. It differs in structure from ergotamine by one amino acid. Other ergot alkaloids found in fescue are lysergic acid amides (e.g. ergonovine) and clavine alkaloids (Porter, 1995).

### *Reason for primary toxin*

The ergopeptide alkaloids are believed to be the major toxins responsible for the multiple fescue toxicosis syndromes seen (Porter and Thompson, 1992). Since ergovaline is the most prominent ergopeptide alkaloid, it probably dictates the likelihood of a toxicosis. Ergovaline is difficult to purify and synthesize, so little direct fescue research has been done with pure ergovaline to prove that it is the primary toxin in fescue. There are multiple reasons to believe that it is the primary toxin, however. An experiment with synthetic ergovaline in sheep reproduced most clinical signs of the summer slump syndrome seen in cattle (Gadberry *et al*., 2003). Ergovaline injected intraperitoneally into cattle for 3 days produced increased rectal temperatures and respiratory rates observed with summer slump (Spiers *et al*., 2005). Ergotamine and bromocryptine, other ergot alkaloids, are able to reproduce fescue toxicosis syndromes (Blodgett, 2001). Ergovaline is very potent as a vasoconstrictor in *in vitro* models (Oliver *et al*., 1998). Ergovaline is a strong prolactin inhibitor, whereas ergonovine, a lysergic acid amide in fescue, is unable to produce typical signs of fescue toxicosis or lower prolactin concentrations in cattle (Oliver *et al*., 1994). Antibodies against ergot alkaloids are able to ameliorate some clinical features of fescue toxicosis in cattle and mice (Hill *et al*., 1994; Rice *et al*., 1998). New novel endophyte varieties of fescue that lack ergovaline, but not other types of fescue toxins, do not cause fescue toxicosis (Roberts and Andrae, 2004). Syndromes similar to fescue toxicosis are seen when ergotized grains infected by *Claviceps purpurea* are ingested by livestock (Thompson *et al*., 2001). Finally, dopamine $D_2$ antagonists, which stimulate prolactin secretion, are able to alleviate most of the toxic effects of fescue (Lipham *et al*., 1989; Cross, 1997).

### *Seasonal variation*

The concentration of ergot alkaloids in fescue pastures varies with the season (Rottinghaus *et al*., 1991). Ergovaline is low in the spring, reaches peak concentrations in seed heads during the summer months, decreases somewhat during the early fall and rebounds with fall regrowth. Seed heads contain the highest concentration of ergovaline. Stockpiled fescue pasture has more ergot alkaloids early in the winter than late in the winter (Roberts and Andrae, 2004). Drought and rainy conditions tend to increase ergovaline concentrations (Arechavaleta *et al*., 1992; Aldrich-Markham *et al*., 2003). Fertilization of fescue pastures with nitrogen- and phosphorous-based fertilizers or poultry litter also increases ergot alkaloid concentrations (Stuedemann and Seman, 2005). Since ergovaline is really a mycotoxin and mycotoxin production and persistence is dependent on multiple seasonal and environmental conditions, concentrations of ergovaline in tall fescue would be expected to vary from season to season and year to year (Lyons *et al*., 1986).

# PHARMACOKINETICS/ TOXICOKINETICS

## Absorption

Little research has been devoted to *in vivo* absorption of ergot alkaloids in livestock. After cannulation of ruminal, gastric and mesenteric veins of sheep consuming E+ fescue, ergot alkaloids were only detected in ruminal veins (Hill, 2005). However, *in vitro* tissue specimens of rumen, reticulum and omasum are all capable of ergot alkaloid transport. Ergovaline is hard to detect in rumen fluid and is metabolized by rumen microbes to lysergic acid. Other researchers have found 50–60% of ingested ergovaline in abomasal contents, but minimal remaining amounts of ergovaline in ileal contents or feces (Oliver, 1997). Whether or not ergovaline is absorbed in the live animal quickly and effectively prior to metabolism by rumen microbes is not known for sure.

## Distribution/metabolism

Ergovaline is only in ppb or low ppm in E+ tall fescue, so the dilution factor in the body and sensitivity of various methods make evaluation of the concentration in any organ extremely difficult. Therefore, little is known about the distribution of ergovaline and other ergot alkaloids in the body. Intravenous injection of several ergopeptides in calves documented a distribution and tissue equilibrium phase in serum lasting approximately 1 h (Moubarak *et al.*, 1996). This was followed by an elimination phase with a half-life of approximately 20–30 min. It is known that multiple systems in the body may show some effects of ergot alkaloid consumption including the cardiovascular system, central nervous system and abdominal fat. Ergovaline is believed to be metabolized in the liver by the cytochrome P450 3A4 subfamily of enzymes (Moubarak and Rosenkrans, 2000; Moubarak *et al.*, 2003). Cytochrome P450 3A4 is responsible for adding one or two hydroxyl groups to the peptide ergolene ring to make it more hydrophilic for excretion (Moubarak and Rosenkrans, 2000). This enzyme family is inducible in rats treated with dexamethasone, but is not induced in rats with prior ergot alkaloid exposure (Moubarak *et al.*, 2003). However, sheep fed E+ fescue had increased hepatic activity of mixed function oxidases (Zanzalari *et al.*, 1989). The indole ring of ergopeptide alkaloids may also undergo eventual oxidation (Moubarak and Rosenkrans, 2000). Whether or not other groups of enzymes are involved in metabolizing or conjugating ergovaline is unsure.

## Excretion

Metabolites of ergot alkaloids have been measured indirectly with lysergol antibodies in bile and urine of cattle (Stuedemann *et al.*, 1998). Ninety-six percent of the metabolites in cattle are found in urine. Ergot alkaloids are detected in urine within 12 h of exposure to E+ fescue and are maximal within 24 h. After removal from a fescue pasture, ergot metabolites are gone within 48 h from the urine of cattle. Similarly, post-term mares when removed from E + fescue pastures show signs of impending parturition within 48 h (Schmidt and Osborn, 1993).

# MECHANISMS OF ACTION

## Dopaminergic agonist

### Prolactin inhibition

Ergovaline is a dopamine $D_2$ receptor agonist (Oliver, 1997). Dopamine agonists have a negative feedback mechanism on prolactin secretion by the pituitary. Prolactin inhibition is one of the most consistent problems in multiple species experiencing fescue toxicosis. Ergopeptine alkaloids have 10-fold greater potency for dopamine $D_2$ receptor binding than ergoline alkaloids (Larson, 1997).

#### *Lactation suppression*

One of the roles of prolactin is induction of mammary gland growth and milk production. Lack of prolactin is often associated with agalactia at parturition in many species including the horse and pig. However, ruminant species have a placental lactogen that can overcome the lack of prolactin stimulation of the mammary gland at birth (Cross, 1997). Nevertheless, lower prolactin concentrations in dairy and beef cows consuming E+ fescue may decrease milk production by approximately 50% after the perinatal period is past (Schmidt and Osborn, 1993; Thompson *et al.*, 2001).

#### *Effect on other reproductive hormones*

Prolactin is involved in maintaining corpus luteal function and gonadotropin secretion (Porter and Thompson, 1992). Altered luteal function in heifers grazing E+ fescue results in reduced circulating progesterone. Fescue consumption has been associated with low progesterone production in mares and cows and high estradiol concentrations in mares (Cross, 1997; Thompson *et al.*, 2001). These imbalances of reproductive hormones lead to early pregnancy problems in cattle and late pregnancy problems in horses. Ergopeptide potency for prolactin inhibition has been correlated with inhibition of ovum implantation in rats (Fluckiger *et al.*, 1976). Ergovaline is intermediate among the ergopeptides in its ability to inhibit implantation, but is approximately 2-fold more potent than ergotamine.

#### *Effect on hypothalamic thermoregulatory center*

Another role of dopamine or prolactin is control of the thermoregulatory center in the hypothalamus (Strickland *et al.*, 1993). Diminished prolactin or dopamine receptor perturbation causes the thermoregulatory center to deregulate and cause hyperthermia or hypothermia in the animal. Deregulation is more likely when environmental temperatures are outside of the thermoneutral range of the animal (Spiers *et al.*, 2005). Fescue foot problems are more likely at temperatures less than 8ºC (Tor-Agbidye *et al.*, 2001), whereas summer slump problems are more apparent when temperatures exceed 31ºC (Schmidt and Osborn, 1993; Spiers *et al.*, 2005). Metoclopramide, a dopamine $D_2$ antagonist, decreases body temperature in steers grazing E+ fescue (Lipham *et al.*, 1989).

#### *Effect on lipogenesis*

Prolactin also has a role in lipogenesis through control of metabolism of cholesterol and triglycerides by the liver (Strickland *et al.*, 1993). Cattle suffering from summer slump traditionally have low serum cholesterol and triglyceride concentrations (Oliver, 1997). Low serum cholesterol is also commonly found in cattle herds with abdominal fat necrosis (Schmidt and Osborn, 1993). Necrotic abdominal fat is lower in ether-extractable material, but has a much higher cholesterol content of the ether-extractable fraction. Lipolysis in cattle experiencing fescue toxicosis is decreased (Thompson *et al.*, 2001). Metoclopramide, a dopamine antagonist and prolactin enhancer, increases serum cholesterol levels in steers grazing E+ fescue pastures (Lipham *et al.*, 1989). Serum triglycerides and cholesterol are also reduced by alpha-1 adrenergic receptor antagonists and alpha-2 adrenergic agonists, which are both physiologic effects of ergot alkaloids (Oliver, 1997).

#### *Effect on winter hair loss*

Change in photoperiod with the end of winter and the start of spring normally will increase prolactin production and stimulate shedding of long winter hair in favor of new spring hair coat growth (Thompson *et al.*, 2001). Associated with a decrease of prolactin, cattle experiencing fescue toxicosis often fail to shed some or all of their long winter hair. This long hair may become bleached out by the summer sun and contributes to an unthrifty appearance.

#### *Effect on immunity*

Prolactin is considered an immunomodulator (Strickland *et al.*, 1993). Impaired immune function from E+ fescue seed was noted in mice and rats, whereas cattle were not affected. However, numerous other E+ fescue studies in cattle cite decreased antibody response, reduced globulins or increased morbidity and mortality (Thompson *et al.*, 2001). In contrast, Rice *et al.* (1997) noted increased humoral immunity in cattle fed E+ fescue.

### *Miscellaneous neurologic effects*

Other miscellaneous neurologic effects include a negative effect of dopamine agonists on feed intake. Use of a dopamine antagonist, metoclopramide, increased feed intake in lambs fed E+ fescue without an effect on body temperature (Thompson *et al.*, 2001). Nervous behavior in cattle fed E+ fescue might be related to the ability of ergopeptide alkaloids to release dopamine in *in vitro* synaptosomal preparations (Larson, 1997).

## Alpha-2 adrenergic agonist

### *Vasoconstriction*

#### *Gangrene of extremities*

Ergovaline acts as an alpha-2 adrenergic agonist on blood vessels, especially arterioles (Oliver, 1997). The persistent vasoconstriction of peripheral arterioles in the back legs of cattle consuming fescue is believed to be responsible for thickening of the smooth muscle wall of the arterioles seen with fescue foot problems (Thompson *et al.*, 2001). Chronic exposure of cattle to E+ fescue makes their alpha-2 adrenergic receptors more reactive to ergot alkaloids (Oliver, 1997).

#### *Decreased heat loss*

Constriction of blood vessels in the skin of cattle also contributes to hyperthermia during the summer months. In addition to the thermoregulatory effects of dopamine/prolactin on the hypothalamus, the decreased dissipation of heat through the skin of cattle is believed to contribute to the higher body temperature observed when summer temperatures are at or above 30ºC (Thompson *et al.*, 2001).

### *Serum enzyme decrease*

Multiple serum enzyme decreases in cattle have been associated with inhibition of adenyl cyclase levels due to alpha-2 adrenergic activity of ergovaline (Oliver, 1997). Ergovaline inhibits cyclic AMP production via the alpha-2a adrenergic receptor (Larson, 1997). Besides the aforementioned decrease in serum cholesterol and triglycerides, there are also decreases in alkaline phosphatase, gamma glutamyltransferase, aspartate aminotransferase, alanine aminotransferase, creatinine kinase, lipase and lactic dehydrogenase (Oliver, 1997). Potentially, the inhibition of ATPase in brain and kidney (Moubarak *et al.*, 1993) may be mediated by the same mechanism.

### *Oxidative stress*

A few studies have noted oxidative stress effects in cattle grazing E+ fescue pastures (Oliver, 1997). Alpha-2 adrenergic receptor agonists have the capability of depleting glutathione, a peptide integral in defending against oxidative stressors. Lakritz *et al.* (2002) noted reduced glutathione concentrations in whole blood samples from cattle exposed to heat stress and E+ fescue.

### *Renal-related effects*

Alpha-2 adrenergic receptor agonists decrease antidiuretic hormone release by the pituitary (Oliver, 1997). This causes an inability of cattle to concentrate their urine. Ergot alkaloids also block aldosterone production in the

adrenals (Oliver, 1997). Decreased aldosterone and antidiuretic hormone promote diuresis and cattle coming to feedlots from E+ fescue pastures have a reputation for producing a muddy wallow in their pens. Aldosterone action could also be compromised by lowered kidney sodium/potassium ATPase activity seen with ergot alkaloid exposure (Oliver, 1997).

## Serotonergic agonist

Ergot alkaloids also act on serotonergic-2 receptors (Oliver, 2005). Ergovaline is an agonist at serotonergic-2 receptors of uterine and umbilical arteries (Dyer, 1993). This serotonergic activity in blood vessels causes persistent vasoconstriction *in vitro*. Serotonergic activity of ergot alkaloids might also be important in the enhanced mitogenesis of vascular smooth muscle, hypothalamic thermoregulatory center effects, pulmonary vasoconstriction and brochoconstriction, and appetite suppression seen with fescue toxicosis (Oliver, 1997, 2005).

# TOXICITY

## Cattle

### *Summer slump*

Summer slump or summer syndrome is the most common and costly syndrome seen in cattle with fescue toxicosis. Although it is most dramatic during the summer when environmental temperatures reach above 31°C, the problem can occur during any time of the year (Schmidt and Osborn, 1993; Stuedemann and Seman, 2005). Slump refers to the fact that cattle just "ain't doing right." Cattle have an unthrifty appearance with rough hair coats that often haven't shed from the winter. The sun may bleach out the hair coats. Because of their high body temperatures, cattle spend more time in the shade or watering holes during the day and less time consuming forage. Beef cows consuming E+ fescue produce approximately 50% less milk for their calves, which results in lower weaning weights (Schmidt and Osborn, 1993). At weaning time, calves raised on E+ fescue pasture may be 30–40 kg lighter than similar calves on endophyte free forage (Schmidt and Osborn, 1993). Other potential clinical signs include nervousness, increased salivation, increased rate of respiration, delayed puberty and reduced conception rates (Schmidt and Osborn, 1993). The reduced conception rates are thought to occur in cattle during the early embryonic period and are not associated with late term abortions or stillborn calves (Thompson *et al*., 2001). Although sudden deaths during hot summer months have been reported, negligible mortality is associated with summer slump.

### *Fescue foot*

Fescue foot refers to a syndrome seen in cattle during the late fall or winter months when dietary ergovaline concentrations exceed 400 ppb (Tor-Agbidye *et al*., 2001). It is not nearly as common as summer slump. Peripheral vasoconstriction from cold environmental temperature is additive to the vasoconstrictive properties of ergot alkaloids. Additional factors that explain why fescue foot appears as opposed to summer slump are not known. Considerations could reflect a concentration difference of ergovaline in the fescue, a difference in concentration of other vasoconstrictive ergot alkaloids or a host of multifactorial concomitant conditions. Vasoconstriction tends to be more severe in rear legs than front legs. The twitch of the tail and sometimes the tips of the ears are also affected. Vasoconstriction of the back legs is between the coronary band of the hooves and the fetlock area. Areas proximal to the vasoconstriction may be congested. Areas distal to the vasoconstriction undergo gangrenous necrosis with hooves potentially being sloughed. Cattle have visibly swollen rear legs with a shifting rear leg lameness, muscle tremors, rough hair coats, knuckling of the pastern and arching of the back (Spiers *et al*., 2005). Later on, they may become prostrate.

### *Lipomatosis*

Lipomatosis is a syndrome of fat necrosis affecting abdominal fat stores in mature cattle (Schmidt and Osborn, 1993). If mesenteric fat surrounding intestines is involved, scanty feces, bloat or intestinal obstruction may result. Perirenal fat may also be affected without causing significant clinical problems. Fat in the pelvic canal may become necrotic and hardened and cause dystocia problems. Although the hardened fat may be detected sometimes by rectal palpation, the discovery is often made at necropsy as an additional finding unrelated to the cause of death of the animal. The incidence of fat necrosis in cowherds is highest in those herds with the lowest concentrations of serum cholesterol (Stuedemann and Seman, 2005).

## Sheep and goats

Sheep may be affected by fescue and have a syndrome very similar to summer slump in cattle. Ewes grazing fescue have decreased milk production and increased early embryonic mortality (Schmidt and Osborn, 1993; Thompson *et al*., 2001). Weight gains and skin temperature in young lambs may be decreased (Gadberry *et al*., 2003). Fescue foot problems are possible in sheep with threshold

dietary concentrations of 500 ppb ergovaline and environmental temperatures of 7.8ºC (Tor-Agbidye *et al.*, 2001). Additionally, ergot alkaloids are known to cause tongue necrosis in sheep along with reproductive infertility problems (Thompson *et al.*, 2001). Goats may experience lipomatosis (Smith *et al.*, 2004).

## Horses

### *Reproductive term dysfunction*

Reproductive problems in late term mares are the most common fescue problem for horses (Cross, 1997; Blodgett, 2001). Mares are most susceptible in late gestation after day 300 of gestation. Failure to remove mares from fescue pasture or hay during the last month of gestation may cause the mare to prolong her pregnancy by 20–27 days (Cross, 1997; Blodgett, 2001). During this extra gestation length, the foal becomes ganglier. Even though the foal spends more time *in utero*, it is typically dysmature with unerupted incisor teeth and overgrown hooves. Early abortion problems are possible but not common. Lack of prolactin in the mare along with decreased progesterone and increased estradiol levels cause multiple problems (Cross, 1997; Blodgett, 2001). The mare does not prepare well for parturition and may experience dystocia problems with tearing of the vagina, which can result in death or rebreeding problems. The chorioallantois may precede the foal through the birth canal and be seen as a "red bag" presentation. Retained placentas are also more common with fescue toxicosis. The placenta doesn't rupture at the cervical star and the placenta may be thick and edematous. If the foal is able to break out of the edematous placenta and not suffocate, it often faces an agalactic mare with minimal colostral antibodies for passive transfer. Foal death associated with dystocia problems or failure of passive transfer is common.

### *Infertility problems*

Early embryonic death losses in mares similar to that experienced by cows are not commonly recognized. Fertility of mares consuming fescue pastures or hay tends to be fairly high. One study in mares noted trends of increased early embryonic mortality (Brendemuehl *et al.*, 1994); whereas another study found no loss in pregnancies between days 21 and 300 of gestation, but lower progestogen concentrations between days 90 and 120 (Brendemuehl *et al.*, 1996).

## Camelids (llamas and alpacas)

Little research has been done with fescue toxicosis in camelid species. Llamas and alpacas have hyperthermia problems in summer months. Because of the ability of fescue to directly affect the thermoregulatory center in the hypothalamus and decrease dermal heat loss via vasoconstriction, fescue should be considered a potential contributor to the heat stroke syndrome seen in llamas and alpacas.

# TREATMENT

## Non-specific treatment

Cattle experiencing summer slump toxicosis are generally unthrifty and are normally just treated by removal from fescue forage or by dilution of the ergovaline content of their overall diet. This is accomplished by feeding supplemental non-fescue forage or concentrates. Clovers or Bermuda grass are often over sown into fescue pastures and aid in dilution for a few years (Thompson *et al.*, 2001). Establishing shade or water holes will help to cool hyperthermic animals. Gangrenous problems with fescue foot are treated with broad-spectrum antibiotics to diminish secondary invaders.

## Specific treatment

A dopamine $D_2$ antagonist has been developed to treat agalactia and prolonged gestation problems in mares (Cross, 1997). The generic name of the drug is domperidone and it is marketed as an oral gel called Equidone®. It is commonly given orally at 1.1 mg/kg once a day during the week before anticipated parturition if the mare shows no signs of milk production. Agalactia in a mare that has already foaled can be treated twice a day with the same dose as above until milk flow resumes.

## Prevention

### *Domperidone*

Domperidone can be given once a day to mares kept on fescue during the last 10–14 days before expected parturition (Cross, 1997). The dose is the same as for treatment above. Removal of the mare from fescue pasture and hay during the last month of gestation will also prevent a foaling problem.

## Novel or non-endophyte fescue

Endophyte-infected tall fescue pastures can be replanted with other grasses, non-endophyte fescue or new novel varieties of endophyte-infected fescue. Renovation requires a non-selective herbicide (e.g. paraquat, glyphosate) to

kill off the pasture grasses and planting with a smother crop for a season before spraying again with a herbicide and replanting with another pasture grass (Roberts and Andrae, 2004). Estimated costs of renovation are approximately $450/hectare (Fribourg and Waller, 2005). Non-endophyte fescue has been used, but it is not very drought, insect, nematode or herbivore resistant. Stand persistence is therefore not good. Novel endophyte varieties have been developed by infecting endophyte free varieties of fescue with endophytic strains that produce the peramine of tall fescue, but minimal or no ergot alkaloids (Roberts and Andrae, 2004; Fribourg and Waller, 2005). Several varieties have shown promise including MaxQ® and ARK Plus®. The novel varieties have insect and drought resistance without adversely affecting cattle, horses or sheep.

### Ammoniation of hay

Ammoniation of hay will degrade the ergovaline content of hay and make it safe to feed (Thompson *et al.*, 2001). Ammoniation requires enclosing the hay in an air-tight tent structure and pumping anhydrous ammonia gas into the tent for a period of time. This process, although effective, is time intensive and costly and generally has not been well accepted.

### Feed supplements

Several different types of feed additives have been investigated as ways to ameliorate fescue toxicosis. A glucomannan product (FEB-200®) from yeast cell walls that purport to bind ergovaline in the gastrointestinal tract and prevent its absorption improved cattle performance (Fribourg and Waller, 2005). Another feed supplement from seaweed, Tasco®, will ameliorate some oxidative effects of tall fescue causing immunosuppression in cattle (Fike *et al.*, 2001; Saker *et al.*, 2001). Just supplementing livestock with concentrates will decrease the overall dose of ergovaline from fescue.

### Pasture considerations

Pastures might be made less toxic by dilution with other grasses or legumes like Bermuda grass or clover, cutting seed heads from the pasture during the most toxic part of the summer, increasing the grazing pressure during the summer to avoid seed heads, or moving cattle to a non-fescue pasture during the warmest summer months (Stuedemann and Seman, 2005). Ergovaline content of stockpiled fescue also decreases by midwinter.

## CONCLUDING REMARKS

Tall fescue toxicosis is the major grass-induced forage problem in the United States (Oliver, 1997). Since the problem is really a mycotoxin (i.e. secondary metabolite of an endophytic fungus), the magnitude of the problem varies every year. Sometimes a lot of ergovaline is produced in a particular fescue pasture and in other years very little is produced and the nutrient rewards of fescue can be very profitable. Researchers are attacking the problem from two different angles. One attempt is to replace tall fescue with a novel endophytic fescue that is not toxic for animals, but still is drought and insect resistant. This has been accomplished, but the costs of pasture renovation are still considerable and some hilly terrain is not suitable for renovation. The other approach has been to find an antidote or preventative for the fescue problem. Domperidone is a suitable treatment or preventative for pregnant mares, but residue concerns will likely prevent its use in the near future for food producing animals. Other possible preventatives for food animals are still being investigated and include adsorbent feed supplements and vaccines.

# Mushroom toxins

*Birgit Puschner*

## INTRODUCTION

It is very difficult to confirm exposure to mushroom toxins, and thus, clinical reports of mushroom poisoning are uncommon and there are most likely many unreported cases. Mushroom poisonings of humans and animals can demand extensive effort from clinicians and toxicologists and often involve emotion and publicity. The public expects the toxicology profession to provide guidance and a coherent approach regarding poisoning cases. While it is estimated that very few species are lethal to humans, it is not clear how many of the mushrooms worldwide contain potentially toxic compounds. New species are being discovered continuously and for many species, toxicity data is unavailable. In veterinary medicine, data regarding mushroom toxicity is sparse, however, it is possible that mushroom poisonings are more common in animals than humans as a result of the propensity of accidental exposure.

## BACKGROUND

The frequency of mushroom poisoning is likely to be low because of the lack of methods to confirm exposure to toxic mushrooms. Most cases are diagnosed by positive identification of the suspect mushroom along with the occurrence of consistent clinical signs. In the case of animals, mushroom exposure is even more difficult to prove since animals are often left unattended and a history of ingestion is not available. Between 2002 and 2005, over 700 cases of mushroom intoxication have been registered by the ASPCA Animal Poison Control Center, mainly in dogs, and also in cats. California accounted for 11% of these cases, the highest among all states. California also leads the United States in the number of reported cases of mushroom poisoning in humans, with approximately 2000 cases reported in 2004. Many factors influence the toxicity of mushroom toxins, such as genus and species of mushroom, geographic location where the mushroom is grown, preparation of mushroom prior to ingestion and the individual's susceptibility. While not inclusive of all mushroom toxins, this chapter is organized by the various types of toxins, providing detailed information on their toxic mechanisms, toxicokinetics, diagnostic, and therapeutic approaches with a focus on veterinary medicine.

## HEPATOTOXIC CYCLOPEPTIDES

Worldwide, most fatalities are caused by exposure to cyclopeptides. Three genera, *Amanita*, *Galerina*, and *Lepiota* (Lincoff *et al.*, 1977a) are known to contain hepatotoxic cyclopeptide toxins. The most toxic cyclopeptide-containing mushrooms are *Amanita phalloides*, the ubiquitous Death Cap or Death Angel and *Galerina sulpices*. *A. phalloides* is found throughout North America, commonly in association with oaks and birch, and is the species most frequently resulting in fatalities in humans (Mitchel, 1980; Barbato, 1993). In Eastern Europe, *G. sulpices* is considered the species most commonly associated with human fatalities, followed by *A. phalloides* (Klan, 1993). There are three groups of cyclopeptides, including the amatoxins, phallotoxins, and virotoxins. Amatoxins are bicyclic octapeptides and include the amanitins ($\alpha$-, $\beta$-, $\gamma$-, and $\varepsilon$-amanitins), amanin, amanullin, and proamanullin (Vetter, 1998). Severe poisonings and lethality are mainly attributable to the amanitins. The bicyclic heptapeptides phallotoxins were once thought to be the cause for gastrointestinal clinical signs, however they are no longer believed to exert any

*Veterinary Toxicology, Edited by Ramesh C. Gupta*

acute toxicity. Although the amount of research is limited, bicyclic heptapeptides virotoxins are not considered to have toxic effects after oral exposure. Therefore, phallotoxins and virotoxins are not discussed further.

## Pharmacokinetics/toxicokinetics

Definite data on bioavailability for amanitins is lacking, although there are known species differences (Faulstich and Fauser, 1980). In humans, bioavailability of amanitins appears to be much greater than in rodents, dogs, and rabbits. Within animal species, the absorption rate of amanitins is estimated to be much greater in dogs than in mice and rabbits, and rats appear resistant to the toxic effects of amanitins. α-amanitin is taken up by cells in the gastrointestinal tract where the first damaging effects are seen (Gundala *et al.*, 2004). Following systemic absorption, α-amanitin is taken up by the hepatocytes via a sodium-dependent transport system (Kroncke *et al.*, 1986). The α-amanitin has a low volume of distribution, and the renal clearance is high and similar to the creatinine clearance (Faulstich *et al.*, 1985). Following intravenous (i.v.) administration in dogs, it was shown that the plasma half-life of amanitins is short ranging from 25 to 50 min and that amanitins are not detectable in plasma after 4–6 h. There is no known metabolism or plasma protein binding of the α-amanitin. Between 80% and 90% of the administered dose of amanitins are eliminated in urine and up to 7% are eliminated in the bile (Faulstich *et al.*, 1985). After oral ingestion of *A. phalloides* in humans, α- and β-amanitins were detected in plasma up to 36 h after ingestion, and in urine up to 72 h post-exposure (Jaeger *et al.*, 1993). This may partly be due to slow intestinal absorption, entero-hepatic circulation, and reduced renal elimination resulting from nephrotoxicity. Plasma and urine amanitin concentrations do not seem to correlate with the clinical severity or outcome.

Amanitins can be detected in urine well before any clinical sign, whereas routine laboratory tests such as blood CBC (complete blood count) and serum chemistry profiles are unremarkable until liver or kidney damage has occurred. Early recognition of exposure is critical since survival rates are greatly improved with timely therapeutic intervention. Amanitin concentrations in kidneys and liver in people ingesting *A. phalloides* have been detected up to 22 days post-ingestion. The kidneys contain higher concentrations than liver, indicating that toxins are bound to renal tissue.

## Mechanism of action

Amanitins are of greatest significance because, unlike phalloidins, they are heat stable, and are not degraded by the acid environment of the stomach or by freezing (Himmelmann *et al.*, 2001). Therefore, amanitins are toxic by ingestion, whereas phalloidins have only been shown to be toxic when experimentally administered by parenteral routes. Amanitins exert their toxicity by inhibiting nuclear RNA polymerase II (Lindell *et al.*, 1970; Wieland, 1983). The decrease in mRNA and associated decrease in protein synthesis result in cell death. Cells with a high metabolic rate, such as hepatocytes, crypt cells, and proximal convoluted tubules of the kidneys are most commonly affected. While this mechanism is well established, more recent research has suggested that other cellular effects may contribute to the toxicity of amanitins. In mice, apoptosis contributed to amanitin-induced liver failure (Leist *et al.*, 1997) and in pancreatic rat islets, α-amanitin resulted in a dose-dependent insulin releasing and a β-cytotoxic effect (De Carlo *et al.*, 2003). Acute tubular necrosis in the kidneys is believed to be a result of reabsorption of amanitins by renal tubules after glomerular filtration.

The clinical course can be divided in four phases, with the initial phase being the latency period of approximately 8–12 h. The second phase is characterized by severe gastrointestinal signs such as nausea, vomiting, bloody diarrhea, and severe abdominal pain. In dogs, the onset of clinical signs is generally 6–24 h after mushroom ingestion. Beagles that were experimentally given amanitins developed vomiting and diarrhea starting 16 h after sublethal oral exposure. Gastrointestinal signs improved after 60 h (Vogel *et al.*, 1984). The gastroenteric phase is often followed with a lag period of several hours to a few days during which the human or animal will appear to have recovered. During this third phase, close monitoring of liver and kidney function is essential in order to prevent misdiagnosis. The final stage begins approximately 36–84 h after exposure to amanitins. In this stage, fulminant liver, renal, and multiorgan failure may occur. In dogs, significant elevations in serum of aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase, and bilirubin are commonly observed (Vogel *et al.*, 1984; Kallet *et al.*, 1988). Coagulopathy, encephalopathy, and coma are common sequelae with liver failure (Vogel *et al.*, 1984). In humans, a combination of the prothrombin index along with serum creatinine concentrations determined between 3 and 10 days after ingestion was most useful as predictors of death (Ganzert *et al.*, 2005). Although no controlled study exists in dogs, both prothrombin (PT) and partial thromboplastin (PTT) times are important liver function parameters and may provide critical information in the assessment of a case (Tegzes and Puschner, 2002). If the animal survives the hepatopathy, renal failure may occur as a consequence of proximal and distal tubular necrosis (Kallet *et al.*, 1988; Tegzes and Puschner, 2002). Clinical signs of renal failure include polyuria, polydypsia, vomiting, and anorexia. Severe hypoglycemia may occur in dogs after the gastrointestinal

phase, and is associated with the breakdown of liver glycogen (Faulstich and Fauser 1980). In a study where dogs were given amanitin toxins or pieces of *A. phalloides* mushrooms in lethal doses, 50% of dogs died from hypoglycemia 1 to 2 days after exposure (Faulstich and Fauser, 1980). In clinical cases, dogs must be monitored closely for hypoglycemia, and treatment may be necessary. Clinical signs of hypoglycemia in dogs and cats include seizures, coma, and death. Finally, it is important to note that not all cases present with the classic four stages. In cases of large exposure to amanitins, or ingestion by puppies, the animal may die within 24 h (Cole, 1993).

## Toxicity

Amanitins are extremely toxic. The i.v. median lethal dose ($LD_{50}$) of α-amanitin in dogs is 0.1 mg/kg body weight (Faulstich and Fauser, 1980). Based on an oral dosing study in dogs, the oral $LD_{50}$ for methyl-γ-amanitin was estimated to be 0.5 mg/kg body weight. In mice and rats, the i.v. $LD_{50}$ of α-amanitin is 0.35 and 3–4 mg/kg body weight, respectively, illustrating significant species differences. Guinea pigs and rabbits are considered about equally sensitive to amanitins as dogs with i.v. $LD_{50}$'s of α-amanitin of 0.1 and 0.2 mg/kg, respectively. In humans, the estimated oral $LD_{50}$ of α-amanitin is 0.1 mg/kg body weight. Considering the average concentration of amanitins per mushroom, one *A. phalloides* has the potential to kill an adult, while it may require two mushrooms to cause death in a dog.

## Treatment

There is no specific antidote for amanitins. Despite the evaluation of numerous treatment options, no specific therapy has proven to be effective. Even with supportive measures, the reported mortality rate from Amanita poisoning in humans is 20–40%, and is often higher in children (Enjalbert *et al.*, 2002). To date, in humans with amanitin poisoning, silibinin, penicillin, and *N*-acetylcysteine (NAC) are most commonly recommended along with decontamination procedures and supportive care. Similar approaches have been used with variable success rates in dogs suffering from amanitin poisoning (Tegzes and Puschner, 2002). Prompt and aggressive measures are required to improve prognosis.

Although the exact mechanisms of silibinin and penicillin are not fully understood, both compounds reduce the uptake of amanitins into hepatocytes. Silibinin (also known as silybin) is the main component of silymarin and provides most of the hepatoprotection that is attributed to milk thistle. Silibinin is also a free radical scavenger, and has immunostimulatory and iron binding properties (Mayer *et al.*, 2005). Experimentally, silibinin was shown to be effective when given twice to dogs at a dose of 50 mg/kg i.v., 5 and 24 h after exposure to *A. phalloides* (Vogel *et al.*, 1984). Dosed dogs had better indices of liver function as assessed by serum elevations of AST, ALT, bilirubin, and prolonged PT. On histopathology, no hepatic lesions were found. The recommended i.v. dose for silibinin in humans is an initial bolus infusion of 5 mg/kg followed by a continuous rate infusion of 20 mg/kg/day for a minimum of 3 days (Karlson-Stiber and Persson, 2003). Side effects of silibinin administration are rare, but include anaphylactic reactions, mild laxative effects, and interactions with certain phase I and phase II metabolism enzymes (Venkataramanan *et al.*, 2000). Recently, the usefulness of penicillin G alone, not in combination with silibinin was shown to be ineffective in humans with amanitin poisoning (Enjalbert *et al.*, 2002). However, mice given 1000 mg/kg of penicillin G intraperitoneally (i.p.) 8 h after exposure to a lethal dose 95 ($LD_{95}$) of amanitin had less morbidity and mortality than control mice (Floersheim, 1972). In dogs, i.v. administration of 1000 mg/kg of penicillin G at 5 h post *A. phalloides* exposure was considered an effective treatment (Floersheim, 1978). Based on recent data, administration of silibinin appears to have greater therapeutic benefit than penicillin G (Enjalbert *et al.*, 2002) at least in humans. Such data is not available for animals. This is also true for the use of antioxidants in amanitin poisoning cases, where information regarding the efficacy has only been published for humans but not animals. The antioxidants evaluated in humans are NAC, cimetidine, and ascorbic acid. Most information is available for NAC, which was shown to be as effective as silibinin in reducing mortality in humans after amanitin poisoning (Enjalbert *et al.*, 2002). In a mouse model, NAC administration was not effective (Schneider *et al.*, 1992). Although efficacy data of NAC administration in dogs with amanitin poisoning is lacking, there is no reason not to include the glutathione precursor in the treatment regimen. Ascorbic acid and cimetidine are known hepatocyte protectors and may be of benefit when managing amanitin poisoning in dogs, but specific data is not available. In contrast, thioctic acid and steroids are no longer recommended in the treatment of amanitin poisoning.

A variety of decontamination procedures have been applied in humans and include hemodialysis, hemoperfusion, activated charcoal, plasmapharesis, forced diuresis, and nasoduodenal suctioning. Controversy still remains about the efficacy of many of these procedures as specific data does not exist. There is general agreement however, that activated charcoal is beneficial in adsorbing toxins within the gastrointestinal tract as well as those that re-enter it due to entero-hepatic recirculation. In dogs, multidose activated charcoal is given every 2–6 h until 2–3 days post-ingestion. Close monitoring, fluid replacement, and supportive care are essential parts of the treatment in amanitin poisonings. As part of vigorous supportive care, i.v. fluids, correction of hypoglycemia and electrolyte

imbalances, vitamin $K_1$, and plasma transfusions should be considered, dependent on the clinical presentation of each poisoned patient. In humans, liver transplantation has been used successfully in patients with fulminant liver failure. At this time, liver transplantation is not an option for animals poisoned with amanitins.

Diagnosis of amanitin toxicosis is aided by identification of amanitin-containing mushrooms in the environment of the animal. Mushroom pieces found in gastric contents can confirm exposure. Accurate mushroom identification will require consultation with an experienced mycologist. Detection of amanitins in biologic specimens is confirmatory, but these tests are not routinely available at diagnostic laboratories. Recently, a liquid chromatography/mass spectrometry method was developed and successfully applied to confirm amanitin poisoning in five humans and a dog (Puschner, personal communication). The method is highly sensitive, specific and rapid, and detects α- and β-amanitins. This is an improvement over the commercially available ELISA that is validated for specimens of human origin and does not detect β-amanitin (Butera *et al.*, 2004), although it is known that some *Amanita* spp. contain only β-amanitin. Recently, a competitive ELISA was constructed that allows for the detection of β-amanitin in human serum and urine, but this assay is not yet available in clinical settings (Abuknesha *et al.*, 2004). Rapid confirmation of amanitins in suspect exposures assists in the early recognition of exposure, while a negative result can prevent unnecessary hospitalization. In a recent study, it was also shown that the newspaper test of Wieland, or Meixner test, should not be used alone to identify amanitin-containing mushrooms (Beuhler *et al.*, 2004). In suspect cases of aminitin poisoning, serum and urine samples should be collected at various time points beginning as early after exposure as possible. In post-mortem presentations, liver and kidney samples are suitable for testing to confirm exposure. The suspect mushroom or vomited gastrointestinal contents should also be saved for further analysis.

Differential diagnoses in dogs and cats with a clinical presentation that involves gastroenteritis and hepatic failure include other toxic ingestions such as blue-green algae, xylitol cocklebur, cycad palm, aflatoxin, gyromitrin, and acetaminophen overdose. The history and geographic environment of the animal can help to eliminate most of the toxicant differentials on the list.

# HYDRAZINES

*Gyromitra* species are members of the false morel family, Helvellaceae and are usually found under conifers, aspens, and sometimes around melting snow banks. The species most commonly associated with poisoning and studied in most detail is *Gyromitra esculenta*, but the toxins have been found in other species of Helvellaceae (Viernstein *et al.*, 1980). These include *Gyromitra gigas*, *Gyromitra fastigiata*, *Gyromitra infula*, *Helvella crispa*, and *Helvella lacunose*. The toxins associated with false morel poisoning are hydrazine analogues. The toxins are heat labile, volatile, and water soluble (Michelot and Toth, 1991). The process of boiling and drying decreases, but does not completely eliminate the toxin concentrations (Pyysalo, 1976). People who eat only a few of the cooked mushrooms may ingest sufficiently detoxified amounts so as to remain symptom free. This has caused misunderstandings among people of the potential lethality of these mushrooms. Animals generally eat raw mushrooms; therefore any exposure to these mushrooms may result in serious morbidity and mortality. Poisoning by some species of *Helvella*, *Verpa*, *Morchella*, *Peziza*, *Disciotis*, and *Sarcosphaera* closely resembles the syndrome caused by gyromitrin. It has been speculated that these mushrooms also contain hydrazines, though analysis has yet to confirm the presence of these toxins (Lincoff and Mitchel, 1977b).

## Pharmacokinetics/toxicokinetics

There is very limited information available. Toxicosis can result after oral and inhalation exposure. Ingestion of gyromitrin (acetaldehyde *N*-methyl *N*-formylhydrazine) containing mushrooms results in the hydrolysis of gyromitrin to *N*-methyl-*N*-formylhydrazine, which is further metabolized to monomethylhydrazine. The degree of hydrolysis is dependent on the pH in the stomach, but it is not complete (Wright *et al.*, 1978). Inhalation of the fumes during the cooking process can also result in poisoning. Once hydrazines reach the liver, they are further metabolized to reactive intermediates, such as methyl cations and free methyl radicals (Gannett *et al.*, 1991).

## Mechanism of action

Gyromitrin is considered a gastrointestinal irritant leading to clinical signs of vomiting, abdominal pain, and diarrhea 6–12 h after ingestion of the poisonous mushroom (Coulet and Guillot, 1982). The principal toxin responsible for convulsions seen in severe cases of gyromitra poisoning is monomethylhydrazine. Monomethylhydrazine inhibits pyridoxal phosphokinase resulting in decreased pyridoxal 5-phosphate concentrations (Lheureux *et al.*, 2005). Depletion of pyridoxal 5-phosphate leads to decreased γ-aminobutyric acid (GABA) synthesis and an increase in glutamic acid concentrations. Because of a study in mice, in which GABA concentrations in the brain were not significantly decreased after methylhydrazine exposure (Maynert and Kaji, 1962) other mechanisms have been proposed. In addition to the gastrointestinal irritation and neurotoxicity, liver and renal failures as well as hemolysis

have been described. *N*-methyl-*N*-formylhydrazine inhibits cytochrome P450 and glutathione metabolizing enzymes (Braun *et al.*, 1979) and can lead to liver necrosis. However, the highly reactive metabolites, such as methyl cations generated in the liver may significantly contribute to the hepatic injury. Furthermore, the hydrazine analogues present in false morels are carcinogenic in laboratory animals (Toth and Gannett, 1994). Only one case report exists in the veterinary literature. A 10-week-old dog vomited 2–3 h after chewing on a mushroom later identified as *G. esculenta* (Bernard, 1979); 6 h post-ingestion, the dog was lethargic, became comatose, and died 30 min later. Histopathologic findings included renal tubulonephrosis, periascinar hepatic degeneration, and erythrophagocytosis.

## Toxicity

In humans, there seems to be great individual variability with regards to the toxicity of false morel poisoning. In mice, the oral $LD_{50}$'s of gyromitrin, *N*-methyl-*N*-formylhydrazine, and monomethylhydrazine are 344, 118, and 33 mg/kg, respectively (Wright *et al.*, 1978). In humans, the estimated lethal dose of gyromitrin is 20–50 mg/kg for adults and 10–30 mg/kg for children (Schmidlin-Meszaros, 1974). Toxicity information for dogs or cats has not been established. Gyromitrin concentrations in fresh *G. esculenta* are estimated from 0.12% to 0.16%.

## Treatment

In humans, most patients develop only mild gastrointestinal symptoms and recover fully within several days after exposure. Management is principally supportive. Early decontamination is often not possible because of the delayed onset of clinical signs. Administration of activated charcoal has been recommended, although efficacy studies have not been performed. Correction of fluid and electrolytes are important measures along with the administration of pyridoxine. The recommended dose in humans is 25 mg/kg i.v. over 15–30 min. The dosing can be repeated but should not exceed more than 20 g/day. While pyridoxine can successfully control seizure activity, it has no benefit in preventing liver injury. In dogs, pyridoxine has been used successfully for non-mushroom toxin-induced seizure activity. It can be used alone or in combination with diazepam. Combination therapy has better efficacy than pyridoxine alone (Villar *et al.*, 1995). The dose for dogs is 75–150 mg/kg body weight, given i.v., during acute phases of seizure activity. Diazepam is given to dogs and cats at 0.5–1.0 mg/kg i.v. to effect. Phenobarbital is not recommended for seizure control because of its cytochrome P450 inducing capability. Administration of folinic acid has been recommended in humans, but controlled studies have not been performed. The cytochrome P450 inhibitor cimetidine and NAC to the prevent hepatic injury should be considered. The dosing is same as that given in acetaminophen-induced hepatic injury. Hemodialysis has been reported in the literature in the treatment of gyromitrin poisoning but its role in removing gyromitrin or its toxic metabolites is not known.

Diagnosis of gyromitrin toxicosis is aided by identification of gyromitrin-containing mushrooms in the environment of the animal. Identification by a mycologist is important to distinguish between the true morels from the false morels. Detection of gyromitrin, hydrazine analogues, or metabolites in biologic specimens is not routinely available and diagnosis is mainly based on clinical clinicopathologic findings, and mushroom identification.

# MUSCARINIC AGENTS

The genera with the highest concentrations of muscarine are in the genera *Inocybe* and *Clitocybe*, though muscarine is also found in lower concentrations in many other genera including *Entoloma* and *Mycena* (Young, 1994). Muscarine was first discovered and characterized in *Amanita muscaria*, but concentrations of muscarine are only about 0.0003% (Eugster and Schleusener, 1969). In comparison, *Inocybe* and *Clitocybe* species have muscarine concentrations between 0.1% and 0.33%. *Inocybe* and *Clitocybe* species have worldwide distributions and are relatively common. *Inocybe* species grow in association with either conifers or broadleafed trees. *Clitocybe* species grow on forest litter or grassland humus. The risk of poisoning remains after cooking because of the heat stability of muscarine. There is one published report of a muscarine-containing mushroom, *Inocybe phaeocomis* poisoning in a dog (Yam *et al.*, 1993).

## Pharmacokinetics/toxicokinetics

There is limited data available. The naturally occurring form of muscarine is the (L)+ form. In general, quarternary ammonium compounds are poorly absorbed after oral exposure. Once absorbed muscarine is quickly distributed throughout the body and clinical signs develop within 30 min to 2 h of ingestion. Because of its quaternary configuration, muscarine does not cross the blood–brain barrier and its cholinergic effects are entirely peripheral. A portion of the ingested muscarine is eliminated unchanged in urine, but detailed toxicokinetic studies have not been performed.

## Mechanism of action

Muscarine acts in the peripheral nervous system, where it competes with acetylcholine at its receptor binding sites. The muscarinic cholinergic receptors that are able to bind

muscarine are found in the heart in both its nodes and muscle fibers, in smooth muscles, and in glands. They do not occur in skeletal muscles. Once bound to the receptor, muscarine mimics the effect of acetylcholine as a neurotransmitter. Toxicity occurs because of uncontrolled stimulation of the receptors. Under normal circumstances, acetylcholinesterase degrades excess acetylcholine into acetate and choline, preventing overstimulation by acetylcholine. Muscarine is not susceptible to inactivation by acetylcholinesterase (Young, 1994) and overstimulation of the receptors occurs. Clinical signs appear within a few hours, and include salivation, lacrimation, vomiting, diarrhea, abdominal pain, miosis, and bradycardia (Stallard and Edes, 1989). Clinical signs in the dog eating *Inocybe phaecocomics* were observed 3 h after exposure and included salivation, diarrhea, vomiting, depression, and collapse (Yam *et al.*, 1993).

## Toxicity

In mice, the i.v. $LD_{50}$ of muscarine is 0.23 mg/kg (Waser, 1961). The lethal dose of muscarine in humans is estimated to be between 180 and 300 mg and the ingestion of a single mushroom containing 0.33% muscarine on a dry weight basis can be lethal (Bresinsky and Besl, 1990a).

## Treatment

Treatment includes early decontamination, administration of activated charcoal, and fluid rehydration. If life-threatening clinical signs are present, atropine should be administered. Atropine acts by competing with both acetylcholine and muscarine at cholinergic muscarinic receptor sites. After giving a test dose to determine its efficacy, atropine can be given repeatedly until symptoms are abolished or until cessation of salivation. Doses in dogs and cats are 0.2–2.0 mg/kg, where one-fourth of the dose is given i.v., and the remainder is given either subcutaneously or intramuscularly. Other criteria for therapeutic endpoint with atropine include ease of respiration and lack of respiratory secretions. Mydriasis is not an indicator of its effectiveness. Because atropine also competes with acetylcholine at the receptors, ongoing treatment must be carefully monitored for its anticholinergic effects. These include tachycardia, gastrointestinal stasis, severe behavioral changes (e.g. delirium), and hyperthermia. The dose of atropine should be reduced or discontinued with these adverse effects.

# ISOXAZOLES

Poisoning in this group is attributed to the heat-stable isoxazoles derivatives, ibotenic acid, and muscimol. These toxins are found in *Amanita pantherina* (panther cap, panther agaric) and *A. muscaria* (fly agaric), the two mushrooms most commonly associated with poisonings in humans in this group (Hall and Hall, 1994). The mushrooms grow from summer to autumn in coniferous and deciduous forests, and are abundant in the Pacific Northwest where they are often found under Douglas fir trees. Other species containing these toxins include *Amanita gemmata*, *Amanita smithiana*, *Amanita strobiliformis*, and *Tricholoma muscarium* (Lincoff and Mitchel, 1977c). There are a few published reports of poisoning in dogs (Naude and Berry, 1997) and cats (Ridgway, 1978) after ingesting *A. pantherina*.

## Pharmacokinetics/toxicokinetics

Definite data on the toxicokinetics of muscimol and ibotenic acid have not been established. Based on the rapid onset of clinical signs after oral exposure to the poisonous mushrooms, rapid absorption of the toxins is suspected. Once absorbed, muscimol and ibotenic acid appear to cross the blood–brain barrier by an active transport system. Ibotenic acid decarboxylates to form muscimol in the stomach, liver, and brain (Nielsen *et al.*, 1985). Muscimol and ibotenic acid can be detected in urine within 1 h of exposure (Ott *et al.*, 1975).

## Mechanism of action

The major toxins in this group are muscimol and ibotenic acid, but other active substances have been identified, although with minor pharmacologic activities. Though both muscimol and ibotenic acid are present in mushrooms, muscimol is further derived from ibotenic acid by spontaneous decarboxylation that can occur during dehydration of the mushroom, during digestion in the stomach, or after absorption in a variety of tissues. Therefore, muscimol is likely the major toxin resulting in clinical signs of poisoning. Muscimol is a potent agonist at $GABA_A$, a partial agonist at $GABA_C$ receptors, and inhibits neuronal and glial GABA uptake. $GABA_A$ and $GABA_C$ receptors are chloride channels that mediate synaptic inhibition, although the receptors differ pharmacologically (Chebib and Johnston, 1999). On activation by muscimol, the membrane permeability for anions increases, usually resulting in a slight, short-lasting hyperpolarization and associated decreased excitability of the receptive neuron. Effects on the CNS are similar to those produced by therapeutic doses of diazepam. Ibotenic acid activates inhibitory glutamate receptors (Cleland, 1996). Interestingly, these ligand-gated ion channels differ from any of the excitatory glutamate receptor families and are much more closely related to the glycine and GABA receptors (Cleland and Selverston, 1998).

Typical clinical signs of muscimol toxicosis begin with 30 min to 2 h after ingestion and have been termed the "pantherine–muscaria" syndrome in humans. In humans, clinical signs include mydriasis, dryness of mouth, ataxia, confusion, euphoria, dizziness, and tiredness. Gastrointestinal signs are not consistently seen in cases of isoxazole poisoning. Full recovery is expected within 1–2 days. In cats, clinical signs have been observed within 15–30 min after ingestion of *A. pantherina* (Ridgway, 1978). After a brief period of sedation, cats experienced a 4-h long state of excitement with pronounced muscle spasms, followed by a deep sleep. Cats are expected to fully recover within 24 h after ingestion, especially if decontamination measures are taken. In dogs, clinical signs observed after ingestion of *A. pantherina* included disorientation, opisthotonus, paresis, seizures, paddling, chewing movements, miosis, vestibular signs, respiratory depression, coma, and death (Hunt and Funk, 1977; Naude and Berry, 1997). Recoveries are recorded within 12–24 h after aggressive supportive care measures including mechanical ventilation during periods of respiratory depression; however death was reported in several dogs. Similar clinical signs were reported in a dog that survived *A. muscaria* poisoning (Martin, 1956).

## Toxicity

In mice, the oral $LD_{50}$ is 22 mg/kg for muscimol and 38 mg/kg for ibotenic acid (Hall and Hall, 1994). In rats, the oral $LD_{50}$ is 45 mg/kg for muscimol and 129 mg/kg for ibotenic acid. The i.p. $LD_{50}$ of muscimol is 2.5 mg/kg in mice and 3.5 mg/kg in rats. In humans, the toxic threshold is estimated to be 6 mg of muscimol and 30–60 mg of ibotenic acid (Halpern, 2004). The concentration of ibotenic acid in *A. muscaria* was estimated at 100 mg/kg fresh, while the concentration of muscimol was below 3 mg/kg fresh weight. Thus, an average size fruit body of *A. muscaria* weighing 60–70 g can contain a toxic concentration. In dogs, toxicity data is not available. However, postmortem examination of puppies indicated that the ingestion of a single *A. pantherina* can be lethal (Hunt and Funk, 1977).

## Treatment

Treatment of exposed animals is mainly symptomatic and supportive. Decontamination measures should be considered in recent exposures, though emetics are only recommended in animals that are not at risk for developing aspiration pneumonia. Specific measures to control seizures are not without complication. Benzodiazepines, as GABA agonists, may potentiate any CNS depression. Therefore, when diazepam is used, CNS and respiratory depression may be severe and prolonged, necessitating the use of mechanical ventilation. As long as ventilation is maintained adequately, the prognosis for recovery is good. Diazepam can be given to dogs and cats at 0.5 mg/kg i.v. to effect, and can be repeated as needed every 10 min for up to three doses. Other drugs to control seizures include phenobarbital and pentobarbital. Phenobarbital is dosed at 6 mg/kg i.v. Pentobarbital is given at 5–15 mg/kg i.v. to effect to dogs and cats. These, too, are agonists at the GABA receptors, and can potentiate CNS and respiratory depression. Careful monitoring of the animal's oxygenation status is vital until the animal is fully awake and alert. Supplemental oxygen can be used if necessary. General supportive measures of unconscious animals include maintaining hydration with i.v. fluids, maintaining the airway free of respiratory secretions, and frequent position changes to prevent decubitus skin ulcerations. In humans, the use of atropine is contraindicated because of the atropine-like clinical presentation in poisonings.

# PSILOCIN AND PSILOCYBIN

Mushrooms that contain psilocybin are commonly referred to as hallucinogenic or magic mushrooms. *Psilocybe*, *Panaeolus*, *Conocybe*, and *Gymnopilus* are the four genera in North America that contain psilocybin (Smolinske, 1994). Many of these mushrooms are coprophilic and grow in fields and animal pastures, particularly in the northwest and southeast United States. The majority of mushrooms contain only psilocybin, but some, such as *Psilocybe cyanescens* contain psilocybin and psilocin. The concentrations of psilocybin and psilocin are influenced by growth conditions, geographic location, storage conditions, and species. Species commonly found in the Pacific Northwest contained between 1.2 and 16.8 mg/kg psilocybin on a dry weight basis. If psilocin was present, concentrations could reach up to 9.6 mg/kg on a dry weight basis (Smolinske, 1994). Psilocin and psilocybin are sensitive to heat. In addition, some of the mushrooms in this group contain other pharmacologically active substances such as serotonin and tryptophan. There is only one published report of hallucinogenic mushroom ingestion in a dog (Kirwan, 1990).

## Pharmacokinetics/toxicokinetics

Psilocybin is a pro-drug and is rapidly dephosphorylated to psilocin. Dephosphorylation can take place in a variety of tissues, but high activity has been identified in kidney and liver of rodents (Horita and Weber, 1961) and in plasma of humans (Grieshaber *et al.*, 2001). However, the

general assumption is that complete conversion of psilocybin to psilocin occurs prior to absorption into the systemic circulation (Laatsch, 1996). In humans, the absolute bioavailability of psilocin liberated from orally administered psilocybin was estimated to be 52.7 ± 20% (Hasler *et al.*, 1997). Once absorbed, psilocin is further metabolized in plasma to 4-hydroxy-tryptophole (4HT) and 4-hydroxyindole-3-acetic acid (4HIAA). Psilocin crosses the blood–brain barrier and concentrates in brain tissue (Horita and Weber, 1961). Psilocin is excreted unchanged or as psilocin–glucuronide in urine and to some extent unchanged via the bile (Hasler *et al.*, 2002).

### Mechanism of action

Psilocin is the pharmacologically active metabolite of psilocybin. Because of its structural similarity to serotonin, psilocin exerts its effects in the CNS by stimulation of serotonin receptors (McKenna *et al.*, 1990). Psilocin primarily activates 5-$HT_{2A}$ receptors, but has affinity for 5-$HT_{1A}$ receptors as well. Activation of 5-$HT_{2A}$ receptors leads to increased cortical activity via glutamatergic excitatory post-synaptic potentials (Aghajanian and Marek, 1997). Activation of 5-$HT_{1A}$ receptors results in the inhibition of pyramidal cell activity (Puig *et al.*, 2005). Additionally, psilocin may also have peripheral effects that involve serotonergic receptors. In humans, psilocin psychoactive effects similar to those produced by LSD are observed within 20–30 min of ingestion and include visual hallucinations, intensified hearing, and incoordination. Other autonomic-mediated effects can include increased heart rate, increased blood pressure, mydriasis, tremors, and increased temperature. The effects can last up to 8 h, but hallucinogenic activity rarely exceeds 1 h. Clinical signs in dogs include ataxia, vocalization, overt aggression, nystagmus, and increased body temperature (Kirwan, 1990). In contrast to the CNS effects after exposure to isoxazoles, there is no subsequent coma. Sedation may be necessary until behavioral signs resolve.

### Toxicity

In many countries psilocybin and psilocin are classified as controlled substances, e.g. in the United States, Great Britain, and Germany. In humans, oral exposure to 10–20 mg of psilocybin can cause mood changes and hallucinations. Information regarding lethal doses in animals are not found in the literature.

### Treatment

The management of hallucinogenic mushroom poisonings is primarily supportive and in most cases, treatment is not necessary. Gastric emptying procedures have not proven beneficial and are not recommended. The effect of activated charcoal in poisonings is not known, but activated charcoal administration can be considered. If severe neurologic signs occur, such as seizures, diazepam is considered the first line medication. Diazepam can be given to dogs and cats at 0.5–1.0 mg/kg i.v. in increments of 5–10 mg, to effect. If diazepam is unsuccessful, subsequent seizures can be controlled with phenobarbital at 6 mg/kg to effect. Additionally, control of body temperature is an important factor of the symptomatic care.

Diagnosis of psilocybin exposure is confirmed by the detection of psilocin and psilocin–glucuronide in urine, serum, and blood. A number of methodologies are available and are routinely used in forensic investigations (Kamata *et al.*, 2003; Albers *et al.*, 2004). Because of the infrequent presentation of hallucinogenic mushroom poisoning in animals, these methodologies are not routinely available at veterinary diagnostic laboratories.

## GASTROINTESTINAL IRRITANTS

This group includes mushrooms that result in gastroenteritis as the primary clinical sign. There are very few reports in the veterinary literature. Genera included are *Agaricus*, *Boletus*, *Chlorophyllum*, *Entoloma*, *Lactarius*, *Omphalotus*, *Rhodophyllus*, *Scleroderma*, and *Tricholoma*. The specific toxins in most have not been identified (Spoerke, 1994). One of the mushrooms in this group commonly reported to cause poisoning is *Chlorophyllum molybdites*. This mushroom is commonly found in the United States except for the colder, northern areas and the principal toxin has not been clearly identified. Clinical signs of nausea, vomiting, and diarrhea appear 1–6 h after ingestion in humans, and there is complete recovery within 24–48 h (Blayney *et al.*, 1980). *Omphalotus olearius*, *Omphalotus subilludens*, and *Lampteromyces japonicus* contain illudin S (Bresinsky and Besl, 1990b). Illudin S is a sesquiterpene with a unique chemical structure. In humans, vomiting and diarrhea occur 1–2.5 h after ingestion (French and Garrettson, 1988). In a pot-bellied pig, death has been reported 5 h after ingesting a fruiting body of *Scleroderma citrinum* (Galey *et al.*, 1990). The pig vomited and collapsed 20 min after exposure and remained weak and recumbent until its death. The toxins in *S. citrinum* have not been characterized. In *Boletus satanas*, lectins may contribute to serious gastroenteritis in man. Lectins, which are storage proteins that may play a role in plant defense, are widely distributed in many species of mushrooms (Wang *et al.*, 1998).

Poisonings by mushrooms of this group are rarely fatal, hence they are likely to be underreported by owners, and

rarely recorded in the literature. After a usually short latent period of 15 min to 2 h after ingestion, an animal may present with vomiting, diarrhea, and abdominal pain. Usually, these clinical signs resolve spontaneously within a few hours, but they may last a day or 2. The clinical signs may resemble any other common cause of gastroenteritis in small animals, including bacterial and viral infections, sudden diet changes or eating spoiled foods, and inflammatory-mediated syndromes such as acute pancreatitis. The diagnostic challenge is that many of the more toxic mushrooms can initially cause these same clinical signs. Cyclopeptides cause vomiting and diarrhea after a lag period similar to that seen with the gastrointestinal irritants. Therefore, any animal presenting with gastrointestinal signs after a known history of mushroom ingestion must be treated thoroughly.

Treatment is entirely non-specific and supportive. Vomiting is a hallmark of poisoning by gastrointestinal irritant mushrooms. Thus, in most cases the stomach has already been emptied and emetics are not necessary. Activated charcoal is thought to adsorb most of the toxins in this group and should be administered orally unless there is protracted vomiting. There are no specific antidotes for the toxins in this group. Treatment should focus on rehydration, correction of serum electrolyte abnormalities, and possibly antiemetics.

## ORELLANINE

There are several cyclopeptide-containing mushrooms that cause renal failure without any hepatic insult. Mushrooms of the genus *Cortinarius* contain the cyclopeptide orellanine (Danel *et al.*, 2001). In North America, there are only a few reported cases in humans, but poisonings occur with much greater frequency in western and central Europe. In humans, symptoms may not appear for 2–20 days after ingestion. Initially, people experience nausea, vomiting, and abdominal pain. This is followed by intense thirst, chills, polyuria or oliguria, and then possibly, anuria. Hemodialysis may be necessary until renal function gradually improves. There are no reports of orellanine poisoning in animals.

## RAMARIA FLAVO-BRUNNESCENS

This mushroom is found in North America, Australia, China, Brazil, and Uruguay and has caused poisoning in cattle and sheep (Kommers and Santos, 1995). *Ramaria flavo-brunnescens* is exclusively found in Eucalyptus woods and thus, the poisoning has been termed "eucalyptus sickness". Clinical signs have been observed as early as 3 days after exposure to the mushrooms, but may be delayed until 6 days post-exposure. Typically, the animals develop anorexia, salivation, diarrhea, and recumbency. This is followed by alteration in keratinization, which becomes apparent by loss of hair and hooves, similar to what is seen in chronic selenosis. The toxins have not been identified, but are most likely volatile and interfere with the incorporation of sulfur-containing amino acids.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Overall, the number of reported mushroom poisonings in animals is low, although this is likely a result of the lack of methods to confirm exposure. In humans, most cases are diagnosed by positive identification of the suspect mushroom, which is a very difficult task in veterinary medicine. The chances of obtaining an intact and representative mushroom are slim because animals are often left unattended and a history of ingestion is not available. The development of new analytical techniques to identify mushroom toxins in biological samples of poisoned animals will provide insight into the true frequency of mushroom poisonings. Currently, therapeutic measures are primarily based on both mechanisms of toxicity and clinical signs. Rapid toxin identification would allow for a confirmed, early diagnosis, which is especially important in cases where intensive care is necessary to save lives. In order to develop analytical techniques for specific mushroom toxins, further research is necessary in the area of toxin characterization. Although thousands of mushrooms exist worldwide, only a few have been researched in-depth. It is also important to improve our knowledge of the distribution kinetics and the efficacy of commonly recommended, but poorly evaluated decontamination procedures for many poisonous mushrooms.

# Cottonseed toxicity

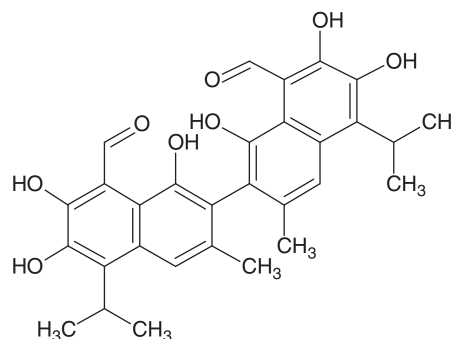
*Steven S. Nicholson*

## INTRODUCTION

Whole cottonseeds are a product of cotton (*Gossypium*) production. They are approximately 20% oil and 20% protein and contain polyphenolic pigments one of which is the toxic component gossypol ($C_{30}H_{30}O_8$). Gossypol is a yellow liquid located within the pigment or oil glands in the cotton plant. In cottonseed these glands appear as brown to black specks within the white matrix of the seed. The content of gossypol in whole cottonseed ranges from 0.02% to 6.64% and is thought to provide resistance to insects (Price *et al.*, 1993). Gossypol is recognized for its toxic effect on cardiac, hepatic, pulmonary, and reproductive systems. Whole cottonseed, cottonseed meal, and cottonseed hulls are important feedstuffs. Cottonseed meal is a 36–41% protein supplement used in beef and dairy rations. Cottonseed hulls are used as a fiber source in cattle rations. The risk of gossypol toxicosis limits the amount of cottonseed meal in the diet of swine, poultry, dogs, and other monogastric animals as well as pre-ruminant calves and lambs. The literature does not describe clinical cases in equids. Adverse effects of gossypol on reproduction in humans and animals may occur in certain situations.

## BACKGROUND

Gossypol is one of the several polyphenolic compounds found in the pigment glands of whole cottonseed. Some gossypol is bound to protein in the stomach contents of ruminants. Cottonseed cake remains after oil is extracted from the seeds. Removal of the oil by commercial processors leaves cottonseed meal containing gossypol in two forms, free, the toxic form, and bound. Methods of extraction of the oil include mechanically extracted cottonseed meal containing 0.06% free gossypol and the expander solvent method cottonseed meal containing 0.14% free gossypol (NCPA, 2005). A solvent only method of extraction produced cottonseed meal with free gossypol content up to 0.6%. Bound gossypol is bound to amino acids in the meal and is considered unavailable for digestion. Some bound gossypol may be digested and absorbed by ruminants.



Gossypol

## PHARMACOKINETICS/ TOXICOKINETICS

Intake of free gossypol at a toxic level for a period of days or weeks by susceptible animals leads to the appearance of toxic effects. Gossypol tends to accumulate in the liver and kidneys. Little or no gossypol was detected in milk from cows fed cottonseed products (Lindsey *et al.*, 1980). Half-life of gossypol in three dairy cows ranged from 40.7 to 67.5 h (Lin *et al.*, 1991). Low-dietary iron leads to increased gossypol absorption and iron added to the diet can reduce absorption (Haschek *et al.*, 1989). Tissue concentrations in

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

swine, from highest to lowest, were found in muscle, liver, fat, and red blood cells. In swine, gossypol is metabolized in the liver to various compounds, conjugated as glucuronides and sulfates, and excreted in the feces (Abou-Donia, 1989). In poultry, gossypol reacts with iron in egg yolks to produce an olive green color. Cyclopropenoid fatty acids in cottonseed meal causes egg whites to become pink.

## MECHANISM OF ACTION

Considerable evidence points to oxidative stress, formation of reactive oxygen species, and DNA scission, characteristics of redox cycling by electron transport in biosystems (Kovacic, 2003). Myocardial necrosis, congestive heart failure, and secondary hepatic changes, account for clinical signs and course of the toxicosis. Death may occur suddenly and unexpectedly in some cases.

## TOXICITY

Toxic levels of free gossypol in the diet produce cardiac necrosis and congestive heart failure in swine, dogs, goats, cattle, pre-ruminant calves, and lambs. Dairy cows are susceptible to gossypol toxicosis.

Cottonseed products are seldom fed to horses. Precautions for feeding young horses cottonseed meal include the fact that it is low in lysine and to use meal containing <0.2% gossypol.

High mortality was seen in dairy calves fed cottonseed meal with 250–380 ppm gossypol for the first 10 weeks of life (Holmberg *et al.*, 1988). Gossypol in the diet at 250–300 mg of free gossypol per day for several months apparently caused congestive heart failure in adult goats (East *et al.*, 1989). Holstein calves may develop ascites, diarrhea, and weakness after consuming toxic levels of gossypol in a diet containing cottonseed meal for 70 to perhaps 180 days. In the author's experience (unpublished data) a typical case of gossypol poisoning presents as follows. Holstein calves 3–8 months of age were confined to dry lot and fed up to 3.6–4.5 kg/day of lactating cow ration for 4 months with little or no hay available. The feed contained 600 lb (272 kg) cottonseed meal per ton. The free gossypol content of the cottonseed meal was determined to be 0.6%. Two calves had died a day or so apart from what was thought to be pneumonia because of cough, dyspnea, and blood tinged nasal discharge. Two calves were sick at the time of the farm visit. One had diarrhea, ascites, dyspnea, anemia, and weakness. At necropsy, ascites was marked the liver was swollen, the intestinal tract was edematous, the heart had pale areas within the myocardium, later confirmed as areas of necrosis, and the lungs were edematous. Other causes myocardial necrosis including the plant oleander (*Nerium oleander*), ionophores, excess selenium injection, and white muscle disease were ruled out.

Gossypol poisoning in mature cattle is uncommon but dairy cows can be at risk because they may be fed cottonseed and cottonseed meal during lactation. Dairy cows consuming high levels of cottonseed meal may be at risk of cardiac failure (Jimenez, 1979; Lindsey *et al.*, 1980; Smalley and Bicknell, 1982). High temperature and humidity seem to enhance the risk. Dairy cows tolerated up to 6.2 mg/kg b.w. free gossypol per day for 100 days but 8.8 mg/kg caused red cell fragility, depressed hemoglobin levels, and increased respiratory rate in response to elevated ambient temperatures (Lindsey *et al.*, 1980). Erythrocyte fragility at days 28 and 56 and elevated serum alkaline phosphatase were noted but adverse reproductive effects were not seen in crossbred heifers fed a diet of 30% cottonseed (Calhoun *et al.*, 1991). Consumption of a high gossypol diet for 170 days had no effect on the health of lactating dairy cows, but it increased plasma gossypol concentrations and impaired reproductive performance (Santos *et al.*, 2003). Ammoniation of cottonseed meal to reduce aflatoxin content was thought to have enhanced the toxic effects of gossypol in dairy cattle fed 6–9 lb/day (Smalley and Bicknell, 1982).

Lambs fed a diet containing 900 ppm free gossypol for 3–4 weeks died suddenly or after exhibiting signs of cardiac failure (Morgan *et al.*, 1988). Clinical signs included sudden death and/or chronic dyspnea syndromes. Serum chemistry alterations in the lambs included high serum total lactate dehydrogenase and lactate dehydrogenase liver-specific isoenzyme activities. Serum total creatine kinase activity decreased markedly in lambs of all groups treated with gossypol at 45, 136, or 409 mg/day. All lambs given 409 mg of gossypol per day died before the end of the 30-day study.

In swine, dietary levels of 200–300 ppm free gossypol result in cardiac insufficiency and respiratory distress with mortality rates exceeding 50% (Haschek *et al.*, 1989).

In dogs cardiotoxicity associated with prolonged gossypol intake is similar to that in other species. Four dogs died, with lesions compatible with those described in experimental gossypol poisoning, after eating food sprinkled with cottonseed meal over a period of months. The amount of free gossypol fed was approximately 5.4–5.7 mg/kg/day for an unknown duration (Patton *et al.*, 1985). Rabbits and guinea pigs are susceptible as well.

In chicks, severe cases of perivascular lymphoid aggregate formation, biliary hyperplasia, and hepatic cholestasis were observed in chicks fed 800 and 1600 mg/kg of purified gossypol in feed (Henry *et al.*, 2001). This study also shows that histopathological changes in liver due to gossypol also occur at levels lower than the levels that affect body weight.

In fish, pathological effects of gossypol in tilapia (*Oreochromis* spp.) were decline in body weight, low

hemoglobin and hematocrit levels, abundance of immature red blood, and abnormal spleen morphology (Garcia-Abiado *et al.*, 2004). In rainbow trout feeding diets containing cottonseed meal over a total period of 10 months did not result in differences in growth and mortality compared to the control group ($p > 0.05$). Gossypol was transferred to the eggs and embryo survival increased linearly as gossypol content in the diet was increased (Blom *et al.*, 2001).

Adverse male reproductive effects are of concern since studies have found a decrease in testicular steroidogenesis and spermatogenesis in pubescent rams and bulls (Lin *et al.*, 1981; Kramer *et al.*, 1991). Reversible male infertility has been reported for some animal species and humans (Abou-Donia, 1989). In peripubertal bulls, gossypol (8 mg/kg/day for 56 days) increased sperm abnormalities. The number of sperm with proximal droplets was significantly higher in the gossypol-treated bulls, suggesting testicular degeneration, but the effects were reversible (Hassan *et al.*, 2004).

Extensive damage to the germinal epithelium has been shown in both rams and bulls which were fed diets containing gossypol and is of major concern (Randel *et al.*, 1992). However, cottonseed meal has been and remains an important winter-feeding supplement for beef cattle herds in southwestern United States.

Signs and lesions of gossypol toxicosis include myocardial necrosis, congestive heart failure, centrilobular necrosis of the liver, pulmonary edema, and perhaps mild hemoglobinuria caused by RBC fragility. Mild to moderate anemia may be present. Ascites, diarrhea, and edema of the intestinal tract secondary to congestive heart failure may be seen. Dairy cows and lambs may die suddenly with minimal lesions. Death caused by heart failure could occur several weeks after last consumption of toxic levels of gossypol.

Diagnosis of toxicosis includes history of prolonged dietary exposure, clinical signs, and lesions compatible with acute or chronic heart failure, and elimination of other potential causes.

## TREATMENT

Remove gossypol sources in the diet. Treatment of food animals affected by gossypol toxicosis is impractical. Dogs may benefit from therapy designed to strengthen heart function in congestive heart failure.

## CONCLUDING REMARKS

Pelleting reduced free gossypol by as much as 70% in whole cottonseed and by 48% in cottonseed meal (Barraza *et al.*, 1991). Pelleting represents a mechanism to decrease the toxicity of gossypol in cottonseed. Adding iron sulfate to the diet has a protective effect.

# Toxicity of yew (*Taxus* spp.) alkaloids

*Christina R. Wilson and Stephen B. Hooser*

## INTRODUCTION

Taxines, the principle toxic alkaloids derived from yew (*Taxus* spp.) plants, are responsible for numerous animal deaths each year. They are produced by members of the *Taxus* spp., evergreen trees or shrubs that are commonly used as ornamental landscaping plants. From their leaves and branches numerous taxine alkaloids have been isolated and characterized chemically. However, the degree of toxicity of each individual compound can vary. For the toxic members of the group, their primary mechanism of toxicity appears to be as antagonists of calcium channels in cardiac myocytes. This effect can cause disturbances in electrical conduction and rapid onset of adverse clinical signs often ending in death due to heart failure.

## BACKGROUND

### Plant characteristics

Yews (*Taxus* spp., Taxaceae) are evergreen plants often used for ornamental landscaping in many parts of the United States, Europe, and elsewhere throughout the world. Common varieties in the United States are English Yew (*Taxus baccata*), American Yew (*Taxus canadensis*), Japanese Yew (*Taxus cuspidata*), and Pacific or Western Yew (*Taxus brevifolia*), (Kingsbury, 1964). These plants can be highly toxic and have been implicated in human and animal poisonings. The poisonous taxine alkaloids have been reported to be present in the foliage, bark, and seeds of the plants, but not in the fleshy scarlet aril (berry) (Bryan-Brown, 1932; Kingsbury, 1964).

### Historical references

References to yew toxicity date back over two millennia (Bryan-Brown, 1932). In the first century, B.C.E., Julius Caesar (102–44 B.C.E.) wrote of Catuvolcus, the king of Eburones, who poisoned himself with yew "juice" (Fröhne and Pfänder, 1984). Ancient Celts committed ritual suicides by drinking extracts from yew foliage and used the sap to poison the tips of their arrows during the Gaelic Wars (Foster and Duke, 1990; Hartzell, 1995). Some primitive cultures are reported to have used yew extracts as hunting and fishing aids (Watt and Breyer-Brandwijk, 1962; Hartzell, 1995). During the 18th and 19th centuries, decoctions of yew leaf were documented as having been used as an abortifacient or an emmenagogue by women in Europe and India (Bryan-Brown, 1932; Watt and Breyer-Brandwijk, 1962), however, toxic side effects stemming from these usages may also have occurred.

### Chemical characterization

The first report of preparation of an amorphous, white, non-crystalline powder called, "taxine" was from analysis of yew foliage (*Taxus baccata* L.) for alkaloid content reported in 1856 by Lucas. It was isolated in crystalline form approximately 20 years later by Marmé, a French scientist (Hilger and Brande, 1890), but it wasn't until 1956 that Graf and Boeddeker (1956) discovered that taxine was a mixture of heterogeneous compounds. Further investigations recognized two major types of taxine alkaloids: taxine A and taxine B (Graf, 1956).

By subjecting the taxine extracts to electrophoresis (Graf, 1956), two major bands were noted. The fastest

**FIGURE 74.2** Structural formulas for taxines B.

moving band was designated taxine A which comprised approximately 1.3% of the total alkaloid extract. The slower migrating band, taxine B, represented approximately 30% of the total alkaloid fraction extracted from *T. baccata* L. (Graf, 1956; Graf and Bertholdt, 1957). Subsequent analysis elucidated the molecular formula of taxine A as well as its basic physical and chemical properties (Graf and Bertholdt, 1957; Graf *et al.*, 1982; and Table 74.1a and Figure 74.1a). The structural formula of taxine A was reported almost 25 years later (Graf, 1982) and an analog, 2-deacetyltaxine A ($C_{33}H_{45}NO_9$), from the leaves of *T. baccata* (Table 74.1b) in 1994 (Poupat *et al.*, 1994; Figure 74.1b). The structure of taxine B was first reported in 1986 (Graf *et al.*, 1986) which was slightly revised in 1991 (Ettouati *et al.*, 1991; Table 74.1c and Figure 74.2a). Purified taxine fractions from *Taxus* spp. reveal the presence of several taxine B-related compounds. Isotaxine B ($C_{33}H_{45}NO_8$), a structural isomer of taxine B, is present as a major constituent in the alkaloid fractions (Poupat *et al.*, 1994; Jenniskens *et al.*, 1996; Adeline *et al.*, 1997; Potier *et al.*, 1997; Table 74.1d and Figure 74.2b). Present as minor constituents in *Taxus* spp. are 1-deoxytaxine B (Figure 74.2c) and 1-deoxyisotaxine B (Figure 74.2d) (Jenniskens *et al.*, 1996; Potier *et al.*, 1997). Also present as minor constituents, at approximately 2% of the total concentration, are the taxine B pseudoalkaloids 13-deoxo-13α-acetyloxy-taxine B ($C_{35}H_{49}NO_9$), 13-deoxo-13α-acetyloxy-1-deoxytaxine B ($C_{35}H_{49}NO_8$), and 13-deoxo-13α-acetyloxy-1- deoxy- nortaxine B ($C_{34}H_{47}NO_8$) (Appendino *et al.*, 1997). Within the last decade the importance of the antineoplastic drug, taxol, a related member of the taxane diterpenoid family, has spurred the discovery and chemical characterization of over 350 members of this chemical class (Itokawa, 2003).

## PHARMACOKINETICS/ TOXICOKINETICS

For reasons probably related to their acute toxicity and the lack of pharmaceutical uses for the toxic taxine alkaloids, pharmacokinetic studies have not been published. However, extensive pharmacokinetic studies have been reported for the widely used antineoplastic drugs, paclitaxel (isolated from *T. brevifolia*) and docetaxel (synthesized via a taxane precursor from *Taxus bacatta*), which are also members of the taxane diterpenoid family. In studies with these two compounds, it has been found that they are both highly protein bound (>95%) in the serum. In addition, paclitaxel exhibits non-linear kinetics at therapeutic doses while the kinetics of docetaxel are linear. They are both metabolized in the liver by cytochrome P450 enzymes. Work done with docetaxel indicates that this is primarily the result of metabolism by CYP3A4 to pharmacologically inactive oxidation products which are excreted in the bile through a *p*-glycoprotein-dependent

mechanism (Gustafson *et al*., 2003; Baker *et al*., 2006). Less than 10% of the excretion is through the kidneys. Tissue distribution is extensive except for the central nervous system and testes. The elimination half-life for paclitaxel is 5–7 h (two compartment model) or 20 h (three compartment model) while the elimination half-life for docetaxel is 12 h (two compartment model) or 13 h (three compartment model). Liver insufficiency or the co-administration of compounds which modulate P450 activity may influence the activity of these antineoplastic drugs (Brown, 2003) and presumably, the activity of more acutely toxic members of the family such as taxines A and B.

## PHYSIOLOGY/MECHANISM OF ACTION

The earliest investigations of crude extracts of taxine alkaloids published in 1921 described effects that were primarily cardiovascular. When administered by the intraperitoneal or intravenous routes in rabbits and dogs, hypotension and cardiac arrest occurred in both species (Bryan-Brown, 1932). Additionally, when toxicity was severe enough to result in cardiac abnormalities, it was noted that peristaltic contractions of the gastrointestinal (GI) tract ceased.

The first extensive pharmacological research of taxines was reported by Bryan-Brown in 1932. Electrocardiographic analysis of isolated perfused hearts of rabbits and frogs revealed that crude taxine extracts gradually induced bradycardia resulting in diastolic cardiac arrest. More recent investigations have indicated that taxines depress atrioventricular (AV) conduction in a dose-dependent manner in isolated frog heart having the greatest effect on ventricular rate (Smythies *et al*., 1975; Tekol and Kameyama, 1987). In those studies, that effect could not be inhibited by the administration of atropine, vagotomy, or ganglionic/adrenergic blockade (Bryan-Brown, 1932; Vohora, 1972). It was thus concluded that the hypotension induced by taxine extracts was not mediated via the sympathetic or parasympathetic nervous systems, but rather by a direct action on myocardium (Vohora, 1972).

Large differences in the cardiotoxicity of taxine A and taxine B have been reported (Bauereis and Steiert, 1959; Alloatti *et al*., 1996). Administration of taxine B administered either *in vivo* or *in vitro* has shown that taxine B is more cardiotoxic than taxine A (Bauereis and Steiert, 1959; Alloatti *et al*., 1996). In the heart, taxine B causes inotropic effects while eliciting marked changes in AV conduction. In isolated, perfused guinea pig hearts, a 5 μM concentration of taxine B markedly increased AV conduction time and QRS duration (widening of the QRS interval), while 1 μM concentrations (lowest concentration used) significantly reduced heart rate (Alloatti *et al*., 1996). These changes led to AV conduction blocks and complete diastolic cardiac arrest. This marked increase in QRS duration (wide QRS interval) has also been reported in a case of human poisoning by yew ingestion (Matthew *et al*., 1993). Experimental administration of *Taxus* extracts intravenously to pigs also resulted in widening of QRS complexes as evaluated by electrocardiography. In those studies, sodium bicarbonate was not effective in reversing the widening of the QRS interval (Ruha *et al*., 2002). Additionally, taxine B causes a marked reduction in the maximum rate of depolarization of the action potential in isolated papillary muscle and thus, resembles the action of class I antiarrhythmic drugs (e.g. flecainide, procainamide, quinidine) (Bauereis and Steiert, 1959; Tekol, 1985; Alloatti *et al*., 1996). In contrast, taxine A has minimal effects on AV conduction time and QRS duration. Even at the highest concentration used (10 μM), taxine A induced only mild reductions in heart rate (Alloatti *et al*., 1996).

Taxines have lesser effects on other organs. In the few studies reported, crude taxine extracts have adverse effects on involuntary muscle, but not on voluntary muscle (Bryan-Brown, 1932; Vohora, 1972). Uterine contractions, relaxation of the intestines, and contraction of the duodenum and ileum have been noted in experimental animals dosed with yew extracts (Bryan-Brown, 1932; Vohora, 1972). More recently, Tekol and Gögüsten (1999) reported that taxine sulfate inhibits peristaltic movement in rabbit jejunum with a median inhibitory concentration ($IC_{50}$) of $1.86 \times 10^{-5}$ g/ml.

Due to their instability and the lack of purified taxines A and B for experimental use, research delving into the mechanism of action of taxines has frequently involved using crude extracts of taxines from yew. However, because taxine B is present at higher concentrations and is more potent than other taxines, it is assumed that the primary adverse effects of taxines in the following investigations are primarily the result of the activity of taxine B. Investigations of taxine extracts on cardiomyocytes and axons indicated that taxines cause an increase in cytoplasmic calcium by altering both calcium and sodium channel conductances (Smythies *et al*., 1975; Tekol, 1985, 1991; Tekol and Kameyama, 1987). Further electrophysiological investigations demonstrated that taxines are calcium and sodium channel antagonists (Tekol and Kameyama, 1987; Tekol and Gögüsten, 1999). However, recent investigations regarding the cardioselectivity of taxines have provided more conclusive evidence that their mode of toxicity is as calcium channel antagonists (Tekol and Gögüsten, 1999). In those studies, isolated aorta, atrium, and jejunum from rabbits were used to compare the cardioselectivity of taxines to verapamil, a known calcium channel antagonist. From these experiments, Tekol and Gögüsten (1999) concluded that the mechanism of action of taxines is

primarily based on its $Ca^{+2}$-channel antagonistic properties. It is likely that the toxicity of taxines in animals and humans also occurs through this same mechanism.

## TOXICITY

With the exception of the aril, all parts of the yew plant, including the seed within the aril, contain taxine alkaloids and are extremely poisonous. One study in laboratory rodents has indicated that higher toxicity is found in stems compared to leaves (Shanker *et al*., 2002). Although maximal concentrations occur during the winter (Watt and Breyer-Brandwijk, 1962), toxic amounts of taxines remain in the plants throughout the year and are not appreciably decreased by drying (Alden *et al*., 1977). It has been reported that the cardiotoxic taxines A and B are relatively abundant in English Yew (*T. baccata*) and Japanese Yew (*T. cuspidata*), yet only minimal amounts are found in Pacific Yew (*T. brevifolia*) (Tyler, 1960; Suffness, 1995; Itokawa, 2003).

Fatal animal toxicoses have been reported in the United States, Canada, Europe, and Asia (Kingsbury, 1964; Lee *et al*., 2003). The majority of these occur in domestic livestock including cattle (Casteel and Cook, 1985; Panter *et al*., 1993), horses (Karns, 1983; Cope *et al*., 2004; Tiwary *et al*., 2005), sheep (Rae and Binnington, 1995) and goats (Coenen and Bahrs, 1994), but have also been reported in dogs (Evans and Cook, 1991; Taksdal, 1994), a bear (Bacciarini *et al*., 1999), fallow deer in captivity (Wacker, 1983), emus (Fiedler and Perron, 1994), budgies (Shropshire *et al*., 1992), canaries (Arai *et al*., 1992), and experimentally in pigs (Ruha *et al*., 2002). It is interesting to note that yew (*Taxus baccata*) is often eaten by white-tailed deer (*Odocoileus virginianus*) in the United States without apparent adverse effects. This may be due, in part, to increased ruminal detoxification of the taxines present in the yew (Weaver and Brown, 2004). Clinical cases resulting in poisoning are often accidental and are frequently a result of livestock being unwittingly fed clippings from yew (*Taxus* spp.) bushes. Because of the difficulties in obtaining purified, stable taxines in quantities sufficient for mammalian studies, minimum lethal dose ($LD_{min}$) values were, in the past, assessed through the oral administration of yew leaves and branches (Watt and Breyer-Brandwijk, 1962; Clarke and Clarke, 1988). Utilizing these values, and estimating that 1 g of yew leaves contains approximately 5 mg of taxines (Smythies *et al*., 1975; Tekol, 1985; Jenniskens *et al*., 1996; Tekol and Gögüsten, 1999), minimal toxic doses of taxines (mg/kg body weight) in animals can be estimated and are summarized in Table 74.2. The body weights of the animals listed are average values for adult animals only (Spector, 1956). From Table 74.2, it is evident that the minimal toxic dose of taxines varies between species. Comparatively, horses are more sensitive ($LD_{min}$ of 1.0–2.0 mg/kg) and chickens are least sensitive ($LD_{min}$ of 82.5 mg/kg) to yew toxins.

Adverse clinical signs in livestock can vary depending on the amount of yew ingested. However, in most cases of acute poisoning, animals are often found dead 24 h or less after ingestion without demonstrating abnormal behavior or adverse signs of toxicity. In subacute poisonings, which have been reported infrequently, clinical signs may include: ataxia, bradycardia, dyspnea, muscle tremors, recumbency, and convulsions leading to collapse and death (Evers and Link, 1972; Casteel and Cook, 1985; Veatch *et al*., 1988; Evans and Cook, 1991; Tekol, 1991;

**TABLE 74.2 Oral lethal doses of yew leaves in animals**

Arai *et al*., 1992). In cases of deliberate yew poisoning in humans, adverse symptoms of toxicity are similar to those reported in animals. Yew ingestion results in dizziness, pupil dilation, nausea, vomiting, diffuse abdominal pain, tachycardia (initially), muscle weakness, and convulsions (Czerwek and Fischer, 1960; Fröhne and Pribilla, 1965; Schulte, 1975; Blyth, 1884). In some cases, these symptoms can proceed to bradycardia, bradypnea, diastolic cardiac standstill, or death (Fröhne and Pribilla, 1965; Schulte, 1975; Blyth, 1884; Sinn and Porterfield, 1991).

A diagnosis of yew poisoning in animals is frequently based on a history of exposure and identification of the yew (*Taxus* spp.) in the digestive tract. It is not uncommon that poisoning is associated with pruning bushes and then feeding the trimmings to the livestock. In some instances, it is difficult to readily obtain this information from the owners. In suspect cases, yew fragments (sometimes visible only by microscopic examination) are often found in the mouth, stomach content, rumen content, and/or small intestine. On occasion, exposure may be indicated in the history, yet gross identification of plant material is unconfirmed. This can be especially true in species that chew their food more thoroughly, such as horses. In these cases, diagnosis of taxine poisoning often requires a more detailed microscopic and/or chemical evaluation of the GI contents (Karns, 1983; Tiwary *et al*., 2005). Chemical analysis of GI contents (particularly stomach/rumen contents) via gas chromatography/mass spectroscopy (GC/MS), liquid chromatography/mass spectroscopy (LC/MS), or thin-layer chromatography (TLC) can be used to confirm the presence or absence of taxine alkaloids in extracts from stomach/rumen contents (Stahr *et al*., 1977; Kite *et al*., 2000; Tiwary *et al*., 2005). Of these techniques, GC/MS and LC/MS are the most sensitive. Currently, the only chemical standards available for these analyses are crude extracts from *Taxus* spp. bushes, not unlike the standards that have been used for the past 100 years.

There are no lesions at post-mortem examination which are pathognomonic in animals that have died due to yew toxicosis. Indeed, neither gross nor microscopic abnormalities (with the exception of large pieces of yew leaves and stems, if they are present in the GI tract) are generally seen (Kingsbury, 1964; Alden *et al*., 1977; Ogden, 1988; Rooks, 1994). An exception to this is a recent case of *Taxus* spp. toxicosis in a horse in which ecchymotic hemorrhages were visible grossly along the endocardial surfaces of the ventricles, and microscopically, mild multifocal necrosis of the myocardium was identified in the ventricular wall and papillary muscles of the heart (Tiwary *et al*., 2005). In subacute poisonings, gastroenteritis may be evident, however the inflammation is probably due to an irritant oil present in the yew and not taxine (Watt and Breyer-Brandwijk, 1962; Kingsbury, 1964; Evans and Cook, 1991). Rarely, other gross changes have been reported at necropsy. These have included moderate to severe rumenitis, superficial hemorrhages in the right ventricular myocardium and right atrium, and mild focal interstitial myocarditis (Ogden, 1988; Panter *et al*., 1993).

## TREATMENT

Death is frequently the first adverse clinical sign in animals that have eaten toxic amounts of yew. In these animals, treatment is unrewarding. However, in instances where known ingestion has recently occurred, it is important to remove the plant material from the GI tract and limit absorption. Rumenotomy, followed by replacement therapy with a mixture of mineral oil, electrolytes, activated charcoal, and alfalfa pellets has been effective in treating some cases of *Taxus* spp. poisoning in ruminants (Casteel and Cook, 1985). There is no specific antidote for taxine poisoning. Atropine or lidocaine has been suggested to be beneficial in alleviating the cardiodepressant effect of taxine (Kingsbury, 1964; Schulte, 1975). However, in experimental animal studies (Bryan-Brown, 1932; Vohora, 1972), and in human cases where the cardiac response to attempted treatment was closely monitored via electrocardiography, classic antiarrhythmic therapy has proven ineffective (Willaert et al., 2002). Additionally in humans, a variety of clinical measures such as the administration of circulatory stimulants, artificial respiration, and cardiac pacemakers have not been able to prevent death from yew intoxication (Fröhne and Pfänder, 1984).

## CONCLUSION

Although much progress has been made during the last few decades in identifying the toxins and active diterpenoid taxanes in plants of the genus *Taxus*, their mechanisms of action, and their physiological effects, yew intoxication in animals remains a fairly frequent, often fatal, and largely preventable cause of livestock losses. Since the earliest indication of ingestion of toxic amounts of yew is death, and since there is no antidote and no effective treatments other than evacuation of the GI tract and prevention of absorption, education of the public as to the inadvisability of feeding yew trimmings to livestock is currently the best deterrent to *Taxus* spp. toxicoses.

# Aflatoxins

*Robert W. Coppock and Ralph G. Christian*

## INTRODUCTION

Aflatoxins, on a worldwide scale, are important mycotoxins in human foods and animal feedstuffs (Williams *et al.*, 2004). Aflatoxin contamination causes economic losses of corn, cottonseed, peanuts, sorghum, wheat, rice and other commodities, and economic losses of processed food and feedstuffs. Commodities considered unsafe for human consumption can be incorporated into animal feedstuffs (Coppock and Swanson, 1986). Gourami and Bullerman (1995) are of the opinion that aflatoxicosis in domestic animals is considerably more prevalent than it is diagnosed. Health effects occur in companion animals, livestock, poultry and humans because aflatoxins are potent hepatotoxins, immunosuppressant, and mutagens and carcinogens (Clegg and Bryson, 1962; Allcroft and Lewis, 1963; Eaton and Gallagher, 1994). Aflatoxins are teratogenic (Robens and Richard, 1992). Aflatoxicosis in the human population, especially in areas stricken by poverty and drought and other adverse growing conditions, is an important public health problem (Williams *et al.*, 2004).

Most governmental jurisdictions regulate the levels of aflatoxins allowed in animal feedstuffs and human foods because of their toxicity. Worldwide, aflatoxins because of their prevalence and toxicity are important in public health. Public health concerns center on both primary poisoning from aflatoxins in commodities, food and feedstuffs, and relay poisoning from aflatoxins in milk. The allowable levels of aflatoxins in animal feedstuff and human foods vary with governmental jurisdictions. Regulatory information for aflatoxins is usually posted on government websites.

## BACKGROUND

### Identification of aflatoxins

Aflatoxins, in the late 1950s and early 1960s, were identified as the cause of the mysterious turkey "X" disease in Great Britain (Clegg and Bryson, 1962; Allcroft and Lewis, 1963). Aflatoxins were identified as carcinogenic in rainbow trout (Newberne and Butler, 1969). In the United States, studies on aflatoxins incriminated aflatoxins as the cause of epizootic hepatitis in dogs and as the cause of moldy corn poisoning in pigs (Newberne *et al.*, 1966).

## AFLATOXIN PRODUCTION

### Aflatoxigenic fungi

The most commonly recognized aflatoxigenic fungi are *Aspergillus flavus*, *A. parasiticus* and *A. nomius*. Other fungi reported to produce aflatoxins are *A. bombycis*, *A. ochraceoroseus* and *A. pseudotamari* (Klich *et al.*, 2000; Bennett and Klich, 2003; Mishra and Das, 2003). *Aspergillus flavus* and *A. fumigatus* have also been identified as pathogens in animals and humans (Barton *et al.*, 1992; Drakos *et al.*, 1993; Pepeljnjak *et al.*, 2004). Aflatoxins can be produced in tissues by toxigenic fungi. Assays of cultured *A. flavus* and *A. fumigatus* isolated from tissues have shown these fungi can produce aflatoxins, and chemical analyses of infected tissues have shown aflatoxins to be present (Matsumura and Mori, 1998; Mori *et al.*, 1998; Pepeljnjak *et al.*, 2004).

*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

Aflatoxins being produced in tissues have not been shown to cause liver lesions typical of aflatoxicosis. Aflatoxigenic fungi infect animals and humans that often are immunocompromised. Systemic aspergillosis by aflatoxigenic fungi was considered to contribute to immunosuppression (Mori *et al.*, 1998).

Aflatoxigenic fungi have worldwide distribution. In temperate and tropical areas these species of *Aspergillus* have ubiquitous distribution and are found in soil used for growing crops (Gourami and Bullerman, 1995). These fungi also have distribution in storage areas, processing facilities and in the distribution systems for manufactured products. The production of aflatoxins is associated with spore production by species of *Aspergillus* (Calvo *et al.*, 2002). Strains of *A. flavus* can vary in aflatoxin capability from non-toxic to highly toxigenic and are more likely to produce more aflatoxin (AF) $B_1$ ($AFB_1$) than $AFG_1$. Strains of *A. parasiticus* generally have less variation in toxigenicity and generally produce $AFB_1$ and varying amounts of $AFB_2$, $AFG_1$ and $AFG_2$. Chemical structures of these mycotoxins are shown in Figure 75.1.

Versicolorin A and sterigmatocystin mycotoxins are intermediates in the synthesis of aflatoxins. Strains of *Aspergillus versicolor* have been reported to convert versicolorin A and sterigmatocystin to $AFB_1$ and $AFB_2$ (Gourami and Bullerman, 1995). Aflatoxin (AF) $M_1$ ($AFM_1$) and $AFM_2$ are the 4-hydroxylated metabolites of $AFB_1$ and $AFG_1$, respectively. These metabolites can occur in aflatoxin contaminated feedstuffs and in the milk and tissues. Chemical structures of $AFM_1$ and $AFM_2$ are shown in Figure 75.2.

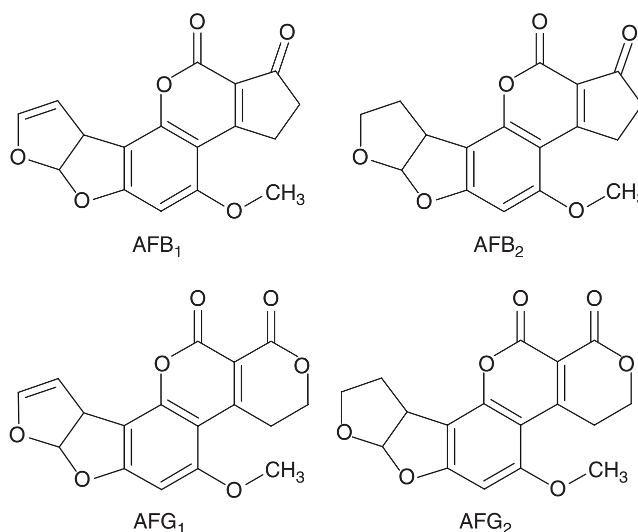

**FIGURE 75.1** Structural formulas of aflatoxins.

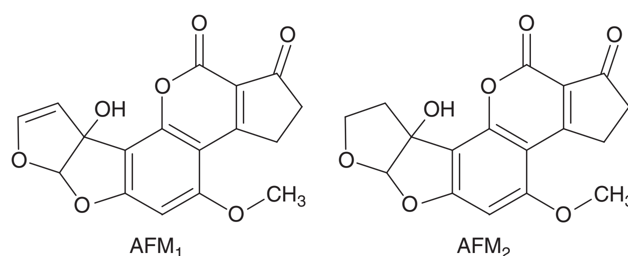

**FIGURE 75.2** Chemical structures of $AFM_1$ and $AFM_2$.

## Aflatoxin production in feedstuffs

All cereal crops can contain aflatoxins. Intensive cropping practices and decreased genetic diversity in cereal crops probably contribute to increased preharvest infections of commodities with fungi that produce aflatoxins (Lillehoj, 1992; Brown *et al.*, 1999). Preharvest contamination of crops with aflatoxins occurs in the temperate and tropical regions. The seeds in growth-stressed plants are the most susceptible to fungal invasion and aflatoxin production. The most common recognized plant stressors are drought, insect damage and timing of irrigation. Postharvest contamination occurs worldwide when conditions in the storage unit exist for the growth of aflatoxigenic fungi.

The primary recognized aflatoxigenic fungi in corn and sorghum are *Aspergillus flavus*, *A. parasiticus* and *A. nomius*. Of these fungi *A. flavus* is the species that has been most studied. *Aspergillus flavus* grows in plant-source debris on the soil (Gourami and Bullerman, 1995). Aflatoxigenic fungi can grow in feedlot manure (Hendrickson and Grant, 1971). Insects spread the spores of aflatoxigenic fungi to plants and the fungi colonize areas of insect damage. The flower and silk in corn can be portals of entry for species of *Aspergillus* (Diener *et al.*, 1987).

Aflatoxin contamination can rapidly occur (Coppock *et al.*, 1989). Lee *et al.* (1986) showed that maturing corn kernels in the ear on the plant inoculated with *A. flavus* had 0.3–2 ppb aflatoxins present at 2 days after inoculation, 950–2800 ppb aflatoxins present at 4 days after inoculation and 3600–4500 ppb aflatoxins present at 7 days after inoculation. The *A. flavus* infection reduced the starch content of the kernel by 12%. Kojic acid was present at 2700 ppb 16 h after inoculation. High moisture corn and sorghum lightly inoculated with *A. flavus* was shown to produce ppm levels of aflatoxins within 48 h (Winn and Lane, 1978). Overmature sweet corn was shown to contain 2.36 ppm $AFB_1$ and 0.21 mg of $AFB_2$ (Hall *et al.*, 1989). Sweet corn has been considered more hazardous than field corn because of its higher free sugar content.

Cottonseed can be a source of aflatoxins in animal diets. Preharvest contamination of cottonseed occurs (Jaimi-Garcia and Cotty, 2003). Insect damage, timing of irrigation or rain, relative humidity around the bolls, stage of

maturity and variety of cotton can be factors in causing preharvest contamination of cottonseed with aflatoxins (Russell *et al.*, 1976; Lillehoj *et al.*, 1987). In stored cottonseed growth of aflatoxigenic fungi may occur when the average moisture level in stored cottonseed is greater than 7–8%. The lipids and proteins in cottonseed enhance aflatoxin production (Mellon and Cotty, 1998; Mellon *et al.*, 2000).

Peanut hay, peanuts and peanut by-products are an important source of mycotoxins (McKenzie *et al.*, 1981; Cullen and Newberne, 1994). Aflatoxins generally are the most concentrated in the seeds. The growth of aflatoxigenic fungi can occur in stored peanuts when moisture exceeds 8% and ambient temperature is above 25°C. Drought-stressed peanuts have decreased native resistance to infection by aflatoxin producing fungi (Wotton and Strange, 1987). Phytoalexin produced by the infected peanut seed increased and inhibited the growth of *A. flavus*, but aflatoxin levels continue to increase for an additional day. Drought-stressed peanut seeds have decreased production of phytoalexin and aflatoxin production in drought-stressed peanut kernels is limited by available moisture.

Distillers by-products can be a source of aflatoxin (Hesseltine, 1984). Corn and other high starch commodities contaminated with aflatoxins can be salvaged by using them for alcohol production. Aflatoxins are not destroyed by the fermentation process. On a dry matter basis, the concentration of aflatoxins in the stillage, compared to aflatoxins in the feedstock, is increased due to the loss of starch. Approximately 40% of the aflatoxins are in the syrup (distillers solubles) fraction and 60% are in the solids fraction. Aflatoxins generally are not found in the alcohol fraction.

## MOISTURE LEVEL OF GRAIN

The most common methods of preventing the growth of aflatoxigenic fungi in dry-stored commodities are by controlling the moisture level. Water available for aflatoxigenic fungi in stored grain is best indicated by equilibrium relative humidity or water activity ($a_w$) of water in the air around the grain (Caddick, 2003). The $a_w$ is equal to % relative humidity/100. Temperature of the grain is important as the $a_w$ increases with temperature. In cereal grains aflatoxigenic fungi generally cannot grow when the $a_w$ is below 0.65. A lower $a_w$ is required for protection of oilseeds. Oilseeds have more available water on the seed surface because less moisture is absorbed by the seed. The greater the oil fraction of the seed the less water that is absorbed into the seed. For most cereal grains, storage moisture of 12% is recommended for a wide range of grain temperatures, and for oilseeds the storage moisture from $<8\%$ to 9% is recommended for wide range of temperatures inside the storage unit.

Measuring moisture with a grain tester provides the average moisture of the kernels. This measurement can misinterpret the storability of grain. If the moisture is heterogeneously distributed among the seeds or pellets hot spots can occur. This phenomenon occurs because a microbial microcosm exists around each high moisture seed and that microcosm can meet the requirements for fungal growth and mycotoxin production. This is the reason why high and low moisture grain should not be blended. In the microcosm with a favorable $a_w$ level, growth of aflatoxigenic fungi can occur. The metabolism of microorganisms in the microcosms produces moisture and some microorganisms can also produce heat. Insects and other pests in grain also produces moisture and hot spots can form because of insect and other pests in stored grain. Monitoring multiple areas of a storage unit is essential for preventing the production of mycotoxins.

Samples for aflatoxin analyses should be placed in moisture-proof bags to prevent desiccation. As soon as possible after sampling, the individual moisture content of at least 100 seeds or pellets should be determined to identify moisture distribution in the kernels or pellets.

## SAMPLING

Aflatoxins in the bulk lot of feedstuffs are generally assumed to be the same as the mycotoxins identified in the sample (Whitaker, 2003). For this reason the samples obtained should be representative of the feedstuffs. A representative sample may be difficult to obtain because the distribution of aflatoxins in the suspect feedstuff can be highly heterogenous. For this reason, a single random sample may not represent the aflatoxin levels in the feedstuffs sampled. A small percentage of the kernels in a lot of wheat, barley, corn, cottonseed and peanuts may be contaminated with very high concentrations of aflatoxins. Sampling error can occur even with a well-designed sampling protocol (Whitaker, 2003). Interpretations of analytical findings should reflect the sampling procedure, and aflatoxicosis cannot be ruled out based on negative chemical analyses of feedstuffs. Another sampling problem is the available feedstuff for laboratory testing may be limited because the majority of the suspect feed has been consumed by livestock or poultry. In these situations feed may be available from the edges of the feed trough, or clumps of feed retained in the feed handing equipment.

Aflatoxin can be present in clumps of feedstuffs (Crockcroft, 1995). These clumps may contain high level of aflatoxins and only a few animals may have consumed feed from this source, or the clumps were mixed with the feed and fed to a large number of animals.

## CHEMISTRY OF AFLATOXINS

Aflatoxins have a difuranocoumarin chemical structure. Approximately 18 aflatoxins have been chemically characterized. Aflatoxins are in two chemical groups, the difurocoumarocyclopentenone series (includes $AFB_1$, $AFB_2$, $AFB_{2A}$, $AFM_1$, $AFM_2$, $AFM_{2A}$ and aflatoxicol) and the difurocoumarolactone series (includes $AFG_1$ and $AFG_2$). The "B" Group fluoresce blue in long wavelength ultraviolet light and the "G" Group fluoresce green. The primary aflatoxins of concern in feedstuffs are $AFB_1$, $AFB_2$, $AFG_1$ and $AFG_2$. Analytical results for aflatoxins generally are the sum of the concentrations of these four toxins. $AFB_1$ is the most potent aflatoxin and this chemical form is generally the most abundant in feedstuffs and foods. The order of toxicity is $AFB_1 > AFG_1 > AFB_2 > AFG_2$. Hydroxylated aflatoxin metabolites are excreted in milk and the important metabolites are $AFM_1$ and $AFM_2$ (Garrido *et al.*, 2003). $AFM_1$ is the toxic metabolite of $AFB_1$ and $AFM_2$ is the hydroxylated form of $AFB_2$. Although $AFM_1$ and $AFM_2$ are commonly associated with milk and other edible animal product, these compounds can also be produced by aflatoxigenic fungi.

The toxicologist generally assumes that the level provided in the analytical findings represents the level of aflatoxins in the substances at issue. The toxicologist should know the sampling and analytical method(s) used and the limitations of these methods before interpreting analytical results. For the analytical results it is important to know the method(s) employed, the reference standards used including internal standards, and an estimate of the percent extracted from the matrix. If this information is not available or is not known to the toxicologists, a risk exists in misinterpreting the qualitative and quantitative results. It is our opinion that chemical methods are the most reliable for testing a wide variety of substances for aflatoxins.

## PHARMACOKINETICS/ TOXICOKINETICS

### Absorption

Aflatoxins are efficiently absorbed by passive diffusion from the gastrointestinal tract and are primarily transferred from the intestine to hepatic portal blood (Hsieh and Wong, 1994). Very little aflatoxins appear to be transferred into the lymphatic system (Kumagai, 1989). Young animals absorb aflatoxin more efficiently than older animals. Rats at 2.5 weeks of age absorbed $AFB_1$ at a rate ~15 times greater than rats 4–5 weeks of age. Cattle were given single oral dose of aflatoxins from rice culture (42% $AFB_1$ and 27% $AFB_2$) in gelatin capsules (Cook *et al.*, 1986). $AFB_1$ and $AFM_1$ were observed in venous blood (jugular vein) 30 min after dosing and reached maximal levels 4–8 h after dosing. The maximal levels of $AFM_1$ occurred before $AFB_1$ and the maximal blood levels of $AFB_1$ generally were higher than $AFM_1$. These findings suggest that aflatoxins are rapidly absorbed from the rumen. Rats have been shown to absorb $AFB_1$ most efficiently from the duodenum and jejunum (Kumagai, 1989). The rate of absorption of $AFB_1$ in rats is dependent on concentration providing evidence that aflatoxins are absorbed by passive diffusion. The rate of $AFB_1$ absorption from the duodenum of rats in diestrus was greater than the rate of absorption of $AFB_1$ from the duodenum in rats in mid-lactation.

### Metabolism and excretion

Biotransformation is important in the toxicology of aflatoxins. The most important organ for biotransformation is the liver, and biotransformation can also occur in the kidney and intestinal tract. The majority of research has focused on the biotransformation of $AFB_1$. With the exception of the $AFB_1$-8,9-epoxide, the biotransformation products are less toxic than $AFB_1$. Cytochrome P450 ($AFB_1$ hydroxylase) has a key role in the biotransformation of $AFB_1$ to $AFB_1$-8,9-epoxide. The formation of $AFB_1$-8,9-epoxide is considered to be the most significant biotransformation pathway because the $AFB_1$-8,9-epoxide forms adducts with DNA, RNA and proteins. Conjugation of $AFB_1$-8,9-epoxide with glutathione is considered to be an important detoxification pathway. Other biotransformation products of $AFB_1$ are $AFQ_1$ which can be metabolized to $AFH_1$. $AFB_1$ is also metabolized to $AFP_1$, $AFM_1$, aflatoxicol and other metabolites. The $AFP_1$, $AFM_1$, $AFQ_1$ and aflatoxicol form glucuronide and sulfate conjugates.

Cattle were given a single oral doses (ranging from 0.2, 0.4, 0.6 and 0.8 mg/kg body weight) of aflatoxins from rice culture (42% $AFB_1$ and 27% $AFB_2$) in gelatin capsules (Cook *et al.*, 1986). $AFM_1$ was identified in rumen contents 2 h after dosing. This observation suggests that $AFM_1$ is formed by the flora and fauna in the rumen. Urine from these cattle contained $AFB_1$ and $AFM_1$. Kuilman *et al.* (1998, 2000) showed that bovine hepatocytes metabolized $AFB_1$ to $AFM_1$ (48% metabolized in 8 h), $AFB_1$ dihydrodiol and minor levels of $AFB_1$ glutathione conjugate. Liver preparations from calves previously treated with β-naphthoflavone had increased *in vitro* transformation of $AFB_1$ to $AFM_1$ when compared to liver preparations from calves that had not been previously treated with β-naphthoflavone (Bodine *et al.*, 1982). Hatch *et al.* (1982) showed that hepatic damage by $AFB_1$ in goats was increased by pretreatment with phenylbutazone and benzoflavones. Hepatic Kupffer and endothelial cells in the rat have been shown to have upregulated activity of $AFB_1$ hydroxylase,

the enzyme that converts $AFB_1$ to $AFM_1$ (Gemechu-Hatewu *et al.*, 1996). The P450 inducers used were phenobarbitol, isosafrole, Aroclor 1254 and 3-methylcholanthrene.

Aflatoxins are excreted in milk, eggs, urine, semen, bile and feces. Excretion of aflatoxins in milk is discussed in following sections (see Residues). Bingham *et al.* (2004) identified $AFM_1$ and AFP in dog urine. $AFM_1$ and aflatoxicol have been shown to be formed by hens and are transferred to the egg (Qureshi *et al.*, 1998). Dogs dosed with 100 μg $AFB_1$/kg body weight excreted $AFM_1$ in the urine and 90% of the $AFM_1$ excreted occurred within 12 h after dosing (Bingham *et al.*, 2004). Humans exposed to dietary aflatoxins excrete $ABM_1$, $AFP_1$ and $AFB_1$-$N^7$-guanine in urine (Groopman *et al.*, 1985). Aflatoxins have been shown to be excreted in boar semen (Picha, 1986). Rats excrete $AFB_1$ into the intestinal tract via bile and the intestinal mucosa also excretes aflatoxins (Kumagai, 1989).

## Residues

Residues of aflatoxins, especially $AFM_1$ can occur in edible animal products. The foodstuffs of greatest public health concern are milk, dairy products, especially those made from casein, and liver and kidney (Applebaum *et al.*, 1982). Aflatoxins can be present in meat. Most governmental jurisdictions regulate the permissible level of aflatoxin in edible animal products.

### *Milk*

Aflatoxins can be present in processed milk products. Issues regarding aflatoxin contamination of fluid milk generally increase when regional contamination of commodities (e.g. corn, sorghum, cottonseed) occurs before harvest (Applebaum *et al.*, 1982). Milk products such as cheese and dried milk also can become directly contaminated with aflatoxins by fungal growth in these substrates. Aflatoxins appear in cow milk within 12–48 h after ingestion (Applebaum *et al.*, 1982; Frobish *et al.*, 1986). The amount of dietary aflatoxins being excreted in milk varies with the high value reported being as 3% and the low value being reported as 0.17% (Applebaum *et al.*, 1982; Stubblefield *et al.*, 1983; Price *et al.*, 1985; Frobish *et al.*, 1986). To compare with other mammalian species, humans excrete 0.09–0.43% of dietary intake in breast milk, sheep excrete 0.112% of the dietary $AFB_1$ as $AFM_1$ in the milk, and aflatoxins in sow milk have been shown to be ~1000-fold less than the aflatoxins in the diet (Zarba *et al.*, 1992; Silvotti *et al.*, 1997; Battacone *et al.*, 2003). The stage of lactation is important for excretion of aflatoxins (Veldman *et al.*, 1992). The percentage of aflatoxins in milk has been reported to increase with increasing milk yields (Frobish *et al.*, 1986). Cows in early lactation can excrete from 3.8% to 6.2% of the dietary $AFB_1$ as $AFM_1$ in the milk, and cows in late lactation can excrete 1.8% to 2.5% of the dietary $AFB_1$ as $AFM_1$. This phenomenon is independent of the level of $AFB_1$ in the diet and appears to be linked to cows having upregulation of $AFB_1$ metabolism during early lactation. The phenomenon of excreting more $AFM_1$ in milk during early lactation must be considered in calculating safe dietary levels of aflatoxins for dairy cattle, and may be of importance in calculating the rations for other milk producing animals. Herd-specific analytical data can be used to calculate the dietary:milk ratio for aflatoxins. Our experience has shown that this approach is accurate to predict aflatoxins in milk after changes have been made to reduce dietary aflatoxins. The dietary threshold for aflatoxins excretion in cow milk appears to be ~15 ppb dietary level or 230 μg $AFB_1$/cow/day. Aflatoxins in milk generally disappear within 24–72 h after all the aflatoxins have been removed from the diet.

Residues of $AFM_1$ in milk have been studied in dairy sheep (Battacone *et al.*, 2003). The ratio of $AFB_1$ in the diet to $AFM_1$ in milk was not affected by the dose of aflatoxins. Sheep receiving a single dose of $AFB_1$ excreted 0.032% of the dose as $AFM_1$ in milk. The mean value was 0.112% of the dietary $AFB_1$ was excreted as $AFM_1$ in the milk.

Aflatoxins are excreted in sow milk. The levels of aflatoxins in sow milk increased over a 25-day lactation period. The sows were fed diets containing 800 ppb $AFB_1$ or a diet containing 400 ppb $AFB_1$ + 400 ppb $AFG_1$ for entire gestation and lactation period (Silvotti *et al.*, 1997). The average ratio of aflatoxins in the diet to aflatoxins in milk was ~1000:1.

The general consensus in the scientific literature is that aflatoxins are stable in milk, and are primary associated with milk protein. Aflatoxins in raw milk slowly decrease by 11–25% in 1–3 days of storage at 5°C. Approximately 75% of aflatoxins in milk are found in the casein (protein) fraction and 25% in the whey fraction of milk. Aflatoxins are also found in butter and the division is ~84% in butter milk and ~16% in butter. Aflatoxins are concentrated in cheese, and the concentration factor varies with the type of cheese and cheese-making procedures. $AFM_1$ is decreased during yogurt manufacturing and a decreasing the pH of yogurt decreases the levels of $AFM_1$ (Govaris *et al.*, 2002).

### *Residues in meat*

Aflatoxins generally are found in liver, kidney and edible parts of the gastrointestinal tract. Aflatoxins are not known to accumulate in the body fat. Two-week-old turkey poults were fed diets containing 50 and 150 ppb $AFB_1$ (Richard *et al.*, 1986). The poults were killed at 11, 13, and 1 or 2 weeks after being fed the 50 and 150 ppb diets for 11 weeks (1 or 2 weeks on aflatoxin free diet). At 50 ppb feeding level for 11 weeks $AFB_1$ was found in liver (0.02–0.09 ng/g), kidney (0.01–0.02 ng/g) and gizzard (0.043–0.162 ng/g), and $AFM_1$ was not shown to be in

**TABLE 75.1 Levels in ng/g or ng/ml of aflatoxins in tissues after steers were fed a diet containing 800 ppb aflatoxins for 17.5 weeks (Richards *et al.*, 1983)**

| Toxin | Liver | Kidney | Muscle | Heart | Lung | Rumen |
|---|---|---|---|---|---|---|
| $AFB_1$ | 0.37 | 0.09 | 0.002 | 0.004 | 0.014 | 13.05 |
| $AFM_1$ | 1.07 | 4.82 | 0.115 | 0.14 | 0.29 | 1.66 |

liver, kidney and gizzard. Feeding 50 ppb aflatoxins for 13 weeks increased the residues of $AFB_1$ and $AFM_1$; for $AFB_1$ liver contained 0.02–0.13 ng/g, kidney contained 0.01–0.34 ng/g and gizzard at trace to 0.113 ng/g; $AFM_1$ in liver was 0.11–0.14 ng/g and kidney contained 0.01–0.07 ng/g. At the 150 ppb feed level, fed for 11 weeks, $AFB_1$ in liver was 0.08–0.13 ng/g, kidney was 0.025–0.08 ng/g and gizzard trace to 0.22 ng/g; $AFM_1$ was 0.03–0.10 ng/g in liver and 0.09–0.13 ng/g in kidney. Aflatoxin $M_1$ was not shown to be present in the gizzard. Breast and thigh muscles did not contain aflatoxins. Birds on the 150 ppm diet for 11 weeks and the control diet (no aflatoxins) for 2 weeks essentially had cleared the aflatoxins from the liver, kidney and gizzard. Steers fed a diet containing 800 ppb aflatoxins for 15 weeks and then placed on an aflatoxin free diet for 2.5 weeks did not have residues of aflatoxin in heart, skeletal muscle, liver and kidney (Richard *et al.*, 1983). Steers fed a diet containing 800 ppb aflatoxins for 17.5 weeks did have residues of aflatoxins (Table 75.1).

## TOXICODYNAMICS

### Mechanisms of action

The metabolism of aflatoxins, unlike many other mycotoxins, is closely linked with toxicity (Eaton and Gallagher, 1994). $AFB_1$ is metabolized in a P450-dependent reaction to $AFB_1$-8,9-epoxide which forms adducts with macromolecules in the cell. The affinity of $AFB_1$-8,9-epoxide in decreasing order for macromolecules is DNA > RNA > protein. The formation of these adducts is considered important in the toxicity of aflatoxins. The DNA adduct is formed with $N^7$-guanine and this adduct is relatively resistant to DNA repair processes. Upregulation of the P450 system increases the toxicity of aflatoxins. Species sensitivity to aflatoxins is linked to the rate of bioactivation and the rate of detoxification. $AFB_1$-8,9-epoxide is primarily detoxified by Phase II synthetic reactions. In mammals glutathione *S*-transferase-mediated conjugation is an important detoxification pathway, and species differences in part account for differences in species susceptibility. Other Phase II pathways that decrease the toxicity of aflatoxins include formation of glucuronide and sulfates.

### Immunotoxic effects

The immunotoxic effects of aflatoxins are of public health and economic importance. The native resistance to disease is reduced and vaccine protection is also impaired. The apparent clinical signs of aflatoxicosis may be limited to increased occurrences and severity of infectious diseases. Recovery from infectious disease may be prolonged and require additional treatments. A clue to immune dysfunction is often infections caused by organisms that generally are not considered to be pathogens. Studies have shown that the immunotoxicity of aflatoxins could be a teratogenic effect of aflatoxins. A literature review is provided for the immunotoxic effects of aflatoxins in different species.

The immunotoxic effects of aflatoxins have been studied in pigs. Treatment with $AFB_1$ has been shown to shorten the incubation period of *Serpulina (Treponema) hyodysenteriae* in pigs (Joens *et al.*, 1981). Pigs given $AFB_1$ and infected with *S. hyodysenteriae* also had a longer period of diarrhea. Feeding weanling piglets a diet containing 140 or 280 ppb aflatoxins (~70% $AFB_1$) for 4 weeks caused an increase in serum γ-globulin (Marin *et al.*, 2002). At the 280 ppb level, a reduced immune response to *Mycoplasma agalactiae* was observed. There were indications that interleukin-1β and tissue necrosis factor-α expression was decreased by exposure at the 280 ppb level. Sows were fed diets containing 800 ppb $AFB_1$ or a diet containing 400 ppb $AFB_1$ + 400 ppb $AFG_1$ for entire gestation and lactation period (Silvotti *et al.*, 1997). At 25 days of age the piglets born to the sows were found to have decreased immune functions in lymphoproliferative response to mitogens, monocyte-derived macrophages failed to have induced oxygen bursts and granulocytes had reduced chemotactic response. There is some evidence that *in utero* exposure of piglets to $AFB_1$ interferes with zinc metabolism and low plasma zinc decreases cell-mediated immunity because of a decrease in a zinc-dependent thymic hormone (Mocchegiani *et al.*, 1998).

Aflatoxins have been shown to be immunotoxic in ruminants. Feeding a diet containing 2 ppm aflatoxin (83.4% $AFB_1$, 12.3% $AFB_2$, and $AFG_1$ and $AFG_2$) to lambs for 37 days increased serum γ-globulin, decreased bacteriostatic activity in serum and decreased cellular immunity (Fernandez *et al.*, 2000). Studies done *in vitro* have shown that aflatoxin inhibits thymidine uptake by phytohemagglutinin-stimulated lymphocytes (Bodine *et al.*, 1984). Holstein steers (183 kg) fed a diet containing ~375 ppb aflatoxin for 17.5 weeks were observed to have a decrease in delayed cutaneous hypersensitivity (Richard *et al.*, 1983). Changes were not observed in antibody production (*Brucella abortus* antigen) and lymphoblastogenesis. Cattle were administered 0.3 mg of $AFB_1$ equivalent/kg of body weight for 12–14 days (Brown *et al.*, 1981). Before administration of aflatoxins, the cows were previously infected intramammary with

*Streptococcus agalactiae*, *Staphylococcus aureus* and *S. hyicus*. Clinical evidence of mastitis was not observed, but 3 of 4 cows had increased bacteria in the milk. The California mastitis test scores increased after the last dose of aflatoxins were given. Steers were administered a single oral dose of 0.6 or 0.8 mg $AFB_1$/kg body weight (Thurston *et al.*, 1986). Complement activity and bacteriostatic activity of serum decreased for 48–72 h and then returned to baseline at 7 days. In the same study cattle were administered 0.25 mg $AFB_1$/kg body weight/day for 14 days. The bacteriostatic activity of serum decreased until day 11 and then remained decreased for 29 days.

The immunotoxic effects of aflatoxins have been studied in poultry. Immunotoxic effects in poultry are lymphocytopenia, reduced T-cell counts and reduced native resistance to disease (Pier and Heddleston, 1970). Two-week-old turkey poults were placed on a diet containing 50 and 150 ppb aflatoxins for 11 weeks (Richard *et al.*, 1986). The poults were vaccinated with sheep red blood cells (SRBC) or *Pasteurella multocida* at 4 weeks and the vaccinations repeated at 8 weeks. Poults in the 150 ppb group had an increase in humoral response to *P. multocida* at 4 weeks and a decreased response to SRBC at 8 weeks. Three-week-old chicks were injected intramuscularly with 0.250 mg $AFB_1$ every 2 days for four administrations of $AFB_1$ (Otim *et al.*, 2005). At 3 and 6 weeks of age the chicks were vaccinated with Newcastle virus vaccines. Hemagglutination reaction to Newcastle disease virus was reduced. The immunosuppression of aflatoxins (from cultures of *A. flavus* NRRL 5518) were found to be additive with fowl adenovirus serotype-4 (Shivachandra *et al.*, 2003). The response to dinitrochlorobenzene hypersensitization was also reduced by $AFB_1$. Hens were fed diets containing 0.2, 1.0 and 5.0 ppm $AFB_1$ and fertile eggs were collected (Qureshi *et al.*, 1998). All chicks from hens given aflatoxins had reduced macrophage phagocytic activity and reactive oxygen burst. Antibody titers to SRBC were not changed on the primary vaccination, but the secondary response was depressed in chicks from hens given the diet containing $AFB_1$. A study by Sur and Celik (2003) showed decreased development of the bursa of Fabricius was observed in chicks after the egg was injected with 10 μg $AFB_1$ at day 7 of incubation.

## Reproductive and teratogenic effects

Reproductive and possible teratogenic effects have been reported for aflatoxins. Aflatoxins have been shown to be disruptive of sperm production and fertility in mice. An intraperitoneal dose of 50 μg of $AFB_1$/kg body weight/day (estimated to be equivalent to ~330 ppm in diet) was given to male mice for varying intervals (Agnes and Akbarsha, 2003). At 35 days, fertility testing showed a decrease in litter size, and tissue examination showed a decrease in spermatozoa numbers present in the caudal epididymis. When the numbers of spermatozoa decreased, forward mobility of spermatozoa was decreased and abnormal spermatozoa were observed. Sows were fed a diet containing 800 ppb $AFB_1$ or 400 ppb $AFB_1$ + 400 ppb $AFG_1$ from day 60 of pregnancy to day 28 of lactation (Mocchegiani *et al.*, 1998). Pigs born to the sows on the 800 ppb $AFB_1$ diet had reduced birth weights. Reduced birth weights was more pronounced in piglets born to sows consuming the diet containing 400 ppb $AFB_1$ + 400 ppb $AFG_1$. Pregnant rats were administered 0.3 mg of $AFB_1$/kg body weight on gestation days 11–14 or gestation days 15–18 (Kihara *et al.*, 2000). The offspring of these rats showed that prenatal exposure to $AFB_1$ caused a delay in early response development, decreased learning ability and impaired locomotor coordination.

# PATHOLOGY

## Clinical pathology

Acute aflatoxicosis causes changes in clinicopathology parameters. The activities of liver enzymes in serum are increased and the increased activity is indicative of hepatic damage. Once released into serum the activities of hepatic enzymes decrease as metabolic processes remove the hepatic enzyme from serum. Increased activity of hepatic enzymes in serum includes γ-glutamyl transpeptidase (transferase) (GGT), aspartate aminotransferase (AST, previously identified as SGOT), alkaline phosphates (ALP), sorbitol dehydrogenase (SDH), ornithine carbamyl transferase (OCT) and isocitric dehydrogenase (ICD). The activities of hepatic enzymes in serum that have been reported to be the most consistently elevated in aflatoxicosis are GGT, AST and SDH. The elevated activity of ALP is variable in aflatoxicosis. The timing of hepatic enzyme determinations in terms of the pathogenesis aflatoxicosis is important and enzymatic activity must be interpreted in context of the temporal aspect of aflatoxicosis. The activity of GGT has a slower temporal decrease than AST.

The clinicopathology of aflatoxicosis has been studied in cattle, sheep, goats, pigs, dogs and horses. Steers were given single oral doses (0.2, 0.4, 0.6 and 0.8 mg/kg body weight) of aflatoxins (Cook *et al.*, 1986). Increase in the serum activity of SDH and AST and not ALP was observed. The increase started at 8 h after dosing and reached maximal activity at 24–48 h and then rapidly decreased. Brucato *et al.* (1986) administered a single oral dose of 1 mg $AFB_1$/kg body weight to calves. Serum AST and GGT activities were increased within 2 days. After 2 days, the AST activity rapidly decreased whereas the GGT activity was elevated for 3 weeks. Aflatoxicosis from consuming high levels of aflatoxins in a concentrate has occurred in

cattle with an increase in serum activity of AST and no increase in GGT activity (Crockcroft, 1995). Feedlot steers fed a diet containing 600 ppb $AFB_1$ for 155 days had an increase in AST, ALP and SDH (Helferich *et al.*, 1986). Steers fed diets containing 60 and 300 ppm $AFB_1$ did not have an increase in AST, ALP and SDH. Holstein calves (70 kg) were fed a diet containing 5 ppm aflatoxins for 3 weeks (Wyatt *et al.*, 1985). Serum activity of lactic acid dehydrogenase (LDH) decreased, ALP peaked on treatment day 7 and then decreased, and AST increased to study day 14 and then plateaued. Holstein steers (183 kg) fed a diet containing ~375 ppb aflatoxin for 17.5 weeks were observed to have an increase in SDH and a decrease in AST activities (Richard *et al.*, 1983). Vaid *et al.* (1981) reported chronic aflatoxicosis in cattle consuming $AFB_1$ (0.11 ppm) contaminated groundnut cake. Hepatic enzymes in serum with increased activity were ALP and AST in 1 of 4 animals sampled. Timing of the blood sampling in terms of aflatoxicosis was not given, and these animals had histopathology consistent with aflatoxicosis. A study by Lynch *et al.* (1970) in calves suggested that the threshold dose for $AFB_1$ to increase ALP was 0.1 mg/kg body weight fed for 6 weeks. Goats given 3 mg of $AFB_1$/kg body weight by intramuscular injections had increased serum activity of AST which peaked at 32–40 h and then decreased (Hatch *et al.*, 1982; Clark *et al.*, 1984). Wethers had elevated serum activity of AST and GGT after consuming groundnut cake containing 750 ppb $AFB_1$ (Suliman *et al.*, 1987). Growing barrows were fed a diet containing 1, 2, 3 or 4 ppm aflatoxins for 28 days (Harvey *et al.*, 1988). On day 14, serum activity of AST and GGT increased in pigs fed the 4 ppm diet, on day 21 ALP increased in barrows fed the 4 ppm diet and AST increased in all pigs fed aflatoxins, and on day 28 ALP and activity was increased in pigs fed aflatoxins, GGT was increased in pigs fed the 3 and 4 ppm diets and serum AST activity was increased in pigs fed the 4 ppm diet. Dogs (1.5 years old) administered intravenously 15 doses of 0.05 mg $AFB_1$/kg body weight for 15 days had increased serum activity of ALP and ICD (Chaffee *et al.*, 1969). The clinicopathology of aflatoxicosis has been studied in horses. Weanling ponies were administered $AFB_1$ at 0.0, 0.5, 1.0 and 2.0 mg/kg body weight (Bortell *et al.*, 1983). Serum activity of GGT was increased in all ponies administered $AFB_1$. The GGT activity increased until day 3 and then decreased. Serum activity of alanine aminotransferase (ALT) was not increased. Ponies given 4, 5, 6 and 7.4 mg $AFB_1$/kg body had an increase in serum ALT and the activity of ALT increased until the ponies died at 33–46 h after dosing (Bortell *et al.*, 1983).

Serum chemistry is useful in the diagnosis of aflatoxicosis. Prothrombin time is generally increased and frank hemorrhage can occur. Serum bilirubin levels are also increased and photosensitization can occur. The changes in hematologic parameters generally are due to hemoconcentration and blood loss.

## Macroscopic and microscopic pathology

The pathology of aflatoxicosis has been described in several species. Edema including anasarca and edema fluid in the peritoneal and thoracic cavities can be observed (Osweiler and Trampel, 1985; Bastianello *et al.*, 1987; Coppock *et al.*, 1989; Hall *et al.*, 1989). The gall bladder, bile duct, abomasal wall and colonic mesentery may be edematous. There may be edema of the omentum near the stomach or abomasum and in the colonic mesentery. Gall bladder edema may be marked in cattle and pigs. Edema of the brain has been reported for horses (Angsubhakorn *et al.*, 1981).

Hemorrhage into the gastrointestinal tract, into body cavities and on body organs has been reported. Hemorrhage is due to decreased production of clotting factors by the liver. Acute aflatoxicosis in cattle, horses, pigs and dogs may result in serious hemorrhages in the gastrointestinal tract, on serosal surfaces, on the epicardium and endocardium, in skeletal muscle, perirenal and in the urinary bladder (Cysewski *et al.*, 1968; Chaffee *et al.*, 1969; Greene and Oehme, 1976; McKenzie *et al.*, 1981; Bortell *et al.*, 1983; Jakhar and Sadana, 2004). Pigs can also have hemorrhage occurring in the pleural and in the peritoneal cavity. The urine may be dark red colored.

Liver and kidney lesions occur. The liver may be swollen, friable and congested. Histologically, the liver may have necrosis in variable patterns. In the rat, monkey and duckling, the necrosis is reported to be periportal, while in cattle, pigs, horses, goats and sheep, the pattern is recorded to be centrilobular (Butler, 1964; Newberne *et al.*, 1966; Cysewski *et al.*, 1968; Samarajeewa *et al.*, 1975; Carlton and Szczech, 1978; Angsubhakorn *et al.*, 1981; Abdelsalam *et al.*, 1989; Coppock *et al.*, 1989; Mathur *et al.*, 1991). In the dog the pattern may be either or both periportal and centrilobular, while in the rabbit the pattern is reported to be midzonal (Newberne *et al.*, 1966; Chaffee *et al.*, 1969; Clark *et al.*, 1980). Hyperplasia of the bile duct cells occurs rapidly in ducklings and may be present in horses, dogs and chickens, and mild bile duct cell hyperplasia may be seen in cattle and pigs (Newberne and Butler, 1969; Ketterer *et al.*, 1975; Coppock *et al.*, 1989). Renal lesions of protein in proximal tubules and glomerular spaces are recorded in horses and rats (Butler, 1964; Newberne and Butler, 1969; Bortell *et al.*, 1983). Hemosiderin deposition in tubule cells occurs in horses (Angsubhakorn *et al.*, 1981). Cardiac myofiber degeneration is recorded in horses and rats (Butler, 1964; Angsubhakorn *et al.*, 1981). Brain lesions of focal malacia in the cerebral hemispheres in horses were recorded in one report (Angsubhakorn *et al.*, 1981), but have not been reported by others or in other species. However, hepatic encephalopathy could occur as a result of liver damage.

Subacute lesions observed at necropsy include firm, pale livers in all species and clear yellow ascites and pleural fluid accumulation especially in pigs and dogs (Newberne

and Butler, 1969). Icterus is usually present. Edema of the mesentery near the colon and perirenal edema may be present in pigs and cattle (Osweiler and Trampel, 1985; Bastianello *et al*., 1987; Coppock *et al*., 1989; Hall *et al*., 1989). Histologic changes include bile duct proliferation, hepatocyte necrosis and early fibrosis of the liver (Newberne and Butler, 1969). Regeneration of hepatocytes may be found in dogs, nodular hyperplasia may be present in turkeys, trout and ducklings (Newberne *et al*., 1966; Newberne and Butler, 1969; Bastianello *et al*., 1987). Variation in the size of hepatocytes, with some megalocytes and binucleate cells is recorded in many reports. Chronic liver lesions are characterized by firm, fibrous pale livers, by nodular hyperplasia and, in some cases, neoplasia. Icterus is present. Pulmonary edema may occur. Pneumonia is reported in calves as likely secondary to edema and the effects of aflatoxin on the immune system. Lesions of photosensitization have been reported in cattle.

## DIFFERENTIAL DIAGNOSIS

The lesions of aflatoxicosis and those of pyrrolizidine alkaloid toxicosis have been observed to be very similar especially in cattle (Loosmore and Markson, 1961). Cattle are generally considered to be more susceptible to pyrrolizidine alkaloids. When aflatoxins and pyrrolizidine alkaloid are at issue, it is important to examine pasture, forage, concentrate feeds and gastrointestinal contents to determine the presence of poisonous plants that may contain pyrrolizidine alkaloids. It is the experience of the authors that domestic animals with signs of aflatoxicosis never fully recover.

## TREATMENT AND OUTCOMES

A specific treatment for aflatoxicosis has not been identified. Aflatoxins from all sources should be removed from the diet. Symptomatic care of the affected animals is recommended. Animals on a low protein diet are more susceptible to aflatoxins (Cullen and Newberne, 1994).

Supplementing diets with choline and methionine, and *N*-acetylcysteine is probably beneficial (Cullen and Newberne, 1994; Valdivia *et al*., 2001). Adding vitamin E to swine diets containing 2.5 ppm aflatoxins did not have a protective effect on the severity of aflatoxicosis (Harvey *et al*., 1994). Increasing dietary zinc did not appear to be of benefit to calves fed a diet containing 5 ppm aflatoxins (Neathery *et al*., 1980). There is some suggestion that selenium provided some protection to Japanese quail fed a diet containing 1 ppm $AFB_1$ (Jakhar and Sadana, 2004). Excessive dietary selenium increases the toxicity of aflatoxins. Pimpukdee *et al*. (2004) found that a proprietary alumino-silicate (feed anti-caking agent) protected chicks from hepatic loss of vitamin A linked to aflatoxins in the diet. Feeding sodium bentonite was considered protective to pigs (Schell *et al*., 1993). Diaz *et al*. (2004) showed that sodium bentonite and MTB-100 (derived from cell wall of yeast) reduced $AFM_1$ in milk.

## AFLATOXIN INTERACTIONS

Multiple mycotoxins can occur when different feed ingredients are blended to manufacture a finished feed. When one mycotoxin is found in feedstuffs, the toxicologist should consider that additional mycotoxins of a different group may be present (Huff *et al*., 1988). The presence of multiple mycotoxins can alter the dose–response curve. Therein, the level of a mycotoxin that is generally considered to be safe can be altered by presence of other mycotoxins. The interactions of mycotoxins may vary between the indicators of effect. The interactions may be additive for one parameter and synergistic for another.

A feeding study in mice showed that a combination of fumonisin $B_1$ ($FB_1$) at 10 ppm and $AFB_1$ at 10 ppb increased feed consumption and decreased weight gains over a 90-day study interval (Casado *et al*., 2001). Liver lesions were considered to be intensified by the combination and this effect increased temporally. $AFB_1$ and $FB_1$ combination were shown to decrease feed conversion and feed consumption in feeder pigs (Dilkin *et al*., 2003). The dietary levels were 30 ppm $FB_1$ and 50 ppb $AFB_1$. Pigs were fed a diet containing aflatoxins produced in rice culture and a diet containing $FB_1$ produced in corn culture, and a diet containing both the rice and corn cultures (Harvey *et al*., 1995). The interactions of aflatoxins and $FB_1$ for immunologic and liver disease parameters were essentially additive. Cultures containing aflatoxins and $T_2$ toxin when fed in combination to Japanese quail and the interactions appeared to be additive (Madheswaran *et al*., 2004). Increased abnormal chicks were observed when ochratoxin A (2 $\mu$g) and $AFB_1$ (0.5 $\mu$g) were injected into eggs on day 3 of incubation (Edrington *et al*., 1995). Calves were fed diets containing ochratoxin A and $AFB_1$ (Patterson *et al*., 1981). The sources of the mycotoxins were naturally contaminated barley or naturally contaminated groundnut meal. The dose of ochratoxin A was 390–540 $\mu$g/kg body weight and the dose of $AFB_1$ was 10–13 $\mu$g/kg body weight. No adverse health effects were observed when the toxins were fed individually or as a mixture likely because of the ability of rumen organisms to degrade the mycotoxins.

Preexisting disease can increase susceptibility to aflatoxins. Osuna *et al.* (1977) concluded that preexisting liver flukes increased the susceptibility of cattle to aflatoxins and the interactive effect was additive. Henry *et al.* (2002) estimated that the presence of hepatitis B surface antigen in serum increased the human susceptibility to aflatoxins by a factor of 30. Shivachandra *et al.* (2003) showed the immunosuppression of aflatoxins were additive with fowl adenovirus serotype-4. Ethanol was found to potentiate $AFB_1$-induced hepatocarcinogenesis (Tanaka *et al.*, 1989).

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Aflatoxins, on a world scale, are one of the most important groups of mycotoxins (Lanyasunya *et al.*, 2005). The interactive effects of aflatoxins with infectious diseases and other chemical toxins have been demonstrated. Many fungal metabolites have been characterized. Although not classified as mycotoxins, these fungal metabolites should be investigated for interactive effects with aflatoxins.

# Trichothecenes

*Michelle S. Mostrom and Merl F. Raisbeck*

## INTRODUCTION

While hundreds of fungal metabolites have been discovered that are potentially toxic in animals, five mycotoxins are generally recognized as an agricultural problem in North America: deoxynivalenol (DON), fumonisin, zearalenone, aflatoxin, and ochratoxin. This chapter focuses on DON and the other trichothecenes.

More than 180 trichothecene mycotoxins have been recognized in the past 40 years (Grove, 1988, 2000). These fungal metabolites are a group of sesquiterpenoids characterized by a tetracyclic 12,13–epoxytrichothec-9-ene skeleton and a variable number of acetoxy or hydroxyl group substitutions. The epoxy group at C-12 and C-13 is considered essential for toxicity (Figure 76.1). Trichothecenes can be broadly divided into two groups, macrocyclic and non-macrocyclic trichothecenes, based on the presence of a macrocyclic ring linking C-4 and C-15 with diesters (roridin series) and triesters (verrucarin series). *Fusarium* molds or fungi are the most economically important source of trichothecene mycotoxins. The genus includes many field fungi capable of infecting wheat, corn, barley, oats, and forages. *Fusarium* is most common in temperate climates, but contamination of grains is reported worldwide (Placinta *et al*., 1999; JECFA, 2001; CAST, 2003).

Trichothecenes are potent inhibitors of protein synthesis and are toxic to molds, bacteria, plants, and animals. The hallmark clinical sign of trichothecene toxicosis in animals is feed refusal, which has led to speculation that animals may not voluntarily consume enough contaminated ration to cause marked poisoning; however, when the only available feedstuffs are contaminated with trichothecenes, poisoning may result. Clinical signs include emesis, feed refusal and weight loss, immunomodulation, coagulopathy and hemorrhage, and cellular necrosis of mitotically active tissues such as intestinal mucosa, skin, bone marrow, spleen, testis, and ovary (CAST, 2003). Trichothecenes have caused lethality in horses (Rodricks and Eppley, 1974), man (Joffe, 1974), and cattle (Hsu *et al*., 1972), but most recent scientific interest has focused on subclinical syndromes including nutritional impairment (Rotter *et al*., 1996), loss of production from contaminated feeds, and immunosuppression (Bondy and Pestka, 2000; Pestka and Smolinski, 2005).

Some of the confusion about clinical effects of trichothecenes results from the discrepancy between controlled experiments and field studies, and from the variable toxicity of contaminated feedstuffs. Studies using experimental animals and purified trichothecenes often suggest a dose–response relationship for a particular clinical effect that is not supported by field observations. Some naturally

| Trichothecene | R1 | R2 | R3 | R4 | R5 |
|---|---|---|---|---|---|
| T-2 toxin | OH | OAc | OAc | H | $OCOCH_2CH(CH_3)_2$ |
| HT-2 toxin | OH | OH | OAc | H | $OCOCH_2CH(CH_3)_2$ |
| Diacetoxyscirpenol | OH | OAc | OAc | H | H |
| Neosolaniol | OH | OAc | OAc | H | OH |
| Calonectrin | OAc | H | OAc | H | H |

contaminated grains are more toxic than can be accounted for by their known mycotoxin content. Controlled experiments using identical methods and similar test animals may yield marked variation, both qualitatively and quantitatively, in response to different batches of naturally contaminated feed. It seems likely that spontaneous trichothecene mycotoxicoses in livestock are complicated by the presence of unidentified mycotoxins or additional fungal metabolites in the ration. Diagnosis may also be frustrated by the difficulty of obtaining a representative feed sample to test and appropriate analytical methodology to identify fungal metabolites.

## BACKGROUND

Mold-infected grains have been associated with ill health in livestock and man for over a 100 years. In European Russia and Eastern Siberia, "scabby grains" and "moldy hay" have long been recognized as toxic, and in Japan, a red mold disease or "Akakabi-byo" of wheat caused gastroenteritis in man (Saito and Ohtsubo, 1974). Alimentary toxic aleukia (ATA) of human beings and a similar condition (stachybotryotoxicosis) of horses were associated with overwintered grains and hay during the 1930s and 1940s in the former USSR. Delayed harvest resulted in overwintering of grain, and the cold, wet conditions resulted in the growth of mold on overwintered grain and hay. These molds were later identified as *Fusarium sporotrichioides*, *Fusarium poae*, and *Stachybotrys alternans* in grain and hay, respectively, and several trichothecene mycotoxins were isolated. The primary toxin associated with ATA was identified as 4β,15-diacetoxy-3α-hydroxy-8α-[3-methylbutyryloxy]-12,13-epoxytrichothec-9-ene or T-2 toxin. A brief description of ATA is informative as it illustrates the classical effects of potent trichothecenes, mainly epithelial irritation or dermonecrosis, gastrointestinal irritation, and immunosuppression (Joffe, 1974). Clinically, ATA involved four stages. Stage one occurred shortly after ingestion of toxic grains. Symptoms included a burning sensation of the mouth, tongue, esophagus, and stomach and inflammation of the gastrointestinal mucosa accompanied by vomiting, diarrhea, salivation, dizziness, and tachycardia. This stage lasted from 3 to 9 days, and coincided with the initial clinical appearance of leukopenia. Stage two was termed the latent or leukopenic stage because the victim felt normal and could function normally, but major changes were occurring in the hematopoietic system including progressive leukopenia with granulocytopenia, and a relative lymphocytosis. Anemia, icterus, and lowered immune resistance to infections were typical of this stage and some reports describe abnormalities in the central and autonomic nervous functions. Stage two lasted from 2 to 8 weeks, with eventual recovery if exposure stopped. If victims continued to consume contaminated grain, the syndrome progressed to a third stage. In stage three, leukopenia worsened and thrombocytopenia and decreased fibrinogen resulted in anemia and petechial hemorrhages on the skin of the trunk, lateral surfaces of the arms, the thighs, face, and head. Nasal, gastric, and intestinal hemorrhages were noted. Necrotic lesions could appear in the throat, gums, buccal mucosa, larynx, and vocal cords with secondary bacterial infections. Lymph node enlargement was observed, and death from stenosis of the glottis was reported. If the victim survived, stage four consisted of a convalescent period of 2 or more months while bone marrow recovered. The clinical signs of ATA in humans have been reproduced in cats given repeated doses of T-2 toxin (Lutsky *et al.*, 1978).

The fungus usually involved in scabby grain blights was identified as *Gibberella zeae* (Schwabe) or *Fusarium graminearum*, its asexual or conidial phase (reviewed by Marasas *et al.*, 1984). A trichothecene, chemically described as 3,7,15-trihydroxy-12,13-epoxytrichothec-9-en-8-one, was isolated from barley (Morooka *et al.*, 1972) and field corn infected with *F. graminearum* (Vesonder *et al.*, 1973) and given the trivial name, vomitoxin. Vomitoxin, also known as Rd toxin, 4-deoxynivalenol, or DON, was demonstrated to be the *Fusarium* toxin responsible for feed refusal and emesis in monogastric animals fed contaminated corn (Vesonder *et al.*, 1976). Subsequently, an acetylated form of DON, 3-acetoxy-7,15-dihydroxy-12,13-epoxytrichothec-9-en-8-one (3-ADON) was isolated from a *Fusarium* culture that was more toxic than DON in male DDY mice (Yoshizawa and Morooka, 1973).

### Sources

Trichothecenes are produced by several genera of fungi, including *Fusarium*, *Stachybotrys*, *Myrothecium*, *Trichothecium*, *Trichoderma*, *Cephalosporium*, *Cylindrocarpon*, *Verticimonosporium*, and *Phomopsis* (Scott, 1989). Trichothecene mycotoxins (baccharinoids) have also been isolated from Brazilian plants, notably *Baccharis* spp.; however, all medically and economically important sources to date have been fungal, especially *Fusarium. Fusarium* is a major agricultural plant pathogen of temperate growing regions, where it causes *Fusarium* head blight in wheat, barley, triticale, and other grains. *F. graminearum* has an optimum temperature range for growth of 26–28°C at a water activity ($a_W$) greater than 0.88. *Fusarium culmorum* grows optimally at 21°C when $a_W > 0.87$. While increased rainfall will increase *Fusarium* head blight, the incidence of blight is primarily affected by moisture at anthesis when the temperature is in the optimum range (Miller, 2002). Moisture at silk emergence and wet weather later

in the season increase *Gibberella* or pink ear rot caused by *F. graminearum* in corn.

*Fusarium* species vary in toxigenic potential by strain, which in turn varies with geographic location. Mycotoxin production by *Fusarium* fungi is heavily dependent on oxygen, environmental pH, osmotic tension, and sometimes temperature. For example, DON is produced under conditions of low oxygen tension, whereas zearalenone (a non-trichothecene, estrogenic mycotoxin) production by the same fungi requires oxygen saturation, usually occurring after field crops senesce (Miller, 2002). Unusually cool weather conditions in late summer and early fall, coupled with heavy rainfall in the upper Mid-west of the United States can result in widespread, severe *Fusarium* infestation, and mycotoxin production. For example, the moldy corn epidemic in Wisconsin during 1962 and 1963 that lead to the isolation of toxigenic fungi and the discovery of several important Type A trichothecenes, including T-2 toxin occurred in such conditions (Bamburg *et al.*, 1968) and again in 1992, climatic conditions produced a bumper crop of various toxigenic *Fusarium*, *F. sporotrichioides*, *F. poae*, and *F. graminearum* in Wisconsin corn samples and the isolation of several trichothecenes (DON, T-2 toxin, HT-2 toxin, diacetoxyscirpenol (DAS), neosolaniol, and T-2 tetraol) and zearalenone (Park *et al.*, 1996).

Trichothecenes can be chemically classified into four types based on substitutions at five positions of the trichothecene skeleton, including Type A which includes T-2 toxin and HT-2 toxin (Figure 76.1); Type B including nivalenol and DON (Figure 76.2); Type C including crotocin (Figure 76.3); and Type D or macrocyclics (Figure 76.4). Type A trichothecenes include some of the most toxic trichothecenes, T-2 toxin, its deacetylated metabolite, HT-2 toxin, and DAS (or anguidine). These are most commonly produced for research in *F. sporotrichioides* and *F. poae* cultures. Both of these *Fusarium* spp. produce toxic metabolites in light or darkness and at low temperatures ($<-2$°C), however, sharp fluctuations in temperature increases the toxicity of extracts. In addition to ATA, moldy grains produced under low temperature conditions have been associated with moldy corn toxicosis (hemorrhagic disease), moldy bean hull intoxication, moldy cereal emesis, fusariotoxicosis, and dendrodochiotoxicosis (myrotheciotoxicosis) (Smalley and Strong, 1974).

The Type B trichothecenes are characterized by a keto group at C-8 and hydroxyl group at C-7. These are common natural field contaminants of grains and include DON and its acetylated derivatives, nivalenol ($3\alpha,4\beta,7\alpha$, 15-tetrahydroxy-12,13-epoxytrichothec-9-en-8-one), and fusarenon-X (4-acetylnivalenol) produced by *F. culmorum* and *F. graminearum*, and other, closely related fungi. They are less toxic than the other classes of trichothecenes without the C-8 keto substitution, such as T-2 toxin, DAS, and the macrocyclic trichothecenes.

*F. graminearum* most commonly occurs in southern China, North America, and eastern Europe, and *F. culmorum* more commonly occurs in western Europe. In North America, *F. graminearum* characteristically produces DON, which can co-occur with another 8-ketotrichothecene, 15-acetyldeoxynivalenol (15-ADON), but in Asia *F. graminearum* almost always produces DON with 3-ADON (Miller *et al.*, 1991). Although not a trichothecene, the estrogenic mycotoxin zearalenone is often found together with DON in North America. Other strains of *F. graminearum*, mostly of Japanese origin, produced nivalenol and fusarenon-X, zearalenone, and butenolide. *F. culmorum* strains from the Netherlands produced predominately DON and 3-ADON, while strains of *F. crookwellense*, collected from four continents, produced 4,15-diacetylnivalenol regardless of the source. More serious adverse effects could be underestimated from moldy corn if only DON, and no acetylated DON or additional trichothecenes, are assayed.

The Type C trichothecenes typically have a second epoxide ring at C-7,8 that are neither produced by *Fusarium*, nor are these trichothecenes associated with adverse effects in livestock. Crotocin (or antibiotic T) is a Type C trichothecene produced by *Cephalosporium crotocinigenum* and

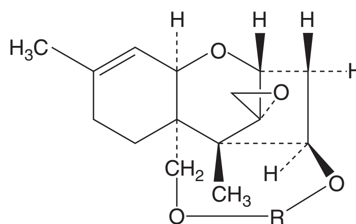

**FIGURE 76.4** Chemical structure of Type D trichothecenes and one example substitution.

*Trichothecium roseum* and has low toxicity in mice (Cole and Cox, 1981). In contrast with Type C trichothecenes, the Type D trichothecenes are potent, cytotoxic compounds with a macrocyclic ring linking C-4 and C-15 on the trichothecene skeleton. The genus *Myrothecium*, including *M. roridum*, *M. leucotrichum*, and *M. verrucaria*, can produce verrucarins and roridins that are diesters of the trichothecene verrucarol and acutely toxic to mammalian cell lines *in vitro* and to a wide range of animals with *in vivo* exposure (Mantle, 1991). No consistent naturally occurring toxicoses have been attributed to the *Myrothecium* toxins (Mantle, 1991).

While *Fusarium* does not produce Type D trichothecenes, the fungus *S. alternans* Bonorden (synonyms *S. atra* Corda and *S. chartarum* (Ehrenberg ex Link) Hughes), which grows worldwide on cellulosic vegetation and particularly on mildewed wet straw, produces macrocyclic trichothecene mycotoxins (including satratoxins G and H, verrucarin J, and roridin E) that are stable, highly toxic, and cause characteristic cytotoxic effects (Bata *et al.*, 1985). Although horses are the most sensitive species, stachybotryotoxicosis has been described in numerous animals, including zoo animals, in many countries of Europe, South Africa, and India.

In North America, the trichothecenes produced by *Fusarium* are the major contaminates in cereal crops. Optimal production of T-2 toxin by *F. sporotrichioides* in grains occurs at 6–12°C (as compared with zearalenone production at an optimal 19–20°C). Park *et al.* (1996) noted that trichothecene concentrations were increased in corn kept in the field and harvested later in cold winter temperatures (grain moistures often greater than 40%), but zearalenone levels were highest in samples collected in the early fall. The co-occurrence of T-2 toxin, DON, and zearalenone in field corn also occurs quickly after hail damage in the late summer or fall as hail damage allows fungi to invade the forming seed. Delayed harvests under wet conditions affect other crops. In the United States upper Mid-West, a humid, wet fall allowed field molds, such as *Alternaria*, *F. graminearum*, and *Phomopsis*, to infect soybeans and produce mycotoxins that include HT-2, DAS, DON, and zearalenone (Jacobsen *et al.*, 1995).

In unusually wet, cool periods, *Fusarium* mycotoxins not only occur in the grain, but also in the vegetative part of the plant. *Fusarium* infection of immature corn generally results in higher trichothecene and zearalenone concentrations in the cob, as compared with the mycotoxin concentrations in the kernels. Thus, avoiding incorporation of the cob in animal feed can potentially reduce exposure to mycotoxins. Usually, grain stored at moisture concentrations less than $0.70a_W$ or 14.5% moisture by weight is not susceptible to fungal growth or mycotoxin production.

Mycotoxin production occurs in hay, green feed, straw, and silage. Hay baled wet or stored in higher moisture conditions (>20%) is subject to molding. Fungal growth in silage usually takes place on the front edges of silage in bunker silos or where silage is not adequately packed and aerobic conditions exist. *Fusarium* occurrence increases with the practice of no till farming and utilizing corn in crop rotations. Hay, straw, or silage from *Fusarium*-contaminated wheat, barley, oats, and corn can contain high levels of trichothecenes, particularly DON and acetylated metabolites. Straw and hay contamination with DON may be as high as 100–150 mg DON/kg (dry weight basis) in wet years (Mostrom *et al.*, 2005).

Of the trichothecenes, DON is probably the most commonly detected in cereal grains throughout the world (Rotter *et al.*, 1996; CAST, 2003). This mycotoxin is resistant to milling and processing and readily enters the animal feed and human food chains. Foodborne trichothecene contamination, in particular DON, has been linked to acute human toxicoses in China, India, and Japan, but little information is available regarding potential health effects from chronic exposure (Bhat *et al.*, 1989; Kuiper-Goodman, 1994; JECFA, 2001).

## TOXICOKINETICS

Trichothecenes undergo all four basic reactions in xenobiotic metabolism. Phase I hydrolysis and oxidation and phase II glucuronide conjugation occur in the body tissues, while reduction of the 12,13-epoxide is thought to occur through microbial action in the gastrointestinal tract; although T-2 toxin is the only trichothecene for

which all four basic reactions or pathways occur simultaneously in the same animal (Swanson and Corley, 1989). The ability to remove the epoxide oxygen (deepoxidation) is an important step in the detoxification of trichothecenes. Orally administered trichothecenes do not accumulate to a significant extent in the body and are rapidly excreted within a few days in urine and feces (bile) (Swanson and Corley, 1989).

Understanding the toxicokinetics of trichothecenes is important for understanding potential effects in animals. Swine are especially sensitive to DON and kinetic parameters have been studied related to intravenous and acute and chronic oral DON exposures (Coppock *et al.*, 1985a; Prelusky *et al.*, 1988, 1990; Prelusky and Trenholm, 1991; Goyarts and Dänicke, 2006). Following an intravenous dose of DON at 1 mg/kg body weight in swine, the mycotoxin distributed rapidly to all tissues and body fluids and declined to negligible levels in all tissues sampled except urine and bile within 24 h (Prelusky and Trenholm, 1991). DON can be detected very rapidly (less than 2.5 min) in the cerebral spinal fluid following intravenous administration in swine; following oral administration of DON in pigs, the plasma DON concentrations correlated closely with cerebral spinal fluid DON levels (Prelusky *et al.*, 1990). Extensive DON tissue accumulation was not detected after dosage indicating that accumulation of edible tissue residues in swine is unlikely at low level DON exposure (Prelusky and Trenholm, 1991). Coppock *et al.* (1985a) reported no detectable residues of DON in skeletal muscle 24 h after intravenous DON administration in pigs. The reported half-life of DON in pigs after an intravenous injection of DON at 0.5 mg/kg body weight ranged between 2.08 and 3.65 h, suggesting that 97% of DON given would be eliminated in 10.1–18.3 h (Coppock *et al.*, 1985a). Following a lower intravenous dose of DON in pigs (0.053 mg/kg body weight), serum DON concentrations decreased biphasically with terminal elimination half-lives ($t_{1/2}\beta$) of between 4.2 and 33.6 h (Goyarts and Dänicke, 2006).

After oral exposure, DON is rapidly and nearly completely absorbed in the stomach and proximal small intestine of pigs (Dänicke *et al.*, 2004a). Pigs dosed with DON at 5.7 mg DON/kg diet chronically for 4 weeks or with one single oral acute exposure (one feeding) had quick absorption of greater than 50% of the DON administered that was highly distributed, with an apparent volume of distribution ($V_d$) higher than total body water, and serum elimination half-lives of 6.3 and 5.3 h in the chronic and acute DON-fed pigs, respectively (Goyarts and Dänicke, 2006). A total of 97% of the DON dose (five elimination half-lives) would be eliminated in 31.5 and 26.5 h after feeding DON chronically or in one single, acute exposure, respectively. The majority of DON ingested from dietary exposure was eliminated in the urine and feces, with urine being the main excretory route of DON in an unmetabolized form. Similar results were reported by Prelusky *et al.* (1988) who observed that after intravenous DON administration (0.30 mg/kg) in swine DON was rapidly cleared primarily unchanged in the urine, with minor elimination in bile. The metabolite deepoxy-DON was found in pigs fed the DON-contaminated diet chronically or for a period of longer than 4 weeks (Goyarts and Dänicke, 2006). Eriksen *et al.* (2003) fed pigs a commercial diet containing 3-ADON at 2.5 mg/kg for 2.5 days. Following ingestion, DON was quickly detected in the plasma (indicating deacetylation), with approximately 42% present as a glucuronide conjugate. DON was excreted mainly in urine, with a smaller amount excreted in feces. Deepoxy-DON constituted 52% of the 3-ADON metabolites detected in feces. The deepoxy-DON metabolite increased in concentration from the distal small intestine to the rectum indicating that deepoxidation occurs in the hindgut, which would have minimal influence on toxicity because of major absorbance of DON in the upper gastrointestinal tract.

In contrast with the poor metabolism of DON by swine, the rumen is capable of extensive metabolism of DON and other trichothecenes. The major metabolite of oral DON in ruminants is 3α,7α,15-trihydroxytrichothec-9, 12-diene-8-one (deepoxy-deoxynivalenol or DOM-1). Deepoxidation of DON to DOM-1 is considered a deactivation step resulting in a non-cytotoxic compound; thus, ruminal metabolism serves a protective function. Because biotransformation occurs in the rumen, little parent compound is available for absorption (Prelusky *et al.*, 1986a; He *et al.*, 1992). Côté *et al.* (1986) reported cows fed high concentrations of DON (66 mg/kg diet for 5 days) excreted approximately 20% of the DON fed in urine and feces as unconjugated DOM-1 (96%) and DON (4%). Preliminary data from the study suggested to the authors that a portion of the remaining 80% of the dose was excreted as glucuronide conjugates of DON and DOM-1 in urine. Dänicke *et al.* (2005) utilized six cannulated dairy cows to evaluate DON and zearalenone metabolism and the effects of *Fusarium*-contaminated wheat on nutrient utilization. The cows were fed a 50:50 mixture of grass silage and contaminated wheat (3.1 mg DON/kg and 0.186 mg zearalenone/kg total ration) providing approximately 25 mg DON/cow/day intake or 0.04 mg DON/kg body weight/day for 4 weeks. The ration was restrictively fed and no feed refusal was observed. Only a small fraction (about 4–28%) of DON was recovered at the duodenum in the form of DON and DOM-1. DOM-1 accounted for 89% of duodenal flow of this mycotoxin. The authors concluded that extensive ruminal metabolism or absorption by rumen mucosa resulted in low DON recovery in the duodenum. No changes were detected in pH or volatile fatty acid concentrations in rumen fluid from cows fed control wheat versus *Fusarium*-contaminated wheat. In contrast, the ammonia concentrations in rumen fluid

were significantly higher from 90 min to 5 h after feeding the *Fusarium*-contaminated wheat, as compared to control wheat. Additionally, the flow of utilizable protein and microbial protein were reduced at the duodenum, suggesting altered ruminal protein utilization could be either the result of mycotoxins in the rumen or from *Fusarium* damage to the structure (cell wall) of wheat grain.

Prelusky *et al*. (1986a) reported that sheep dosed intravenously with DON rapidly excreted two major metabolites of DON as conjugated DON and conjugated DOM-1 in urine, with elimination half-lives of 2.2 and 3.1 h, respectively. Total recovery was 66.5% of the dose, with 63% in the urine and 3.5% in the bile made up of primarily conjugated DOM-1. This suggests the predominant route for elimination in sheep is biotransformation prior to excretion.

Poultry have a greater tolerance to trichothecenes than monogastric mammals because of poor absorption following oral exposure, extensive metabolism, and rapid elimination from the body (Prelusky *et al*., 1986b; Gauvreau, 1991). Oral administration of DON in turkeys (*Meleagris gallopava*) revealed that 0.96% of the dose was absorbed from the gastrointestinal tract with rapid excretion of DON and its metabolites in urine and excreta (Gauvreau, 1991). The terminal elimination half-life in turkeys following an intravenous dose of DON was about 44 min. Tissue residues of DON and/or metabolites declined rapidly to trace levels.

Lactating cows or laying hens consuming elevated concentrations of DON (>5 mg/kg) transfer minimal concentrations of DON to the milk or eggs, respectively. Charmley *et al*. (1993) fed 0.59, 42, and 104 mg DON/head/day from contaminated corn and wheat for 10 weeks in a lactation study and found no detectable residues (<1 ng/ml) of DON or DOM-1 in milk. Prelusky *et al*. (1984) evaluated the absorption and distribution of a single large oral dose, 920 mg of DON via rumen intubation, given to each of two lactating cows. Maximum blood levels occurred 4.7 and 3.5 h after DON administration and were 200 and 90 ng/ml serum (DON and conjugates, respectively). By 24 h post-dosing only trace levels (<2 ng DON/ml serum) were detected. Free and conjugated DON were detected in cow's milk at low levels (<4 ng/ml) with an estimated 0.0001% of administered dose excreted in milk. Following a 5-day oral exposure trial to high concentrations of DON (~66 mg/kg in the diet), lactating dairy cows excreted unconjugated DOM-1 in the milk at concentrations up to 26 ng/ml (Côté *et al*., 1986). No DON was detected (detection limit of 10 μg DON/kg tissue) in eggs or tissues of Leghorn chicks and laying hens and broiler chickens fed a ration containing 4–5 mg DON/kg for 28–160 days (El-Banna *et al*., 1983). Valenta and Dänicke (2005) did not detect DON, DOM-1, or glucuronide conjugates of these compounds in the yolk or albumen of laying hens fed a maize diet containing 11.9 mg DON/kg dry matter for 16 weeks.

T-2 toxin metabolism has been studied in laboratory and agricultural animals. Metabolism of T-2 toxin generally results in reduced toxicity with deacetylation of T-2 toxin to HT-2 (at C-4), to 4-deacetylneosolaniol, and to T-2 tetraol. T-2 toxin is considered 1.5–1.7 times as toxic as HT-2, which is 4.8 times as toxic as T-2 tetraol (Ueno *et al*., 1973). Human and bovine liver homogenates are capable of deacetylating T-2 toxin *in vitro* to HT-2 toxin (Ellison and Kotsonis, 1974). T-2 toxin and metabolites in swine can be eliminated as glucuronide conjugates into bile and undergo deconjugation in the intestinal tract by microbial action and enterohepatic recirculation (Corley *et al*., 1985).

After receiving three daily oral doses of 180 mg T-2 toxin/day (equivalent to dietary levels of 31–35 mg T-2 toxin/kg), a lactating Jersey cow (375 kg) was orally dosed with 156.9 mg of tritium-labeled T-2 toxin (Yoshizawa *et al*., 1981). The cow showed a good appetite, but milk and urine production decreased by 38% and 50%, respectively, during the experimental period. Plasma concentrations peaked at 8 h after the tritium-T-2 toxin dose, at 64 ppb (ng/g) T-2 toxin equivalents, and by 72 h, almost all radioactivity had been eliminated in the urine and feces, in a ratio of 3:7, respectively. About 0.2% of the tritium-T-2 toxin dose was transmitted into the milk with the maximum level of radioactivity in milk at 16 h post-tritium dose of 37 ppb (T-2-toxin equivalents). The cow was killed and tissues were analyzed for T-2 toxin. T-2 toxin was rapidly metabolized and little T-2 toxin accumulated in organ tissues (muscle, liver, kidney, fat, heart, bile, ovaries, and mammary gland), but bile and liver contained higher tritium residues than whole blood. The authors considered that a large amount of the absorbed toxin and its metabolites were eliminated via the bile into the intestinal tract. The delayed elimination of large amounts of radioactivity in the feces indicated that T-2 toxin and its metabolites probably recirculate in the enterohepatic system.

A pregnant Holstein cow was intubated with 182 mg of purified T-2 toxin daily (equivalent to about 0.5 mg T-2 toxin/kg body weight) for 15 consecutive days (Robison *et al*., 1979). Milk samples collected on days 2, 5, 10, and 12 contained T-2 toxin ranging from 10 to 160 ng/g. The dose given to this cow corresponds to an unusually high feed concentration of 50 mg T-2 toxin/kg; therefore, the authors considered it unlikely that T-2 toxin would be detectable in milk at T-2 toxin concentrations found naturally in feeds. The authors fed a sow (170 kg) T-2 toxin at 12 mg/kg diet (equivalent to 0.5 mg T-2 toxin/kg body weight/day) for 220 days. Six days post-parturition a milk sample was analyzed for T-2 toxin and contained 76 ng/g. Glávits and Ványi (1995) described a "perinatal form of T-2 toxicosis" in swine in Hungary. The authors reported T-2 toxin was excreted in the milk of sows causing lesions, characteristic of T-2, in organs of suckling pigs, including

degeneration and necrosis of cells in the bone marrow, and death.

## Microbial metabolism

In the ruminant, significant metabolism of trichothecenes occurs in the rumen and gastrointestinal tract prior to absorption. King *et al*. (1984) noted almost complete transformation of DON to a deepoxidation product when DON was incubated *in vitro* with rumen fluid for a 24-h period. Swanson *et al.* (1987) reported DON was partially converted to deepoxidated DON (DOM-1) by rumen microbes. Rumen microbes, in particular protozoa, appear to be active in the deacetylation of the trichothecenes T-2 toxin and DAS to HT-2 and monoacetoxyscirpenol (Kiessling *et al*., 1984). The authors reported no effect of ovine rumen fluid on DON metabolism; however, the incubation only lasted 3 h. Several rumen bacteria with esterase activity (*Butyrivibrio fibrisolvens*, *Selenomonas ruminantium*, and *Anaerobivrio lipolytica*) degraded T-2 toxin to HT-2 toxin and T-2 triol, but *B. fibrisolvens* also produced neosolaniol (Westlake *et al*., 1987a, b). The authors suggested that at least two different *B. fibrisolvens* enzymes, differing in their specificity for side chains, were responsible for T-2 toxin degradation.

Microbes in the large intestines of chickens are capable of complete DON transformation *in vitro* to a deepoxy metabolite, whereas no metabolism of DON was reported with the *in vitro* incubation of swine large intestinal contents (He *et al*., 1992). In contrast, Hedman and Pettersson (1997) reported that five of six pigs (weighing about 18 kg) fed nivalenol at 2.5 or 5.0 mg/kg in the diet for 1 week excreted a deepoxidated nivalenol in feces. After 3 weeks on the nivalenol diet, the sixth pig acquired the ability to deepoxidate nivalenol. Additionally, DON was deepoxidated during *in vitro* incubation with microbes that had deepoxidated nivalenol. No deepoxidated nivalenol was detected in feces after feeding a diet of 2.5 or 5 mg nivalenol/kg diet to broiler chickens for 3 weeks, although an unidentified metabolite was found (Hedman and Pettersson, 1997). The ability of microbes to acquire the capability to deepoxidate or detoxify trichothecenes may account for the time course of clinical signs associated with trichothecene ingestion. Microbial adaptation may require a period of several weeks during which the host animal is exposed to more of the toxic parent trichothecene. The rate and location of deepoxidation of trichothecenes prior to absorption is important in the development of toxic effects. Formation of deepoxides higher in the gastrointestinal would reduce the potential toxicity of the trichothecene. Biotransformation of DON is inhibited by low pH *in vitro*, with a pH of 5.2 completely inhibiting DON metabolism either by inactivating the microorganisms or specifically inhibiting the deepoxidation process of DON (He *et al*., 1992). This may have major implications in the metabolism of DON by ruminants on higher grain diets causing production of organic acids that reduce the rumen pH. As can be seen by the foregoing, the apparent resistance of ruminants to trichothecenes is due to ruminal metabolism.

# MECHANISM OF ACTION AND TOXICITY

Trichothecenes have multiple effects on eukaryotic cells, including inhibition of protein, RNA, and DNA synthesis, alteration of membrane structure and mitochondrial function, stimulation of lipid peroxidation, induction of programmed cell death or apoptosis, and activation of cytokines and chemokines (Table 76.1). It is believed that

**TABLE 76.1 Trichothecene effects on eukaryotic cell functions**

| Effect | References |
|---|---|

the primary effect of trichothecenes is inhibition of protein synthesis as all of the other reported effects might be secondary to decreased protein synthesis (Rocha *et al.*, 2005).

## Protein synthesis inhibition

Trichothecenes bind to ribosomes in eukaryotic cells, in particular to the 60S ribosomal subunits, and interfere with peptidyl transferase activity (McLaughlin *et al.*, 1977). Inhibition of protein synthesis requires an intact 9,10 double bond and the C-12,13 epoxide. Trichothecenes can be divided into two groups based on their site of action on protein synthesis, either preferential inhibition of initiation or inhibition of elongation or termination. Trichothecenes with hydroxyl and acetyl substitutions at both C-3 and C-4, such as T-2 toxin, DAS, scirpentriol, and verrucarin A, predominantly inhibit initiation, and compounds such as trichodermin, crotocol, crotocin, and verrucarol inhibit elongation or termination (McLaughlin *et al.*, 1977). The cytotoxicity of DON, a trichothecene with a keto group at C-8 and a hydroxyl group at C-7, results from protein synthesis inhibition at the ribosomal level during the elongation and termination step in mammalian cells (Ueno, 1983; Ehrlich and Daigle, 1987). In an *in vivo* study, Robbana-Barnat *et al.* (1988) dosed Balb-c mice with DON by intraperitoneal injection (4, 10, 20, and 80 mg DON/kg body weight) followed by an injection of radio-labeled leucine, killed the mice 5 h post-dosage, and determined leucine incorporation into proteins. Mice dosed intraperitoneally at 10 mg DON/kg body weight or more had marked inhibition of protein synthesis in cardiac tissue. Mice fed a diet with 10 mg DON/kg ration for several weeks exhibited cardiac lesions, primarily foci of calcified pericarditis, which suggested a preferential effect on cardiac tissue in the mice. In an *in vivo* low dose DON study in pigs, protein synthesis (using the "flooding dose technique" with radio-labeled phenylalanine as tracer and expressed as fractional synthesis rate) was significantly reduced in kidneys, spleen, and ileum of pigs exposed orally to 5.7 mg DON/kg diet for about 4 weeks (Dänicke *et al.*, 2006). Protein synthesis of the liver, skeletal and cardiac muscle, mesenteric lymph nodes, duodenum, jejunum, pancreas, and lung was not significantly affected by oral DON exposure.

Trichothecenes inhibit both RNA and DNA synthesis. Using hepatoma cells and phytohemagglutinin-stimulated lymphocytes in an *in vitro* culture, Rosenstein and Lafarge-Frayssinet (1983) reported T-2 toxin inhibited DNA synthesis. DON was demonstrated to inhibit DNA synthesis in splenic lymphocytes and human peripheral blood lymphocytes (Mekhancha-Dahel *et al.*, 1990). Thompson and Wannemacher (1986) reported trichothecenes strongly inhibited RNA synthesis in HeLa cells and had only slight inhibitory effects on Vero cells. The inhibition of nucleic acid synthesis is generally considered secondary to protein synthesis. T-2 toxin inhibited mitochondrial protein synthesis and electron transport action in rat liver cells and *in vivo*, although high doses were used in the studies (Pace, 1983; Pace *et al.*, 1988).

## Lipid peroxidation

T-2 toxin is thought to increase production of oxygen radicals, overwhelming the scavenging system for oxygen radicals and resulting in cell injury. Rizzo *et al.* (1994) administered a single oral dose of DON or T-2 toxin at 28 or 3.6 mg/kg body weight, respectively, to male Wistar rats on antioxidant deficient diets. Liver peroxides, as measured by thiobarbituric-acid-reactive substances, increased 21% and 268% in rats administered DON or T-2 toxin, respectively. Significant decreases in hepatic glutathione concentration and superoxide dismutase activity occurred in the treated rats, as compared with the controls.

Vila *et al.* (2002) studied the effects of T-2 toxin, given by oral gavage at dosages of 4 and 6.25 mg/kg body weight, on vitamin E status and lipid peroxidation in female CD-1 mice. Lipid peroxidation was evaluated by the plasma and organ content of malondialdehyde (MDA). Mice had a decrease in plasma vitamin E concentration 16 h after toxin treatment, and the concentration remained significantly depressed for up to 48–72 h. The MDA content of liver increased significantly 24–48 h after T-2 toxin administration, as compared with control mice, and returned to the control range after 72 h. These findings suggest that T-2 toxin results in lipid peroxidation in mice and vitamin E is consumed by scavenging free radicals from damage by T-2 toxin.

## Neurotransmitter effects

DON produced two main clinical signs in monogastrics, vomiting, or emesis at higher concentrations and reduced food consumption or feed refusal at lower concentrations (Forsyth *et al.*, 1977). The exact mechanism(s) of action of DON which result in feed refusal is/are not known. DON could act directly via a central mechanism controlling hunger or satiety or possibly peripherally through non-specific mechanisms inducing lethargy or depression. Prelusky *et al.* (1992) evaluated the effects of DON on brain biogenic amine concentrations after administration of a single intravenous dose of 0.25 mg DON/kg body weight to young swine (15–23 kg body weight). Norepinephrine was significantly increased and dopamine significantly decreased in the brain regions of the hypothalamus, frontal cortex, and cerebellum for up to 8 h post-treatment, as compared with control animals. Serotonin or 5-hydroxytryptamine was initially increased 1 h post-treatment in

the hypothalamus and by 8 h post-treatment was significantly decreased in the hypothalamus and frontal cortex, as compared with controls. The authors concluded that changes in neurotransmitters were not consistent with known neurochemical changes associated with chemically induced anorexia, but might be due to other toxicological responses, such as vomiting. Neurotransmitter concentrations were measured in the cortex, hypothalamus, and pons of starter pigs (9.3 kg) fed 21 days of control and *Fusarium*-contaminated feeds (approximately 3.9 and 5.8 mg DON/kg diet) and in 1-day-old male broiler chicks fed *Fusarium*-contaminated feeds (approximately 6.3 and 9.7 mg DON/kg diet) for 56 days (Swamy *et al*., 2004). The pigs on mycotoxin-contaminated feeds had alterations in regional brain neurochemistry, including a linear increase in cortex serotonin concentrations with a linear decrease in hypothalamic tryptophan and norepinephrine concentrations and pons dopamine concentrations. At the end of the broiler study, chicks on mycotoxin-contaminated diets had linear increases of serotonin in the pons and cortex, and norepinephrine and dopamine concentrations in the pons. Perhaps through peripheral action on serotonin-3 receptors, rodents displayed inhibited gastric emptying in a dose-related manner when DON was given orally at 50–1000 $\mu$g/kg body weight (Fioramonti *et al*., 1993). Intestinal propulsion was reduced at the highest dose (1000 $\mu$g/kg). This effect is not common to all trichothecenes because T-2 toxin accelerated gastric emptying under similar experimental conditions (Fioramonti *et al*., 1987).

While the exact role(s) of these neurotransmitters in eating disorders is/are not known, Swamy *et al*. (2004) suggested that stimulation of serotonergic and $\alpha_2$-noradrenergic receptors in the hypothalamus of the brain was important in feeding behavior. The increase in serotonergic neurotransmitter concentrations and decrease in norepinephrine concentrations in the brains of pigs fed mycotoxin-contaminated diets might explain some aspects of feed refusal.

Borison and Goodheart (1989) evaluated neural factors involved in the acute emetic, cardiovascular, and respiratory effects of T-2 toxin injected (intravenously or intraperitoneally) at 2 mg/kg body weight in cats. While the causation of vomiting has been attributed to the stimulation of the chemoreceptor trigger zone in the area postrema of the medulla oblongata, area postrema-ablated cats exhibited vomiting 5 h after T-2 administration, as compared with normal cats that vomited within an hour of T-2 administration, and generally persisted in vomiting until the time of death at about 12 h. The authors concluded that the area postrema was not the sole receptor site of trichothecene action to induce emesis. They hypothesized that a possible mechanism of delayed vomiting from trichothecenes may be similar to that of acute radiation sickness in cats exhibiting emesis and malaise, which is mediated by neural afferent pathways from the abdomen that traverse the vagus nerve and dorsal columns of the spinal cord.

## Immunotoxicity

The molecular basis for cytotoxic effects of trichothecenes and immunosuppression is directly or indirectly related to inhibition of protein synthesis. The most potent immunosuppressive trichothecenes are T-2 toxin, DAS, DON, and fusarenon-X, which are the most potent protein synthesis inhibitors (Corrier, 1991). In addition, the occurrence of other secondary metabolites from *Fusarium* associated with trichothecene biosynthesis, such as substituted neosolaniols and calonectrins, inhibit T- and B-lymphocytes when evaluated in mouse spleen lymphocyte proliferation assays (Bondy *et al*., 1991). The most widely studied trichothecene because of potential acute toxicity and use as a chemical warfare agent is T-2 toxin. T-2 toxin caused necrosis and lymphoid depletion in the thymus, spleen, and lymph nodes of a variety of laboratory animals (Ueno, 1977; Hayes *et al*., 1980; Taylor *et al*., 1989), swine (Weaver *et al*., 1978a), cattle (Osweiler *et al*., 1981), and sheep (Friend *et al*., 1983). Necrosis and thymic depletion have been reported in the thymus, bursa of Fabricius and spleen in chickens treated with T-2 toxin (Hoerr *et al*., 1981). Age of exposure is important, as neonatal animals are more sensitive than older animals. Holladay *et al*. (1993) dosed pregnant mice by oral gavage with 1.2 or 1.5 mg T-2 toxin/kg body weight on gestational days 14–17 and found that lymphocyte progenitor cells appear to be more sensitive than thymocytes to T-2 toxin, and are responsible for fetal thymic atrophy and potential immunosuppression seen with T-2.

Trichothecenes have been shown to both stimulate and impair humoral immunity, cell-mediated immunity, and host resistance in experimental and food animals (reviewed by Corrier, 1991; Pestka and Bondy, 1994; Rotter *et al*., 1996; Bondy and Pestka, 2000; Pestka and Smolinski, 2005). The dose and duration of toxin exposure in relation to the timing of the immune assay determined whether stimulation or suppression resulted. For example, Bottex *et al*. (1990) reported contradictory effects in Swiss mice given intraperitoneal doses of 5.3 or 2.7 mg DAS/kg either prior to (range of −10 to −3 days) or following (range of +3 h to +5 days) intraperitoneal injection of *Salmonella typhimurium*. Mice injected with DAS prior to *Salmonella* infection had a lower mortality rate than control mice given just *Salmonella*. In contrast, mice injected with DAS following infection had a significantly higher mortality than controls given *Salmonella*. Similar results were observed in mice given intraperitoneal injections of DAS either prior to or following antigenic stimulation with sheep erythrocytes. The splenic plaque-forming cell

response against sheep erythrocytes was increased in mice given DAS prior to the antigenic stimulation and significantly inhibited in mice given DAS after antigenic stimulation.

Immunostimulation after small doses of trichothecenes apparently results from induction of immune- and inflammation-associated genes. Trichothecene doses that partially inhibited translation upregulated expression of immune-related genes including proinflammatory cytokines and chemokines, cyclooxygenase 2, and inducible nitric oxide synthase (Azcona-Olivera *et al.*, 1995; Zhou *et al.*, 1997; Ji *et al.*, 1998; Moon and Pestka, 2002; Pestka *et al.*, 2005). DON regulated interleukin (IL) 2, a cytokine considered to be a central growth and death factor for antigen-activated T-cells, and IL-8, a proinflammatory chemokine that affects host-defense induction of trafficking neutrophils across vascular walls (Pestka *et al.*, 2005).

The frequent occurrence of DON in cereals and potential chronic exposures to contaminated feed sources has focused attention on DON immunomodulation in animals, particularly the impact on susceptibility to infections and altered vaccination responses. Tryphonas *et al.* (1986) suggested a no-effect level in Swiss–Webster mice of 0.25–0.50 mg DON/kg diet/day based on *Listeria monocytogenes* challenge, serum $\alpha_2$- and $\beta$-globulins, and splenic lymphocyte proliferation to phytohemagglutinin P. Rotter *et al.* (1994) reported no significant differences in lymphocyte proliferation responses to phytohemagglutinin or pokeweed mitogens between treatments of pigs fed 0, 0.95, 1.78, and 2.85 mg DON/kg diet. The pigs responded well to primary immunization with sheep erythrocytes. However, pigs fed higher concentrations of 1.78 and 2.85 mg DON/kg diet, and pair-fed control pigs developed the maximum titer 7 days later than controls. As the level of DON contamination increased, pigs showed increased albumin concentrations, decreased $\alpha$-globulin concentrations, and increases in the albumin/globulin ratios. Similarly, Accensi *et al.* (2006) observed no significant changes in lymphocyte proliferation to mitogens or in cytokine production of IL-4 and interferon-$\gamma$ in young swine fed low doses of DON (0, 0.28, 0.56, and 0.84 mg/kg diet) for 4 weeks. Øvernes *et al.* (1997) reported a reduction in secondary antibody responses to tetanus toxoid injections in pigs fed 1.8 and 4.7 mg DON/kg feed for about 9 weeks, but no titer reductions to sheep erythrocytes, human serum albumin, paratuberculosis vaccine, or diphtheria toxoid. Peripheral blood lymphocyte responses to phytohemagglutinin were increased in pigs fed 4.7 mg DON/kg feed for 9 weeks.

In a high dose exposure of poultry to DON, Harvey *et al.* (1991) reported a reduction in immune responses to Newcastle vaccination in Leghorn hens fed a ration of naturally DON-contaminated wheat at 18 mg DON/kg feed for 18 weeks. DON fed at increasing concentrations (5.8–13.6 mg DON/kg feed) to day-old turkey poults for 12 weeks reduced contact sensitivity responses to dinitrochlorobenzene (a CD8+ T-lymphocyte cell-mediated response), but DON-fed turkeys generated primary and secondary antibody responses to sheep erythrocytes (a CD4+ T-lymphocyte humoral response) similar to the control group, which was exposed to very low concentrations of DON in the feed (Chowdhury *et al.*, 2005a). In a similar experiment with day-old Pekin male ducklings fed a naturally contaminated ration with DON (6.3–18.6 mg DON/kg feed) for 6 weeks, the cell-mediated response to dinitrochlorobenzene was decreased with no effect on the antibody response to sheep erythrocytes (Chowdhury *et al.*, 2005b). Consumption of contaminated grains by both turkey poults and ducklings resulted in only minor impacts on serum chemistries and hematology, and no effect on body weight gains or feed consumption in the duckling study.

While T-2 toxin exposure in numerous laboratory animal models and other species causes immunosuppression, the specific functions of various cell type affected by the mycotoxin have not been definitively ascertained (Taylor *et al.*, 1989). T-2 toxin given by intraperitoneal administration to mice reduced thymus weights, inhibited antibody synthesis against sheep erythrocytes, and prolonged skin graft rejection times (Rosenstein *et al.* 1979). Rabbits given 0.5 mg T-2 toxin/kg body weight per os for 17 or 28 days had reduced antibody responses to aerosolized *Aspergillus fumigatus* challenge (Niyo *et al.*, 1988). Calves dosed orally with T-2 toxin at 0.6 mg/kg/day for 43 days had depressed mitogen responsiveness to phytohemagglutinin at 1, 8, and 29 days of toxin administration and decreased mitogen responsiveness to concanavalin A and pokeweed mitogens on day 29 of toxin administration (Buening *et al.*, 1982). Phagocytosis of 2-hydroxymethacrylate particles by neutrophils was not altered in pigs fed T-2 toxin for 21 days (Rafai *et al.*, 1995b). The authors reported humoral immunity, as measured by titers against horse globulin, a T-dependent antigen, was significantly decreased in pigs fed 14–21 days of T-2 toxin at 0.5, 1, 2, and 3 mg/kg feed. Additional evidence of impaired T-lymphocyte function was found in the reduction of mitogen-induced lymphocyte proliferation tests with phytohemagglutinin, concanavalin A, and purified horse IgG at 2 and 3 mg T-2 toxin/kg feed. The authors remarked on minor histological changes including a decrease in the size of thymic lobules and lobular cortex of the thymus, a decrease in white pulp of the spleen, and regressive changes (interpreted as depletion of lymphocytes) of the germinal centers of lymph nodes of T-2 treated pigs.

Humoral immune responses to anaplasma vaccine were not different between T-2 treated and control calves, but calves dosed with 0.6 mg T-2 toxin/kg body weight had significantly lower concentrations of $\alpha$-, $\gamma$-, $\beta_1$-,and $\beta_2$-serum protein fractions and elevated albumin/globulin

ratio compared with control calves (Osweiler *et al.*, 1981). Serum IgA and IgM concentrations were significantly lower for the high dose T-2 toxin calves, as compared with controls. Pathological changes included decreases in body and thymus weights of T-2 toxin treated calves. Histologically, thymii from calves dosed with 0.3 mg T-2/kg body weight exhibited cortical thinning with loss of mature lymphocytes and fibrous connective tissue separating individual thymic lobules. The high dose calves had almost complete replacement of normal thymic architecture with fibrous connective tissue and loss of the normal lobular pattern and mature lymphocytes. Calves (158–225 kg) dosed orally with T-2 toxin at 0.5 mg/kg body weight for 28 days had reduced serum IgG, IgM, albumin, globulin, and complement proteins (Mann *et al.*, 1983). Lambs treated orally with a high dose of T-2 toxin (0.6 mg T-2 toxin/kg body weight) daily were leukopenic on day 7 and lypmphopenic on days 7 and 14 (Friend *et al.*, 1983). On day 7 of this study, lambs showed decreased lymphocyte blastogenic responses to concanavalin A and lipopolysaccharide. Mitogen responses improved by day 21 of T-2 exposure. At necropsy no differences in parasite loads were noted among T-2 treated lambs, suggesting that the dosage of T-2 toxin did not reduce immunity to a threshold allowing a fulminating coccidiosis to occur in treated lambs. Lambs showed no significant alteration of peripheral blood lymphocyte blastogenesis to phytohemagglutinin after 34 days of DAS treatment (5 mg/kg diet), as compared with control lambs (Harvey *et al.*, 1995).

### IgA

Increased serum IgA and potential IgA dysregulation and nephropathy have been reported in rodents after high (about 25 mg/kg) dietary DON exposure. Forsell *et al.* (1986) reported dose-dependent increases in serum IgA and decreases in serum IgM in female B6C3F1 mice fed 0.5, 2, 5, 10, and 25 mg DON/kg diet for 8 weeks. Further investigation with B6C3F1 mice showed that feeding 25 mg DON/kg diet for 4 weeks increased serum IgA, and continued DON feeding for 24 weeks increased serum IgA 17-fold over controls (Pestka *et al.*, 1989). Mice exhibited a shift from primarily monomeric IgA to polymeric IgA and increased *in vitro* splenocyte production of IgA from both spontaneous-and lipopolysaccharide-stimulated cultures. The DON-associated increase in serum IgA resulted from stimulation of CD4+ and IgA+ lymphocytes in Peyer's patches and in the spleen (Pestka *et al.*, 1989; Dong *et al.*, 1991). DON fed mice showed marked mesangial IgA accumulation based on immunofluorescence staining of kidney tissue (Pestka *et al.*, 1989). In humans, deposition of IgA in the mesangium and capillary loops of the kidney can lead to a focal, non-progressive glomerulonephritis (Jones *et al.*, 1997).

Elevated serum IgA in animals exposed to oral DON does not appear to be consistent across species. Elevations in serum IgA concentrations were not observed in horses fed DON-contaminated feed (exposure of ~0.06–0.1 mg DON/kg body weight/day) (Johnson *et al.*, 1997; Raymond *et al.*, 2005). Bergsjo *et al.* (1992) did not detect any significant differences in serum IgA concentrations in pigs fed DON-contaminated diets from 0.5 to 4 mg/kg feed for 100 days. The authors stated that variation between individuals in the group and the low number of pigs per group ($n = 8$) might not have revealed small differences. Weaned pigs fed low concentrations of DON (<0.84 mg DON/kg diet) for 4 weeks (Accensi *et al.*, 2006) or fed higher concentrations of DON (at 5.8 mg/kg) for 3 weeks (Swamy *et al.*, 2003) showed no consistent changes in serum IgA. In contrast, Goyarts *et al.* (2005) found that finishing pigs fed DON-contaminated wheat (6.5 mg DON/kg diet) *ad libitum* had a significant increase in serum IgA concentrations, with male pigs significantly higher than females. Significant differences in serum IgA concentrations were not observed in control and DON fed pigs on the restricted feeding regimen (assured similar feed intake at the lowest level for all animals of both control and DON groups).

## Apoptosis

Apoptosis, a form of programmed cell death, has been proposed to explain the loss of lymphocytes and hematopoietic cells during trichothecene poisoning (Pestka *et al.*, 1994; Shinozuka *et al.*, 1998). Apoptosis normally serves as a self-regulating pathway in the immune system that reduces excessive inflammation and prevents autoimmune disease (Dong *et al.*, 2002); however, inappropriate activation by trichothecenes results in dysfunction. Activation of mitogen-activated protein kinases (MAPKs) by satratoxins and other trichothecenes correlated with and preceded apoptosis (Yang *et al.*, 2000). The authors used two myeloid models, RAW 264.7 murine macrophages and U937 human leukemic cells, in a cleavage assay and determined the potency of cytotoxicity to be satratoxin G, roridin A, verrucarin A > T-2 toxin, satratoxin F, H > nivalenol and vomitoxin. Using flow cytometry cell cycle analysis and phenotypic staining to study *in vitro* effects, Pestka *et al.* (1994) demonstrated that DON could either inhibit or enhance apoptosis in T-, B-, and IgA+ cells from murine spleen and Peyer's patch. Apoptosis was dependent on lymphocyte subset, source of tissue, and glucocorticoid induction. Islam *et al.* (1998) demonstrated *in vivo* that T-2 toxin, given by intraperitoneal injection to mice, induced thymic atrophy, DNA fragmentation, and histopathological changes in thymic tissue characteristic of apoptosis, including cell shrinkage and nuclear condensation. Macrophages appeared to be very sensitive

to trichothecenes and could undergo trichothecene-stimulated apoptosis (Zhou *et al.*, 2005). The authors suggested that in addition to trichothecenes binding to the 60S ribosomal subunits and producing translational inhibition, another molecular pathway for trichothecene induction of apoptosis was through triggering a ribotoxic stress response activating MAPKs. MAPKs modulate cell physiological processes, such as cell growth, differentiation, and apoptosis, and are important for signal transduction in immune responses (Dong *et al.*, 2002). For example, T-2 toxin given orally to pregnant rats on day 13 of gestation induced apoptosis in neuroepithelial cells of the fetal rat brain that coincided with expression of oxidative stress-related genes (such as heat shock protein 70 and heme oxygenase) and subsequent activation of MAPKs and caspase-2, which are important factors in cell signaling pathways for apoptosis (Sehata *et al.*, 2004).

## Cell membrane function

At low concentrations (0.4 pg/ml to 4 ng/ml), T-2 toxin altered several cell membrane functions in L-6 myoblasts, including uptake of calcium, rubidium, and glucose, incorporation of thymidine or leucine and tyrosine into DNA or protein, and residual cellular lactate dehydrogenase (Bunner and Morris, 1988). Changes occurred within 10 min of exposure, suggesting to the authors that T-2 toxin directly or indirectly affected glucose, nucleotide, and amino acid transporters and calcium/potassium channel activities independent of protein synthesis inhibition.

## Reproductive toxicity

No studies have indicated that DON is a reproductive toxin at concentrations typical of naturally contaminated feed. Friend *et al.* (1986) reported significant weight reductions in young male and female pigs fed DON-contaminated feeds at 3.7 and 4.2 mg DON/kg (~0.14 and 0.17 mg/kg body weight/day) feed for 7 weeks; however, no significant histological changes were observed in the testis (seminiferous epithelium) or ovary (follicle). In contrast, several studies indicate that T-2 toxin can affect reproduction. Glávits *et al.* (1983) reported in a field case involving a large swine herd infertility in gilts and sows that coincided with the detection of T-2 and HT-2 toxins at 1–2 mg/kg feed. Pathology revealed cystic degeneration of the ovaries and uterine atrophy. Huszenicza *et al.* (2000) evaluated low oral T-2 toxin exposures of 0, 0.3, or 0.9 mg T-2 toxin/day and 9 mg T-2 toxin/day for 3 weeks in ewes and heifers, respectively, on a rich, acidosis-inducing concentrate diet. The results suggested that in ewes and heifers rumen acidosis along with exposure to low oral T-2 toxin intake might delay maturation of the dominant ovarian follicle and ovulation and shorten corpora lutea lifespan (lower plasma progesterone concentrations); although the number of animals in the experiment was small. In an equine study of trotter mares, the horses were given 7 mg purified T-2 toxin/day in oats (~0.01 mg/kg body weight/day) for 32–40 days beginning on estrous cycle day 10 (Juhasz *et al.*, 1997). Skin lesions were noted around the mouth of three horses; however, no adverse effects were noted on the length of the interovulatory interval, luteal, and follicular phases of the estrous cycle, plasma progesterone profiles, or follicular kinetics. Uterine flushing of five mares in the trial yielded three embryos suggesting that T-2 toxin had no detrimental effect on ovarian activity, fertilization, or oviductal transport.

In pregnant rats, T-2 toxin crosses the placenta and is distributed to fetal tissues (Lafarge-Frayssinet *et al.*, 1990). Rousseaux and Schiefer (1987) reported that T-2 toxin caused fetal death at high doses (associated with maternal toxicity), with fetal toxicity primarily in the central nervous system and skeletal system. T-2 toxin administered intravenously at approximately one-third or one-sixth of the $LD_{50}$ (0.41 or 0.21 mg/kg body weight) to sows at the beginning of the third trimester of pregnancy caused vomiting 90 min post-injection with the sows becoming listless and aborting their litters 48–80 h later (Weaver *et al.*, 1978b). In another study, three sows were fed purified T-2 toxin in a standard swine ration at 12 mg/kg diet for up to 220 days, causing clinical signs of repeat breeding, small litters (four piglets) and small (0.37–0.65 kg) piglets, which had no gross or histological lesions attributable to T-2 toxin (Weaver *et al.*, 1978a). The sows did not develop changes in the complete blood count, total protein, or alterations in the bone marrow. These studies used concentrations of T-2 higher than commonly found in feeds screened for visible molds.

Thirty 3-week-old Single Comb White Leghorn hens were fed either purified T-2 toxin or DAS at 2 mg/kg diet for 24 days (Diaz *et al.*, 1994). Egg production dropped about 7% in hens fed either T-2 or DAS on days 13–18 of the study, but recovered to near normal by day 24. Shlosberg *et al.* (1984) reported acute, severe reduction in egg production, feed refusal, depression and recumbency, cyanotic appearance of the comb and wattles, and some blue-green discoloration of droppings in a flock of 8-month-old laying hens. Following delivery of new feed, the mean daily egg production dropped from about 2400 to 150 eggs on day 5 of the new feed (94% drop in production). The feed was changed on day 6 and improvement in clinical signs and normal levels of egg production resumed about 12 days later. Mortality was not changed in the flock; however, necropsies of hens that died after 4 days of the new feed revealed atrophy of the ovaries and abnormally small oviducts. The authors hypothesized that the hens were exposed to a small quantity of highly contaminated trichothecene mycotoxin feed causing direct effects on the female reproductive tract and drop in egg production.

The feed sample analyzed for mycotoxins contained T-2 toxin and HT-2 toxin at 3.5 and 0.7 mg/kg, respectively, which the authors thought might be unrepresentatively low. Brake *et al.* (1999) reported low levels of purified DAS (≤5 mg DAS/kg diet) fed to broiler hens from 67 to 69 weeks of age increased fertility, with little effect on hatchability of fertile eggs. In contrast, DAS fed at 10 or 20 mg/kg diet to broiler males from 25 to 27 weeks of age decreased the hatchability of fertile eggs, which the authors attributed to direct toxic effects on the testes (and obviously on sperm). Reproductive toxicity associated with trichothecenes generally occurs when exposures reach maternally toxic concentrations, but natural trichothecene-contaminated diets can pose a serious risk to reproductive performance of livestock (Francis, 1989).

## Genotoxicity and teratogenesis

Trichothecenes are not mutagenic in bacterial assays, but *in vitro* exposure of Chinese hamster cells to DON at concentrations less than 1 mg/ml caused chromatid breaks (Hsia *et al.*, 1988). A 2-year chronic study in B6C3F1 mice fed diets containing 0, 1, 5, or 10 mg DON/kg diet revealed no consistent toxic effects, though mice fed higher concentrations of DON gained less weight than controls (Iverson *et al.*, 1995). DON did not consistently alter clinical chemistry or hematology parameters. The pathology revealed a reduction in development of pre-neoplastic and neoplastic lesions in the liver that may have resulted from reduced feed intake and reduction and body weights.

When considering the etiology of congenital malformation, the role of maternal toxicity must be evaluated. Maternally toxic doses of trichothecenes can be embryotoxic, with fetal death common in both birds and mammals, generally few frank congenital defects are observed in surviving fetuses, though anomalies in the nervous and skeletal systems have been noted (Francis, 1989). Khera *et al.* (1982) studied the embryotoxicity of DON in pregnant Swiss–Webster mice dosed orally with purified DON at concentrations of 0–15 mg DON/kg body weight for 4 days on gestational days 8 through 11. Mice dosed with 5–15 mg DON/kg body weight apparently resorbed the embryos, but no adverse effects were noticed in the dams given 2.5 mg DON/kg body weight. A number of skeletal malformations were observed in offspring of mice dosed at 1, 2.5, and 5 mg DON/kg body weight, but no adverse effects were reported in offspring of mice dosed at 0.5 mg DON/kg body weight.

DON fed to rabbits on days 0 through 30 of gestation at increasing levels of 0.3–2.0 mg/kg body weight/day caused 100% fetal resorption at 1.8 and 2.0 mg/kg/day and reduced body weight in rabbit does (Khera *et al.*, 1986). Dosages of 0.3 and 0.6 mg DON/kg body weight/day did not produce adverse effects in rabbit fetuses at term and were not maternotoxic. The authors concluded that DON did not produce a teratogenic response in rabbits. A two-generation study of female reproduction and teratology in CD-1 mice fed 0, 1.5, and 3 mg T-2 toxin/kg in a semi-synthetic diet did not reveal any significant differences in major or minor defects among treatment groups (Rousseaux *et al.*, 1986). No long-term reproductive or teratological effects were noted.

Minor malformations described as delayed ossification and un-withdrawn yolk sac were reported in chick embryos from hens fed rations containing DON at 2.5 and 3.1 mg DON/kg diet (Bergsjo *et al.*, 1993a).

## Clinical pathology

Trichothecenes, in particular T-2 toxin, have been associated with hemorrhagic syndromes; however, the effects are not consistently seen in experimental studies across species (Raisbeck *et al.*, 1991). Prolonged activated partial thromboplastin time and decreased hematocrit, leukocyte count, and serum alkaline phosphatase activity were observed in rabbits injected with 0.5 mg T-2 toxin/kg body weight (Gentry and Cooper, 1981). In contrast, rabbits given 2 mg T-2 toxin/kg body weight orally displayed oral lesions, diarrhea, and anorexia but no significant changes in hematological and biochemical parameters. Young mice and rats fed purified T-2 toxin at concentrations of 10–20 mg/kg for 2–4 weeks were relatively resistant to hematopoietic suppression, but developed atrophy of the thymus and thymus-dependent lymphoid tissue and lymphopenia (Hayes and Schiefer, 1982). Lambs dosed orally with 0.6 mg T-2 toxin/kg body weight/day displayed significantly prolonged prothrombin times on day 7 (Friend *et al.*, 1983). Although lambs fed DAS (5 mg/kg diet) for 34 days showed significant decreases in several serum clinical chemistry values (cholinesterase and urea nitrogen), no changes were noted in prothrombin times, white blood count, or other hematological parameters (Harvey *et al.*, 1995). Growing pigs fed purified DAS at 0, 2, 4, 8, and 9 mg/kg diet for up to 9 weeks exhibited decreased feed consumption and weight gain (Weaver *et al.*, 1981). No changes in hemoglobin concentration, total red or white blood cell counts, and terminal bone marrow smears or in serum activities of aspartate or alanine aminotransaminases or lactate dehydrogenase were reported in the pigs. DAS given intravenously to pigs, cattle, and dogs produced moderate-to-severe necrosis of bone marrow hematopoietic elements 8 h post-administration (Coppock *et al.*, 1989). The authors ranked species sensitivity to DAS destruction of bone marrow hematopoietic elements; most sensitive species were pigs and dogs and least sensitive species were cattle.

The clinical signs observed in laboratory animals treated with T-2 toxin and DAS are those of a radiomimetic

poison with damage to the lymph nodes, thymus, spleen, and bone marrow. A single dose of a potent trichothecene releases stored leukocytes into the blood stream but repeated administrations damage the hematopoietic system, depleting the leukocyte population. Lutsky *et al.* (1978) reported a marked depletion of leukocytes, similar to ATA, in cats dosed orally at 0.06–0.10 mg T-2 toxin/kg body weight for 24 days. T-2 toxin given intravenously to calves at 0.25 mg/kg body weight caused a marked decrease in leukocyte and neutrophil counts, with a small increase in serum aspartate aminotransferase and lactate dehydrogenase activities (Gentry *et al.*, 1984). In a study of lambs dosed orally at 0, 0.3, and 0.6 mg T-2 toxin/kg body weight for 21 days, examination of the myeloid:erythroid ratio of sternal bone marrow of the lambs revealed on day 12 that the ratio was significantly increased in 0.6 mg T-2 toxin/kg body weight lambs (Friend *et al.*, 1983). The bone marrows of these lambs appeared hypocellular with degenerating cells and pyknotic nuclei, and cells of the myeloid series predominated with few metarubricytes and more immature erythroid cells. None of the lambs were anemic, no hemorrhage was observed; nor were any significant differences found in hematological parameters. At the end of the 21-day study, the lambs were killed and necropsied. The highest dosed lambs had little body fat and pale bone marrow. In the 0.6 mg T-2 toxin/kg body weight lambs, the splenic white pulp was less cellular than low T-2 dosed and control lambs. The cortices of the mesenteric lymph nodes of T-2 treated lambs were thin, as compared with control lambs, and the lymphocyte population of the medullary and paracortical areas and germinal centers of the mesenteric lymph nodes were markedly depleted.

Starter pigs fed T-2 toxin at 0.5, 1, 2, and 3 mg/kg diet (average daily intakes 0.38, 0.81, 1.24, and 1.42 mg T-2 toxin, respectively) for 3 weeks showed significant decreases in leukocyte counts, and pigs fed 2 and 3 mg T-2 toxin/kg had significant decreases in red blood cell counts, mean corpuscular volume, and hemoglobin concentration on day 21 of the study (Rafai *et al.*, 1995b). The authors suggested that T-2 toxin affects hematopoiesis in young pigs at low concentrations (0.5 mg T-2 toxin/kg diet). In contrast, no effects on leukocyte counts or lymphoid tissue morphology were found in pigs fed 1, 2, 4, or 8 mg T-2 toxin/kg diet for 8 weeks (Weaver *et al.*, 1978a), nor were changes in hematocrit, hemoglobin concentration, or erythrocyte counts found in pigs fed 0.4, 0.8, 1.6, or 3.2 mg T-2 toxin/kg feed for 5 weeks (Friend *et al.*, 1992). However, microcytic, hypochromic anemia was reported in pigs fed higher concentrations of T-2 toxin at 10 mg/kg diet for 21–28 days (Harvey *et al.*, 1990).

Patterson *et al.* (1979) could not reproduce a feed-associated hemorrhagic disease syndrome in weaned calves or piglets by dosing orally with either purified T-2 or DAS (0.1 mg toxin/kg body weight for 36 days to pigs and 0.2 mg toxin/kg body weight for 11 days to calves) or with whole cultures of *F. tricinctum* containing T-2 toxin. While none of the pigs displayed clinical signs of toxicity, the calves dosed with 0.2 mg T-2 toxin/kg body weight did became weak, anorectic, and died with evidence of a prolonged partial thromboplastin time.

Oral lesions were observed in most birds fed T-2 toxin diets, but no significant changes were observed in hemoglobin, hematocrit, and erythrocyte counts in the Leghorn laying hens fed T-2 toxin (0, 0.5, 1, 2, 4, and 8 mg/kg diet) (Chi *et al.*, 1977). Serum activities of alkaline phosphatase and lactate dehydrogenase and uric acid concentrations were elevated in hens fed 8 mg T-2 toxin/kg diet, as compared with controls. In a high dose T-2 toxin study, plasma protein concentrations decreased by 15% after the first week and by 20% after the third week in hens fed T-2 toxin (20 mg/kg diet) for 21 days, as compared with control birds (Wyatt *et al.*, 1975). After receiving T-2 toxin for 3 weeks, treated hens had about 30% lower leukocyte counts than the control hens. No differences were observed in prothrombin times, erythrocyte counts, hematocrit, hemoglobin concentrations, or spleen and heart weight.

No consistent changes in serum enzyme activities have been associated with trichothecenes in animals. Low dietary concentrations of DON (<0.84 mg/kg diet) fed to weanling pigs for 4 weeks caused no significant changes in plasma enzyme activities, glucose, urea, bilirubin, and hematological parameters during the study (Accensi *et al.*, 2006). Controlled studies of T-2 toxin fed to swine resulted in altered serum concentrations of glucose and other parameters associated with decreased feed intake and changes in metabolism. Pigs fed 1, 2, and 3 mg T-2 toxin/kg feed for 3 weeks had significantly lower plasma glucose concentrations, as compared with control pigs and pigs dosed at 0.5 mg T-2 toxin/kg diet (Rafai *et al.*, 1995a). The decrease in plasma glucose was attributed to glucose malabsorption or to enhanced glucose degradation. Schiefer and Beasley (1989) suggested that in acute T-2 toxicosis in pigs, the ability of glucocorticoids to induce enzymes associated with heptaic gluconeogenesis and convert amino acids into glucose is reduced. Following an acute, intravenous toxic dose of DAS in pigs, Coppock *et al.* (1985b) reported the pigs developed hypoglycemia and depletion of liver glycogen stores. The authors attributed changes in blood glucose concentrations to cellular damage of endocrine and exocrine pancreas and adrenal gland by DAS.

## TOXICITY

Trichothecenes are toxic to all animal species that have been tested. The Type D trichothecenes, macrocyclics such as the verrucarins and roridin E, are the most acutely toxic

trichothecenes, followed by the Type A compounds, DAS and T-2 toxin, Type B, nivalenol, and the lowest acute toxicity is associated with the Type C trichothecene, crotocin (Ueno, 1983). Neonatal animals are more susceptible. T-2 toxin, the first trichothecene recognized as a naturally occurring mycotoxin, has been studied extensively because of its relative ease of production and its potential as a chemical warfare agent, but T-2 toxicosis is rare in North America. Oral $LD_{50}$ concentrations for T-2 toxin in laboratory animals did not demonstrate marked species differences in sensitivity, but agricultural species do vary in their sensitivity to the different trichothecene toxins. For example, based on toxicity the species susceptibility to DON are ranked as pig (most sensitive), followed by rodent > dog > cat > poultry > ruminants (least sensitive) (Prelusky *et al.*, 1994).

Diarrhea is fairly common following trichothecene ingestion and altered intestinal absorption of compounds and impaired permeability is caused by morphological and functional damage to intestinal mucosa (Ueno, 1983). Epithelial irritation, particularly associated with the metabolites of *F. sporotrichioides*, is considered the underlying cause of oral and cutaneous inflammatory lesions noted in ATA, stachybotryotoxicosis, and fusariotoxicosis of chickens. Dermal toxicity is common to many trichothecenes and the basis for screening toxicity of trichothecenes using dermal bioassays. The chemical structure of trichothecenes determines their dermal toxicity and their cytotoxicity in cultured cell lines. Macrocyclic trichothecenes and T-2 toxin, HT-2 toxin, and DAS (Type A trichothecenes) caused marked epithelial irritation, while nivalenol and DON (Type B trichothecenes) were weak dermal irritants in a guinea pig dermal bioassay (Ueno, 1984). Topical applications of purified T-2 toxin to various animal species caused similar morphological changes, including hyperemia, swelling, exudation, and necrosis with subsequent formation of scabs that fall off (Pang *et al.*, 1989). Histological changes included vascular dilation, edema, congestion, and infiltration of neutrophils, mononuclear, and mast cells in the dermis with varying degrees of epidermal necrosis. The mechanism by which trichothecenes induced cutaneous damage is unknown. Ueno (1984) suggested that increased vascular permeability has a role in inducing cutaneous injury from trichothecene administration. Release of chemical mediators of inflammation could initiate changes leading to microvascular injury in dermal tissue.

In addition to the direct clinical effects on animals, Goyarts *et al.* (2005) noted in natural DON-contaminated wheat that DON significantly increased metabolizable energy, nitrogen retention digestibility of organic matter, crude protein, crude fat, and crude fiber of the cereal grain. However, positive effects of a DON-contaminated diet did not compensate for adverse effects on feed intake or performance in weight gain in swine. Matthaus *et al.* (2004) reported marked changes in nutrient characteristics in *Fusarium*-contaminated wheat, with increased activities of non-starch polysaccharide hydrolyzing enzymes. This may represent a type of "pre-digestion effect" (Dänicke *et al.*, 2004b). Contrary to the positive findings of DON on feed digestibility, DiCostanzo *et al.* (1994) reviewed data reporting that moldy corn had decreased nutritional value, particularly lowered crude fat, along with energy and crude protein values.

### *Swine*

Clinical effects associated with DON ingestion in pigs include feed refusal, weight loss, poor performance, gastrointestinal irritation (such as diarrhea, colic, and rectal prolapse), squamous hyperplasia of the gastric lining, and possible immunomodulation. The DON dose affecting feed intake and rate of gain in swine studies varied with the age of the pig, source of DON (purified versus natural contamination), and exposure conditions (*ad libitum* versus restrictive feeding and duration of exposure). In a chronic study of the effects of DON on grower (starting weight of about 26 kg) and finisher swine, Goyarts *et al.* (2005) fed DON-contaminated wheat at about 6.5 mg DON/kg diet for 11 weeks in both *ad libitum* and restricted feeding regimens. Swine fed the DON-contaminated diet *ad libitum* showed significant reductions in feed intake (15% less) and weight gain (13% less), but the feed-to-gain ratio was not affected. The lower growth performance in swine fed the DON-contaminated diet was attributed to lower voluntary feed intake because no differences were detected in weight gain for control and DON fed swine on the restricted feeding regimen. Similarly, Rotter *et al.* (1994) attributed depressed growth of growing pigs to reduced voluntary feed intake of DON-contaminated diets. Chavez and Rheaume (1986) observed that pigs fed DON-contaminated diets generally consume small amounts of feed continuously throughout the day. Pigs not only consumed less DON-contaminated feed when fed *ad libitum*, but also required more time to consume an equivalent amount of feed compared with a control group (Goyarts *et al.*, 2005).

Pollmann *et al.* (1985) fed DON-contaminated wheat at increasing concentrations of 0–2.8 mg DON/kg diet to starter pigs (7.7–8.3 kg) and concentrations of 0–4.2 mg DON/kg diet to growing/finishing pigs (60.5 kg). In the starter pigs, feed intake declined when the DON concentration was greater than 1 mg DON/kg diet, which was more noticeable during the first week of exposure. No clinical signs, including vomiting, were observed nor were lesions observed in examined organs. Vomiting was the only adverse clinical sign observed in growers fed a diet of DON at 2.8 mg/kg for 42 days. Feed refusal was observed in growers fed DON at 2.2, 2.8, and 4.2 mg/kg diet. Pigs (25 kg) fed naturally contaminated oats at 2 and 4 mg DON/kg feed experienced a dose-related depression of weight gain in the first 8 weeks of the trial (Bergsjo *et al.*,

1992). The authors determined a no-effect level based on feed intake, weight gain, and feed efficiency in growing pigs (25 kg initial weight) of 0.5 and 1.0 mg DON/kg feed. In contrast, Friend *et al*. (1982) fed pigs a diet of 0.7 mg DON/kg feed and saw an immediate reduction in feed consumption, which gradually recovered to nearly normal feed intake. Significant reductions in feed intake and weight gain occurred in pigs fed corn silage, naturally contaminated with 1.3 mg DON/kg feed (Young *et al*., 1983). However, Chavez (1984) reported no reduction in weight gain or feed consumption in piglets (initial weight 7 kg) fed naturally contaminated wheat at DON concentration <2.5 mg DON/kg diet. Williams *et al*. (1988) observed that naturally DON-contaminated wheat fed to growing pigs inhibited voluntary feed intake linearly with dietary concentrations of DON up to 16 mg DON/kg feed. They also noted vomiting and signs of abdominal distress at dose rates from 0.055 to 0.097 mg DON/kg body weight. These values are close to the minimum oral emetic dose of young swine (9–10 kg) at 0.1 mg DON/kg body weight (Forsyth *et al*., 1977).

Using naturally contaminated oats at 0, 0.7, 1.7, and 3.5 mg DON/kg feed, Bergsjo *et al*. (1993b) examined clinical effects in growing pigs (~21 kg) fed *ad libitum* for 95 days. The daily weight gain of pigs fed 3.5 mg DON/kg feed was 82% of the control pigs over the whole experiment. Significant decreases in body weight gain, slaughter weight, and feed utilization were observed in pigs fed a diet of 3.5 mg DON/kg. The authors concluded that 1.7 mg DON/kg feed, in an otherwise adequate diet which contained only minor traces of other mycotoxins, depressed daily feed intake. Dänicke *et al*. (2004b) reported no significant effects on the performance of finishing pigs when fed DON at concentrations of 0.2, 0.7, 1.2, 2.5, and 3.7 mg/kg diet.

Pigs fed higher DON-contaminated diets (>3.6 mg/kg diet) have significant weight reductions (Friend *et al*., 1986) and reduced feed consumption (Forsyth *et al*., 1977), as compared with controls. Significant reductions in the feed-to-gain ratio in swine were only observed at higher DON and zearalenone concentrations, 9.1 and 11.0 mg DON/kg feed and 1.2 and 2.0 mg zearalenone/kg feed, and not at lower DON concentrations (<0.5, 2.6, 5.0, and 8.3 mg DON/kg feed) when naturally contaminated wheat was fed to growing pigs for 14 weeks (Williams *et al*., 1988). In contrast, Swamy *et al*. (2002) reported a significant decrease of about 30% in feed intake and growth performance, but not in the feed-to-gain ratio, in growing pigs fed naturally contaminated DON at 5.6 mg/kg *ad libitum* for 21 days. In another study with swine, Swamy *et al*. (2003) reported an increase in feed efficiency in pigs fed DON and suggested that pigs adjusted to the reduction in feed intake by improving feed utilization.

Based on reviews of the literature, Dänicke *et al*. (2001) suggested dietary DON concentrations in livestock feeds that ensured no adverse effects on animal health or performance if all production conditions are optimal (Table 76.2). These suggested concentrations of DON in livestock feed are similar to the US Food and Drug Administration (FDA) advisory guidelines for DON in livestock feed. Eriksen and Pettersson (2004) proposed lower guidelines for DON in livestock feed based on risk assessment of data from toxic effects (Table 76.2).

**TABLE 76.2 Recommended values for concentrations of DON in the final ration**

| Animal species/type | DON[a] | DON[b] | DON[c] |
|---|---|---|---|
| Pigs | 1 | 1 | 0.3 |
| Pre-ruminant calf | 2 | | |
| Dairy cow/pregnant cattle | 5 | 2[d] | – |
| Beef cattle | 5 | 5 | – |
| Poultry (laying hens, broilers) | 5 | 5 | 2.5 |

[a]Values for critical concentrations of DON in diets of pigs, ruminants, gallinaceous poultry (mg/kg, 88% dry matter) (Dänicke *et al*., 2001).
[b]Values are in mg/kg for the final ration (FDA advisory guidelines).
[c]Risk assessment guidelines (Eriksen and Pettersson, 2004).
[d]Under the "intended use" dairy cattle would in the "all other animal species".

Sex-related differences have been reported in pigs fed DON-contaminated feed, but the findings are equivocal. Côté *et al*. (1985) reported lower weight gains in castrated male pigs, as compared to female pigs, in the first 4 weeks of feeding DON-contaminated feeds at 3.1 and 5.8 mg DON/kg. Conversely, Goyarts *et al*. (2005) reported that *ad libitum* fed castrated male pigs had significantly higher feed intake and weight gains, as compared with female pigs, during the 11-week exposure to DON-contaminated feed (about 6 mg DON/kg diet) in grower swine; whereas, Bergsjo *et al*. (1992) and Williams *et al*. (1988) reported no interactions between sex and weight gains at any dietary DON concentrations.

Rotter *et al*. (1994) concluded that pigs show a physiobiochemical adaptation response to DON-contaminated diets ranging from 0.95 to 2.85 mg DON/kg. Even at the lowest dose, 0.95 mg DON/kg diet (0.11 mg DON/kg body weight/day), pigs showed a reduction in feed consumption over the first 2 days of the experiment but were able to adapt by the end of 28 days. Overall gains of pigs on DON-contaminated diets were no different than pair-fed controls. This result is consistent with those of Friend *et al*. (1986) and Bergsjo *et al*. (1992) who reported that swine could adapt to dietary DON contamination. Morphological changes in pigs fed the highest DON-contaminated feed were a reduction in thyroid size and a higher degree of folding and thickening of the esophageal region of the stomach (Rotter *et al*., 1994). In a similar study, Øvernes *et al*. (1997) fed growing pigs (25 kg) naturally DON-contaminated oats at 0.6, 1.8, and 4.7 mg DON/kg feed, both restricted and *ad libitum* for about 100 days. No changes in feed intakes were detected in pigs fed DON-contaminated rations *ad libitum*, but feed intakes

were significantly reduced in pigs fed restricted levels of 1.8 and 4.7 mg DON/kg feed. Post-mortem examination of the pigs revealed no differences in the stomach mucosal appearance between the different DON-treatment groups. The authors hypothesized that when DON-contaminated feed is freely available, pigs would reject less feed than when offered large quantities for a limited period. Results of this study in growing pigs indicated that using naturally contaminated oats at levels up to 4.7 mg DON/kg feed might cause slight immunosuppression, but did not represent a serious health problem.

In a study at low T-2 toxin concentrations, Rafai *et al*. (1995a) fed 7-week-old pigs (~9 kg) a diet with 0.5, 1, 2, 3, 4, 5, 10, and 15 mg/kg of purified T-2 toxin for 3 weeks, with average daily intakes by experimental pigs of T-2 toxin between 0.029 and 0.23 mg T-2 toxin/kg body weight/day. No vomiting or diarrhea was observed in any group, but pigs fed 10 and 15 mg T-2 toxin/kg diet became somnolent and huddled as if chilled. Feed consumption was decreased (not significantly) and serum aspartate aminotransferase activity was significantly increased in pigs by the lowest T-2 toxin concentration. Pigs fed 3.0 mg T-2 toxin/kg feed had significant decreases in weight gain, but not feed conversion, for 3 weeks. After 9–14 days on 4, 5, 10, or 15 mg T-2 toxin/kg diet, pigs began to show signs of dermatitis and crusting of the skin and the snout, with inflammation becoming more severe with time. Histological examination of affected skin revealed hyperkeratosis, parakeratosis, acanthosis, and superficial to deep erosions into the subepithelial layer in all groups exposed to T-2 toxin. Pigs at the higher T-2 toxin dosages had involvement of the skin and mucous membranes of the prepuce, tongue, and renal pelvis (urothelium). The authors of this study concluded that the no-effect level of T-2 toxin for performance was probably less than 0.5 mg T-2 toxin/kg diet. In contrast, growing crossbred pigs (18 kg) fed 8.0 mg T-2 toxin/kg diet for 30 days showed reduced feed consumption and weight gain but no changes in clinical appearance, as compared with controls (Harvey *et al*., 1994).

Toxicoses from macrocyclic trichothecenes have occurred in pigs housed on straw litter infected with *Stachybotrys* (Dankó, 1975). The clinical signs included irritation, necrosis, and hemorrhages, and are similar to those described for cattle with stachybotryotoxicosis (see Ruminants).

### *Horses*

Few experimental trichothecene studies using the equine species have been published. Five adult horses (~444 kg) were fed DON-contaminated barley (average range of 36–44 mg DON/kg grain) and consumed approximately 1.27 kg barley/horse/day (44–55 mg DON/horse/day or about 0.099–0.124 mg DON/kg body weight/day) for 40 days (Johnson *et al*., 1997). The horses had access to free-choice pasture grass. No signs of feed refusal were observed in the horses, and though not weighed, all animals appeared to gain weight and improve body condition according to the authors. No remarkable changes were detected in any hematological or serum biochemical parameters. Both serum IgG and IgA decreased in a linear manner through the trial. The authors attributed decreases in serum total protein, globulin, and albumin to changes in the hydration status of the animals and voluntary water consumption during the study. The authors also suggested that gastric microflora detoxified DON prior to absorption. Raymond *et al*. (2003) fed mature, non-exercising mares a blend of naturally contaminated wheat and corn (15.0 mg DON and 0.8 mg 15-ADON/kg diet), with and without 0.2% glucomannan polymer (an adsorbent), for 21 days. Control mares consumed approximately 0.004 mg DON/kg body weight/day, the mycotoxin group 0.029 mg DON/kg body weight/day, and the mycotoxin plus adsorbent group 0.051–0.058 mg DON/kg body weight/day. Feed intake was significantly reduced in the mycotoxin fed groups, as compared with the control group. The authors reported that $\gamma$-glutamyltransferase activities were increased in mares fed the mycotoxin diet on days 7 and 14, but not on day 21 of the trial. Unfortunately, no serum chemistry analyses were undertaken prior to the experiment on day 0 to establish a common baseline for the horses. Additional serum chemistry parameters and hematology were not affected by the diets. In a subsequent study of exercised horses, mares were fed one of three treatments, a control diet, a mycotoxin diet (11.2 mg DON/kg, 0.7 mg 15-acetyldeoxynivalenol/kg diet), and a mycotoxin diet (14.15 mg DON/kg feed, 0.7 mg 15-acetyldeoxynivalenol/kg diet) with 0.2% glucomannan polymer for 21 days (Raymond *et al*., 2005). Feed intake and weight gains were depressed in horses fed the mycotoxin-contaminated diets, as compared with control mares. No effect of diet was seen on hematology or serum chemistries, which included $\gamma$-glutamyltransferase activities, nor were any differences noted in athletic ability measured by time-to-fatigue treadmill step tests. Feeding 2% glucomannan polymer as an adsorbent did not prevent a depression in feed consumption in this study.

Lethal trichothecene mycotoxicoses from *Stachybotrys* have been recognized in field cases involving horses in the former USSR, particularly the Ukraine since the late 1930s (reviewed by Forgacs, 1972; Dankó, 1975; Hintikka, 1978). Stachybotryotoxicosis typically occurred during indoor feeding of horses with *S. alternans*-contaminated straw or hay. The horse is very sensitive to *Stachybotrys* toxins, with 1 mg of pure *Stachybotrys* toxin considered a lethal dose. Soviet authors described two forms of the disease, “typical” or prolonged disease and “atypical” or acute disease, based on the dose and duration of toxin ingested. The typical form, which is further subdivided

into three stages, was more common, and occurred after continuous consumption of sub-lethal quantities of moldy vegetation. The first stage occurred 2 or 3 days following consumption of moldy feed. Irritation, and later necrosis, occurred wherever the toxin(s) contacted tissue, especially the oral, nasal, and ocular mucous membranes. Clinical signs of conjunctivitis, lacrimation, and profuse salivation, along with spontaneous nosebleeds, hemorrhage of mucous membranes, maxillary lymph node swelling, and dysphagia also occurred. The first stage lasted 2–3 days or could persist for a month. The second stage lasted 15–50 days and was characterized primarily by clinicopathological changes; clinical signs were nonspecific. An initial leukocytosis was followed by leukopenia and thrombocytopenia and, in some cases, blood failed to clot. During the third stage, thrombocytopenia and leukopenia worsened, horses became febrile (40–41.5°C), anorexic, and prone to colic. Weight loss, recumbency, and septicemia were common. This stage lasted 1–6 days and usually ended in death.

The atypical form of stachybotryotoxicosis was peracute (1–3 days) and associated with high concentrations of *Stachybotrys* toxins in the feed. This form was characterized by nervous system irritation or depression, cardiac arrhythmias, pulmonary edema, and hemorrhages of serosal and mucosal membranes and muscular tissue, muscle necrosis, and oral ulcers. Post-mortem findings were characterized by hemorrhage and necrosis of tissues (Hintikka, 1978). Hemorrhages occurred on serous and mucous membranes and in the spleen, liver, lungs, brain, spinal cord, lymph nodes, and most notably in muscle tissue. Clearly circumscribed necrotic foci, yellow to brown-gray in color, were seen on oral mucosa, with the entire digestive tract generally appearing hemorrhagic and necrotic.

In addition to toxicoses involving macrocyclic trichothecenes, historical accounts of equine deaths were reported in horses provided moldy feed in northern Japan. Horses developed clinical signs and died after consuming moldy bean hulls, which were commonly used as fodder and bedding especially in the winter and spring (Ishii *et al*., 1971). The clinical signs of affected horses were central nervous system disturbances including convulsions and cyclic movements, depressed respiration, icterus, and bradycardia. Several trichothecenes, including T-2 toxin, DAS, and neosolaniol, were associated with the clinical syndrome, but cause–effect was not established.

### Dogs and cats

Trichothecenes are fairly heat stable compounds and following incorporation into pet food diets, DON remains stable during extrusion and drying (Hughes *et al*., 1999). The authors reported that DON concentrations (from a naturally contaminated wheat source) greater than 4.5 ± 1.7 or 7.7 ± 1.1 mg DON/kg diet reduced feed intake in dogs and cats, respectively. When DON concentrations reached 8–10 mg/kg feed, clinical signs of vomiting and reduced feed intake and body weight occurred in dogs and cats. Dogs that had been previously exposed to DON-contaminated feed preferentially selected uncontaminated dog food; dogs with no previous experience with DON-contaminated dog food consumed equal quantities of DON-contaminated and uncontaminated food.

### Ruminants

During wet growing seasons, DON contamination of cereal grains can be sufficiently high to make grains unsuitable for human food or swine feed. Anderson *et al*. (1996) evaluated the use of naturally scab-infected barley with elevated DON concentrations (about 35 mg/kg) in beef growing/finishing and pregnant heifer rations. The authors fed increasing levels of DON to crossbred steers for 84 days, at 0.9, 3.7, 6.4, and 9.2 mg DON/kg diet, during the growing period and for 100 days during the finishing period at 1.1, 5.0, 8.8, and 12.6 mg DON/kg diet. No significant differences were found in beef performance including feed intake, feed efficiency, rate of gain, or carcass quality. The authors concluded that DON-contaminated feed could be provided up to 9 mg/kg diet during bovine growth and up to 12 mg/kg diet during finishing without adverse effects. In separate study, the authors fed pregnant yearling heifers DON-contaminated barley, 36.8 mg/kg at 3.6 or 5.4 kg/head/day (about 10.2 or 13 mg DON/kg diet, respectively) from mid-gestation through the first 45 days of lactation. No significant changes were noted in feed intake, heifer weight gain, or calf body weights. Calf weight gains were higher for calves nursing heifers fed the DON-contaminated barley during calving and lactation. In a 3-year follow-up of the experimental heifers retained in the herd, all 14 control heifers had been culled for non-pregnancy after 3 years, whereas only 8 vomitoxin-fed heifers had been culled for non-pregnancy suggesting feeding DON had no impact on subsequent reproduction (Anderson, 2006). The authors concluded that barley unsuitable for human food could be utilized in beef rations and fed safely at 10–12 mg DON/kg diet to pregnant cows.

Trenholm *et al*. (1985) reported an initial slight decrease in feed intake of dry cows fed a wheat–oats-contaminated diet with 6.4 mg DON/kg concentrate. The cows returned to normal feed consumption by the end of the sixth week of exposure, with no differences reported in body weight. The only trichothecene mycotoxin apparently tested in the contaminated wheat was DON, so the presence of additional mycotoxins could not be discounted. Charmley *et al*. (1993) fed primparous Holstein cows DON-contaminated wheat and corn at increasing concentrations of 0.07, 4.95, and 12.09 mg DON/kg of dry matter concentrate (daily

DON intake of 0.59, 42, and 104 mg, respectively) for 10 weeks in a lactation study. The total mixed ration was formulated to support 25 kg milk/day and a milk fat level of 3.8%. No changes were observed in total milk output or intake of concentrate or forage. Cows fed 4.9 mg DON/kg concentrate had the lowest milk fat content, which the authors did not attribute to DON intake. Similar results were reported by Ingalls (1996) who fed high-producing dairy cows DON-contaminated barley diets up to 14.6 mg DON/kg concentrate dry matter (about 8.5 ppm in diet, 0.31 mg DON/kg body weight) for 3 weeks and found no significant changes in milk production or feed intake between controls and treated cows.

Oral T-2 toxin dosing studies in calves resulted in more severe clinical signs. Pier *et al*. (1976) dosed young Jersey calves, 35–78 kg, with oral gelatin capsules for 30 days at 0.08, 0.16, 0.32, and 0.64 mg T-2 toxin/kg body weight (one calf per dose level). The authors estimated that the lower T-2 doses were realistic, as a 50 kg calf would have to eat 2 kg of corn containing 2 mg T-2 toxin/kg to mimic the lowest dose of 0.08 mg T-2 toxin/kg feed. All T-2 toxin dosages caused mild enteritis and loose feces in calves. At the higher dosage levels of 0.32 and 0.64 mg/kg, bloody feces were apparent, and the calves became anorexic, dehydrated, and lost body weight. The calves had elevated serum aspartate aminotransferase activities and prolonged prothrombin times. The high dose calf died on day 20 of the trial. Post-mortem lesions in the highest T-2 toxin dosed calves were ruminal ulcers and abomasitis, while the lower dosed calves had mild enteritis. Abomasal ulcers were described in the calf dosed at 0.16 mg T-2 toxin/kg body weight.

Osweiler *et al.* (1981) dosed beef calves (85–200 kg) orally with 0.1, 0.3, and 0.6 mg purified T-2 toxin/kg body weight/day for 6 weeks, and found that 0.3 mg/kg (mimic ~10 mg T-2/kg diet) decreased feed consumption with no outwards signs of clinical disease. A clinically effective dose of 0.6 mg/kg (mimic ~20 mg T-2/kg diet) produced marked differences in body weight gain, as compared with control animals. All calves in the high dose group (0.6 mg T-2 toxin/kg body weight) refused to eat the concentrate portion of their diet starting on the second day of the trial and consumed a limited portion of diet provided throughout the entire 6 weeks of T-2 toxin exposure. The high T-2 toxin dosed calves had intermittent diarrhea, soft tan to dark, semi-fluid feces, and became thin with rough hair coats. Calves dosed with 0.3 mg/kg generally showed a lack of interest in eating the total amount of feed provided. No coagulopathies were observed in the T-2 toxin treated calves. The authors questioned whether cattle would consume T-2-toxin-contaminated feed in the range of 10–20 mg/kg for a sufficient time to produce clinical signs.

Weaver *et al*. (1977) intubated daily a pregnant Holstein cow (third trimester of gestation) with 182 mg of purified T-2 toxin for 15 days. On the fourth day of dosing the cow delivered a bull calf that was also intubated with T-2 toxin at 0.6 mg/kg body weight for 7 consecutive days, and then on alternate days for a total of 16 days treatment. The calf became severely depressed, with hind-quarter ataxia, knuckling of rear feet, and anorexia. Complete blood counts, serum total protein, and several liver enzymes were within the normal range for both cow and calf throughout the treatment. Gross and microscopic lesions were seen only in the cow and included congestion of the small intestine mucosa and a ruminal ulcer. Histological changes were congestion of the lamina proprial blood vessels of the omasum, rumen, jejunum, and ileum, and edema of the submucosa, muscular layers, and serosa of the cecum and colon. The bone marrows of both animals were normal.

In a field case, anorexia, periodic elevated temperatures, abortions in mid-gestation, and a 20% death loss were associated with feeding moldy, high moisture corn to lactating Holstein dairy cows during a 5-month period in late winter (Hsu *et al*., 1972). Post-mortem lesions of extensive hemorrhages on serosal surface of internal viscera were reported. Among the fungi cultured from the corn were *F. tricinctum*, *F roseum*, and *F. moniliforme* and various *Penicillium* spp. A sample of feed taken in late May contained 2 mg T-2 toxin/kg, which the authors estimated as a low concentration because of losses during analysis. The authors assumed other toxins were also present and contributed to clinical toxicity, but were not analyzed.

Stachybotryotoxicosis in cattle occurred mainly as large outbreaks in young animals (Dankó, 1975; Hintikka, 1978). Clinical signs included lethargy, inappetance, bloody diarrhea, and epistaxis. In chronic toxicosis, changes in the hematology appeared to be the initial toxic event. After a leukocytosis of short duration, leukopenia and thrombocytopenia developed. Clinical signs appeared gradually with hematological changes and were similar to those seen in the "typical" form of horses. Cows could abort during the second half of gestation with hemorrhagic lesions apparent in the fetus and fetal membranes. Mortality could be as high as 90–100% in affected cattle. Toxicosis in sheep was similar to cattle. Additionally, sheep exhibited hyperthermia and progressive anemia with marked impairment of the lymphoid system (Schneider *et al.*, 1979) and wool loss with skin hemorrhaging (Hajtós *et al*., 1983).

Dankó (1975) commented that animals preferred to eat *Stachybotrys*-contaminated straw rather than good-quality hay because of a flavor produced by the mold in the straw, but this observation was not supported in other literature. *Stachybotrys* toxins appeared more toxic in an acidic pH (Dankó, 1975). Therefore, ruminants were considered relatively resistant because of salivation and the higher pH environment of the rumen. Feeding a high carbohydrate diet, which lowers rumen pH, could enhance

the toxic effects of *Stachybotrys*. Treatment of animals affected with *Stachybotrys* mycotoxins was generally unrewarding due to severe damage to the lymphoid system. Immunosuppression of both humoral and cellular systems was an important clinical effect from toxins of *Stachybotrys*.

Ovine responses to trichothecene exposure are similar to cattle. Seven crossbred lambs (mean weight of 17.9 kg) between 3 and 6 months of age consumed a DON-contaminated wheat ration (15.6 mg DON/kg) for 28 days with no significant changes in behavior, clinical signs, feed consumption, hematology, or serum clinical chemistries compared to a control group (Harvey *et al.*, 1986). In an experiment using purified DAS, crossbred ewe lambs (average 38 kg) were fed *ad libitum* 5.0 mg DAS/kg diet for 34 days (Harvey *et al.*, 1995). The lambs developed diarrhea during the first week of the study, with a significant decrease in feed intake and weight gains by the end of the exposure period. No dermal or oral lesions were observed in DAS treated lambs, nor were gross lesions observed at necropsy of the lambs. The authors fed lambs a diet contaminated with both aflatoxin at 2.5 mg/kg feed and DAS at 5.0 mg/kg feed and noted a synergistic response in the marked reductions in feed intake and weight gains.

Friend *et al.* (1983) dosed 6–8-week-old male lambs with purified T-2 toxin in gelatin capsules at 0, 0.3, and 0.6 mg/kg body weight for 21 days. All lambs had bouts of diarrhea, but several lambs dosed with 0.6 mg T-2 toxin/kg body weight had prolonged periods of diarrhea, appeared unthrifty, and started fleece-pulling at the end of 3 weeks of treatment. At necropsy, T-2 treated lambs appeared to have smaller and less active thymic tissue, as compared to the control group, and lesions of focal rumenitis with parakeratosis and infiltration by polymorphonuclear cells.

### Poultry

Poultry are not as sensitive to the effects of trichothecenes as swine, but are probably more sensitive than ruminants. Day-old chickens fed DON-contaminated feed at 9 or 18 mg DON/kg diet for 7 weeks had decreased relative and absolute liver weights, but showed no changes in feed intake (Kubena *et al.*, 1985). Chickens fed high DON concentrations in rations (>15 mg DON/kg) exhibited feed refusal and weight loss (Kubena *et al.*, 1987; Kubena and Harvey, 1988). DON contamination of rations up to concentrations of 18 mg/kg feed provided to laying hens did not affect hatchability of eggs (Lun *et al.*, 1986; Bergsjo *et al.*, 1993b). Bergsjo *et al.* (1993a) fed a naturally contaminated oat diet to White Leghorn laying hens at concentrations of 0.12–4.9 mg DON/kg feed for 70 days. Low concentrations of 3-ADON (0–0.63 mg/kg) and zearalenone (trace to 0.55 mg/kg) were detected in the diets. No significant differences in feed intake, weight gain, egg production, body weight at hatching, and viability of the chicks were found between treatment groups.

Purified T-2 toxin added to a commercial laying hen ration at 20 mg T-2 toxin/kg diet for 3 weeks caused raised oral lesions, yellowish-white to gray in color, during the first week of T-2 toxin administration on the sublingual and palatine areas, and then on the tongue and corners of the mouth (Wyatt *et al.*, 1975). Feed consumption by hens decreased by about 25% compared with control diet intake during the first week of T-2 toxin exposure, with the treated laying hens showing a significant weight loss after 1 week of the trial. Egg production of the T-2 toxin treated hens declined by 20% in the second and the third week of exposure; the eggshell thickness was significantly decreased after 3 weeks of T-2 toxin exposure.

In a study of 27-week-old laying hens fed *ad libitum* diets containing purified T-2 toxin at 0 (control), 0.5, 1, 2, 4, and 8 mg/kg feed for 8 weeks, the highest dosage caused a significant decrease in feed consumption, egg production, and shell thickness, as compared with hens fed the control diet (Chi *et al.*, 1977). Fertility and progeny performance were not altered by feeding T-2 toxin, but hatchability of fertile eggs was significantly decreased in hens fed 2 and 8 mg/kg, as compared with hens fed the control diet. Oral lesions, circumscribed and proliferative plaques, were noticed after the second week in hens fed 4 and 8 mg/kg and after the third week in hens fed 0.5 mg/kg. Severity and incidence of lesions were proportional to dietary T-2 toxin concentration. No significant histopathological changes were observed in the liver, heart, kidney, brain, or bone marrow, but necrotic lesions were observed in the gizzard and crop. Diaz *et al.* (1994) fed hens both T-2 toxin and DAS, each at 2 mg/kg feed in the diet. Hens exhibited oral lesions, a significant decrease in feed consumption (decline of about 12%) and egg production (decline of 15%), as compared with controls.

Generally, concentrations of T-2 and HT-2 toxin greater than 1 mg/kg are not common in grains except in wet years in the upper Mid-west of the United States; often, HT-2 toxin is found at higher concentrations than T-2 toxin. Rafai *et al.* (2000) evaluated such relatively low levels (0, 0.2, 0.4, 0.6, 0.8, 1, 2, 3, and 4 mg T-2 toxin/kg diet) of exposure for 7 weeks in day-old Pekin ducklings. Within 2 days after starting the experiment, most ducks fed T-2 toxin developed oral lesions. The dermatotoxic lesions gradually disappeared in the ducks fed less than 3 mg T-2 toxin/kg feed. Ducks fed 3 and 4 mg T-2 toxin/kg feed refused the diet in the first week and from weeks 3 to 7. The feed intakes of ducks fed 0.6–4 mg T-2 toxin/kg feed were generally less than that of the control group. No significant dose-related changes were noted in serum chemistry and hematology. Similar dose-related oral lesions were reported in day-old Muscovy ducks

within 16 h of exposure to T-2 toxin and DAS at 0.25, 0.5, or 1 mg/kg feed (Shlosberg *et al.*, 1986). Decreased body weights, thymus, spleen, and bursa of Fabricius weights were noted in 6-week-old mallards fed 2 mg T-2 toxin/kg feed for 9 days (Neiger *et al.*, 1994). Microscopic lesions were observed in lymphoid organs and included a moderate decrease in thymic cortical lymphocytes.

### *New trichothecene concern*

In North America during the mid-1990s, interest focused on *Stachybotrys chartarum* or black mold found in damp buildings as a possible cause of idiopathic pulmonary hemorrhage in infants (Dearborn *et al.*, 1999). Epidemiological investigations of pulmonary hemorrhage in infants found an association with airborne fungi including *Stachybotrys*. *S. chartarum* produces a variety of secondary fungal metabolites, including simple trichothecenes (trichodermol, trichodermin, and verrucarol), macrocyclic trichothecenes (verrucarins B and J; roridins D, E, isoE, and L-2; the satratoxins F, isoF, G, isoG, H, and isoH), and spirocyclic drimanes that are recognized immunosuppressants (Jarvis, 2003). *S. chartarum* appears to divide into two chemotypes, one produces the macrocyclic trichothecenes and the other produces a class of diterpenoids, the atranones that to date have not been shown to possess significant biological activity (Jarvis, 2003). The characterization of natural products from *Stachybotrys* species and any relationship to clinical disease remains a challenge.

## TREATMENT

The first action is to stop exposure to moldy feed. If using screenings or poor-quality grain, cleaning the grain by removing broken, shriveled kernels and washing the grain can lower mycotoxin contamination. Generally, clinical signs of feed refusal will disappear within 7 days after removal of the contaminated feed. Animals return to production within 14 days.

No specific therapies for trichothecene mycotoxicoses are available. Some trichothecenes undergo enterohepatic recirculation and are excreted in the feces. The use of activated charcoal, which binds toxins within the gastrointestinal tract and prevents toxin reabsorption, plus magnesium sulfate, was beneficial as part of a therapeutic protocol for treatment of acute, T-2 toxicosis in swine (Poppenga *et al.*, 1987). Metoclopramide, given intravenously immediately prior to and following T-2 toxin administration, was only partially successful as an antiemetic (Poppenga *et al.*, 1987). A number of binders, such as clay and zeolitic products, have been suggested for use with trichothecene-contaminated feed to prevent absorption by animals. Their efficacy has not been proven and marked species variations exist. The US Food and Drug Administration has not approved any ingredient for use as a trichothecene mycotoxin binder.

## CONCLUSIONS

Trichothecene mycotoxins occur worldwide however both total concentrations and the particular mix of toxins present vary dramatically with environmental conditions. Proper agricultural practices such as avoiding late harvests, removing overwintered stubble from fields, and avoiding a corn/wheat rotation that favors *Fusarium* growth in residue can reduce trichothecene contamination of grains. Storage of grains at less than 13–14% moisture (less than $0.70a_W$) and hay/straw at less than 20% moisture are important in preventing trichothecenes production. Once produced, trichothecenes are stable compounds and can remain present at toxic concentrations in feed for years. Field reports of trichothecene toxicity in livestock in North America generally involve DON contamination of feed. Acute, high dose exposures are not common. More typically, chronic to sub-chronic exposures to low dose DON-contaminated feed in swine occurs and leads to nutritional impairment, poor production, and possible immune susceptibility to infections.

Due to the vague nature of toxic effects attributed to low concentrations of trichothecenes, a solid link between low level exposure and a specific trichothecene(s) is difficult to establish. Mold identification and determination of fungal spores can indicate feedstuffs of deteriorated quality, but provide no information as to the presence or concentration of mycotoxins that actually cause adverse health effects. Multiple factors, such as nutrition, management, and environmental conditions impact animal health and need to be evaluated with the knowledge of the mycotoxin(s) and concentrations known to cause adverse health effects. Future research evaluating the impact(s) of low level exposure on livestock may clarify the potential impact on immunity.

Trichothecenes are rapidly excreted from animals, and residues in edible tissues, milk, or eggs are likely negligible. In chronic exposures to trichothecenes, once the contaminated feed is removed and exposure stopped, animals generally have an excellent prognosis for recovery (Prelusky *et al.*, 1994).

# Zearalenone

*Michelle S. Mostrom*

## INTRODUCTION

Zearalenone is a nonsteroidal estrogenic mycotoxin produced by several species of *Fusarium* fungi. The primary producer of zearalenone is *Fusarium graminearum* (teleomorph *Gibberella zeae*). Additional *Fusarium* fungi capable of producing zearalenone include *F. culmorum*, *verticillioides* (*moniliforme*), *sporotrichioides*, *semitectum*, *equiseti*, and *oxysporum*. Contamination of cereal grains by zearalenone has been reported worldwide, primarily in temperate climates. Typically, zearalenone concentrations are low in grain contaminated in the field, but increase under storage conditions with moisture greater than 30–40%. Zearalenone has major effects on reproduction that can lead to hyperestrogenism. Prepubertal swine are the most sensitive species. Typical clinical signs of hyperestrogenism are swelling of the vulva, increase in uterine size and secretions, mammary gland hyperplasia and secretion, prolonged estrus, anestrus, increased incidence of pseudopregnancy, infertility, decreased libido, and secondary complications of rectal and vaginal prolapses, stillbirths and small litters. This chapter describes toxicity of zearalenone and its major metabolites in animals.

## BACKGROUND

Estrogenism in swine was reported in the mid-1920s in the Midwest US (McNutt *et al*., 1928). A condition of swelling and eversion of the vagina in young gilts and swelling of the prepuce in males was associated with consuming moldy corn. Prolapse of the vagina and occasionally the rectum were noted as secondary effects. With replacement of the moldy corn with clean corn, the animals recovered to normal, but if exposure to moldy corn continued, eversion of the uterus, secondary infections, and death occurred. Mirocha *et al*. (1971) noted high death losses in some herds and hypothesized that mortality was related to vaginal and rectal prolapses and subsequent septicemias; however, the presence of additional mycotoxins could not be excluded in causing death. Stob *et al*. (1962) isolated an active metabolite with uterotrophic and anabolic activities from culture of *G. zeae* (*F. graminearum*).

The *Fusarium* compound found in corn with uterotrophic activity was named zearalenone, previously known as F-2, and is chemically described as 6-(10-hydroxy-6-oxo-*trans*-1-undecenyl)-β-resorcylic acid lactone (Figure 77.1). At least seven derivatives of zearalenone have been found that naturally occur in corn. Zearalenone and uterotrophic active derivatives were classified as estrogens in the sense that they produce estrus or cornification of the vagina of adult mice (Mirocha and Christensen, 1974). Zearalenone can be produced on numerous substrates, including wheat, barley, corn, corn silage, rice, sorghum, and occasionally in forages. Production in soybeans is uncommon. Moisture content and the presence of oxygen are critical factors for zearalenone production. In laboratory cultures, *Fusarium* growth occurs during a 3-week period at moisture levels

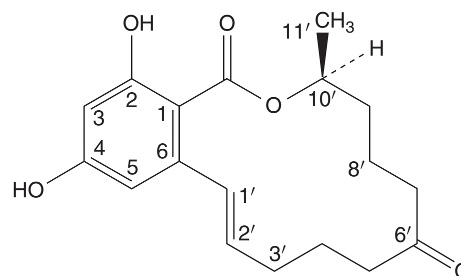

**FIGURE 77.1** Chemical structure of zearalenone.

over 20% and temperature between 20°C and 25°C. If the fungus is stressed by cool temperatures of 8–15°C for several weeks, zearalenone can be produced. Production of zearalenone in the field is similar to that in the laboratory, with alternating moderate and low temperature weather capable of stimulating zearalenone production. Zearalenone can be produced fairly quickly in the field during wet weather in the late summer or early fall weather following hail damage to corn. Very high concentrations of zearalenone, which can occur naturally in some field samples, generally result from improper storage at high moisture rather than production in the field. Corn stored in a crib and exposed to winter weather was particularly prone to fungal invasion and production of zearalenone. In addition to the co-occurrence of other estrogenic metabolites, such as α- and β-zearalenol, zearalenone is commonly detected in grains with another *Fusarium* mycotoxin deoxynivalenol. Zearalenone is heat stable, but can be partially destroyed during extrusion cooking of cereals (Castells *et al.*, 2005).

## TOXICOKINETICS

Zearalenone is fairly rapidly absorbed following oral exposure (Dailey *et al.*, 1980). Following a single oral dose of 10 mg zearalenone/kg body weight to 15–25 kg pigs, the absorption was approximated to be 80–85% (Biehl *et al.*, 1993). Zearalenone and associated metabolites were found in the plasma of a pig in less than 30 min after initiating feeding with parent compound. Following zearalenone administration, zearalenone can be localized in reproductive tissues (ovary and uterus), adipose tissue, and interstitial cells of the testes (Ueno *et al.*, 1977; Kuiper-Goodman *et al.*, 1987). The reported biological half-life of total plasma zearalenone radioactivity following oral dosage in pigs is 86 h (Biehl *et al.*, 1993). Species differences in zearalenone susceptibility might be related to hepatic biotransformation, with the highest amount of α-zearalenol, which has increased estrogenic activity compared to α-zearalanol and zearalenone produced by pig hepatic microsomes, whereas chicken microsomes produced the highest amounts of β-zearalenol, which has lower estrogenic activity (Malekinejad *et al.*, 2006). Pigs readily conjugated almost all absorbed zearalenone and α -zearalenol through glucuronidation. While the liver plays a major role in glucuronidation, the intestinal mucosa is also active. Zearalenone was reduced to α- and β-zearalenol in sow intestinal mucosa homogenates (duodenum and jejunum) *in vitro* (Olsen *et al.*, 1987). Gastro-intestinal flora can aid in the metabolism of zearalenone. Zearalenone can undergo rumen metabolism, with reduction to mostly α-zearalenol and to a lower amount of β-zearalenol (Kiessling *et al.*, 1984). Whether rumen metabolism will increase or decrease zearalenone toxicity depends on absorption by the gastrointestinal tract, liver metabolism by hydroxysteroid dehydrogenase, and competition at the cytosolic receptor sites in the animal species.

Zearalenone undergoes extensive enterohepatic circulation and biliary excretion in most species. The major route of excretion for most species is through the feces, although rabbits primarily excrete zearalenone in the urine. Most zearalenone administered in a dose is excreted within a 72-h period. Approximately 94% of radio-labeled zearalenone, given orally to White Leghorn laying hens at 10 mg/kg body weight, was eliminated through the excreta within 72 h post-dosing (Dailey *et al.*, 1980). No major retention of radio-labeled activity was found in edible muscle tissue, but lipophilic metabolite(s) were reported in egg yolk (at about 2 mg/kg concentration) 72 h post-dosing.

Concern has focused on potential residue of zearalenone and its metabolites in milk, eggs, and foods and precocious development of sexual characteristics in young female girls (Kuiper-Goodman *et al.*, 1987; JECFA, 2000). Zearalenone and α- and β-zearalenols can be transmitted into the milk of sheep, cows, and pigs administered high doses of zearalenone (Hagler *et al.*, 1980; Mirocha *et al.*, 1981). Hyperestrogenism has been reported in lambs and pigs nursing dams dosed with zearalenone (Hagler *et al.*, 1980; Palyusik *et al.*, 1980). Dairy cows fed rations with purified zearalenone at 50 mg zearalenone/day and 165 mg zearalenone/day for 21 days had no detectable concentrations of zearalenone or α- and β-zearalenol in the milk or plasma (Prelusky *et al.*, 1990). One cow dosed with 544.5 mg zearalenone/day for 21 days had maximum concentrations of 2.5 ng zearalenone/ml and 3.0 ng α-zearalanol/ml in the milk. Cows dosed orally with a 1-day dose of 1.8 or 6 g zearalenone had maximum milk levels on day 2 of 4.0 and 6.1 ng zearalenone/ml, respectively. This research indicates that minimal transmission of zearalanone occurs into milk and only for a short period of time after exposure to high concentrations of zearalenone.

Following intubations of tritiated-zearalenone into the crops of 7-week-old broiler chickens, the greatest accumulation of radioactivity occurred in the liver 30 min post-administration, which became a trace of radioactivity by 48 h post-administration (Mirocha *et al.*, 1982). Only zearalenone was detected in muscle tissue at approximately 4 ppb at 48-h post-administration, indicating the zearalenone residues in edible tissue are minimal.

## MECHANISM OF ACTION

Zearalenone undergoes reduction of the 6′ ketone to a secondary alcohol, which leads to two diastereoisomeric zearalanols (α and β), that are naturally occurring fungal

metabolites. The α-zearalanol metabolite, which is less estrogenic than α-zearalanol but 3 times more estrogenic than zearalenone, is an anabolic growth-promoting compound, zearanol or Ralgro®, used in both cattle and sheep commercially.

Zearalenone and metabolites can interact directly with the cytoplasmic receptor that binds to 17β-estradiol and translocate receptor sites to the nucleus (Katzenellenbogen *et al*., 1979). In the nucleus, stimulation of RNA leads to protein synthesis and clinical signs of estrogenism. Following subcutaneous injection of the compounds, the zearalanols and zearalenone stimulated production of a specific uterine protein and increased uterine weights. Within the resorcylic acids, α-zearalenol exhibited the greatest binding affinity for cytosolic estrogen receptors, while zearalenone and β-zearalenol displayed much lower binding affinities (Fitzpatrick *et al*., 1989). The hydroxylation of zearalenone to α-zearalenol apparently is an activation process, whereas the production of β-zearalenol would be a deactivation process. The relative binding affinity of α-zearalenol was greater in the pig than in the rat or chicken. Interspecies variations in sensitivity to zearalenone in the feed could be related to different metabolites produced and the relative binding affinities of zearalenone and metabolites formed.

Zearalenone can also act on the hypothalamic–hypophysial axis. Using 70-day-old Yorkshire gilts (20–27 kg) fed 1.5–2 mg zearalenone/kg feed for 45–90 days, Rainey *et al*. (1990) determined that prepubertal exposure to zearalenone affected the hypothalamic–hypophysial axis and the luteinizing hormone (LH) surges that lasted for at least 44 days post-exposure. However, zearalenone consumption did not delay the onset of pubertal estrus nor impair conception rates, ovulation rates, or number of fetuses. Slightly older prepubertal gilts (178 days of age and 94 kg) fed 10 mg zearalenone daily for 2 weeks had suppressed mean serum concentrations of LH, but the onset of puberty and subsequent reproduction were not adversely affected (Green *et al*., 1990). Male rats, 70 days old, dosed orally with zearalenone at 20 mg/kg body weight for 35 days had elevated serum prolactin concentrations but showed no changes in serum LH and follicle stimulating hormone concentrations, body and testes weights, or in spermatogonia, spermatocytes, and spermatids (Milano *et al*., 1995). At relatively high concentrations *in vitro*, approximately 400 μM, zearalenone appeared to act directly on interstitial cells of the testes inhibiting steroidogenesis (Fenske and Fink-Gremmels, 1990).

While zearalenone primarily affects reproduction, it may have additional effects. During exposure of *in vitro* cell lines, zearalenone acted as a ligand for human pregnene X receptor (hPXR), which can activate a transcription factor regulating the expression of numerous hepatic drug-metabolizing enzymes, including expression of cytochrome P450 enzymes (Ding *et al*., 2006). This suggests a potential for zearalenone to induce metabolism of drugs.

At natural contamination levels in feeds, zearalenone does not appear to impact the immune response. Results from *in vitro* studies of zearalenone and metabolites α-and β-zearalenol and α- and β-zearalanol and mitogen testing with leukoagglutinin, concanavalin A, and pokeweed revealed that these mycotoxins inhibited mitogen-induced proliferation of both B and T lymphocytes (Forsell and Pestka, 1985). No treatment differences were observed in B6C3F1 mice fed a diet with 10 mg zearalenone/kg diet for 8 weeks and control mice that were tested with a splenic plaque-forming response to sheep erythrocytes and a delayed hypersensitivity response to keyhole hemocyanin (Pestka *et al*., 1987).

## TOXICITY

Zearalenone has low acute toxicity in most species. In most natural conditions, concentrations of zearalenone in feed ingredients are less than 20 mg/kg (ppm) and generally less than 5 mg zearalenone/kg feed (Sundlof and Strickland, 1986). Prepubertal swine are most sensitive to zearalenone, ruminants may exhibit some adverse affects, and poultry appears to be the least sensitive species. Females are more sensitive than males, and cycling female pigs may be more sensitive than pregnant sows. Pregnant swine may abort. Abortions have been associated in field cases with natural *Fusarium* mold exposure, but have not been reproduced with purified zearalenone (Mirocha and Christensen, 1974). Younger male pigs appear to be more sensitive than older males and can undergo atrophy of the testes and enlargement of mammary glands.

### Swine

Gilts fed rations with 0, 3, 6, or 9 mg purified zearalenone/kg feed that started the day after they showed the first estrus were bred at subsequent heat periods (Young and King, 1986a). A majority of gilts fed 6 or 9 mg zearalenone/kg feed became pseudopregnant based on examination of their reproductive tracts or plasma progesterone levels. Gilts fed rations with 3 mg zearalenone/kg feed had no reproductive effects. After removal of zearalenone from the diet, approximately half of the gilts fed 6 or 9 mg zearalenone/kg feed returned to estrus spontaneously. Edwards *et al.* (1987a) reported luteal maintenance and extended inter-estrous intervals in sexually mature gilts fed purified zearalenone at concentrations of 5–10 mg/kg feed from days 5 to 20 of the estrous cycle. Approximately 86% of the retained corpora lutea underwent spontaneous regression and most gilts came into estrus within the next 30 days. In a subsequent study,

Edwards *et al*. (1987b) fed prepubertal gilts a diet with 0 or 10 mg zearalenone/kg feed for 30 days from 145 to 193 days of age, switched the gilts to a control diet, and then exposed the gilts to a mature boar. While treated gilts displayed vulvar swelling during the 30-day feeding period and were delayed in showing first estrus, the proportion of gilts showing estrus with exposure to the boar was similar between treatment and control gilts, and subsequent cycling was not affected when the treated feed was removed. Young *et al*. (1990) reported an increased weaning-to-estrus interval and embryonic mortality (measured as a decreased ratio of fetuses to corpora lutea) and a decreased number of fetuses per sow in second parity sows fed 10 mg zearalenone/kg diet. No reproductive effects were observed in prepubertal gilts fed a ration with 0.5 mg zearalenone/kg feed (Friend *et al*., 1990).

Young gilts (30–35 kg) administered 5 mg of purified zearalenone *per os* daily developed swelling of the vulva on the 4th day of treatment, an approximate daily dose of 0.143–0.167 mg zearalenone/kg body weight (Mirocha and Christensen, 1974). Gilts dosed with 1 mg of purified zearalenone daily for 8 days developed pronounced vulvar swelling. Gilts exposed to higher concentrations of zearalenone may show atrophy of the ovaries along with edema and cellular proliferation of all layers in the uterus. Kuiper-Goodman *et al*. (1987) noted a no adverse effects level for zearalenone in pigs reaching puberty at 0.06 mg zearalenone/kg body weight/day.

Male swine fed a high concentration of zearalenone (30 mg/kg feed) appeared to initially have accelerated maturation of spermatogenesis, which occurred 1.5–2 months earlier than control animals (Ványi and Széky, 1980). Although germinal epithelium damage was limited to several foci initially, with continued zearalenone exposure the damage became widespread with proliferation of the interstitium around seminiferous tubules. Young and King (1986b) fed lower levels of zearalenone in the diet (0, 3, 6, and 9 mg zearalenone/kg feed) to boars from 32 days of age up to 145 or 312 days of age. Feeding up to 9 mg zearalenone/kg feed to the boars did not affect the libido, but the boars fed the highest dose of zearalenone produced lower total and gel-free volumes of semen with lower total motile sperm. Zearalenone does not appear to affect mature boars. No adverse effects in reproductive parameters, including testicular size, libido, sperm motility and morphology, plasma testosterone and 17β-estradiol concentrations, were reported in mature Yorkshire boars fed increasing concentrations of purified zearalenone at 0, 2, 20, and 200 mg/kg ration for 8 weeks (Ruhr *et al*., 1983).

The European Union (2006) guidance values for zearalenone in feedstuff (with a moisture content of 12%) for piglets and gelts is 0.1 mg/kg or ppm, for sows and fattening pigs is 0.25 mg/kg, and for calves, dairy cattle, sheep, and goats is 0.5 mg/kg.

## Ruminants

Several case reports have associated dairy herd health problems and zearalenone in moldy feed. Young dairy heifers, 6–14 months of age, developed slight enlargement of at least one mammary gland quarter while fed moldy corn in a ration (Bloomquist *et al*., 1982). Following a change in the ration, the heifers returned to normal 7 weeks later. Zearalenone contamination of the moldy ration was detected by thin-layer chromatography. Roine *et al*. (1971) reported turbid discharge from the vulva, obvious estrous behavior lasting for 1–2 weeks, and infertility in dairy cows and heifers. Strains of *F. graminearum* and *culmorum* were isolated from the feed that caused an increase in uterine weight in rats and were capable of producing between 3 and 9.5 mg zearalenone/kg feed. Ványi *et al*. (1974) reported a drop in milk production, feed intake, and swelling of the vulva in diary cows exposed to varying concentrations of zearalenone, ranging from 5 to 75 mg zearalenone/kg feed. In an experimental study, 18 cycling heifers were dosed with 0 or 250 mg of purified zearalenone daily through one non-breeding estrous cycle and the next two consecutive estrous cycles during which the heifers were bred (Weaver *et al*., 1986a). The authors calculated that treated heifers were given an average of 250 mg zearalenone/364 kg body weight/day or 0.69 mg zearalenone/kg body weight/day. The control and treated heifers had conception rates of 87% and 62%, respectively, at a statistical probability of $p < 0.065$. Eighteen dairy cows (three cows per group) dosed orally with 0, 31.25, 62.5, 125, 250, and 500 mg of purified zearalenone daily for two consecutive estrous cycles had no changes in serum progesterone concentration, erythrocyte and leukocyte blood counts, packed cell volume, estrous cycle length, clinical health, or sexual behavior (Weaver *et al*., 1986b).

Zearalenone can affect ewe reproduction when ewes are exposed to the mycotoxin prior to mating. Zearalenone, administered orally at concentrations greater than 3 mg/animal/day, given to ewes prior to mating depressed ovulation rates and reduced lambing percentages (Smith *et al*., 1990). Ewes administered a similar range of oral doses of zearalenone (0, 1.5, 3, 6, 12, and 24 mg/ewe/day) for 10 days, starting 5 days after mating, showed no effect of zearalenone exposure after mating on pregnancy rate or embryonic loss. Breeding rams fed a diet containing 12 mg zearalenone/kg feed for 8 weeks had no significant adverse effects on semen volume, concentration, motility, or morphology during the trial and for 6 weeks after zearalenone feeding was ceased (Milano *et al*., 1991).

## Equine

Gimeno and Quintanilla (1983) reported estrogenic signs of edematous vulvas, prolapsed vaginas, oversized uteruses, and internal hemorrhage in mares and severe flaccidity of

genitals in two male horses fed corn screenings for 30 days in a field exposure. All sick animals collapsed with respiratory paralysis and sudden blindness, and died quickly. Analysis for zearalenone in the feed detected 2–3 mg zearalenone/kg diet. While the authors tested for a variety of mycotoxins by thin-layer chromatography, fumonisins in the corn screenings were not determined because they had not been recognized as mycotoxins and a cause of death in horses. Fumonisins would have to be considered as a primary cause of some of the adverse effects, particularly blindness and death, in these horses.

In a study of six cycling trotter mares, Juhász *et al*. (2001) determined that daily oral administration of 7 mg purified zearalenone starting 10 days after ovulation until the subsequent ovulation had no adverse effect on reproduction. Zearalenone had no effect on the length of the interovulatory intervals, luteal and follicular phases of the ovary, and did not significantly affect uterine edema. The authors noted that zearalenone exposure started 10 days after ovulation and the exposure period to zearalenone was short in this study. The dose of purified zearalenone represented a natural contamination of feed of about 1 mg zearalenone/kg feed and ranged between 0.013 and 0.010 mg zearalenone/kg body weight/day for approximately 8–10 days.

### Poultry

Growing female White Leghorn chickens dosed orally once with 15 g zearalenone/kg body weight showed no adverse effects in reproductive tissues (Chi *et al*., 1980). In a second experiment, chickens dosed orally or intramuscularly with increasing concentrations of zearalenone (0–800 mg/kg body weight) for 7 consecutive days had increased oviduct weights with increasing zearalenone doses. Poultry appear to be fairly resistant to the effects of zearalenone.

## TREATMENT

Quick removal of zearalenone contaminated feed from the ration and replacement with clean feed is essential. Generally, 3–7 weeks following removal of the contaminated feed, animals will return to normal reproductive status. No zearalenone mycotoxin binder has been proven to be efficacious in any species of livestock by the US Food and Drug Administration.

## CONCLUSIONS

Maintaining moisture concentrations less than 15–16% in feeds should adequately prevent zearalenone production during storage. When naturally contaminated feed must be used, incorporation into rations for less susceptible species, such as feedlot animals or poultry, should be considered. At naturally occurring concentrations of zearalenone in grains, residues in meat, milk, and eggs are probably not significant.

# Fumonisins

*Geoffrey W. Smith*

## INTRODUCTION

Fumonisins ($B_1$ and $B_2$) are a group of naturally occurring mycotoxins produced by the fungus, *Fusarium verticillioides* (formerly *F. moniliforme*). These toxic metabolites that are usually found in corn have been implicated in field cases of porcine pulmonary edema (PPE) (Harrison *et al.*, 1990; Osweiler *et al.*, 1992; Colvin *et al.*, 1993) and equine leukoencephalomalacia (ELEM) (Wilson *et al.*, 1990a). Experimentally, fumonisin has been shown to cause liver damage in multiple species including pigs, horses, cattle, rabbits, and primates (Jaskiewicz *et al.*, 1987; Voss *et al.*, 1989; Haschek *et al.*, 1992; Osweiler *et al.*, 1993; Ross *et al.*, 1993; Gumprecht *et al.*, 1995) as well as species-specific target organ toxicity, such as lung in pigs (Haschek *et al.*, 1992), brain in horses (Ross *et al.*, 1993), kidney in rats, rabbits, and sheep (Voss *et al.*, 1989; Edrington *et al.*, 1995; Gumprecht *et al.*, 1995), and esophagus in rats and pigs (Casteel *et al.*, 1993; Lim *et al.*, 1996). Epidemiologic data has linked ingestion of corn contaminated with *F. verticillioides* to human esophageal cancer (Rheeder *et al.*, 1992), and fumonisins have been shown to be hepatocarcinogenic in rats and mice (Gelderblom *et al.*, 1988; Howard *et al.*, 2001).

## BACKGROUND

### Chemical structure

First isolated in 1988, the fumonisins are a group of structurally related compounds with the terminal carboxy group composed of propane-1,2,3-tricarboxylic acid involved in ester formation with the C-14 and C-15 hydroxy groups. The 20C chain base carries either 2-acetylamino or 2-amino-12,16-dimethyl-3,5,10,14,15, pentahydroxyicosane (Figure 78.1). The structures of $FB_1$ and $FB_2$ have been shown to have the empirical formulas of $C_{34}H_{59}NO_{15}$ and $C_{34}H_{59}NO_{14}$, respectively, with the only difference being the hydroxyl group present at the C-10 position in $FB_1$ (Bezuidenhout *et al.*, 1988). Four additional fumonisin metabolites have been isolated ($B_3$, $B_4$, $A_1$, and $A_2$), but appear to occur in much lower concentrations than $FB_1$

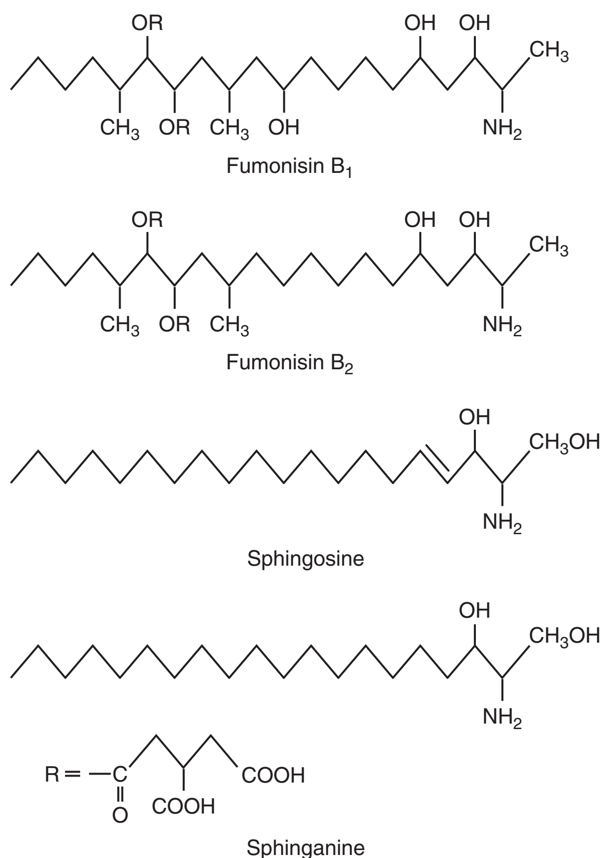

**FIGURE 78.1** The structure of fumonisin $B_1$, fumonisin $B_2$, sphingosine, and sphinganine (modified from Diaz and Boermans, 1994; reprinted with permission from Smith and Constable, 2004).

or $FB_2$, and are not considered important at this time (Gelderblom *et al.*, 1992).

### Occurrence and distribution

Apart from reports of fumonisin $B_1$ and $B_2$ in "black oats" feed from Brazil (Sydenham *et al.*, 1992), and in New Zealand forage grasses (Mirocha, 1992), the only commodities in which fumonisins have been detected so far are corn and corn-based foods. The occurrence of $FB_1$ in the forage grass was accompanied by mono- and dimethyl esters which may or may not have been artifacts (Mirocha *et al.*, 1992). ELEM has long been associated with the consumption of moldy corn, and has been reported in many areas of the world. However, cases of ELEM that were directly associated with fumonisin-contaminated feed have been reported in South Africa and Egypt (Thiel *et al.*, 1991), the United States (Wilson *et al.*, 1990a; Ross *et al.*, 1991), Brazil (Sydenham *et al.*, 1992), Hungary (Bela and Endre, 1996), Spain (Cerrillo *et al.*, 1996), New Caldonia (Bailly *et al.*, 1996), Mexico (Rosiles *et al.*, 1998), and Iran (Raoofi *et al.*, 2003). Additionally, cases of PPE have been associated with fumonisin-contaminated feeds in the United States (Harrison *et al.*, 1990; Osweiler *et al.*, 1992), Brazil (Sydenham *et al.*, 1992), Hungary (Fazekas *et al.*, 1998), and Thailand (Patchimasiri *et al.*, 1998).

Commercial corn-based human feedstuffs from retail outlets in several countries frequently contain fumonisins (Sydenham *et al.*, 1991; Pittet *et al.*, 1992; Stack and Eppley, 1992). Corn meal and corn grits appear to be the biggest problems, as up to 2.98 μg $FB_1$/g and 0.92 μg $FB_2$/g have been found in corn meal and up to 2.55 μg $FB_1$/g and 1.07 μg $FB_2$/g in corn grits (Sydenham *et al.*, 1991). Only very low incidences and levels of $FB_1$ have been recorded for corn flakes breakfast cereal in Switzerland, the United States, and South Africa (Sydenham *et al.*, 1991; Pittet *et al.*, 1992; Stack *et al.*, 1992). A survey in Maryland showed that nearly 100% of corn-based food products (including corn muffin mixes, corn chips, corn tortillas, corn flakes breakfast cereal, corn starch, infant mixed cereal, and corn grits) purchased in grocery stores contained some level of fumonisins with concentrations ranging up to 7.5 μg/g (Castelo *et al.*, 1998). Corn-based food products purchased in Arizona and Nebraska were also frequently (>85%) contaminated with fumonisins with concentrations up to 5.2 μg/g being reported (Castelo *et al.*, 1998).

## PHARMACOKINETICS/ TOXICOKINETICS

The pharmacokinetics of fumonisin $B_1$ have been examined in several species including rats, pigs, cattle, laying hens, and primates (Shephard *et al.*, 1992, 1995; Prelusky *et al.*, 1994; Vudathala *et al.*, 1994; Prelusky *et al.*, 1995; Richard *et al.*, 1996; Martinez-Larranaga *et al.*, 1999). In general, fumonisin is rapidly absorbed following intravenous or intraperitoneal administration and is eliminated in both the feces and urine. Levels are undetectable by 24 h after dosing in virtually all species and significant concentrations (residues) have not been found in muscle, milk, or eggs. Following oral dosing, very little fumonisin $B_1$ is typically found in the serum of animals indicating low bioavailability.

More specifically, the toxicokinetics of radiolabeled fumonisin $B_1$ were examined after intragastric (0.5 mg fumonisin $B_1$/kg) or intravenous (0.4 mg fumonisin $B_1$/kg) administration to bile-cannulated and non-cannulated pigs (Prelusky *et al.*, 1994). Fumonisin derived radioactivity was not detected in the plasma of pigs dosed intravenously after 180 min in the non-cannulated group, or after 90 min in the cannulated group. Urinary excretion began within 3 h of administration and virtually ended after 8 h, accounting for only a small amount of administered toxin. Fecal excretion of fumonisin persisted for 48 h. The excretion in the intravenously dosed group occurred primarily via the bile, with biliary excretion greatest during the first 4 h, but persisting for 24–36 h.

Plasma radioactivity in intragastrically dosed pigs was first detected 30–45 min after dosing, with maximal activity present between 60 and 90 min. As reflected in plasma and elimination data, systemic bioavailability of the dose ranged from 3% to 6%. Excretion of the fumonisin occurred primarily via feces, with only trace amounts excreted via urine or bile.

At 72 h after administration, tissue radioactivity was highest in the liver, kidney, and large intestine in all groups. Intragastrically dosed groups had 10–20-fold lower tissue concentrations than did intravenously dosed groups, and only intravenously dosed groups had measurable radioactivity in brain, lung, and adrenal. Thus, it seems that liver and kidney are the primary organs of fumonisin metabolism and excretion in the pig, and that enterohepatic circulation prolongs the persistence of fumonisin in the body. The toxicokinetics of fumonisin $B_1$ in horses has not been evaluated.

When pigs were fed fumonisin at daily concentrations between 50 and 500 μg of fumonisin $B_1$ per kg of body weight for the last 5 months before slaughter, no muscle or kidney residues were detected (Liguoro *et al.*, 2004). Fumonisin $B_1$ was not detected in the eggs from laying hens following either intravenous or oral administration (Vudathala *et al.*, 1994). Although negligible concentrations have been shown to cross the mammary barrier (Spotti *et al.*, 2001), the toxin was not detected in milk from cattle that consumed a diet-containing fumonisins (Richard *et al.*, 1996). Therefore, it appears that fumonisin residues in meat, milk, or eggs does not represent a hazard or food safety concern for humans consuming these products.

# MECHANISM OF ACTION

## Sphingolipid alterations

Fumonisins are structurally related to sphingosine, the major long chain base backbone of cellular sphingolipids (Figure 78.1). They are competitive inhibitors of sphinganine and sphingosine *N*-acyltransferase (also known as ceramide synthase), key enzymes in the *de novo* sphingolipid biosynthetic pathway (Figure 78.2). These *N*-acyltransferase enzymes are responsible for catalyzing the acylation of sphinganine and the reutilization of sphingosine derived from sphingolipid turnover. This inhibition by fumonisin has been characterized *in vitro* using liver and brain microsomes, as well as in intact mammalian cells in culture (hepatocytes, neurons, renal cells, and macrophages) (Merrill *et al*., 1995). Fumonisin $B_1$ blocks the incorporation of radiolabeled serine into the sphingoid base backbone of ceramides and complex sphingolipids and prevents the conversion of sphinganine to sphingosine via addition of the 4,5 *trans* double bond, which occurs after acylation of sphinganine. Fumonisin also blocks reacylation of sphingoid bases (primarily sphingosine) released by hydrolysis of more complex sphingolipids (Merrill *et al*., 1995).

Sphingolipids are located in cellular membranes, lipoproteins (especially low-density lipoproteins), and other lipid-rich structures. Complex sphingolipids are critical for the maintenance of membrane structure, particularly microdomains such as caveolae. They also serve as binding sites for extracellular matrix proteins as well as for some microorganisms, microbial toxins, and viruses, and regulate the behavior of growth factor receptors (Merrill and Sweeley, 1996). Complex sphingolipids function as precursors for second messengers that mediate cell responses to growth factors, cytokines (including tumor necrosis factor-$\alpha$), differentiation factors, and 1,25-dihydroxyvitamin $D_3$. Therefore, sphingolipids are involved in the regulation of cell growth, cell-to-cell communication, differentiation, and neoplastic transformation (Hannun and Bell, 1989).

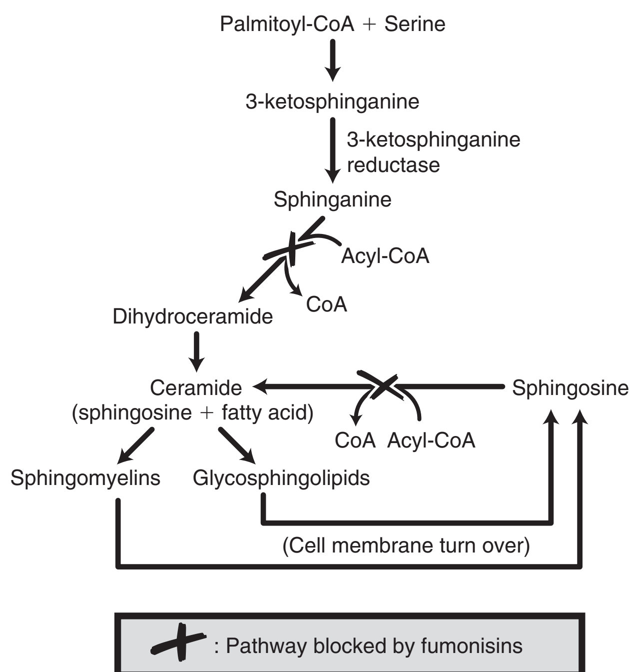

**FIGURE 78.2** The effects of fumonisin on the sphingolipid biosynthetic pathway (modified from Diaz and Boermans, 1994; reprinted with permission from Smith and Constable, 2004).

This enzyme inhibition by fumonisin produces a disruption of sphingolipid metabolism resulting in increased sphinganine and sphingosine along with a decrease in complex sphingolipids in the serum and tissues of animals (Wang *et al*., 1991). These elevations in concentrations of sphinganine and sphingosine have also been observed *in vivo* in several species including pigs, horses, and calves (Riley *et al*., 1993; Goel *et al*., 1996; Smith *et al*., 1999, 2000; Mathur *et al*., 2001). This disruption of sphingolipid metabolism is generally accepted as the probable mechanism of fumonisin toxicity, however only in pigs has the pathophysiology been definitively determined.

PPE has been shown to be a direct result of acute left-sided heart failure related to an increase in plasma and myocardial sphinganine and sphingosine concentrations (Smith *et al*., 1999, 2000; Constable *et al*., 2000). Sphingosine is an important intracellular second messenger that inhibits L-type calcium channels in myocardial cells, thereby decreasing sarcoplasmic reticulum $Ca^{2+}$-induced $Ca^{2+}$-release and cardiac contractility (McDonough *et al*., 1994; Webster *et al*., 1994). As sphingosine concentrations begin to increase in pigs that consume fumonisin, myocardial calcium channels are blocked and contractility begins to decrease (Constable *et al*., 2000; Smith *et al*., 2000). Ultimately, this decrease in cardiac contractility causes acute left ventricular failure and pulmonary edema (Figure 78.3).

The mechanism of ELEM may also be a direct result of fumonisin-induced increases in sphingosine concentrations. A recent study demonstrated that fumonisin administration-induced cardiovascular dysfunction in horses (Smith *et al*., 2002). This study demonstrated an association between neurologic signs, increased serum and myocardial sphingosine concentrations, and cardiovascular depression in fumonisin-treated horses. At necropsy, horses with leukoencephalomalacia have histologic evidence of cerebral edema in the brain. Another study has reported that fumonisin-treated horses also have elevated protein, albumin, and IgG levels in cerebrospinal fluid samples (Foreman *et al*., 2004). Taken together, these findings indicate that fumonisin toxicity in horses is associated with the development of vasogenic cerebral edema as a

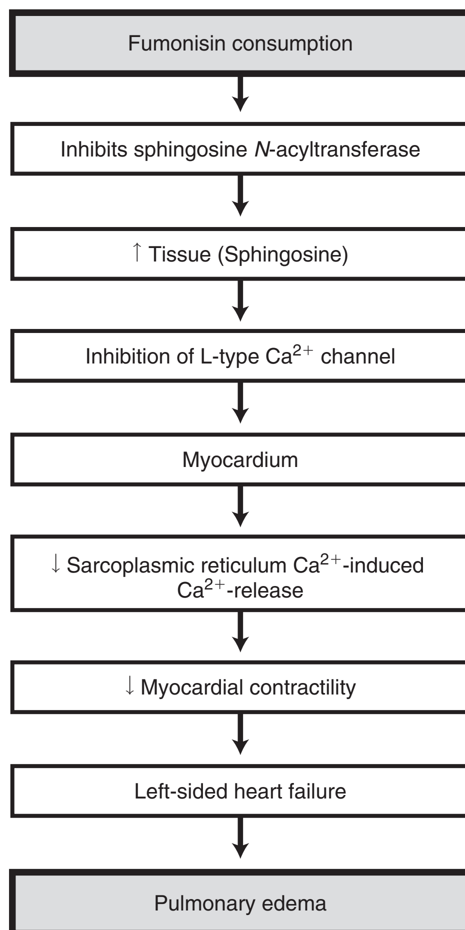

**FIGURE 78.3** Mechanism of fumonisin-induced pulmonary edema in swine. Fumonisin inhibition results in increased tissue sphingosine and sphinganine concentrations. The increased sphingosine concentrations inhibit the L-type $Ca^{2+}$ channels of cardiac myocytes resulting in decreased myocardial contractility. This decrease in contractility results in acute left-sided heart failure and pulmonary edema.

direct result of increased blood–brain barrier permeability. Horses are a species that are dependent on autoregulation of cerebral blood flow when they lower their head to graze. Because of gravitational forces, distal carotid artery pressure can increase tremendously when the animal bends to eat or drink. However, this rise in carotid pressure does not create a significant increase in cerebral blood flow due to the constriction and dilation of cerebral arterioles which maintain normal cerebral blood pressures (Faraci and Heistad, 1990). It has been shown that L-type calcium channels are the primary mediators of vascular tone in these cerebral arterioles (Michelakis *et al*., 1994). Therefore, it has been hypothesized that fumonisin-induced increases in sphingosine concentrations inhibit the calcium channels in cerebral arterioles leading to the inability to maintain normal cerebral blood pressure and vasogenic cerebral edema. This hypothesis will require further research to be proven definitively.

# TOXICITY

Fumonisin has been shown to cause liver damage in multiple species including pigs, horses, cattle, rabbits, and primates (Jaskiewicz *et al*., 1987; Voss *et al*., 1989; Haschek *et al*., 1992; Osweiler *et al*., 1993; Ross *et al*., 1993; Gumprecht *et al*., 1995) as well as species-specific target organ toxicity, such as lung in pigs (Haschek *et al*., 1992), brain in horses (Ross *et al*., 1993), kidney in rats, rabbits, and sheep (Voss *et al*., 1989; Edrington *et al*., 1995; Gumprecht *et al*., 1995), and esophagus in rats and pigs (Casteel *et al*., 1993; Lim *et al*., 1996). This chapter will focus on fumonisin toxicity in pigs and horses since they are the most common clinical poisonings dealt with in veterinary medicine, however cattle and poultry will be briefly discussed.

## Spontaneous and experimental fumonisin toxicosis in swine

In early research prior to the initial isolation and characterization of fumonisins, *F. verticillioides* culture material was reported toxic to swine (Kriek *et al*., 1981). In that experiment, 3 pigs were fed *F. verticillioides* culture material grown on corn. Two of the 3 pigs fed the culture material in this study died within 5 days of pulmonary edema. The third pig was fed culture material for 89 days and was then killed following a period of feed refusal.

The 1989 corn crop in many midwestern and southeastern parts of the United States was heavily infected with *F. verticillioides*, and contaminated screenings fed to animals led to fatal outbreaks of PPE (Harrison *et al*., 1990; Osweiler *et al*., 1992). This syndrome was also reproduced experimentally with contaminated corn screenings and purified fumonisin $B_1$ (Harrison *et al*., 1990; Osweiler *et al*., 1992).

Lung and liver are the major target organs of fumonisin toxicosis in pigs; however, other organs have been reported to be affected. Pigs which ingest fumonisin at concentrations high enough to cause pulmonary edema usually die after about 4 days in field cases (Osweiler, 1992) and after 3–6 days of fumonisin exposure experimentally (Haschek *et al*., 1992; Motelin *et al*., 1994; Gumprecht *et al*., 1998). Pigs which survive chronic exposure to high doses of fumonisin without developing pulmonary edema typically demonstrate hepatic disease with anorexia, weight loss and generalized icterus (Osweiler *et al*., 1992; Colvin *et al*., 1993). Hepatic toxicity occurs at doses significantly

lower than those necessary to cause pulmonary edema (Colvin *et al.*, 1993; Motelin *et al.*, 1994).

## Fumonisins in swine-pulmonary effects

Pulmonary edema (Figure 78.4) has been reported in pigs fed naturally contaminated fumonisin-containing food, fumonisin-containing culture material or following i.v. administration of fumonisin (Harrison *et al.*, 1990; Haschek *et al.*, 1992; Osweiler *et al.*, 1992; Motelin *et al.*, 1994). Reported concentrations of fumonisin required to produce pulmonary edema have been variable, presumably due to variability in susceptibility among exposed animals (Table 78.1). However, other constituents in the diet and analytical detection related to the ability to extract fumonisin from different matrices could account for some of the variability. In addition, some reports have reported only the concentration of fumonisin $B_1$ associated with the development of pulmonary edema, while others have reported both fumonisin $B_1$ and fumonisin $B_2$. Fumonisin $B_2$ usually occurs at about 30% of fumonisin $B_1$ in naturally contaminated corn, and is generally considered to be equitoxic to fumonisin $B_1$ (Ross *et al.*, 1994). Reported doses that induced pulmonary edema in swine include 100 ppm of fumonisin $B_1$ and fumonisin $B_2$ in naturally contaminated corn (Motelin *et al.*, 1994), 16 mg fumonisin $B_1$/kg/day as fumonisin-containing culture material (Colvin *et al.*, 1993), and 20 mg fumonisin $B_1$/kg/day as culture material (Gumprecht *et al.*, 1998). Fumonisin-induced pulmonary edema has also been reported with naturally contaminated corn (330 mg of fumonisin $B_1$ per kg of feed) in Hungary (Fazekas *et al.*, 1998), Brazil (Sydenham *et al.*, 1992), and Thailand (Patchimasiri *et al.*, 1998).

A more recent study has suggested that even lower concentrations of fumonisins may be able to induce pulmonary edema in swine (Zomborszky *et al.*, 2000). Fumonisin $B_1$ was fed added to the feed of weaned pigs at doses of 0, 10, 20, and 40 ppm for 4 weeks as fumonisin-containing culture material (5 pigs per group). Computed tomography of the lungs and magnetic resonance imaging of the brains were performed prior to the study and at 2 and 4 weeks of fumonisin feeding. Histopathology was also done at the time of necropsy (4 weeks). The results of this study showed that all 5 pigs fed fumonisin $B_1$ at 40 ppm developed "severe" pulmonary edema as assessed by computed tomography and histopathology. Two of the 5 pigs fed fumonisin $B_1$ at 20 ppm had "severe" pulmonary edema while 2 other pigs in the group had "mild" edema. In the 10 ppm group, 3 of the 5 pigs were reported to have "mild" pulmonary edema. Magnetic resonance studies of the brain were not able to identify any significant changes during the course of the study in any group.

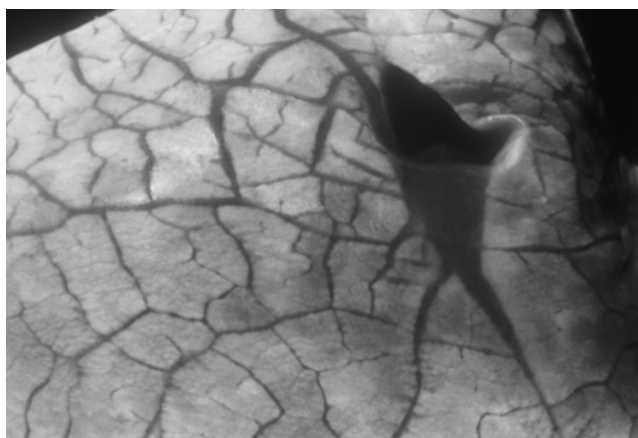

**FIGURE 78.4** Lung from a pig fed fumonisin-containing culture material at a dose of 20 mg fumonisin $B_1$ per kg of body weight for 4 days. Pulmonary edema is characterized by severe widening of the interlobular septa (reprinted with permission from Smith and Constable, 2004). This figure is reproduced in color in the color plate section.

Clinical signs associated with the development of pulmonary edema consistently begin 3–6 days after initiation of exposure to a high concentration of fumonisins. These include dyspnea and open mouthed breathing, increased respiratory rate, cyanosis of skin and mucous membranes, inactivity and sudden death (Osweiler *et al.*, 1992). Pigs usually die within a few hours after the onset of definitive respiratory distress. Histologically, pulmonary edema is present by day 3 of fumonisin exposure (Gumprecht *et al.*, 1998) and is characterized by interstitial edema around airways and vessels, in interlobular and subpleural connective tissues, and in alveolar interstitium (Harrison *et al.*, 1990; Haschek *et al.*, 1992; Osweiler *et al.*, 1992; Gumprecht *et al.*, 1998). Lymphatics are dilated and alveolar edema is often present. Fluid is also present within the thoracic cavity.

In ultrastructural studies using immersion fixed lungs, the endothelium was found to be swollen, vacuolated, and sometimes missing in pigs with pulmonary edema (Haschek *et al.*, 1992). Additional studies using intravascularly perfused lungs (to allow better examination of the vascular system) demonstrated accumulations of fragmented membranous material in the cytocavitary region of endothelial cells (Gumprecht *et al.*, 1998).

## Fumonisins in swine-hepatic effects

Hepatic changes in pigs exposed to fumonisins include elevation of liver associated enzyme activities, altered clinical chemistries, changes in sphingolipid parameters, and morphological alterations. In pigs, hepatic toxicity occurs prior to the development of pulmonary edema,

**TABLE 78.1 Effect of fumonisin in pigs**

| Number of animals | Dose and route | Duration | Toxic effects | References |
|---|---|---|---|---|
| *Experimental studies using purified fumonisin* | | | | |

| 6 pigs | Feed containing 47 ppm $FB_1$ fed *ad libitum* | 28 days | Decreased feed consumption; Elevated AST, GGT, ALP, and creatinine; hepatic and renal lesions; medial hypertrophy of the pulmonary arteries | Harvey *et al*. (1996) |
| 10 pigs | 20 mg of $FB_1$ per kg of BW/day, in feed | 7 days | Pulmonary edema and cardiovascular abnormalities | Smith *et al*. (1996a, b) |
| 2 pigs | 14.5 and 16 mg of $FB_1$ per kg of BW/day, in feed | 4 days | Severe pulmonary edema; renal lesions | Fazekas *et al*. (1998) |
| 24 pigs | 20 mg of $FB_1$ per kg of BW/day, in feed | up to 5 days – some pigs were euthanized each day of the study | All 12 pigs euthanized on days 0, 1, and 2 had no lesions<br>2/5 day 3 pigs and all of the day 4 and 5 pigs had pulmonary edema<br>Elevations in liver enzymes and hepatic lesions seen on day 2 – bile acids first liver parameter to increase | Gumprecht *et al*. (1998) |
| 6 pigs | 20 mg of $FB_1$ per kg of BW/day, in feed | 5–6 days – pigs were euthanized as they developed pulmonary edema | Increased pulmonary artery pressure, pulmonary artery wedge pressure and decreased cardiac output, heart rate, and mean arterial pressure | Smith *et al*. (1999) |

**TABLE 78.1 (Continued)**

| Number of animals | Dose and route | Duration | Toxic effects | Reference |
|---|---|---|---|---|
| 5 pigs | Feed containing 40 ppm $FB_1$ fed *ad libitum* | 4 weeks | No clinical signs – gross pulmonary edema evident at necropsy | Zomborszky *et al.* (2000) |
| 5 pigs | Feed containing 20 ppm $FB_1$ fed *ad libitum* | 4 weeks | 2 of the 5 pigs had gross pulmonary edema – 2 additional pigs had mild evidence of edema present histologically | Zomborszky *et al.* (2000) |
| 4 pigs | Feed containing 20 ppm $FB_1$ fed *ad libitum* | 28 days | 3 of the 4 pigs had mild pulmonary edema evident histologically | Zomborszky *et al.* (2000) |
| 7 pigs | 20 mg of $FB_1$ per kg of BW/day, in feed | 3 days | Decreased left ventricular contractility; heart rate, cardiac output, and mechanical efficiency of the left ventricle | Constable *et al.* (2000) |
| *Experimental studies using naturally contaminated corn screenings* | | | | |
| 6 pigs | 105–155 ppm $FB_1$ in corn screenings fed *ad libitum*) | Up to 28 days | 3 of 6 pigs developed pulmonary edema; liver and pancreatic lesions | Harrison *et al.* (1990) |
| 8 pigs | 92 ppm $FB_1$ in corn screenings fed *ad libitum* | Up to 21 days | 6 of 8 pigs developed pulmonary edema; the remaining 2 pigs were icteric with increased liver enzymes | Osweiler *et al.* (1992) |
| 5 pigs | 175 ppm ($FB_1 + FB_2$) as corn screenings mixed in a complete ration | Up to 14 days | 3 of 5 pigs developed pulmonary edema; hepatotoxicity; decreased weight gain | Motelin *et al.* (1994) |
| 5 pigs | 101 ppm ($FB_1 + FB_2$) as corn screenings mixed in a complete ration | Up to 14 days | Elevated GGT, ALT, AST, ALP, and bilirubin; liver lesions; decreased weight gain | Motelin *et al.* (1994) |
| 5 pigs | 39 ppm ($FB_1 + FB_2$) as corn screenings mixed in a complete ration | 14 days | Histologic liver lesions | Motelin *et al.* (1994) |
| *Reported fumonisin concentrations from naturally occurring outbreaks* | | | | |
| 34 pigs from 2 farms | 105–155 ppm $FB_1$ | Unknown | Lethal pulmonary edema | Harrison *et al.* (1990) |
| 16 pigs from 9 farms | All feed samples associated with pulmonary edema contained $\geqslant$20 ppm $FB_1$ to a maximum of 330 ppm $FB_1$ | Unknown | Lethal pulmonary edema | Osweiler *et al.* (1992) |

and alterations are time and dose dependent (Motelin *et al.*, 1994). Increased activities of serum enzymes such as alkaline phosphatase (ALP), aspartate aminotransferase (AST) and gamma glutamyl transpeptidase (GGT) and concentrations of total bilirubin, bile acids, and cholesterol have been reported as early as 1 day after the initiation of fumonisin exposure (Harrison *et al.*, 1990; Haschek *et al.*, 1992; Osweiler *et al.*, 1992; Colvin *et al.*, 1993; Motelin *et al.*, 1994; Gumprecht *et al.*, 1998). These alterations reflect hepatocyte damage, as well as altered hepatic function.

Morphologic alterations are dose related and progressive with continued ingestion of fumonisins. Following short-term exposure, changes include hepatic cord disorganization, cytoplasmic vacuolation, apoptosis, scattered necrosis, and increased cell proliferation (Harrison *et al.*, 1990; Osweiler *et al.*, 1992; Motelin *et al.*, 1994; Gumprecht *et al.*, 1998). Histologic alterations were observed as early as 2 days after the initiation of treatment with a lethal dose (Gumprecht *et al.*, 1998), and at a concentration as low as 23 ppm when fed for 14 days (Motelin *et al.*, 1994). Long-term fumonisin exposure can result in fibrosis or development of hyperplastic nodules in the liver (Harrison *et al.*, 1990; Casteel *et al.*, 1993). Ultrastructurally, large accumulations of proteinaceous and membranous material were observed in the Space of Disse in pigs that developed fumonisin-induced pulmonary edema (Haschek *et al.*, 1992). Hepatocytes lost microvilli from their sinusoidal face while numerous Kupffer cells contained multilamellar bodies.

## Fumonisins in swine-cardiovascular effects

Fumonisins have been shown to decrease left ventricular contractility, heart rate, cardiac output, mean arterial pressure, arterial and mixed venous blood $O_2$ tensions, and systemic oxygen delivery, while increasing mean pulmonary artery pressure, oxygen consumption, and oxygen extraction ratio in swine (Smith *et al.*, 1996a, b, 1999, 2000; Constable *et al.*, 2000; ). The decrease in cardiac contractility leads to acute left ventricular failure and pulmonary edema in pigs exposed to high concentrations of fumonisin in feed. Chronic exposure to lower levels of fumonisin leads to the development of right ventricular hypertrophy and medial hypertrophy of the small pulmonary arteries in pigs, likely a result of pulmonary hypertension (Casteel *et al.*, 1994).

## Fumonisins in swine-immunologic effects

Fumonisins have also been shown to predispose pigs to respiratory disease. In one case–control study, swine farms with $\geqslant$20 ppm of fumonisin in the feed were at significantly greater risk for pneumonia as compared to farms with low fumonisin concentrations (Bane *et al.*, 1992). As the concentration of fumonisin in the feed increased, the risk of respiratory disease continued to increase. Later it was shown that exposure to fumonisins depressed pulmonary intravascular macrophage function, and pigs exposed to this toxin had decreased pulmonary clearance of blood-borne particulates and bacteria when compared to control animals (Smith *et al.*, 1996c). In a more recent study, exposure to fumonisin exacerbated respiratory disease in a *Pasteurella multocida* challenge model (Halloy *et al.*, 2005). Pigs that were fed 0.5 mg of $FB_1$ per kg of body weight/day for 7 days had delayed growth, increased coughing and more severe lung lesions that control pigs. Therefore, at levels well below those needed to cause hepatic lesions or pulmonary edema, fumonisins are likely to reduce growth rates and increase disease in pigs.

## Fumonisin toxicosis in horses: historical

Several outbreaks of a neurologic disease in horses occurred in the United States in the early 1900s with thousands of deaths reported in several states. The earliest citation of neurologic deaths associated with the feeding of contaminated corn was from Maryland (MacCallum and Buckley, 1902). The condition was commonly referred to as "cerebrospinal meningitis" and presented with fairly characteristic signs. The duration of disease varied from a few hours to a week, and the brains from affected horses had "softened" areas in the cerebrum involving only the white matter. Additional outbreaks were subsequently reported from Kansas, Iowa, Mississippi, and North Carolina. A similar disease, described as "epizootic cerebritis" had been encountered in 1891, however it is not known whether this was associated with corn (Butler, 1902). When feed from an outbreak of "leucoencephalitis" in Kansas was fed to a horse, it died after developing neurologic signs (Butler, 1902). At necropsy, the left cerebral hemisphere was "soft to the touch, and when cut through, the white matter was broken down extensively, nearly the entire hemisphere being involved." Several attempts were made to identify an infectious agent in the brain of affected horses and all were negative (MacCallum and Buckley, 1902). The authors concluded that a toxic etiology was likely.

In central Illinois, more than 5000 horses died during the winter of 1934–1935 from a syndrome referred to as "cornstalk disease" (Graham, 1935). Brain tissue suspensions and filtrates were inoculated into laboratory animals, however no infectious etiology could be identified. Graham then placed 8 horses into a field-containing cornstalks in Rantoul, Illinois. Two of these animals died, 23 and 26 days after being placed in the field (Graham, 1936). These outbreaks were similar to those reported in 1893 and 1914 which had occurred following a summer drought (Graham, 1936). Neurologic deaths with similar lesions were also reported in Iowa during the winter of 1914 and in the spring of 1935 (Schwarte *et al.*, 1937). Histologic examination of the brain revealed no evidence of infectious agents. This "syndrome" was then subsequently reproduced by feeding moldy corn and corn fodder to 5 horses (Schwarte *et al.*, 1937). A similar disease syndrome was identified and confirmed by feeding trials in Egypt (Badiali *et al.*, 1968; Wilson and Maronpot, 1971) and in South Africa (Marasas *et al.*, 1976). At necropsy, these studies were able to consistently demonstrate swelling of the cerebral hemispheres and flattening of the overlying gyri. On coronal sections, there were cavities of varying sizes with liquefactive necrosis of subcortical white matter in one or both cerebral hemispheres (Figure 78.5). There was also scattered multifocal hemorrhages in the surrounding white matter (Marasas *et al.*, 1976; Haliburton *et al.*, 1979). Based on these findings, Marasas and his associates coined the term "equine leukoencephalomalacia" as a distinct clinical and morphologic syndrome in horses associated with the feeding of corn (Marasas *et al.*, 1976).

*F. verticillioides* was later isolated from corn collected from field outbreaks in Egypt, and leukoencephalomalacia was subsequently reproduced in donkeys fed corn inoculated with the fungus (Wilson and Maronpot, 1971). In South Africa however, samples of corn inoculated with *F. verticillioides* produced liver damage and icterus in several horses and donkeys, but not brain lesions (Kellerman *et al.*, 1972). Marasas *et al.* (1976) then produced a batch of culture material using a strain of *F. verticillioides* from an outbreak of leukoencephalomalacia to produce liver damage and neurologic disease in a horse. It was then

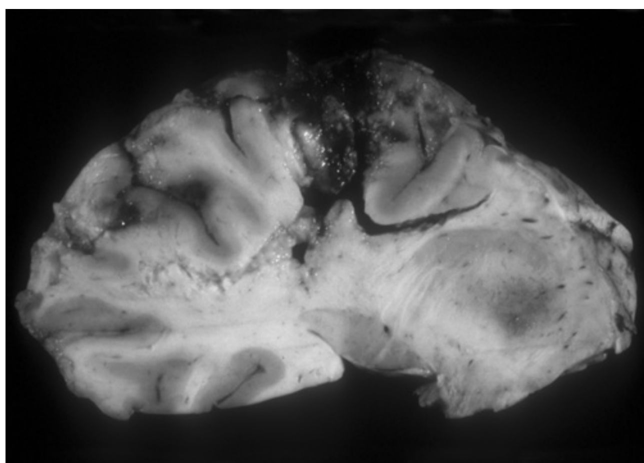

**FIGURE 78.5** A cross-section of a cerebral hemisphere from a horse demonstrating liquefactive necrosis of the white matter typical of ELEM (reprinted with permission from Smith and Constable, 2004). This figure is reproduced in color in the color plate section.

concluded that both hepatic disease and ELEM were manifestations of the same toxicosis, with different clinical syndromes occurring depending on toxin dose and length of exposure. Following the isolation and purification of fumonisin $B_1$ in the late 1980s, ELEM was experimentally induced by the administration of purified toxin (Marasas *et al.*, 1988; Kellerman *et al.*, 1990).

## Spontaneous and experimental fumonisin toxicosis in horses

Since the discovery of fumonisin $B_1$ as the causative agent of ELEM, many more disease outbreaks associated with the feeding of corn have been reported (Wilson *et al.*, 1990a; Ross *et al.*, 1991; Uhlinger, 1991; Binkerd *et al.*, 1993; Christley *et al.*, 1993; Ross *et al.*, 1993; Wilkins *et al.*, 1994; Bailly *et al.*, 1996; Bela and Endre, 1996; Cerrillo *et al.*, 1996; Rosiles *et al.*, 1998). Purified fumonisin $B_1$ has induced ELEM when administered orally (Kellerman *et al.*, 1990) and intravenously (Marasas *et al.*, 1988; Laurent *et al.*, 1989; Foreman *et al.*, 2004). Purified fumonisin $B_2$ has also induced ELEM when given orally (Ross *et al.*, 1994). Fumonisin $B_3$ is suspected to be much less toxic than either $B_1$ or $B_2$ (Ross *et al.*, 1994). Fumonisin $B_1$ is considered to be the primary cause of ELEM however, as fumonisin $B_2$ is usually present in concentrations that are 20–40% of fumonisin $B_1$ (Ross *et al.*, 1991). Although ELEM has occurred in horses eating commercial feedstuffs (Wilson *et al*, 1990b; Ross *et al.*, 1991), the feeding of corn screenings has been more frequently associated with ELEM, because fumonisin concentrations are much higher in screenings than in whole kernels of corn (Binkerd *et al.*, 1993). Fumonisin $B_1$ also appears to survive the pelleting process for equine feeds (Ross *et al.*, 1991).

Leukoencephalomalacia has been reproduced with intravenous administration of fumonisin $B_1$ in three separate studies (Marasas *et al.*, 1988; Laurent *et al.*, 1989; Foreman *et al.*, 2004). Marasas *et al.* (1988) administered 0.125 mg fumonisin $B_1$/kg of body weight, i.v. q24 h which produced ELEM in 9 days. Laurent *et al.* (1989) administered 0.1 mg fumonisin $B_1$/kg of body weight, i.v. q24 h for 16 days followed by 0.2 mg/kg/day for 2 additional days. Leukoencephalomalacia was induced in 18 days. Foreman *et al.* (2004) administered 0.05, 0.1, or 0.2 mg fumonisin $B_1$/kg of body weight i.v. q24 h to 10 horses and all developed neurologic signs and were euthanized between days 4 and 12 of the study. In contrast, horses dosed with 0.01 mg fumonisin $B_1$/kg of body weight for 28 days in this study did not develop neurologic signs. Purified fumonisin $B_1$ has also been administered orally in other studies (1.25 or 2.5 mg fumonisin $B_1$/kg of body weight, p.o., q24 h), producing mild edema of the brain stem and hepatic disease in 11–12 days in 2 horses. In a subsequent study, animals were fed 0.6–4.0 mg fumonisin $B_1$/kg of body weight, p.o., q 24 h for 33 or 35 days, producing hepatotoxicity and neurologic signs starting on days 22 and 24 in two weanling horses (Kellerman *et al.*, 1990).

Doses of fumonisin reported from naturally occurring cases of fumonisin have varied (Table 78.2). One field report calculated that the ingestion of 0.6–2.1 mg fumonisin $B_1$/kg of body weight would induced ELEM in 24–28 days (Wilson *et al.*, 1990b). Another study found that leukoencephalomalacia was associated with ingestion of feed-containing fumonisin $B_1$ concentrations greater than 10 ppm, and concluded that feed with fumonisin $B_1$ concentrations greater than 10 ppm was not safe to be fed to horses (Ross *et al.*, 1991).

## Neurologic and hepatic effects in horses

Several reports have considered ELEM and hepatotoxicity to be two separate syndromes associated with fumonisin toxicity in horses, with the terms "classic neurotoxic syndrome" and "hepatic syndrome" being used (McCue, 1989). However, it appears more likely these are not true "distinct" syndromes but are related to the concentration of fumonisin in the feed, the duration of toxin consumption, and the tolerance of the individual horse to fumonisin. In some outbreaks, horses have died from ELEM while other horses have died from hepatotoxicity, and occasionally individual horses exhibiting both neurologic and hepatic signs have been described. Reported clinical signs associated with hepatic disease include icterus, mucous membrane petechiae, and swelling of the lips or muzzle (Uhlinger, 1991; Ross *et al.*, 1993).

Ross *et al.* (1993) described an experimental study where 1 horse died acutely with "mild encephalopathy

**TABLE 78.2 Effect of fumonisin in horses**

| Number of animals | Dose and route | Duration | Toxic effects | References |
|---|---|---|---|---|
| *Experimental studies using purified fumonisin* | | | | |
| 1 horse | 0.125 mg/kg/day, i.v. | 7 treatments over 9 days | Leukoencephalomalacia<br>Elevated AST, GGT | Marasas *et al*. (1988) |
| 1 horse | 2.5 mg/kg/day, p.o. (by gavage) | 6 doses over 11 days | Severe hepatosis<br>Elevated AST, GGT | Marasas *et al*. (1988) |
| 1 horse | 1.25 mg/kg/day, p.o. (by gavage) | 6 doses over 11 days | Mild hepatosis<br>Elevated AST, GGT | Marasas *et al*. (1988) |
| 1 horse | 0.1 mg/kg/day, i.v. and 0.2 mg/kg/day, i.v. | 0.1 mg/kg dose given for 16 days then 0.2 mg/kg dose given for 2 additional days | Leukoencephalomalacia | Laurent *et al*. (1989) |
| 1 horse | 1.25–4.0 mg/kg, p.o. | 20 doses given over 35 days | Leukoencephalomalacia<br>Elevated AST | Kellerman *et al*. (1990) |
| 1 horse | 1.0–4.0 mg/kg, p.o. | 20 doses given over 33 days | Leukoencephalomalacia<br>Elevated AST, GGT | Kellerman *et al*. (1990) |
| 13 horses | 0.01–0.20 mg/kg, i.v. | Up to 10 days | Leukoencephalomalacia at 0.10 and 0.20 mg/kg – hepatic toxicity only at lower doses | Smith *et al*. (2002), Foreman *et al*. (2004) |
| *Experimental studies using fumonisin-containing culture material* | | | | |
| 2 horses | Diet contained 19 ppm $FB_1$ and was fed *ad libitum* | 27 days | None | Schumacher *et al*. (1995) |
| 2 horses | Diet contained 200 ppm $FB_1$ and was fed *ad libitum* | 12 and 16 days | Leukoencephalomalacia<br>Increased GGT | Schumacher *et al*. (1995) |
| 2 horses | 2 diets containing 65 and 130 ppm $FB_1$ and was fed *ad libitum* | −65 ppm fed for 10 days<br>−130 ppm fed for an additional 17 days | Leukoencephalomalacia<br>Increased GGT | Schumacher *et al*. (1995) |
| *Experimental studies using naturally contaminated corn screenings* | | | | |
| 4 ponies | diet contained 44 ppm $FB_1$ and was fed *ad libitum* | 10–97 days | 2 horses died with ELEM on days 10 and 45<br>–2 horses were normal after 97 days | Wang *et al*. (1992) |
| 4 ponies | Diets contained between 1 and 22 ppm $FB_1$ and were fed *ad libitum* | 238–326 days | ELEM in 2 of 5 horses<br>Moderate to mild hepatosis in all 5 horses | Wilson *et al*. (1992) |
| 5 ponies | Diet contained 8 ppm $FB_1$ and was fed *ad libitum* | 180 days | Mild histologic lesions in the brain and liver at necropsy | Wilson *et al*. (1992) |
| 4 ponies | Diets contained between 1 and 88 ppm $FB_1$ and were fed *ad libitum* | 9–120 days | ELEM in all 4 ponies (day 9–120) – also severe hepatosis in 2 ponies | Ross *et al*. (1993) |
| *Reported fumonisin concentrations from naturally occurring outbreaks* | | | | |
| 18 horses | 37–122 ppm $FB_1$ | Unknown | ELEM confirmed in 14 horses | Wilson *et al*. (1990) |
| 45 horses | 8–126 ppm $FB_1$ | 7–35 days | All cases had confirmed leukoencephalomalacia | Ross *et al*. (1991) |
| 6 horses | 370 ppm $FB_1$ and 105 ppm $FB_2$ | Unknown | 4 horses died with ELEM;<br>2 horses with neurologic signs apparently recovered | Wilkins *et al*. (1994) |

and hepatic necrosis" after 9 days of fumonisin exposure whereas 2 other horses died after 75 and 78 days of ELEM. The horse that died on day 9 showed neurologic signs prior to death ("visual impairment, mild ataxia, and slight head tremors") and had histologic evidence of leukoencephalomalacia at necropsy, however his death was primarily attributed to hepatotoxicity. This study lead to a common generalization that high doses of fumonisin were likely to induce hepatotoxicity, whereas lower doses of toxin over a longer period of time were

necessary to induce ELEM (McCue, 1989; Plumlee and Galey, 1994). However in other experimental studies, intravenous administration of fumonisin $B_1$ induced ELEM in 9 days (Marasas *et al.*, 1988) and 18 days (Laurent *et al.*, 1989). In a large study with varying doses of fumonisin, horses treated with higher doses developed leukoencephalomalacia (in 5–8 days), whereas horses that received lower concentrations developed primarily hepatic lesions without any evidence of neurotoxicity (Foreman *et al.*, 2004). Therefore, it can be concluded ELEM results from an acute exposure to feed-containing high concentrations of fumonisin $B_1$, while hepatotoxicity occurs with chronic ingestion of lower levels.

Serum biochemical changes associated with fumonisin toxicity in horses have been predominantly related to hepatotoxicity (increased AST, Wang *et al.*, 1992; increased AST and GGT, Laurent *et al.*, 1989; Kellerman *et al.*, 1990; increased GGT and SDH, Schumacher *et al.*, 1995; increased AST, GGT, and ALP, Ross *et al.*, 1993; increased AST, GGT, ALP, total bilirubin, and bile acids, Wilson *et al.*, 1992; and "elevated liver enzymes," Ross *et al.*, 1994). Serum cholesterol concentrations have not been examined.

The neurologic signs are usually summarized as sudden onset of one or more of the following: frenzy, aimless circling, head pressing, paresis, ataxia, blindness, depression, and hyperexcitability (Ross *et al.*, 1991; Wilson *et al.*, 1992). Other reports have stated that "the disease started with lack of appetite, followed by the disturbance of swallowing and chewing indicating the paralysis of cephalic and pharyngeal muscles. Paralysis of cephalic and cervical muscles spread to the muscles of the extremities and trunk. The animals moved with difficulties, tottering and ataxia developed. Signs of 'blindness' developed in one animal. At the final stage of disease, the affected animals lied down and died" (Bela and Endre, 1996). In a comprehensive study, early neurologic signs included mild proprioceptive abnormalities, including hindlimb ataxia, delayed forelimb placing reactions, and decreased tongue tone and movement (Foreman *et al.*, 2004). These signs progressed over 12–48 h to become more readily apparent. Hindlimb and trunkal ataxia in particular became more apparent with time. A variety of behavioral changes were observed including depression, hyperesthesia, and intermittent dementia. All horses had intact menace and pupillary light responses at the time of death.

Cerebrospinal fluid findings from horses with ELEM include elevations in protein concentration, albumin, and IgG concentrations and increased albumin quotients (Foreman *et al.*, 2004). Cerebrospinal fluid red blood cell, leukocyte, and glucose concentrations along with creatine kinase activity are not altered in horses with neurologic disease. Along with the histopathologic findings, these cerebrospinal fluid changes indicate the presence of a vasogenic cerebral edema in horses with leukoencephalomalacia.

### Fumonisin toxicity in cattle

Adult beef cattle appear relatively resistant to fumonisin. Feeder calves fed a diet-containing fumonisin concentrations up to 148 ppm for 31 days had only mild hepatotoxicity (Osweiler *et al.*, 1993). Although it is tempting to speculate that cattle are able to break down the toxin, it has been shown that fumonisin is poorly metabolized by the rumen. Instead, it is thought that cattle have an increased tolerance to fumonisin because of differences in the mechanism of action. In milk-fed calves treated with purified fumonisin $B_1$, the kidney was the target organ of toxicity (Mathur *et al.*, 2001). However, this study also demonstrated that sphingosine and sphinganine concentrations did not increase in the serum and tissues of calves to the same degree that has been shown in pigs and horses.

When a group of 26 dairy cattle were fed a ration containing 100 ppm of fumonisin for the first 70 days of their lactation period, they had a significant decrease in dry matter intake and a lower milk yield as compared to the control group (Diaz *et al.*, 2000). Milk production averaged 7 kg lower in the group fed the ration-containing fumonisin and there was a 13% decrease in feed intake over the duration of the study period. Therefore, it has been recommended to avoid fumonisin concentrations higher than 30 ppm in the total ration of dairy cattle.

### Fumonisin toxicity in poultry

Fumonisins can be toxic to both chickens and turkeys with concentrations in the feed as low as 100 mg/kg causing decreased body weight gain, diarrhea, and hepatotoxicity (Ledoux *et al.*, 1992; Bermudez *et al.*, 1997). There has also been an association between *F. verticillioides* (the fungus that produces fumonisin) and an acute death syndrome recognized in young chicks called spiking mortality syndrome. It was initially hypothesized that fumonisins were directly cardiotoxic to poultry and were the cause of this syndrome; however, more recent research has suggested moniliformin (another *F. verticillioides* produced mycotoxin) is primarily responsible.

## DIAGNOSIS AND TREATMENT

In addition to pathologic findings in animals, diagnosis of fumonisin toxicosis typically relies on detecting the actual toxin in feed samples. Fungal culture of feeds has little value in diagnosing fumonisin toxicosis because some corn samples contain very high concentrations of toxin with low levels of fungus, while other samples have heavy growths of *Fusarium* fungus with little to no detectable fumonisin. This is partly because the fungus that produces fumonisin

also produces other mycotoxins. Therefore, the definitive diagnosis of fumonisin toxicosis in animals must involve analyzing the feed for the presence of the actual toxin. Many diagnostic laboratories across the world offer assays to detect both fumonisin $B_1$ and $B_2$ in corn and feed samples. The two most commonly used methods for toxin detection are based on high performance liquid chromatography (HPLC) and enzyme-linked immunosorbent assay (ELISA). To date, there are no commercially available assays that detect fumonisin in serum or tissues of animals.

Another assay that may be used more commonly in the future to diagnose fumonisin toxicosis in animals is the sphinganine to sphingosine ratio (Sa:So ratio). Because of the fumonisin-induced disruption of sphingolipid biosynthesis (Wang *et al*., 1992), the Sa:So ratio increases in the serum and tissues of pigs and horses exposed to fumonisin. It has been suggested that this assay could be used to diagnose fumonisin toxicosis when feed analysis is not possible. Sphinganine and sphingosine data may be available from enough pigs and horses in the near future to provide values for normal and affected animals.

To date there have been no treatments described for either ELEM or PPE. Generally, the onset of clinical signs is acute and the progression of disease is rapid for both syndromes. The most important treatment is to identify and remove the source of contaminated feed to prevent other animals from developing clinical signs.

Guidelines for the maximum recommended levels of fumonisins in animal feeds have been published by the FDA Center for Veterinary Medicine (Table 78.3). It is important that livestock producers be aware of these guidelines and have their corn periodically tested for mycotoxins. Research has not yet found effective ways to decrease fumonisin concentrations in animal feedstuffs through processing or feed additives (i.e. binding agents). Corn-containing significant levels of fumonisin should be discarded, diluted with corn-containing lower concentrations of fumonisin, or fed to a less-sensitive species (i.e. ruminants or poultry interested for slaughter).

**TABLE 78.3 Recommended levels for total fumonisins ($B_1$ and $B_2$) in animal feeds**

| Animals | Recommended maximum level of total fumonisins in corn to be used for feed (ppm) | Recommended maximum level of total fumonisin in the ration (ppm) |
|---|---|---|
| Horse[a] | 5 | 1 |
| Swine | 20 | 10 |
| Ruminants[b] | 60 | 30 |
| Poultry[c] | 100 | 50 |
| Ruminant and poultry breeding stock[d] | 30 | 15 |
| Catfish | 20 | 10 |
| Other animals[e] | 10 | 5 |

From the United States Food and Drug Administration, Center for Veterinary Medicine.

[a] Includes donkeys, asses, and zebras.

[b] Cattle, sheep, goats, and other ruminants that are >3 months of age and are being fed for slaughter.

[c] Turkeys, chickens, ducklings, and other poultry being fed for slaughter.

[d] Includes lactating dairy cows, bulls, laying hens, and roosters.

[e] Includes dogs and cats.

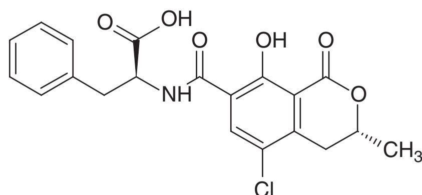
# Ochratoxins and citrinin

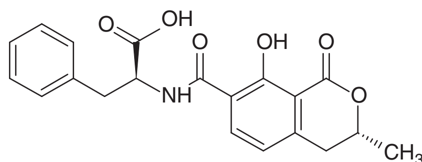
*Ramesh C. Gupta*

## INTRODUCTION

Ochratoxins and citrinin are produced by several species of genera *Aspergillus* and *Penicillium*. The two most common species that produce ochratoxin A (OTA) are *Aspergillus ochraceus* and *Penicillium verrucosum*. These fungi are ubiquitous and the potential for contamination of animal feed and human food is widespread. *Aspergillus* spp. appears to produce ochratoxins at conditions of high humidity and temperature, whereas some *Penicillium* spp. may produce ochratoxins at temperatures as low as 5 °C. OTA has been found in a variety of food/feed, with levels in commodities used as feed ranging up to 27 ppm, and with levels in foodstuffs for human consumption in the range of trace to about 100 ppb. Unlike OTA, the occurrence of ochratoxin B is rare. Chemical structures of OTA and ochratoxin B are shown below. Ochratoxin B lacks chlorine and thereby it is less toxic than OTA.

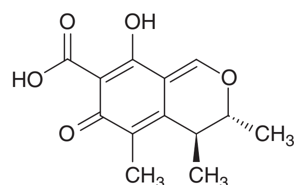


Ochratoxin A



Ochratoxin B

Citrinin was first isolated as a pure compound from a culture of *P. citrinum* in 1931. Later, it was also isolated from *A. ochraceus*, *P. verrucosum*, and related species that contaminate grain. In 1951, yellowish colored rice imported from Thailand to Japan was found to be contaminated with *P. citrinum*, which contained citrinin. Synthesized citrinin is also used in biological research, as it induces mitochondrial permeability pore opening and inhibits respiration by interfering with complex I of the respiratory chain. The structure of citrinin is shown below.



Citrinin

Both OTA and citrinin cause nephropathy in animals and they have also been implicated as the cause of Balkan endemic nephropathy in humans. The literature reveals that OTA has been studied to a greater extent than citrinin, partly because OTA is at least 10 times more toxic than citrinin. This chapter describes in detail the toxicity of ochratoxins and citrinin in animals.

## BACKGROUND

The fungi producing ochratoxins and citrinin are commonly encountered in animal feed and human food around the world. They are encountered with great frequency in the

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

Balkan area. Both ochratoxins and citrinin are fungal metabolites. There are two major ochratoxins (A and B). OTA occurs naturally with a greater frequency in a variety of cereal grains (barley, wheat, oats, corn, and beans), peanuts, dried fruits, grapes/raisins, cheese, and other food products. OTA accumulates in the food chain because of its long half-life. Citrinin usually co-occurs with OTA, and commonly contaminates cereal grains, including wheat, barley, oats, corn, and rice. Citrinin also contaminates peanuts and fruits. The levels of OTA and citrinin have been found far lower in human food than in raw animal feed, because during processing and baking of human food citrinin is almost eliminated and OTA is significantly reduced. Compared to OTA, ochratoxin B is rarely found and very less toxic.

Both OTA and citrinin are well-known nephrotoxins. OTA is also carcinogenic to rodents (Creppy *et al.*, 1985) and possesses teratogenic (Arora *et al.*, 1983), immunotoxic (Stormer and Lea, 1995), neurotoxic (Bruinink and Sidler, 1997; Sava *et al.*, 2006), mutagenic (Stetina and Votava, 1986), and genotoxic (Meisner *et al.*, 1983) properties. In humans, exposure to OTA and citrinin has been linked with Balkan endemic nephropathy, a chronic kidney disease associated with tumors of the renal system, which can be fatal. Co-occurrence with OTA of citrinin has been implicated in nephropathy of pigs in Denmark, Sweden, Norway, and Ireland. Citrinin and OTA are also involved in avian nephropathies. Residues of OTA have been detected in the tissues of pigs in slaughterhouses, and it has been shown, under experimental conditions, that residues can still be detected in tissues 1 month after the end of exposure. Due to long half-life of OTA in the feed and biological system, serious concerns have been raised about the animal health, as well as for human consumption of meat. Thus, it appears that both OTA and citrinin seriously affect animal health and economic impact is enormous.

## TOXICOKINETICS

In most animal species, OTA is absorbed from the stomach because of its lipid soluble, non-ionized, and acidic properties ($pK_a = 7.1$) (Kumagai and Aibara, 1982; Kumagai, 1988). Absorption of OTA also takes place in the intestine, is involved in enterohepatic circulation, and its biliary excretion is very efficient. OTA is distributed to various organs, mainly to the kidneys. Liver, muscle, and fat contain lower concentrations. The overall percentage of OTA absorption is found to be 66% in pigs, 56% in rats, 56% in rabbits, and 40% in chickens (Suzuki *et al.*, 1977; Galtier *et al.*, 1981). After a single oral dose, the maximum concentrations of OTA are found within 10–48 h in pigs and rats (Galtier *et al.*, 1979, 1981), 2–4 h in ruminant calves (Sreemannarayana *et al.*, 1988), after 1 h in rabbits, and after 0.33 h in chickens (Galtier *et al.*, 1981). Maximum tissue concentrations in rat tissues occur within 48 h.

The serum half-life of OTA is long and varies widely among species, for example 24–39 h in mice, 55–120 h in rats, 6.7 h in quail, 510 h in Macaca mulata monkeys (Hagelberg *et al.*, 1989), 72–120 h in pigs, 4.1 h in chicken (Galtier *et al.*, 1981), and 840 h in a volunteer (Benford, *et al*. 2001).

In pigs, it has been observed that the kidney is generally the most heavily contaminated tissue with OTA, and that the levels in the blood are about 5-fold greater than in the kidney. Krogh *et al*. (1976) illustrated that if the level of OTA in swine kidney is 12.1 ng/g (resulting from about 1000 ng/g in the feed), its levels would be 7.8 ng/g in the liver, 4.2 ng/g in the muscle, and 2.8 ng/g in the adipose tissue. OTA in ruminants is usually hydrolyzed in the forestomach by protozoans and bacterial enzymes, and consequently little OTA is found in the tissues (Hult *et al*., 1976).

Residue of OTA can be passed in the milk of rats, rabbits, and women, but very little is passed in the milk of ruminants because of its metabolism by the ruminal microflora. The major routes of excretion are urine and feces, and excretion is influenced by the extent of the enterohepatic circulation and binding to serum albumin and other macromolecules (Galtier *et al*., 1980; Hult and Fuchs, 1986). The association constant for the binding of OTA to serum albumin is $7.1 \times 10^4$ per mol for pigs, $5.1 \times 10^4$ per mol for chickens, and $4.0 \times 10^4$ per mol for rats (Galtier *et al*., 1981).

In various tissues of all species that are examined, OTA is hydrolyzed to ochratoxin *alpha*, which is the major metabolite. This detoxication process takes place in cecum of rats and is facilitated by bacterial microflora (Galtier, 1978). The enzymes responsible for hydrolysis to ochratoxin *alpha* in cows and rodents are carboxypeptidase A and chymotrypsin. Suzuki *et al*. (1977) demonstrated that the rat tissue homogenates of the duodenum, ileum, and pancreas also have a high activity to catalyze this reaction. Activity of these enzymes in liver and kidney is low. Studies in mice suggest that OTA circulates from the liver into the bile and into the intestine, where it is hydrolyzed to ochratoxin *alpha* (Moroi *et al*., 1985). About 25–27% of OTA, given either i.p. or orally to rats, was found as ochratoxin *alpha* in the urine. Its presence in the urine can be explained by reabsorption from the intestine. A similar mechanism of intestinal reabsorption of ochratoxin *alpha* has been suggested to occur in ruminant calves (Sreemannarayana *et al*., 1988). For details of biotransformation of OTA, refer to an extensive review by Benford *et al*. (2001).

From animal studies, it is clear that OTA has a high degree of bioavailability, low plasma clearance rate, and long tissue half-life. All metabolites of OTA are less toxic than the parent compound.

## MECHANISM OF ACTION

OTA produces a variety of toxic effects in several organs, and therefore multiple mechanisms are involved. In addition to nephrotoxicity, OTA disrupts blood coagulation (Gupta *et al*., 1979) and glucose metabolism (Pitout, 1968). OTA is immunotoxic (Stormer and Lea, 1995), teratogenic (Arora *et al*., 1983), and carcinogenic (Creppy *et al*., 1985). A brief description of mechanisms involved in common toxic effects is given below.

### *Protein synthesis*

A dose-related inhibition of protein synthesis was found in mice given OTA intraperitoneally at a dose $\geqslant$1 mg/kg body weight. The degree of inhibition of protein synthesis 5 h after administration of OTA at 1 mg/kg dose was 26% in liver, 68% in kidney, and 75% in spleen as compared with controls (Creppy *et al*., 1984).

### *Nephrotoxicity*

Both OTA and citrinin are potent nephrotoxins. At high doses, OTA affects both renal function and morphology, as indicated by increased weight, urine volume, blood urea nitrogen, urinary glucose, and proteinuria (Hatey and Galtier, 1977). The last two findings indicate that the site of reabsorption (i.e. the proximal convoluted tubules) is damaged. OTA specifically causes defect of the organic anion transport mechanism located on the brush border of the proximal convoluted tubules and basolateral membranes. OTA also adversely affects the organic ion transport system by which OTA enters proximal tubular cells. The middle (S2) and terminal (S3) segments of the proximal tubule of the isolated nephron were found to be the most sensitive to the toxic effects of OTA (0.05 mmol/l), as shown by a significant decrease in cellular ATP and a dose-related decrease in mitochondrial ATP content (Jung and Endou, 1989).

Mitochondrial dysfunction has been shown to be involved in the development of OTA-induced toxicity in proximal renal tubule cells (Aleo *et al*., 1991). OTA toxicity is associated with inhibition of both protein and RNA synthesis (Dirheimer and Creppy, 1991). OTA is known to interfere with the charging of tRNA with amino acids. OTA treatment can increase oxidative stress in peripheral organs. Administration of OTA to rats (1 mg/kg) resulted in a 22% decrease in $\alpha$-tocopherol plasma levels and a 5-fold increase in the expression of the oxidative stress responsive protein heme oxygenase-1, specifically in the kidney (Gautier *et al*., 2001).

### *Neurotoxicity*

Although toxic effects of OTA on the CNS have not yet been fully characterized, evidence strongly suggests that OTA has potential for neurotoxicity. Bruinink *et al*. (1998) demonstrated that OTA is neurotoxic and may affect selected structures of the brain. This mycotoxin has complex multiple mechanisms of action that include evocation of oxidative stress, bioenergetic compromise, inhibition of protein synthesis, production of DNA single-stranded breaks, and formation of OTA–DNA adducts (Sava *et al*., 2006). These authors found that administration of OTA in mice, at a single dose (3.5 mg/kg) that is approximately 10% of the reported $LD_{50}$, caused widespread oxidative injury in six discrete brain regions.

### *Immunotoxicity*

There is ample evidence, resulting from studies conducted in several animal species, that under certain conditions of treatment, OTA can produce defects in the structure and/or function of elements comprising the immune system (Pohland *et al*., 1992). The size of the mouse thymus was reduced to 33% that of controls after four i.p. injections of OTA at 20 mg/kg body weight on alternate days, a dose which caused minimal nephrotoxicity. Bone marrow depression was found to be dose related, significantly decreased marrow cellularity, including a reduction in bone marrow macrophage–granulocyte progenitors, a decreased number of hematopoietic stem cells, a significant decrease in erythropoiesis, and increased phagocytosis by macrophages (Boorman *et al*., 1984). The effects of OTA on the bone marrow and lymphatic cell population may reflect the sensitivity of these cells to the inhibition of protein synthesis induced by OTA. These effects on the structural components of the immune system indicated that OTA is likely to have an effect on immune function.

In chickens fed diets containing OTA at a concentration of 2–4 mg/kg for 20 days, the lymphoid cell population of immune organs was decreased (Dwivedi and Burns, 1984a), and IgA and IgM in lymphoid tissues and serum were decreased (Dwivedi and Burns, 1984b). Complement activity was slightly affected in birds fed diets containing 2 mg/kg for 5–6 weeks (Campbell *et al*., 1983). Immune suppression was observed in chickens fed diets containing OTA at 0.05 or 2 mg/kg for 21 days. Treated animals showed reduced total serum protein, lymphocyte counts, and weights of the thymus, bursa of fabricus, and spleen (Singh *et al*., 1990).

### *Carcinogenicity*

The exact mechanism by which OTA induces carcinogenicity is unknown, although both genotoxic and non-genotoxic modes of actions have been proposed.

## TOXICITY

The toxic effects of OTA have been studied extensively in a number of domestic, companion, and experimental

animals. Toxic effects of OTA have also been studied in humans. Overall toxicity of OTA is greatly influenced by species, sex, and route of administration. Based on acute toxicity data, dogs and pigs are the most sensitive species and rats and mice the least sensitive. Oral $LD_{50}$ values (expressed as mg/kg body weight) of OTA are reported to be 46–58 in mouse, 20–30 in rat, 3.9 in neonate rat, 0.2 in dog, 1 in pig, and 3.3 in chicken (Harwig *et al.*, 1983). $LD_{50}$ values via i.p. route are reported to be 22–40 in mouse and 20–30 in rat; and with i.v. route, 26–34 in mouse and 13 mg/kg in rat. It causes renal toxicity, nephropathy, and immune suppression in several animal species. The acute $LD_{50}$ (expressed as mg/kg body weight) of citrinin is reported to be 50 (oral) and 67 (s.c. or i.p.) in rat, 35–58 in mouse, and 19 (i.p. or i.v.) in rabbit. Citrinin causes kidney damage and mild liver damage in the form of fatty infiltration. Other toxic effects include vasodilatation, constriction of the bronchi, and increased muscular tone.

All the animals studied so far have been found susceptible to orally administered OTA with a varying degree of response. It is important to mention that at higher doses OTA causes alterations in kidneys and also in other organs and tissue, but renal lesions can be found at an exposure level that is identical to those occurring environmentally. Ochratoxin B is rarely found as a natural contaminant and is much less toxic than OTA. The other ochratoxins have never been encountered in natural products.

Weanling Fischer 344/N rats of both sexes receiving OTA by gavage in maize oil at a dose of 0.06, 0.12, 0.25, 0.5, or 1 mg/kg body weight/day for 5 days/week for 91 days, showed growth retardation and a reduced relative kidney weight in males at the two higher doses. Karyomegaly of dose-related severity was observed in the proximal tubules at all doses. Milder renal changes consisting of tubular atrophy were seen at a dose of 1, 4, or 16 mg/kg body weight/day on 5 days/week for a total of 12 doses over 16 days. Rats receiving the highest dose had diarrhea and nasal discharge and died before the end of the study. Increased relative weights of kidneys, heart, and brain, thymus atrophy, forestomach necrosis and/or hyperplasia, and hemorrhage of adrenal glands were seen at the two higher doses. Bone marrow hyperplasia and nephropathy were seen at all doses, involving renal tubular degenerative and regenerative changes (NTP, 1989).

OTA has been shown to produce nephrotoxic effects in all animal species examined, with the exception of adult ruminants (Pohland *et al.*, 1992). The nephrotoxic potential of OTA is well documented from all experimental studies, with a feed level of 200 ppb causing nephropathy in pigs and rats. Evidence strongly supports that OTA is involved in porcine nephropathy, which is characterized by degeneration of the proximal tubules, atrophy of the tubular epithelium, interstitial fibrosis in the renal cortex and hyalinized glomeruli. Field cases of OTA-induced nephropathy in farm animals have long been recognized. Benford *et al.* (2001) suggested that the adverse effect at the lowest effective dose in several mammalian species is nephrotoxicity, and this is likely also to be true in humans. Citrinin is also nephrotoxic, but it is 10 times less toxic than OTA.

In a series of experiments, sows were given feed containing OTA at a concentration of 0.2, 1, or 5 mg/kg (equivalent to 0.008, 0.04, and 0.2 mg/kg body weight/day), for a period of 5 days, 8 or 12 weeks, or up to 2 years. Decreased renal function, nephropathy, and reduced renal enzyme activity were observed. Progressive nephropathy but no renal failure was seen in pigs given feed containing 1 mg/kg for 2 years (Krogh *et al.*, 1976; Krogh and Elling, 1977; Elling *et al.*, 1985).

Beagle dogs receiving OTA in capsule form at a dose of 0.1 or 0.2 mg/kg body weight/day for 14 days showed tubular necrosis and ultrastructural changes in the proximal tubules at all doses. Necrosis of lymphoid tissues of the thymus and tonsils was also seen at all doses (Kitchen 1977a, b, c).

In another set of experiments, young beagle dogs were given OTA and citrinin separately and combined for 14 days (Kitchen *et al.*, 1977b). OTA was administered by capsule at 0.1 and 0.2 mg/kg; and citrinin (5 and 10 mg/kg) dissolved in ethanol was given by i.p. injection. Clinical signs of toxicosis with 10 mg/kg citrinin and the higher combined doses included anorexia, retching, tenesmus, weight loss, prostration, and death. Severity of the clinical disease and mortality were increased when the mycotoxins were combined, which indicated synergism. The clinicopathological abnormalities reflected renal damage, cellular and granular casts, ketones, protein, and glucose were in the urine of dogs given large doses of citrinin alone or combined with OTA. In pathological studies, these authors found gross lesions, such as focal peritonitis and intestinal intussusceptions with citrinin. Changes in the kidneys of dogs given OTA were degeneration and necrosis with desquamation of tubular epithelial cells, primarily in the straight segment of the proximal tubules. Dogs given 10 mg/kg citrinin had similar changes in the distal tubules and collecting ducts. Dogs given combined doses of citrinin and OTA had degeneration and necrosis in proximal and distal tubules, and in thin segments and the collecting ducts, and ulceration of the mucosa of the intestine.

In experimental studies, dogs given citrinin showed serous nasal discharge and lacrimation (Carlton *et al.*, 1974; Kitchen *et al.*, 1977a, b). It is important to mention that citrinin is a very strong emetic in dogs, which is a protective mechanism in this species. Therefore, it is very unlikely that dogs will be poisoned by citrinin alone because high amounts of this mycotoxin will induce emesis and feed refusal.

Chicken, turkeys, and ducklings are all susceptible to OTA and it appears that OTA-contaminated feed has

major economic impact on the poultry industry. Feed levels as low as 200 ppb produced renal changes in the course of 3 months in rats and pigs. Field cases of OTA-induced nephropathy are regularly encountered in pigs and poultry. Clinical signs of ochratoxicosis include retarded growth rate, reduction in weight gains, poor feed conversion, reduced egg production, poor egg shell quality and nephrotoxicity/nephropathy, and mortality. Feed refusal has been observed in turkeys.

In chickens, OTA at a dose rate of 3.6 mg/kg can cause 5% mortality. Ochratoxin B at the dose rate of 54 mg/kg causes lowered growth rate, edema of visceral organs, and accumulation of uric acid in kidneys, liver, heart, and spleen. These mycotoxins induce suppression of blood formation in bone marrow, and lymph formation in spleen and bursa of fabricus. Highest toxicity of OTA is found to be in broiler chickens. Broiler chickens given OTA at a dietary concentration of 4 mg/kg for 2 months caused 42% mortality (Gibson *et al.*, 1990). This toxin is involved in reduced growth rate at 5 ppm, high mortality rate at 4–8 ppm, and cessation of egg production at 4 ppm.

In chickens, nephrotoxicity and hepatotoxicity occurs at dietary levels of 250 μg/g of citrinin with liver and kidney enlargements of 11% and 22%, respectively. Necropsy of affected birds revealed the presence of pale and swollen kidneys (Wyatt, 1979). Citrinin is at least 10 times less nephrotoxic than OTA.

Griffiths and Done (1991) described an outbreak of citrinin toxicosis in a herd of cows, which ingested citrus pulp (visibly moldy) pellets that contained 30–40 ppb citrinin. Affected cows showed signs of pruritis, pyrexia, and hemorrhagic syndrome. Signs of the syndrome occurred within 3 days of ingesting the citrus pulp, which was fed for 21 days. Five calves whose dams had been fed citrus pulp were subsequently born with superior prognathism. Older animals were more susceptible to citrinin. The clinical signs, gross pathology, and histology were suggestive of citrinin involvement.

OTA has been well tested for carcinogenicity by oral administration in mice and rats. When OTA was administered in the diet, hepatocellular tumors (designated as well-differentiated trabecular adenomas), renal-cell tumors (renal cystadenomas and solid renal-cell tumors), hepatomas (some exhibiting the trabecular structure), and hyperplastic hepatic nodules were observed in male mice (IARC, 1993). In another study, administration of OTA in the diet-induced hepatocellular carcinomas and adenomas in female mice. Gavage administration of OTA to male and female rats resulted in a dose-related increase in the incidence of renal-cell adenomas and adenocarcinomas. Furthermore, metastasis of the renal-cell tumors was also observed in male and female rats. OTA also increased the incidence and multiplicity of fibroadenomas of the mammary gland in female rats (NTP, 1989, IARC, 1993). In essence, these data suggest that OTA increases the incidence of hepatocellular tumors in mice of each sex and produces renal-cell adenomas in male mice and in rats of each sex. Based on sufficient evidence of carcinogenicity in experimental animals, OTA is classified as a possible carcinogen in humans (Group 2B) (IARC, 1993).

OTA is known to induce teratogenicity in mice, rats, hamsters, and chicken. Details of teratogenic effects are described in Chapter 18. Citrinin has been demonstrated to be mutagenic in hepatocytes (Bailly *et al.*, 2002). There is limited evidence for the carcinogenicity of citrinin to experimental animals.

## TREATMENT

There is no specific antidote for ochratoxin(s) or citrinin toxicity. Recovery is usually slow. Immediate removal of the suspected feed and replacement with clean feed supplemented with increased vitamin levels can be rewarding. Growth of *A. ochraceus* in a common food, such as cereals, can be controlled or minimized by drying them rapidly and thoroughly. Effective approaches to grain storage include fumigation, aeration and cooling, sealed storage, and controlled atmosphere in tropical and subtropical regions where insect damage is a major problem. Citrinin is less of a problem because it is heat unstable. Citrinin is also likely to be destroyed during brewing. Presence of propionic acid destroys citrinin when added as a preservative to protect stored barley destined for animal feed from molding during storage. Currently, highly sophisticated methods are available to detect these mycotoxins at ppb or below levels in food/feed or their products, so as to prevent animal health from toxicosis and economic loss.

## CONCLUSIONS

OTA and citrinin both contaminate a wide range of animal feed and human food. Human risk is less because the levels of these mycotoxins are minimized during processing and baking, but the raw feed remains a potential source for animal poisoning. OTA accumulates and has a long half-life in feed. These mycotoxins have a serious impact on the health of animals, especially, pigs, dogs, and poultry. Pigs and dogs are most sensitive, while rats and mice are least sensitive. In general, females are more sensitive than males. The kidney is a major target organ (as evidenced by functional and morphological changes) for both mycotoxins, but a few other organs are affected as well. In animal studies, OTA has been found to be a nephrotoxin, neurotoxin, immune suppressant, mutagen, carcinogen, and teratogen.

## ACKNOWLEDGMENT

I would like to thank Mrs. Debra A. Britton and Mrs. Denise M. Gupta for their assistance in preparation of this chapter.

# Tremorgenic mycotoxins

*Tim J. Evans and Ramesh C. Gupta*

## INTRODUCTION

Fungi belonging to the genera *Penicillium, Aspergillus, Claviceps*, and *Neotyphodium* can produce tremorgenic mycotoxins, which are secondary fungal metabolites that elicit either intermittent or sustained tremors in vertebrate species (Cole and Cox, 1981; Selala *et al.*, 1989; Burrows and Tyrl, 2001). Over 20 mycotoxins containing a tryptophan-derived indole moiety, including: penitrem A, roquefortine, verruculogen, tryptoquivaline, aflatrem, paspalinine, and paxilline, as well as, the paspalitrems and lolitrems (Table 80.1 and Figure 80.1), have demonstrated tremorgenic potential in animals and humans (Selala *et al.*, 1989; Burrows and Tyrl, 2001). Several other fungal metabolites, such as paspaline, paspalacine, and cyclopiazonic acid, are chemically related to these mycotoxins but have been shown to not be tremorgenic (Knaus *et al.*, 1994). Tremorgen-producing fungi grow on a wide variety of foodstuffs, including dairy or grain-containing products intended for human consumption (e.g. cheeses and pastas), stored grains and nuts (e.g. peanuts and walnuts) and a number of forages (e.g. legumes and grasses) consumed by livestock species, and even garbage and compost piles can be sources of tremorgenic mycotoxins (Burrows and Tyrl, 2001; Boysen *et al.*, 2002; Young *et al.*, 2003).

Although there have been several human cases in which tremors and convulsions were attributed to consumption of mold-contaminated food containing penitrem A (Gordon *et al.*, 1993; Lewis *et al.*, 2005), this chapter will focus on the toxicity of tremorgenic mycotoxins in animal species. Dogs, because of their relatively indiscriminate appetite and frequently unsupervised roaming behavior, appear to be very susceptible to intoxication by penitrem A, as well as roquefortine (Boysen *et al.*, 2002; Young *et al.*, 2003). Mycotoxin-associated stagger syndromes in livestock, also described in the literature as "grass staggers" (not to be confused with "grass staggers" or "grass tetany" related to hypomagnesemia), have most frequently occurred following the ingestion of endophyte (*Neotyphodium lolii*) infected perennial ryegrass (*Lolium perenne*) or consumption of Dallisgrass (*Paspalum dilatatum*) or Bahiagrass (*Paspalum notatum*) contaminated by sclerotia of *Claviceps paspali*.

**TABLE 80.1 Representative tremorgenic mycotoxins, associated fungi, and substrates**

| Tremorgenic mycotoxin | Associated fungi | Common substrates |
|---|---|---|
| Penitrem A | *Penicillium crustosum*<br>*Penicillium cyclopium*<br>*Penicillium commune*<br>*Penicillium* spp. | Meat, cereals, nuts, cheeses, eggs, fruits, processed and refrigerated foods, refuse, compost piles |
| Roquefortine | *Penicillium roqueforti* | Same as penitrem A and sometimes concurrently with penitrem A |
| Janthitrems A, B, and C | *Penicillium janthinellum* | Perennial ryegrass |

# BACKGROUND

## Penicillium-associated tremorgenic mycotoxins

Although a variety of different fungi synthesize indole–diterpene mycotoxins having specific tremorgenic effects on the central nervous system (CNS), tremorgens produced by *Penicillium* spp. (especially penitrem A and roquefortine) are the most commonly encountered of these mycotoxins. Penitrem A is a potent neurotoxin which causes a syndrome characterized by sustained tremors and, at high doses, convulsions and death in laboratory and farm animals (Wilson, 1971; Arp and Richard, 1981; Peterson and Penny, 1982; Shreeve *et al.*, 1983; Hocking *et al.*, 1988; Breton *et al.*, 1998; Cavanagh *et al.*, 1998). Dogs can be poisoned by eating walnuts and a variety of other unused or discarded foodstuffs infected with *Penicillium* spp. (Boysen *et al.*, 2002; Young *et al.*, 2003), and field cases of poisoning have also been documented in cattle, sheep, and horses

(Cavanagh *et al.*, 1998; Hocking *et al.*, 1988; Boysen *et al.*, 2002; Walter, 2002; Young *et al.*, 2003). *Penicillium crustosum* is an especially common foodborne fungus that causes spoilage in a wide variety of foods, including meat, cereals, nuts, cheese, eggs, fruits, and processed and refrigerated food, and almost all *Penicillium crustosum* isolates produce the mycotoxin penitrem A (Hocking and Pitt, 2003; Rundberget *et al.*, 2004). Roquefortine can also be synthesized by *Penicillium* spp. (Hooser and Talcott, 2006), and, interestingly, *Penicillium crustosum*, as well as several other P*enicillium* spp., can produce penitrem A and roquefortine concurrently following growth and sporulation (Vesonder *et al.*, 1980; Wagener *et al.*, 1980; Kyriakidis *et al.*, 1981; Mantle *et al.*, 1983; Boysen *et al.*, 2002; Young *et al.*, 2003). Three other tremorgenic mycotoxins, janthitrem A, B, and C (molecular weight 601, 585, and 565, respectively) can also be produced by a species of *Penicillium* (i.e. *Penicillium janthinellum*), and these tremorgens have been associated with staggers outbreaks in sheep grazing ryegrass (Gallagher *et al.*, 1980; Burrows and Tyrl, 2001).

## Aspergillus-associated tremorgenic mycotoxins

Verruculogen, another common tremorgenic mycotoxin containing the indole moiety and associated with tremors in mice, rats, and farm animals, is produced by species of *Aspergillus*, as well as *Penicillium* (Gallagher and Latch, 1977). Other tremorgenic mycotoxins isolated from a species of *Aspergillus* (i.e. *Aspergillus terreus*) include territrem A and B, which were previously designated as $C_1$ and $C_2$, respectively (Ling *et al.*, 1979). Although most often associated with the production of aflatoxins, *Aspergillus flavus* can also produce tremorgenic aflatrem and other indole–diterpene mycotoxins (e.g. paspalinine) in contaminated corn (Burrows and Tyrl, 2001).

## Neotyphodium-associated tremorgenic mycotoxins

In Australia, New Zealand, and North America, perennial ryegrass (*Lolium perenne*) infected with the endophyte *Neotyphodium lolii* (formerly *Acremonium lolii*) has been associated with a "grass staggers" syndrome in horses, deer, cattle and, especially, sheep, which is frequently referred to as "perennial ryegrass staggers" and is distinct from annual ryegrass toxicosis (Galey *et al.*, 1991; Cheeke, 1998; Burrows and Tyrl, 2001). *Neotyphodium lolii* concentrates in the caryopsis/seed and the outer, lower leaf sheaths of perennial ryegrass, and the "staggers" syndrome is most often observed after several days of exposure to endophyte-infected ryegrass toward the end of summer when there is shortage of pasture (Galey *et al.*, 1991; Cheeke, 1998). Ergovaline and other ergot alkaloids produced by *Neotyphodium lolii* can cause a clinical syndrome resembling "fescue toxicosis" (Cheeke, 1998). However, the classic neurological signs of perennial ryegrass staggers (e.g. ataxia, muscle rigidity, and convulsive episodes) are indistinguishable from those associated with *Penicillium* and *Aspergillus* species and also result from the adverse effects of neurotoxic indole–diterpene tremorgens, which include lolitrems A, C, and D, lolitrem precursors (e.g. paxilline and lolitriol) and, especially, lolitrem B (Cheeke, 1998; Burrows and Tyrl, 2001).

## Claviceps-associated tremorgenic mycotoxins

While *Claviceps purpurea* is notoriously associated with "classic" ergotism in human and animals and, historically, occasional tremors or convulsions (i.e. nervous ergotism or convulsive ergotism) in livestock (Burrows and Tyrl, 2001; Evans *et al.*, 2004), other species of *Claviceps* produce toxicoses primarily characterized by a tremorgenic "staggers" syndrome (Burrows and Tyrl, 2001). Sheep, horses, and cattle, in particular, can develop a "grass staggers" syndrome several days following the ingestion of mature Dallisgrass (*Paspalum dilatatum*) or Bahiagrass (*Paspalum notatum*) infected with the sclerotia of *Claviceps paspali* (Cheeke, 1998; Burrows and Tyrl, 2001). "Dallisgrass staggers" and "Bahiagrass staggers" have most frequently been observed in the southeastern United States, Central and South America, parts of Europe and South Africa, as well as Australia and New Zealand. Traditionally, the ergot alkaloids produced in large quantities by *Claviceps purpurea* and in much smaller quantities by *Claviceps paspali* were thought to be responsible for the tremors observed in conjunction with exposure to both species of *Claviceps* (Cheeke, 1998). However, it is now understood, at least with respect to the "staggers" syndromes associated with *Claviceps paspali* and, less commonly, *Claviceps cinerea* (fungal infections of *Hilaria* spp. (curly mesquite, curlygrass, galleta, etc.)), that the large concentrations of indole–diterpene tremorgenic mycotoxins (i.e. paspalinine and paspalitrems A, B, and C) found in the sclerotia of these species of *Claviceps* are responsible for the neurotoxicity. As with other "grass staggers", *Claviceps*-related tremorgenic syndromes are characterized by exercise-exacerbated nervousness, "wild" facial expressions, belligerent attitude, tremors, ataxia, convulsions, and occasional deaths attributed primarily to misadventure (Burrows and Tyrl, 2001).

## Bermudagrass staggers

Periodic episodes of tremors have been observed in cattle in the southern United States and Oklahoma and Texas,

as well as horses in California, which have been ingesting mature Bermudagrass (*Cynodon dactylon*) (Cheeke, 1998; Burrows and Tyrl, 2001). The ergot-type alkaloids ergonovine and ergonovinine, which can be produced by several species of *Claviceps*, were isolated in one instance of "Bermudagrass staggers". However, *Claviceps*- or endophyte-associated paspalitrem-type indole alkaloids are suspected of being the primary Bermudagrass tremorgens (Cheeke, 1998; Burrows and Tyrl, 2001). It should be kept in mind that, while the onset and duration of the various "staggers" syndromes might vary somewhat, the tremorgenic neurotoxicities associated with Bermudagrass, perennial ryegrass, Dallisgrass, Bahiagrass, and aflatoxin-infected corn are essentially identical to one another (Cheeke, 1998).

## TOXICOKINETICS

Tremorgenic indole-containing mycotoxins are lipophilic molecules that easily cross the blood–brain barrier and gain the access to the CNS (Patterson *et al.*, 1981). Although there might be some subtle differences between compounds and species of animals, tremorgenic indole–diterpene alkaloids are generally rapidly absorbed from the gastrointestinal tract, and the toxic signs, depending on the specific toxins and the exposed species, are usually seen within several hours (especially penitrem A and roquefortine in dogs) to a few days (frequently lolitrems and paspalitrems in ruminants) following ingestion of contaminated foodstuffs (Burrows and Tyrl, 2001; Hooser and Talcott, 2006). As evidenced by the lack of a cumulative effect following repeated doses, these particular mycotoxins do not appear to accumulate in the body (Peterson and Penny, 1982). Despite some hepatic metabolism, these mycotoxins are usually eliminated mainly through biliary excretion into the feces (Burrows and Tyrl, 2001; Hooser and Talcott, 2006). Young animals are more sensitive than adults to the toxicity of tremorgenic mycotoxins, with 5-month-old lambs being more susceptible than 15-month-old sheep to verruculogen toxicity (Peterson *et al.*, 1982).

## MECHANISM OF ACTION

It should be pointed out that, although related in structure, tremorgenic mycotoxins do not exert toxicity by a single common mechanism, and the exact mechanisms involved in neurotoxicity induced by these tremorgens are yet to be fully elucidated. These mycotoxins work at a different functional level of the nervous system than other mycotoxins having more widespread targets for toxicity associated with the inhibition of basic cellular functions, such as protein synthesis. Several pharmacological/toxicological mechanisms of tremorgenic action have been proposed, and, in general, tremorgenic mycotoxins interfere with excitatory amino acid neurotransmitter release mechanisms (Wilson, 1971; Norris *et al.*, 1980; Selala *et al.*, 1989). In experimental studies, the inhibitory action of these mycotoxins at gamma aminobutyric acid (GABA) receptors was demonstrated (Stern, 1971; Hotujac and Stern, 1974; Hotujac *et al.*, 1976; Selala *et al.*, 1989; Abramson, 1997). Gant *et al.* (1987) studied the effects of four tremorgenic and one nontremorgenic mycotoxins on $GABA_A$ receptor-binding in the rat's brain, and, in essence, with high concentrations, the tremorgenic action of these mycotoxins might, in part, be due to inhibition of $GABA_A$ receptor function.

Among the tremorgenic mycotoxins, penitrem A has been studied the most for the elucidation of its mechanism of action and toxicity. There is convincing evidence suggesting that penitrem A acts on the CNS to induce seizures (Sobotka *et al.*, 1978; Arp and Richard, 1981). Penitrem A was shown to increase the spontaneous release of aspartate and glutamate, as well as GABA (Norris *et al.*, 1980). Glutamate and aspartate are the neurotransmitters of the parallel fibers and the climbing fibers, respectively, which are two major excitatory inputs to Purkinje cells. There is also evidence for a penitrem A-induced partial decrease in glycine levels in the brain in association with pathology related to penitrem A exposure (Catovic *et al.*, 1975). Cavanagh *et al.* (1998) demonstrated that, in rats, penitrem A can cause widespread degeneration of Purkinje cells and foci of necrosis in the cerebellar granular cell layers. These striking lesions are confined to the cerebellum, with no lesions found elsewhere in the brain. Cerebellar Purkinje cells are the primary targets cells for the adverse effects of penitrem A. Penitrem A-induced tremors might also be partly explained by a presynaptic inhibition of inhibitory interneurons.

Verruculogen-induced tremors in rats have been associated with an increased level of excitatory neurotransmitters (glutamate and aspartate) in the lateral ventricle, suggesting subcortical, verruculogen-induced tremorgenic activity. Selala *et al.* (1989) demonstrated that tremorgenic mycotoxins can be partial agonists of GABA. Verruculogen increases spontaneous glutamate and aspartate release *in vivo* in guinea pig ileum preparations. Verruculogen also causes an increase in contractile responses to electrical field stimulation, which has been attributed to enhanced release of acetylcholine from presynaptic nerve terminals.

Although paxilline blocks high-conductance $Ca^{2+}$-activated $K^+$-channels, some related nontremorgenic fungal metabolites, such as paspalinine , have also been shown to inhibit these particular ion channels (Burrows and Tyrl, 2001). Paxilline also inhibits the cerebellar inositol 1,4,5-triphosphate receptor. Paspalinine and the paspalitrems are thought to impair GABA- and glycine-mediated inhibitory pathways (Burrows and Tyrl, 2001).

# TOXICODYNAMICS

## Central effects

Tremorgenic mycotoxins are a group of fungal metabolites which are known to act on the CNS, causing sustained tremors, convulsions, and, occasionally, deaths in animals. In general, the clinical signs and symptoms typically observed during tremorgenic mycotoxicoses include diminished activity and immobility, followed by hyperexcitability, muscle tremor, ataxia, tetanic seizures, and convulsions (Cole and Cox, 1981). These symptoms are reversible if the affected animal is removed from the contaminated feed source, and the incidence of death is generally limited by the emetic effect of tremorgenic mycotoxins. In dogs, the overall clinical picture involves the development of muscle tremors and seizures but can also frequently include vomiting, behavior alterations, hyperthermia, depression, coma, and pulmonary edema.

Depending on the level of tremorgenic mycotoxin exposure, death can occur in some instances within 2–4 h and is usually secondary to respiratory compromise, metabolic acidosis, and hyperthermia. In severe cases, clinical signs of toxicosis can persist for several days, and fine tremors can be seen for a week or more.

The tremors produced by penitrem A are very similar in most species and begin within a few minutes of intraperitoneal (IP) injection and even sooner with IV injection. The tremors can be sustained and lead to both ataxia and episodic spasms (Cavanagh *et al.*, 1998). Larger doses of penitrem A can cause seizures, massive liver necrosis, and death (Hocking *et al.*, 1988). In a histopathological study in rats, Breton *et al.* (1998) revealed that penitrem A induced dose-related injuries in the cerebellum with massive degeneration of Purkinje cells and a significant vacuolization within the molecular layer.

## Peripheral effects

Tremorgenic mycotoxins have also been studied for peripheral effects (McLeay *et al.*, 1999). The tremorgenic mycotoxins, such as penitrem A, paxilline, and lolitrem B can have profound effects on electromyographic (EMG) activity of smooth muscle of the reticulorumen in conscious sheep, with a time course of action similar to their respective characteristic effects on the induction (1–2, 15–20, and 20–30 min) and the duration (1–2, 1–2, and 8–12 h) of tremors. Response to penitrem A revealed a greater sensitivity of smooth muscle than skeletal muscle. The excitatory local effects were partially blocked by atropine, indicating that stimulation of muscarinic cholinergic receptors was involved. Increased local activity may mediate a reflex inhibition of cyclical contractions. However, a nontremorgenic isomer of lolitrem B (31-epilolitrem B) had no effect on the reticulorumen. The intensity and duration of the effects of lolitrem B (up to 12 h) indicate that severe disruption of digestion may occur in animals grazing endophyte-infected pasture.

## Genotoxicity

Five tremorgenic mycotoxins (fumitremorgen B, paxilline, penitrem A, verruculogen, and verrucosidin), which have been associated with molds found in fermented meats, were assessed for genotoxicity (Sabater-Vilar *et al.*, 2003). The mycotoxins were tested in two short-term *in vitro* assays using different genotoxic end points, in different phylogenetic systems, with the use of mammalian-microsome assay and the single-cell gel electrophoresis assay of human lymphocytes. The findings revealed that all of the tested mycotoxins, with the exception of penitrem A, exhibited a certain degree of genotoxicity. Verrucosidin appeared to have the highest toxic potential, testing positive in both assays. Verruculogen tested positive in the *Salmonella*/mammalian-microsome assay, and paxilline and fumitremorgen B caused DNA damage in human lymphocytes.

## Acute toxicity

Acute toxicity data are available for only few of the tremorgenic mycotoxins. It should be noted that the relative doses resulting in lethality in different species might not necessarily be reflective of the relative tremorgenic potentials of these mycotoxins. The $LD_{50}$ of penitrem A in mice is 15–19 mg/kg, IP (Ling *et al.*, 1979). The $LD_{50}$ of verruculogen is reported to be 15.2 mg/kg, IP, and 266 mg/kg, following oral exposure, in the chicken. The corresponding $LD_{50}$ values verruculogen in mice are 2.4 mg/kg, IP, and 127 mg/kg, following oral exposure. The $LD_{50}$ value of territrem A in mice is 15–19 mg/kg, IP (Ling *et al.*, 1979).

## Potential interactions

In previous studies, concurrent production of roquefortine and penitrem A by various species of *Penicillium* (e.g. *Penicillium crustosum, Penicillium cyclopium* Westling, and *Penicillium commune*) was demonstrated in culture extracts (Vesonder *et al.*, 1980; Wagener *et al.*, 1980; Kyriakidis *et al.*, 1981; Mantle *et al.*, 1983). Braselton and Rumler (1996) first reported the concurrent presence of both tremorgenic mycotoxins in naturally occurring field cases of canine intoxication and raised the issue of the potential synergistic interactions between the two tremorgens. In two recent cases, both Boysen *et al.* (2002) and Young *et al.* (2003) diagnosed concurrent intoxication with penitrem A and roquefortine in several dogs. Given that roquefortine and

penitrem A have similar mechanisms of action, there would seem to be a potential for some sort of synergistic interaction between the two tremorgenic mycotoxins or at least a reduction in the amount of ingested contaminated material required for the onset of clinical signs. Likewise, it would seem logical in instances of "grass staggers" that a greater concentration of multiple, potential tremorgenic mycotoxins in contaminated forages would increase the likelihood and, potentially, the severity of observed intoxications.

# CLINICAL ASPECTS OF TREMORGENIC MYCOTOXICOSES

## Diagnosis

Diagnosis of tremorgenic mycotoxin-related intoxication is based on a history of exposure to or consumption of moldy food/feed, clinical signs of tremors and seizures and detection of tremorgenic mycotoxin(s) in the suspected source material, vomitus, gastrointestinal tract contents, or bile. Differential diagnoses should rule out ethylene glycol, strychnine, metaldehyde, methylxanthines, pyrethroids, nicotine, organochlorine insecticides, bromethalin, acetylcholinesterase-inhibiting insecticides, other potential neurotoxicants, and eclampsia in pregnant animals (Hooser and Talcott, 2006). It needs to be pointed out that in field cases of perennial ryegrass staggers, as well as Dallisgrass and Bahiagrass staggers, the onset of clinical signs is most likely related to the intake of the mycotoxins lolitrem B and paspalinine and/or paspalitrems, respectively. The effects of these tremorgenic mycotoxins could potentially be more insidious and longer lasting than those of penitrem A (Burrows and Tyrl, 2001; Hooser and Talcott, 2006). Depending on the laboratory, tremorgenic mycotoxins can generally be quantified using HPLC/MS (Rundberget and Wilkins, 2002), GC/ MS/MS (Braselton and Rumler, 1996), or TLC (Hooser and Talcott, 2006). Analyses for roquefortine and penitrem A are generally more likely to be available to clinicians than analytical procedures for the other tremorgenic mycotoxins.

## Treatment

In a small animal setting the minimum initial database should include a complete blood count, serum biochemical profile, and assessment of acid–base status and urinalysis (Hooser and Talcott, 2006). Depending on the species, the time period since exposure and the presence and severity of clinical signs, suspected poisoned animals should be decontaminated by emesis, gastric lavage, activated charcoal, and/or administration of cathartics. Given that intoxications with tremorgenic mycotoxins can be characterized by convulsions or, conversely, severe depression and coma, care should be taken to not induce vomiting when contraindicated by an increased risk for aspiration pneumonia. Tremors and seizures can be controlled by diazepam or methocarbamol. Animals unresponsive to these medications can be treated with barbiturates. The animal should be periodically assessed for metabolic acidosis, hyperthermia, pulmonary edema, and aspiration pneumonia. With proper initial and ongoing assessment and in the absence of complications, affected animals should recover relatively uneventfully following removal from the source and appropriate decontamination and other therapeutic procedures.

## Prevention

Care should be taken to avoid the presence of moldy feedstuffs in areas where animals have unsupervised and unrestricted access, and potentially contaminated materials should be disposed of properly. Trash receptacles should have securely fitting lids, and animals should not be free to roam in areas where discarded foodstuffs or refuse are stored. Livestock should not be fed overtly mold-contaminated forages or concentrates. With respect to "grass staggers", appropriate stocking rates should be maintained, and management practices should be instituted which ensure that animals have access to young growing plants, especially in pastures dominated by perennial ryegrass, Dallisgrass, Bahiagrass, or Bermudagrass (Burrows and Tyrl, 2001).

# CONCLUSIONS

Tremorgenic mycotoxins containing a tryptophan-derived indole moiety affect many mammalian species, especially sheep, cattle, and dogs. Roquefortine and penitrem A are produced by several species of *Penicillium*, and dogs exposed to these potent tremorgens exhibit tremors and, potentially, severe convulsive episodes and seizures. Several common forages, especially perennial ryegrass, are susceptible to infection by fungi capable of producing indole–diterpene tremorgenic mycotoxins, such as lolitrems and paspalitrems, which cause "grass staggers" in susceptible species. Although multiple mechanisms are involved in the neurotoxicity of tremorgenic mycotoxins, impaired GABA- and glycine-mediated inhibitory pathways and abnormal excitatory neurotransmitter (i.e. glutamate and aspartate) release appear to play major roles in the onset of clinical signs. Removal of the animal from contaminated foodstuffs usually results in recovery, but severely poisoned animals should be properly assessed, their tremors and/or seizures controlled, and appropriate

steps taken to avoid complications. Whenever possible, animals should not have unrestricted and unsupervised access to mold-contaminated foodstuffs.

# Slaframine

*Geoffrey W. Smith*

## INTRODUCTION

Slaframine is an alkaloidal mycotoxin produced by the fungus *Rhizoctonia leguminicola* that causes profuse salivation (slobbers) in animals. *R. leguminicola* is a common fungal pathogen of red clover (*Trifolium pratense*) and causes a syndrome known as black patch disease in the plant. Ingestion of clover hay containing slaframine causes salivary episodes that last from several hours to over 3 days in ruminants and horses. Although the disease is short term and animals generally recover without treatment, the dramatic clinical signs associated with slaframine ingestion make it readily apparent to livestock owners. Diagnosis can be made by identification of *R. leguminicola* in suspect forage or by the detection of slaframine in plasma samples from exposed animals.

## BACKGROUND

Outbreaks of profuse salivation in cattle were initially reported in the late 1940s and 1950s from agricultural experiment stations in the midwestern United States (O'Dell *et al.*, 1959). Most of these cases were associated with the feeding of second-cutting red clover hay. In 1956, it was first reported that fungal contamination of red clover with *R. leguminicola* was associated with a pasture disease called black patch, which derives its name from the appearance of affected areas in the field and not the characteristic black lesions on the leaves of affected plants (Croom *et al.*, 1995). Although its primary host is red clover, black patch disease has been reported in other legumes including white clover, soybeans, kudzu, cowpea, blue lupine, alsike clover, alfalfa, lespedeza, and milk vetch (Smalley and Sanderson, 1993). However, in most of these cases, infected red clover plants were present in the same areas of the field. Fungal infestations are usually associated with periods of wet weather and high humidity (Croom *et al.*, 1995). Transmission is thought to be primarily seedborne as the fungus overwinters on contaminated hay and can survive at least 2 years on contaminated seed.

## CHEMISTRY AND TOXICOKINETICS

Several laboratories were able to isolate the "slobber-causing" agent in *R. leguminicola*-contaminated red clover (Aust and Broquist, 1965; Rainey *et al.*, 1965) and in 1968 the chemical structure was described as 1-acetoxy-6-aminooctohydroindolizine (Gardiner *et al.*, 1968). The term slaframine became the most commonly used word for describing this compound (Aust *et al.*, 1966). Slaframine is a piperidine or indolizidine alkaloid (Figure 81.1) with the empirical formula $C_{10}H_{10}N_2O_2$ which gives it a molecular weight of 198 Da (Croom *et al.*, 1995).

Slaframine is activated by hepatic microsomal enzymes into a ketoimine (Figure 81.1) that is required to produce clinical signs. In cattle, the onset of salivation is shorter with more direct routes of administration; with intravenous injections producing salivation faster than intraperitoneal or intramuscular routes which are in turn faster than the subcutaneous route (Croom *et al.*, 1995). It has been suggested that slaframine is metabolized in the liver by a microsomal flavoprotein oxidase to the ketoimine metabolite (Guengerich and Aust, 1977) consisting of a quaternary nitrogen separated from an acetate ester by two carbon atoms (Figure 81.1). This structure is very similar to that of acetylcholine, a parasympathetic neurotransmitter.

## MECHANISM OF ACTION

Pharmacologically, slaframine would be classified as a cholinergic agonist and/or a parasympathomimetic chemical. The majority of the available data indicate that the clinical signs produced by slaframine are due to its high affinity for the $M_3$ muscarinic receptor subtype which is believed to be important in the control of exocrine and endocrine glands (Croom *et al.*, 1995). Early studies demonstrated that the increased salivation associated with slaframine toxicity could be blocked with pre-administration of atropine (Aust, 1970). Additionally, mortality in broiler chicks when slaframine is dosed at the $LD_{50}$ can be significantly decreased by the pre-administration of the muscarinic receptor antagonists atropine (which has affinity for $M_1$, $M_2$, and $M_3$ receptors), and pirenzepine ($M_1$ and $M_2$ selective), but not gallamine which is $M_2$ selective (Croom *et al.*, 1995). The pre-administration of the $M_3$ selective antagonist 4-diphenylacetoxy-*N*-methylpiperidine methiodide (4DAMP) can also block the increase in pancreatic fluid output induced by slaframine (Walker *et al.*, 1994). Furthermore, slaframine has no effect on the cardiovascular system or arterial pressure at doses stimulatory to exocrine glands (Aust *et al.*, 1968), nor does it inhibit blood cholinesterase activity (Crump *et al.*, 1967; Hagler and Croom, 1989).

The stimulation of $M_3$ muscarinic receptors by slaframine produces a profound stimulation of exocrine glands, particularly the salivary gland and pancreas. Steers given an intramuscular administration of purified slaframine had resting salivary flow rates 50–70% greater than saline treated controls (Froetschel *et al.*, 1986). Similar findings documenting increases in saliva production both in cattle and sheep have been reported in other studies as well (Bird *et al.*, 1993; Hibbard *et al.*, 1995). Additional reported physiological effects of slaframine include increased pancreatic enzyme secretion (Aust *et al.*, 1968; Aust, 1970), increased rumen pH and rate of nutrient passage, and decreased ruminal motility in cattle (Croom *et al.*, 1995).

## TOXICITY

Clinical signs of slaframine toxicity are similar in all species. Following exposure to contaminated forages, animals begin to salivate profusely. Experimentally, a single dose of slaframine produces salivation for 6–10 h. However, clinically affected animals can "slobber" for several days, presumably because they have continued access to slaframine-contaminated forages (Figure 81.2). Other clinical signs can include anorexia, diarrhea, frequent urination, and bloat. Decreased milk production can be expected in dairy cattle, likely related to a decrease in feed intake (Crump, 1973). Although slaframine toxicosis has been experimentally induced in a variety of species including swine, poultry, cats, dogs, guinea pigs, and rodents; naturally occurring cases are primarily reported in horses and ruminants (Crump *et al.*, 1967; Sockett *et al.*, 1982; Croom *et al.*, 1995).

Cyanosis and open-mouth breathing have been reported under experimental conditions in sheep, swine, and guinea pigs. Pigs also were observed to vomit, became dyspneic, and collapse with stiffened pelvic limbs (Crump *et al.*, 1967). Only mild salivation was noted in a small chicken fed slaframine, and clinical signs resolved within a few hours. The $LD_{50}$ in day old broiler chicks was estimated at approximately 81.6 mg/kg of body weight (Croom *et al.*,

1995), but higher doses (250–300 mg/kg) were required to produce death in guinea pigs (Crump *et al.*, 1967). Gross lesions in these animals consisted of vascular congestion of the thoracic and abdominal cavities. Pulmonary edema, disruption of the alveolar structure, emphysema, and hepatic centrilobular necrosis were noted histologically. Death in these animals was attributed to suffocation from pulmonary edema and/or emphysema.

The clinical signs associated with the "slobbers syndrome" as described under field conditions include salivation, lacrimation, feed refusal, bloating, stiff joints, diarrhea, and weight loss. However, very few of these signs have been seen following the administration of purified slaframine under experimental conditions. That has led to speculation that the alkaloid swainsonine might also be involved in producing clinical signs in classic slaframine toxicity (Croom *et al.*, 1995). Swainsonine is another alkaloid produced by *R. leguminicola* and has a similar structure to slaframine. Although it is better known for its association with locoweed toxicity, it is possible that swainsonine is partially responsible for some of the clinical signs classically observed with the "slobbers syndrome."

## DIAGNOSIS AND TREATMENT

Diagnosis of slaframine toxicity is generally made by observation of clinical signs (salivation) in animals consuming legume forage, particularly red clover hay. Further tests can identify the fungus *R. leguminicola* in the hay which usually can be easily isolated in culture (Figure 81.3). Although chemical analysis for slaframine is not usually necessary, chromatographic methods for detecting the toxin in hay, plasma, or milk have been described (Hagler and Croom, 1989; Imerman and Stahr, 1998).

Treatment is not usually indicated as animals usually recover spontaneously when the contaminated hay is removed, however clinical signs may persist for 1–2 days following removal of the toxic forage. In severe cases, atropine may be of benefit to reverse the parasympathomimetic effects of slaframine, however it is unlikely to be completely resolving clinical signs. In guinea pigs, simultaneous administration of atropine and a lethal dose of slaframine prevented clinical signs for 5 h, after which mild salivation was observed. When atropine was given 2–4 h after slaframine administration, profuse salivation was observed, however there was no mortality (Crump *et al.*, 1967). Atropine should be used with caution in ruminants and horses because of possible gastrointestinal side effects. Therefore, treatments other than removing the contaminated hay are not usually recommended in affected animals.

Control of black patch disease remains a major problem for agronomists. Fungicides applied before flowering do not reduce seed infection, and ground sprays at the time of plant growth in the spring and/or immediately after the first hay cutting have not been shown to reduce fungal contamination. Prevention requires selecting *R. leguminicola* varieties that are less susceptible to fungal infection and chemically treating seed prior to planting. Feasible mechanisms to detoxify or degrade the toxin in pasture and/or hay have not been found. Therefore control of slaframine outbreaks rely on completely replacing contaminated forages.

# Ergot

*Steven S. Nicholson*

## INTRODUCTION

Ergot is a general term that applies to all species of the fungus *Claviceps.* Ergotism refers to the disease conditions associated with ingestion of toxic levels of ergot by animals and humans. Ergot contaminated rye (*Secale cereale*) used as flour was responsible for numerous episodes of human ergotism in Europe during the Middle Ages. The genus *Claviceps* includes very specialized fungi which parasitize the flowers of grasses and cereal grains with no other part of the plant infected. Recently ergot alkaloids produced by *Claviceps cyperi* in nutsedge was described as a toxicant in dairy cattle (Naude *et al*., 2005). This chapter primarily addresses alkaloids produced by *Claviceps purpurea* and the various toxic effects, called ergotism, which they produce in animals and humans. The source of exposure to animals includes ergot infected grains in feeds such as barley, rye, wheat, and oats as well as, infected seeds in forages consumed while grazing or in hay and silage. Clinical syndromes include gangrene of the extremities of cattle and horses, hyperthermia and production loss in cattle, agalactia, and abortion in swine, agalactia, and reproductive effects in mares**.**

Clinical disease associated with *Claviceps* has a parallel in fescue grass toxicosis (see chapter 82) where gangrenous ergotism, hyperthermia, production loss in cattle, and adverse effects on reproduction and lactation in horses are similar (Evans *et al*., 2004). The seeds of fescue grass can be infected with *C. purpurea* but the ergot alkaloids of fescue grass toxicosis are produced by the endophyte fungus *Neotyphodium coenophialum*. Ergot alkaloid induced fescue toxicosis has been studied in much more detail than has ergotism from ingested *C. purpurea* sclerotia.

Ergovaline produced in perennial and annual ryegrasses by the endophyte fungus *Neotyphodium lolii* is associated with clinical toxicosis (Schneider *et al*., 1996; Bourke, 2003).

## BACKGROUND

*C. purpurea* has a host range exceeding 200 species of grasses. It is distributed worldwide in temperate climatic zones. During infection by *C. purpurea*, the ovary of the grass seed or cereal grain is replaced by fungal mycelia. A sticky exudate known as honeydew is produced that contains conidia which can be transferred to infect other seeds. The honeydew hardens to form a hard brown, purple, or black compact mass of fungal tissue called a sclerotium. The ergot bodies or sclerotia contain up to 1.2% dry weight of toxic alkaloids (Burrows and Tyrl, 2001). Sclerotia of most *Claviceps* species are one to four times larger than the host seed and are readily identified in cereal grains. Compared to sclerotia in oats or barley the sclerotia are quite small in grass seeds such as Bahia grass (*Paspalum notatum*). Sclerotia fall to the ground to over winter and later complete the fungal life cycle by germinating and producing ascospores capable of infecting the ovary of developing seeds.

Alkaloids from *C. purpurea* are among the most important natural products used by the pharmaceutical industry. Prior to the industrial cultivation of *C. purpurea* in pure culture, ergot was grown as a crop on rye (*Secale cereale*) under field conditions for use in manufacture of important medicinal drugs. Synthesized ergot alkaloids have a variety of uses in human and veterinary medicine. Chemical structures of some of the ergot alkaloids are shown in Figure 82.1.

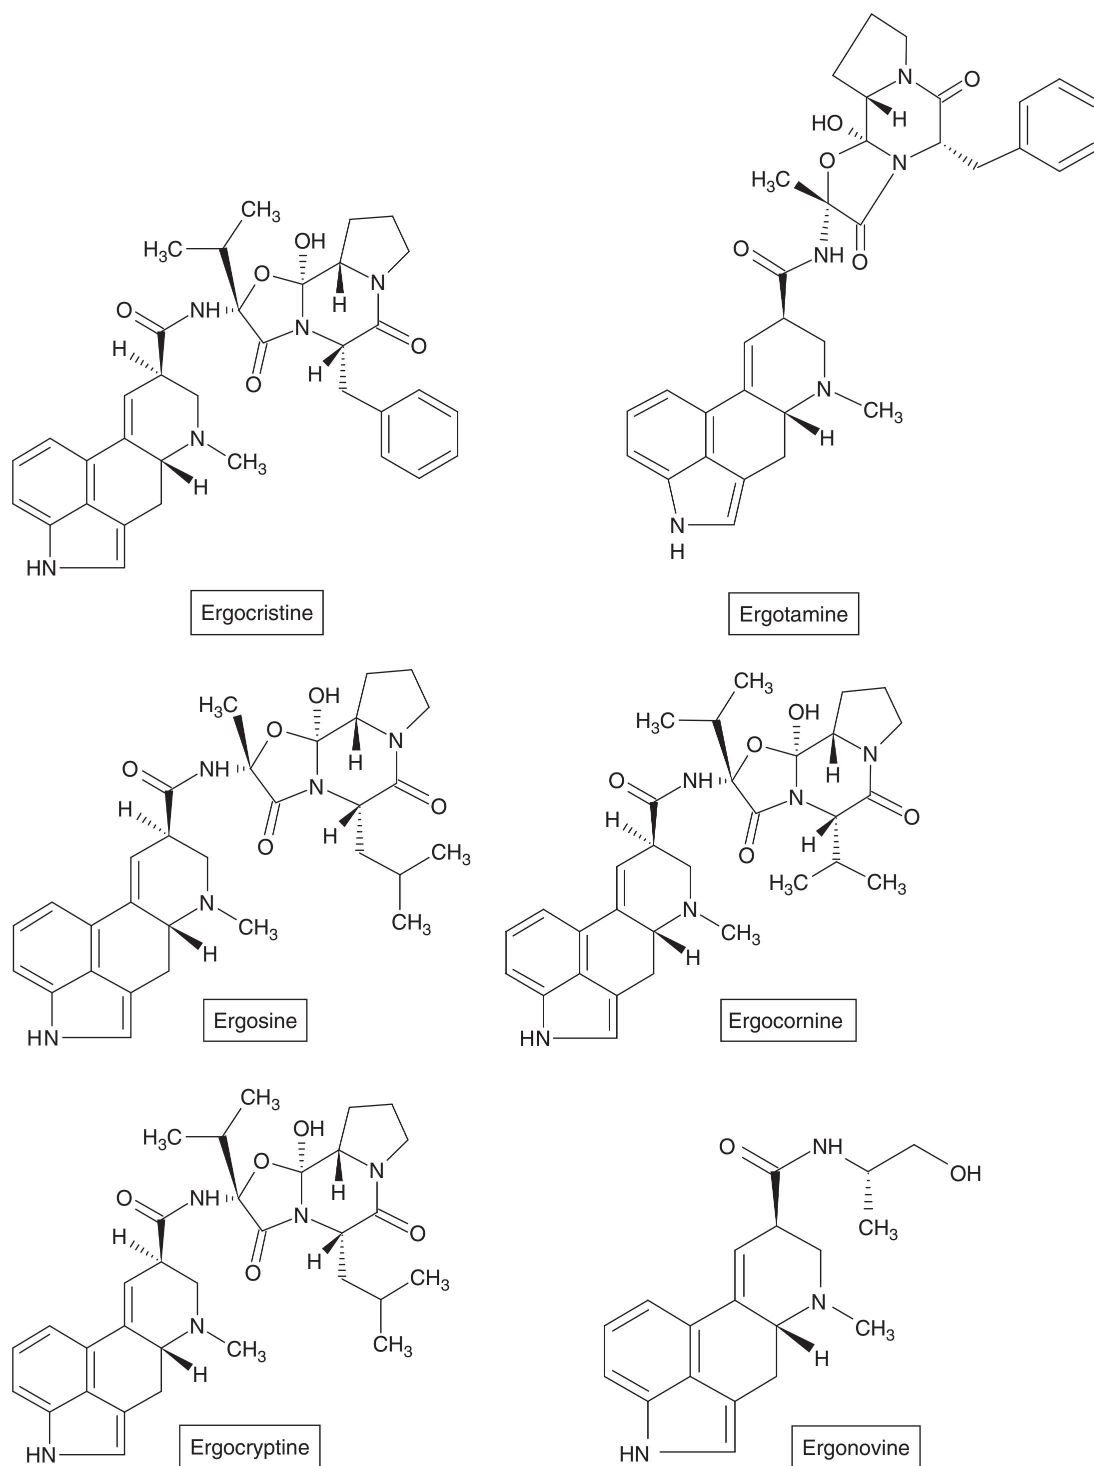

**FIGURE 82.1** Chemical structures of some ergot alkaloids.

## PHARMACOKINETICS/ TOXICOKINETICS

Ergot alkaloids responsible for most clinical signs and lesions are of the ergopeptine class including ergotamine, ergocristine, ergosine, ergocornine, ergocryptine, and ergovaline (Cheeke, 1998; Carson, 1999; Burrows and Tyrl, 2001; Evans *et al*., 2004). Injected intravenously ergopeptine alkaloids are rapidly cleared from the blood by the liver (Cheeke, 1998) and excreted in the bile (Evans *et al*., 2004).

These alkaloids are not secreted in the milk of cows (Cheeke, 1998).

## MECHANISM OF ACTION

Ergot alkaloids have structures similar to the biogenic amines norepinephrine, serotonin, and dopamine. Vasoconstriction is produced by an agonist activity and this effect varies with different vascular beds. Hyperthermia and uterine stimulation are other effects. The alkaloids are antagonistic to dopamine at $D_1$ vasodilatory receptors. Dopaminergic activity at $D_2$ receptors causes inhibition of prolactin secretion (Goldstein *et al.*, 1980). The dopamine antagonist domperidone is an effective treatment in mares suffering agalactia and uterine effects induced by ergot alkaloids in endophyte infected tall fescue grass (Redmond *et al.*, 1993).

## TOXICITY

Expression of clinical toxicoses caused by ergot alkaloids occurs in four forms in livestock. These include cutaneous and gangrenous lesions of the tail and extremities, hyperthermia and production loss, reproductive failure, and a convulsive or nervous form. The latter is apparently uncommon, not well documented, and is perhaps caused by acute ingestion of a large dose of sclerotia. Muscle tremors and hyperexcitability are signs in cattle caused by nonergot compounds produced by *Claviceps paspali* in seeds of Dallis grass.

In countries where cereal grains in commerce are subject to regulatory oversight the presence of ergotized seed at significant levels in food and feedstuffs is not common. Ergotism in cattle caused by sclerotia ingested while grazing remains a sporadic problem in the United States (Burrows and Tyrl, 2001).

The cutaneous and gangrenous form of ergotism is associated with subacute or chronic ingestion of the ergopeptine alkaloids. Cold temperatures enhance the clinical effects. Constriction of small arteries and arterioles leads to necrosis affecting all four limbs, tips of the ears, and distal third of the tail. Distinct lines separating normal tissue from nonviable tissues appear. The odor of rotting flesh may be obvious and affected animals may continue to walk until sloughing of the digits occurs.

Hyperthermia was noted in steers exposed to sunlight and fed 180 mg/kg/body weight of *C. purpurea* even at moderate ambient temperatures and humidity (Bourke, 2003).

Hyperthermia induced by high ambient temperature and humidity in lactating dairy cattle reduces feed intake, milk production, and increases embryonic losses. Ingestion of ergot alkaloids enhances this effect (Al-Tamimi *et al.*, 2003). Hyperthermia and a 30% drop in milk yield occurred in succession in two Holstein dairy herds ($n$ = 240 and $n$ = 150 milking cows, respectively) on the South African Highveld (Naude *et al.*, 2005). Examination of the maize silage from both farms revealed that it was heavily contaminated with nutsedge which contained minute sclerotia, identified as those of *Claviceps cyperi*. This was the first report of bovine ergotism not associated with the grass family Poaceae infected with *C. purpurea* or endophytes. High levels of total ergot alkaloids, predominantly ergocryptine, were found by LC-MS in the silage, as well as in the total mixed ration (115–975 ppb and 65–300 ppb, respectively). The ergot alkaloid content (mainly ergocryptine) of the maize silage on the second affected farm was 875 ppb. A significant 4.6 l decrease in milk production in a herd of Holstein–Friesian dairy cows in Australia was associated with high concentrations of endophyte produced ergovaline (1.6 μg/g) in ryegrass silage (Lean, 2001). Simultaneously, milk somatic cell counts increased significantly over a comparable period and reproductive performance declined. Body condition score and coat condition of cows were adversely affected.

Sheep are susceptible to the vasoconstrictive effects of ergopeptine alkaloids but ergot toxicosis is described as typically mild and not accompanied by gangrenous lesions (Greatorex and Mantle, 1973). Sloughing of the tip of the tongue is said to occur (Burrows and Tyrl, 2001). The effects of ergot alkaloids in swine are primarily those of agalactia, production loss, and an impact on reproduction. Diets containing 0, 1, and 10 g ergot (*C. purpurea*) per kg were fed to 12 pigs in the body weight range of 30–115 kg (Mainka *et al.*, 2005). Tendencies toward reduced feed intake and low rate of weight gain were observed at a feeding level of 4.66 mg total alkaloids per kg diet. At that level protein digestibility was significantly reduced. Birth weight in pigs is reduced, stillborns increased, and neonatal mortality increased due to agalactia in the sow (Lopez *et al.*, 1997).

Agalactia, small, weak foals, stillborn foals, and placental edema occur in pregnant mares ingesting ergot alkaloids in the last month of gestation. This is a common occurrence in mares grazing endophyte infected tall fescue grass in the United States. Similar effects caused by ingestion of *C. purpurea* sclerotia are seldom reported perhaps because heavily infected ergot cereal grains are generally kept out of feed grain commerce. There remains the situation where heavily contaminated cereal grain screenings could be fed to horses. Twelve pregnant mares fed black oat (*Avena strigosa*) during the pre-delivery period experienced agalactia and delivered weak and unviable foals, which showed no suckling reflex and died within a

few hours of birth. *C. purpurea* sclerotia were identified in 0.22% of the examined oat seeds (Copetti *et al*., 2002).

Chickens develop gangrene involving the comb, beak and toes, weight loss and debilitation. Rabbits are extremely sensitive to the hyperthermic effects caused by ergot alkaloids (Burrows and Tyrl, 2001). Ergot alkaloids are embryocidal and abortifacient in laboratory animals (Mantle, 1969).

In dogs and rodents corpora lutea are essential to maintain pregnancy. In these animals ergot alkaloids inhibit prolactin secretion causing loss of corpora lutea and abortion. Ergot alkaloids in oats fed to female mink bred to untreated males caused reduced numbers of kits born compared to controls (Sharma *et al*., 2002). There was a significant effect on kit survivability with no kits surviving in the 12 ppm group. Serum prolactin was significantly depressed in the three ergot alkaloid groups compared to the control group. This study indicated that ingestion of ergot alkaloids at 3 ppm or higher resulted in reproductive toxicity in mink.

## TREATMENT

Removing the source of ergot from the animals' diet is an obvious first step in treatment. The hyperthermic effect in dairy cattle should abate within 1–2 weeks. Animals that have developed gangrene of the extremities would not be expected to recover and should be euthanized.

The dopamine antagonist domperidone is an effective treatment in mares to prevent agalactia and uterine effects induced by ergot alkaloids in endophyte infected tall fescue grass (Redmond *et al*. 1993; Redmond *et al*., 1994).

## CONCLUDING REMARKS

Ergot infection in cereal grains and grasses remains a concern for livestock and horses. Commercial cereal grain screenings and cereal grains produced and fed on the farm, and not inspected, are potential sources of ergotized grain. Exposure while grazing infected grasses may go unnoticed initially, especially if management is not aware of the risk.

## INTRODUCTION

Ionophores are compounds that form lipid soluble, dynamically reversible complexes with cations and by this means facilitate specific ionic transport across biological membranes (Pressman, 1976; Reed, 1982; Taylor *et al.*, 1982; Riddell, 2002). There are two major subclasses of ionophores: (1) neutral ionophores, which are highly toxic because they form charged complexes that are capable of perturbing biologic membranes and action potentials and (2) carboxylic ionophores, which form zwitterionic complexes with cations and promote electrically neutral cation exchange diffusion that is tolerated better in intact organisms. The ionophoric activity may alter normal concentration gradients resulting in cellular ion imbalance, pH change, calcium overload, lipid peroxidation, and disruption of plasma membranes. The alteration in the membrane transport of ions is the basis for the metabolic, organic, and functional effects of this class of compounds. Since their pharmacologic activity is dose-related, the usefulness of carboxylic ionophores is based on selective toxicity to protozoan parasites and bacteria and margins of safety in the approved target species. Desirable effects occur when animals are provided feed containing approved dosage ranges, but higher levels may result in adverse effects.

This chapter attempts to provide an overview of ionophores as they relate to veterinary medicine, with emphasis on ionophore-induced toxicity. Large numbers of ionophore safety and toxicity studies have been conducted in support of marketing approval, but results of many studies are unpublished. For this reason, information presented was gleaned from published laboratory and field reports of toxicoses in various species of animals, available reviews, and Freedom of Information summaries obtained from the US Food and Drug Administration (FDA). However, due to space limitations, not all information can be included, hence apologies are extended to laboratory scientists and field researchers whose work has been omitted or inadvertently missed.

## BACKGROUND

Presently, seven carboxylic ionophores (Figure 83.1) are approved for the control of coccidiosis and promotion of growth and feed efficiency in several animals of economic importance. Since their introduction, carboxylic ionophores have played significant roles in livestock and poultry production systems throughout the world. Monensin, first introduced as Coban® in the United States for the control of coccidiosis in chickens in 1971, was later marketed in 1975 as Rumensin® to promote growth and/or increase feed efficiency in cattle. Similarly, lasalocid has been marketed since 1977 as Avatec® for chickens and since 1982 as Bovatec® for cattle. Salinomycin, narasin, and maduramicin were approved for chickens in 1983, 1986, and 1989, respectively while laidlomycin and semduramicin were approved in 1994 for use in cattle and chickens, respectively.

Other benefits of ionophore use include: (1) reduction of coccidial oocyst discharge in ruminants (Stockdale, 1981; Parker *et al.*, 1986), (2) prevention of acute bovine pulmonary edema and emphysema (Hammond *et al.*, 1980; Nagaraja *et al.*, 1982; Nocerini *et al.*, 1985), (3) decreased incidence of bloat (Lowe *et al.*, 1991), (4) prevention of ruminal lactic acidosis (Duffield *et al.*, 2002), and (5) amelioration of ketosis in lactating dairy cows (Heuer *et al.*, 2001). The reduction of deaths in some cattle herds has

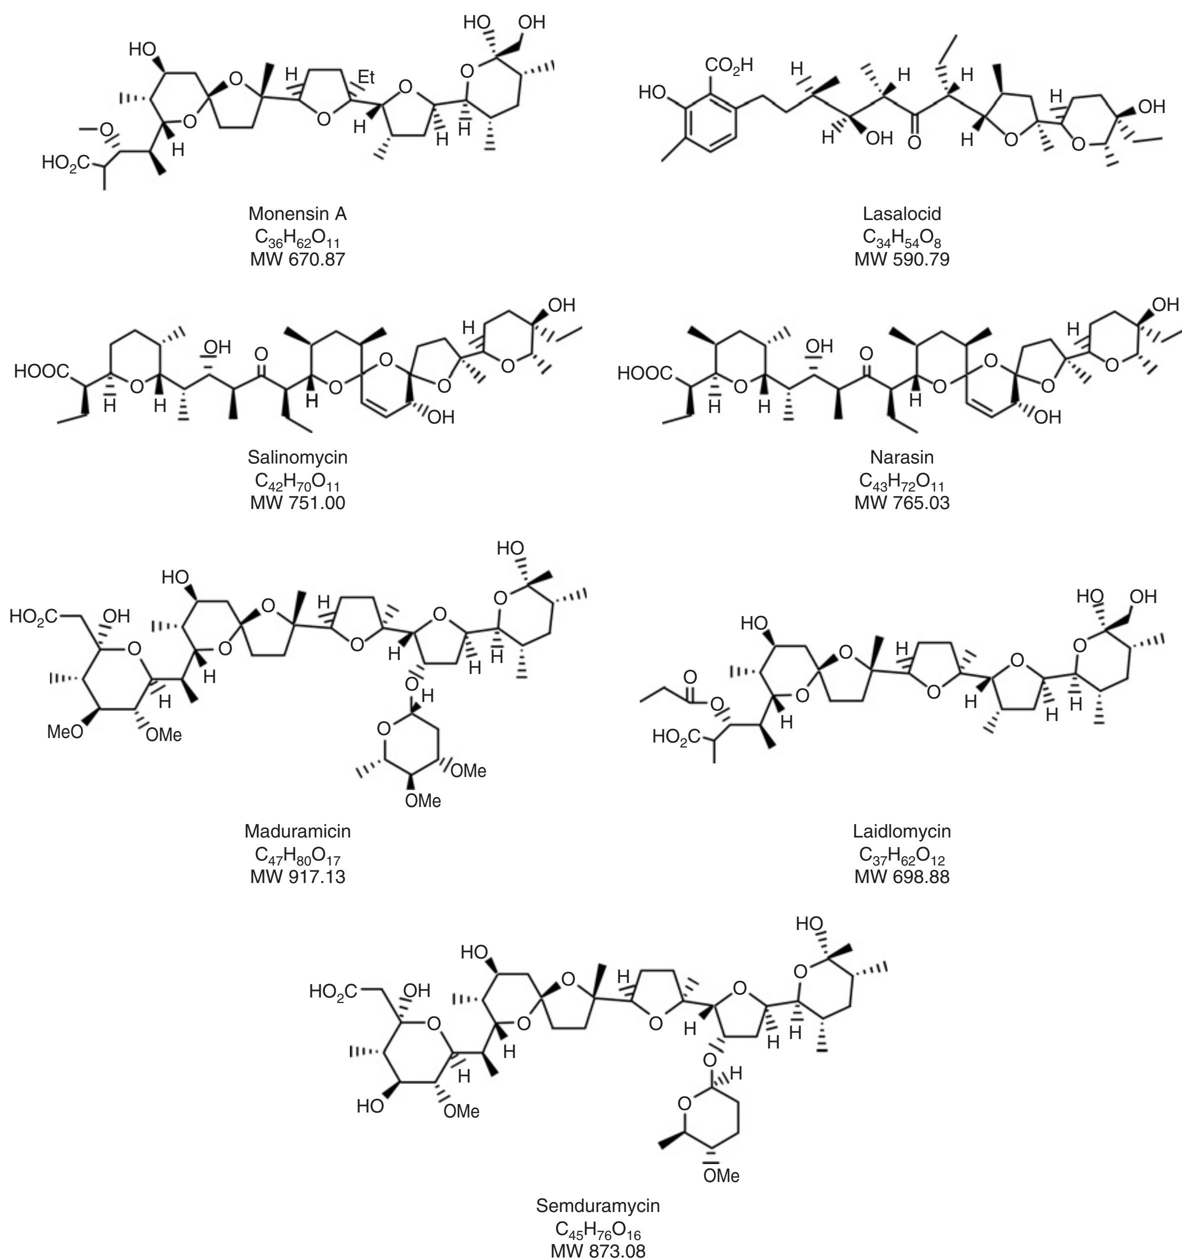

**FIGURE 83.1** Structures of carboxylic ionophores.

been hypothetically related to the reduction of indigestion, metabolic stress, bloat, and enterotoxemia associated with monensin feeding (Black and McQuilken, 1980).

Potential uses of the ionophores are under experimental investigation in many parts of the world and off-label use of some ionophores is known to occur. Monensin has been used for the control of toxoplasmosis in pregnant sheep (Buxton *et al.*, 1988), disseminated visceral coccidiosis in cranes (Carpenter and Novilla 1992), gregarine infections in shrimp (Jones *et al.*, 1994; Fajer-Avila *et al.*, 2005), and diarrheal disease in swine (Kyriakis, 1989; Kyriakis *et al.*, 1993). The use of monensin to improve efficiency of milk production in dairy cattle has recently been approved in the United States (FDA, 2004). Experimental studies on the use of ionophores for the treatment of malaria (Adovelande and Schrevel, 1996; Gumila *et al.*, 1997), lead poisoning (Hamidinia *et al.*, 2002), and as an aid in the potentiation of anti-cancer therapies (Griffin *et al.*, 1993; Shaik *et al.*, 2001) have been conducted. These studies were conducted in cell culture or as challenge studies in laboratory animals and have shown some degree of efficacy. In spite of these encouraging results, there have been no reports of investigational use of ionophores in humans.

# PHARMACOLOGY/ PHARMACOKINETICS

## Pharmacology

Investigational studies were conducted to determine if ionophores had any undesirable pharmacological properties. A series of general pharmacology studies (Table 83.1) conducted with monensin was reviewed recently (Novilla, 2004). Earlier, Hanley and Slack (1982) reviewed the pharmacology of lasalocid. The studies with monensin assessed its effects on the central, peripheral, and autonomic nervous systems and the digestive, respiratory, and cardiovascular systems. The test systems with doses and route of administration and no-observed-effect-level (NOEL) are shown below.

In mice, an oral dose of 10 mg monensin/kg body weight produced no significant effects on general behaviors, coordinating activity in skeletal muscles, electroshock seizures, and acetic acid writhing. However, slight sedation, decreased sensitivity to tactile stimulation, slight depression of muscular coordination, and depressed acetic acid writhing occurred at 30 mg/kg. In cats, immobilized by D-tubocurarine or anesthetized with urethane and $\alpha$-chloralose, an oral dose of 30 mg/kg produced no effect on the electroencephalogram and the spinal reflex. At the same dose in anesthetized cats, the heart rate, electrocardiogram, respiration, and blood pressure responses to epinephrine, acetylcholine, histamine, and contractions of the nictitating membrane in response to electrical stimulation of the cervical sympathetic ganglion were not affected. Charcoal meal transit in mice was not affected by an oral dose of 10 mg/kg while 30 mg/kg significantly depressed the transit rate. Gastric secretion was not affected by an oral dose of 30 mg/kg in rats. In isolated guinea pig ileal preparations, monensin in a bath concentration of $10^{-5}$ g/ml had no antagonistic effects on contractures induced by acetylcholine, histamine, and barium chloride. In the rat anti-carrageenin edema test, monensin given orally at 30 mg/kg did not significantly inhibit carrageenin-induced edema of the hind paw.

The studies targeting specific organ systems of laboratory animals indicated that monensin at a dose of 10 mg/kg orally produced no effect on the central, peripheral, and autonomic nervous systems or the respiratory and digestive systems. However, striated (heart and skeletal) muscle has been identified as the primary target of toxicity in laboratory animals and domestic livestock given large doses of monensin and other ionophores by oral or parenteral routes (Todd *et al.*, 1984; Novilla and Folkerts, 1986; Novilla and Todd, 1991; Van Vleet *et al.*, 1991; Dowling, 1992).

The cardiovascular effects of oral and intravenous (IV) administration of monensin were evaluated in conscious

**TABLE 83.1 General pharmacology studies on monensin**

| Test system | Species | Monensin dose (mg/kg) | Route | NOEL (mg/kg) |
|---|---|---|---|---|
| General behavior | Mouse | 0, 10, and 30 | Oral | 10 |
| Coordinating activity of skeletal muscles | Mouse | 0, 10, and 30 | Oral | 10 |
| Anti-electroshock seizures | Mouse | 0 and 30 | Oral | 30 |
| Analgesic effect | Mouse | 0, 10, and 30 | Oral | 10 |
| Spinal reflex | Cat | 0 and 30 | Oral | 30 |
| Electroencephalogram (D-tubocurarine immobilized) | Cat | 0 and 30 | Oral | 30 |
| Circulatory, respiratory, and autonomic effects | Cat | 0 and 30 | Oral | 30 |
| Charcoal meal transit | Mouse | 0, 10, and 30 | Oral | 10 |
| Gastric secretion | Rat | 0 and 30 | Oral | 30 |
| Isolated ileum | Guinea pig | $1 \times 10^{-5}$ g/ml | *In vitro* | $1 \times 10^{-5}$ g/ml |
| Carragenin-induced edema | Rat | 0 and 30 | Oral | 30 |
| Cardiovascular study | Dog (conscious) | 0, 0.0069, 0.0138, 0.0345, 0.0690, and 0.138 | IV | 0.0345 |
| | | 0, 0.138, 0.345, 0.690, and 1.38 | Oral | 0.345[a] |
| Cardiovascular and respiratory effects | Dog (anesthetized) | 0, 0.00069, 0.0014, 0.0035, 0.0069, 0.014, 0.035, 0.069, 0.14, 0.35, 0.69, and 1.4 | IV | 0.0035 |
| | Pig (anesthetized) | 0, 0.00069, 0.0014, 0.0035, 0.0069, 0.014, 0.035, 0.069, 0.14, 0.35, and 0.69 | IV | 0.0035 |

[a] Based on transient increases in coronary blood flow at doses ≥0.69 mg/kg.

dogs (Holland, 1978). In the oral study, doses of 0, 0.138, 0.345, 0.69, or 1.38 mg monensin/kg body weight in 15 ml of 10% acacia were given by gavage to 4, 4, 6, 6, or 4 dogs, respectively. Effects were limited to increased coronary blood flow at doses ⩾0.69 mg monensin/kg. At the 0.69-mg/kg dose, coronary flow increased from 24 ml/min before dosing to a maximum of 40 ml/min 17.5 min after dosing. At the 1.38-mg/kg dose, coronary flow increased from 18 ml/min predosing to a maximum of 49 ml/min 13 min after dosing. In both cases, coronary blood flow had returned to normal levels by 30 min after dosing. Heart rate and mean blood pressure of monensin-treated dogs did not change significantly from the controls at any dose level. Coronary artery flow did not increase following doses of 0.138 and 0.345 mg monensin/kg. In the IV study, coronary blood flow, blood pressure, and heart rate were measured in each of 6 dogs given total cumulative doses of 0.0069, 0.0138, 0.0345, 0.069, and 0.138 mg monensin/kg body weight. Four control dogs were given dextrose alone. Coronary artery flow significantly increased at 0.069 and 0.138 mg/kg and mean blood pressure increased significantly at the 0.138 mg/kg. Coronary artery flow did not change significantly following doses of ⩽0.0345 mg/kg while heart rate did not change significantly from the controls at any dose level. Mean blood pressure also did not change significantly at dose levels of 0.0069, 0.0345, and 0.069 mg/kg. Based on the transient increases in coronary blood flow observed in these studies, the NOELs were 0.345 and 0.0345 mg monensin/kg following oral and IV dosing, respectively.

The cardiovascular effects of monensin are similar to those observed for lasalocid (De Guzman and Pressman, 1974; Osborne *et al.*, 1977). Hypothetically, based on their inotropic and chronotropic properties, ionophores were considered as potential therapies for human cardiac disease (Pressman, 1976; Saini *et al.*, 1979; Hanley and Slack, 1982).

These pharmacology studies are considered relevant to the overall safety of ionophores as they provide insight into the secondary pharmacological actions and support the margins of safety for exposure in humans during the manufacturing processes or in the mixing or handling of the premixes in preparing feeds for the target species. With regard to the dog cardiovascular studies, monensin-induced increases in coronary blood flow observed at oral doses of 0.69- and 1.38-mg/kg were transient and considered not to be toxicologically important. At these doses, the respective increases of 67% and 172% in blood flow are in the physiological range by virtue of the autoregulatory coronary flow reserve (Cruickshank, 1992; Feliciano and Henning, 1999). Further, the phenomenon was not considered to be deleterious because recognized indicators of cardiovascular toxicity, such as increased blood pressure and/or heart rate, were not observed concurrently in the oral study. If it can be assumed that the relative potency of IV dosing to produce increased blood pressure is 11 times greater than by oral dosing (Holland, 1978), then the equivalent dose of 1.52 mg monensin/kg given orally by capsule would be expected to produce this change. According to Pressman and Fahim (1983), a single oral dose of 2.0 mg/kg in dogs produced increased heart rate and arterial pressure for up to 2 h after dosing, hence the lower dose of 1.38 mg monensin/kg may be considered as the no observed adverse effect level (NOAEL). If one takes 0.69 mg monensin/kg as a pharmacologically significant oral dose and 0.345 mg/kg as a NOEL for humans, then a 60-kg person would require 41.4 mg of monensin to manifest a transient effect on coronary blood flow while 20.7 mg monensin will have no effect (Donoho, 1984).

Human exposure to systemic levels of monensin and other ionophores high enough to produce any toxicological effects is very unlikely. With the use of safety equipment and close adherence to good manufacturing practices (GMPs) and label instructions, personnel manufacturing and handling ionophore products should not be subjected to undue risk. Furthermore, it is highly unlikely for these exposures to occur in humans consuming meat and milk products from animals fed a complete feed formulated with ionophores because residues are extremely low (Novilla, 2004).

## Pharmacokinetics

Tissue residue and metabolism studies were required to be conducted on all marketed ionophores to support human safety. For monensin, several studies with both $^{14}C$-monensin and unlabeled compound have shown that following oral administration in cattle and other species, monensin is rapidly absorbed and extensively metabolized by the liver and that most of the administered monensin and its metabolites are excreted in the bile. Results of biochemical studies on the metabolic fate of monensin in animals have been published (Davison, 1984; Donoho, 1984; Atef *et al.*, 1993). The metabolite pattern for monensin is similar in cattle, chickens, rats, turkeys, sheep, and pigs. Metabolite characterization studies indicated that hydroxylation (*o*-demethylation and oxidation) is the primary metabolic pathway of monensin resulting in low concentrations of a large number of polar metabolites in the feces of $^{14}C$-monensin-dosed animals. The pattern of metabolites in cattle and rats is similar. Based on radiolabeled studies in steers and dairy cows, the liver had the highest total monensin residue following zero withdrawal (Donoho *et al.*, 1978; Herberg *et al.*, 1978; Kennington *et al.*, 1995). Parent monensin and five metabolites were identified in liver, bile, and/or feces from monensin-treated steers and dairy cows. Studies have shown that metabolite M-1 (*o*-desmethyl monensin) was 20 times less active than parent monensin, the marker residue. Hence, the suspected first step in monensin metabolism appears to eliminate most of the biological

activity. Plasma levels of monensin are low and decline rapidly in cattle treated with monensin. In cattle administered $^{14}C$-monensin, residues of radioactivity depleted rapidly from the tissues. In a recent tissue residue study, no monensin was detected in extracted fat, liver, kidney, and muscle tissues from cattle given feed containing 100 ppm to provide a dose of 0.9 mg monensin/kg body weight/day for 28 days (Coyle and Walker, 2005). Feeding of muscle, liver, and other viscera from cattle provided dietary levels of 165-ppm monensin (5 times the approved use level) to rats and dogs for 3 months produced no adverse effects (Gossett *et al.*, 1975). Moreover, monensin does not accumulate in tissues of animals even when given intoxicating doses (Donoho, 1984; Atef *et al.*, 1993). Thus, exposure of humans to residues of monensin in meat or milk from animals treated according to the label instructions will be very limited and will be due primarily to the parent compound. Furthermore, when residues, primarily the parent compound, are present in animal products intended for human consumption, they will be at minimal levels for which a sufficient margin of safety has been demonstrated in the toxicology studies (Novilla, 2004).

Pharmacokinetic studies with other marketed ionophores generated data similar to that of monensin. Results of these studies in the Freedom of Information (FOI) summaries facilitated determination of the safe residue concentration, acceptable daily intake, marker residue and tolerance, and withdrawal time by the US FDA.

## MECHANISM OF ACTION

Carboxylic ionophores are known to form cationic ($Na^+$, $K^+$, $Ca^{2+}$) complexes (Figure 83.2) that enhance their transport across bimolecular lipid membranes (Pressman, 1976; Pressman and Fahim, 1982, 1983; Taylor *et al.*, 1982; Reed, 1982; Reed and Bokoch, 1982; Mollenhauer *et al.*, 1990). However, ion proclivities differ and evidence gathered in various laboratories indicates that carboxylic ionophores may have multiple effects at the cellular level.

In this diagram, monensin, classified as a $Na^+$ selective ionophore, binds to $Na^+$ outside the cell, carries it into the cell, and produces higher intracellular concentrations of $Na^+$. Influx of $Na^+$ is counterbalanced by an efflux of $K^+$ but, since $K^+$ efflux is slow, an initial efflux of proton ($H^+$) occurs, which may result in intracellular alkalosis. With salinomycin and narasin and others that show $K^+$ selectivity, the $K^+$ egress is countered by an initial $H^+$ ingress, which could result in intracellular acidification. Salinomycin and narasin preferentially complex with $K^+$ over $Na^+$ at a ratio of 4:1. An ionophore-mediated rise in intracellular $Na^+$ is known to increase the intracellular levels of $Ca^{2+}$ due to an ATPase-driven exchange mechanism at the cell membrane

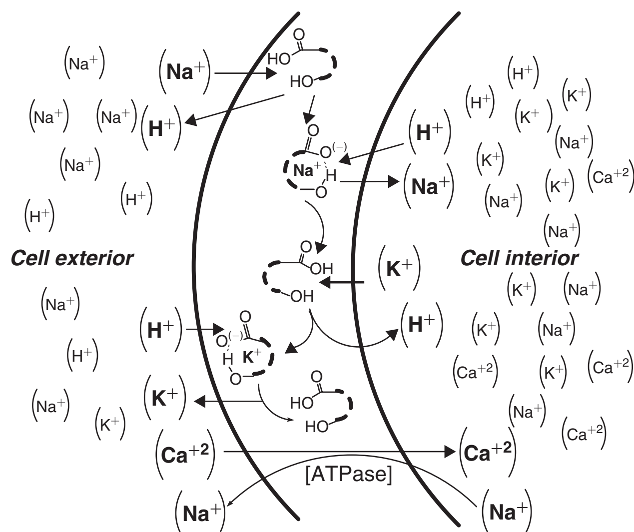

**FIGURE 83.2** Diagram of cation ion exchange diffusion across plasma membranes facilitated by monensin. Large arrows indicate major transport activity.

(Mubagwa *et al.*, 1997; Meral *et al.*, 2002). Monensin was reported to shorten the duration of the action potential and suppressed the pacemaker potential in cardiac tissue (Sutko *et al.*, 1977; Tsuchida and Otomo, 1990). These membrane current effects were related to transmembrane alterations in the gradients of $Na^+$ and $K^+$ions and to increased intracellular $Ca^{2+}$ following the increase in cytoplasmic $Na^+$ concentration, probably via a $Na^+/Ca^{2+}$ exchange mechanism. Lasalocid directly translocates $Ca^{2+}$ because it forms complexes with divalent cations with a range of complexing and transport capabilities including primary amines, e.g., catecholamines (Reed and Bokoch, 1982; Hanley and Slack, 1982). Monensin also causes release of catecholamines from cultured adrenal chromaffin cells and salinomycin causes a multifold augmentation of plasma catecholamines in animals. Catecholamines and toxic oxidation products have been implicated in myocardial necrosis through greater influx of $Ca^{2+}$ and formation of free radicals.

By special immunohistochemistry staining, monensin treatment was shown to increase $Na^+K^+$-ATPase and $Ca^{2+}$-ATPase and nitric oxide (NO) synthase activities in the heart of chickens (Calo *et al.*, 2002, 2003). NO, the product of NO synthases, is recognized as a regulator of calcium homeostasis. Alterations in the concentrations of $Ca^{2+}$ and other cations extracellularly as well as changes in their intracellular distribution have been associated with changes in subcellular organelles and cell damage (Dubardieu and Shier, 1992; Shier and Dubourdieu, 1992; Calo *et al.*, 2002, 2003; Sandercock and Mitchell, 2003, 2004).

Carboxylic ionophores directly affect the asexual and sexual developmental stages of eimerian coccidia by causing the normal transport of $Na^+$ and $K^+$ ions to fail (Smith and Strout, 1979; Smith and Galloway, 1983). In studies with free *Eimerian* sporozoites, monensin causes increased

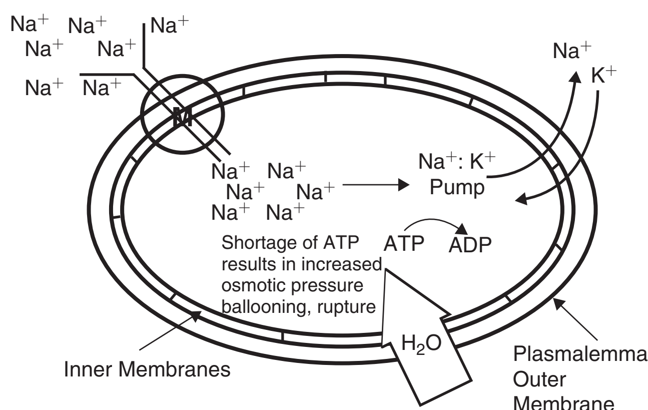

**FIGURE 83.3** Effect of ionophores on ion and water dynamics in the coccidia. M: monensin. From Thomas *et al.* (1985). Elanco Animal Health.

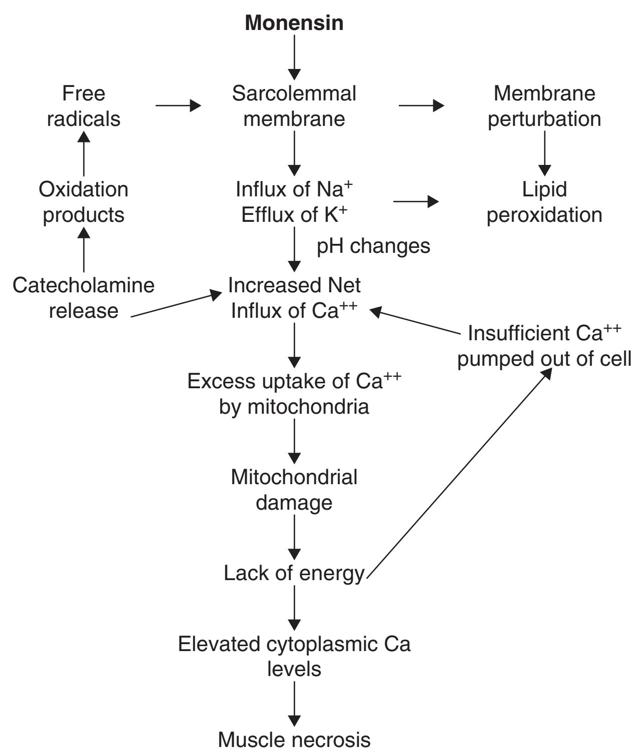

**FIGURE 83.4** Probable sequence of events induced by monensin in muscle cells. Adapted from Novilla and Folkerts (1986).

$Na^+$ levels in the parasite, increased activity of the sodium pump, decreased intra-sporozoite ATP, and stimulation of glycolysis (Smith *et al.*, 1981). Continuous exposure to monensin results in an increased osmotic gradient within the developing sporozoan parasite (Figure 83.3). Water follows and the organisms utilize energy to maintain intracellular homeostasis. When energy is exhausted the parasite swells with damage to organelles and death ensues (Smith and Strout, 1980; Smith *et al.*, 1981; Mehlhorn *et al.*, 1983). While most ionophores target free coccidial stages in the intestinal lumen (sporozoites and merozoites), the first intracellular generation (trophozoites) was most sensitive to lasalocid (Long and Jeffers, 1982; Ruff, 1982).

Similar events occur in susceptible bacteria. By reducing acetic and butyric acid producing (Gram-positive) bacteria and promoting growth of propionic acid producing (Gram-negative) bacteria, ionophores improve the efficiency of rumen fermentation resulting in a greater retention of feed energy in metabolizable nutrients (Richardson *et al.*, 1976; Bergen and Bates, 1984; Russel, 1987; Russel and Strobel, 1989). Monensin, lasalocid, and laidlomycin have been shown to alter the molar ratios of volatile fatty acids (VFAs) such that there is increased propionate and decreased acetate and butyrate without altering total VFA concentration.

# TOXICITY

## Pathogenesis

The exact mechanism of the toxicity induced by ionophores is not known. However, reasonable hypotheses have been generated based on their inherent ionophoric activity (Van Vleet *et al.*, 1983c, 1991; Novilla and Folkerts, 1986). All ionophores facilitate transmembrane ion fluxes and dissipation of ion gradients, which are exaggerated at toxic levels. Cells respond to the metabolic insult by expending energy to maintain homeostasis. When homeostatic mechanisms are exceeded, toxicity ensues from excessive influxes of $Na^+$ and $Ca^{2+}$ leading to degeneration and necrosis of cardiac and skeletal muscle cells (Figure 83.4). Although the ionophore mode of action is simple, four biochemical changes, including intracellular pH effects, calcium overloading, catecholamine release, and lipid peroxidation, probably occur during ionophore toxicoses.

In the diagram, monensin facilitates cation exchange diffusion as it intercalates with plasma membranes (Pressman, 1976; Reed, 1982; Riddell, 2002). The exaggerated pharmacologic activity at toxic levels disrupts not only osmotic gradients but the intracellular pH as well. Since drastic changes in acid base balance are incompatible with life, the pH shifts may be responsible for the peracute deaths observed with very high toxic levels of ionophores (Novilla and Folkerts, 1986). The monensin-induced entry of $Na^+$ is followed by entry of calcium, due to an ATPase-driven exchange mechanism at the cell membrane. A calcium ionophore like lasalocid or A23817 promotes $Ca^{2+}$ entry directly. Ionophores are known to trigger the release of $Ca^{2+}$ from intracellular stores further increasing $Ca^{2+}$ levels in the cytoplasm.

Two other mechanisms contribute to calcium overloading: exaggerated release of neurotransmitters like

catecholamines and increased peroxidation of lipids. Monensin, lasalocid, and salinomycin have been reported to release of catecholamines from adrenal chromaffin cells, transport catecholamines directly, or augment catecholamine plasma levels, respectively. The degradation products of catecholamines have been implicated in myocardial necrosis through the formation of free radicals and calcium influx (Singal *et al.*, 1981; Yates *et al.*, 1981; Reichenback and Benditt, 1982). Since ionophores are lipophilic and have detergent properties, dose-related perturbations of plasma membranes can promote increased lipid peroxidation. It is known that lipid peroxidation promotes membrane damage, and consequently, increased $Ca^{2+}$ influx.

Since they are not mutually exclusive, one or more of the above pathogenetic mechanisms may increase calcium concentrations in the cell. The rise in intracellular calcium can be buffered by calcium pumps in the plasma membrane, mitochondria, and sarcoplasmic reticulum. However, toxicity overwhelms this buffering mechanism and a vicious cycle ensues, resulting in calcium overloading. Elevated calcium levels then activate muscle proteases and phospholipases which initiate degradative processes (disassembly of myofilaments and membrane damage) in striated muscle and ultimately cell death (Van Vleet *et al.*, 1983c, 1991; Trump *et al.*, 1989; Sandercock and Mitchell, 2003, 2004).

## Occurrence

Generally, marketed ionophore products have been found to be safe and effective in the target species provided the approved dosage ranges. However, excessive ionophore feed concentrations have resulted in the ionophore toxic syndrome (Novilla, 1992). Toxic syndromes have occurred from the following: (1) feed-mixing errors or ingestion of premix concentrates with unsafe amounts of ionophores; (2) extra label use, either accidental or intentional, have resulted in adverse reactions in horses, dogs, rabbits, adult poultry, ostriches, camels, deer, water buffaloes, and humans; and; (3) drug incompatibilities with other compounds such as tiamulin, chloramphenicol, and macrolides such as triacetyloleandomycin have also resulted in toxicity.

Feed-mixing errors have caused most toxicity problems in animals for which ionophore use has been approved. Reports of toxicity in the target species have been reviewed (Potter *et al.*, 1984; Novilla and Folkerts, 1986; Dowling, 1992). Among the non-target species, horses appear to be the most susceptible and fish the most tolerant to high levels of ionophores. Except for a direct exposure to a monensin premix following a barn break-in, horse toxicity cases have resulted from feed contamination at the mill (Whitlock *et al.*, 1978; Ordidge *et al.*, 1979; Muylle *et al.*, 1981; Rollinson *et al.*, 1987; Matsuoka *et al.*, 1996; Bezerra *et al.*, 1999; Bila *et al.*, 2001; Peek *et al.*, 2004). Similarly, feed mill contamination of commercial dog food (Wilson, 1980; Hazlett *et al.*, 1992; Safran *et al.*, 1993), cat food (Van der Linde-Sipman *et al.*, 1999), and concentrate ration for ostriches (Baird *et al.*, 1997) have resulted in toxicoses.

In humans, there are two publications of intentional exposure to monensin. According to Kouyoumdjian and associates (2001), a 17-year-old Brazilian male admitted ingesting monensin premix (Rumensin®, exact amount unknown), probably to develop muscle. Instead he fell ill, was hospitalized, and died from acute rhabdomyolysis with renal failure. Although the amount of monensin ingested in this case was not estimated, in another case cited, two deaths among 6 people that consumed baked goods made with premix was attributed to monensin exposure of at least 10× the optimum daily dose fed to cattle. In another report from Brazil, a 16-year-old farm worker who ingested approximately 500 mg of monensin (5 g of Rumensin® 100 premix) "to become stronger" developed an early and severe rhabdomyolysis followed by acute renal failure, heart failure, and death (Caldeira *et al.*, 2001).

In target species, culprit feeds usually contained 5× the maximum approved ionophore use level in the total mix ration provided to the affected animals, with two exceptions. Toxic episodes have occurred from amending cattle and sheep rations with poultry litter (30% or above) containing maduramicin residues and incompatibilities with drugs concurrently administered via feed or drinking water. Poultry litter contained levels of maduramicin which proved to be toxic to cattle and sheep (Fourie *et al.*, 1991; Bastianello *et al.*, 1991; Shlosberg *et al.*, 1992). Various antibiotics, including tiamulin, chloramphenicol, and macrolides, and sulfa drugs, such as sulfachlorpyrazine, have been reported to potentiate ionophore toxicity (Frigg *et al.*, 1983; Weisman *et al.*, 1984; Dowling, 1992; Anadon and Reeve-Johnson, 1999). Among drug combinations that resulted in adverse effects in cattle (Basaraba *et al.*, 1999), chickens (Frigg *et al.*, 1983; Umemura *et al.*, 1995, Mazlum *et al.*, 1985), turkeys (Horrox, 1980; Weisman *et al.*, 1980, 1983; Dorn *et al.*, 1983; Broz and Frigg, 1987), and swine (Pott and Skov, 1981; Stanfield and Lamont, 1981; Wanner, 1984; Miller *et al.*, 1986), the most frequently reported drug interaction is with the pleuromotilin derivative, tiamulin. According to Meingassner *et al.* (1979), tiamulin interferes with the metabolic degradation of monensin in the liver, causing the ionophore to accumulate to toxic levels. The primary step in monensin metabolism is *o*-demethylation (Donoho, 1984) which is catalyzed by several P-450 enzymes (Ceppa *et al.*, 1997; Nebbia *et al.*, 1997). Witkamp *et al.* (1995, 1996) considered the formation of tiamulin metabolite inhibitory (MI) complexes with P-450 enzymes to be the basis of the toxic interaction, similar to that reported with macrolide antibiotics (Anadon and Reeve-Johnson, 1999). However, Szücs *et al.* (2004) reported no evidence of tiamulin MI complexes and that tiamulin directly inhibited CYP3A and two other enzymes, CYP1A2 and CYP2E1,

involved in monensin-*o*-demethylation. Whether similar alterations in ionophore metabolism occur with other drugs is not clear but is an active area of research.

The incidence of ionophore toxicity in all species appears to be low (Novilla and Folkerts, 1986). This is based on periodic reviews of product complaints submitted to the US FDA, as well as from a perusal of the literature. This is remarkable considering the widespread use of ionophore products. In the United States, more than 90% of broiler chickens and about 75% of cattle marketed yearly have consumed ionophores at least part of their lifetime. More information and reports of adverse reactions are available on monensin than for the other ionophores because of monensin's long-standing and widespread use in food animals. However, all the other ionophores can produce a similar toxic syndrome following overdosage, misuse, and drug interaction.

Over the years, several acute toxicity ($LD_{50}$) studies have been conducted in laboratory and domestic animals with monensin, lasalocid, salinomycin, and narasin. Due to a change in FDA regulations, there is limited or no $LD_{50}$ data for the other marketed ionophores (Oehme and Pickrell, 1997). Available data for most species are shown in Table 83.2.

The $LD_{50}$ of monensin varies from 214 mg/kg in broiler chickens to 1.4 mg/kg in horses, the most sensitive domestic animal species to ionophore toxicoses. In ionophore toxicoses, there is a progression of events from ingestion of a particular product. Dose and time factors influence the outcome. The greatest risk of intoxication is upon initial exposure, since animals will not consume highly contaminated feed. After an overdose, repeated daily intake of high levels of ionophores is not possible when anorexia occurs (Potter *et al.*, 1984; Matsuoka *et al.*, 1996).

Safety studies have shown that consumption by horses of complete feed containing the maximum approved use level of monensin for cattle is harmless. This is probably true for lasalocid or laidlomycin as well since there are no

confirmed reports of ionophore toxicoses in horses used in cattle feedlots. Results of acute toxicity studies with ionophores in domestic animals indicate that the horse is the most sensitive species; the chicken, least sensitive; and cattle, intermediate.

From studies in ponies given toxic doses of monensin, Amend *et al.* (1981) found that the death pattern from single, high toxic doses by gavage varied from peracute death in less than 24 h; acute death in 24–96 h; subacute death in 4–14 days; and chronic death after 14 days. The latter is not a chronic toxicity by definition, but delayed death secondary to congestive heart failure (CHF), a recognized consequence of ionophore toxicoses. Deaths from CHF may occur in some animals that survive the acute toxic episode depending upon the affected area in the heart and the cardiac reserve. In cattle, peracute deaths from monensin toxicity have not occurred. In fact, no deaths have been recorded earlier than 3 days even after high-level ($LD_{50}$) toxic exposure (Potter *et al.*, 1984).

Blood level studies suggest that horses, compared to cattle, are not able to clear monensin rapidly from the blood (Donoho, 1984). This was probably related to the oxidative efficiency of P-450 demethylating enzymes in the liver. Working with liver microsomes from horses, pigs, broiler chickens, rats, and cattle, Nebbia and associates (2001) found that horses had the lowest catalytic efficiency which may explain the greater susceptibility of horses to the ionophore-induced toxicosis, relative to the other species. However, not all levels of monensin are toxic to horses (Matsuoka, 1976; Matsuoka *et al.*, 1996). In a sub-chronic feeding study in horses, all 3 horses provided a complete ration containing 330-ppm monensin (or 300 g/ton, 10× the maximum cleared level of monensin in complete feeds for feedlot cattle) and one out of three horses given 121-ppm monensin died during the 1-month feeding period. However, 3 horses provided 33-ppm monensin have maintained typical levels of feed intake and suffered no ill-effects attributable to treatment (Table 83.3).

There are no confirmed field reports of ionophore toxicoses in horses used in cattle feedlots. After evaluating the effects of monensin in either supplements or blocks in pasture horses, Matsuoka and co-workers (1996) made the following conclusions that may apply to other marketed ionophores as well: (1) horses on pasture may consume, at initial exposure, enough supplement containing high levels of monensin to be toxic and/or lethal; (2) following an initial high-level monensin exposure, consumption of treated feed, supplement or block is negligible; and (3) horses can consume certain levels of monensin without suffering any ill effect indicative of toxicity.

**TABLE 83.3 Effect of feeding monensin in complete feed to horses for 28 days**

| Monensin level | Effect |
|---|---|
| 33 ppm (cattle use level) | Transient anorexia[a] |
| 121 ppm (broiler use level) | May be toxic |
| 330 ppm (10× cattle use level) | Lethal |

[a]Occurred in weeks 2 and 3 of the study.

## Clinical signs

Physical signs reported for ionophore toxicoses across several animal species are the following: anorexia, diarrhea, depression, hypoactivity/reluctance to move, dyspnea, leg weakness, ataxia, and recumbency. Most of these clinical signs occur in all animals studied but variations in their occurrence have been observed. For instance, diarrhea is commonly observed with monensin toxicity in cattle and poultry but has not been reported in either horses or dogs. The most consistent clinical sign in animals that have ingested toxic levels of ionophores is partial to complete anorexia (Novilla and Folkerts, 1986).

In chickens, anorexia is associated with diarrhea, drowsiness, extreme weakness, and sternal recumbency with legs extended posteriorly (Hanrahan *et al.*, 1981). In target animal safety and toxicity studies, depression of growth and feed conversion as well as higher mortality occur in broilers fed 5 times the recommended level of monensin for 8 weeks (Novilla, 2004). Broiler breeders exposed to high levels of ionophores manifest severe drops in egg production, anorexia, depression, paralysis, and death in sternal recumbency (Perelman *et al.*, 1993; Lin, 1995). Similar signs were reported in turkeys with toxicity induced by monensin, salinomycin, and narasin (Stuart, 1978; Beck and Harries, 1979; Salyi *et al.*, 1988; Ficken *et al.*, 1989). Mortality was variable but high death losses (up to 96.7%) were recorded with salinomycin (Halvorson *et al.*, 1982).

In cattle, clinical signs of monensin toxicosis include anorexia, diarrhea, ataxia, recumbency, depression, and non-responsiveness to visual stimuli (Potter *et al.*, 1984; Schweitzer *et al.*, 1984; Van Vleet *et al.*, 1983c). There is a definite correlation between onset of clinical signs and amount of monensin consumed. All intoxicated cattle manifest partial to complete anorexia. Severely intoxicated animals develop anorexia within 24 h. Animals exposed to lower levels may take up to 48 h to develop anorexia. Diarrhea usually is evident in 24–48 h in animals receiving high doses of monensin. Exposure to low doses may result in a delay of up to 5 days in the onset of diarrhea. Onset of depression follows a similar pattern, being observed by day 3 in animals receiving excessive monensin overdoses while being observed after 1 week in animals receiving less than excessive overdoses. Rapid breathing and ataxia may be present only in animals that have consumed extremely high levels. In cattle, death occurs without any manifestations of struggle.

Galitzer and co-workers (1982) found that lasalocid-intoxicated cattle manifested early signs of forced watery diarrhea, muscle tremors, and greater cardiac and respiratory rates followed by or concurrent with anorexia. Delayed signs of cardiac insufficiency were evident 7–10 days after administration of the toxic dose. The temporal occurrence of clinical signs (Table 83.4) and mortality from ionophore toxicity was clearly documented by Potter *et al.* (1984) in a multiple bolus dosing trial with monensin in cattle.

The onset and severity of toxic effects induced by monensin were dose-related. In the study, anorexia was the most consistent clinical sign of toxicity and no deaths occurred earlier than 4 days after exposure to high toxic doses of monensin. However, multiple bolus dosing does not simulate actual field conditions since repeated exposure to toxic levels is not possible when anorexia occurs. Further, the onset and severity of toxicity from bolus dosing is different than that via feed (Buck *et al.*, 1976)

Sheep and goats have clinical signs similar to cattle (anorexia, diarrhea, ataxia) but affected lambs frequently exhibit labored breathing, frothing at the mouth, and kicking at the abdomen (Confer *et al.*, 1983; Newsholme *et al.*, 1983; Bounque *et al.*, 1986; Egyed *et al.*, 1987; Agaoglu *et al.*, 2002). Dogs with ionophore toxicoses become weak and develop a rapid onset of paresis progressing to flaccid paralysis of the anterior and posterior limbs, tongue laxity, and dyspnea (Wilson, 1980; Safran *et al.*, 1993; Condon and Mckenzie, 2002; Segev *et al.*, 2004). In pigs, anorexia, diarrhea, lethargy, dyspnea, ataxia, knuckling at the fetlock, and myoglobinuria were present prior to lateral recumbency and death from ionophore toxicoses (Van Vleet *et al.*, 1983a, b; Miller *et al.*, 1986; Van Halderen *et al.*, 1993; Plumlee *et al.*, 1995).

As in cattle and other species, anorexia is the first and most consistent clinical sign finding (Table 83.5) in the horse with ionophore toxicoses.

Diarrhea has not been observed with either monensin or lasalocid but was reported with salinomycin and narasin (Matsuoka *et al.*, 1996; Whitlock *et al.*, 1978; Hanson *et al.*, 1981; Novilla and Folkerts, 1986; Rollinson *et al.*, 1987). Profuse sweating was also observed with monensin, salinomycin, narasin, and laidlomycin but not with lasalocid toxicity. Horses with leg weakness and ataxia generally progress to recumbency. Once recumbent, horses frequently attempt to rise with trashing of the limbs until death supervenes. This is in contrast to cattle that die without signs of struggling.

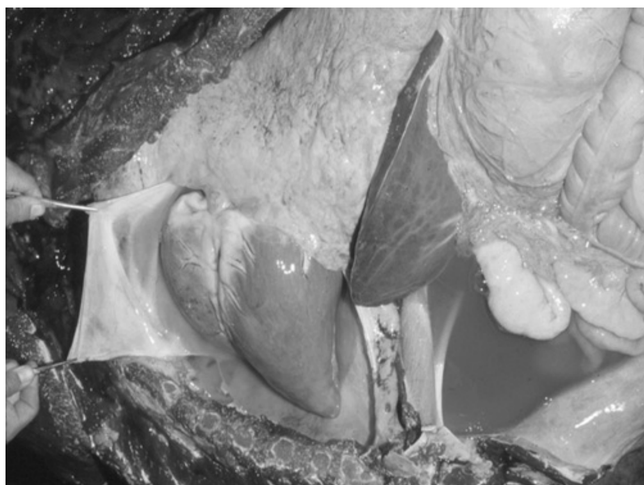

**FIGURE 83.5** Thoracic and abdominal viscera from a mare that died 7 days following a single gavage dose of 1.65 mg monensin/kg body weight. Note the fluid accumulation in the body cavities and the pale areas and epicardial hemorrhages on the heart. This figure is reproduced in color in the color plate section.

## Postmortem findings

Necropsy findings in animals with ionophore toxicoses include hemorrhages and pale areas in the heart, pale areas in some limb muscles, pulmonary edema, hydrothorax, ascites, and inflammation of the stomach and intestines (Nation *et al.*, 1982; Van Vleet *et al.*, 1983a, b, c; Galitzer *et al.*, 1986b; Salles *et al.*, 1994). Animals that die soon after exposure often will have no lesions, since they had not had time to develop or they may be masked by postmortem changes. Those with lethal doses surviving longer than a week may have hydropericardium, pulmonary edema, hydrothorax, ascites, reddish-mottled liver, and subcutaneous edema of the abdomen and limbs (Figures 83.5).

At necropsy, cutting the ventricular and thigh muscles transversely often shows the diffuse pallor (Figure 83.6) of myonecrosis induced by toxic levels of ionophores. Skeletal muscle lesions may be quite severe in sheep, pigs, and dogs, moderate in cattle and minimal to slight in horses. For this reason, myoglobinuria, evidenced by red urine, has been observed in pigs, sheep, and dogs but not in cattle or horses.

## Histopathologic findings

Target organs damaged by toxic doses of monensin and other ionophores were identified to include the heart and skeletal muscles in all species studied (Todd *et al.*, 1984; Novilla and Folkerts, 1986; Ficken *et al.*, 1989; Van Vleet *et al.*, 1991; Dowling 1992). In addition, neurotoxic effects have been reported for lasalocid (Shlosberg *et al.*, 1985; Safran *et al.*, 1993), narasin (Novilla *et al.*, 1994), and salinomycin (Van der Linde-Sipman *et al.*, 1999). The

**FIGURE 83.6** Diffuse pallor in cross sections of the heart from the same mare described in Figure 83.5 legend. This figure is reproduced in color in the color plate section.

development of muscle lesions varies among species. The heart is primarily affected in horses, skeletal muscle in pigs and dogs, and there is about equal tissue predilection in rats, chickens, and cattle. Morphologic effects include degeneration, necrosis, and repair of cardiac and skeletal muscle fibers with a variable inflammatory component and secondary lesions of CHF. Neuropathic changes occurred in peripheral nerves and the spinal cord. Focal swelling, fragmentation, loss of axons, and formation of digestion chambers filled with macrophages were observed in both sensory and motor nerves, and there was vacuolation with swelling, degeneration, and fragmentation of myelin sheaths and axons in the spinal cord.

The most important change is a toxic myopathy characterized by focal areas of degeneration, necrosis, and repair in cardiac and skeletal muscles with a variable inflammatory component (Van Vleet *et al.*, 1991; Novilla and Folkerts, 1986). Muscle lesions are similar to those described for compound A204, the first polyether antibiotic tested at Lilly Research Laboratories (Todd *et al.*, 1970). Doses and time

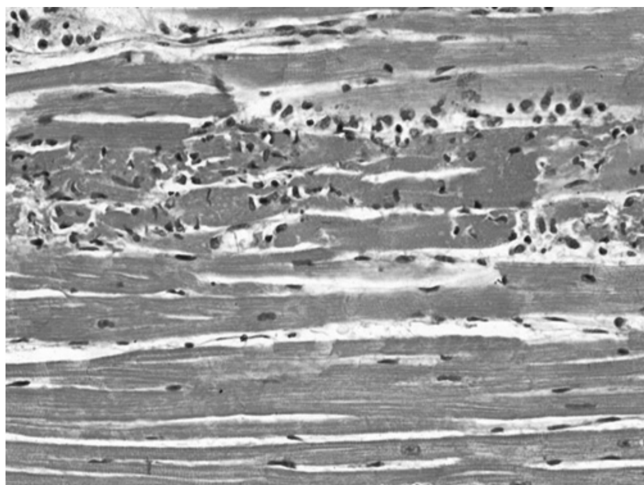

FIGURE 83.7 Early necrotic focus in the left ventricle of a gelding that died 20h following gavage with 2.5mg monensin/kg body weight. Necrotic muscle fibers have sparse infiltration of neutrophils and lymphocytes. H&E. Original magnification ×64. This figure is reproduced in color in the color plate section.

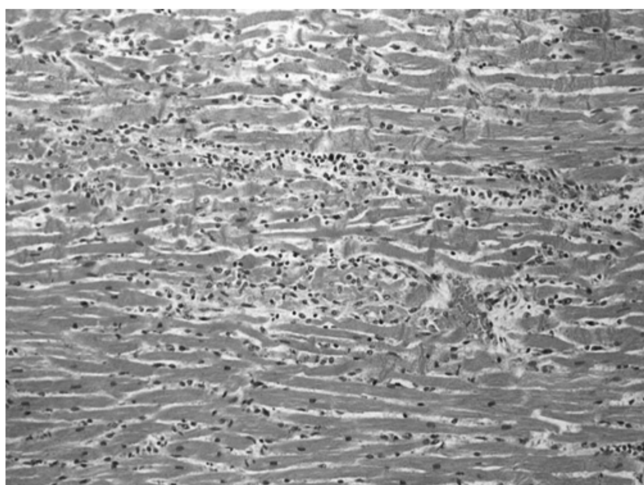

FIGURE 83.8 Larger foci of myofiber necrosis with contraction bands in the interventricular septum from a horse euthanized 72h following a single oral dose of 1.65mg monensin/kg body weight given by gavage. More cellular infiltrates with lymphocytes, macrophages, and few eosinophils are present. H&E. Original magnification ×10. This figure is reproduced in color in the color plate section.

factors influence the severity and distribution of lesions in ionophore toxicoses (Figures 83.7 and 83.8).

Generally, no significant lesions are seen by light microscopy in animals that die immediately, and animals that die after an acute course may have only a few scattered degenerated fibers in the heart and highly active muscles, such as the diaphragm. Lesions are most pronounced within 7–14 days following ingestion of a toxic dose and are accompanied by profound attempts at repair. Skeletal muscle fibers regenerate rapidly, and lesions are completely healed in about a month (Figure 83.9). Heart muscle fibers

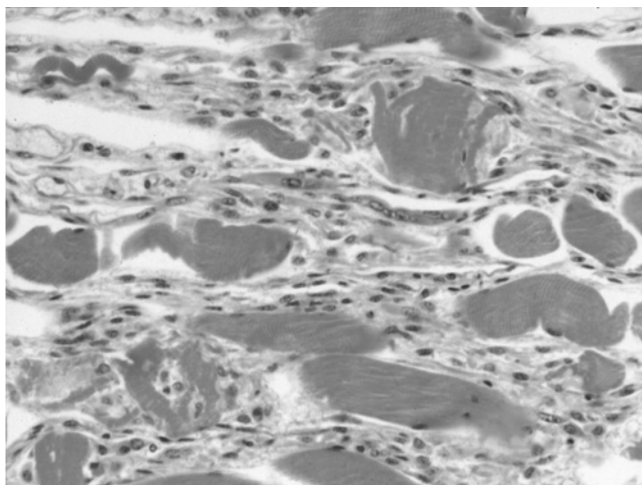

FIGURE 83.9 Skeletal muscle from a steer that died 6 days after a gavage dose of 39.8mg monensin/kg body weight. Notice the fragmented and regenerating fibers. H&E. Original magnification ×80. This figure is reproduced in color in the color plate section.

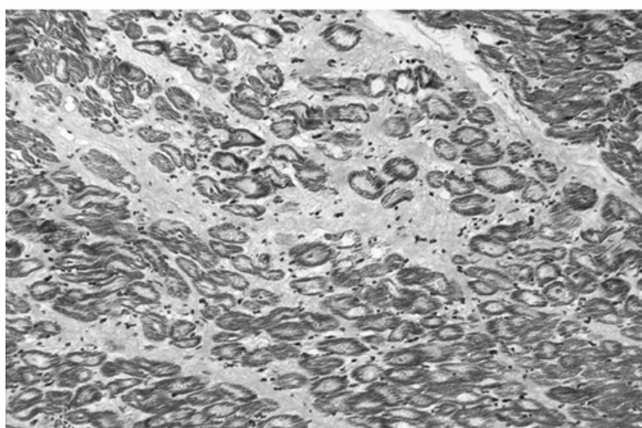

FIGURE 83.10 Hearts from animals that survived acute ionophore toxicity. Top: section of left ventricle with focal interstitial fibrosis from another steer, cohort of that described in Figure 83.9 legend, euthanized 28 days after a gavage dose of 39.8mg monensin/kg body weight. H&E. Original magnification ×20. Bottom: interstitial fibrosis in the left ventricle from a gelding that survived a gavage dose of 2mg monensin/kg body weight for 4 months. Masson's trichrome. Original magnification ×32. This figure is reproduced in color in the color plate section.

(Figure 83.10) do not regenerate, but repair takes place by replacement fibrosis. Secondary lesions of CHF, including heart dilatation and hydropericardium, lung edema, liver necrosis, and fluid accumulation in the thoracic and abdominal cavities, may be present, depending upon the severity of heart damage and the potential cardiac reserve.

Observations to date indicate that in horses, the heart suffers the greatest damage from monensin toxicoses with little or no involvement of skeletal muscles. This finding is in contrast to dogs and pigs in which the lesions are most pronounced in skeletal muscles. Chickens, cattle, and rodents have about equal predilection for cardiac and skeletal muscle lesions.

## Other laboratory findings

Mitochondrial swelling, myelin figures, and lipid vesicles were observed ultrastructurally in cardiac and skeletal muscles of ponies given monensin at 4 mg/kg and observed for 79 h (Mollenhauer *et al.*, 1981, 1984). Early degenerative changes of sarcoplasmic vascuolation from swollen mitochondria and accumulation of lipid were described in cattle and in pigs with monensin toxicosis (Van Vleet and Ferrans, 1983, 1984). Severely injured mitochondria had marked swelling, disrupted cristae, and dense matrical granules. Scattered myelin figures were present in muscle cells with numerous disrupted mitochondria. Subsequently necrosis occurred in degenerated myocytes and was characterized by dense fibers with intact sarcomeres or disrupted fibers with hypercontraction bands. Necrosis was followed rapidly by extensive macrophage infiltration with lysis of disrupted organelles and contractile material. Similar ultrastructural findings were observed in hearts and skeletal muscles of sheep given monensin (Confer *et al.*, 1983; Anderson *et al.*, 1984) and in skeletal muscles of broilers simultaneously given triacetyloleandomycin in the drinking water and monensin in the feed (Umemura *et al.*, 1984). Regeneration as evidenced by myoblast proliferation was observed as early as 4 days post-treatment in pigs and sheep.

Hematologic parameters are not significantly affected by ionophore toxicosis (Van Vleet *et al.*, 1983a, b, c; Condon and McKenzie, 2002, Segev *et al.*, 2004). Elevation of serum enzymes, notably creatine kinase, lactate dehydrogenase, and aspartate transaminase may indicate damage to cardiac and skeletal muscles (Wilson, 1980; Amend *et al.*, 1981; Van Vleet *et al.*, 1983b, c; Galitzer *et al.*, 1986a; Hall, 2001). Alkaline phosphatase, inorganic phosphorus, and total bilirubin levels are also higher, while serum levels of calcium and potassium are lower. The progressive hypokalemia and attendant cardiac conduction disturbances demonstrated in ponies were considered the life-threatening events in early acute monensin toxicosis (Amend *et al.*, 1981).

## Diagnosis and differential diagnosis

Since all ionophores in the market place are likely to produce a similar toxic syndrome in overdosage and misuse situations, six important criteria must be considered before a diagnosis of toxicity is given (Beck and Harries, 1979; Novilla and Folkerts, 1986). These include: (1) history of feed-related problem, usually affecting a group of animals; (2) ionophore laboratory assays; (3) clinical signs manifested during the toxicity episode; (4) gross postmortem lesions; (5) microscopic pathology; and (6) exclusion of nutritional, infectious, and other toxic factors.

History assumes great significance when the problem is connected to the introduction of newly formulated feed or supplement to the herd or flock. Since clinical signs and lesions are not pathognomonic, feed analysis for the amount and type of ionophore in the ration is necessary for diagnosis. With the availability of seven ionophores in the marketplace, the use of an efficient and highly selective laboratory assay is indicated. Newer methods have been developed to determine one or more ionophores in feeds and tissues (Hormazabal *et al.*, 2002; Bertini *et al.*, 2003; Ebel *et al.*, 2004). Several samples of the feed should be submitted for analysis, including residual material from the feeder, trough, auger, or feed bin. Feed assays may prove exposure to a particular product but significantly higher than the recommended levels must be found for a confirmatory diagnosis. Otherwise, concurrent use of an incompatible drug must be documented. In the absence of proof of a gross feed-mixing error, a wide list of differential diagnoses needs to be excluded in order to return a presumptive diagnosis.

Initially, ionophore toxicoses may be suspected when there is a history of a feed-related problem in a group of animals; clinical signs of anorexia, diarrhea, labored breathing, depression, locomotory disorder, recumbency, and death; lesions affecting heart and skeletal muscles; or CHF. The clinical signs and lesions induced by toxic levels of ionophores are not pathognomonic. However, a history of recent introduction of newly formulated feed or supplement to a flock or herd in which signs and lesions are present may cause one to suspect that acute intoxication has occurred. Dose and time factors influence the severity and distribution of lesions. Animals that die soon after exposure may not have muscle lesions discernible by light microscopy. Lesions are likely to be found in animals that survived longer than a week. The most active skeletal muscles may be involved when the heart is not affected or is only slightly affected. Since changes can be missed because of their focal distribution, more intense tissue sampling to include one section each of the atria, ventricles, and interventricular septum of the heart, the diaphragm, and muscles of the abdomen and thigh is desirable. Some animals with substantive heart damage from very high levels of monensin and other ionophores may later develop CHF.

Although a presumptive diagnosis of ionophore toxicosis can be made based on history, clinical signs, lesions, and considerations of differential diagnosis, specific assays are needed for confirmatory diagnosis. With seven ionophores currently in use, the need for confirmatory laboratory assays cannot be overemphasized. In monensin toxicosis, values greater than 5 times the recommended use level in the feed provided affected animals are usually confirmatory. Assays on stomach contents from peracute and acute cases of toxicity can prove exposure but values obtained have been low. Only minimal residues of monensin have been detected in target tissues of cattle and chickens given monensin (Donoho, 1984; Atef *et al.*, 1993). Further, blood levels of monensin are low or undetectable even in intoxicated animals, and accumulation in target tissues does not occur.

Ionophore toxicosis may be confused with acute infectious diseases, deficiencies, and other intoxications (Kingsbury, 1964; Hubert and Oehme, 1968; Beck and Harries, 1979; Van Vleet *et al.*, 1983a, b, c; Novilla and Folkerts, 1986; Dowling, 1992). In the differential diagnosis of monensin toxicosis, myopathic conditions should be considered first. In cattle, these would include: (1) ionophore toxicoses, (2) vitamin E and selenium deficiencies, (3) poisonous plant ingestion e.g., senna, coyotillo, white snakeroot, vetch, and (4) the common, yet puzzling, sudden death syndrome with myocardial necrosis. Ionophore toxicosis usually involves an accompanying history of feed supplementation or feed change and usually involves many animals. Clinical signs are anorexia, diarrhea, lethargy, ataxia, and the suggestion of damage to striated muscles. Vitamin E and selenium deficiency occur sporadically and produce prominent degeneration and necrosis with calcification of cardiac and skeletal muscles. Plant poisonings are usually localized to areas where the toxic plants are indigenous. For instance, coffee senna (*Cassia occidentalis*) poisoning occurs in the southeastern United States. It may cause anorexia, diarrhea, and the production of dark urine, but generally causes more pronounced lesions in skeletal muscles than in the heart. The coyotillo plant (*Karwinskia huntholdtiana*) in southwest Texas and Mexico produces limberleg in sheep and goats characterized by progressive weakness of the legs, muscular incoordination, recumbency, respiratory distress, and death. Lesions are observed both in cardiac and skeletal muscles as well as peripheral nerves and the liver. White snakeroot (*Eupatorium rugosum*), a plant indigenous to much of eastern Canada and the United States, causes "trembles" in goats, sheep, cattle, horse, and swine. Cardiac and skeletal muscle lesions may be present in animals that ingested this plant. However, with trembles there is constipation, blood in feces, an odor of acetone in the breath, and severe fatty degeneration in the liver and kidney that are not seen in ionophore toxicities. Hairy vetch (*Vicia villosa*) also produces myocardial necrosis but, unlike monensin toxicosis, it produces dermatitis, conjunctivitis, and abortion as well as lesions in the kidneys, adrenal glands, lymph nodes, and thyroid gland. The syndrome of sudden death with myocardial necrosis in cattle, especially calves, is common but sporadic in occurrence and is associated with lesions in cardiac but not skeletal muscle (Bradley *et al.*, 1981). Hence, clinical history and detailed pathologic studies will help distinguish among ionophore toxicosis, acute infectious diseases, deficiencies, and other intoxications.

From a clinical standpoint, respiratory diseases, particularly infectious bovine rhinotracheitis and the shipping fever complex, are initially considered in the differential diagnosis for cattle because of the respiratory difficulties that occur with ionophore toxicosis. At necropsy, however, pneumonic lesions are consistent with these diseases. Animals with acute bovine pulmonary edema and emphysema or fog fever, nitrogen dioxide intoxication, or rape, turnip, or kale poisoning also exhibit respiratory difficulties; but, in these conditions, gross lesions will include severe interstitial and interlobular emphysema or pneumonia or both rather than edema. The incoordination, stiff wobbly gait, and loss of visual reflexes may lead one to suspect polioencephalomalacia and thromboembolic meningoencephalitis but, in these conditions, histologic lesions present in the brain are confirmatory. Unequivocal central nervous system lesions have not been found in cases of monensin toxicity in any species. However, lesions in the spinal cord and peripheral nerves occurred with lasalocid toxicosis in chickens (Shlosberg *et al.*, 1985; Perelman *et al.*, 1993). Peripheral neuropathic changes have also been reported in cats exposed to salinomycin-contaminated feed (Van der Linde-Sipman *et al.*, 1999) and in dogs given narasin (Novilla *et al.*, 1994). Salt poisoning will cause nervous signs, paralysis, and diarrhea, but knowledge that insufficient amounts of water were available to the animals will also point to this problem. Eosinophilic meningoencephalitis is pathognomonic for salt poisoning in pigs, but this lesion does not occur in other species. Laboratory procedures used to confirm a diagnosis include assays of serum, cerebrospinal fluid, and brain tissue for sodium concentrations (Buck *et al.*, 1976). In cattle, urea toxicosis must be considered when sudden collapse, bloat, violent convulsions, terminal tetanic spasms, and high death losses occur within 10 min to 4 h from exposure to newly formulated feed. Deaths occurring earlier than 72 h have not been reported in cattle gavaged with high doses of monensin (Potter *et al.*, 1984).

In poultry, differential diagnoses should include nutritional (focal) myopathy, coffee senna toxicity, botulism, sodium chloride (salt) toxicity, mycotoxicosis by cyclopiazonic acid, and other myopathic mycotoxins, round heart disease, and in the turkey, the knockdown (downer) syndrome. Although no striated muscle lesions are produced in botulism and sodium chloride toxicity, clinical signs of limberneck and lesions of "water belly" may be confused

with ionophore toxicoses. On the other hand, birds affected with salt poisoning may have enlarged hearts or have enlarged pale kidneys from urate nephrosis (Swayne *et al.*, 1986). Monensin *per se* does not produce "barebacks" in broiler chickens, and downers among replacement birds may be suffering from viral arthritis. Therefore, this common reovirus infection must be excluded as a cause of the problem in chicken flocks. In commercial turkeys reared in confinement, focal myopathy has been attributed to deficiencies in vitamin E or selenium associated with rapid growth (Maronpot *et al.*, 1968; Wilson *et al.*, 1990). Nutritional myopathy may mimic skeletal muscle lesions induced by ionophore toxicoses; but unlike those of nutritional myopathy, ionophore-induced lesions are monophasic and polyfocal with little or no mineralization. Muscle lesions also occur in deep pectoral myopathy (Siller 1985), coffee senna toxicity (Simpson *et al.*, 1971), and toxicoses from the mold toxins, cyclopiazonic acid (Cullen *et al.*, 1988) and moniliformin (Engelhardt *et al.*, 1989). Their clinical presentation and presence of other lesions will help distinguish these conditions.

Round heart disease, also known as Roundheart–Edema–Ascites syndrome or spontaneous cardiomyopathy, occurs sporadically in turkeys and other fowl (Gough *et al.*, 1981; Czarnecki 1984; Julian *et al.*, 1992). Clinical signs indicate the presence of heart failure but the exact cause has not been determined. A genetic predisposition has been suggested because it is more common in certain lines of turkeys, particularly those having a rapid rate of early muscle development. Some of the predisposing factors include low levels of oxygen and high levels of carbon dioxide in the incubator, poor brooder house ventilation, and overcrowding during transport. Exposure to these factors may occur days or weeks prior to onset of illness. In contrast, monensin toxicity occurs as a sudden outbreak in a flock of birds accidentally provided toxic levels due to a feed-mixing error. Among birds that survive the acute toxic episode, a few, depending upon the extent and location of heart damage and the potential cardiac reserve, may subsequently develop dilatation of the heart and secondary signs of CHF.

Another condition that needs to be distinguished from monensin toxicity is the turkey knockdown syndrome. Turkey knockdown has been defined as any condition affecting the neuromuscular system to the extent that a bird is unable to stand or walk (Wages, 1993). A necrotizing myopathy, particularly of the rear limbs, has been reported in turkeys with the knockdown syndrome (Cardona *et al.*, 1992, 1993). Unfortunately, striated muscles have limited responses to injury (Van Vleet *et al.*, 1991) and lesions induced by any ionophore, including monensin are not pathognomonic (Novilla, 1992). Although monensin feed inclusion rates in knockdown cases are within or slightly above the maximum recommended level of 99 ppm (Wages and Ficken, 1988; Cardona *et al.*, 1992, 1993) monensin has been implicated as a causative factor because the clinical and pathologic findings are similar to those induced by monensin toxicity. However, unlike monensin toxicity, the turkey knockdown syndrome is characterized by: (1) low incidence and fatality rates; (2) acute onset of paresis/paralysis; (3) no anorexia, birds will eat if able to reach feeders; (4) no diarrhea; (5) affected birds are alert; (6) unable to vocalize; (7) presence of widespread skeletal muscle lesions that are subacute to chronic in character, generally no heart lesions; and (8) rapid recovery following change of feed. These observations were confirmed in an epidemiological case controlled study of knockdown cases in the Shenandoah Valley of Virginia that evaluated various factors, including management, environment, health, feed, water, pathology, and clinical pathology analytes (Evans *et al.*, 2000). Serum vitamin E levels were significantly lower in affected birds (Meldrum *et al.*, 2000). Feed and/or water intake alterations were highly correlated with the incidence of turkey knockdown and modification of practices affecting feed/water intake reduced the incidence of knockdown in one farm from 6 in 1999 to 0 in 2000.

In pigs, vitamin E and selenium deficiency, gossypol poisoning, and porcine stress syndrome (PSS) should be considered in the differential diagnosis since skeletal or cardiac lesions may be found in these conditions (Van Vleet *et al.*, 1984b; Van Vleet and Ferrans, 1984). In monensin toxicosis, the striated muscle lesions appear more frequently and are more severe in skeletal muscle than in cardiac muscle. Myoglobinuria may also be present. Widespread cardiac and skeletal muscle lesions, vascular damage, dietetic hepatosis, and gastric ulceration may be found in vitamin E and selenium deficiency. With PSS, cardiac, and skeletal muscle lesions may or may not be observed following a history of stress.

For horses, the exertional myopathies, such as equine rhabdomyolysis (Monday morning disease) and hyperkalemic periodic paralysis, plant poisoning from coffee senna and white snakeroot should be excluded along with blister beetle intoxication, colic, and laminitis (Whitlock *et al.*, 1978; Amend *et al.*, 1981; Novilla and Folkerts, 1986). Complete herd history, clinical examination, successful supportive treatment, and necropsy may help differentiate these conditions from ionophore toxicoses.

## TREATMENT

When ionophore toxicity is suspected, a feed change to a non-ionophore medicated ration must be made immediately and the affected group(s) of animals maintained on this ration until all diagnostic procedures are completed. At the present time, there is no known antidote or treatment for ionophore toxicity (Table 83.6). Although previous

**TABLE 83.6** Some biomarkers of ionophore toxicity

| | |

| • Elevated<br>– AST<br>– CK<br>– LDH<br>– Alkaline phosphatase<br>– BUN<br>– Bilirubin | • Decreased<br>– Calcium<br>– Potassium<br>• No change<br>– Sodium |

antidotal trials failed, the search continues (Mitema *et al.*, 1988). Nonetheless, it may be difficult to find a drug that can block up to four pathogenetic mechanisms, acting singly or in concert, that are involved in the toxicoses. Therapeutic interventions have been largely supportive. For horses, Amend *et al.* (1981) recommended supportive treatment with mineral oil, activated charcoal, and aggressive fluid and electrolyte replacement with potassium and phosphorus supplementation, including means to reduce cardiac work. However, supportive therapy may not be practical on a herd or flock basis.

Van Vleet and co-workers (1983a, 1987) obtained protection against the development of *clinical* monensin toxicity in pigs treated with selenium and vitamin E (selenium as selenite at 0.25 mg/kg and vitamin E as a-tocopherol acetate at 17 lU/kg) prior to a single oral dose of 50 mg monensin/kg ($LD_{50}$ 16.7 ± 3.57 mg/kg). A similar regimen in cattle administered toxic doses of monensin provided only partial protection (Van Vleet *et al.*, 1985) but clinical signs in pigs with tiamulin-induced salinomycin toxicity were ameliorated following administration of vitamin E. The protection against the toxicoses was theorized to be produced by stabilization of cellular membranes since selenium and vitamin E are known to prevent and control peroxidation-mediated cellular injury (Tappel, 1981; Van Vleet, 1986). Monensin, like all polyether carboxylic ionophores, is lipophilic and may produce dose-dependent membrane perturbations and increased lipid peroxidation, which could lead to degradative processes. Further studies are needed to determine whether vitamin E and selenium administration may have an important role in the prevention and treatment of ionophore toxicoses.

Until proper and effective therapy is available, prevention of ionophore toxicoses by (1) proper use from the implementation of good feed manufacturing and feeding practices at the feed mill and farm level; (2) avoidance of overdosing of feeds for approved species, which may carry over to feeds for non-target species; and (3) adherence to species restrictions will help prevent the adverse effects associated with this class of compounds.

## CONCLUSIONS

Seven ionophores – monensin, lasalocid, salinomycin, narasin, maduramicin, laidlomycin, and semduramicin – are marketed globally for use as anticoccidial drugs for poultry and/or growth promotants in ruminants. Off-label usage of ionophore products is known to occur since other uses continue to be investigated and applied in many countries. It is likely that basic and applied research on these versatile compounds could lead in the future to product line extensions to other target species and potential development of novel therapeutics for unmet needs in veterinary and human medicine.

Generally, these feed additives have been found to be safe and effective in target animal species, but toxic syndromes have resulted from overdosage, misuse, and drug interaction. Among the domestic species, horses are the most sensitive to ionophore toxicoses; poultry, the least sensitive; and cattle, intermediate. However, even for the horse, there is a threshold level of exposure below which no adverse effects are observed. Consumption of complete feed containing the maximum approved use levels of either monensin, lasalocid, or laidlomycin is harmless. Dose and time factors influence the severity and outcome of the toxic exposure. Results of controlled studies and confirmed field reports of toxicity indicate that the greatest risk of intoxication is upon initial exposure to ionophore-containing feed or supplement. Following sublethal exposure, consumption of culprit feed or supplement is negligible because of anorexia. Animals that die acutely after high levels of exposure often will have few or no lesions. Those that die later have profound striated (cardiac and/or skeletal) muscle lesions and changes secondary to CHF in some animals that survive the acute toxic episode.

Confirmatory diagnosis requires efficient laboratory assays to determine the identity and amounts of the ionophore involved and a thorough consideration of differential diagnosis. These cannot be overemphasized. There is no known antidote or specific treatment for ionophore toxicoses and treatment is largely supportive. Judicious use, avoidance of overdosing, and adherence to species recommendation will enhance livestock production and help prevent the occurrence of adverse effects associated with this class of compounds.

# Nonprotein nitrogen (urea) and hyperammonemia

*Patricia A. Talcott*

## INTRODUCTION AND BACKGROUND

Nonprotein nitrogen (NPN) intoxication is not an uncommon occurrence in ruminants. It has long been recognized that ruminal microbes of cattle and sheep can utilize NPN to synthesize proteins that can replace a portion of their total dietary protein requirements. Given that feeding NPN sources are typically cheaper than feeding expensive true protein, the practice of adding NPN to ruminant's diets is relatively commonplace. Feed grade urea ($CO[NH_2]_2$) is the cheapest, most effective, and most available nitrogen source. Other NPN compounds, which may be less readily available and more expensive, include ammonium acetate ($CH_3CO_2NH_4$), ammonium bicarbonate ($NH_4HCO_3$), ammonium carbamate ($NH_2CO_2NH_4$), ammonium lactate ($CH_3CHOHCO_2NH_4$), ammonium sulfate ($[NH_4]_2SO_4$), monoammonium phosphate ($NH_4H_2PO_4$), biuret ($NH_2CONHCONH_2$), dicyanodiamide ($NH_2C[NH]NHCN$), and diammonium phosphate ($[NH_4]_2HPO_4$). All these NPN sources consist of varying nitrogen content and protein equivalent; so addition of these products into the diet requires stringent nutritional dietary examination. Many of these supplements are solids and can be directly mixed into the mineral or grain component of the diet. Some, such as urea, can be added to molasses-based liquid products or into solid mineral blocks. Ammoniated beet pulp, citrus pulp, straw, silage, molasses, and rice hulls have also been used to supplement the protein content of a ruminant's diet. Ruminants can also be poisoned by gaining access to some fertilizers that can contain over 40% urea.

## TOXICITY

All mammalian species are potentially susceptible to NPN poisoning via the consumption of ammonium-containing feeds, if the dose is high enough. When urea is added to the ruminant's diet, it is rapidly broken down by bacterial urease in the rumen to ammonia. The ammonia is then utilized by the rumen bacteria, along with soluble carbohydrates, to synthesize amino acids and proteins (hence the name "nonprotein nitrogen"). Most of the excess ammonia produced is protonated to the ammonium ($NH_4$) ion and is trapped in the rumen. If this excess ammonia production continues, the rumen pH increases. When ammonia concentrations become too high too quickly, significant amounts get absorbed systemically. In the bloodstream, ammonia travels via the portal circulation to the liver where it is incorporated into the urea cycle and urea is then excreted in the urine via the kidneys or secreted into the saliva. Toxicities occur when this entire system becomes overwhelmed resulting in a clinical significant hyperammonemia. Excess ammonia has been shown to inhibit the citric acid cycle (Hatch, 1977), to cause a lactic acidosis, and to interfere with cerebral energy metabolism and the sodium–potassium ATPase pump. The systemic metabolic acidosis is thought to be related to a hyperkalemia, and it is this abnormality that can ultimately lead to cardiac arrest.

Factors that potentially can predispose ruminants to poisonings with these compounds include low energy diets, high rumen pH (e.g., rumen impaction), elevations

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

in body temperature (enhances urease activity), dehydration, stress, concurrent disease, alterations in rumen microflora, and hepatic insufficiency. The lack of a readily available supply of soluble carbohydrates markedly affects the rumen bacteria's ability to utilize the ammonia. It is generally recommended to slowly introduce increasing levels of NPN in the diet over a period of several days to allow the rumen bacteria to adapt to the ammonia source. Most poisonings in ruminants occur as a result of inadequate implementation of an adaptation period, improper mixing of the supplement into the diet, and unlimited/unrestricted access to palatable liquid NPN supplements. NPN poisoning in monogastrics is not common.

Toxic and lethal doses are difficult to establish in ruminants due to all the predisposing factors that can enhance or decrease their sensitivity to these compounds. The oral lethal dose for urea in horses is 4.0 g/kg BW and the oral lethal dose for ammonia salts is 1.5 g/kg BW (Hintz *et al.*, 1970). A reported oral toxic dose for urea in nonacclimated cattle is 0.44 g/kg BW (Word *et al.*, 1960), whereas a lethal dose is in the 1.0–1.5 g/kg BW range (Osweiler *et al.*, 1976). Adapted cattle can tolerate much higher levels in their diets. Biuret is considered one of the safest of NPN compounds, and a reported lethal dose in cattle is 8.0 g/kg BW (Haliburton and Morgan, 1989). A single dose of 116 g of urea caused clinical signs of toxicity in cattle, whereas a dose of 57 g did not (Dinning *et al.*, 1948). Davis and Roberts (1959) reported that 0.3 g/kg BW urea was toxic to unacclimated cattle.

## CLINICAL SIGNS

The onset of clinical signs following introduction of a toxic NPN source into an animal's diet can be extremely quick; frequently within 30 min. A delay in the onset of clinical signs can be due to a wide variety of factors, including dose, method of introduction, and degree of adaptation. In general, most cases of NPN poisoning in ruminants involve some history of some type of "recent" feed change. Commonly reported clinical signs include uneasiness and ataxia, muscle tremors, excessive salivation, weakness, labored breathing, abdominal pain, and bloat. The progression of clinical signs is generally quite rapid and recumbency, convulsions and death typically ensue within 4 h. Hyperthermia, marked jugular pulse, cardiac arrhythmias, vomiting/regurgitation, and cyanosis have also been reported (Haliburton and Morgan, 1989). Rarely do animals survive once clinical signs start without some type of rapid treatment intervention.

## DIAGNOSTIC CRITERIA

The diagnosis of NPN intoxication rests mainly on a compatible history of exposure to a NPN source, compatible clinical signs with rapid progression to death, and clinical diagnostic laboratory data. Rarely do you find significant postmortem changes. Common findings at necropsy include generalized congestion of visceral organs, evidence of bloat, and mild to moderate pulmonary edema. Subepicardial and myocardial hemorrhages have also been reported. There are several diagnostic aids that can assist the veterinarian in confirming an NPN poisoning.

First, assessing the rumen pH either antemortem or shortly after death is a very useful tool. In animals succumbing to NPN intoxication, rumen pH is typically greater than 8–10. A markedly elevated rumen pH postmortem will gradually revert to normal over time due to continuous microbial activity postmortem. Other causes of excessive rumen pH can include rumen impactions or other problems leading to a "dead" rumen, or excessive salivary secretions.

Elevated ammonia concentrations in various biological specimens (e.g., serum, plasma, ocular fluid, and abomasal or rumen fluid) can be analytically confirmed by various methods. All samples should be collected and frozen immediately for delivery to the diagnostic laboratory, to prevent loss of the highly volatile ammonia. Samples collected postmortem should be retrieved shortly after death; decomposition of tissues can cause either increases or decreases in ammonia levels which can muddle the interpretation. Ammonia concentrations typically greater than 1.0 mg/dl in serum or plasma and greater than 80 mg/dl in rumen or abomasum contents are diagnostically significant.

Lastly, ammonia, nitrogen, or urea levels can be assessed in the "suspect" feed source. These analyses should be quantitative, and should assist the veterinarian in determining whether a mixing error was responsible for the clinical problem.

## TREATMENT

Rapid intervention is necessary in order for affected animals to survive. This is rarely possible except in experimental settings. Poisonings generally occur on a large scale (rarely a single animal problem) and in a setting (e.g. feedlots, pastures typically located in more rural settings) where it is nearly impossible to implement appropriate rapid therapies. Treatments are generally thought to be effective if initiated within 20 min after the onset of clinical signs, and prognosis is poor for recumbent animals.

Five percent acetic acid (i.e., vinegar) should be orally infused into the affected animal; 2–6 l in cattle and 0.5–1.0 l in sheep and goats (Lloyd, 1981). This should be immediately followed by a large volume (5–10 gallons) of cold water. The acetic acid will lower the rumen pH and shift the concentrations of ammonia to the ammonium ion, which will slow down the systemic absorption of $NH_3$. The cold water will lower the rumen temperatures and slow down the urease enzyme, responsible for the hydrolysis of urea to ammonia. Animals that respond to this treatment may relapse. If this should occur, the drench should be cut in half. Recumbent and convulsing animals respond poorly to this treatment. Other nonspecific, supportive therapies may include anticonvulsant therapy (e.g., phenobarbital, pentobarbital) and intravenous fluid therapy to correct fluid deficits and any existing elemental or electrolyte abnormalities.

Animals that do recover from the acute insult do not appear to suffer any recognizable long-term effects, though abortions have been reported to occur in pregnant animals.

## AMMONIA

NPN poisonings resulting in hyperammonemia should not be confused with ammonia poisoning. Synonyms include ammonia gas, anhydrous ammonia, and liquid ammonia. Livestock can be poisoned by ammonia, either through inhalation or ingestion, through its use as a fertilizer. Ammonia readily dissolves in water to form ammonium hydroxide. Anhydrous ammonia is colorless and highly irritating that causes corrosive injury to the mucous membranes of the eyes, lungs, and skin. Inhalation of ammonia can lead to severe bronchiolar and alveolar edema, and airway destruction that can result in respiratory failure and death. Dermal contact or oral exposures lead to corrosive skin lesions and corrosive damage to the mucosal lining of the oral cavity, esophagus and stomach.

## CONCLUSIONS

All mammalian species are susceptible to urea/ammonia poisoning. Though poisoning occurs with a greatest frequency in cattle by consumption of the contaminated feed. Diagnosis is based on clinical signs, and analysis of the body tissues/fluids and feed for urea and ammonia levels. Treatment includes oral administration of acetic acid (vinegar) and symptomatic and supportive therapies.

CHAPTER

# 85

# Water quality and contaminants

*Michael P. Carlson and Steve Ensley*

## INTRODUCTION

Water is essential for all forms of life. The availability of adequate quantities and quality of water partially dictates the types of life and numbers of individuals that an environment can sustain, and may be a limiting factor for livestock production systems. Less water may be available for animal production and what is available may be of poorer quality as water supplies for human use become limited. Large-scale animal production practices and emphasis on animal performance may increase the demands on water delivery systems and increase concern about water quality. Water quality generally refers the suitability of water for some purpose. Parameters used to assess water quality vary depending upon its proposed use, and may include color, odor, taste, bacterial content, mineral content, salinity and the amounts of inorganic or organic compounds.

The intent for this chapter is to provide the reader with information about water to aid in the assessment of water quality for use by companion and production animals. Some of the more readily accessible water quality standards applicable to drinking water for animals are highlighted. Detailed discussions of the mechanisms by which those chemicals cause adverse effects may be found elsewhere in this book. Information is also provided about the daily amounts of water required by animals as an aide in the assessment of cases of possible exposure of animals to water-borne poisons. Lastly, the risk assessment of blue-green algae poisoning is discussed in this chapter.

## THE ASSESSMENT OF WATER QUALITY

Water quality may be assessed upon several occasions: to determine if the available water is suitable for a particular purpose, to determine if there has been a significant change in water quality or to determine if adverse health effects that are occurring may be attributable to water contamination. Numerous commercial, governmental and academic laboratories offer water quality analytical services. The assessment of the analytical results from such laboratories requires some sort of standards against which to compare the results. National, state or provincial, or local governments may regulate water quality and water quality standards may be established by any or all of those governmental bodies. The quality of drinking water intended for consumption by humans is almost always more extensively regulated than for any other water use.

Reports of results of water quality analyses often include water quality standard ranges against which to assess the reported results. They may include graphical comparisons of the results to the water quality standards, making identification of parameters that fall outside of the standard limits easily identifiable. Such reports often use water quality standards intended for human drinking water. Assessment of the results of water quality analyses must be done using standards that are applicable for the intended use of the water and which are in force for the venue at which the water is to be used. The suitability of water intended for use as drinking water by animals is better assessed using drinking water standards for animals instead of standards for humans. Otherwise, animal owners may take unnecessary and costly actions to mitigate what are erroneously believed to be unacceptably high risk of some sort of adverse health effect.

## WATER QUALITY STANDARDS FOR ANIMALS

Water quality standards for animals are not the same as nor are they enforced with the same authority as are those

for humans. Water quality recommendations for animals have been made by the USEPA (1973) and the National Academy of Sciences (NAS, 1974) in USA, and in Canada in 1999 (Canadian Council of Ministers of the Environment, 2005a, b). Table 85.1 lists water quality recommendations for livestock taken from each of those sources for selected chemicals. The toxic effects cited in the NAS document are also listed in that table to give the reader some idea of the adverse health effects for the chemicals that were known at the time the document was written. These publications include recommendations for water use by animals other than livestock. Recommendations for other animals are

**TABLE 85.1 Water quality recommendations for selected chemicals for livestock**

| Chemical | Toxic effects* | Upper concentration limit (mg/l) | | |
|---|---|---|---|---|
| | | USEPA (1973) | NAS (1974) | Canadian (CCME, 2005a) |
| Arsenic | Mice @ 5 mg/l: non-toxic through three generations, tissue accumulation.<br>Guinea pigs @ 1 mg/l: increased thyroid colloid. | 0.2 | 0.2 | 0.025 (interim) |
| Cadmium | Mice @ 5, 10 mg/l: reduced longevity at lower dose, second generation did not survive at higher dose.<br>Rats @ 5 mg/l: reduced longevity.<br>Rabbits @ 0.1 mg/l: swollen kidney epithelium @ 6 months.<br>Dos @ 0−5 mg/l: tissue concentration proportional to intake. | 0.050 | 0.05 | 0.08 |
| Calcium | – | – | – | 1000 |
| Chloride | – | – | – | – |
| Chromium | Rats, rabbits @ 500 mg/l, 25 mg $Cr^{6+}$/l: first concentration is maximum non-toxic level based on growth, second concentration decreased water intake and tissue content 9 times that when $Cr^{3+}$ was substituted. | 1.0 | 1.0 | 0.050 ($Cr^{III}$, $Cr^{VI}$) (interim) |
| Copper | Steers @ 12 g $CuSO_4 \cdot 5H_2O$/day as drench: body weight decrease, fatal in 65 days.<br>Turkeys @ 625 mg/l: decreased feed and water intake, fatal. | 0.5 | 0.5 | 1.0 (cattle), 5.0 (swine, poultry), 0.5 (sheep) |
| Fluoride | Calves and cattle @ 100 mg/l, 11.8 mg/l: first concentration decreased feed intake, growth and Ca absorption, bones decalcified; second concentration mottled teeth.<br>Sheep @ 5–20 mg/l: severe mottled teeth, decreased wool production, decreased health.<br>Hogs @ 6–10 mg/l: severe mottling of teeth.<br>Mice @ 10 mg/l: no innate toxicity. | 2.0 | 2.0 | 2.0, 1.0 (if also in feed) |
| Hardness | – | – | – | – |
| Iron | Cattle @ 17 mg/l: pasture irrigation water produced scouring, decreased body weight and milk production. | – | – | – |
| Lead | Calves @ 100 mg/l: died after 4 months of drinking $Pb(NO_3)_2$.<br>Rats and mice @ 5, 25 mg/l: lower concentration reproduction ceased in second generation, higher concentration hypertension and higher death rates due to infections. | 0.1 | 0.1 | 0.1 |
| Mercury (inorganic) | Humans @ 30 μg/l, 75–30 mg/l: lower concentration readily absorbed into tissues, higher concentrations fatal. | 1.0 | 0.010 | 0.003 |
| Nitrate (as N)<br>(as $NO_3^-$) | Studies cited, too numerous to list here, involved concentrations from 90 to 4158 mg nitrate–nitrogen/l in sheep, pigs, cattle, chickens, turkeys and guinea pigs. | 23 ($NO_3^-$ + $NO_2^-$)<br>100 ($NO_3^-$ + $NO_2^-$) | 100 ($NO_3^-$ + $NO_2^-$) 440 | 100 ($NO_3^-$ + $NO_2^-$) |
| Nitrite (as N)<br>(as $NO_2^-$) | Studies cited, too numerous to list here, involved concentrations from 20 to 240 mg nitrite–nitrogen/l in pigs, cockerels, poults, chicks, laying hens, turkeys, rats and guinea pigs. | 3.0<br>10 | 10<br>33 | 10 |

*Summary of effects reported in Table 11 of NAS (1974) at the listed animals and concentration or dosage.

listed in Table 85.2. Readers may find them to be more applicable than the livestock recommendations in certain circumstances.

## USEPA water quality criteria for animals

The USEPA published proposed water quality standards for irrigation, livestock, aquatic life, wildlife, public freshwater, marine aquatic life and recreational water in 1973. The criteria were formulated and published by the USEPA pursuant to the Federal Water Pollution Control Act Amendments of 1972 and the Water Quality Act of 1965. The report states: "Almost all of the criteria are taken from the recommendations of the National Academy of Science's report on Water Quality Criteria (1974) developed under contract to the Environmental Protection Agency." As far as we have been able to determine, those recommendations have not been revised since their publication.

## National Academy of Sciences recommended limits in drinking water for livestock and poultry

The NAS report published in 1974 summarizes what was known at the time of publication about effects of nutrient and toxic substances that were found in water consumed by domesticated animals. It also contains information about water requirements and the percentages of recommended intake of various substances provided by normal daily water consumption, and toxic concentrations for various species. The publication includes a table summarizing the effects of toxic concentrations of various chemicals in water for various domestic and laboratory animals. The information included in those tables is too extensive to reproduce in this chapter. Readers are urged to consult them as needed.

An *ad hoc* committee of the National Research Council's Committee on Animal Nutrition reviewed the scientific literature related to minerals and toxic substances in the

diets and water for animals. Its findings and recommendations were published as a second revision of mineral tolerances of animals (NAS, 2005). Drinking water standards cited in that revision still refer to the 1974 NRC publication (NAS, 1974).

## Canadian environmental quality guidelines

Canadian water quality standards for agricultural use, including livestock, were first published in a document titled *Canadian Water Quality Guidelines* in 1987 by the

*Recommended concentration limits are expressed as the fraction of either lethal concentration-50 ($LC_{50}$) or lethal dose-50 ($LD_{50}$). The concentration listed thereafter is the maximum concentration considered acceptable.

Canadian Council of Resource and Environment Ministers (CCREM). That organization was later renamed the Canadian Council of Ministers of the Environment (CCME). In April 1996, CCME began work that consolidated national environmental quality guidelines for water, soil, sediment, tissue residues and air into one document, which was published as *Canadian Environmental Quality Guidelines* by CCME. The guidelines are continually reviewed and updated as deemed necessary.

## DRINKING WATER QUALITY STANDARDS FOR HUMANS

Drinking water quality standards for selected chemicals that are published by the USEPA (1973, 2004), Canada (Federal-Provincial-Terrestrial Committee on Drinking Water, 2004) and the World Health Organization (WHO, 2004) are listed in Table 85.3. They are included in this

**TABLE 85.3 Water quality recommendations for human drinking water: selected contaminants**

| Body establishing guidelines | Maximum acceptable concentration (mg/l) | | | Potential health effects from exposure above maximum acceptable concentration (USEPA, 1973) |
|---|---|---|---|---|
| **Chemical** | **USEPA (1973)** | **Canadian (Health Canada, 2004)** | **WHO (2004)** | |
| Arsenic | 0.010 | 0.025 | 0.01 (provisional) | Skin damage or problems with circulatory system; may have increased risk of cancer |
| Cadmium | 0.005 | 0.005 | 0.003 | Kidney damage |
| Calcium | – | – | – | – |
| Chloride | 250 (secondary) | ≤250 (esthetic objective) | No health concerns at usual concentrations | – |

chapter to allow readers to compare standards for animals and humans. The adverse health effects listed in USEPA documents for each chemical are also listed in the table.

In the United States, legal limits called maximum contaminant levels (MCLs) have been established for about 90 contaminants. If contaminant concentrations in public water supplies and certain private supplies are found to be above applicable MCLs, then the water supplier must take action to bring the contaminant concentration down below the MCL. Meanwhile, an alternate source of water that meets the standards must be provided. In the United States, there are primary and secondary water standards for human drinking water (USEPA, 1973). Primary drinking water standards are legally enforceable and water providers cannot provide water containing contaminants higher than their respective MCLs. Secondary standards are non-enforceable guidelines for contaminants that may cause cosmetic effects, such as skin or tooth discoloration, or unacceptable esthetic effects, such as unacceptable taste of, odor from or discoloration of the water.

Primary standards are established considering the adverse health effect caused by the contaminant and the dose at which such effects occur. *A reference dose (RFD or RfD) is estimated based upon the amount of the contaminant to which a person may be exposed on a daily basis that is not anticipated to cause the adverse health effect over a person's lifetime*. Consequently, the standards may not reflect the risk of adverse health effects in animals, and care should be used applying them to water intended for consumption by animals. A complete listing of drinking water standards and health advisories applicable to humans is compiled as needed by the USEPA Office of Water. The latest available at the time this chapter was written was published in 2004 and may be accessed on the USEPA website (USEPA, 2004).

# WATER CONSUMPTION TABLES

The dose of a water-borne contaminate may have to be estimated in cases of suspected toxicoses and may be calculated if the contaminant's concentration in the water and the amount of water consumed by the victims are known. Contaminant concentration in the water may be determined by analysis, but water consumption by the victims is rarely known with certainty. Water consumption varies by species, weather condition, diet and state of health. All of those factors and their interactions make the determination or estimation of minimal water requirements difficult if not impossible. Additionally, daily water requirements are not necessarily met solely by drinking water consumption.

Use water consumption data to calculate doses of water-borne poisons, if such data are available. If not, use the data in Table 85.4, which was taken from the NAS publication (1974), to estimate water consumption. Those data should be modified for situations falling outside of the defining parameters listed in the title.

**TABLE 85.4 Anticipated water consumption of various adult animals of medium weight in temperate climates**

| Animal | Expected consumption (l/day) |
|---|---|
| Beef cattle | 26–66 |
| Dairy cattle | 38–110 |
| Horses | 30–45 |
| Swine | 11–19 |
| Sheep and goats | 4–15 |
| Chickens | 0.2–0.4 |
| Turkeys | 0.4–0.6 |

Data are from NAS (1974).

## RATIONALE FOR LIVESTOCK RECOMMENDATIONS

The rationales for the chemicals included in Table 85.1 livestock recommendations included in the USEPA Proposed Criteria for Water Quality Volume 1 (1973) are summarized below. Information listed was what was known at the time the recommendations were formulated and may not reflect current knowledge of the effects of the chemicals. Our addenda are so noted.

The EPA writes in its introduction to the document:

"Acceptable limits specified in the recommendations were derived by the application of scientific judgment to lethal dose or lethal concentration data in a manner that provides a margin of safety to test organisms. For those substances whose effects are more aptly described as undesirable such as impairing aquatic habitats, causing taste and odor problems in water supplies, or reducing the esthetic or recreational quality of a water body, limits which minimize these effects were established on the basis of field and laboratory investigations. Acceptable levels of toxic materials for which specific numerical maximum acceptable concentrations are not prescribed are determined by applying an application factor to locally derived $LC_{50}$ data. By basing criteria on effects on the most sensitive important species, a desirable degree of regional and local variation is introduced, allowing water quality standards to depend on local conditions. An 'important species' in the criteria is defined as an organism that is: (a) commercially or recreationally valuable; (b) is rare or endangered; (c) affects the well-being of some species within (a) and (b) or (d) is critical to the structure and function of the ecological system. A 'rare or endangered' species is any species so officially designated by the US Fish and Wildlife Service."

Toxicity of some of the common water toxicants is described here in brief.

### Arsenic

Toxicity of arsenic depends upon its chemical form, relating primarily to rate of excretion. Inorganic oxides are generally more toxic than are organic forms of arsenic. Acute toxicities for farm animals were given in Table 85.5. Arsenic acid fed to lactating cows at up to 1.25 mg/kg b.w. for 8 weeks, equivalent to an intake of 60 l of water containing 5.5 mg arsenic/l daily by a 500 kg animal was absorbed and rapidly excreted in the urine with no increase of arsenic content of milk. No toxicity was observed.

**TABLE 85.5 Acute toxicity of inorganic arsenic by species**

| Species | Toxicity (g/animal) |
|---|---|
| Poultry | 0.05–0.10 |
| Swine | 0.15–1.0 |
| Sheep and goats | 10.0–15.0 |
| Horses | 10.0–15.0 |
| Cattle | 15.0–30.0 |

Wadsworth 1952 as cited by USEPA (1973).

**TABLE 85.6 Effects of cadmium in various species**

| Species | Amount and source | Effect |
|---|---|---|
| Human | 15 mg/l in popsicles | Sickening |
| Male rats | 4.5 mg Cd/kg b.w. | Permanent sterility |
| Rats or mice | 5 mg/l in drinking water | Reduced longevity |
| Pregnant hamsters | 2 mg/kg b.w. of $CdSO_4$ by i.v. injection | Dose on day 8 of gestation caused fetal malformations |

Data are from USEPA (1973).

### Cadmium

Effects of cadmium in various species are listed in Table 85.6. A small fraction of cadmium is absorbed in ruminants, with most of what is absorbed going to the kidneys and liver. The cow is "found to be very efficient in keeping cadmium out of its milk." Most major animal products, including beef and milk, seem "quite well protected against cadmium accumulation."

### Chromium

Chromium is not readily absorbed by animals. Most of what is ingested is excreted in the feces. It does not appear to concentrate in mammalian tissue or its concentration to increase with age. It is concluded that up to 5 mg/l of chromium II or VI in drinking water should not be harmful to livestock. That level may be unnecessarily high and the 1.0 mg/l level is recommended to provide a "suitable margin of safety." Of course, recommended maximum level in drinking water for livestock is <0.1 ppm (Puls, 1994).

## Copper

Copper is an essential trace element so some is required in the diet to maintain good health. Swine appear to be more tolerant to copper with dietary concentrations of 250 mg/kg or higher improving live weight gains and feed efficiency. Copper does not appear to accumulate in tissues. Sheep are very susceptible to copper toxicosis. A diet containing 25 mg/kg fed to sheep is considered toxic. About 9 mg per animal per day is considered safe.

## Fluorine (Authors' addendum: fluorine and fluoride seem to be used synonymously)

Consumption of drinking water with 2.0 mg/l may produce some tooth mottling, but it is not excessive with respect to animal health or deposition in meat, milk or eggs. Chronic fluorosis of livestock has occurred with water content of 10–15 mg fluoride/l. Total ration content of 30–50 mg fluoride/l (sic) for dairy cattle is considered a safe upper limit. Transfer to milk occurs to a very small extent and to a greater degree in eggs. Fluoride at 1.0 mg/l in drinking water did not harm livestock.

## Hardness (Authors' addendum)

Hard water does not appear to have a deleterious effect on animals, but it often is reported as part of water quality analysis. Hardness is a measure of the calcium and magnesium ions present in the drinking water. Water with high total dissolved solids (TDS) or salinity may or may not be hard water. Hardness of water may be measured as grains/gallon or in ppm. One grain per gallon is equivalent to 17 mg calcium and magnesium per liter. Water is classified according to calcium and magnesium salt content as follows: soft water ranges from 0 to 60 ppm, hard water varies from 120 to 180 ppm and very hard water is >180 ppm.

## Iron

In small quantity, iron is essential to animal life, while in excessive quantity it is considered toxic. Due to its involvement in Fenton reaction, iron is known to produce excessive free radicals, thereby causing oxidative stress. Brain, lungs and liver are the major sites of iron toxicity. Maximum recommended levels of iron water for humans, livestock and poultry are <0.3, <0.4 and <0.4 ppm, respectively. Dietary iron concentrations of at least 4000 mg/kg were found to cause phosphorus deficiency and to be toxic to weanling pigs. Concentrations <3000 mg/kg apparently were not toxic. Elevated dietary iron may antagonize copper, manganese and sulfur in lactating dairy cattle. In poultry, iron level >200 ppm in diet is considered toxic (Puls, 1994).

## Lead

The toxicity of lead had not been clearly established quantitatively. Daily intake of 6–7 mg/kg b.w. had been suggested as a threshold dosage in cattle, but that is difficult to establish. A concentration of 0.05–0.1 mg/l in drinking water is considered safe for livestock. Drinking water containing 5 mg/l consumed by rats and mice over the course of their life times produced toxic effects. Death rates of older animals increased, especially in males. Death was not caused by overt lead toxicosis, but was due to an increased susceptibility to "spontaneous infections."

## Mercury

Mercury content in surface water was found to usually be <5 μg/l, but methylation of mercury in bottom sediments bordering mercury deposits resulted in the continuous presence of mercury in solution. The relative stability of methyl mercury and its high absorption from the gut contributes to its oral toxicity. It has been suggested that livestock blood and tissue lead content be kept below 0.1 and 0.5 mg/kg, respectively, to protect humans who might consume those tissues. The safe contamination level for fish consumed by humans has been set at 0.5 mg/kg by the USFDA. However, that did not take into consideration other possible sources of dietary mercury. "In views of these facts the limits prescribed herein are reduced by a factor of 10 to reduce the significance of levels from meat products in comparison with those of fish."

## Nitrate and nitrite

Nitrite is more toxic to livestock than is nitrate. Usually nitrite is produced by the reduction of nitrate to nitrite, which occurs in the rumen; in moistened feeds, such as freshly chopped green forage; or water containing sufficient organic matter to sustain microbes. Natural waters may contain "high levels" of nitrate, but they usually contain very low concentrations of nitrite. Nitrate in cattle feed did not seem to pose a hazard to humans consuming dairy products or meat produced from cattle eating the nitrate-containing feed. "Animals fed nitrate continuously develop some degree of adaptation (sic) to it." "Assuming maximum water consumption by dairy cattle of 3–4 times the dry matter intake, the concentration of nitrate to be tolerated in water should be about one-fourth of that tolerated in the feed. This would amount to about 300 mg/l of nitrate."

**TABLE 85.7 Effects of nitrate and nitrite administered to non-ruminants**

| Species | Concentration, dosage or dose | Observed effect(s) |
|---|---|---|
| Gilts from weaning through two farrowing seasons | 330 mg/l (nitrate) | No adverse effects |
| Growing pigs | 330 mg/l (nitrate) | No adverse effects |
| Chick and laying hens | Up to 300 mg/l (nitrite) | No effects on growth or production |
| | Up to 200 mg/l (nitrite) | No effects on growth or production |
| Turkey pullets | 200 mg/l (nitrite) | Decreased growth |
| Turkeys, laying hens and turkeys | 200 mg/l (nitrite) | Reduced liver vitamin A stores |
| | 50 mg/l (nitrite) | No adverse effects observed |

Data are from USEPA (1973).

Effects of nitrate and nitrite at various concentrations given to non-ruminants are summarized in Table 85.7. It appears that ingestion of water containing up to 300 mg/l nitrate or 100 mg/l nitrite was well tolerated by all classes of livestock and poultry studied under controlled experimental conditions.

Authors' addendum: Crowley and associates (1974) conducted a 35-month study in Wisconsin comparing reproductive efficiency and lactational performance for a 54 cow Holstein herd that consumed drinking water containing either 19 or 374 ppm nitrate. During the last 15 months of the study, cattle drinking the elevated nitrate-containing water had the highest services per conception and lowest first service conception rates. The average milk yield was not significantly different between the two groups but the total milk yield for the entire 35-month study was lower in the elevated water nitrate group. This small difference in milk yield in the elevated nitrate-containing drinking water was thought to be due to an increased dry period due to lower conception rates.

The authors have never encountered a case of acute nitrate or nitrite toxicoses due to the consumption of drinking water, unless the water had been hauled to the animals in a fertilizer tank. Such cases have always involved cattle and occur when the availability of drinking water is disrupted and drinking water must be hauled to the animals from someplace else. Such circumstances may occur when water freezes during stretches of very cold weather or the water pump fails and cannot be rapidly repaired. Deaths often occur relatively rapidly; owners often report finding dead victims within a few meters of the contaminated water tank. Ocular fluid collected from dead victims usually contains nitrate in excess of 100 μg nitrate/ml and nitrite in excess of 2 μg nitrite/ml. Ocular fluid collected from dead victims of forage nitrate toxicosis usually contains less nitrate than ocular fluid from dead victims of water nitrate toxicosis. If the fertilizer tank contained ammonium nitrate, then death may be the result of either excessive ammonia or nitrate exposure, and the determination of the exact cause of death is mostly academic. Under no circumstances do we recommend that a tank that has contained fertilizer be used to haul drinking water to animals, even if it has been "thoroughly washed out." Theoretically, a fertilizer tank may be cleaned sufficiently to haul drinking water, but not practically.

## Total dissolved solids

"Total dissolved solids" is defined in the NAS publication (1974) as the concentration of all dissolved constituents in water. "Salinity" is often used synonymously with "total dissolved solids," although that assumes that all of the dissolved solids are saline. Salinity is more than a measurement of the total amount of sodium and chloride present in water. Salinity also includes anions such as carbonates expressed as oxides, bromide and iodine expressed as chlorine, and cations such as calcium, magnesium, bicarbonate and sulfate but does not include organic matter.

The USEPA does not include recommendations for TDS, but the NAS provides criteria for classification of water based upon TDS content established for the US Geological Society. Criteria for two classification systems are listed in Table 85.8. Note the differences in the classification and the use of brine in both, but with different criteria for inclusion in that classification. It has been our experience that those classifications contribute little to the assessment of water quality for animals as we have never encountered an instance where those water classifications have been used to describe the TDS content. Nevertheless, they are included here. More useful information about the use of saline waters for livestock is provided under the section titled "A Guide to the Use of Saline Waters for Livestock" in the NAS publication, starting on p. 48 (1974):

> "Several factors need to be considered in assessing the suitability of saline water for livestock use, including kind, age and sex of the animals; pregnancy or lactation status; physical exertion; climatic conditions; diet and its moisture and mineral content; production expectations; water salt content; access to other water sources; and the adaptation to available water sources. Weight given to those factors is largely a matter of judgment, but TDS is the single most reliable factor that can be determined."

TABLE 85.8 Water classifications based upon total dissolved solid content

| Davis & DeWiest classification (1966) | | Robinove *et al.* classification (1958) | |
|---|---|---|---|
| Water classification | TDS content (mg/l) | Water classification | TDS content (mg/l) |
| Fresh water | <1000 | Slightly saline | 1000–3000 |
| Brackish water | 1000–10,000 | Moderately saline | 3000–10,000 |
| Salty water | 10,000–100,000 | Very saline | 10,000–35,000 |
| Brine | >100,000 | Brine | >35,000 |

Data are from NAS (1974).

TABLE 85.9 Guide to use of saline waters for livestock and poultry

| Water TDS content (mg/l) | Expected health or performance effects |
|---|---|
| <1000 | None expected for any livestock class. |
| 1000–2999 | None expected for any livestock class. May cause temporary diarrhea or watery droppings in animals unaccustomed to the water. |
| 3000–4999 | Should be none. May cause temporary diarrhea or be refused at first by animals unaccustomed to the water. Poor water for poultry, often causing watery droppings, increased mortality and decreased growth, especially in turkeys. |
| 5000–6999 | Reasonably safe for dairy and beef cattle, sheep, swine and horses. Avoid use of water approaching the higher limit for pregnant or lactating animals. Unacceptable for poultry; use for poultry will almost always be accompanied by some type of problem, especially near the upper limit, such as reduced growth or production. |
| 7000–10,000 | Unfit for poultry and probably swine. Considerable risk may exist for pregnant or lactating cows, horses, sheep and the young of those species. Considerable risk for animals subject to heavy heat stress or water loss. Generally use of such water should be avoided, although older ruminants, horses and even poultry and swine may subsist on it for long periods of low stress. |
| >10,000 | Unacceptable risks for any livestock class. |

Taken from NAS (1974).

The NAS did not recommend the use of highly saline water for livestock but acknowledged that circumstances may arise such that saline water may be all that is readily available. Table 85.9 lists the guidelines for use of saline water for livestock and poultry. If high-TDS water is to be used, the following points should be considered, too:

1 Alkalinities and nitrate should be considered whenever water contained >3000 mg TDS/l is to be used. Alkalinities of 2000 mg $CaCO_3$ detract from the suitability of water. Hydroxide is more harmful than carbonate, which is more harmful than bicarbonate.
2 If offered the choice between two water sources, one highly saline and one less saline, they will choose the less saline source.
3 Animals can tolerate high saline water for a few days if they are then given low saline water.
4 Water intake usually increases with soluble salt content, except in cases of extremely high saline content, which animals may refuse to drink.
5 Abrupt changes from a low to high saline water will likely cause more problems than a gradual change.
6 Decreased water intake is very likely accompanied by decreased feed intake. So, animals with high production expectations may not produce as well showing "deleterious effects from waters of lower salts content than animals on a maintenance regimen."
7 Highly saline water may furnish enough minerals to be considered in dietary mineral formulations. And salt content of the diet may contribute to the toxicity of saline water, particularly if salt is added to control feed intake. Generally, water should not normally be relied upon as a source on essential inorganic minerals.

## Selenium

At the time that the USEPA formulated its recommendations, no substantiated case of livestock poisoning by selenium in water had been found. However, selenium toxicosis was found in wildlife exposed to high-selenium-containing irrigation runoff water. Agricultural drainage water entering Kesterson Reservoir in California ranged from 0.140 to 1.40 mg/l (140 to 1400 ppb) during 1983–1985.

TABLE 85.10 Zinc toxicity in diets for various animals

| Dietary per water Zn content | Species and effect(s) |
|---|---|
| 1000 mg/kg in diet | Swine tolerated it; |
| ⩾2000 | Swine: toxic |
| 2320 mg/l in water | Chickens: reduced water consumption, egg production, body weight |
| >500 mg/kg in diet, as oxide | Ruminants: toxic |

Data are from USEPA (1973).

## Sulfate

No recommendation for sulfate was made by the USEPA probably because the association between sulfate exposure and polioencephalomalicia in ruminants had not yet been discovered. The Canadian recommendation is 1000 mg/l. Exposure to elevated sulfates in drinking water can result in a transient diarrhea. Animals usually acclimate to an elevated level of drinking water sulfate in 3–7 days and no longer exhibit diarrhea. Methemoglobin was increased 450% in cattle consuming drinking water containing sulfates at 3493 ppm.

## Zinc

Zinc is relatively non-toxic. The findings cited in the EPA document are summarized in Table 85.10. Increased zinc intake increased the zinc content of body tissue, but its accumulation was not great and tissue content fell rapidly after zinc intake was reduced.

# HEALTH EFFECTS OF CYANOTOXINS FROM WATER

The effects of cyanotoxins from water on humans are discussed by Kuiper-Goodman *et al*. (1999), and serve as the basis for risk assessment for exposure from drinking and recreational water by the World Health Organization (WHO, 2004). Relevant information from their chapter is summarized here. A more detailed discussion of cyanotoxins may be found elsewhere in this book (Chapter 58).

## Cyanotoxins

Toxic effects after exposure to cyanobacteria are evidenced by retrospective epidemiological studies of human disease, factual and anecdotal reports of disease in animals, and toxicological studies of cyanotoxins. Cyclic peptides, like microcystins, are specific liver poisons in mammals and of particular concern to human health. Acute toxicoses cause liver hemorrhage and death from liver failure. Chronic toxicoses may promote liver and other cancers.

Alkaloid neurotoxins, like anatoxins and saxitoxins/paralytic shellfish poison (PSP), have shown only acute toxicoses in mammals. Information about anatoxins is sparse. Some of the alkaloid toxins, especially PSP, accumulate in marine and freshwater biota, which may place animals and humans consuming such biota at risk of exposure after consuming them.

Cyanobacterial lipopolysaccharides (LPS) can elicit allergic and toxic responses in humans, although little is known about their acute or chronic effects. They should be considered whenever gastrointestinal (GI) and respiratory signs are reported or observed.

## Adverse health effects in humans

Drinking water has been associated with GI illness throughout history. Pathogenic bacteria and viruses are common causes of such illness, and evidence for GI illness caused by cyanotoxin exposure needs to take such etiologies into account. Cases of GI and hepatic illness that can be reliably attributed to cyanotoxins have all been coincidental with lysis of cyanobacterial blooms, either natural or artificial. Lysis releases cyanotoxins from the cells into the water.

Artificial lysis occurs after water treatment with copper sulfate to destroy blooms in water reservoirs, and poisonings subsequent to such treatment have been reported in the Unites States and Australia. Water filtration after the treatment can remove cell fragments, but not dissolved cyanotoxins.

Individuals at greater risk of cyanotoxicoses are the young, who drink a higher volume of water than adults in proportion to their body weights and subjects with liver disease or kidney damage. Chronic effects in humans are of great concern because of the potential of exposure to low concentrations of cyanotoxins in drinking water over the course of a lifetime. Results of animal experiments have indicated chronic exposure to microcystins may promote tumor growth.

Epidemiological studies of the incidence of human hepatocellular carcinoma in China have identified three risk factors: hepatitis B viral infection, exposure to aflatoxin $B_1$ in food and the source of drinking water. Cancer mortality is lower when the source of drinking water is from deep well than when it is from surface waters. Cyanobacteria are abundant in the same areas where the incidence of hepatic carcinoma is highest.

There have been repeated reports of adverse effects in swimmers exposed to cyanobacterial blooms, such as skin

irritation and GI symptoms. Deep blisters on skin under bathing suits have been reported, particularly after contact with the marine cyanobacterium *Lyngbya majuscule*, which is believed to occur when the organism becomes trapped against the skin under the bathing suit. Effects may be due to allergic reactions to cyanobacterial pigments or direct contact with the cyanotoxins. Individual sensitivity to cyanotoxins varies significantly.

Health effects in humans exposed to cyanobacteria in recreational waters include headache, nausea, vomiting, muscular pain, painful diarrhea, abdominal pain, blistering of the lips, sore throats, skin rashes, fever and eye or ear irritation, usually within 7 days of exposure. Severity of symptoms appears to be related to full-body immersion, the amount of water ingested and the duration of exposure. Severe pneumonia attributed to aspiration of a *Microcystis* toxin was reported to have occurred in two British army recruits after they swam in and underwent canoe training in water containing a dense bloom of *Microcystis* spp.

## Effects in animals

Reports of deaths due to cyanotoxicoses have been reported for cattle, sheep, dogs, horses, pigs, coots, ducks, skunks and mink exposed to water containing cyanobacteria. Animals consuming food in which cyanotoxins may accumulate, may also suffer from cyanotoxicoses. Secondary photosensitization may occur in animals exposed to hepatotoxic cyanotoxins. Post-mortem examination may reveal evidence of cyanobacteria in stomach content, or liver injury. However, in cases of neurotoxic cyanotoxins, no post-mortem lesions are usually found.

## Cyanotoxins in drinking water

Falconer *et al*. (1999) described how guideline values for cyanotoxins in water were derived. Information from that chapter that can assist in the assessment of risk from such exposure is summarized here. The World Health Organization has established a provisional guideline for human drinking water of 0.001 mg/l of microcystin-LR (total cell-bound and extracellular) (WHO, 2004). Canada has established a cyanobacterial toxin maximum acceptable concentration of 0.0015 mg/l (as microcystin-LR) (Health Canada, 1999). Australia has established a standard of 0.0013 mg/l of total microcystins as microcystin-LR toxicity equivalents (TE) (Australian Water Quality Guidelines, 2004). The USEPA has not yet established a standard. Potential carcinogenicity is the effect upon which those standards are based. Standards for drinking water for animals have not been established.

## Recreational water exposure

Routes of exposure to cyanotoxins for people and animals from recreational waters include direct contact with the skin (most important for sensitive areas such as the mouth, ears, eyes and throat, and the area covered by bathing suits worn by humans), swallowing and inhalation of water.

Absorption of cyanotoxins after swallowing, contact with nasal mucosa or inhalation is likely to be important during water-contact activities. Absorption through nasal and pharyngeal mucosa is more likely to occur when activities involve submersion of the head or inhalation of aerosols produced by water spray. Cumulative liver damage may occur by repeated microcystin intake during periods of daily water activities, especially if the activities take place in areas where scums are or have been present.

## Safe practices for drinking water

Draw drinking water from sources that do not harbor cyanobacteria, such as groundwater or surface water not supporting cyanobacterial growth.

Cyanobacterial-contaminated water may be used for drinking water if the cyanobacterial cells are removed without lysing them because most cyanotoxins are cell bound. Removal of released cyanotoxins from the water may be possible, but it may also be difficult and expensive. Risk of cyanotoxicosis should be considered high after algae-infested water is treated with copper sulfate. Critical control points for assessing the safety of drinking water are listed in Table 85.11.

All animals should be denied access to bodies of water containing visible discoloration that cannot be attributed to some other source other than algae or cyanobacteria. Areas in which scum has formed should be considered very high risk for acute cyanotoxicosis, regardless of the color of the scum. Identification of the microbial components of the scum may help with the risk assessment.

## Safe practices for recreational waters

Surveillance of recreational waters for algal blooms can be effective in minimizing or preventing exposure, but adequate surveillance of such waters for blooms may be difficult. Governmental agencies may not be able to survey all recreational waters within their jurisdiction adequately, so the burden of surveying recreational waters for the presence of blooms may rest with the users of the waters. Once blooms have been detected in public waters, provision of information to the public is usually the responsibility of public authorities.

Algal blooms are usually regarded as more of a nuisance than a toxic hazard. They are often associated with

**TABLE 85.11 Critical control points for assessing the safety of drinking water**

| Control point | Remarks |
|---|---|
| Water source | Groundwater less risky than surface waters. Water sources contaminated by surface runoff pose higher risks. |
| Presence of cyanobacteria; tendency of bloom formation | Bloom formation less likely during periods of high flow or deep vertical mixing, and are more likely during periods of low flow or stagnation. Historical evidence of algal blooms increases risk; blooms may be cyclic. Nutrient input, especially nitrogen and phosphorus, increases risk. Absence of cyanobacteria reduces risk. |
| Cell lysis | Most cyanotoxins are cell bound and may be removed with the cells. Lysis may occur naturally as the bloom dies, or artificially by treatment, pumping or transport. |
| Water treatment systems | Cyanotoxins may be removed by filtration through activated charcoal or by oxidation, but effectiveness of treatment should be monitored. |

Adapted from Table 5.1 in Falconer *et al.* (1999).

unpleasant odors and offensive appearances. They may be regarded as normal in areas where they occur frequently or regularly, and their toxic potential may be unknown or disregarded. The presence of any algal bloom, regardless of its color, location or time of occurrence, should be considered to pose a high risk of cyanotoxicosis and all animals should be denied access to such areas, whether it is in the water or on the shore. The detection of algal scum formation is problematic if routine monitoring is carried out at 1–2-week intervals. Scum formation may occur in the matter of hours to days. Daily inspection for scum formation after cyanobacteria are found to be present is recommended.

The availability of ELISA kits for the detection of microcystins makes it easier to monitor recreational waters for the presence of microcystins. Chorus and Cavalieri (2000) do not recommend risk assessment for cyanotoxicoses be based upon chemical analysis for specific cyanotoxins for two reasons: (1) only some of the substances causing health outcomes are known and can be detected and (2) epidemiological studies indicate some health effects are not due to known cyanotoxins. They recommend that a monitoring program focus surveillance efforts on sites that are likely to present a risk.

## Monitoring strategy for freshwater cyanobacteria

Kuiper-Goodman *et al*. (1999) recommend the following strategy for monitoring freshwater for cyanobacteria, consisting of the three steps listed below. Each will be briefly discussed, and serve a prerequisites for the following step:

1 Determine the carrying capacity of the water body for cyanobacteria.
2 Inspect the site to detect biomass developments.
3 Quantitatively assess the biomass as the basis for risk assessment when biomass developments occur.

### *Determine the carrying capacity of the ecosystem for cyanobacteria*

Algal and cyanobacterial growth requires nitrogen and phosphorus and the availability of those nutrients limits the numbers of algae and cyanobacteria that can grow in a body of water. Phosphorus is usually the limiting factor of the two and total phosphorus, not *ortho*-phosphorus, should be measured because algae and cyanobacteria can store sufficient phosphorus to support their growth. If total phosphorus is found to be $>0.02\,mg/l$, then Step 2 monitoring activities should commence. Inspect the water body area to determine if a source or sources of phosphorus or nitrogen input are present, like sewage, fertilization near the water body or erosion.

### *Inspect the site to detect biomass developments*

The frequency of monitoring should be no longer than every 2 weeks and should be concentrated in areas in which a biomass most likely will appear, i.e. leeward shorelines. Visual inspections should include the following activities, each serving as its successors prerequisite:

A Determine water transparency. If the lake bottom cannot be seen at 50 cm depth along the shoreline, or if the Secchi transparency is $<1\,m$, then go to Step B.
B Determine if greenish discolorations of the water are present along or near the shoreline, indicating the presence of algal or cyanobacterial masses. If so, go to Step C.
C Determine if greenish discolorations of the water are present on the surface anywhere on the body of water.

**TABLE 85.12 Guidelines for use of recreational waters**

| Situation | Health risk | Recommended action |
|---|---|---|
| Scum is present | High for acute poisoning and short-term health effects (skin irritation, GI illness). Humans are not likely to ingest scum mats or scum-contaminated water, but animals may. Animals may also be exposed when they groom themselves after contact with scum. Young animals or children playing with, in or around scum are at risk. | Prevent contact with scum; prohibit water-contact activities. |
| 100,000 cyanobacterial cells/ml; 50 μg chlorophyll a/l with dominance of cyanobacteria | Moderate to high for short-term adverse health effects, potential for chronic effects. | Watch for scums. Restrict water-contact activities; continue to monitor the situation, post on-site risk advisory signs. |
| 20,000 cyanobacterial cells/ml; 10 μg chlorophyll a/l with dominance of cyanobacteria | Low to moderate for short-term irritative or allergenic effects. | Post on-site risk advisory signs. |

Adapted from Falconer *et al.* (1999).

**TABLE 85.13 Expected microcystin content of water based upon the amount of microcystin-producing cyanobacteria present**

| Number of cyanobacterial cells | Expected microcystin concentration |
|---|---|
| 100,000 cyanobacterial cells/ml | Associated with about 20 μg/l of microcystins, if microcystin-producing cyanobacterial predominate. |
| 20,000 cyanobacterial cells/ml | Associated with 2–4 μg/l of microcystins, if microcystin-producing cyanobacterial predominate. |

Falconer *et al.* (1999).

***Quantitatively assess the biomass as the basis for risk assessment when biomass developments occur***

Either of two quantitative measurements may be performed: (i) microscopic examination of samples collected from the biomass to identify if cyanobacteria are present, and if so, what kind; (ii) quantitate the concentration of chlorophyll a present.

Guidelines for the use of recreational waters based upon those measurements are detailed by Falconer *et al.* (1999) and are summarized in Table 85.12. Falconer *et al.* (1999) do associate microcystin concentrations with numbers of cyanobacteria cells present in water, which may be valuable as an additional risk assessment variable if microcystin-producing cyanobacteria predominate in the biomass. The association is listed in Table 85.13.

Once algal blooms have occurred in a body of water, they should be considered to pose a high risk of cyanobacterial toxicosis until the microorganisms in them have been reliably identified. There are numerous publications on cyanobacteria that describe cyanobacterial blooms as being blue-green in color, but the absence of blue-green coloration in a bloom does not necessarily lessen its toxic hazard. The safest course of action is to deny access by animals to the bloom area.

The single most effective action that animal owners can take to protect their animals from cyanotoxicoses is to prevent their animals from making any contact with any scum or biomass in the water or on shorelines. It is not usually possible to determine if the scum or biomass is or is not cyanotoxigenic by visual inspection alone, so any biomass or scum should be considered potentially toxic.

Once an animal has been exposed to a bloom, it is advisable to monitor the animal closely for signs of cyanotoxicoses. Algal scum may be visible on its coat or around its mouth or muzzle and is a good indicator that dermal exposure to cyanobacteria may have occurred and is suggestive that algae may have been ingested. It is not usually possible to determine how much of the scum might have been ingested. It is expected that human swimmers involuntarily swallow 100–200 ml of water in one session, and water skiers and sailboard riders may ingest significantly more.

# 86

# Basic concepts of analytical toxicology

*Anant V. Jain and Beverly Arnold*

## INTRODUCTION

Veterinary analytical toxicology deals with the chemical analysis of ante-mortem, post-mortem, and environmental specimens to assist the veterinary practitioner in the diagnosis of poisoning. The chemical analytical data reported to the veterinarian is of utmost importance. The correct data will lead to correct diagnosis. The erroneous data may lead to disaster; the client may lose large number of animals. The erroneous data may also lead to legal ramifications. Thus, correctness of analytical data is of paramount importance for veterinary analytical toxicology. Chemical measurements are based on the principles of analytical chemistry. In practice, the analytical chemist–toxicologist uses analytical methods to get the final results. It should be pointed out that by nature analytical results are variable. The science of trace analysis (analysis at parts per million (ppm) or parts per billion (ppb)) is not as precise as most layman and many scientists view it to be (Rogers, 1986). Analytical methods once devised are, like life forms, subject to evolution. Natural selection as mediated by analytical chemists, ensures that only the fittest analytical methods survive. Therefore, an analytical method must be fit for purpose. It should be pointed out that most of the advancements and improvements in the analytical methods have been by making necessary changes and improvements in various steps used in an analytical method. The papers by Sawyer (1988) and Seiber (1988) clearly demonstrate this point for pesticide analysis. The important steps in chemical analytical measurements are (i) decomposition or extraction of the sample, (ii) clean up and separation of analyte from bulk impurities (sample matrix), (iii) pre-concentration of analyte, (iv) detection and measurement of the analyte, and (v) the generation of the report. The purpose of this chapter is to provide the analytical chemist/toxicologist, an overview of the brief history of early, and recent developments in chemical measurements, and above all the basis for scientifically sound chemical analytical measurements.

## HISTORY OF CHEMICAL ANALYSIS

### Early history of chemical analysis

Chemical analysis began on the 8th day (McCrone, 1987), Adam; recovering after cooperating with god, in creating Eve, felt first pangs of hunger. He went around and harvested different kinds of colorful berries, and set down for dinner with Eve. Eve rejected some berries due to foul smell (nose as detector). The bitter tasting ones were rejected next (taste as detector), and the delicious ones were consumed. Thus, first chemical detectors were nose, tongue, and eye; *the five senses were used as chemical detectors for a long time*.

The alchemists, in their futile attempts to make gold from base metals introduced the techniques of filtration, decantation, and distillation. Alchemist's zeal, however unsuccessful, leads to a reservoir of observations.

Observations followed observations, and when a large body of knowledge was available, it was named *chemistry*. Those observations, which dealt with the production of substances, were termed chemical synthesis, and those related to determining what the substances were called chemical analysis. The analysis could be carried out in solution as well as in dry state. The solution methods were termed "wet" methods, and were further divided into volumetric and gravimetric. These methods used sight (visual observation) as detection device. The dry methods also used sight as the detector.

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

Archimedes, while running naked through the street, and shouting, *eureka, eureka* introduced the use of numerical properties for chemical analysis in the concept of specific gravity (density).

The volumetric and gravimetric methods were used for chemical analysis for a long time. These were the principle chemical analytical methods up to 19th century.

## Recent history of chemical analysis

In recent years, research in analytical chemistry has focused mainly on the development and application of physical and physicochemical analytical methods, instrumental methods of analysis. Instrumental chemical analysis began with Bunsen (Bunsen burner fame) in 1860, who introduced flame emissive spectrometry, and discovered metals rubidium and cesium. There are a large number of instruments available today for chemical analysis. The most important of these which have found routine use in veterinary analytical toxicology laboratories are (i) chromatographic techniques coupled with a large number of detectors, (ii) spectrometry and spectrophotometry, both for visible and ultraviolet range of the light spectrum, (iii) atomic absorption spectrophotometry, (iv) inductively coupled plasma spectrometry, and (v) mass spectrometry.

Chromatographic methods in general are the most common methods used at the determinative step for the organic compounds. Chromatography is a separation technique, which separates the impurities in the sample solution from analyte. According to International Union of Pure and Applied Chemistry (IUPAC), chromatography is a method used primarily for the separation of the components of a sample in which the components are *distributed* between *two phases*, one of which is stationary while the other moves. The stationary phase may be a *solid*, or a *liquid supported on a solid,* or a *gel.* The *stationary phase may be packed in a column, spread as a layer, or distributed as a film, etc.* The mobile phase may be gaseous or liquid. Thus there are two movements in chromatographic system, the mobile phase movement – which is usually at a constant rate; the other is the movement of the components of the sample. The movement of the component depends upon their relative distribution between the stationary phase and the mobile phase. This results in the separation of the components. This separation process coupled with the detection and measuring device completes the chromatographic system. Chromatography can be conducted in gas phase, known as gas chromatography (GC), liquid phase, known as liquid chromatography (LC), and on a glass or paper coated with solid adsorbent, known as thin layer chromatography (TLC). A variation of LC is known as high-pressure liquid chromatography (HPLC), since high pressure is used to force the solvent through the chromatographic column. Gas chromatographic equipment can be interfaced with large number of detectors such as, flame ionization (FID), electron capture (ECD), nitrogen phosphorus (NPD), flame photometric (FPD) (responds to phosphorus, and sulfur only), Hall electrolytic conductivity (HECD) (responds to halogens only), and mass spectrometer. HPLC can also be coupled with various detectors such as UV/VIS spectrophotometric detector, fluorescence detector, electrochemical detector, refractive index detector, and mass spectrometric detector. Chromatographic techniques coupled with a detector are represented by hyphenated abbreviations. For example a gas chromatograph equipped with FPD is known as GC–FPD. Sometimes this is also represented as GLC–FPD, due to the nature of the stationary phase of the chromatographic column used. Most of the time a liquid phase is coated on a solid support and packed in a glass column. Recently, silica columns of very small diameter are used in GC, and are known as capillary columns. In these columns, the liquid phase is usually bonded to the inner surface of the silica capillary.

Instrumental methods have surpassed the traditional gravimetric and volumetric analysis in speed and sensitivity.

# TRUENESS (ACCURACY) OF CHEMICAL ANALYTICAL RESULTS

With all the furious activity in the development of various analytical instruments, the question still remains, how good are your results. One can use the most expensive and sophisticated instrument on the market, but still have to prove that the analytical results so obtained are indeed accurate. As mentioned in the introduction, that the analytical results by nature are variable, it is more essential to prove the correctness of the results. Let me give a brief history why this is important.

After the Civil War (1861–1865), American agriculture has been on the march, and farmers have been trying to produce more and more per unit of land. Synthetic fertilizers are used extensively. Various state governments are trying to verify the claims made by the fertilizers manufacturers to protect the consumer (farmer). The problem was that different laboratories got widely different results for the same ingredient in the fertilizers. There were no uniform methods for fertilizer analysis. In order to control this chaos, Mr. J. T. Henderson, Agriculture Commissioner of Georgia, called a meeting of various interested parties. On May 15, 1884 the meeting took place at the Senate Chambers at the Capitol in Atlanta (Helrich, 1984).

Dr. Charles Shepard, a commercial chemist from Charleston, South Carolina, addressed the meeting and stressed the need for uniform and validated methods for

the analysis. He dramatized the effect of nonuniform methods of analysis was having on the monetary value of fertilizers. He told the convention "a 1% difference in the analysis of phosphoric acid made a difference of $50,000 in the annual production of a "good-sized factory". This presentation had a lasting effect on the attendees and was decided that the group again meet at AAAS, American Association for the Advancement for Science, in Philadelphia, on September 4–10, 1884. The Philadelphia meeting became the first meeting of "Association of Official Agricultural Chemists", then known as AOAC. Now this association is known as AOAC International. Over the past 122 years AOAC International has developed a process for validating and harmonizing analytical methods. Method validation is the key for determining the performance of analytical methods, and the reliability of the results obtained. AOAC International is committed to analytical excellence and worldwide confidence in analytical results using a defined method validation process.

## ANALYTICAL METHOD VALIDATION

There are several types of validation for analytical methods. AOAC International (Fredrick Ave, Gaithersburg, MD, USA) is the leading organization that conducts methods validation under its auspices. AOAC International conducts the following types of method validation:

1 Performance tested method (PTM)
2 Peer-verified method (PVM)
3 Official methods of analysis (OMA)

*AOAC Official methods* are referenced in the US Code of Federal Regulations (CFR) and are used worldwide by regulated industry, product testing laboratories, and academic institutions. AOAC International is an independent association devoted to promoting methods validation and quality measurements in analytical sciences. It provides full review and validation of approved standard methods of analysis, promotes uniformity, and reliability in statements of results, and develops and promotes criteria useful for laboratory accreditation and analyst certification.

### Performance tested methods

There are a large number of rapid test kits available for chemical and biological analysis. In order to verify the claims made by the kit manufacturer about the performance of test kits, AOAC International introduced the concept of PMT. The applicant (kit manufacturer) submits the performance data of the test kit along with the application fee. AOAC International appoints a panel of experts to review the performance data. If the review of performance data is satisfactory, an expert laboratory is selected to check the performance of the test kit. If the performance is as claimed the test kit is awarded the status of PMT.

### Peer-verified programs

PVM methods The AOAC® *Peer-Verified Methods*℠ Program is intended to provide a class of tested methods which have not been the subject of a full collaborative study. Through a less intensive process, the program provides a rapid entry point for methods, which are recognized by AOAC at a level of validation for methods not otherwise evaluated. The distinguishing aspect of an AOAC *Peer-Verified Methods*℠ is that its performance has been checked in at least one other independent laboratory. Eventually, it is expected that most PVMs will undergo full interlaboratory collaborative studies and obtain *Official Methods*℠ status. An explanation of the PMT, PVT, and OMA is available at www.aoac.org.

### Single laboratory validation

In order for a method to be validated as PTM, PVM, and finally as *Official method* it must first be validated in a single laboratory. In international trade and regulatory affairs, only validated methods are acceptable. The method need not to be validated under the auspices of AOAC International, but evidence is required that the method is suitable for the intended purpose such that similar results are obtainable from other competent laboratories. In order to gather this information, single laboratory validation (SLV) is essential. Various standard setting organizations such as International Standards Organization (ISO) and AOAC International (AOAC) have established standards for SLV of methods of analysis. AOAC has more than 120 years experience in collaboratively validating methods of analysis. These standards require that certain performance characteristics (attributes) of an analytical method must meet specified standards. Many analytical methods published in the scientific literature may not meet the criteria specified in the above standards. They usually lack the essential attributes required for the recognized validation process.

The performance characteristics are the specificity, the ability to distinguish the analyte from other substances; applicability – as the matrices and the concentration range, and reliability. Reliability is the most important characteristic of an analytical method and is expressed in terms of % recovery, repeatability, and reproducibility. Repeatability

and reproducibility are expressed in terms of relative standard deviation within laboratory and between laboratories, respectively ($RSD_r$, $RSD_R$). Intermediate precision, another term, which is important for SLV, is the intermediate repeatability relative standard deviation ($RSD_{ri}$). It is also very important that the analytical method is fit for its intended purpose. For example, a method intended for the determination of lead (Pb) in drinking water at ppm or ppb level is not fit for the analysis of lead ore (% composition level). If such a method is used for the determination of lead in an ore, the error, and the variability will be too large, and the analysis may not serve its purpose, i.e. whether to mine or not mine a certain location. Thus fitness for purpose is very important.

There are only few methods, which have been validated for use in veterinary analytical toxicology. These methods are listed in the *Official methods of AOAC International* (AOAC, 2000). An on-line version of OMA is available as the membership benefit for members of AOAC International. Thus, it is important that any method used in veterinary analytical toxicology is at least validated within the laboratory.

The American Association of Veterinary Laboratory Diagnosticians (AAVLD) is also an accrediting organization for veterinary diagnostic laboratories in USA. AAVLD has been emphasizing the use of validated methods in diagnostic laboratories. It should be pointed out that any method from the scientific literature does not become a validated method by simply rewriting it in ISO format. In order to be validated, the laboratory must prove that the method has acceptable performance characteristics of required attributes. If the laboratory hires a new analyst, the analyst should show that he (she) could get results consistent with the performance characteristics of the method. Many federal laboratories, such as the Food Safety and Inspection Service (FSIS), United States Department of Agriculture (USDA) (FSIS–USDA, 1995) require this.

## AN EXAMPLE OF AN SLV FOR THE GAS CHROMATOGRAPHIC DETERMINATION OF SELENIUM (Se) IN BLOOD AND LIVER

An illustrated example of the SLV for the determination of selenium in liver and whole blood is given here. In our laboratory there was a need for the determination of selenium (Se) in fresh liver and whole blood. The literature survey showed a large number of methods for the determination of Se using widely differing techniques such as fluorometry, AA, and GLC with electron capture detector (GLC–ECD). Due to the limitation in appropriate instrumentation, and conversation with another colleague, we decided on the GLC/ECD method. The method of Poole *et al*. (1977) as modified by Ross and Lund (1982) was selected. The method involves the wet digestion of the sample (0.1–1 g) in concentrated nitric acid with magnesium nitrate, the mixture is heated on a hot plate below 100°C till all the liquid evaporates, and after that the temperature is raised to remove the brown fumes of nitric acid. The residual nitric acid is removed by placing the sample in a muffle furnace at 500°C for 30 min. After cooling the sample, the ash is dissolved in concentrate hydrochloric acid for 10 min, at 100°C. To the solution, 10 ml of 20% urea is added and the mixture is allowed to cool; 4 ml of 1% solution of 1,2-diamino-4-nitrobenzene is added. The solution is transferred to a 50 ml stoppered polyethylene centrifuge tube quantitatively with the aid of 5 ml water. The contents of the tube are mixed, and 5 ml of toluene is added to the tube and vigorously shaken for 30 s, and phases are allowed to separate. About 2 ml layer of toluene is passed through a column of anhydrous sodium sulfate packed in a pasture pipette. The toluene layer is collected in pyrex screw cap tube, and 1 μl of the toluene (containing Se derivative) is injected in the gas chromatograph fitted with ECD. A Tracor (MT 222) gas chromatograph fitted with a 6 ft glass column with 1/4 in. internal diameter packed with 1.5% OV-17 and 0.95% OV-225 was used. The oven temperature was 200°C and detector temperature was 300°C. The carrier gas nitrogen flow was maintained at 60 ml/min. The Se retention time was about 3 min.

## CALIBRATION CURVE: HOW TO MEASURE A QUANTITY OF INTEREST

The modern chemical analytical instruments use physical properties for the measurement of analyte concentration. Thus, analytical instrument has to be optimized, and calibrated to detect and report the information about concentration of an unknown. The instrument is calibrated to test the response against a series of known standards of the analyte. The result of this experiment is a plot of response versus concentration, known as calibration curve. Calibration curves are functions of an instrument's response to a range of known concentration levels of reference material. In some cases the concentration level may be too low to be detected by the particular instrument in use, in other cases it may be too high and overload the detector. The optimal range of concentration level for detection is usually narrow. Ideally, this narrow range represents a linear response. The analytical chemist prefers to work in this linear range, since data analysis is comparatively easy in this range. The calibration standards from the reference material should be made with utmost care and

**TABLE 86.1** Se calibration curve data

| | Concentration | Response |
|---|---|---|
| | xi | yi |
| | 0 | 0 |
| | 0.1 | 2.1 |
| | 0.25 | 5.8 |
| | 0.5 | 10.9 |
| | 0.75 | 17 |
| $r$ | 0.99951739 | |
| | $b$ | $a$ |
| | 22.5308311 | −0.049865952 |

accuracy. The concentration of the analyte in the unknown sample is calculated by using a mathematical relationship between concentration and response, known as the regression equation for the calibration curve. The regression equation takes the form, response ($y$) = slope of the curve ($b$)+ $y$ intercept.

$$y = bx + a \quad \textbf{86.1}$$

We can determine the value of $b$ and $a$, from the calibration curve data, and the concentration of analyte in the sample, $x$, can be calculated according to Eqn. 86.2

$$x = \frac{\mathrm{y} - \mathrm{a}}{b} = \frac{Response - Intercept}{Slope} \quad \textbf{86.2}$$

The response is read from the instrument, and the slope and intercept are obtained from the calibration curve.

## GOODNESS OF LINEARITY OF CALIBRATION CURVE

The degree of linearity of the calibration curve is determined by the correlation coefficient, $r$, and as well as plotting the detector response on $y$-axis, and the concentration of the reference standards on the $x$-axis. The value of $r$, varies from −1.0 to + 1.0. A value of 1 indicates that there is positive linear relationship between the detector response and the standard concentration. The data for a typical calibration curve for Se is shown in Table 86.1. The data in Table 86.1 shows a linear relationship, and the calibration curve shows a straight line, shown in Figure 86.1.

The value of $r$, is calculated on Excel spreadsheet using the function, = correl(array $y$, array $x$). The values of the slope $b$, and intercept $a$, are calculated by using the function, = linest(array $y$, array $x$). In order to get both values ($b$ *and* $a$), place the data for concentration, $x$, *and* the response, $y$, columns as shown in Table 86.1. Run the "linest" function in a column just below marked, $b$. Hold the shift, and ctrl key and hit enter, both values will appear on the spreadsheet.

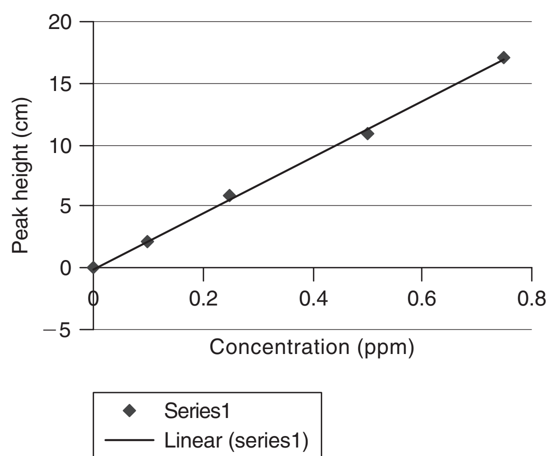

**FIGURE 86.1** Se calibration curve.

The correlation coefficient, slope, and the intercept can also be calculated with the aid of equations (3, 4, and 5) given below (Miller and Miller, 1992)

$$r = \frac{\sum_i \{(x_i - \bar{x})(y_i - \bar{y})\}}{\sqrt{\left\{\left[\sum_i (x_i - \bar{x})^2\right]\left[\sum_i (y_i - \bar{y})^2\right]\right\}}} \quad \textbf{86.3}$$

$$b = \frac{\sum_i \{(x_i - \bar{x})(y_i - \bar{y})\}}{\sum_i (x_i - \bar{x})^2} \quad \textbf{86.4}$$

$$a = \bar{y} - b\bar{x} \quad \textbf{86.5}$$

The regression equation for the calibration is as follows:

$$y = 22.53x + (-0.0499)$$

### Recovery and accuracy

The recovery and accuracy was determined with the use of standard reference bovine liver (1577a) from the National Institute of Standards and Technology (NIST), Gaithersburg, MD. The mean value of Se in the NIST standard 1577a was reported to be 0.71±0.07 ppm. Duplicate samples of NIST bovine liver sample were run on 10 different days. A new calibration curve was made each day with new Se standards (obtained from Perkin Elmer). The results of Se concentration in NIST bovine liver are shown in Table 86.2.

The mean recovery from NIST 1577a bovine liver is 0.6852 ppm. Thus, recovery % is:

% Recovery = (Laboratory mean recovery/NIST value) × 100

% Recovery = 0.6852/0.71 = 96.5%

The % recovery is well within the values recommended in AOAC guidelines (AOAC, 2003) that are shown in Table 86.3.

**TABLE 86.2 Se recovery data**

| Replicate | Day 1 | Day 2 | Day 3 | Day 4 | Day 5 | Day 6 | Day 7 | Day 8 | Day 9 | Day 10 | Mean |
|---|---|---|---|---|---|---|---|---|---|---|---|
| 1 | 0.754 | 0.678 | 0.614 | 0.517 | 0.696 | 0.769 | 0.662 | 0.690 | 0.560 | 0.740 | 0.668 |
| 2 | 0.804 | 0.753 | 0.709 | 0.663 | 0.691 | 0.772 | 0.663 | 0.619 | 0.560 | 0.790 | 0.7024 |
| Mean | | | | | | | | | | | 0.6852 |

**TABLE 86.3 Acceptable recovery values for various analyte concentrations**

| Concentration | Recovery limits (%) |
|---|---|
| 100% | 98–101 |
| 10% | 95–102 |
| 1% | 92–105 |
| 0.1% | 90–108 |
| 0.01% | 85–110 |
| 0.001% (10 ppm) | 80–115 |
| 0.0001% (1 ppm) | 75–120 |
| 1 ppb | 70–125 |

## Precision

The precision of an analytical method is represented by the standard deviation for the method for replicate measurements. There are two kinds of standard deviations that can be computed for the laboratory method. One is the standard deviation for within day run, i.e. the standard deviation for replicate samples that are analyzed on a given day, the other is the standard deviation for among days analysis. Since the routine samples are analyzed on days when the laboratory receives them, the standard deviation for "among days" applies for the routine samples. The manual calculations, for the calculations of this standard deviation, are complex. Fortunately, AOAC International has the software for calculating these standard deviations, and is available from Dr. Joanna Lynch (jl72@cornell.edu), Cornell University, Ithaca, NY. This software is developed for evaluating interlaboratory (collaborative) studies. However, this is also applicable for the determination of within day, and among days standard deviation. This software can also determine the % recovery for the method.

The within day standard deviation ($s_r$), also known as repeatability, is calculated, from the software as 0.0480 ppm, and the relative standard deviation, $RSD_r$, which is represented by the relationship

$$\%RSD_r = \frac{s_r}{\bar{x}} \times 100 = 7\% \qquad \textbf{86.6}$$

But our true standard deviation for repeatability is among days standard deviation, thus the true repeatability relative standard deviation is calculated by using $s_R$ (0.082) (from AOAC software). For replicate measurements made on different days within a laboratory, it is also known as intermediate precision. For clarity purpose, this relative standard deviation is represented as $\% RSD_{ri}$. *The true repeatability relative standard deviation* (among days) is:

$$\%RSD_{ri} = \frac{s_R}{\bar{x}} \times 100 = 11.97\% \qquad \textbf{86.7}$$

Although the recovery is within AOAC International guidelines, does it belong to the same population as the NIST bovine liver 1577a? The answer to this question is obvious. The 95% confidence limit for the NIST bovine liver is given in the certificate of analysis as $0.71 \pm 0.07$ ppm. The laboratory mean recovery of 0.69 ppm (0.6852 rounded to two decimal places) is within the confidence limit as provided by NIST certificate of analysis. Thus, it can be concluded that there is no significant difference between two means. At this point the only thing to be answered is how good the laboratory relative standard deviation ($RSD_{ri}$) is. This is determined by the use of HorRat values.

## HorRat values

For SLV work the HorRat value is given by the relationship,

$$HorRat_r = RSD_{ri} \ / \ PRSD_R \qquad \textbf{86.8}$$

where $RSD_{ri}$ is the relative standard deviation for among days analysis (Eqn. 86.8), and $PRSD_R$ is the predicted relative standard deviation for between laboratories analysis. How do we find $PRSD_R$? It can be predicted based on concentration of the analyte (Horwitz *et al.*, 1980; Horwitz, 1982). Based on the data from 100 years worth of interlaboratory method validation studies conducted under AOAC International auspices, Horwitz determined that relative standard deviation between laboratories and within laboratory is dependent on the analyte concentration. The relationship is expressed by the equation:

$$PRSD_R\% = 2C^{-0.15} \qquad \textbf{86.9}$$

where $C$, is expressed as the mass fraction. The above equation can be expressed in spreadsheet notation: $PRSD_R$ % =2 × $C$^ (−0.15). For example a concentration of 1 ppm is expressed as 1.000E−6 (1 μg/g). Thus for an analyte concentration of 1 ppm the calculated:

$$PSRD_R\% = 2 \times (10.00E{-}07)\text{^}(-0.15) = 16\% \quad \textbf{86.10}$$

Another observation of Horwitz that was confirmed by Thompson and Lowthian (1997) is that the precision of analytical methods at any given concentration does not improve with time, despite the advances in analytical technology. The mean value of selenium in NIST bovine liver is 0.71 ppm, thus, the predicted relative standard deviation for between laboratories is

$$PSRD_R\% = 2 \times (7.1E{-}7)\text{^}(0.15) = 16.7\%$$

Thus, the HorRat value for our method for the determination of selenium is:

$$HorRat = 11.97/16.7 = 0.71$$

The accepted HorRat values for single laboratory method validation are from 0.5 to 1.3. Thus, the relative standard deviation for our method is well within the accepted limit. The linearity of the calibration curve, the percent recovery, the relative standard deviation, and HorRat value clearly show that the method meets the validation criteria.

## Shewhart chart

The basic concept behind Shewhart's control chart is the distinction between two categories of variation. A process will either display "controlled variation" or it will display "uncontrolled variation." When a process displays controlled variation its behavior is indiscernible from what might be generated by a "random" or "chance" process. On the other hand, when a process displays uncontrolled variation, then something markedly different has occurred from what would have been expected from a random or chance process, and therefore an "assignable cause" can be attributed to that occurrence. Also, seeing its effect has been large enough to notice, it is surely worth the effort to try to identify this assignable cause.

Given this distinction, the control chart is a technique for detecting which type of variation is displayed by a given process. The objective is to give the user a guide for taking appropriate action – *to look for assignable causes* when the data display uncontrolled variation, and *to avoid looking for assignable causes* when the data display controlled variation.

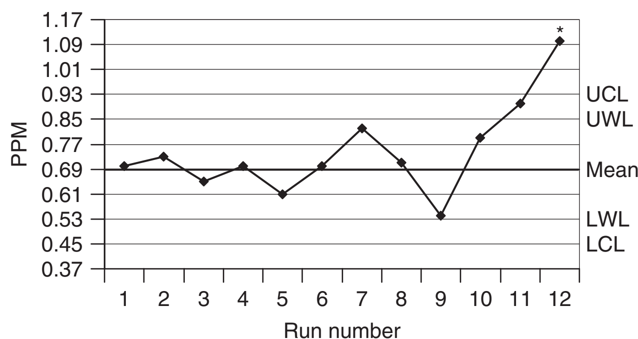

**FIGURE 86.2** Shewhart chart – Se assay.

Shewhart looked upon the control chart as the voice of the process – one can use the chart to understand how a process is behaving. Therefore, a process is said to be "in control" only when it has demonstrated, by means of a reasonable amount of data, that it is performing consistently and predictably. Moreover, from a practical perspective, such a process is, in essence, *performing as consistently as possible*. Therefore, any process that is not performing "as consistently as possible" may be said to be "out of control." Thus, the control chart is a procedure for characterizing the behavior of a process.

Figure 86.2 shows the Shewhart control chart for our GC method for selenium determination in NIST bovine liver 1577a. In normal distribution, two standard deviations of the mean consist of 95% of the values, and three standard deviations comprise 99% all the values, which can result from random variation in the process. Thus, for each run, if we plot the difference from the mean on $y$-axis, and number of run on $x$-axis, it provides us a pictorial view of the variation in the process. If our values fall within two standard deviations from the mean, the process is statistically under control. Thus, two standard deviations in positive or negative direction form the upper and lower warning limits. If the observation from the run is coming very close to the warning limit line that means the process is nearing its statistical control limit. If the values go beyond three standard deviations from the mean that means, the process is out of control, and that certain errors other than the random variation are entering the process. At this time, the analysis for routine samples should be stopped, and the reason for the error be investigated. When the problem is solved, only then the routine testing shall begin. In Figure 86.2, an asterisk marks the point at which the method is out of statistical control.

## EXAMPLE OF AN INTERLABORATORY (COLLABORATIVE) STUDY FOR THE VALIDATION OF SEMI QUANTITATIVE METHOD

Any method must be fit for the purpose. Nitrate causes poisoning in ruminants. The nitrate containing forages are usually responsible for this poisoning. The guidelines for feeding ruminant with nitrate containing forages are as follows (on dry matter basis) (Guthrie, 1986):

- Forages with nitrate concentrations less than 1000 ppm are considered safe under all conditions.
- Forages with 1000–5000 ppm nitrate should be safe to feed to *nonpregnant animals* under all conditions.
- Forages containing more than 2500-ppm nitrate should be limited to 50% of the total ration for *pregnant and lactating* animals. Erratic and low milk production is expected when nitrate concentration in forages exceeds 2500 ppm.
- Forages containing 5000–10,000 ppm nitrate may be fed safely to *nonpregnant and nonlactating* animals if limited to *50% of the total ration*. For *lactating and pregnant animals*, such forage should be limited to 25% of the total ration. Abortions and drop in milk production should be expected if such forage is greater than 25% of the total ration.
- With forages containing greater than 10,000-ppm nitrate, abortions, acute symptoms, and death should be expected. Thus, these forages should not be fed to ruminants.

Results of an intralaboratory study reported by Jain (1993) indicated that nitrate content of forage could be estimated using a test strip. Thus, a collaborative study was conducted to demonstrate the validity of the screening test for nitrate in forages.

Six forage samples were made for the collaborative study (Jain *et al*., 1999). The nitrate concentration in forage samples ranged from <1000 ppm nitrate to >10,000 ppm nitrate. Five samples were made from field cases submitted to the Athens Veterinary Diagnostic Laboratory. Two of them were mixture of forages. The sixth specimen was also a mixture of forages, and was provided by the Veterinary Diagnostic Center, University of Nebraska, Lincoln. The forage specimens were dried overnight at 60°C in a convection oven, ground using a Wiley Mill to pass through a 2-mm screen, and then thoroughly mixed in twin shell blender. Samples for each collaborator were prepared by placing 1.0 g of forage in a 50 ml plastic centrifuge tube labeled with a coded number. Five blind replicates of each of the six forage samples were prepared for each collaborator. The samples were labeled with numbers 1–30, and were sent to 20 different laboratories across USA.

Table 86.4 shows the results from various laboratories. The laboratory recorded the range number of a given sample. For example for sample number 21, which is in range number 1, all the laboratories, except laboratory U, identified the sample correctly in range number 1. The complete results were received from 19 laboratories. The statistical analysis of the data was conducted according McClure (1990). The published collaborative report does not show how the calculations for statistical parameters were

The * to the left of the number indicates that the range was incorrectly determined.

[a]Results of laboratories I and M were deleted from statistical analysis as outliers based on *chi-square* test and inspection, Mcclure (1990).

made, it only shows final results. The step-by-step calculations are shown in this chapter for the benefit of the reader.

## Outlier results

First, the results were tested for outlier values, if any, using *chi-square* statistics ($Q$). The null hypothesis is that labs do not have significantly different proportions of correct results. Table 86.5 shows the recast of the data in Table 86.4 for statistical purposes to reflect correct (1), and incorrect (0) results, and is used for computation of $Q$ *statistic*, by Eqn. 86.11:

$$Q = \frac{(L-1)\left(L\sum T_i^2 - \left(\sum T_i\right)^2\right)}{\left(L\sum S_j - \sum S_j^2\right)} \qquad \textbf{86.11}$$

where $L$ is the number of laboratories reporting the results, $T_i$ is the number of correct results by the laboratory ($i$) and $S_j$ is the total number of correct results for sample ($j$). Thus, referring to Table 86.5,

$$Q = \frac{(19-1)(19(16023) - (551)^2)}{19(551) - (10145)}$$

$$Q = \frac{18(836)}{324}$$

$$Q = 46.44$$

This calculated value of chi-square is greater than the critical value of 28.87 for 18 ($L$-$1$) degrees of freedom. Thus, the null hypothesis is disapproved, and there are significantly different proportions of correct results. By inspection, the laboratories I and M appear to be outliers. After rejecting the outliers the test was repeated, and the calculated value of statistic ($Q$) was found to be 15.775, which is less than the critical value of 26.29 for 16 degrees of freedom (note that the results of laboratories I and M were rejected).

## Sensitivity rate

The sensitivity rate ($p+$) is the probability that the method will classify a test sample in a "given range" provided that the sample is in that "given range." For example, samples 2, 4, 6, 10, 11, 12, 13, 16, 21, and 27 are range 1 samples; whereas, all other samples are in "another range." For statistical analysis, we are saying that all samples listed under range 1 in Table 86.4 are correctly identified if they are identified as 1 in the table. Any other number in table for range 1 is considered as misidentification, and is considered a negative value for range 1. The data for the calculations of sensitivity rate and its standard error for various ranges is shown in Table 86.6.

$$(p_+) = \frac{\sum a_i}{\sum m_i} \qquad \textbf{86.12}$$

where $\sum a_i$ is the total number of correct results for a given range, $\sum m_i$, is the total number of results for that range. Thus, the sensitivity for range 1,

$$(p_+) = \frac{169}{170} = 0.994$$

The standard error for sensitivity for each range can be calculated by the formula

$$s.e.(p_+) = \left\{\frac{\left(\sum a_i^2 - \left(\sum a_i\right)^2/L\right)}{\sum (\bar{m})^2 \; L(L-1)}\right\}^{1/2} \qquad \textbf{86.13}$$

Thus for range 1,

$$s.e.\ (p_+) = \sqrt{\frac{1681 - 1680.0588}{100 \times 17 \times 16}} = 0.006$$

This means that for range 1, if large numbers of observations were made, 6 out of 1000 observations will misidentify range 1, and 994 observations will correctly identify range 1.

The sensitivity rate and standard error for other ranges can be calculated similarly.

## Specificity rate ($p_-$)

The specificity ($p_-$) for the "given range" is the probability that the method will classify the test sample in "any other range" provided the test sample was in "another range." For range 1 all samples, which are not in range 1, are in "another range." The value of ($p_-$) can be calculated by Eqn. 86.12. For specificity rate calculations, $m$, *is* 20 since there are 20 samples in ranges 2, 3, and 4. Thus the total of all $m$ values is 20 × 17 (340, since there were 17 laboratories). The total of correct values for specificity rate is 339, since only laboratory Q has a range 2, 3, or 4 sample identified as range 1 sample. The data for calculations of specificity rate and its standard error is shown in Table 86.7.

Thus specificity rate for range 1 is, $(p_-) = \frac{339}{340} = 0.997$.

The standard error for specificity rate using Eqn. 86.13 is:

$$s.e.\ (p_-) = \sqrt{\frac{6741 - 6760.059}{400 \times 17 \times 16}} = 0.003$$

| Y | 20 | 400 | 0 | 0 | 26 | 676 | 1 | 26 | 25 | 625 | 0 | 0 | 20 | 400 | 0 | 0 |
| Z | 20 | 400 | 0 | 0 | 25 | 625 | 0 | 0 | 25 | 625 | 0 | 0 | 20 | 400 | 0 | 0 |
| $\Sigma m_j$ | 340 | | | | 425 | | | | 428 | | | | 341 | | | |
| $\Sigma m_j^2$ | | 6802 | | | | 10,629 | | | | 10,731 | | | | 6843 | | |
| $\Sigma a_i$ | | | 1 | | | | 2 | | | | 4 | | | | 2 | |
| $\Sigma a_im_j$ | | | | 21 | | | | 52 | | | | 106 | | | | 42 |
| $\Sigma a_i^2$ | | | 1 | | | | 2 | | | | 6 | | | | 2 |
| $(\overline{m})^2$ | 400 | | | | 625 | | | | | 633.9 | | | 402 | | | |

[a] $m_j$ = number of negative readings among both "known" positive and negative samples lab.
[a] $a_i$ = number of negative readings among "known" positive test samples/lab.

## False positive rate ($p_{f+}$)

The false positive rate is the probability that the test sample is in "another range" and has been classified in a "given range." The data for the calculations of false positive rate and its standard error is shown in Table 86.8. The equations for the calculations for false positive rate and its standard error are Eqns 86.14 and 86.15, respectively.

$$\text{False positive rate } (pf_1) = \frac{\sum a_i}{\sum m_j} \qquad \mathbf{86.14}$$

$$s.e.(pf_+) = \sqrt{\frac{\left(\sum a_i^2 - 2(pf_+)\sum a_i m_j + (p_{f+}^2)\sum m_j^2\right)}{L(L-1)(\overline{m})^2}} \qquad \mathbf{86.15}$$

Thus, the false positive rate ($p_{f+}$) for range 1 is = 1/170 = 0.0058823 rounded to 0.006

$$s.e.(p_{f+}) = \sqrt{\frac{1 - 2(0.0058823) \times 11 + 0.0000346}{17 \times 16 \times 100}} = 0.0058395$$

## False negative rate ($p_{f-}$)

The false negative rate is the probability that a test sample is in a "given range" and the sample has been classified in "another range." The data for the calculations of false negative rate and its standard error is shown in Table 86.9. Thus, the false negative rate ($p_{f-}$), and its standard error for various ranges can be calculated from the Eqns 86.14 and 86.15, respectively.

False negative rate ($p_{f-}$) for range 1 =1/340 = 0.0029411 = 0.003 and its standard error is

$$s.e.(p_{f+}) = \sqrt{\frac{1 - 2 \times (0.003) \times 21 + 0.0612}{17 \times 16 \times 400}} = 0.0029 = 0.003$$

**TABLE 86.10 Performance parameters for various ranges**

| Parameter | Range 1 | Range 2 | Range 3 | Range 4 |
|---|---|---|---|---|
| Sensitivity rate ($p_+$)[a] | 0.994 | 0.977 | 0.965 | 0.988 |
| Standard error of ($p_+$) | 0.006 | 0.016 | 0.026 | 0.008 |
| Specificity rate ($p_-$)[b] | 0.997 | 0.991 | 0.993 | 0.997 |
| Standard error of ($p_-$) | 0.003 | 0.005 | 0.004 | 0.003 |
| False Positive Rate ($p_{f+}$)[c] | 0.006 | 0.046 | 0.012 | 0.006 |
| Standard error of ($p_{f+}$) | 0.006 | 0.025 | 0.012 | 0.006 |
| False negative rate ($p_{f-}$)[d] | 0.003 | 0.005 | 0.007 | 0.006 |
| Standard error of ($p_{f-}$) | 0.003 | 0.003 | 0.006 | 0.004 |

[a] The sensitivity rate ($p_+$) is the probability that the method will classify a test sample in a "given range" provided the sample is in that "given range."
[b] The specificity rate ($p_-$) is the probability that the method will classify the test sample in "another range" provided the test sample is in "another range."
[c] The false positive rate ($pf+$) is the probability that the test sample is in "another range" and has been classified in a "given range."
[d] The false negative rate ($pf_-$) is the probability that a test sample is in given range, and the sample has been classified in "another range."

### Performance parameters for the method

Various performance parameters are shown in Table 86.10.

## LABORATORY QUALITY MANAGEMENT

The quality of a laboratory product depends on the quality system that is followed by the laboratory. Just what is quality and why is it so important? Quality system has a different meaning in different laboratories but they share the same key elements to ensure the quality and integrity of the product. A quality system has elements that are of quality assurance (QA) nature and others are of a quality control (QC) nature. The quality system is also referred as QA/QC. Some laboratories work under the standards of a certain organization such as ISO, AOAC, or AAVLD whereas some laboratories develop their own quality system customized to the needs of the laboratory (Tebbett, 2003).

### Quality assurance

ISO standard 9000:2000 defines QA as part of the quality management focused on providing the confidence that quality requirements will be fulfilled. All QA programs have similar elements: they are designed to ensure that (1) the sample is not contaminated, (2) is handled by personnel who are trained for that specific job and are using equipment that is properly calibrated and procedures that are validated, and (3) that everything is documented and that records can be accessed when needed (Tebbett, 2003). Good quality produces good results. It gives the laboratory an edge over competitors and makes the customers happy because they can rely on the integrity of the results produced. Poor quality wastes time, supplies, and money (Archer, 2005). The accuracy of the result is questionable which casts a shadow on everything that the laboratory produces.

### Quality control

Quality control refers to the steps taken during the analytical process to ensure that the process produces reliable measurements data that is fit for the purpose.

## CONCLUSIONS

"Prove it!" What would be your response to that challenge to the data generated by your investigation or services? Can you prove the accuracy of your data? Yes, you can prove the integrity and accuracy of your results if the validated analytical method was used in conjunction with reference materials traceable to recognized source, and you have on hand the validation data. Just saying that we use validated methods in our laboratory is not enough. The analysis of reference materials traceable to sources recognized by measurement bodies with client samples is essential to provide defensible data of such quality that is useful to the client. Even the validated methods must be repeated in the laboratory to confirm that the laboratory is able to get the performance parameters as reported in the validated method. The record keeping of the validation of performance parameters is part of the quality management plan. In order to ascertain that the method is performing under statistical control, a control sample should be run with each batch of samples. The value of the control sample gives the indication of the performance of the method on a given day. Analyzing control sample with each batch of samples is also part of the quality management program. Each laboratory must have a sound quality management (QA/QC) program.

## ACKNOWLEDGMENT

We would like to thank Teresa Morrison for the laboratory work used in this chapter. One of us (A.V. Jain) thanks Gagan, my wife, whose encouragement and support made this chapter possible. I thank Dr. W. Horwitz, who encouraged me to be proficient in the use of statistics for the evaluation of analytical data, Dr. D. Mowery who assisted with the statistical analysis of nitrate study, and Dr. T. Sriram who answered many of my questions regarding statistics. Our thanks to Mr. Jim Scott, for thoroughly reading the chapter and making many helpful suggestions.

# Sample submission for toxicological analysis

*Anant V. Jain*

## INTRODUCTION

Is my patient poisoned? This question arises almost in every veterinary practice. An accurate diagnosis is the single-most important factor in dealing with animal poisons. The offending agent may be known or unknown. If the offending agent is known, specific treatment and prevention can be initiated. Often the toxic agent is unknown. In this instance, efforts are limited to supportive care and symptomatic therapeutic measures.

Chemical analysis is very important in establishing diagnosis of poisoning. Chemical analysis is usually done at the veterinary diagnostic laboratories, and there are many veterinary diagnostic laboratories in USA. A list of accredited and allied laboratories is available at www.aavld.org. Most of these laboratories are partially funded by respective states, thus, the services of veterinary diagnostic laboratories are available at a reasonable price to the client. Familiarity with the chemical analysis services provided by diagnostic laboratory in your area and its fee structure are extremely important in the effective use of the services provided by the laboratory.

The objective of this chapter is to provide with guidelines for proper samples submission to diagnostic laboratories. Each diagnostic laboratory has a submission form, which should be completed in full to get the most efficient service for chemical analysis. All of the diagnostic laboratories require complete history, clinical signs, and postmortem findings. This information greatly aids the laboratory personnel to decide on the best course for the chemical analysis.

## REQUIRED INFORMATION FOR SAMPLE SUBMISSION

### History

A detailed history of the circumstances associated with poisoning is the first step for a successful diagnosis. The investigation of poisoning case is as much detective work as is veterinary medicine, and chemical analysis. Three detectives are partners in this endeavor – veterinarian, client, and the analytical laboratory. The veterinarian must be ready to gather as many pieces of the puzzle together as possible. Fitgerald (2001) discusses in detail various elements of a good history. Osweiler *et al*. (1985) and Osweiler (1996) provides a checklist for a good history.

### Clinical signs

Clinical signs are very important in reaching the diagnosis of a poisoning. Clinical signs can narrow the search for toxic agents. Ask the client for sequence of clinical symptoms. Describe clinical signs in detail. It is not enough to say that the patient was observed with central nervous system (CNS) signs. It is essential to provide the complete sequence of events as to how the patient acted.

### Postmortem findings

If the animal has expired, it is imperative to perform a necropsy. It is better to perform the necropsy at site since

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

it can provide very valuable information. If it is not possible to perform the necropsy at the site send the body to the diagnostic laboratory. A qualified pathologist will conduct the necropsy and collect the appropriate sample for histological as well as for toxicology testing. If it is poisoning then why worry about necropsy and histological examination? Simply test for toxicants and it should give us a diagnosis. Unfortunately, life is not that simple. There are thousands of chemicals that can cause poisoning in animals. *There is no simple test for all the poisons*. Some poisons produce extensive lesions, other only slight tissue alterations, and some produce on lesions at all. Based on this information the pathologist can provide assistance in the selection of toxicants to test for.

## Chemical analysis

Chemical evidence is often an indispensable aid in diagnosing toxicological problems. Used properly, chemical analysis can provide the most important evidence of poisoning. Analytical data should be used in conjunction with history, clinical signs, necropsy findings, and histological examination. The importance of clinical signs, postmortem findings, and chemical analysis has been described in detail in previous reports (Osweiler *et al*., 1985; Poppenga and Braselton, 1990; Galey, 2000, 2001, 2004; Puschner and Galey, 2001; Volmer and Meerdink, 2002).

# SAMPLE COLLECTION AND SUBMISSION FOR TOXICOLOGY ANALYSIS

A list of various types of samples which can be useful in the investigation of poisoning cases is given in Table 87.1.

Each sample should be stored in a separate container, and the container should be labeled with an indelible ink

**TABLE 87.1 Samples for toxicology testing**

| Sample | Amount | Tests for which sample can be used | Comments |
|---|---|---|---|
| *Antemortem Samples* | | | |
| Blood | 10–20 ml | Heavy metals, trace elements, anticoagulants, antifreeze, cholinesterase, cyanide, chlorinated hydrocarbon pesticides | Refrigerate sample. Use anticoagulant such as EDTA or heparin. Use *Royal blue tubes* with anticoagulant |
| Serum | 10–20 ml | Some metals like Cu, Zn, and nitrate/nitrite, ammonia, drugs (particularly sulfa drugs) | Separate clot from the serum. Refrigerate or freeze (if it will take long during shipping). Amount required for single test will be much less. Check with the testing laboratory. If Zn assay is desired use *Royal blue tubes* without any additive or anticoagulant |
| Urine | 50–100 ml | Alkaloids, some metals, antibiotics, cantharidin, drugs, sulfa drugs, oxalates, and paraquat or diquat | Freeze. Especially useful for paraquat or diquat |
| Feces | 250 g | Drugs, various poisons excreted mainly in bile | Freeze. Indicator of recent exposure |
| Biopsy specimen: liver | | Metals | Freeze |
| Milk | 250 ml | Antibiotics, chlorinated insecticides, polychlorinated biphenyls, | |
| Vomitus or gastric aspirate | All available | Various poisons. Heavy metals, anticoagulants, antifreeze, pesticides (all chlorinated hydrocarbons organophosphates, and carbamates) | Freeze. Indicator of recent exposure. In case of gastric aspirate make sure to submit first aspirate |
| Hair | 5–10 g | Pesticides, and some metals such as As and Se | Indicator of recent exposure. Chronic accumulation of metals |
| *Postmortem Samples** | | | |
| Brain | Half | Chlorinated pesticides, pyrethrins, cholinesterase, and metals like, Pb, Na, Hg | Brain should be separated by midline sagittal section. Collect frontal cortex for cholinesterase determination. Freeze |
| Fat | 250 g | Chlorinated pesticides and dioxins | |
| Kidney | 100 g or all available | Metals like As and Pb. Phenolic compounds, oxalates | Freeze |
| Liver | 100 g or all available | Chlorinated pesticides, alkaloids, anticoagulants, aflatoxin $M_1$, and metals | Freeze |

(*Continued*)

**TABLE 87.1 (Continued)**

| Sample | Amount | Tests for which sample can be used | Comments |
|---|---|---|---|
| Ocular fluid | All available | Nitrate/nitrite electrolytes | Freeze |
| Rumen content | 500 g | Various poisons. Heavy metals, pesticides (all chlorinated hydrocarbons organophosphates, and carbamates) | Freeze. Sample should be collected from several locations in the rumen. Rumen content is not a good sample for nitrate/nitrite evaluation |
| Stomach content | 500 g or all available | Various poisons. Heavy metals, anticoagulants, antifreeze, pesticides (all chlorinated hydrocarbons organophosphates, and carbamates) | Freeze |
| *Environmental samples* | | | |
| Baits | All available | Various poisons. Heavy metals, anticoagulants, antifreeze, pesticides (all chlorinated hydrocarbons organophosphates, and carbamates), anticoagulants | Any other information which is available about bait should be communicated to the testing laboratory |
| Feeds | 2 kg | Various poisons. Heavy metals, pesticides (all chlorinated hydrocarbons organophosphates, and carbamates), ionophores | Multiple representative samples should be taken from various places from the stock and mixed thoroughly for a composite sample or retained as individual samples to detect variability in the feed or both. Feed samples are required for ionophores screening |
| Forage (pasture) | 2–5 kg | Various poisons. Usually used for evaluation of nitrate/nitrite | Samples should be taken from multiple locations in pasture and mixed thoroughly for composite sample. Avoid contamination from soil. Refrigerate sample |
| Forage (hay) | 2–5 kg | Various poisons | Samples should be taken from multiple locations using a forage core sampler from baled hay or stacks and mixed thoroughly for composite sample |
| Forage (silage) | 2–5 kg | Various poisons | Freeze |
| Mushrooms | Whole 100 g | Identification cyclic peptide hepatotoxin | Keep cool and dry in paper bag |
| Plants | Entire plant | Identification | Press between sheets of paper |
| Soil | 1 kg | Various poisons | Samples should be taken from multiple locations using a soil core sampler and mixed thoroughly for composite sample |
| Water | 1 l | Nitrate/nitrite, pesticides, and metals | Use clean glass container. Refrigerate sample |

with animal and tissue identification. Place the sample container in a zip-lock bag, squeeze the air out of the bag, seal the zip-lock bag, and label the zip-lock bag also. *Do not add anything to the samples for chemical analysis: no antiseptic, no preservative, no fixative, unless otherwise noted (as for whole blood)?* These instructions apply to all the samples which are collected. Lorgue *et al*. (1996) provides a detailed account for sample collection and dispatch to the laboratory with particular reference to United Kingdom.

## Whole blood

Whole blood should be collected in royal *blue top* vacutainer tubes with anticoagulant. At least 10 ml of whole blood should be collected. If more than one test is required, collect 20 ml blood. Make sure the tube is properly sealed. Refrigerate the sample. *Do not freeze whole blood sample.*

## Serum

The blood for serum samples should be collected in *royal blue top* vacutainer tubes (plain) which contains *no additive or anticoagulants.* After the clot forms, usually less than 30 min, the serum should be separated promptly, and transferred to a clean plastic tube, and freeze the sample.

## Urine

Urine should be collected in a screw cap plastic bottle (4 oz.) and frozen.

## Liver biopsy specimen

Collect about 100–200 mg sample, and immediately freeze, some laboratories may not be able to provide results for

some metals due to small sample size. Contact the laboratory before proceeding with biopsy.

## Milk

Collect in a clean jar and refrigerate.

## Feces

Place feces in heavy duty aluminum foil, wrap it completely, place in zip-lock bag, and freeze.

## Vomitus or gastric aspirate

Place vomitus in a plastic bottle with screw cap and freeze. In case of gastric aspirate make sure to submit first aspirate.

## Hair

Hair samples should be collected using clean scissors or clippers. Do not contaminate with other materials such as blood on gloves. Place the hair sample in a zip-lock bag. Keep it at room temperature.

## Brain, liver, kidney, fat, and other tissue(s) with lesions

Collect appropriate amount of the particular sample (see Table 87.1), place the sample on a heavy duty aluminum foil, fold the corners of aluminum foil to seal the sample, and place the aluminum foil with the sample in the appropriate size zip-lock bag. Handle one specimen at a time and avoid cross contamination. Freeze the tissue samples and fat could be refrigerated. Special attention is needed for brain sample. Brain should be separated by midline sagittal section. Collect the frontal cortex for cholinesterase assay (Gupta, 2004), and freeze the sample until analysis. It should be pointed out that caudate nucleus should not be used for cholinesterase assay, since frontal cortex is better indicator of cholinesterase status (Gupta 2004).

## Ocular fluid

Collect ocular fluid in a small plastic tube and freeze.

## Ingesta (rumen content and stomach content)

Carefully examine the contents of rumen or stomach for extraneous material. Make sure that the extraneous material is sampled for submission. Collect appropriate amount of the particular sample (see Table 87.1), place the sample on a heavy duty aluminum foil, fold the corners of aluminum foil to seal the sample, and place the aluminum foil with the sample in the appropriate size zip-lock bag. Rumen contents should be collected from several locations in the rumen and mixed thoroughly. Rumen content is *not* a good sample for nitrate/nitrite evaluation.

## Baits

Collect all possible bait samples, wrap in heavy duty aluminum foil, and place in a zip-lock bag. Gather all possible information regarding the bait, and forward the information to the testing laboratory along with the sample.

## Feedstuffs

Feedstuffs should be collected from several different locations in bin, crib, or silo. Many mycotoxins, for example, are found in isolated pockets of the feed and therefore, could be missed if one sample is obtained. It is preferable to sample some feed from the troughs or bunks. If the ration is mixed on premises, it is advisable to collect at least one pound each of the various components in the total ration. Samples of dry ration can be submitted in plastic bags, and the bag labeled with the identification of the sample.

## Forage (pasture)

Samples should be taken from multiple locations in pasture and mixed thoroughly for composite sample. Avoid contamination from soil. Refrigerate the sample.

## Forage (hay)

Ideally, hay samples should be taken from multiple locations using a forage core sampler from baled hay or stacks and mixed thoroughly for composite sample. Additional attention should be paid when sampling hay for nitrate/nitrite assay. Nitrate is water soluble. When a bale of hay is exposed to rain, nitrate leaches from top of the bale and percolates through the bale. In this instance, it is preferable to sample hay in the area where water line has stopped. This area usually has very high nitrate concentration. Since this sample is wet, freeze it promptly. Make a notation on the history sheet if the animals were observed to eat hay from this area. In addition, the samples from other parts of the bale should also be submitted.

### Forage (silage)

Silage samples should be taken from multiple locations and frozen promptly.

### Mushrooms

Samples of mushrooms are collected for two purposes: identification of mushroom species and chemical identification of cyclic peptide hepatotoxin. For identification, collect a whole mushroom, and keep it cool and dry in a paper bag. For the presence of cyclic peptide hepatotoxin, collect about 100 g sample and freeze.

### Plants

Plant samples are collected for identification of the plant as well as the identification of plant toxins. It is desirable that the whole plant is collected intact, with roots, and any flowers or buds for identification. Plants can be pressed between sheets of newspaper and sent for identification. Plants for chemical analysis should be wrapped in aluminum foil, placed in a labeled plastic bag, and frozen.

### Soil

Samples of soil for chemical analysis should be taken from multiple locations using a soil core sampler and mixed thoroughly for composite sample.

### Water

Collect samples of water in clean glass containers.

### Samples for histological examination

In addition to samples for chemical analysis, samples of tissues fixed in formalin should also be submitted for histological examination. The importance of histological examination of tissue sample has already been discussed in an earlier section of this chapter.

### Samples for nutritional elemental analysis

Whole blood and serum are analyzed for this purpose. For elemental analysis, whole blood should be collected in royal blue top vacutainer tubes. For serum samples, the blood should be collected in royal blue top tubes (plain), which contains *no additive or anticoagulant*. After the clot forms, usually less than 30 min, the serum should be separated promptly and transferred to a clean plastic tube and frozen. The manuscript by Hancock *et al*. (1988) provides excellent information about the number of animals to be sampled for laboratory analysis for herd health management. It contains information tables for sample size required to estimate prevalence or attribute with a given confidence limit.

### Submission forms

All of the veterinary diagnostic laboratories have submission forms. Cases are not accepted in absence of submission forms. Complete the submission form as thoroughly as possible. Include all the information as discussed in earlier sections. Remember that there are three detectives in solving the poisoning problem – the client, the practitioner, and the analytical toxicologist at the diagnostic laboratory. It has been our experience that an accurate, fully completed submission form greatly helps laboratory colleagues to take the most appropriate analytical approach.

## SHIPPING REGULATIONS FOR DIAGNOSTIC SPECIMENS

Most of the countries have regulations for shipping diagnostic specimens. In USA the rules are published in the "Code of Federal Regulations" (CFR). One can access CFR on Internet. Go to google, type in code of federal regulations, and it takes you to the home page for regulations. In the search box, type diagnostic specimens, and it takes you to the regulations for transporting diagnostic specimens. Following is a summary of the current rules for transporting diagnostic specimens:

### Packing diagnostic specimens for transport: summary

- You as the shipper – not the transport company – are responsible for the shipment until the package reaches the consignee.
- The diagnostic specimens should be packaged in triple packing, consisting of primary, secondary, and the outer packing.
- *Primary packaging*: Primary receptacle(s) must be water tight, e.g. screw cap seal with Para film or adhesive tape or similar. Multiple primary receptacles must be wrapped individually to prevent breakage.
- *Secondary packaging*: Use enough absorbent material in the secondary container to absorb the entire contents

of all primary receptacles in case of leakage or damage. Secondary packaging must meet IATA packaging requirements for diagnostic specimens including 1.2 m (3.9 ft) drop test procedure.

- Secondary packaging must be watertight. Follow the packaging manufacturer or other authorized party's packing instructions included with the secondary packaging. Secondary packaging must be at least 100 mm (4 in.) in the smallest overall external dimension. Must be large enough for shipping documents, e.g. air waybill.
- *Outer packaging*: The outer packaging must not contain more than 4 l or 4 kg.
- Each package and the air waybill must be marked with the following exact wording:
  UN 3373 DIAGNOSTIC SPECIMEN
  PACKED IN COMPLIANCE WITH
  IATA PACKING INSTRUCTION 650
- An itemized list of contents must be enclosed between the secondary packaging and the outer packaging. Place in a sealed plastic bag to protect from moisture.
- A shipper's declaration for dangerous goods is *not* required.
- *Fines and penalties*: According to 49 CFR Sec. 171.1 (c) "Any person who knowingly violates a requirement of the Federal hazardous material transportation law. . . . Is liable for a civil penalty of not more than . . . $27,500 . . . and not less than $250 for each violation . . . and shall be fined under Title 18, United States code, or imprisoned for not more than 5 years, or both."

## Dispatch of samples

- Place one or two ice packs (as used for camping) in a polystyrene box. Place all frozen sample packets over ice packs. If whole blood is shipped together, make sure that some insulating material is between the frozen samples and blood. Place the polystyrene box in a rigid box.
- Write the address of the receiving laboratory legibly on the center of the outside box. On the upper left-hand corner write the sender's address.
- The submission form should be attached to the outside of the secondary packing and sealed in a plastic sleeve.
- The parcel should be clearly marked "*diagnostic specimen*" on the outside packing, and sent either by US parcel post, UPS, FedEx, or any other courier. Check with the courier for their special requirements.

# CONCLUSION

Great care should be taken during the collection and shipping diagnostic specimens for chemical analysis. Remember that laboratory results are as good as the submitted specimen. Follow transportation rules carefully, since it involves fine for violations. Diagnostic laboratories are not the enforcers of transportation rules. There was an incidence of a shipping foul up by a practitioner. The courier called the laboratory that they have a package for delivery to the laboratory. However, courier staff was not willing to handle the package, since it was shaking and making funny noises. The laboratory was asked to retrieve the package right away. The senior member of the laboratory went to pick up the package, opened the package, and found a live piglet in the container. Fortunately, the laboratory was informed the day before by the practitioner that he was sending one euthanized piglet for examination. Apparently, the piglet was not given enough euthanasia solution. This incidence happened about 10 or more years ago. Imagine, what would happen today, if a package like this arrived at the courier!

## INTRODUCTION

During the past decade, advances in genomics research have provided massive amounts of information resulting in the completion of entire genome sequences for multiple species. This plethora of genetic information, compiled in genome sequence databases, has been used to characterize changes in gene expression in response to external stimuli such as toxicants (toxicogenomics). Because genomic data reflects changes in gene expression at the mRNA level, DNA sequence databases can be queried to predict what proteins may be present in the cell. However, this approach is problematic because there is a poor correlation between mRNA levels and protein concentrations in cells (Gygi *et al.*, 1999a; Anderson and Seilhamer, 2005). Additionally, the biological activity of proteins is controlled by post-translational protein modifications or protein–protein interactions, both of which cannot be predicted by the genomic data. Therefore, characterizing the entire complement of proteins expressed by genes (proteome) in response to external stimuli serves as a better indicator of the response of an organism, tissue, or cell to toxic insult. This has given rise to the "proteomic" approach to toxicological evaluation.

Toxicoproteomics is broadly defined as the global identification and characterization of proteins expressed in complex biological systems in response to a toxin, toxicant or other adverse chemical or environmental stimulus. Toxicoproteomics can encompass global analysis of all of the proteins expressed, called "shotgun proteomics," or can entail analyzing a subset of proteins of interest, often termed "targeted proteomics." Irregardless of the approach, proteomics-based research has created an analytical challenge, requiring sophisticated, high-throughput analytical techniques and complex computer algorithms.

## ANALYTICAL TOOLS FOR PROTEOMICS ANALYSIS

### Multidimensional separation of proteins and peptides

#### *The proteome and sample complexity*

The initial step in proteome analysis typically involves the separation of intact proteins or peptides generated from proteolytic digestion of protein mixtures. Analysis of these heterogeneous components has proven to be an analytical challenge due to the large dynamic range of proteins and the microheterogeneity of protein expression in biological samples. For instance, serum albumin concentrations can range from 35 to 50 $\times 10^9$ pg/ml and proteins of lower abundance, such as interleukin 6, range in concentration from 0 to 5 pg/ml (Anderson and Anderson, 2002). Therefore, the dynamic range of proteins in serum can be as great as 10 orders of magnitude. The dynamic range problem is also complicated by protein heterogeneity due to polymorphisms, alternative mRNA splicing, or variations in their post-translational modifications. Currently, there are more than 100 different documented classes of post-translational modifications (O'Donovan *et al.*, 2001). When analyzing global proteolytic digests of proteins (i.e. at the peptide level), the sample complexity is compounded further. Proteolytic digests of the serum proteome, which

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

could contain as much as 20,000 proteins, can potentially result in 200,000–600,000 peptides (Anderson and Anderson, 2002; Issaq *et al*., 2005). With this in mind, one can appreciate the analytical challenges encountered when conducting proteomics research in complex biological systems. Attempts to overcome these drawbacks have imposed improvements in sample preparation and separation methodologies, such as two-dimensional gel electrophoresis (2-DGE) and high-performance liquid chromatography (HPLC). Multidimensional levels of separation can be achieved when these techniques are combined affording increased resolution, sensitivity, and accuracy of detection.

### *Two-dimensional gel electrophoresis*

Since its inception in 1975 (O'Farrell, 1975), 2-DGE has become one of the most common platforms for separating and profiling complex protein mixtures. This technique is two-dimensional in that there are two levels of protein separation. The first dimension uses immobilized pH gradient-isoelectric focusing, which separates proteins based on differences in net charge (Görg *et al*., 2000). In the second dimension, proteins are resolved by electrophoresis and separated based on molecular weight. Visualization of resolved protein spots is achieved using universal stains such as Coomassie blue, silver, negative-reversible zinc, fluorescent, or radioisotope labeling dyes (Görg *et al*., 2000; Lopez *et al*., 2000; Ong and Pandey, 2001). If a particular subproteome is targeted for detection, more specific gel stains can be used. For example, detection of target proteins can be accomplished using stains containing antibodies for those proteins of interest or post-translationally modified proteins can be visualized using specialized stains for phosphorylated and glycosylated proteins (Görg *et al*., 2004; Vlahou and Fountoulakis, 2005).

After staining, the gel is digitized and protein concentrations quantitated using sophisticated 2-DGE image analysis software. Comparative analysis between control samples and samples of diagnostic interest can be accomplished using these image analyzers to superimpose the digitized data from multiple gel runs. However, due to the laborious nature of this procedure and the lack of gel reproducibility, comparative analysis is often difficult. In order to circumvent these limitations, fluorescent dyes, known as Cy dyes, have been developed permitting simultaneous analysis of two samples on one gel (Ünlü *et al*., 1997; Hamdan and Righetti, 2002). This technique, called two-dimensional differential in-gel electrophoresis (2-D DIGE), involves labeling each sample with one of two different Cy dye fluorophores, mixing the two samples together, and analyzing them using 2-DGE and fluorescent gel imaging.

While the gel staining techniques used to visualized and quantitate proteins may vary, in all instances protein identification is commonly accomplished using tandem mass spectrometry (MS/MS). Excised protein spots are digested into peptides using proteolytic enzymes and subjected, offline, to MS/MS analysis. The peptide mass fingerprints generated and peptide sequence data are then compared to theoretical peptide masses in protein or genome sequence databases using specialized bioinformatics algorithms.

Despite the fact that improvements in 2-DGE technology have enabled high resolution of separated proteins and enhanced protein identification, some intrinsic problems remain. Limited throughput capabilities, inability to measure low- and high-molecular mass proteins, inter-gel variability, and inefficient detection of basic and hydrophobic proteins are still inherent limitations of this proteomics platform. Irregardless of these limitations, 2-DGE is still a powerful tool for the separation of intact proteins and is the most widely used technique in comparative toxicoproteomic analyses.

### *Multidimensional high-performance liquid chromatography*

Attempts to improve protein separations have warranted the development of gel-free systems for large-scale analysis. Chromatographic strategies used to fractionate proteins and peptides have proven to be a successful alternative to 2-DGE. The chromatographic techniques commonly employed in proteomics research include affinity chromatography, capillary electrophoresis (CE), hydrophobic interaction chromatography, ion exchange chromatography (IEX), reversed-phase chromatography (RPC), and size exclusion chromatography (SEC) (Table 88.1) (Goheen and Gibbins, 2000; Levison, 2003; Goetz *et al*., 2004; Mahn and Asenjo, 2005; Mirzaei and Regnier, 2005; Babu *et al*., 2006; Mondal and Gupta, 2006). These modes of chromatography fractionate proteins and peptides based on their adsorption and desorption on stationary phase supports through mobile phase manipulation. On the protein level, they are commonly used to pre-fractionate samples in order to simplify complexity prior to analysis by 2-DGE or HPLC. Fractionation of proteins using these methods can also be accomplished online using high-throughput HPLC techniques. While this approach has proven to be a successful initial step in protein purification, HPLC fractionation of intact proteins is uncommon in proteomics.

**TABLE 88.1 Protein and peptide fractionation strategies**

| Chromatographic technique | Mode of fractionation |
|---|---|
| Affinity chromatography | Specific biomolecular interaction |
| Capillary electrophoresis | Net positive or negative charge |
| Hydrophobic interaction chromatography | Hydrophobicity |
| Ion exchange chromatography | Net positive or negative charge |
| Reversed-phase chromatography | Hydrophobicity |
| Size exclusion chromatography | Molecular weight |

HPLC is, however, the most widely used analytical tool for separating proteolytic digests of complex protein mixtures. In this approach, all of the proteins in the sample are digested into peptides using a proteolytic enzyme. After digestion, the peptides are separated using HPLC with ultraviolet (UV) detection. When interfaced with MS/MS instrumentation, the amino acid sequences of these peptides can be determined and their respective parent proteins identified using sophisticated bioinformatics tools.

Large-scale analysis of proteolytic digests can compromise the resolving power of HPLC when only one chromatographic fractionation technique is used (Davis and Giddings, 1985a, b). Therefore, orthogonal approaches using multidimensional chromatographic separations are preferred, affording greater peptide resolution and accuracy of detection. The most widely used high-throughput, separation technique is the coupling of IEX and RPC with MS instrumentation. Other examples of multidimensional HPLC/MS techniques can also include RPC/CE chromatography, affinity chromatography/RP chromatography, SEC/IEX/RPC, and SEC/RPC/CE (Issaq *et al*., 2005).

HPLC has also been used for quantitative analysis of protein expression. Relative quantitation of proteins by HPLC is based on the theory that the concentration of the parent protein can be determined by the relative peak areas of UV-detected peptides observed from that protein (Chelius and Bondarenko 2002). Another HPLC-based approach for relative protein quantitation involves the use of internal protein standards (Bondarenko *et al*., 2002). In this technique, biological samples are spiked with an internal standard protein prior to enzymatic digestion of the proteins into peptides. The chromatographic peaks observed are normalized to the peak area of the internal standard and the relative concentrations of the proteins are inferred. While these methods are less labor intensive and circumvent some of the limitations of current issues encountered with comparative proteomics, they are not widely used for relative protein quantitation.

Unlike 2-DGE/MS tools, multidimensional HPLC/MS is amenable to high-throughput analyses and has the ability to resolve peptide mixtures irregardless of molecular mass or hydrophobicity. This is important because resolving peptide mixtures by 2-DGE is impractical due to their narrow isoelectric points and molecular weight ranges and because 2-DGE tools cannot be directly interfaced with MS instrumentation. Even though 2-DGE is superior when separating intact proteins, methods based on pairing multidimensional HPLC and MS technology are becoming more refined and continue to advance proteomics research.

## Protein and peptide microarrays

Protein and peptide microarray technologies offer a complimentary approach to traditional separation methodologies and MS. This emerging technology incorporates the use of a variety of microarray platforms, in a high-throughput format, to probe protein function and determine protein abundance in complex biological samples.

Protein function microarrays use immobilized capture ligands, such as antibodies, antigens, enzymes, proteins, or peptides to screen for protein–protein, protein–enzyme, or protein–drug interactions (Kawahashi *et al*., 2003; Nielsen *et al*., 2003; Zhu *et al*., 2003; Cretich *et al*., 2006). Analytical microarrays, such as those used in surface-enhanced laser desorption (SELDI)/TOF MS, use retentate chromatography for protein profiling and detection (Merchant and Weinberger, 2000; Cretich *et al*., 2006). This technique is capable of on-chip sample fractionation utilizing various chromatographic surface chemistries and can probe for chemical properties in proteins such as phosphorylation, glycosylation, hydrophobicity, or anionic–cationic properties.

Both types of microarrays require spotting or immobilization of a capture ligand or chromatographic media onto a glass slide or other planar solid support, which can result in thousands of spots per slide (MacBeath and Schreiber, 2000; Kumble, 2003). After extensive washing of the array, the samples of interest are added to the microarray and the entire array is scanned to detect proteins or peptides that interact with the ligand or chromatographic media. Protein function can be probed using capture ligands, such as antibodies, antigens, enzymes, proteins, or peptides to screen for protein–protein, protein–enzyme, or protein–drug interactions (Kawahashi *et al*., 2003; Nielsen *et al*., 2003; Zhu *et al*., 2003). Analytical microarrays, such as those used in SELDI/TOF MS, use retentate chromatography for protein profiling and detection (Merchant and Weinberger, 2000; Cretich *et al*., 2006). This technique is capable of on-chip sample fractionation due to specific interactions of proteins or peptides with a variety of chromatographic surface chemistries. These surface chemistries can include affinity ligands such as lectins to probe for glycosylated proteins or other chromatographic media to select for other properties such as hydrophobicity, phosphorylation, or anionic–cationic characteristics.

Detection strategies for protein or peptide microarrays entail either label-free or labeled probe methods (Espina *et al*., 2004; Cretich *et al*., 2006). The label-free strategy is a direct detection method that includes MS, surface plasmon resonance, or atomic force microscopy. SELDI microarray chips commonly use MS-based detection of proteins or peptides. Labeled probe methods involve labeling proteins with a tag that allows them to be detected after binding to a particular ligand. The different labeled probes used include utilizing chromagens (similar to ELISA protocols), chemiluminescence, fluorescence, or radioactive decay-based detection techniques.

Even though microarray technology is relatively new, it is progressively becoming a versatile platform for its potential use in diagnostic toxicology. Although efforts to

standardize array analyses have been challenging, microarrays make it possible to simultaneously screen thousands of samples and profile large numbers of proteins from biological samples.

## Mass spectrometry

Recent developments in hybrid mass spectrometers have revolutionized the ability to analyze proteins and peptides, providing high-throughput automation combined with superior sensitivity and resolving power. In general, mass spectrometers have three components, an ion source, a mass analyzer, and a detector. The ion source is the component in which protein and peptide ions are produced; the mass analyzer separates or resolves these ions based on their mass-to-charge (m/z); and the detector detects the selected ions from the mass analyzer. One stage of mass analysis is commonly used to measure the molecular weights of intact proteins or peptides. However, in order to obtain peptide sequence information, hybrid mass spectrometers are employed. MS/MS, or tandem MS, detects intact peptide ions in the first mass analyzer. Once selected, the peptide ion enters the collision cell where it is fragmented into secondary ions by collision-induced dissociation (CID). These ions are then separated in the second mass analyzer, their m/z ratios detected, and MS/MS spectra are generated. Bioinformatics database tools use the MS/MS data to generate peptide amino acid sequence information and compare them with theoretical sequences in protein or genome databases to identify proteins.

In addition to being essential for protein identification, MS technology is being used for quantitative proteomic profiling. Through the use of stable isotope-coded mass tags, differential quantitation of changes in peptides from control and experimental samples is possible. Quantitation of changes in global protein expression involves proteolytic or chemical labeling of peptides with isotope-coded mass tags prior to separation by HPLC. These labeling reagents are chemically identical; however, one label contains light isotope atoms and the other heavy isotope atoms. Proteolytic labeling entails mass tagging peptides during proteolytic digestion. During proteolysis, enzymatic cleavage results in the incorporation of oxygen at the peptide carboxy-terminus. Exploiting this reaction, $^{18}O$ (heavy) and $^{16}O$ (light) isotopic oxygen labels can be used to differentially label two samples (Stewart *et al.*, 2001). In chemical labeling, which is the most frequently used isotope-coded mass tagging, all peptides are labeled after proteolytic digestion. Examples of these isotope-coded reagents and their labeling strategies are listed in Table 88.2. In isotope tagging, peptides from a control sample are labeled with the light isotope and the peptides from the treated sample are labeled with the heavy isotope. After labeling, both samples are mixed together and fractionated using HPLC. When subjected to MS analysis, the mass spectrometer can distinguish between the two isotope-labeled peptide samples because a predictable mass difference will be observed between the control and experimental peptides. MS-based quantitation is then achieved by calculating the difference between the ion intensities of the light-labeled control peptide and the heavy-labeled experimental peptide samples (Figure 88.1). From this data, differential displays of peptides that increase or decrease in response to a stimulus can be generated.

There are two major types of hybrid mass analyzers used in proteomics research, matrix-assisted laser desorption ionization/time-of-flight (MALDI-TOF/TOF) instruments and electrospray ionization/tandem MS instruments (ESI/MS/MS) (Karas and Hillenkamp, 1988; Fenn *et al.*, 1989; Hillenkamp *et al.*, 1991). The MS technology chosen primarily depends on the type of MS data that needs to be generated from toxicoproteomic experiments. For example, MALDI-TOF/TOF instruments are fast, robust mass analyzers, have a large dynamic range, and do not require labor-intensive sample preparation. MALDI-TOF/TOF instruments have high resolution, making them the instruments of choice when using MS for quantitative proteomic analyses. ESI/MS/MS instruments, including those containing hybrid combinations of quadrupole, 3-D ion trap, linear ion trap, TOF, and fourier transform-ion cyclotron resonance mass analyzers, have approximately four times less peak capacity than MALDI-TOF/TOF; however, they have higher-mass accuracy affording more accurate protein identification (Hopfgartner *et al.*, 2004; Hu *et al.*, 2005; O'Connor *et al.*, 2006; Yates *et al.*, 2006).

**TABLE 88.2 Isotope-coded reagents used for chemical labeling of peptides**

| Reagent | Labeling technique | Reference |
|---|---|---|
| ALICE | Thiol modification of cysteines | Qui *et al.* (2002) |
| AQUA | Synthetic internal standard peptide | Gerber *et al.* (2003) |
| ICAT | Iodoacetylation of cysteine | Gygi *et al.* (1999b) |
| iTRAQ™ | Modification of primary amines | Zieske (2006) |
| GIST | Acylation of primary amines | Ji *et al.* (2000) |
| MCAT | Guanidation of C-terminal lysine | Cagney and Emili (2002) |
| QUEST | Amidination of N-terminal lysine | Beardsley and Reilly (2003) |

Additionally, they are capable of analyzing low-molecular weight peptides and can be directly interfaced with HPLC instrumentation.

Innovative approaches to advance protein identification strategies have spurred the development of new MS technologies. Improvements in ion activation using electron capture dissociation or infrared multiphoton dissociation technologies have been shown to yield more extensive peptide sequence coverage when compared to CID, resulting in significant improvements in protein identification (Wysocki *et al.*, 2005; Bakhtiar and Guan, 2006). Developments in MALDI imaging mass spectrometry (MALDI-IMS) make it possible to simultaneously map peptides and proteins by direct MS analysis of thin tissue sections, providing a means to correlate and monitor changes in protein patterns associated with regions of the tissue that are histologically significant (Chaurand *et al.*, 2005). Additionally, technological advances in large biomolecule ionization and data analysis have enabled the development of miniaturized, portable mass spectrometers capable of direct analysis of complex biological samples (Laughlin *et al.*, 2005; Cooks *et al.*, 2006).

Due to the escalating interest in proteomics research and bioanalytical chemistry, there is an ever-increasing demand for mass spectrometers with improved mass resolution, mass accuracy, and automated data mining capabilities. Hence, development of next generation mass spectrometers is ongoing and constantly impacting proteomics research.

## Bioinformatics tools

As mentioned previously, protein identification is accomplished by using computer search algorithms that correlate MS and MS/MS data with predicted amino acid sequences contained in protein or genome sequence databases. Even though several types of MS and MS/MS search engines have been created, databases that are used more frequently include MASCOT, SEQUEST, Spectrum Mill, X!Tandem, and Protein Prospector (Eng *et al.*, 1994; Clauser *et al.*, 1995; Perkins *et al.* 1999; Robertson and Beavis, 2004; Kapp *et al.*, 2005). Recently, a searchable toxin protein database called Tox-Prot has been created that contains all known animal protein toxins (Jungo and Bairoch, 2005).

Even though the computer algorithms designed for each of these bioinformatics databases are slightly different, their general approach to protein identification is similar. Database search engines compare the experimental precursor m/z ions from each MS/MS scan with hypothetical peptide m/z values from the database. Hypothetical peptide masses from the database that correspond with the experimental mass values are then assigned probability scores. The proteins recognized with the highest scores are indicative of the best probable protein match to the experimental MS/MS data. Some bioinformatics tools assign *p*-values to the correlation scores, providing an additional means for evaluating credibility of protein matches.

Integrating MS technology with bioinformatics tools has become an indispensable tool in proteomics research.

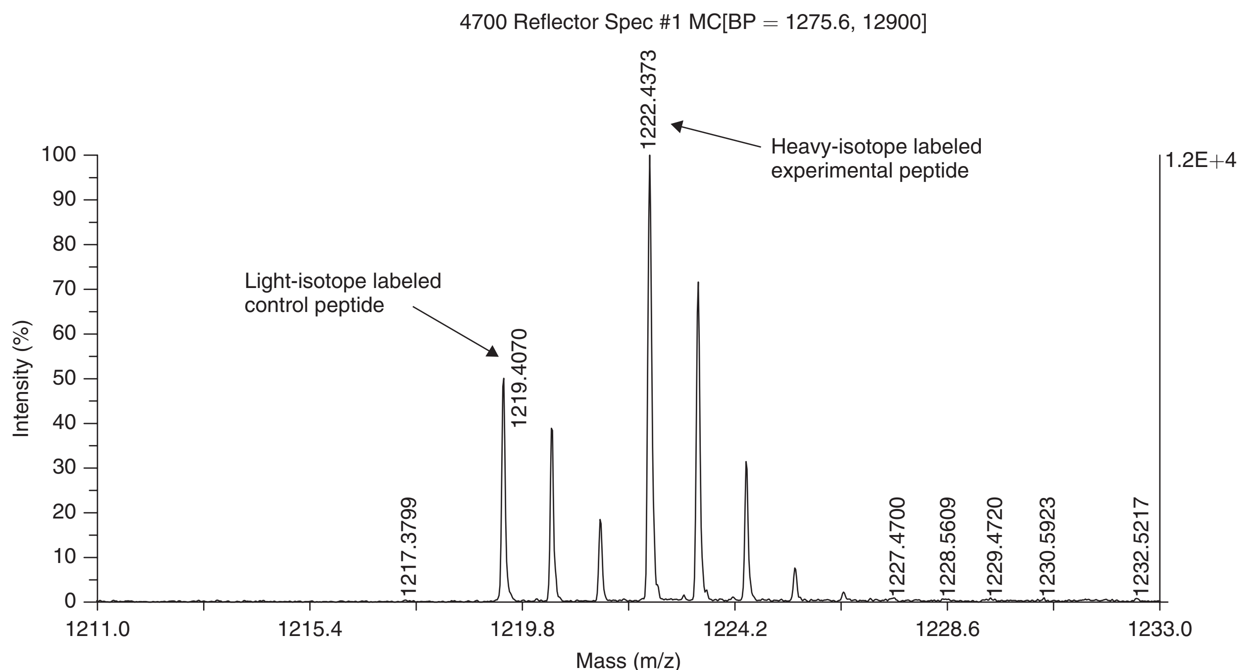

**FIGURE 88.1** MALDI-TOF MS spectrum of GIST isotopically labeled peptides from control and experimental serum samples. Comparison of the relative ion intensities between the two peptides indicate that the peptide present in the experimental sample (at 1222.43 m/z) was present at a higher concentration when compared to the control sample (at 1219.40 m/z).

However, due to the overwhelming amounts of MS and MS/MS data generated from typical proteomics experiments, creating bioinformatics tools that adequately identify and characterize the data has been a tremendous challenge. Credible protein identification is reliant on successful interpretation of MS and MS/MS data. Unfortunately, data interpretation is often complicated by ion suppression, atypical MS/MS peptide fragmentation patterns, ill-defined universal standards for evaluating credible database matches, and inability to define a single protein from one peptide spectrum (Kearney and Thibault, 2003). Additionally, variants of MS instrumentation are developing rapidly and the computer algorithms necessary to correlate the data from these next generation mass spectrometers with information contained in protein or genome sequence databases are lagging. Even though bioinformatics tools are in their early stages of development, integrating MS technology with bioinformatics tools will continue to be an indispensable tool in proteomics research.

## PROTEOMICS APPLICATIONS IN DIAGNOSTIC TOXICOLOGY

Toxicoproteomics embodies the integration of toxicology with current proteomic technology and signifies an innovative approach toward establishing a new knowledge base with regard to the recognition and characterization of cellular responses to toxic agents. The current objectives of toxicoproteomics research are to define molecular mechanisms of toxicity, screen for drug toxicities, and elucidate biomarkers or signature protein profiles in order to more accurately assess, predict, and diagnose toxicities (Kennedy, 2002; Guerreiro *et al*., 2003; Wetmore and Merrick, 2004). For decades, clinical laboratories have relied upon individual protein markers for assessing toxicity. However, some of these single biomarkers can be non-specific and reflect protein leakage from tissues as opposed to the direct effects of toxicants on the tissues alone (Plebani, 2005). Toxicities in biological systems are multifactorial and complex, warranting the identification of multiple biomarkers for accurately diagnosing and classifying toxicity. This makes proteomics research in toxicologic evaluation appealing because these technologies are capable of globally analyzing multiple protein systems. Hence, the potential to better define molecular signatures of toxicity for clinical and diagnostic toxicology is now possible. Several proteomic applications have been applied to gain a better understanding of target organ toxicities including mechanisms of action and biomarkers for a variety of toxicants.

Monitoring liver function is crucial in toxicologic evaluation. Hence, it is no surprise that several toxicoproteomic experiments have been conducted to gain a better understanding of proteins that change with hepatotoxicity. For example, toxicoproteomics has been used to identify metabolic pathways perturbed by drug-induced cirrhosis in rat models. In these studies, thioacetamide and ethanol have both been shown to down-regulate proteins involved in oxidative stress and fatty acid β-oxidation pathways during early phases of cirrhosis (Low *et al*., 2004; Venkatraman *et al*., 2004).

The need to identify early biomarkers of the effects of chemical pollutants and their underlying biochemical mechanisms are also essential in toxicologic evaluation. 2-DGE/MS analysis of aerosol inhalation of JP-8 jet fuel on kidney protein expression has revealed changes in proteins associated with nephrotoxicity, inferring a possible risk to humans exposed to JP-8 jet fuel vapors (Witzmann *et al*., 2000). In the environment, organisms are typically exposed to mixtures of chemical pollutants. The mechanisms of toxicity of these chemical mixtures often involve multiple biochemical pathways. Because this new technology can simultaneously screen for numerous proteins in a single test, proteomics will become a valuable asset for preventative and predictive toxicology and risk assessment.

## CONCLUSION

Toxicoproteomics is still in its infancy. Recognition of the diagnostic accuracy of proteomics data and standardization of methodologies remain a challenge to proteomics researchers. Despite these concerns, toxicoproteomics has the potential to better define molecular mechanisms of toxicity and elucidate biomarkers or signature protein profiles for clinical and diagnostic toxicology. This technology promises to establish new guidelines for preventative and predictive toxicity, ultimately revolutionizing and redefining our future understanding of toxicology.

CHAPTER

# 89

# Microscopic analysis of toxic substances in feeds and ingesta

*Lynn S. Bates*

## INTRODUCTION

Feed microscopy is the scientific discipline and technology for the identification and evaluation of feed ingredients and formula feeds. Basically there are three essential components to a successful microscopic identification. These include an aid to the eye, a trained mind and a collection of reference standards. The feed microscopist uses both the stereomicroscope and the compound microscope to identify unknown particles by comparisons to known reference standards. The experience and training of the microscopist determine the efficacy and speed of the identification. A microscopic analysis can be applied to any type or size of particles but commonly observations ranges from the macroscopic level for the initial gross examinations to the stereoscopic level for centimeter- to millimeter-sized opaque to translucent particles. Translucent and transparent fine particles are examined with the compound microscope to confirm the particle identity at the cellular and sub-cellular levels. In addition, due to the ability of the human mind to sort and classify a wide range of different materials rapidly, the feed microscopist can accomplish a subjective analysis of a feed ingredient in just a few minutes that might take a chemist several hours to accomplish.

It is important to understand from the beginning that feed microscopy is subjective and visual in nature. It is not an objective technology that generates hard numbers. It is designed to identify the feed resources and their inherent quality visually but not to determine the quantity of the individual nutrients within those feed resources. Therein is the real essential value of feed microscopy to the feed manufacturer, quality assurance laboratory, veterinary toxicologist or anyone concerned about feed ingredient quality and its effects on the consuming animal. Feed microscopy is the entire other half of the quality assurance picture that is often discounted because it involves an opinion. It is, however, a powerful technology that plays an important role in the evaluation of any feed or toxicant analysis and an understanding of what microscopy can do needs to be introduced into every general veterinary and toxicology curriculum.

Microscopy is critical to the toxicological examination of feeds because it is the most rapid and practical way to define problems and focus in on potential solutions. Although feed microscopy has not generally been a part of veterinary school curricula, feed microscopists have been part of the diagnostic picture for many years. Veterinary diagnostic laboratories and poison control centers, often located in universities or in a state chemist's office, have utilized feed microscopists as part of their rapid response teams. Unfortunately the number of feed microscopists that are trained and available for veterinary diagnostic work today has declined dramatically to the point that integrating a feed microscopist into the initial toxicological examination is now very difficult. Because the microscopist can sort through more seemingly unrelated but potentially pertinent information about a feed than any other type of analyst and handle more complex situations in feeds than a chemist using standard methods, we need to re-insert a feed microscopist back into the modern veterinarian fast response diagnostic team.

For example, there are absolutely no rapid chemical assays to locate blister beetles or their fragments in alfalfa samples and the analysis of the cantharidin toxicant would take several hours. In contrast, a feed microscopist should be able to locate specific evidence of the beetles in a few

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

minutes without any sample preparation. The knowledge of how and where to look for potential problems in feeds is also a critical part of defining a problem. Although it is more specific to look for the toxin itself, the low concentrations of toxins in feeds make them difficult to detect. It is often more efficacious to find an indicator of the toxin and take appropriate remedial action than spend the time in sample preparation and detailed confirmatory analysis.

## THE SEARCH FOR CLUES

Feed ingredients and finished feeds come in a bewildering array of sources, particle sizes, mixtures and forms. Added to that the other natural materials that are fed, or that animals consume, and the task of identifying toxicological problems appears totally impossible. Certainly that would be the case if we did not have an organized way of identifying and classifying all the potential ingredients in a feed. Basically the majority of feed ingredients and formula feeds are by-products from the food industry. Because they are materials processed out of foods, they are often wet and require drying to be safely stored prior to use. They may also be relatively dry but hygroscopic and difficult to store. They could also be dry but susceptible to oxidation or rancidity due to having been removed from their cellular compartmentalization in nature. For these and numerous other reasons, they are all potential problems for the toxicologist if they are not handled or stored properly. Nevertheless, the clues to identifying which ingredient(s) or feeds are or are not a problem in any situation is right in front of the toxicologist and available to be interpreted. The clues for feed quality are inherent in the visible appearance of each ingredient.

## BACKGROUND: PRINCIPLES OF FEED MICROSCOPY

Feed microscopy is founded on the most basic descriptive aspects of biology and the wide diversity of cellular structures found in natural organisms that are genetically controlled and that do not change from year to year. It is also based on the fact that many of these unique tissues, cellular traits and sub-cellular characteristics are not greatly affected by the moisture, heat, pressure and shear commonly used to manufacture formula feeds. Therefore, not only are these cellular characteristics inherently good identifiers of individual feed ingredients and mixtures, they are equally good for finished formula feed identifications because they maintain their characteristics after they have been intimately mixed, conditioned, pelleted, extruded, or otherwise manufactured into finished feeds. Consequently, feed microscopists can trust these characteristics to make accurate identifications of ingredients and confirm them to the cellular and sometimes the sub-cellular levels. If a micro-chemical or micro-biochemical test is applied to the sample, the feed microscopist can confirm ingredients to the molecular level and watch the reaction in real time in the cells. In addition, they can evaluate feed ingredients, finished formula feeds and, in special instances, the ingesta and fecal wastes from feeds and forages. The latter is a specialized part of the feed microscopy field but one that is particularly important for the toxicologist. In all these situations, the feed microscopist is very much like a medical examiner or a veterinarian toxicologist who uses the unique visual characteristics of organ or tissue morphology, red or white blood cell characteristics or sub-cellular tissue sections to diagnose diseases or other pertinent problems.

Feed microscopy is, in concept, a simple subjective science. It is sometimes further defined as being both art and science due to the need to have steady hands and to develop very good manipulative skills under the microscope. Therefore, if we build on the basic three essentials and add a few hand tools to the well-trained mind, the microscopes and the numerous reference standards mentioned above, we can produce a complete analytical system.

Feed microscopy, due to its conceptual simplicity, is a rapid and relatively accurate technology for identifying materials and problems for which no other direct tests or scientific instruments exist. It is also a relatively rapid way to identify animal problems and it can become an essential complement to objective laboratory analyses. For example, a feed microscopist can identify the residues in a feed bunker that had been rejected by cattle, the contents of dog vomit to identify a feed source or a problem, or perhaps locate evidence of mold growth or mites hidden in a pelleted feed. Subsequently the microscopist can, after locating evidence of a potential feed problem, advise the analytical or toxicology laboratory staff to select appropriate methods to confirm, negate or quantify the extent of the problem. Thus, the feed microscopist is very much like a diagnostician who examines an animal and, based on multiple observed criteria, concludes subjectively that certain definitive laboratory tests should be run to confirm the diagnosis and potential cure.

The feed microscopist, like the diagnostician and toxicologist, must be well versed in the significance of tiny observed differences from the expected norms. Toxicants are not visible at light microscope resolution and feed microscopists are not trained to evaluate tissue samples, organ morphology or animal behavior. However, the particles and structures associated with toxicity such as yew leaves, mold growth or moldy feed, a blister beetle wing fragment, caster bean seed coat fragments and many others can be detected and identified using common feed

microscopy methods. These are the keys to both the identification of potential feed problems and the selection of suitable chemical testing plus the evidence to correlate with the findings of the diagnostician.

Because there are often no specific tests for the small differences that must be detected to ascertain a particular problem, the feed microscopist uses all possible senses to evaluate the feeds. For example, although there is no single instrument that can identify an unknown sample as fish meal or ground corn without a lot of work, a feed microscopist can make those qualitative determinations in a matter of minutes. Thus, organoleptic observations, color of particles, breakage lines, presence of caramelized and charred particles and many other seemingly insignificant details may offer clues to the quality of a feedstuff or help to explain a suspected toxicant situation. An objective laboratory test would be necessary to confirm or deny the actual presence of the suspected toxicant.

Another very important facet of feed microscopy is to detect natural contaminants that are similar to the feed ingredients and particularly for adulterants that are deliberately selected to deceive and not be detected by standard methods. An example of a classical adulterant would be urea used in an ingredient for a monogastric animal ration. The ingredient could command a premium price due to the apparent superior protein content. It would not be detected by the feed manufacturer testing for crude protein. Unless non-protein nitrogen testing was routinely run to detect this type of protein spiking or if a microscopist spotted the urea particles and ordered a non-protein nitrogen test, this adulteration would escape detection.

It should have become obvious by this point that a feed microscopist familiar with the structural characteristics of plants, animals and microbial materials and trained in the proper use of the microscope or other aid to the eye can not only solve certain difficult to solve types of problems such as those of feed quality, but can often aid the chemist or other laboratory analyst to select appropriate tests to solve increasingly more complex problems that we often encounter today. Feed microscopy is particularly well suited for solving complex multifaceted contaminant, adulterant and toxicological problems and should be part of any rapid response team.

## THE APPLICATIONS OF FEED MICROSCOPY

Although the concepts of feed microscopy are quite simple, there are numerous ways to achieve accurate results. The more techniques and methods the microscopist masters, the easier it will be to handle the wide range of sample matrices and problem samples that will be encountered. Some techniques require essentially no sample preparation whereas others might require flotation, sieving or other separations to assist the analyst. There are no absolutes in feed microscopy as is the case with most subjective examinations. Therefore, it is essential that the microscopist have a full understanding of the available techniques and methods so that the most appropriate tests are applied and the most scientifically accurate information can be established from the available evidence in any sample. If the sample size is limited, then certain tests might have to be run before others so that the reagents of the first test will not confound the results of subsequent tests. Thus, the feed microscopist should be well versed in chemistry and biochemistry to be a key member of a rapid response team.

The trained mind of the feed microscopist may also be thought of as a computer with a massive hard drive and an extreme logic program to sort through the hundreds of facts and "what if" possibilities. That would be true also of any diagnostician dealing with complex situations. One way to understand and appreciate the capabilities of feed microscopy and some of the variables that should be considered in the sorting process to the most applicable methods and techniques for a particular sample is to consider what can be seen at various magnifications.

Feed microscopy is often defined by the level of magnification used. The initial examination would be analogous to a gross morphological description to establish the general direction of each later stage of an analysis. The stereomicroscope or dissecting microscope is the basic workhorse for most feed microscopists just as it is for the veterinary diagnostician or toxicologist. It would be used to aid the eye in a general review of the surfaces of pelleted feed, for example, although a lighted magnifier could be used as well. An examination of a feed ingredient or finished feed generally requires at least 7× magnification to see particles ground through a typical 2 mm hammermill screen. On site, field work can be done with a folding 6× linen tester or a battery operated 10× hand lens but more detailed laboratory work would require at least 7× to 10× magnification. The finer particles in the same hammermilled feed would require 30× to 75× magnification. The color, luster, particle shape, particle size, effects of processing, etc. would be visible at the magnification of the stereomicroscope. Seed coat particles, ground yew leaves, insects and insect fragments, mineral particles and many other particles associated with toxicants could also be examined and confirmed with the stereomicroscope. It is important to keep in mind the relative sizes of structures to be examined and the type of information one can obtain from each. For example, a macroscopic feed examination would involve those characteristics that can be defined by minimal magnification. The naked eye aided by a hand lens or magnifying glass provides sufficient magnification to determine the feed ingredient or formula feed color, shapes of particles and other very obvious

physical characteristics. A finished feed might be described as a densified, polished feed pellet, an extruded star-shaped petfood form, a floating fish particle, a granular crumble of a relatively soft pelleted feed for chickens or perhaps a mixture of silage, whole corn and a concentrated protein pellet for feeder cattle. All of these could be done with a hand lens and a needle probe. Similarly, a suspected feed ingredient or material that accidentally got into a feed might be described by its source. A description could be "weeds along a confinement area with potential toxic seeds," or a note that an on-farm feed mill was using roasted soybeans recovered from a sunken barge. Perhaps late harvested corn with extreme weather damage or restaurant cooking oil with floor sweepings was being used. Every piece of the puzzle needs to be collected and considered because when toxicants get into feeds the situation becomes a forensic analyses.

The higher magnifications of a stereomicroscope would be needed to complete the above examinations. The shift from macroscopic to stereoscopic would allow a more detailed picture of the weathered corn, any potential mold contamination of the recovered water-logged soybeans and the seed characteristics from the ingesta of a free roaming animal. The compound microscope plus some careful sample preparation would be needed to jump up to a cellular or histological analysis. The higher magnification would permit a visible examination of mold mycelia invading the seed structure, the cell types and sub-cellular calcium oxalate crystal inclusions of certain leaves and other definitive structures used for identifications. The compound microscope permits the unique cellular characteristics of all the ingredients to be used for the analysis.

## CLASSIFICATION OF FEED INGREDIENTS BY SOURCES

Feed microscopy can also be sorted, studied and examined by the ingredient sources. This allows parallel comparisons of similar structures which are related uniquely to each species. Each level of detail opens new opportunities for confirming an analysis.

*Processed feed grains, legumes and oilseeds* are whole seed sources that are minimally processed for feeds. Corn (maize) is one of the most common feed grains in the world. It is fed whole, ground or flaked. Grinding and steam flaking enhance the nutrient availability particularly of carbohydrates because corn is primarily a starchy energy source. The extent of starch gelatinization can be observed with polarized light. Grain sorghum and the several millets are smaller seeds that are fed in the same manner. Wheat, barley, rye, oats and rice are more typically food grains but lesser grades are used directly in feeds. The feed microscopist can identify ground particles from each of these sources by their inherent structural characteristics. For example, an examination of an unknown flat particle associated with intact starch could be compared to the modified leaf tissue that in grains is considered as chaff or hull. Wheat chaff is left in the field and is not in direct contact with starch in the seed. Therefore, logically the microscopist would search inwardly to the next flat layer under the hull which is pericarp. The outer pericarp, when ground, often remains attached to other layers of the original ovary wall plus the testa and aleurone layers and is called bran in commercial channels. The unknown would be compared to reference standards of the pericarp or bran for each cereal. If the initial observations that the particle was associated with starch was true, the particle would likely match the cell types and be confirmed as a bran particle of one of the cereals. Knowledge of the structure of all the seeds commonly used in feeds allows a logical comparative examination of any cereal or other feed ingredient.

An example of a confirmed minimal processed legume is cracked or whole fed soybeans. The soybean is the only major feed legume that is fed whole but it is usually roasted to minimize trypsin inhibitors. When whole soybeans are roasted, the seed coat splits transversely to the embryonic axis and remains on the seed. It is a unique characteristic associated with roasting. The extent of roasting could be measured by the residual urease activity. Other legumes such as lentils, lupine, dry beans and peas are found in feeds but not as mainline ingredients and they have no significant trypsin inhibitors that would require heat treatment. Each of these clues leads to a confirmed analysis.

Cottonseed is one of the few oilseeds fed whole as a fiber source in cattle. The seeds are very fuzzy and can be easily identified by the attached cotton fibers that rotate polarized light, have a dumbbell-shaped cross-section and exhibit a slow twist. In addition, the hull is a three-layered achene that is multicolored and unique to cottonseeds. Many of the characteristics exhibited by oilseeds are similarly so specific that tiny particles of the oilseeds can be identified even after they have been hammermilled and processed into finished feeds.

*Processed feed grain, legume and oilseed by-products* are food by-products on which the entire feed industry is based. A wide range of ingredients from the production of foods are available. These include corn bran, corn gluten feed, corn gluten, hominy feed, wheat middlings, wheat bran, barley hulls, rice hulls, oat hulls just to list a few. Legume and oilseed by-products include, soybean hulls, peanut meal and hulls, canola meal, linseed meal, sunflower meal and hulls, safflower meal and hulls, cottonseed meal and hulls, and many less common meals. Each ingredient has specific characteristics at each level of magnification to identify it with confirmation at the cellular level.

These structures can be found in the listed references of this chapter or created by careful dissection of authenticated reference standards.

*Processed by-products from other plants* include citrus pulp, bagasse from sugar cane and beet pulp from sugar beets, fruit pomaces, tomato pomace, potato meal, food gum meals and other food by-products. Almost everything that is not designated human food finds its way into feeds.

*Processed plant products from industrial sources* include distiller's grains and solubles from the power alcohol and distillery industries, fats and oils from off grade edible and detergent oil sources, Aspergillus meal from food and industrial enzyme production and many others. The oils are particularly problematic because they have no visible cellular structures and can get mixed accidentally with miscible industrial liquids and pesticides.

*Processed animal products and by-products* include whole animal meals such as chopped beef, fish meal or poultry, lamb or venison meat. Examples of meat meals include blended meat meal (beef and pork), fish meal from larger trimmed out or canned fish, and all manner of rendered meat products. Feed microscopy is currently the major firewall against BSE (Bovine Spongiform Encephalopathy) or mad cow disease tissues getting into cattle feed.

*Processed natural mineral products and metallic wastes* are the minerals in feed. On rare occasions, ground circuit boards and other electronic and industrial waste that contains metallic components get into feeds. Cadmium, arsenic, lead and other toxicants also find their way into feeds. These can be detected by the microscopist and suitable chemical testing initiated to determine the extent of the problems.

*Processed aquatic products and by-products* include fish meals, shellfish meal, oyster shells, shrimp meal, shrimp shell meal and shrimp head meal, squid meal and other specialized products. Of all the by-product meals, the aquatic ones are the most variable and potentially the most adulterated because they lack specific standard descriptions for trading. The feed microscopist is often quite challenged by these meals in feeds.

## CLASSIFICATION OF FINISHED FORMULA FEEDS BY PROCESSING

We can also classify finished feeds by the type of agglomeration and cooking processes used as an aid to understanding the effects of processing on the feed ingredients. Although the key identifiers will not change dramatically, it is important to understand that the extent of conditioning and moisture incorporation during processing will (1) affect the starch gelatinization and other binding reactions and (2) affect the methods used in the microscopic examination to reverse the hydrothermal bonds and permit easier examinations. Some of the common processes and applications are as follows.

*Pelleted and crumbled feeds* are used to maintain uniform nutritional distribution in feeds. The pelleting operation increases the bulk density and fixes the nutrients so that no segregation occurs during shipment and handling. The pellets are crumbled to make it easier for poultry and small animals to feed. Crumbling increases the surface areas for saliva or other digestive juices to be absorbed and to speed digestion. Crumbling also increases the available surface area for moisture absorption and in humid areas can lead to mold growth. Pelleted feeds have relatively friable structures due to minimum starch gelatinization. They can be readily hand ground in a mortar and pestle. The particles will usually separate adequately to conduct an analysis when aided by solvent flotation and sieving to separate fine particles and fat and ease the identification of fine particles.

*Expanded and extruded feeds* enhance nutrient availability and feeding efficacy primarily by increased gelatinization during conditioning and the ability of the extruder to process higher moisture feed mixtures. The extruder combined with the expander, particularly when the feed is reground or re-extruded for aquaculture feeds and some pet foods, reduces the sizes of the individual feed particles to the point that the feed microscopist can barely identify the sources of the ingredients. The extent of gelatinization is much greater for extruded matrices and they do not separate easily even after mortar and pestle grinding, flotation and sieving. They are a much more difficult matrix to separate and examine.

*Steam conditioned and rolled feeds* have enhanced cell disruption and nutrient availability. The process is used primarily for whole grain corn and sorghum that are to be fermented or reconstituted and fed with silage and other rations. Unless flaked grain has been mixed with other ingredients, no additional separations are needed prior to the microscopic examination.

*Canned pet foods* are specialty soft and wet products with unique attractants and flavors. They require thermal processing to maintain shelf life stability and palatability. They are particularly difficult to analyze but are commercially sterile and not prone to microbial growth or related toxicant problems.

## CLASSIFICATION OF FORAGES BY POINTS OF CONTACT OR POTENTIAL TOXICANTS

Lastly, we can classify feed resources by their natural habitats and their potential for toxicological problems. These

plants and toxicant situations are not commonly seen by the feed microscopist but a good broad knowledge of plant structures makes the feed microscopist particularly well suited to examine them. These include native forages and pasture plants that may be consumed due to animals roaming free on pasture and via casual contacts. Some cut and stored forages and silages that are fed to confined animals may be weathered and spoiled. Exotic and introduced plants may be consumed due to invasive growth in pastures or by accidental cuttings and unknowledgeable feedings. Finally, decorative house plants and some garden materials may be consumed by pets. All these type of forage samples are examined as they are taken. That is, no specific methods are used to reduce the particle size because the evidence will be compromised by additional processing. Instead the particles are separated by hand into appropriate classes to be examined. For example, a whole kernel corn, silage and concentrate pellet feed would be separated on a large tray by hand or with minimal sieving depending on the particle size classes involved. Hand separations are generally easiest, although time consuming. The corn and pelleted concentrate would be dried and each examined separately. The pellet would be handled like any other pelleted feed and analyzed for its component parts. The silage would also be dried and, if a toxicant was suspected, the examination would focus on the purity of the silage including weedy and herbaceous forages, evidence of wild fermentation, mold growth and the extent of uniformity and the presence of additives. Identifications would be based on collected forages from the farm or ranch or keyed to range and pasture plant references. Unknown forages could also be identified through herbarium collections.

## IDENTIFICATION OF INGESTA PARTICLES

The identification of fecal and ingesta samples is very similar to the routine examinations of feeds and forages. Sometimes particles can be isolated directly from the samples. Otherwise the samples require pre-analysis preparation for biological safety for the microscopist. A standard fume hood or air handling unit to isolate aromas and filter out dried dusty particles would also be needed for biological safety.

Digestion, even through a rumen, is similar to the feed manufacturing process and does not destroy the cellular characteristics used for identifications. Thus, the identification of yew or hemlock leaves, cockleburs, crotalaria and other toxic weed seeds and most other plant toxin sources is the same as for forage examinations. Reference standards of the seeds and plant tissues are the key to the identifications, although having some ingesta samples for comparisons is always helpful. Medical laboratory manuals also provide routine methods for the safe handling of fecal sample examinations that can be applied to feed microscopy.

## THE ROLE OF THE ATTENDING VETERINARIAN

Because few feed microscopists are available for on-site examinations, the attending veterinarian should have an understanding of feed microscopy and what it can provide for an investigation. The veterinarian should be aware of the sampling requirements for microscopy, the need to secure both the feed ingredients and the finished feeds from bagged storage, from feed bunkers, from augers and feed mixing, handling and feeding systems, and from any other on farm or confinement locations. Samples from baled hays or forages, silage bunkers, fence rows, pastures and other waste areas available to animals should be retained. In the case of pets and small animals, representative samples should include house plants and decorative plantings and garden areas around the house. Too often the feed microscopist is given only a sample of a suspect feed or ingredient which may or may not be related to the toxicant problem. A more encompassing view should be encouraged. Because sampling is one of the most critical aspects of any toxicant situation, samples representing the earliest possible point in time should be secured as quickly as possible and retained for microscopic examinations.

If an ingesta or fecal sample is available, it should be processed immediately or frozen (iced for short-time transport) at $-10$°C or below to limit microbial activity. The following is a simplified analytical scheme to handle these samples.

*Ingesta or fecal samples* should be separated into the portion for chemical testing and the microscopy aliquot. A 5 or 10 g wet weight aliquot can be rinsed and washed thoroughly through a 260 or 400 mesh stainless steel sieve to retain essentially all particulates but remove all the solubles (assuming no chemical or biochemical testing will be needed on that sample aliquot for extra-cellular constituents). The particulate residues should be transferred from the sieve to a hard surfaced but porous filter paper (standard pleated coffee filters work well) and the sample air dried. Do not heat the sample if any enzyme-based testing will be required. The dried particles, particularly the fibrous cellulosic particles, may be gently rolled in a mortar with the pestle to cause the fibrous particles to separate. Do not attempt to grind them. If the sample is too fatty to separate and the particles cannot be identified due to a

coating of fat, flotation on chloroform (observe the current laboratory safety procedures for the solvent) may be necessary as both a defatting step and a separation of mineral constituents and particulate fines. Defatting will take about three rinses using 2–3 times the volume of the fatty aliquot. When the chloroform has evaporated, the examination can proceed with standard feed microscopy methods comparing the unknown particles with reference standards and confirming the observations at the cellular level. Remember, most of the digestible nutrients will have been removed from the cellulosic cell matrix debris. That may change the appearance slightly but the cellulosic structures will not have changed, depending on passage time, and can be compared to reference standards of ingesta and feces if they are available. Animal tissues would have been digested and would not generally be available for examination.

## FEED MICROSCOPY TRAINING AND AVAILABLE LITERATURE

Although this chapter has briefly introduced feed microscopy and what it can do for toxicological examinations, some mention of where training is available, how one organizes a reference sample collection and sets up a laboratory may be of interest. Because feed microscopy is a "hands-on" practical technology, it is not easily learned from a book. It is instead taught as an intensive short course. An Internet search is currently the best way to locate feed microscopy short courses.

Feed microscopy draws on all the scientific disciplines and information exists but is widely scattered and often out of print and not readily available. The interpretive drawings of Winton and Winton (1932) still stands as one of the best reference sources ever published for food and feed structures. Vaughan (1970) updated the oilseeds with excellent interpretive drawings and some photographs. *The Manual of Microscopic Analysis of Feedstuffs* (Bates *et al.*, 1992) draws the most important technical information together into a single reference book specifically for feed microscopy but it is not a textbook or a training manual. Klein and Marquard (2005) put together an extensive *Atlas of Feed Microscopy* which provides many line drawings that had not been previously available in English. *The Aquaculture Feed Microscopy Manual* (Bates *et al.*, 1995) explored the ingredients commonly used in fish, shrimp and other confined aquatic organisms. *Introduction to Food-Borne Fungi* (Samson *et al.*, 1995) is one of the best references for detailed photos and interpretive drawings of the common molds attacking foods and feeds. What is most notable about the feed microscopy literature is the lack of a single treatise or detailed text for the feed microscopist that covers everything including the cellular keys for identification of forages and pasture plants and the identification of ingesta and fecal particles. Reference standard collections are critical to feed microscopy and ingesta identifications. Typically microscopists share samples or hard to find materials at professional meetings or via mailings. Sample collections of authentic materials are usually provided at feed microscopy short courses.

## THE FEED MICROSCOPY LABORATORY

Feed microscopists generally work alone, not in groups, and their laboratories are reflections of their work habits in whatever space is available. An ideal feed microscopy laboratory work station is centered in a "U" configuration with sinks, hoods, preparation areas, etc. located nearby but not in the immediate microscope area where fumes or solvents might damage the microscopes. Figure 89.1 shows a laboratory with shallow drawer cabinets full of reference standards supporting the work surfaces holding the microscopes. A boom stand stereomicroscopes is at the right side, a large research stereomicroscope is in the center equipped with video and still camera ports and a large frame compound microscope is seen on the left side. A microscope and a second compound microscope are just outside the picture borders along the legs of the "U." A balance, hand tools, reagents, reference materials and many other small items used in the analyses can be seen in the photo along with small cabinets for all types of reference standards.

## THE EQUIPMENT

The following equipment list details briefly the essential items plus many that are useful but may not be available in most laboratories. In all cases, purchase the best equipment that can be justified. Remember many extremely fine used microscopes are available for the starting microscopist:

- *Stereoscope*: Research grade, zoom microscope equipped with a brightfield/darkfield base and trinocular head. The newer models provide more options for digital photomicrography, videography, illumination and depth of field than the older, more simplified microscopes. Because the stereomicroscope is the heart and soul of the equipment used, it should be selected carefully to do all the types of examinations that are anticipated.
- *Compound microscope*: Large frame research model. Many excellent used Leitz, Zeiss and other brands from the

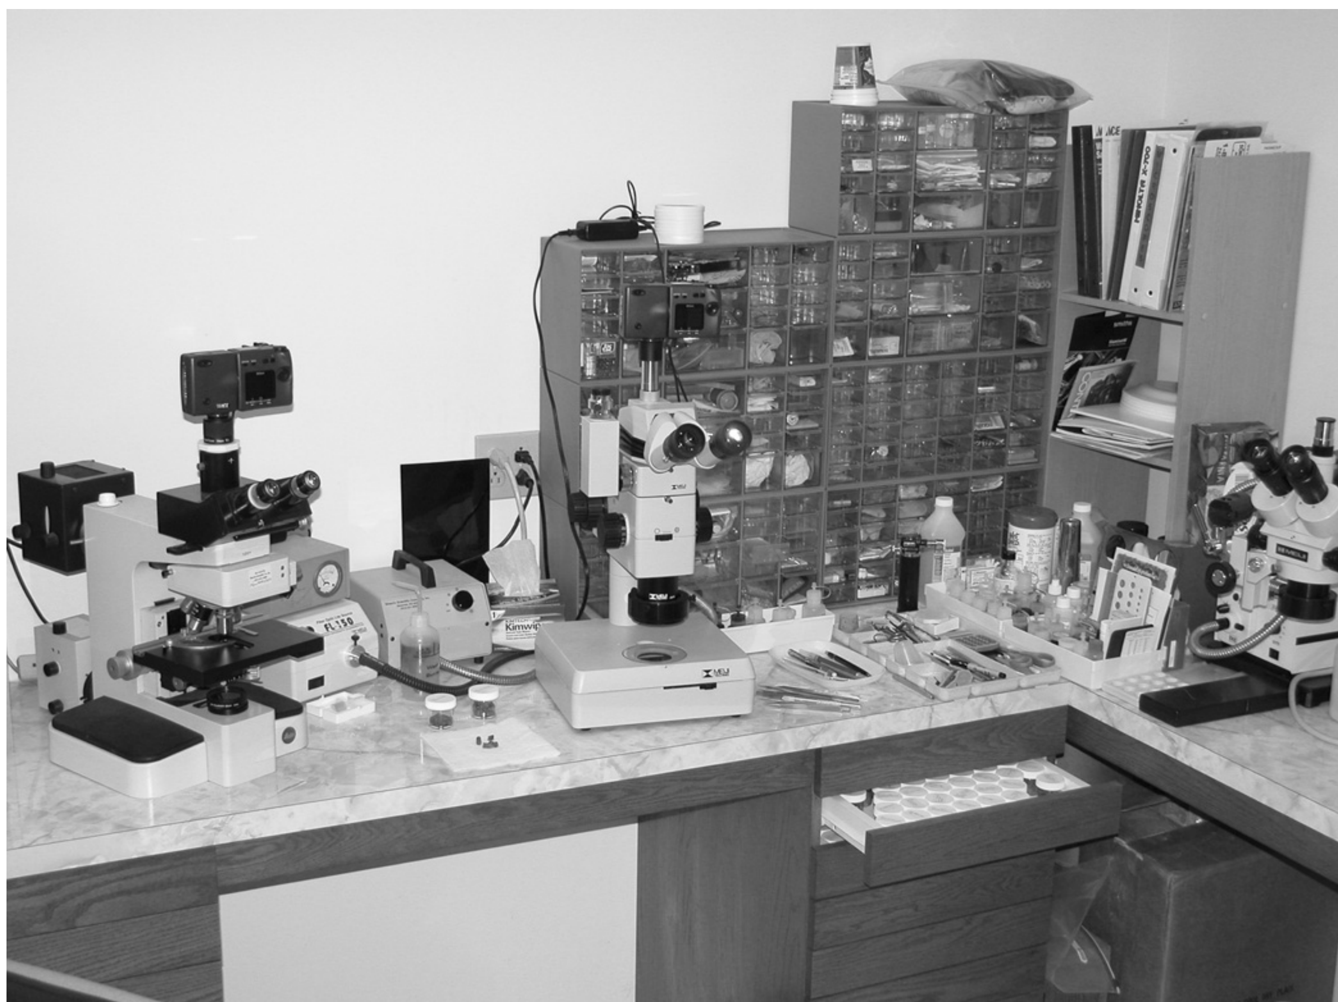

**FIGURE 89.1** An efficient "U"-shaped feed microscopy laboratory configuration.

mid-1980s are still available and serviceable. Most microscopy laboratories cannot justify purchasing the latest research models.

- *Dual compound microscopes*: Bridged for side-by-side comparisons of unknowns and authentic reference standards.
- *Documentation*: Digital cameras can be readily interfaced with microscopes to provide a digital record of observations, reference standards, side-by-side comparisons, etc.
- *Hand tools*: This should include tweezers, needles and probes for manipulating samples, small cutting instruments (scalpel, micro-scissors), glassware and sieves for flotation separations, measuring tools (manual or digital calipers, optical and stage micrometers and measuring cells for particulates). Many microscopists fabricate their own tools or adapt and modify tools from other disciplines. Dentistry picks and probes, tools for clay sculptors, model builders scissors, micro-soldering torches and many other small tools have been adopted for use under the microscope.
- *Reference standards set*: The collection of reference standards (authentics) is a critical aspect of feed microscopy. The reference collection is one of the central three requirements for microscopy and maintaining a collection is a career long endeavor. Every effort should be made to collect multiple samples of each feed ingredient to represent the variations from different parts of a country or different appearances due to heating, drying and other processing variations of manufactured by-products. The underlying cellular structures will remain essentially the same (except for agglomerated and co-mingled by-products) but the appearances may differ.

The reference collection should be preserved in glass or plastic containers that can be well sealed and maintained free of insects. Freeze potentially contaminated samples for 10–15 days before placing them in the collection. No pesticides or other chemicals should be used for preserving a reference collection because natural aromas are an inherent part of the ingredients.

## CONCLUSIONS AND FUTURE EXPECTATIONS

Feed microscopy offers a wide range of applications for the analysis of feed ingredients, finished feeds, ingesta and fecal samples. Although the classical applications of feed microscopy in the feed industry and state compliance laboratories have become relatively static due to a series of events and decisions ranging from load cell technology to least cost formulations to collective terms for labeling, the needs for microscopists in BSE screening and bio-security issues, toxicology and forensic applications have dramatically increased. Thus, this is a time of transition. This chapter illustrates just a fraction of the applications and opportunities for feed microscopists. The identification and evaluation of particulates from foods, feed ingredients, formula feeds, forages, weed seeds and all manner of other sources will continue to expand for many years if the current demand can be interpolated correctly into the future.

CHAPTER

# 90

# Role of pathology in diagnosis

*Manu M. Sebastian*

## INTRODUCTION

All intoxications do not result in gross or histopathological lesions in tissues of exposed animals. Hence the pathological findings should be correlated and interpreted in terms of case history, clinical signs and chemical analysis of the body fluids or ingesta (e.g. no specific pathological lesions for *Clostridium botulinum* toxicity). The gross and histopathological examination of the tissues along with ancillary testing will help to attain a conclusive diagnosis and also rule out other etiologies. Many of the toxicants do leave some histopathological clues in organs like liver, kidney, gastrointestinal (GI) tract, skin, brain, etc. Appropriate samples should be collected for processing in order to attain a conclusive diagnosis. The tissue should be collected in 10% neutral buffered formalin for routine histopathological processing. In veterinary medicine, toxicological investigation of mortality in animals is conducted by postmortem examination. In such investigations pathologists play an important role by correlating and interpreting the case history, clinical signs and pathological findings with analytical findings of body fluids, gastric contents, etc. When field necropsies are conducted appropriate samples (sample collection and shipping have been mentioned in other chapters) should be submitted for analytical examination along with formalin-fixed samples for attaining a conclusive etiological diagnosis. In medico-legal cases the samples should be collected in the presence of qualified law officers and should be appropriately documented. The current chapter covers the pathological lesions observed in domestic animals which are exposed to common toxins/chemicals. This chapter is divided into nine sections which comprise of drugs, feed and food materials, gases, minerals and metals, mycotoxins, plants, pesticides, miscellaneous and zootoxins.

## DRUGS

Several drugs induce adverse reactions in domestic animals. Accidental ingestions of human prescription and over-the-counter medications have been reported in veterinary medicine literature. Antibiotics like penicillin lead to anaphylaxis and hemolytic anemia but there is a no definite microscopic finding. There are several cardiovascular medications like calcium channel blockers and angiotensin-converting enzyme inhibitors, beta blockers and diuretics, tranquilizers, antidepressants, anticonvulsants and muscle relaxants which have been reported to induce adverse reactions in domestic animals, but there are no specific histopathological changes which will aid in the diagnosis of these adverse reactions. Similarly illicit drugs or abused drugs like amphetamine, cocaine, opiates, marijuana, etc. have no specific histopathological lesions which will correlate with the accidental, intentional, or malicious exposure.

Felines are highly sensitive to toxicity for certain drugs as they are deficient in certain types of glucuronyl transferase. The common drugs to which cats are susceptible to toxicity include aspirin, acetaminophen, ibuprofen, preparations containing caffeine, theobromine and theophylline. Several drugs are reported to cause idiosyncratic reactions in different species of domestic animals and the specific pathogenesis is not known. This section covers the common drugs which are used in veterinary medicine and induce adverse reactions in domestic animals with histopathological changes.

### Aminoglycosides

The most important toxic effects manifested by aminoglycosides are nephrotoxicity, ototoxicity and neuromuscular

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

blockage. Aminoglycosides accumulate in the proximal tubular epithelial cells where they are sequestered in the lysosomes and interact with ribosomes and mitochondria resulting in cellular damage (Kahn, 2005).

Gentamycin toxicity has been reported in dogs. Grossly the kidney appears pale. Histopathological changes include tubular epithelial necrosis with regeneration and mineralization. Predominantly the proximal tubules are affected. Lesions will progress from hyaline droplet degeneration with dilated lumen to necrosis of the renal tubular lining epithelium (Sprangler *et al*., 1980). Gentamicin toxicity has also been reported in snakes. In experimental studies conducted on gopher snakes, proximal tubules showed hydropic degeneration and this progressed to tubular necrosis 1 week after the gentamicin was discontinued. In the same experiment the snakes also developed visceral gout with urate crystals in multiple visceral organs (Montali *et al*., 1979).

Neomycin toxicosis has been reported in calves. Experimental exposure of neomycin in calves has reported both nephrotoxicity and ototoxicity (demonstrated clinically). The clinical pathological observations included granular casts in urine, proteinuria and low specific gravity of urine, azotemia, decreased creatinine clearance, polyuria and polydipsia. The histopathological findings included renal tubular epithelial degeneration and necrosis (Crowell *et al*., 1981).

Aminoglycosides can result in ototoxicity and cats are highly sensitive to ototoxicity. The important histopathological finding is the degeneration and loss of the hair cells and supporting sensory structures in the organ of Corti. The zootoxic potential is high for gentamycin (McCormick *et al*., 1985). Erythromycin ethylsuccinate has been reported to induce severe colitis in horses which is associated with major changes of the intestinal microflora. The subsequent growth of *Clostridium difficile* has been demonstrated as a potential etiological agent in antibiotic-induced acute colitis (Gustafsson *et al*., 1997).

## Antifungal agents

Amphotericin B is an antifungal agent and is a drug of choice for systemic mycosis. Toxicosis of this drug can happen at recommended dosage rates. Nephrotoxicity may be related to a decrease in intrarenal blood flow associated with arteriolar vasoconstriction, a subsequent decrease in glomerular filtration rate (GFR) and impaired tubular function. Dogs and cats are the common species affected with more susceptibility in cats. The common histopathological finding includes renal tubular necrosis, dilatation of the tubules and mineralization with mild lesions in the interstitium and glomeruli (Rubin *et al*., 1989). Ketaconazole, an antifungal agent, also has been reported to induce toxicity. The target organ is liver and toxicity is characterized by necrosis of hepatocytes (Ma *et al*., 2003).

Griseofulvin another antifungal agent is known to be teratogenic. Congenital malformations were reported in kittens of cats treated with griseofulvin which affected both brain and skeletal system. The changes in the brain consisted of exencephaly, malformed prosencephalon, caudal displacement and hydrocephalus. The changes in the skeletal system consisted of cranium iridium, spina bifida (C1 – C4 and sacral), abnormal atlantooccipital articulation, cleft palate, absence of maxillae and lack of tail vertebrae. Other pathological observations included cyclopia and anophthalmia with absence of optic nerves and rudimentary optic tracts atresia ani, atresia coli, lack of atrioventricular valves in the heart and absence of external nares and soft palate (Scott *et al*., 1975). Microphthalmia, brachygnathia superior and palatocheiliosis were reported in a foal born to a mare administered griseofulvin in early pregnancy (Schutte and Vanden Ingh, 1997).

## Antineoplastic drugs

Several antineoplastic drugs have been reported to be toxic in domestic animals. Experimental studies of methotrexate in cats have shown axonal degeneration and fibrin deposits in the walls of small vessels (Shibutani and Okeda, 1989).

Experimental studies of 5-fluorouracil and its masked compounds tegafur and carmofur in dogs have been reported to cause neurotoxicity (Okeda *et al*., 1988).

Vincristine, which is an alkylating agent, has been reported to produce peripheral neuropathy in dogs (Hamilton *et al*., 1991).

The common pathological manifestation of adverse reaction of cyclophosphamide therapy in dogs and cats is sterile hemorrhagic cystitis characterized by ulceration, edema and necrosis. Toxic effects of cyclophosphamide in the urinary bladder are by the action of acrolein, a metabolite of cyclophosphamide. Acrolein causes submucosal, edema, necrosis, hemorrhage and fibrosis of the urinary system epithelia (Dhaliwal and Kitchell, 1999; Charney *et al*., 2003). Another antineoplastic drug which has toxic effect is doxorubicin. Experimental studies have shown that doxorubicin can induce degeneration of the myocytes characterized by vacuoles.

Cisplatin is an antineoplastic drug which causes toxic changes in kidney, intestines and bone marrow. Cisplatin or its metabolites are eliminated through urine and hence cause renal toxicity. The exact mechanism of toxicity is not known and may involve the metabolites of cisplatin and not the platinum atom itself. The pathological findings associated with cisplatin treatment in dogs include mild renal tubular atrophy and tubular necrosis. In cats which had saline diuresis to avoid renal toxicity by cisplatin, the

medication resulted in pulmonary toxicity. The gross findings included severe hydrothorax, mediastinal and pulmonary edema. The microscopic observations associated with toxicity included thickening of alveolar septa and congestion with neutrophils, thrombi, mild necrosis and fibrin deposits. Microangiopathic changes were also observed in the alveolar capillaries (Choie *et al*., 1981; Knapp *et al*., 1987; Forrester *et al*., 1993).

## Chloramphenicol

Chloramphenicol is reported to be toxic in cats. The drug is metabolized by the liver and excreted as a glucuronide conjugate which accounts for the increased sensitivity in cats. In experimental studies toxic effects of chloramphenicol in cats include bone marrow suppression with marrow hypoplasia, maturation arrest of erythroid cells, inhibition of mitotic activity and vacuolation of lymphocytes, early myeloid and erythroid cells. Some cats had reduced marrow cellularity, or increased myeloid:erythroid ratio, or both of these. The hematological changes included decreased numbers of neutrophils, lymphocytes, reticulocytes and platelets. In dogs the toxic effects observed in experimental studies include suppression of erythropoiesis, decreased mitotic activity and reduced rate of granulocytopoiesis (Watson, 1977, 1980; Watson and Middleton, 1978).

## Fluoroquinolone

Quinolones have been reported to produce neurotoxicity and convulsions when administered in high dose. High-dose administration of quinolones for long time has reported embryonic loss and maternal toxicity. Joint is the target area for fluoroquinolone toxicity in dogs. Experimental studies in young dogs with difloxacin, a fluoroquinolone, show erosions or vesicles in the articular cartilage. The microscopic findings include necrosis of chondrocytes in the articular–epiphyseal cartilage complexes that was rapidly followed by disruption of extracellular matrix and formation of fissures (Burkhardt *et al*., 1992). The excessive use of quinolones in immature dogs may thus lead to lameness.

Enrofloxacin has been reported to be retinotoxic in cats resulting in blindness by acute and diffuse retinal degeneration. The histopathological observations include outer retinal degeneration, with diffuse loss of the outer nuclear and photoreceptor layers, hypertrophy and proliferation of the retinal pigment epithelium (Gelatt *et al*., 2001).

## Mebendazole and albendazole

Generally, the anthelmintic mebendazole is of low toxicity and has a wide margin of safety in animals. There have been reports of mebendazole toxicosis in a group of Doberman pinschers and dachshunds which were dosed at the recommended therapeutic level. The microscopic findings include centrilobular necrosis of the hepatocytes in the centrilobular areas with loss of hepatocytes, sinusoidal collapse and replacement by hemorrhage. Hepatocytes near portal areas had vacuolations with swollen nuclei. Occasional inflammatory cell infiltrates were present in the portal areas and central veins. The toxicity is considered to be due to an idiosyncratic drug reaction (Polzin *et al*., 1981).

There are reports of albendazole-induced bone marrow toxicity in dogs and cats. The toxicity appears to be dose related in dogs and idiosyncratic in cats. Clinical pathological findings include pancytopenia with severe bone marrow hypoplasia in dogs. In cats hypoplasia of erythroid and megakaryocytic series, but with a left-shifted granulocytic hyperplasia were observed (Stokol *et al*., 1997).

## Minoxidil

Minoxidil a vasoactive drug is used to stimulate hair growth in adult men and women and is available over-the-counter in United States. Pet owners may use the drug for alopecia in animals. Experimental studies have reported cardiovascular toxicity. Experimental studies in dogs indicate that minoxidil can induce pathological changes in the heart which include right atrial hemorrhage, right ventricular papillary necrosis, subendocardial necrosis and fibrinoid necrosis of the small arteries (Jett *et al*., 1988; Mesfin *et al*., 1995).

## Furazolidone

Furazolidone toxicity has been reported in goats. The gross observations included congestion in brain, liver and kidneys. The histopathological findings included degenerative changes in the renal tubules, hepatocyte necrosis and degeneration in the centrilobular areas. The changes in the brain included congestion of white matter in cerebellum and scattered vacuoles around nerve sheaths (Ali *et al*., 1984). The other species in which furazolidone toxicity is commonly reported is young turkey poults. The gross findings include ascitis, bilateral or right side dilatation of ventricles with round apex and congestion of the lung and liver. The histopathological findings include cardiomyopathy and secondary changes in the lung and liver due to cardiac changes (based on right or left-side failure) consisting of pulmonary edema and congestion, degeneration of hepatocytes, fibrosis and bile duct hyperplasia (Simpson *et al*., 1979; Good and Czarnecki, 1980).

## Non-steroidal anti-inflammatory agents and analgesics

NSAIDs are the most widely used analgesics in veterinary medicine, and all have some toxic potential. The NSAIDs and analgesics associated with toxicity in veterinary medicine include salicylates, ibuprofen, ketoprofen, carprofen, naproxen, indomethacin, etodolac, sulindac, oxyphenbutazone, phenyl butazone and piroxicam. The most common adverse effects are GI, renal, hepatic and coagulation disorders. The common species affected are dogs, cats and horses. Cats are more susceptible to salicylate toxicity due to the reduced hepatic glucuronyl transferase system.

NSAIDs cause toxicity of the GI tract, kidneys and liver. GI toxicity is attributed to the direct effect of the drug and inhibition of the cyclooxygenase isoenzyme. NSAIDs cause renal toxicity mainly by the inhibition of prostaglandin synthesis and renal blood flow resulting in renal papillary necrosis. The hepatic toxicity is mostly attributed to idiosyncratic reaction. Gross observations include GI irritation and possible ulceration with associated hemorrhage and possible perforation. Renal tubular or papillary necrosis is also reported in a limited number of cases in dog (Jones *et al.*, 1992).

The toxicity with carprofen has been reported in dogs and primarily affects the liver. Hyperbilirubinemia and high-serum activities of alanine aminotransferase (ALT), alkaline phosphatase and aspartate aminotransferase were the most important clinicopathological abnormalities. Gross findings may include icterus and yellowish

\discoloration of liver. The important histopathological findings are hepatocyte degeneration and necrosis. Hepatocellular necrosis is usually located in the centrilobular areas with mild lymphocytic–histiocytic periportal hepatitis; 13 of 21 reported cases of carprofen hepatocellular toxicosis occurred in the Labrador breed and the cause of breed predilection is not known (Figure 90.1). The toxicity of this drug is considered to be related to an idiosyncratic toxic reaction (MacPhail *et al.*, 1998). In another study carprofen appeared to be well tolerated by dogs after 2 months of administration (Raekallio *et al.*, 2006). Studies in dogs with Celecoxib, a cyclooxygenase-2 inhibitor, have shown that there is evidence for polymorphism in the canine metabolism of the cyclooxygenase-2 inhibitor which may account for some of the toxicity observed in dogs exposed to cyclooxygenase-2 inhibitor (Paulson *et al.*, 1999). Higher than approved dose of medication can result in toxicity. In a study conducted in dogs which received Deracoxib, a selective cyclooxygenase-2 inhibitor, at a dosage higher than that approved by the Food and Drug Adminstration (FDA) for the particular indication being treated, developed GI tract perforation leading to death. Multiple factors were associated with these GI tract injuries (Lascelles *et al.*, 2005).

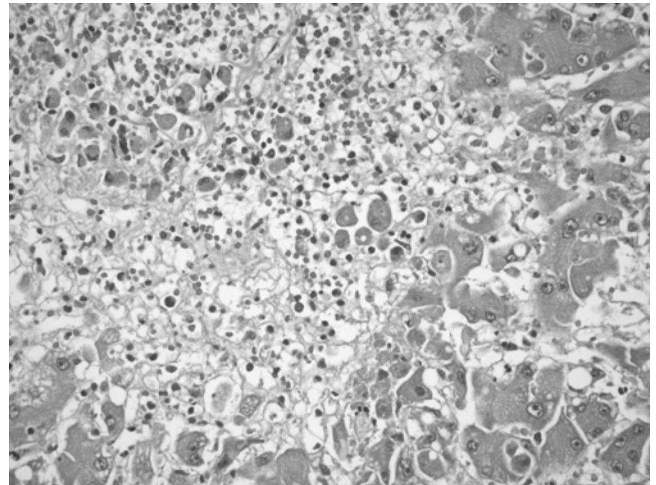

**FIGURE 90.1** NSAID-induced toxicity, liver, canine, hepatocyte necrosis and degeneration in the centrolobular areas with marked biliary stasis, H&E stain, 40×. This figure is reproduced in color in the color plate section.

In dogs other causes of GI tract ulceration include NSAIDs, hepatic disease, mast cell tumor, uremia, stress, and various systemic diseases like disseminated neoplasia, septicemia and disseminated intravascular coagulation.

Horses are susceptible to phenylbutazone toxicity especially when dehydrated and the target organ is kidney. The most common gross observation in experimental studies conducted in horse dosed with phenylbutazone and deprived of water was yellow green radial streak in the renal papillae. The microscopic observations include sloughing of the renal pelvic epithelium including the terminal lining of collective ducts with coagulation necrosis of the underlying papillary interstitium, mineralization of the calyx necrotic papillary interstitium containing nuclear debris and hemorrhage and dilatation of collecting ducts and cortical tubules in wedge-shaped segment of the kidney tissue above area of necrotic papillae. Other lesions observed in experimental studies of horses include ulceration and erosions of the glandular portion of the stomach, submucosal edema of the small intestine, erosions and ulcers of the large colon, ulceration of the gastric mucosa and tongue. Pathological findings in experimental studies of horses exposed to flunixin meglumine (amino nicotinic acid) were glandular mucosal erosion and ulcer of the stomach (Gunson and Soma, 1983; MacAllister *et al.*, 1993).

Recently report of vulture mortality was reported from the Indian subcontinent related to NSAID toxicity. Diclofenac is a NSAID widely available veterinary drug in the Indian subcontinent, used in domestic livestock. Vultures were exposed to the drug when they consumed carcasses of cattle that were treated with diclofenac shortly before death. Experimental studies of this drug in vultures showed marked nephrotoxicity. The gross

observations were primarily deposits of urate on the surface of internal organs related to renal failure. Histopathological findings were acute necrosis of the proximal renal tubular epithelium with minimal inflammatory response and deposits of urate crystals (Oaks *et al*., 2004; Meteyer *et al*., 2005).

## Analgesics

Aspirin, ibuprofen and acetaminophen are the important analgesics which are reported to cause toxicosis in veterinary medicine. Generally, toxicosis is a result of large overdoses, cats are predisposed to toxicosis, for acetaminophen and aspirin.

Cats are more susceptible to aspirin toxicosis than dogs due to saturation of elimination pathway. Anemia, with Heinz bodies and reduced RBC production, is an important clinicopathological finding in cats. Gastric irritation is the most common toxic effect of aspirin. The common pathological finding is gastric ulcers which lead to hematemesis. Toxic hepatitis is also reported rarely (Villar *et al*., 1998).

The common pathological finding with ibuprofen toxicosis is gastric ulcer and is observed in prolonged therapy in dogs. Perforated gastric ulcers are also reported with prolonged ibuprofen therapy. Centrilobular hepatocyte necrosis has been reported in dogs exposed to accidental ingestion of high doses of ibuprofen. Renal lesions including renal tubular necrosis and papillary necrosis have been reported in dogs.

## Acetaminophen

Acetaminophen is a widely used analgesic and antipyretic agent and toxicity has been reported in both dogs and cats. The toxic effects of acetaminophen are a result of increased production of a reactive intermediate, *N*-acetyl-*p*-benzoquinone imine (NAPQI). Another hypothesis cites oxidative stress as the mechanism of hepatocellular damage. NAPQI depletes the cell of glutathione, which is normally protective against oxidative stress. The stress to erythrocytes causes methemoglobinemia. Centrilobular necrosis of the hepatocytes is the most common histopathological finding associated with acetaminophen toxicity. When exposed to toxic levels it can lead to massive necrosis especially in cats. In studies conducted with acetaminophen centrilobular necrosis was observed in dogs, while cats had more diffuse hepatic necrosis. Heinz body formation is one of the most common clinical pathological manifestations of acetaminophen toxicity in cats (Villar *et al*., 1998; Taylor and Dhupa, 2000). Diagnosis is by correlating case history, clinical signs and pathological findings. Blood and serum levels of salicylate concentration are used in human medicine.

## Anticonvulsants

### *Phenobarbital*

Phenobarbital is one of the most commonly used anticonvulsant drugs in dogs. Hepatotoxicity and mortality have been reported infrequently as an adverse effect of phenobarbital medication. Increased serum liver-associated enzymes are reported in phenobarbital treated dogs both with and without clinical signs of liver disease. The common serum biochemical alterations associated with hepatotoxicity include marked increase in serum ALT, serum alkaline phosphatase (ALP), total bilirubin and prolonged sulfobromophthalein excretion. Neutropenia and thrombocytopenia are also reported in dogs treated with phenobarbital. The important histopathological findings in hepatotoxicity associated with phenobarbital therapy are inflammatory cell infiltration, single cell and piecemeal necrosis, fibrosis and vascular abnormalities characterized by markedly thickened vessel walls. In chronic cases macronodular or micronodular cirrhosis is observed (Bunch *et al*., 1982; Jacobs *et al*., 1998; Gaskill *et al*., 2005). Diagnosis is by correlating case history, clinical signs and pathological findings.

Diazepam is a benzodiazepine derivative and possesses anticonvulsant, sedative and skeletal muscle relaxant properties. Toxicity has been reported in cats and liver is the target organ. Elevated ALT and aspartate transaminase (AST) are the clinical pathological observations. The histopathological findings associated with toxicity include centrilobular hepatic necrosis, hyperplasia and proliferation of biliary ductules and suppurative intraductal inflammation. Toxicosis was considered to be an idiosyncratic reaction (Center *et al*., 1996).

### *Primapaste*

Primapaste is a digestive promotant given to new-born foals which contains an iron compound, ferrous fumarate along with probiotic bacteria. The histopathological lesion observed in toxicity associated with primapaste dosing includes massive hepatocellular loss with lobular collapse, with proliferation of bile ducts and postal tract fibrosis. Hepatic encephalopathy associated with liver damage will also be observed in these foals (Divers *et al*., 1983; Acland *et al*., 1984).

### *Albuterol*

Albuterol which is a beta 2-adrenergic agonist is reported to be cardiotoxic in dogs at very high dose (multiples $>$ or $=$ 19 times the clinical dose). The histopathological

findings observed in dogs experimentally exposed to such high clinical dose were mild degrees of left ventricle fibrosis in the papillary muscles. The cardiovascular effects observed were consistent with the known pharmacologic action of beta 2-adrenergic agonists (Petruska *et al.*, 1997).

### *Steroids*

Steroid administration has been reported to cause hepatopathy in dogs. In experimental studies conducted in dogs exposed to prednisolone acetate the light microscopical observations included progressive hepatocellular swelling and vacuolation. The ultrastructural changes included glycogen accumulation, peripheral displacement of organelles and prominent dilatation of bile canaliculi. The prominent clinical pathological changes include progressive increases in serum levels of alkaline phosphatase, gamma-glutamyltransferase and ALT (Rogers and Ruebner, 1977; Rutgers *et al.*, 1995). Monitoring the serum chemistry during therapy will give indication of the pathological changes in the liver.

### *Anabolic steroids*

Stanozolol is a synthetic anabolic steroid and has been used in both animal and human patients. Stanozolol has been reported to be toxic in cats and the target organ is the liver. The significant clinical finding is elevated serum ALT activity. Histopathological observations noted in biopsy specimens include hepatic lipidosis and cholestasis without evidence of hepatocellular necrosis (Harkin *et al.*, 2000).

### *Sulfonamides*

Sulfonamides can cause both acute and chronic toxic effects. The reactions are due to hypersensitivity and direct toxic effect. Anaphylactoid reactions have been reported with sulfonamides. Several adverse reactions have been reported after prolonged treatment including bone marrow depression, hepatitis, icterus, peripheral neuritis and myelin degeneration in the spinal cord and peripheral nerves, photosensitization, stomatitis, keratoconjunctivitis (Kahn, 2005).

The most important organ affected in toxicity is the kidney. Animals with renal toxicity show elevated levels of blood urea nitrogen (BUN) and creatinine. In some animals sulfonamide crystals will be observed in the renal pelvis as a gross finding and kidneys may be gritty in texture when cut. Histopathological observation is primarily renal tubular epithelial necrosis due to the direct action of the crystal and these crystals are visible with polarized light only if the kidney is processed to prevent the dissolution (specimens of kidney tissue should be fixed in a slightly acidified formalin solution or in absolute ethanol) especially with polarized light. The photosensitization associated with sulfonamide is a primary photosensitization due to the activation of the photodynamic substance by ultraviolet light in sunrays (Jones *et al.*, 1996). Rarely hepatic necrosis has been reported with trimethoprim sulfonamide administration in dogs and is considered to be idiosyncratic drug reaction (Twedt *et al.*, 1997).

### *Tetracyclines*

Tetracyclines have been reported to cause toxicity and kidneys are the primary organs affected. Renal tubular necrosis is the common pathological finding. Animals with renal toxicity will show oliguria, marked azotemia, moderate proteinuria, tubular casts in urinary sediment with inability to concentrate urine (Lairmore *et al.*, 1984; Vaala *et al.*, 1987). Intravenous administration of tetracyclines has been reported to cause fatalities and is not recommended in horses (Riond *et al.*, 1992).

### *Vitamins A and K*

The vitamins which are associated with toxicity in veterinary medicine are vitamins A, D and K. Vitamin A toxicity has been reported associated with consumption of improperly mixed feed or food material (liver) with very high concentration of vitamin A. The intoxication has been reported in felines and calves. Increased vitamin A induces premature growth plate closure in calves which is attributed to premature mineralization of columnar cartilage and subsequent endochondral ossification. The disease in cat is characterized by cervical ankylosis, forelimb lameness and in some animals cutaneous hyperesthesia. Pathological observations include marked exostosis on the dorsal and lateral aspects of the cervical vertebrae and sometimes in the occipital bone, fixation of joints of one or both forelimbs. In a cat which had serum vitamin A concentration 4 times normal levels, the pathological lesions observed were fusion of skull and the cervical and first few thoracic vertebrae, alteration of vertebral architecture by deposition of new bone with involvement of sternum and costal cartilages (Goldman, 1992; Palmer, 1993). Calves exposed to vitamin A/D3 in amounts greater than 10 times those recommended have been reported to result in Hyena disease which is an uncommon spontaneous disease of young dairy cattle that causes dwarfism characterized by short pelvic limbs. The pathological findings in these calves included focal to almost complete closure of physes in the humerus, tibia and femur (Woodard *et al.*, 1997). Excess vit A is reported to be teratogenic. Experimental studies in swine during pregnancy show high prevalence of cleft palate and lips.

### *Vitamin $K_3$ (menadione sodium sulfate)*

Toxicity is commonly reported in horse. In experimental studies the gross lesion observed was enlargement and paleness of the kidney. The microscopic lesions include

diffuse or multifocal tubular necrosis and dilation with proteinaceous and cellular debris from red blood cells and neutrophils and casts, diffuse interstitial edema and lymphocytic infiltration regeneration of the tubular epithelium. In animals which survived for 3 months renal tubules showed degeneration, necrosis and dilation. In chronic renal failure following vitamin $K_3$ administration, the kidneys were reduced in size, the capsule adherent and pale streaks of connective tissue may be grossly apparent. Microscopic findings include connective tissue proliferation with mononuclear cell infiltration, moderate hypercellularity of glomeruli with few sclerotic glomeruli. The tubules are dilated but the lining epithelium appears normal with mineral, cellular and proteinaceous casts may be seen in many tubules (Rebhun *et al*., 1984).

#### *Miscellaneous*

There are sporadic case reports of several compounds which are used as food materials or nutraceuticals but no specific pathological findings are associated with most of these cases.

Xylitol a sweetener used in sugar-free chewing gums has been reported to be toxic in dogs leading to severe hypoglycemia resulting in ataxia, seizures and collapse. Xylitol is a strong promoter of insulin release in dogs leading to hypoglycemia but has no or little effect in humans (Dunayer, 2004). Diagnosis is by correlating the history of exposure with clinical signs and clinical pathological findings. In a study conducted on dogs which had 5-hydroxytryptophan (over-the-counter dietary supplement for obesity, depression, etc.) toxicosis the gross finding in two dogs that died was congestion of multiple organs. The histopathological findings included pulmonary edema, diffuse congestion of liver and lung and acute renal tubular necrosis with hemorrhage (Gwaltney-Brant *et al*., 2000).

Halothane a halogenated hydrocarbon inhalant anesthetic agent has been reported to cause hepatic necrosis in human patients. Similar hepatic toxicity has been reported in a dog. The histopathological findings included centrilobular necrosis which extended between central veins and many of these necrotic areas replaced by erythrocytes, hemosiderophages, bilirubin and mixed inflammatory cells. A sharp line of demarcation between viable and necrotic hepatocyte which is a feature (other feature is centrilobular necrosis) of halothane-induced hepatopathy was also observed in this dog (Gaunt *et al*., 1984).

## FEED- AND FOOD-ASSOCIATED TOXICOSIS

The important feed-associated toxins are ammonia, urea, cottonseed meal, ionophores, sulfur (mentioned in metals) and nitrates. Many food materials which are consumed by humans are also shared with cats and dogs and few food materials do induce toxicity in domestic animals. The common food materials which induce some level of toxicity include macadamia nuts and raisin in dogs.

### Non-protein nitrogen (urea/ammonia)

Urea, biuret and ammonium salts serve as sources of non-protein nitrogen (NPN) for ruminants. Mostly ruminants are affected by excessive feeding and incorrect formulation. Pathogenesis is associated with inhibition of citric acid cycle resulting in reduced ATP. Animals show signs of tremors. No specific lesions are observed. Necropsy examination may reveal few changes, but an odor of ammonia is often noted in rumen contents and tissues. The pH of rumen contents is greater than 8. Animals bloat rapidly and carcasses seem to decompose more rapidly than normal (Haliburton and Morgan, 1989).

### Nitrite–nitrate

Toxicity is by consumption of fertilizers with nitrate, consumption of nitrate accumulator plants (accumulate excess nitrate), water from recently fertilized fields and manure pits and also during drought when plants accumulate nitrate. Ruminants are the common species affected but other species can also be affected. The rumen microorganisms reduce nitrate ($NO_3$) ion to nitrite ($NO_2$) ion which leads to methemoglobinemia. Fetuses and neonates are more susceptible than adults. During necropsy chocolate brown-colored blood is observed due to methemoglobin formation. Multifocal hemorrhages may be observed on the serosal surfaces. If fertilizers are consumed congestion may be observed in the GI mucosa. No specific histopathological findings are observed. Diagnosis is by clinical signs and history of exposure. Nitrate/nitrite analysis can be conducted on the blood, serum, forages, feed, water, rumen contents and ocular fluid (aqueous humor). In abortions aqueous humor of aborted fetuses may have increased nitrate concentrations (Kahn, 2005). Other causes of acute death should be ruled out.

### Gossypol

Swine is most common species affected by gossypol. The toxic component is gossypol in the glands of the cottonseeds which appear as tiny black spots. Most gossypol is removed during processing of the seeds. Gossypol has a cumulative effect. Poisoning usually appears abruptly, but signs tend to begin after the animals have been on cottonseed meal for 4 weeks to as much as a year.

The important clinical pathological observation is elevated liver enzymes. The primary organs affected are liver, heart and skeletal muscle. Gross lesions include widespread congestion and edema, large quantities of straw-colored fluid in the peritoneal, pericardial and thoracic cavities edema of lungs. Liver has prominent architecture and may be swollen, pale or congested. Ventricles are dilated. The most prominent histopathological lesion is massive hepatic necrosis and loss and these areas are replaced by erythrocytes leaving a thin zone of intact cells in the periphery. Skeletal and cardiac muscles show varying degrees of necrosis and degeneration. In chronic cases regenerative changes are observed. Pneumonia may also be observed in some cases (Jones *et al*., 1996).

Cottonseed can induce toxicity in dogs and in a report of accidental ingestion of cottonseed bedding by dogs which lead to mortality, the common histopathological lesions were multifocal myocardial degeneration and necrosis, severe pulmonary edema and chronic passive congestion of the lungs, heart, liver and kidneys (Uzal *et al*., 2005).

Diagnosis is based on case history, clinical signs and pathological findings. Differential diagnosis includes hepatosis dietetica, mulberry heart disease (vitamin E/selenium deficiency), coal tar poisoning (phenolics), selenium toxicity, monensin, lasalocid poisoning.

## Ionophores

Monensin, lasalocid, salinomycin, narasin and maduramicin are carboxylic ionophores commonly used as anticoccidial drugs for poultry and as growth promotants for ruminants. Horses are the most susceptible species for ionophore toxicity and other domestic animals are also susceptible. Clinical pathological findings include elevated serum creatine phosphokinase (CPK), lactate dehydrogenase (LDH) and AST. The gross lesions include multifocal pale areas and hemorrhage in the pericardium and epicardium. Microscopic findings include degeneration and necrosis of cardiac and skeletal myocytes with fibrosis in chronic cases (Figure 90.2). Degeneration of the renal tubular epithelium and myoglobinuria are also reported in some cases (Novilla, 1992). Histopathological findings in horses are mostly associated with heart, commonly in the ventricles. The changes in bovines are also common in the heart but pigs have lesion in the skeletal muscles and atrium. Experimental studies in pigs dosed with toxic level of monensin showed pathological changes in the left atrium and consisted of extensive necrosis with contraction bands. The study indicates the selective injury of monensin in pigs to atrial myocardium (Muylle *et al*., 1981; Van Vleet and Ferrans, 1984).

Salinomycin has been reported to induce toxicity to the nervous system in cats. Cats which were exposed to feed material containing salinomycin had acute onset of lameness and paralysis of the hind limbs and forelimbs. Microscopic findings include neuropathy, myelin degeneration of the sensory and motor nerves (van der Linde-Sipman *et al*., 1999). Diagnosis is by case history, chemical analysis of the feed and pathological findings.

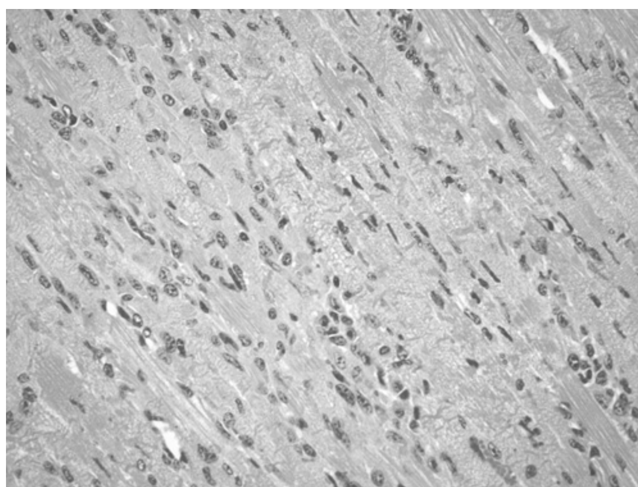

**FIGURE 90.2** Monensin toxicity, heart, bovine, cardiac myocytes show degeneration and some areas myocytes replaced and infiltrated by lymphocytes and histiocytes, H&E stain, 40×. This figure is reproduced in color in the color plate section. (Courtesy Dr. ME Hines, College of Veterinary Medicine, University of Georgia.)

## Raisin

Grape and raisin ingestion has been reported to cause renal toxicity in dogs. The specific mechanism is not known. Clinical pathological findings include hypercalcemia, hyperphosphatemia, elevated BUN and serum creatinine concentrations, all related to renal damage.

Gross lesions are absent and microscopic findings include degeneration and necrosis of proximal renal tubular epithelium with intact basement membrane, regeneration of the tubular epithelium and mineralization. The tubules contain granular and protein casts. In few animals fibrinous arteritis of the large colon was also observed (Eubig *et al*., 2005; Morrow *et al*., 2005).

## Macadamia nuts

Consumption of macadamia nuts has been associated with toxic clinical signs consisting of hind leg weakness, depression and tremors. No mortality has been reported. In experimental studies mild increase in serum triglycerides and serum alkaline phosphatase was detected. The lipase values increased sharply at 24 h and then returned to normal by 48 h after experimental dosing. No

histopathological findings are available in the literature as mortality has not been reported (Hansen *et al.*, 2000).

## GASES

Not much specific pathological findings are observed with exposure to toxic insult of gases. The common gases which induce toxicity in confinement animal housing are ammonia, hydrogen sulfide ($H_2S$), carbon monoxide and nitrogen dioxide. The toxicity of these gases rarely shows any histopathological changes. No gross or histopathological changes are associated with ammonia toxicity. Nitrogen dioxide is associated with silo fillers disease in humans, which is a disease seen in agriculture workers who are associated with silage production and results from the exposure to nitrogen dioxide produced during the fermentation of silage preparation.

### $H_2S$

$H_2S$ is associated with toxicity in pigs and leads to acute death. Liquid manure holding pits is the common source. Sulfide ions act as direct cytotoxic, bind to cytochrome oxidase within mitochondria and block electron transport. Animals dying as a result of $H_2S$ toxicosis are generally cyanotic and may exhibit pulmonary congestion and edema.

A report in cattle resulting in mortality as a result of exposure to $H_2S$ gas from manure pits showed no specific gross lesions. Microscopic findings include massive, diffuse cerebral cortical laminar necrosis and edema characterized by degenerative and necrotic neurons and vacuolations in subcortical white matter (Hooser *et al.*, 2000).

### Carbon monoxide

Exposure to carbon monoxide primarily occurs as a result of improper ventilation. This is common in farrowing houses and lambing sheds and leads to abortion as carbon monoxide cross placenta and cause fetal hypoxia. Common gross lesions in experimental studies in stillborn piglets born to carbon monoxide exposed sows were cherry red discoloration of the subcutaneous tissues, muscle, viscera and accumulation of a large volume of serosanguineous fluid in thoracic cavity. The histopathological findings included malacia of the gray and white matter infiltrated by gitter cell and reactive glial cells, glial cell and vascular proliferation, multifocal hemorrhage and vacuolation of the neuropil (Dominick and Carson, 1983). In many species of animals exposure to carbon monoxide results in acute death and blood has a bright cherry red color. The histopathological findings include degeneration of the neurons in the cerebral hemispheres indicative of hypoxia and ischemia.

## METALS AND MINERALS

Only the most common metals which induce toxicity in domestic animals are mentioned in this section and they include arsenic, copper, fluorine, iron, lead, mercury, molybdenum, selenium, sodium, sulfur and zinc.

### Arsenic

Arsenical compounds cause clinical symptoms related to the GI tract which may be acute or per acute. Herbicides, defoliants, insecticides and arsenic treated wood products are the common sources for toxicosis. Toxicosis is mostly reported in cattle and dogs but all species of domestic animals can be affected.

In acute toxicosis the gross lesions are mostly in the GI tract and consist of severe redness of the gastric/abomasal and intestinal mucosa. The intestinal lumen is dilated and filled with massive amount of fluid. The histopathological findings include marked congestion and hemorrhage in the mucosa of the abomasum and intestine with congestion in submucosa and necrosis of the mucosal epithelium. In some cases the necrosis of the GI tract can lead to perforations (Jones *et al.*, 1996). Arsenic toxicosis though rare is reported in horses also. The gross findings are similar to that mentioned above along with multifocal to coalescing, hemorrhagic ulcers of the mucosa of the cecum and large colon. Histopathological findings include mucosal necrosis and ulceration in the cecum and large colon, vascular thrombosis, necrosis of submucosal blood vessels and infiltration by mixed mononuclear inflammatory cells and neutrophils (Pace *et al.*, 1997).

In subacute cases pale swollen kidney and pale liver are observed and petichial hemorrhages can be observed in the serosal and mucosal surfaces. Renal damage affects all portions of the nephron leading to severe renal tubular necrosis. Histopathological lesions consist of dilation of the vessels, submucosal congestion and edema, necrosis of the intestinal epithelium, renal tubular necrosis and fatty degeneration of the hepatocytes. Nervous system is the target organ of organic arsenicals. The histopathological lesions associated with arsenilic acid are edema of the white matter in the brain and spinal cord with shrunken neurons in the medulla (Selby *et al.*, 1977; Jones *et al.*, 1996).

Diagnosis is by correlating the case history, pathological findings and analytical estimation of arsenic in liver, kidney and other tissues. Differential diagnosis of pathological lesions includes infectious causes and non-steroidal anti-inflammatory agent exposure.

## Copper

Acute copper toxicosis results from accidental ingestion or administration of copper-containing formulations like anthelmintics, foot baths used for livestock, pesticides include fungicides and algaecides at a toxic dose. Copper toxicosis is a problem observed frequently in the sheep. Sheep accumulate copper in the liver in proportion to intake, where there is slow build up of the copper and then there is sudden release which results in hemoglobinuria. Grossly the kidneys have a dark red or bluish black color and the liver will be pale and friable. Microscopic findings include coagulative necrosis of hepatocytes, fibrosis of the portal area and bile duct proliferation with mild infiltration of lymphocytes. The kidney tubules show degeneration of the epithelium. In some cases if the toxic exposure is acute abomasum or stomach has marked hemorrhage and edema (Maiorka *et al.*, 1998). In non-ruminants the lesions observed are pale livers with centrilobular necrosis and gastric ulcers. Diagnosis is by correlating liver copper values with pathological findings and case history.

Hepatic copper accumulation can occur secondary to primary cholestatic disease or as a primary storage disease. Primary copper storage disease is recognized in Bedlington terriers. Copper accumulation occurs secondary to a metabolic defect which inhibits appropriate biliary copper excretion and results in subsequent hepatocellular lysosomal copper accumulation. This defect has been identified as an autosomal recessive inherited trait in the Bedlington terrier. A defect in hepatic metallothionein which binds to copper within the hepatic lysosome is also considered as a pathogenesis. Other breeds reported to be affected by hereditary copper storage disease are West Highland white terrier, Skye terrier and Dalmatian. The animals have pale brown nodular liver. Histopathological findings include copper accumulation in the hepatocytes, starting in the centrilobular areas and extending to other regions resulting in hepatocellular necrosis, inflammation with copper-laden macrophages finally resulting in cirrhosis. Dogs of other breeds such as Doberman pinschers, Labrador retrievers and American and English cocker spaniels have been reported to have elevated copper concentrations in association with chronic hepatitis, but it has not been conclusively proven whether this copper accumulation is primary or secondary to chronic inflammation, fibrosis and cholestasis (Ludwig *et al.*, 1980; Thornburg, 2000).

## Fluoride

Fluoride toxicosis can be acute or chronic and chronic forms are observed commonly. Acute toxicosis is by exposure to insecticides/rodenticides and exposure to volcanic dust exposure. Chronic toxicosis is by exposure to mineral supplements, industrial effluents and fertilizers. Chronic toxicosis is commonly reported in herbivores grazing-contaminated pastures. Volcanic ash from volcanic eruptions has been reported to be a source of fluoride toxicosis in ruminants. Fluoride is metabolized via renal excretion and is preferentially deposited in bones and teeth.

Acute fluoride intoxication produces clinical signs and lesions of gastroenteritis and renal tubular necrosis. In a study conducted in sheep exposed to fluoroacetate, the microscopic findings in acute toxicosis included degeneration and necrosis of myocardial fibers. Subacutely and chronically intoxicated animals had the same findings but were more widespread and in various stages of development or resolution (Schultz *et al.*, 1982).

Chronic fluoride intoxication produces dental and/or skeletal lesions. The common pathological effects of fluoride toxicosis are on the teeth and bones. The common dental lesions include enamel hypoplasia, attrition of molar teeth and crown loss. Teeth have a typical mottling appearance. These lesions develop only if intoxication occurs when the teeth are in the developmental stages. The lesions associated with the skeleton system include kyphosis, hyperostosis and osteodystrophy. The lesions in the bones are observed mostly in the metacarpal, metatarsal and mandible. The marrow cavity becomes smaller in size and the periosteum is thickened. Microscopic findings include thickening of the bony trabeculae osteosclerosis, osteoporosis with periosteal hyperplasia and endosteal resorption. Fluoride toxicosis can also lead to renal injury. In a study conducted in sheep poisoned by sodium fluoride the pathological findings included necrosis of the proximal tubular epithelial cell, necrotizing rumenitis, reticulitis and abomasitis (Shupe, 1980; O'Hara *et al.*, 1982; Maylin *et al.*, 1987). The differential diagnosis includes exposure to heavy metals, ingestion of plants containing oxalates or tannins, mycotoxins, aminoglycosides and chlorinated hydrocarbons.

## Iron

The most commonly affected species is swine especially baby pigs although all other species can be affected. In piglets iron toxicosis results from when too much iron is injected or less often when too much is given orally. Any of the iron complexes and iron salts may be involved. In acute cases there is swelling at the injection site with respiratory distress. The gross lesion at the site includes edema with brownish black discoloration.

Hepatic changes are characterized microscopically by hepatocyte necrosis in the periportal areas. A rare form of less acute nature characterized by hard swelling develops at the injection site. This happens due to massive mobilization of calcium after injection and happens after some days of injection. Calcification may be observed in multiple parts of the body (Patterson and Allen, 1970; Kahn, 2005). Toxicity due to oral preparations leads to gastric ulceration and edema.

Foals given a nutritional preparation which contained an iron compound, ferrous fumarate, induced hepatopathy and histopathological lesions. The lesions are characterized by massive hepatocellular loss with lobular collapse, proliferation of bile ducts and portal tract fibrosis. Hepatic encephalopathy associated with liver damage was also observed in these foals (Divers *et al.*, 1983; Acland *et al.*, 1984). Diagnosis is based on case history, clinical signs and pathological findings.

## Lead

Lead toxicosis is by exposure to lead paint, lead-containing objects like toys foils, etc., plumbing material, tiles and linoleum. Lead toxicosis affects hemoglobin synthesis by inhibiting the enzymes delta-aminolevulinic acid synthetase and ferrochelatase resulting in anemia. Clinical pathological findings suggestive of lead toxicosis are basophilic stippling of erythrocytes and metarubricytosis with minimal polychromasia. Anemia may be microcytic hypochromic to normocytic normochromic (Prescott, 1983). Animals dying of acute lead poisoning have very few microscopic lesions other than mild degenerative neuronal necrosis in the cerebral cortex and mild renal epithelial degeneration.

In chronic cases also the lesions are not outstanding and in few cases the lead source may be found in the GI tract. Ruminants with chronic toxicosis have laminar cortical necrosis of the cerebrum which may appear as flattening and yellowing of the cortical gyri. Histopathological findings include degeneration and necrosis of the neurons in the cerebral laminar cortex with swelling of the cerebral and cerebellar capillary endothelium. Cerebral edema vascular congestion of the meningeal vessels and astrogliosis in the Purkinje and molecular cell layers have also been reported. The changes in the kidney are characterized by degeneration and necrosis of the renal tubular epithelium which may show regeneration. Precipitation of lead sulfide may be seen in the gingiva adjacent to the teeth as a blue discoloration "lead line" but is common in non-human primates and human. In dogs and cats rarely gross lesions are observed and sometimes the lead source may be found in the GI tract with GI hyperemia. Histopathological lesions include edema of the white matter of the brain and spinal cord, myelin degeneration within the cerebellum and cerebrum and spongiosis of the deep cerebral layers. Degenerative changes of the renal epithelial cells and hepatocytes have been reported in chronic lead poisoning in dogs. Intranuclear inclusions may be visible in the renal tubular epithelial cells, but their absence does not rule out lead toxicosis (Jones *et al.*, 1996).

In birds especially waterfowls, lead toxicosis has been reported and the lead shots may be found in the gizzard. The birds are generally emaciated with extensive muscle wasting with atrophy of the breast muscles. Pale streaks may be found in the myocardium which are areas of myocardial necrosis with fibrinoid necrosis of the vessels. Other histopathological lesions in the waterfowl include hepatocellular necrosis, renal tubular necrosis (with or without intranuclear inclusions) edema of the brain, myelin degeneration of the peripheral nerves and necrosis of the gizzard musculature (Locke and Thomas, 1996). Lead can cross the placental barrier and hence cause abortion, resorption and sterility.

Diagnosis is by analytical estimation and history of exposure. Liver and kidney are the preferred samples for analysis of lead. The differential diagnosis in large animals includes primarily rabies, viral encephalitis, polioencephalomalacia, thromboembolic meningoencephalitis, cyanide poisoning, hepatic encephalopathy. In small animals, rabies, distemper, other heavy metal exposure should be ruled out.

## Mercury

Fungicides, preservatives and fixatives are the main sources of mercury toxicosis. Often toxicosis is related to accidental ingestion of obsolete mercury products.

The lesions of mercury toxicosis are distributed in the GI tract, kidney and sometimes in the brain. Gross lesions include gastric ulcers, congestion of the intestinal mucosa, pale swollen kidney and pale liver. Histopathological findings include ulceration in stomach, necrosis of the intestinal mucosa in small intestine and colon, renal tubular degeneration and necrosis especially the proximal tubular epithelium and hepatocyte degeneration. In chronic exposure glomerulonephritis is observed due to antigen–antibody complex deposition. Degeneration of the Purkinje fibers and cardiac muscle fibers is reported in cattle and this may lead to fibros is and mineralization. Mercury compounds can cause fibrinoid degeneration of the media of the leptomeningeal arteries which can lead to cortical necrosis of cerebrum (Jones *et al.*, 1996).

Pathological changes associated with chronic mercury poisoning in cats are mostly confined to the nervous system and include degeneration of neurons and perivascular cuffing in the cerebrocortical gray matter. In the cerebellum the histopathological findings include focal spongiosis of the molecular layer, degeneration and loss

of Purkinje cells and focal atrophy of the granular layer. Other histopathological findings are demyelination in the fiber tracts of dorsal funiculus's in the lateral and ventral corticospinal tracts. Mercury can pass the placental barrier and cerebellar hypoplasia has been reported in kitten born to cats exposed to mercury before and during gestation (Charbonneau *et al.*, 1976; Gruber *et al.*, 1978). Inhalation of mercury vapor induces acute, corrosive bronchitis and interstitial pneumonia. Diagnosis and confirmation can be made by analytical estimation in the kidney. Differential diagnoses include toxicosis by lead, thallium, phenylarsonic feed additive and ethylene glycol toxicosis, encephalitis, polioencephalomalacia, hog cholera (pigs) and erysipelas (pigs).

## Molybdenum

Acute molybdenum toxicosis is mainly due to accidental exposure to oil and gas fields or motor oil. Chronic toxicity is associated with ingestion of green pasture plants grown on soils high in molybdenum. Cattle are highly sensitive for toxicosis. Molybdenum elimination occurs primarily through the renal system, with over 50% of excreted molybdenum found in the urine.

The molybdenum toxicosis induces copper deficiency and hence the symptoms and lesions of copper deficiency will be observed in molybdenum toxicity. This condition has also to be differentiated for a primary copper deficiency. The gross findings of molybdenum toxicity in feedlot cattle include swollen pale friable liver and swollen kidneys. Microscopic findings included hepatocellular degeneration progressing to massive periacinar necrosis and hemorrhage. Kidney showed hydropic degeneration with marked necrosis of the proximal and distal tubular epithelial cells. Experimental studies in sheep showed that molybdenum can induce hepatocellular damage probably due to a direct toxic effect of molybdenum on hepatocytes (Auza *et al.*, 1989; Jones *et al.*, 1996; Swan *et al.*, 1998). Diagnosis is by case history, clinical signs, pathological findings and analytical estimation in liver and kidney. Liver may show low concentration of copper.

## Selenium

Naturally occurring selenium toxicosis is reported mainly in pigs and birds. Excessive supplementation of selenium in rations and chronic exposure to environmental sources are the potential cause of selenium toxicosis. In birds selenium toxicosis is an important problem in selenium-contaminated western wetlands.

There are numerous reports of selenium toxicosis in pigs which is due to excess supplementation in the feed. Gross pathological lesions are mostly confined to the spinal cord and consist of focal, bilateral, depressed areas in the ventral horns of the cervical/lumbar/sacral segments of spinal cord. In a natural outbreak the histopathological lesions consisted of endothelial proliferation and glial cell reaction in the areas with gross lesions and also in some brain stem motor nuclei. Focal symmetrical poliomyelomalacia confined to the cervical and lumbar/sacral spinal cord and few brain stem motor nuclei were reproduced experimentally by feeding high levels of sodium selenite. Chronic lesions, such as roughness of the hair coat, coronitis and sloughing of the hooves, have been reported in cases which survive for longer periods (Harrison *et al.*, 1983; Wilson *et al.*, 1983; Summers *et al.*, 1995a).

In experimental studies conducted in mallard ducks exposed to different levels of selenium the gross lesions observed were bilaterally symmetrical alopecia of the scalp and dorsal cervical midline, broken or lost digital nails and necrosis of the tip of the beak (maxillary nail). Microscopic findings include single cell to full thickness necrosis of keratinocytes and multifocal parakeratosis in stratum corneum of digital and maxillary nails. Areas of alopecia showed mild necrosis. Some birds showed histopathological changes in the liver which consisted of mild-to-moderate generalized hepatopathy with single-cell necrosis, karyomegaly of hepatocytes, hyperplastic bile duct epithelium and/or iron accumulation in Kupffer cells (O'Toole and Raisbeck, 1997).

In acute poisoning heart is the target organ. The prominent pathological findings in experimental studies in sheep were degenerative and necrotic changes in heart (Blodgett and Bevill, 1987). The chronic form of selenium toxicosis is known as the alkali disease and is related to consumption of seleniferous plants over a period of weeks or months. This syndrome is observed in horses and other ruminants and is characterized by shedding of hair in the mane and tail, deep encircling grooves parallel to the coronary band and sometimes results in detachment of hoof from the sensitive laminae. Erosions of the long bones especially distal end of tibia and proximal end of metatarsus are also reported (Jones *et al.*, 1996). Diagnosis is by correlating clinical signs, liver and blood selenium levels and pathological findings.

## Sodium

Sodium toxicosis can occur directly by excess sodium in feed or water or indirectly by deprivation of water. Indirect toxicosis is the most common toxicity reported in ruminants and pigs which are highly sensitive to sodium toxicosis. Water deprivation caused by failure of automatic water system, overcrowding, unpalatable water or reduced temperature leading to freezing of water are the main causes for indirect toxicosis.

The prominent clinical pathological finding is hypernatremia. The gross pathological findings in sodium

intoxication are congestion and edema of the brain and meninges, with petechiae and ecchymosis within the gray and white matter of the cerebrum, cerebellum, brain stem and congestion of the abomasal mucosa. Histopathological changes in ruminants include varying degrees of vasculitis and edema in the meninges, gray and white matter with neuronal degeneration and necrosis. The vascular changes in the brain include endothelial cell swelling, fibrinoid necrosis and perivascular cuffing by neutrophils and eosinophils. Hemorrhages may be present in the brain. In swine the microscopic lesion includes cerebrocortical neuronal degeneration and necrosis, eosinophilic meningoencephalitis with perivascular cuffing by eosinophils. These eosinophils are later replaced by other mononuclear cells. Advanced cases show cavitation with malacia. Inflammation of the GI tract, hemorrhage and ulcers are also reported. Degeneration and edema of the skeletal muscles with anasarca, pulmonary edema and hydropericardium can occur in swine and ruminants (Trueman and Clague, 1978; Scarratt *et al*., 1985; Osweiler *et al*., 1995; Summers *et al*., 1995b). Pulmonary hemorrhage and edema has been reported in a dog that died of hypernatremia. The microscopic lesions in dog include diffuse vacuolation of the white matter of the brain with necrosis of the hepatocytes (Khanna *et al*., 1997).

Diagnosis is by correlating case history, clinical signs, pathological findings and analytical estimation of sodium in ocular fluid. Differential diagnoses should include thiamine deficiency, lead toxicity and sulfur toxicity.

## Sulfur

The important source for sulfur toxicity is high sulfur diet especially sulfur in water. The condition is seen more in summer when there is increased consumption of water with sulfur. Cattle is one of the common species in which toxicosis is reported. The studies conducted in cattle suggest that the level of thiamine is within normal range. Gross lesions include soft and flattened cerebral gyri. Hemorrhage may be seen in acute cases. Histopathological lesions include degeneration and necrosis of the neurons in the cerebral cortex with cortical glial and capillary endothelial hyperplasia. In acute cases there may be moderate to massive hemorrhage present in brain stem. The studies conducted in cattle suggest that the level of thiamine is within normal range (McAllister *et al*., 1993; Gould, 2000). Polioencephalomalacia has also been reported in cows associated with excess barley malt sprout intake because of its higher sulfur content (Kul *et al*., 2006).

Diagnosis is by correlating retrospective dietary analysis with pathological findings. Differential diagnoses should include thiamine deficiency, lead toxicity, water-deprivation/sodium ion toxicity, hypovitaminosis A and *Hemophilus meningoencephalitis*.

## Zinc

Zinc toxicosis has been reported in dogs as a result of ingestion of zinc-containing hardwares, pennies which contain zinc, drinking water, acidic food material from galvanized tanks and containers. Pancreas is the target organ in many species of animals which is exposed to toxic levels of zinc. Severe intravascular hemolysis is the most prominent clinical pathological finding associated with zinc toxicosis in dogs. The gross observations in dogs and cats exposed to zinc were splenomegaly, icterus, enlarged diffused red kidney with hemorrhage. Hepatomegaly may be observed. Liver showed vacuolar degeneration and necrosis of the hepatocytes. Pancreatic histopathological lesions include necrosis of the acinar cells, necrosis of the duct epithelium and interstitial fibrosis with mononuclear cell infiltrate. In pigs pancreatic epithelial cell necrosis, diffuse acinar atrophy and marked interstitial fibrosis are reported due to zinc toxicosis (Luttgen *et al*., 1990; Gabrielson *et al*., 1996).

In experimental studies conducted in sheep exposed to zinc, pancreatic lesions observed at day 7 included necrosis of the pancreatic duct epithelium, periductular inflammation and interlobular fat necrosis. These histopathological lesions were followed by edema, lobular cystic change, atrophy, fibrosis and a ductular hyperplasia. Other prominent lesions observed were necrosis of the hepatocytes and degeneration of the tubular lining epithelium in the kidney (Smith and Embling, 1993).

The histopathological changes observed in experimental studies in veal calves include atrophy and necrosis of pancreatic acinar tissue and multifocal fibrosis of pancreatic acini. The pathological changes in kidney included multifocal renal cortical fibrosis with necrosis in convoluted tubules and loops of Henle and intratubular mineralization. The histopathological observation in the liver was midzonal mineralization. Fibrosis of the adrenal zona glomerulosa was also observed in some animals (Graham *et al*., 1988).

Zinc toxicosis has been reported in foals also. The pathological changes observed in foals born near a zinc smelter were lameness-associated joint swellings that were attributable to severe generalized osteochondrosis. Separation and loss of hyaline cartilage were observed in the pastern and fetlock joints (Gunson *et al*., 1982). Diagnosis is by correlating case history, pathological findings and analytical estimation in liver, kidney and pancreas.

# MYCOTOXINS

Mycotoxins are fungal metabolites which cause pathological, physiological and or biochemical alterations in several species of animals, plants and microbes. The important

mycotoxins which cause natural toxicosis in pets are aflatoxins, penitrem A and roquefortine. Mycotoxicosis can occur as acute, subacute, chronic forms or subclinical conditions. Only mycotoxins which induce gross or microscopic lesions in domestic animals are described in detail in this section.

## Aflatoxins

Aflatoxins are produced by *Aspergillus flavus* and *A. parasiticus*. Aflatoxin B1 is the most toxic and accounts for most of the natural outbreaks. It also has carcinogenic properties. Among animals young turkeys and duckling are highly susceptible to aflatoxins. Young animals and males are more susceptible to the toxin. Natural disease outbreaks are commonly reported in cows, dogs and pigs but rarely in goat and sheep. Horses are rarely affected (Angsubhakorn *et al.*, 1981). Both acute (especially in dogs) and chronic aflatoxicoses are reported and chronic aflatoxicosis is the most common form reported. Prominent clinical pathological finding is elevated liver enzyme levels.

Acute aflatoxicosis due to consumption of feed material with high quantities lead to severe hepatic damage. Clinical pathological changes primarily show elevation of hepatic enzymes especially $\gamma$-glutamyl transpeptidase (transferase) (GGT). Gross pathological findings include citrus and yellowish discoloration of the liver. The common histopathological findings are necrosis and degeneration of the hepatocytes. Necrosis is primarily located in the periportal areas of liver in turkeys, chicken, ducklings, adult rat and cat. In rabbit the hepatic necrosis is observed in midzonal areas. Necrosis is observed in the centrilobular areas in pigs, cattle and dogs. Diffuse necrosis is observed in neonatal rats and trout. Edema and hemorrhage in the gall bladder are found in many cases of canine and porcine aflatoxicosis. Acute aflatoxicosis has also been reported to cause abortion in cows although no specific histopathological lesions were observed in the fetus (Liggett *et al.*, 1986; Jones *et al.*, 1996).

Chronic aflatoxicosis is the most common form reported. It may take weeks or months to develop the disease. Recently aflatoxicosis due to a commercial canine pet food has received national and global attention. The contamination of dog food by aflatoxin resulted in high mortality among dogs. The dogs affected were mostly from the northeastern states of United States and more than 25 countries throughout the world. Toxicosis resulted from contamination of corn used in formulating the feed. The primary lesions in dogs were mostly confined to the liver. The most important feature was hepatocytes degeneration and necrosis of varying degrees with proliferation of bile ductules at the periphery of the hepatic lobule within days of exposure (Figure 90.3). There was proliferation of fibrous connective tissue which leads to periportal fibrosis. There

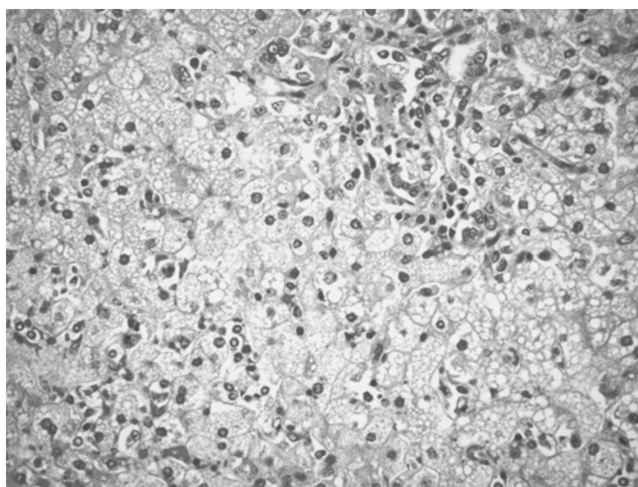

**FIGURE 90.3** Aflatoxicosis, liver, canine, hepatocellular vacuolation with biliary hyperplasia, H&E stain, 40×. This figure is reproduced in color in the color plate section. (Courtesy Dr. S Newman, College of Veterinary Medicine, University of Tennessee.)

was nodular regeneration of hepatocytes with marked variation in nuclear size and some hepatocytes showed megalocytosis (JAVMA, 2006; Newman *et al.*, 2006). Aflatoxin B1 has been reported to be teratogenic in laboratory animals. Diagnosis is by chemical analysis of feed material, correlating case history and pathological findings.

## Fumonisin

Fumonisins are mycotoxins produced by the fungus *Fusarium moniliforme* primarily in corn. The important toxin is fumonisin B1. The susceptible species are horses, ponies, donkeys, swine and rabbits. Sphingolipids which have important roles in membrane and lipoprotein structure and in cell regulation are formed by the turnover of complex sphingolipids and as intermediates of sphingolipid biosynthesis. Fumonisins inhibit ceramide synthase thereby blocking the biosynthesis of complex sphingolipids resulting in accumulation of sphinganine and sometimes sphingosine which act as cytotoxic agents or lead to cell proliferation affecting a wide variety of cellular systems. Alteration in sphingolipid concentrations and functions, especially in the vasculature, also is believed to contribute to the major signs and lesions of fumonisin toxicosis. In swine pulmonary edema induced by fumonisin is suggested to result from acute left-sided heart failure mediated by altered sphingolipid biosynthesis (Wang *et al.*, 1992; Merrill *et al.*, 2001).

In horse, brain and liver are the organs affected. The most common lesion is the liquefactive necrosis in the white matter which may occur as a result of low consumption of the toxin over a long time and the hepatitis which leads to secondary hepatoencephalopathy. Lesions of both types may be present within the same animal.

The clinical pathological findings in horses associated with liver lesion include elevated ALP, ALT, sorbitol dehydrogenase (SDH), GGT and total bilirubin and bile acids. The clinical pathological changes associated with lesions in the brain are high protein and leukocytic pleocytosis in the cerebrospinal fluid. The clinical pathological alterations in porcine toxicosis include increased ALT, ALP, GGT, total bilirubin, bile acids and cholesterol indicative of a hepatic damage.

Gross pathologic findings include liquefactive necrosis in the cerebral white matter (can be unilateral or bilateral) appearing as a cavity with hemorrhagic foci of various sizes in the brainstem. In some animals the liquefaction may extend into the cortex. Adjacent to these areas, the brain may have a greenish-yellow appearance. The gross lesions in the liver include swollen liver, yellowish brown discoloration and irregular pale foci or nodules. In pigs the gross lesions include heavy lung with widened interlobular septa, fluid in the airways and thoracic cavity. Histological findings in the horses with brain involvement are characteristic liquefactive necrosis in the cerebral white matter with hemorrhage predominantly around the cerebral vasculature. The microscopic observations in the liver lesion include centrilobular necrosis and fibrosis, bile stasis, bile duct proliferation, fatty degeneration of hepatocytes and portal fibrosis (Ross *et al*., 1993).

In pigs the histological observations include dilated lymphatics with fluid in the interlobar septa and subpleural areas and edema around vessels and bronchi. The liver lesions include multifocal areas of hepatocyte apoptosis, necrosis, hepatic cord disorganization and hepatocyte proliferation. In long-time experimental exposure studies fibrosis and hyperplasia of the hepatocytes cells with formation of nodules, right ventricular hypertrophy and esophageal plaques (hyperkeratosis and parakeratosis, formation of papillary down growths of the stratum basale of the distal esophageal mucosa) were the pathological observations. In experimental studies of prolonged exposure to low doses in pigs, the pathological observations consisted of proliferation of the connective tissue fibers, around the lymphatic vessels in subpleural and interlobular septa of the lungs, extending to the peribronchial and peribronchiolar areas. Although there was no clinical signs and significant performance impairment in pigs, it resulted in irreversible chronic changes (Osweiler *et al*., 1992; Casteel *et al*., 1993; Colvin *et al*., 1993; Haschek *et al*., 2001).

In experimental studies conducted in calves the microscopic findings were observed in liver and kidney and consisted of proliferation of hepatocytes and bile ductular cells with varying degrees of hepatocyte apoptosis, vacuole formation, karyomegaly, proliferation of proximal renal tubular cells and dilation of proximal renal tubules filled with cellular debris and proteins (Mathur *et al*., 2001).

In broilers the pathological findings include multifocal hepatic necrosis, thymic cortical atrophy, biliary hyperplasia and rickets (Ledoux *et al*., 1992). Experimental administration of fumonisin induces nephrotoxicity in rats, rabbits and sheep. Diagnosis is by history of ingestion, clinical signs, pathological observations and evaluation of the toxin in feed and corn samples by thin layer chromatography (TLC), high-performance liquid chromatography (HPLC) and enzyme-linked immunoabsorbent assay (ELISA).

## Citrinin and ochratoxin

Citrinin is a benzopyran metabolite produced by the toxic strains of *Penicillium* spp. and *Aspergillus* spp. Some hepatotoxic effects have been reported for citrinin but the lethal effects are largely due to the nephrotoxic effects. The specific mechanism of action in kidney is not known. Primary effect is on the kidney and leads to acute tubular necrosis. In pigs, rat and rabbit the proximal segments are affected. Experimental studies show that citrinin induces renal damage in turkeys and ducklings along with hepatic degeneration and lymphoid necrosis.

Ochratoxin is a mycotoxin produced by the toxic strains of *Penicillium* and *Aspergillus* spp. mostly related to improper storage conditions of grain, coffee, etc. Three different ochratoxins have been isolated and characterized (ochratoxins A, B and C). Of these ochratoxin A is the most commonly detected and most toxic among the three. The subchronic and chronic effects of this toxin are more of concern compared to the acute toxicity. Pigs are the most common species to be affected by ochratoxicosis. Clinical pathological changes include increased BUN values, reduced creatinine clearance and urine specific gravity. The gross pathological changes observed in experimental studies of pigs include enteritis, pale tan discoloration of liver, edema and hyperemia of the mesenteric and other lymph nodes. The microscopic findings are mostly confined to the kidney and GI tract which include necrosis of the renal tubular epithelium most frequently affecting the proximal convoluted tubules, dilatation of the tubules, necrotizing enteritis in multiple locations, fatty degeneration of liver and focal necrosis of lymphocytes in the germinal center of the lymph nodes (Szczech *et al*., 1973a; Zomborszky-Kovacs *et al*., 2002).

The gross pathological changes observed in experimental studies of dogs include severe hemorrhagic enteritis of the large intestine, tonsillitis with enlargement and hyperemia of the mesenteric and other lymph nodes. The microscopic findings are similar to that observed in the porcine studies and included necrosis and desquamation predominantly in the proximal convoluted tubules, eosinophilic granular casts in proximal and distal convoluted tubules necrotizing enteritis in multiple locations, fatty degeneration of liver and focal necrosis of lymphocytes in, germinal center of lymph nodes, spleen, tonsil, thymus, and lymphoid nodules in small and large intestine

and nictitating membrane and mild-to-moderate centrilobular necrosis and fatty change of liver (Szczech *et al.*, 1973b; Szczech, 1975).

Ochratoxicosis has been reported commonly in avian species. Experimental exposure of ochratoxin in chicken and turkey poults resulted in skeletal osteopenia with disturbed endochondral and intramembranous bone formation. Experimental studies in young broilers with ochratoxin A show renal edema and tubular necrosis (Wyatt *et al.*, 1975; Duff *et al.*, 1987). Chronic exposure of ochratoxin A is considered as an etiology in Balkan endemic nephropathy and urothelial tumors in human beings.

## Zearalenone

*Fusarium roseum* invade the grain and produce an estrogenic toxin known as zearalenone. Toxicity is commonly reported in swine and is mostly subacute. Anestrum or nymphomania is observed in swine based on the estrous cycle when exposed. Pseudopregnancy with reduced litter size due to fetal resorption or implantation failure may be observed. Gross findings include swelling of vulva, mammary gland hypertrophy, vaginal prolapse, atrophy of the ovaries and uterine hypertrophy. Microscopic observations include edema and hyperplasia of the uterus and proliferation of ducts in the mammary glands. Histopathological findings in experimental studies in pigs include squamous metaplasia in the uterus, uterine duct, cervix, vagina and mammary glands.

Abortions were reported in experimental studies but whether it occurs in field condition is not definitively proved. Abortions may occur at any stage of gestation but usually occur about 3 weeks following the initial consumption of the feed. No specific gross or microscopic findings are observed in the aborted fetuses. Diagnosis is by correlating history of exposure with clinical signs associated with hyperestrogenism and chemical analysis of the feed material (Kurtz *et al.*, 1969; Chang *et al.*, 1979; Stuart and Oehme, 1982). Differential diagnosis should include normal estrus and external genital injury.

## Ergot toxicosis

Commonly called the ergot, the *Claviceps* spp. mainly *Claviceps purpurea* and *Claviceps paspali* infect the developing grass and grain. The main action of the ergot alkaloid which is the important cause of toxicity is stimulation of the smooth muscles contraction, vasoconstriction and adrenergic blockage along with stimulation or inhibition of parts of the central nervous system (CNS).

The common lesion exhibited by ergotism is gangrene in the distal extremity. Grossly they appear as focal cracks on the hoofs and lead to multifocal areas of detachment of the hoof wall. Death has been reported in cattle related to ergotism by GI ulceration. Although inconclusive, cattle and swine may abort as a result of consumption of ergot alkaloid-containing feed material especially during the third trimester of pregnancy. Reproductive problems and neonatal mortality have been reported in horses by ergotism. Diagnosis is by examining the feed or grass for the presence of sclerotia or ergot bodies and analytical testing of the ergot alkaloids in feed material (Riet-Correa *et al.*, 1988; Coppock *et al.*, 1989; Cheeke, 1988). Differential diagnosis includes fescue toxicosis and hypothermia.

## Fescue toxicosis

Fescue toxicosis is caused by the consumption of fescue infested by the fungal endophyte *Neotyphodium coenophialum*. Ergoline and ergopeptine alkaloids are the major toxic principles responsible for this condition. Clinically the condition has four main manifestations which include the fescue foot, summer slump due to altered thermoregulatory mechanisms and hormonal imbalance resulting in reduced production and reproductive problems, fat necrosis in ruminants and equine reproductive problems.

The important clinical pathological finding is hypoprolactinemia in ruminants and hypoprolactinemia and reduced relaxin levels in late gestational mares (Ryan *et al.*, 2001). The gross observations of fescue foot include swelling of the pastern with necrosis and sloughing. Microscopic findings include perivascular edema and hemorrhage, thickening of the blood vessels and fibrosis. In advanced cases necrosis of the bone and septic arthritis are reported. Fat necrosis, is observed grossly as yellowish or chalky white nodules in the mesentery around the intestines. Microscopic finding includes necrosis of the adipocytes with occasional infiltration of macrophages (Strickland *et al.*, 1993; Blodgett, 2001).

In equine prolonged gestation is observed. Dystocia and retention of fetal membranes are commonly reported in pregnant mares. Those foals which are born to mares exposed to fescue toxicosis have high rate of perinatal mortality. The placental membranes show diffuse edema with increased connective tissue. Enlarged thyroid follicles are observed in foals from mares with fescue toxicosis and microscopically they are distended with colloid (Loch *et al.*, 1987; Putnam *et al.*, 1991).

## Sporodesmin

These are mycotoxins found on the spores of fungus *Pythomycus charatrum*. Toxicosis is reported commonly in sheep. The organs which are affected are skin and liver. The gross findings include swollen mottled liver with

icterus, enlarged gall bladder, edema and erythema in the areas exposed to sunlight particularly the ear, eyelid, face and lips. Histological observations in the liver include hepatocyte vacuolations, fibrosis, bile duct hyperplasia, necrotizing pericholangitis and bile stasis. The microscopic changes in the skin include ballooning degeneration of epidermal cells with edema in the epidermal–dermal junction, vesicles and pustule formation with thrombi in the vessels and perivascular inflammation (Hansen *et al*., 1994; Pinto *et al*., 2005).

## Other mycotoxins

Oosporein which is produced primarily by *Oospora colorans* and *Caetomium trilaterale* is observed in feed stuff, cereals and peanuts. It has been reported to be toxic in poultry resulting in nephrotoxicity, visceral and articular gout. The pathological observations in oosporein toxicity include necrosis of the tubular epithelial cells in the proximal tubules with basophilic casts, hyaline casts in the distal tubules with fibrosis and interstitial pyogranulomatous inflammation, urate deposits in various tissues and proventricular enlargement with mucosal necrosis (Pegram and Wyatt, 1981; Brown *et al*., 1987).

Lupinosis is a disease caused by the consumption of lupine plants infected by the fungus *Diaporthe toxica* which produce the toxin phomposin. This condition is totally different from lupine poisoning which is caused by the ingestion of lupines which contain the quinolizidine alkaloids. The disease is common in Australia where lupines are grown as a fodder crop and is a primary disease of sheep although other ruminants and equine can be affected. The primary target organ is the liver. Clinical pathological observation characterized by elevated liver enzymes indicative of hepatic injury is a prominent finding. The disease can be acute, subacute or chronic. In acute and subacute cases the gross findings include icterus and swelling of the liver with bright yellow discoloration and in chronic cases the liver is small and copper tan in color. The microscopic observations include apoptosis of the hepatocytes, karyomegaly and megalocytosis of hepatocytes, fatty degeneration, fibrosis and proliferation of Kupffer cell and bile ducts. Hepatoencephalopathy and myopathy of the skeletal muscles are also reported to be associated with lupinosis (Soler Rodriguez *et al*., 1991; Allen *et al*., 1992; Allen and Randell, 1993).

## Slaframine

Slaframine, also called the slobber factor, is an indolizidine alkaloid synthesized from the fungus *Rhizoctonia leguminicola* which causes the black patch disease in clover. This acts as a parasympathomimetic agent resulting in salivation, lacrimation, urination and defecation. Salivation is one of the first and prominent signs to develop and it continues as long as the toxin persists. Slaframine toxicosis is observed in several domestic animal species including horses, sheep, swine, cattle, cat and dogs. Pathological changes are not recorded in naturally occurring cases as mortality is rare. Diagnosis is by correlating the clinical signs and history of exposure to plants with black patch disease (Crump, 1973).

## Stachybotryotoxicosis

This is a mycotoxin produced by *Stachybotrys* spp. and affects several species of domestic animals. The toxic effect of this mycotoxin was first reported in horses from Eastern Europe. In horses the toxin primarily results in erosions and necrosis in the GI tract characterized by ulcerations in mouth, esophagus and stomach with hemorrhages in the intestinal tract, muscles and lymphoid necrosis. In a suspected field outbreak in sheep with secondary *Pasteruella* spp. septicemia the pathological findings included hemorrhages in the subcutaneous tissue, diaphragm, mediastinum, pericardium, membranes of the peritoneal and pleural cavity. The important histological observations were necrosis and atrophy of lymphoid organs with aplastic anemia (Schneider *et al*., 1979).

Trichothecens are a group of mycotoxins produced by different strains of *Fusarium* spp. of fungi. The toxins in this group which induce toxicity in domestic animals include T-2 toxin, DAS (diacetoxyscirpenol) vomitoxin (deoxynivalenol) and satratoxin (S*tachybotrys*). Natural outbreaks of these toxins causing toxicity are rare. The pathogenesis is related to their ability to inhibit protein synthesis producing a radiomimetic effect. The pathological findings of these toxins are mostly based on experimental studies. T-2 toxin and DAS are highly toxic causing necrosis of skin and in experimental studies these toxins cause necrosis of the lymphoid and myeloid tissues, tissues of the GI tract. Experimental studies in pigs exposed to T-2 toxin had gross lesions consisting of congestion and hemorrhage in lymph nodes, pancreas, GI mucosa, subendocardium, adrenal gland, and meninges with edema in gall bladder, lymph node and pancreas. Microscopic observations include hemorrhage in the organs with gross findings along with degeneration and necrosis of the lymphoid tissues, surface and crypt epithelium of the GI mucosa, mild multifocal necrosis of pancreatic acinar cells, myocytes of myocardium, bone marrow cells, cortical cells of adrenal, epithelial cells lining the tubules in the renal medulla and mild interstitial pneumonia. Vomitoxin ingestion results in vomiting especially in swine although other species are also susceptible (Smalley, 1973; Pang *et al*., 1986, 1987).

## Cyclopiazonic acid

Cyclopiaszonic acid was initially isolated from *Penicillium cyclopium* and later from several *Asperpgillus* spp. and *Penicillium* spp. Peanut is naturally contaminated with this mycotoxin. Chicken exposed to this mycotoxin show ulcerative changes in proventriculus with necrotic changes in liver and spleen. The prominent gross lesions observed in pigs exposed to cyclopiazonic acid included pale liver, gastric ulcers, mucosal hyperemia and hemorrhage throughout the small and large intestines. The histopathological observations included lesions in the GI tract, liver and kidney which were characterized by necrotizing gastroenteritis, hepatocellular necrosis, lobular fatty change in the hepatocytes of the peripheral lobules, necrosis of the renal tubular epithelium with focal suppurative tubulointerstitial nephritis (Lomax *et al.*, 1984).

## Tremorgenic mycotoxins

Tremorgenic mycotoxins (secondary fungal metabolites) contain an indole moiety, which produce tremors or seizures in animals consuming toxic amounts of contaminated foodstuffs. There are at least five groups of tremorgenic mycotoxins: the penitrem group, the paspalitrem group, the fumitremorgins group, the verruculogen group and the tryptoquivaline group. Penitrem and roquefortine are the most important tremorgenic mycotoxins associated with natural outbreaks in small animals. There are no specific microscopic findings in the nervous tissue or muscle tissue. Diagnosis is by analytical examination of the gastric contents, correlating the clinical nervous signs and case history of exposure. Differential diagnosis in small animals includes other causes of tremors like strychnine, organophosphate and carbamate insecticides pyrethroids, mushroom exposure, etc.

In large animals, the tremorgenic mycotoxins include lolitrem B in perennial rye grass, paspalitrems in Dallis grass and Bahai grass and unknown mycotoxin in Bermuda grass tremors. No specific lesions are seen at necropsy or on histopathology, secondary trauma is possible. Diagnosis is based on case history and clinical signs (McLeay *et al.*, 1999).

# PESTICIDES

Many pesticides, including rodenticides, act on the CNS and convulsion may be the only clinical sign observed. The common toxicants which induce acute convulsions in dogs are strychnine, insecticides, metaldehyde, zinc phosphide, methyl xanthines, drugs of abuse, bromethalin and the tremorgenic mycotoxins (roquefortine and penitrem A). Most of these compounds have very less or no specific pathological findings and hence gas chromatography–mass spectrometric analysis of the suspected bait material, stomach contents or vomitus should be conducted for conclusive diagnosis (Braselton and Johnson, 2003).

Insecticides like amitraz, anticholinesterase insecticides like organophosphates and carbamates, metaldehyde, organochlorine insecticides, pyrethrins and pyrethroids do not induce any specific gross or histopathological changes and hence they are not discussed in this section. Similarly avicides like 3 chloro-*p*-toluidine hydrochloride and 4-aminopyridine also do not induce any specific histopathological lesions.

## Anticoagulant rodenticides

Anticoagulant rodenticides are used extensively and accidental ingestion by domestic animals is very common. The most common first-generation coumarin anticoagulant is warfarin and the common second-generation anticoagulants include brodifacoum, bromadiolone and difenacoum.

All coumarins block the vitamin K 2,3-epoxide reductase enzyme. This prevents cycling between the inactive oxidized and the active reduced form of vitamin K in the liver. Reduced vitamin K is essential for the carboxylation and activation of the clotting factors II, VII, IX and X which leads to a coagulopathy due to depletion of the clotting factors.

Anticoagulant toxicity in small animals is diagnosed by the clinical pathological evaluation and includes an altered coagulation panel characterized by prolonged activated clotting time (ACT), one-stage prothrombin time (PT) and activated partial thromboplastin time (PTT). The common gross findings include hemorrhage in the abdominal cavity, thoracic cavity, subcutaneous tissue, subdural space, articular space, heart and lung and blood in GI tract. Histopathological findings include hemorrhages in the serosa of the intestine, meninges and GI tract mucosa. Coumarin-derived anticoagulants can cross the placenta and affect pups which can lead to death of the pups even without affecting the dam. Brodifacoum, a second-generation coumarin anticoagulant, was detected in the liver of pups which died as a result of *in utero* exposure (dam not affected) indicating that fetus is more susceptible to the toxicity than the dam. Differential diagnosis includes disseminated intravascular coagulation, hereditary clotting factor problems, liver diseases and autoimmune thrombocytopenia. Chemical analysis of the liver correlated case history, clinical pathological and necropsy findings will help to confirm diagnosis (DuVall *et al.*, 1989; Chua and Friedenberg, 1998; Sheafor and Couto, 1999; Munday and Thompson, 2003).

## Alpha-naphthyl thiourea

It is primarily used as a rodenticide and baits coating this are readily accepted by animals. The common domestic animals affected by the toxicity are cats, dogs and pigs. The toxicity is attributed to an increase in the permeability of capillaries which results in marked edema of the lungs. The common gross findings include hydrothorax and severe edema of the lungs. GI irritation can lead to congestion in the GI tract. Histopathological finding is predominantly diffused pulmonary edema. Diagnosis is by correlating the case history and pathological findings (Rutili *et al.*, 1982; Michel *et al.*, 1983).

## Bromethalin

Bromethalin is a non-anticoagulant rodenticide developed and released to combat the worldwide problem of rodent resistance to warfarin-like anticoagulant rodenticides. The mode of action is thought to be by uncoupling mitochondrial oxidative phosphorylation in the CNS and hence this compound acts as a neurotoxin in domestic animals. The common domestic animals affected are dogs and cats and it causes acute or chronic signs. Diagnosis is primarily by history of exposure, chemical detection and clinical signs (Dorman *et al.*, 1992; Dunayer, 2003).

The common gross lesions observed in experimental studies conducted in dogs include mild cerebral edema and pulmonary congestion. Microscopic findings included diffuse white matter spongiosis, mild microgliosis, optic nerve vacuolization, mild thickening of Bowman's capsule and occasional splenic megakaryocytes. Ultrastructural changes include occasional swollen axons, intramyelinic vacuolization and myelin splitting at the intraperiod line in the mid brainstem. Microscopic observations of experimental studies conducted in cats were similar to that of dogs and include edema in the white matter of brain with hypertrophied fibrous astrocytes and oligodendrocytes in the white matter of the cerebrum, cerebellum, brain stem, spinal cord and optic nerve. Bromethalin can be detected by gas chromatography in liver, kidney, fat and brain tissues. Diagnosis is primarily by history of exposure, chemical detection and clinical signs (Dorman *et al.*, 1990, 1992).

## Paraquat and diquat

Paraquat is one of the two widely used bipyridyl broad-spectrum herbicides (the other being diquat). The most common route of intoxication is ingestion. Among domestic animals toxic exposure has been reported in cattle, sheep, horses, pigs, poultry and dogs.

Type I pneumocytes are the target cells in acute and chronic poisoning. Paraquat gets actively concentrated in these cells, and causes an increase in both the consumption of oxygen and oxidation of NADPH via NADPH–cytochrome P450 reductase. The resultant reactive oxygen species generated are thought to play a key role in the acute lung injury.

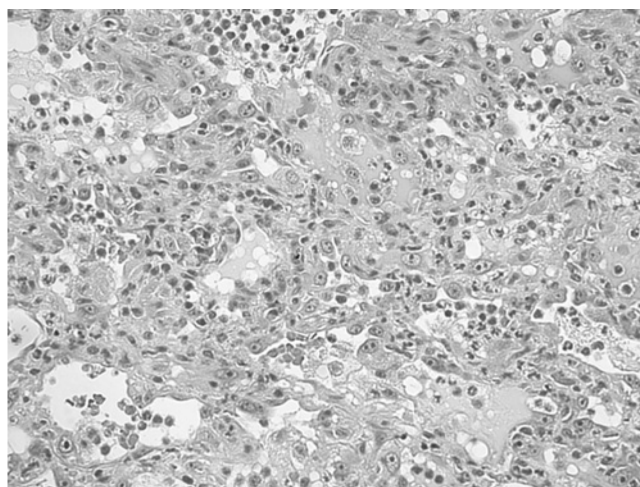

**FIGURE 90.4** Paraquat poisoning, lung, canine, diffuse interstitial pneumonia with type II pneumocyte hyperplasia, H&E stain, 40×. This figure is reproduced in color in the color plate section. (Courtesy Dr. ME Hines, College of Veterinary Medicine, University of Georgia.)

The common gross findings include congestion and hemorrhage of lungs with atlectasis and some areas may have bullous emphysema. In chronic cases the lungs may be shrunken with hemorrhage and edema. The histopathological findings include diffuse interstitial pneumonia with hemorrhage, hyaline membrane formation and type I pneumocyte loss in acute cases. In chronic cases microscopic observations include type II pneumocyte hyperplasia, intralveolar and interstitial fibrosis and emphysema (Figure 90.4). The lung fibrosis develops as soon as 5–10 days after exposure to paraquat. Kidney and liver may also be affected and the histopathological change includes renal tubular epithelial degeneration and hepatocyte degeneration mainly in the centrilobular areas. Diquat toxicity results in intracerebral hemorrhage and acute renal failure. Pulmonary fibrosis is not a common finding with diquat poisoning but studies in rat have shown that diquat may cause alveolar damage by the same mechanism as paraquat, although it is not actively taken up by the lung (Manabe and Ogata, 1987; Nagata *et al.*, 1992; Dungworth, 1993; Ali *et al.*, 1996). Diagnosis is by correlating history of exposure with pathological findings.

## Polychlorinated and polybrominated biphenyls

Polychlorinated biphenyls (PCBs) and polybrominated biphenyls (PBBs) are a class of organic compounds and are known to be causing classic skin lesions in human "chloracne". Isolated cases of poisoning have been reported in

animals and one of the most important cases was the contamination of cattle feed with PBB in Michigan. The only gross pathological change observed was hemorrhage in the serosa of duodenum, ileum and large intestine with hyperemia of the GI mucosa. Histopathological lesions include hemorrhage in the renal interstitial tissue, moderate fatty change without inflammation hemorrhage in the muscle layers and inflammation of the intestinal mucosa (Robens and Anthony, 1980).

Hexachlorophene is a polychlorinated bisphenol compound which has been reported to produce toxicosis in dogs and cats. Toxicosis is by exposure to preparations containing hexachlorophene like soaps and detergents. Prominent neurological signs observed in a litter of pups exposed to hexachlorophene consisted of muscle tremors, ataxia and muscle weakness. No specific gross findings are usually observed. The histopathological finding is characterized by diffuse vacuolation of the white matter and ultrastructurally observation is intramyelinic vacuolation. In another case study of toxicosis in cats the histopathological findings observed were proliferation of astrocytes and microglial cells in the cerebral and cerebellar white matter and corticospinal tracts with vacuolations (Thompson *et al.*, 1987; Poppenga *et al.*, 1990). Diagnosis is by analytical estimation of hexachlorophene in liver and kidney tissue and correlating clinical and pathological findings.

## Cholecalciferol/vitamin $D_3$

Vitamin $D_3$ toxicity in veterinary medicine is by overdosage of vitamin supplements or exposure to rodenticide. Dogs and cats are the common species affected but any species can be affected. The common clinical pathological finding is rapid increase in plasma phosphorus in acute cases and followed by an increase in plasma calcium levels. Common gross findings include hemorrhage in the GI tract and lungs. Histological findings include mineralization in multiple organs including the kidneys, lungs, myocardium, stomach and vessels. In kidneys mineralization of arteries as well as mineral deposition in the tubular basement membranes are observed. Diagnosis is by chemical evaluation of serum, plasma, bile, urine and kidney for PTH/25-hydroxycholecalceferol and correlating pathological findings (Gunther *et al.*, 1988; Fooshee and Forrester, 1990; Talcott *et al.*, 1991). Differential diagnosis includes ethylene glycol toxicity, hypercalcemia of malignancy, chronic renal failure and other causes of hypercalcemia.

## Zinc phosphide and aluminum phosphide

Toxicosis can happen by animals feeding directly on bait or by eating tissues of zinc phosphide-poisoned animals. All domestic animals can be affected and reports are common in dogs. Zinc phosphide and aluminum phosphide releases phosphine gas when in contact with acid contents of the stomach. Both phosphine and intact zinc phosphide are absorbed from the GI tract. The phosphine is believed to cause the majority of acute signs, while the intact phosphide may cause hepatic and renal damage later. These toxicants also induce CNS effects and the specific mechanism is not known.

Gross findings are not specific and include a characteristic acetylene odor of the stomach content, congestion of the gastric mucosa, pulmonary congestion with edema, subpleural hemorrhages, congestion of liver and kidney. Histopathological findings consist of fatty degeneration of hepatocytes in liver, renal tubular degeneration and necrosis in kidney and gastritis (Casteel and Bailey Jr, 1986). Diagnosis is by analysis of stomach contents/vomitus/liver and kidney for phosphine gas and the samples have to be submitted frozen in air-tight containers.

# PLANTS

This section on plants comprises those plants which produce pathological lesions associated with toxicity. Most of these plants cause toxicity as a result of accidental ingestion. This section is divided into subsections on plants affecting various organs, cardiovascular, nervous, GI and liver, skin, hemopoietic, respiratory, reproductive and urinary system.

## Cardiovascular system

This section covers plants which produce pathological lesions in the heart and blood vessels.

### *Summer pheasant's eye (Adonis aestivalis)*

Toxicity occurs by ingestion of contaminated grass or hay. Toxicity is attributed to cardiac glycoside strophanthidin. Gross findings include endocardial hemorrhage and gaseous distension of the GI tract. The microscopic lesions include multifocal necrosis and degeneration of myocytes infiltration of neutrophils with endocardial and epicardial hemorrhage (Woods *et al.*, 2004). Diagnosis is by correlating history of exposure with clinical signs, pathological findings and analysis of stomach content for glycosides.

### *Vitamin D containing plants*

The most common plants which contain calcitriol that accounts for pathogenesis are *Cestrum diurnum*, *Trisetum flavescens* and *Solanum malacoxylon*. The toxicity in *Cestrum*

is attributed to 1,25-dihydroxy-vitamin D-glycoside and that in *S. malacoxylon* to a molecule similar to or identical to 1,25-dihydroxy vitamin D: the plant (*C. diurnum*) is seen in warmer parts of the United States like Florida and is grown as an ornamental plant; *Solanum* spp. is seen in Brazil and Argentina; *Trisetum* spp. in Germany and Austria. The common species affected are cattle and horses. *S. malacoxylon* toxicity is commonly reported in sheep and cattle. Other animals are susceptible experimentally. Adult cows are more susceptible than calves.

The clinical pathological observation in the early stage is hypercalcemia and hyperphosphatemia and later the levels decrease resulting in normal calcium and phosphorus levels. The gross findings include white to tan gritty foci on the surface or inside of heart, great vessels, tendons, ligaments, kidneys, lungs, stomach and bones. In cattle the microscopic findings include cardiac mineralization commonly in the endocardium of left atrium, mineralization of the aorta primarily involving tunica intima and media. Mineralization is observed in several major and minor blood vessels. Other locations in which microscopic evidence of mineralization observed are the following: kidneys, alveolar septa of lung, bronchiolar epithelium, muscles of the intestine and stomach. In cattle osteoporosis, hyperplasia of thyroid C cells and atrophy of parathyroid are also reported in long-time exposure (Collins *et al.*, 1977). Hyperostosis may lead to bone thickening. A dark basophilic band (possibly mucopolysaccharides) separates new bone growth from pre-existing bone (Krook *et al.*, 1975; Durand *et al.*, 1999; Braun *et al.*, 2000). Diagnosis is by correlating history of exposure, pathological findings and estimation of 1,25-dihydroxy cholecalciferol levels in serum.

### *White snake root (Eupatorium rugosum)*

The common species affected by white snake root (*E. rugosum*) are cattle, horses, sheep and goats. The toxic component is tremetol and has been described as a fat soluble, high molecular weight alcohol. The toxic principle is a cumulative poison and repeated exposure to small amounts results in intoxication. The toxin is secreted in the milk more rapidly than by any other route which can result in relay toxicosis to offspring or humans.

The gross findings observed include pale linear streaks in the myocardium or skeletal muscles with or without hemorrhage, increased fluid in pericardial sac and ventral edema. In cattle the common histopathological findings include fatty degeneration of the liver, congestion and multifocal hemorrhage in the heart and GI tract, myocytes necrosis and degeneration of the skeletal muscles especially the shoulder muscles and congestion of the kidney.

In horses the toxin affects the heart. The histopathological findings include myocardial degeneration, necrosis and fibrosis, hepatic changes associated to cardiac changes including centrilobular hepatocyte degeneration with mild necrosis and fatty changes. Kidneys may have tubular degeneration with globin casts in the renal pelvis (Olson *et al.*, 1984; Jones *et al.*, 1996). Diagnosis is made by correlating clinical signs, history of exposure, pathological findings and chemical analysis of the toxin in liver and kidney. The differential diagnosis includes ionophore toxicity, selenium/vitamin E deficiency and oleander toxicity.

### *Coffee senna (Cassia occidentalis)*

Coffee senna, *C. occidentalis*, is a shrub which grows commonly in the southeastern United States. The common species affected are cattle, horse and sheep. The common clinical pathological observations are increase in CPK, serum glutamic oxaloacetic transaminase (SGOT) and LDH. Gross findings include diffuse or focal pale appearance of the skeletal and myocardial muscles. Microscopic observation includes degeneration and necrosis of the myocytes in the skeletal and cardiac myocytes. Lungs have edema and marked congestion. The liver will show secondary changes related to changes in the cardiac musculature consisting of hepatocyte necrosis and fatty degeneration in centrilobular areas. In many cases the kidney show renal tubular degeneration with protein casts (Martin *et al.*, 1981; Suliman *et al.*, 1982; Barth *et al.*, 1994; Jones *et al.*, 1996). Diagnosis is by correlating the history of exposure, pathological findings and appropriate clinical signs. Differential diagnosis includes toxicosis by ionophore, white snakeroot, gossypol and vitamin E/selenium deficiency.

### *Oleander: Nerium oleander*

It is an ornamental shrub seen commonly in southern and southwestern United States. The toxicity is attributed to the cardiac glycoside similar to digitoxin. Almost all species are susceptible. Pathological findings are not common, and rarely subendocardial and abomasal hemorrhages are observed. Pulmonary edema, myocardial degeneration and necrosis are the pathological findings which are rarely observed (Mahin *et al.*, 1984; Galey *et al.*, 1996). Diagnosis is by identification of oleander in the GI tract, analytical estimation of ingesta for oleandrin, history of consumption, appropriate clinical signs and pathological lesions.

### *Cyanogenic glycosides*

Cyanogenic glycosides are present in *Prunus* genus, grasses like *Sorghum*, Sudan and Johnson grass. Consumption may lead to mortality in domestic animals especially in ruminants. Cyanogenic glycosides yield hydrogen cyanide by hydrolysis. Rumen contains large amount of B glycosidase which hydrolyzes glycoside and hence they are more susceptible. Cyanide blocks the cellular respiration so that oxygen is not available for the electron transport in

the cytochrome system. There are no specific lesions as most cases are acute. Blood may have a cherry red appearance immediately after death. Diagnosis is by detecting cyanide content in the plant material from the GI tract, clinical signs and case history (Osweiler, 1996).

#### Water hemlock

Water hemlock (*Cicuta douglasii*) produces acute death and no pathological lesions are commonly observed in intoxication. Experimental studies in sheep have shown skeletal and myocardial degeneration when dosed orally with water hemlock (Panter *et al*., 1996).

#### Taxus

*Taxus* spp. contain an alkaloid toxine, which is a cardiotoxin. Horses and bovines are the most common species affected and it leads to sudden death. Gross lesion is absent except for hemorrhage in the endocardium of ventricles. Histopathological lesions in horses include occasionally multifocal areas of mild necrosis in the papillary muscle and ventricular musculature, congestion and interlobular edema in lungs. Diagnosis is by chemical analysis of the stomach content and correlating with clinical signs (Panter *et al*., 1993; Tiwary *et al*., 2005).

#### Black walnut

Toxicosis is observed in horses when exposed to shavings. Juglone, a toxic compound found in all parts of plants of the walnut tree family Jugans, is the toxic component. Most common clinical signs were moderate to severe laminitis (Obel grade 2 or 3), pitting edema of the distal portion of the limbs and rapid respiratory rate. Some animals may show signs of colic, anorexia and lethargy. Histopathological findings observed in experimental studies include necrosis of dermal tips of dorsal primary epidermal laminae. The laminae may also show proliferative epithelial response characterized by numerous mitotic figures and clusters of epithelial cells (Uhlinger, 1989; Galey *et al*., 1991).

### GI system

Many plants produce irritation of the oral cavity and also the GI tract. Irritation is caused by the oxalate crystals, their thorns which are sharp, and the histamine-releasing compounds in these plants. The common plants which produce these clinical signs are nettles (*Urtica* and *Laportea*), burdock (*Arctium lappa*), goatheads (*Tribulus terrestris*), wild barley (*Hordeum*) and *Cactus* spp. Some of these plants may penetrate the oral cavity or skin and lead to secondary bacterial infection and inflammation.

### Liver

#### Pyrrolizidine alkaloids

The common genus of plants which contain pyrrolizidine alkaloids are *Senecio*, *Crotalaria*, *Heliotropium*, *Echium*, *Tirchodesma* and *Amsinckia*. Liver is the target organ for toxicosis. Pyrrolizidine is activated in the liver by mixed function oxidases to the toxic alkaloid, pyrrole. Monocrotaline, the pyrrolizidine alkaloid in *Crotalaria* spp., has hepatotoxic, nephrotoxic, pneumotoxic and fetotoxic effects.

Clinical pathological changes include increased AST, SDH, ALP and GGT mostly in acute cases. Gross findings include swollen pale yellowish discolored liver or shrunken liver depending on the duration of exposure. The histopathological findings include periacinar necrosis and endothelial damage to the hepatic venules and small hepatic veins, widespread portal fibrosis, bile duct proliferation and megalocytosis. In cattle, chronic pyrrolizidine toxicosis produces pronounced hepatic bridging portal fibrosis which infiltrates along the sinusoids to dissect lobules and separate individual cells. Megalocytosis is by the continued nucleoprotein synthesis, coupled with mitotic inhibition. These megalocytic cells can range up to 20 times that of normal cells. The other compounds which cause megalocytosis are *Lantana camara*, *Lippia* spp., *Cycas* spp., aflatoxins and nitrosamines (Baker *et al*., 1991; Craig *et al*., 1991). In sheep, long-term consumption of pyrrolizidine-containing plants may lead to elevated levels of liver copper leading to copper toxicity. *Crotalaria* species induce pneumotoxicity. *Crotalaria* poisoning in horses is characterized by histopathological lesions in the lung which include diffuse alveolitis with fibrosis and hyaline membrane formation (Nobre *et al*., 1994).

#### Cocklebur (Xanthium spp.)

The glycoside carboxyatractyloside is the toxic principle of *Xanthium* spp. The seeds and the cotyledonous seedlings contain the toxin. Pigs and cattle are more commonly affected but the disease is also occasionally mentioned in sheep, and rarely in horses. Liver is the target organ. The most prominent histopathological finding in cocklebur poisoning is acute and severe centrilobular to massive necrosis of the liver. Ascitis may be seen related to liver injury. Chronic hepatitis is observed in animals which recover from toxic insult. Other pathological findings include gastroenteritis, with thickening of the mucosa, hepatic and cardiac hemorrhage. Renal injury leading to tubular degeneration is observed in some cases. The gross lesions in experimental studies of pigs include marked serofibrinous ascitis, edema of the gallbladder wall and lobular accentuation of the liver. Histopathological lesion is acute to subacute centrilobular hepatic necrosis (Stuart *et al*., 1981; Witte *et al*., 1990). The differential diagnosis of acute centrilobular hepatic

necrosis in ruminants includes blue-green algae, *Cestrum* spp., *Lantana camara*, etc.

#### *Lantana camara*

Toxicity is associated with triterpene acids lantadene A and lantadene B. Sheep and cattle are the common species affected. The major clinical effect of acute *Lantana camara* is photosensitization, the onset of which often takes place 1–2 days after consumption of a toxic dose. Subacute poisoning is more common. In severely affected cattle, lesions may appear at the muzzle, mouth and nostrils. Ulceration may be present in the cheeks, tongue and gums, while swelling, hardening, peeling of mucous membranes and deeper tissues occur in the nostrils. The common gross lesions in internal organs include yellowish discolored liver, icterus, general edema with gallbladder distention and gross changes in the skin. Histopathological lesions include megalocytosis, bile stasis in the canaliculi and focal hepatocyte necrosis. Skin lesions are characterized by ulceration and necrosis. Necrosis of renal tubular epithelium and myocardial injury are also observed in some cases. Hemorrhages are observed in some organs (Sharma *et al*., 1988). Diagnosis is by evidence of consumption, appropriate clinical signs and lesions.

#### *Cycads*

Cycad palms occur in tropical and subtropical climates. Cycasin is a glycoside that has been demonstrated to be responsible for acute hepatotoxic effects. Cattle, sheep, dogs, swine, horses, goats are susceptible. Two distinct syndromes, neurologic and hepatic–GI, have been described in ruminants. The prominent gross findings include ascitis and pale shrunken liver, in ruminants. Hemorrhage and GI mucosal necrosis is observed in dogs. Histopathological findings include hepatocyte necrosis and degeneration, centrilobular and extending to midzonal areas (dogs), hepatocellular megalocytosis, periacinar necrosis, fibrosis around central veins, cholestasis and bile duct hyperplasia in ruminants. The neurologic syndrome of cycad toxicosis in cattle is called Zamia staggers. The syndrome is characterized clinically by weight loss followed by lateral swaying of the hindquarters, with weakness, ataxia and proprioceptive defects in the rear limbs. Demyelination and axonal degeneration are present in the brain, spinal cord and dorsal-root ganglia. Surviving cattle remains ataxic and have hindquarter muscle atrophy (Hooper *et al*., 1974; Reams *et al*., 1993; Jones *et al*., 1996; Albretsen *et al*., 1998). Diagnosis is by evidence of consumption, appropriate clinical signs and lesions.

#### *Alsike and red clover*

These are members of the *Leguminosae* family. Toxicity is reported commonly in equines. Liver is the primary target organ and secondary photosensitization can occur. The specific toxin is not identified. The common significant clinical pathological finding is the elevated serum GGT and ALP levels and in some animals increased ALT and SDH. Gross findings include enlarged or shrunken liver. The prominent microscopic findings include bile duct proliferation with fibrosis. The fibrosis can be periportal, perilobular or centrilobular and is usually absent in the sinusoids. Chronic lesions will compress the hepatocytes leading to shrunken appearance of the liver. Mild-to-moderate inflammation and necrosis are also observed (Colon *et al*., 1996).

Diagnosis is by evidence of consumption, clinical signs of hepatic damage and pathological findings. The common differential diagnosis includes Theiler's disease and pyrrolizidine toxicity.

## Hemopoietic system

#### *Damaged/moldy sweet clover hay*

Sweet clover is grown throughout the central and northern United States and southern Canada. Toxicity is reported primarily in cattle. Formation of dicoumarol results in the dimerization and oxidation of the compound coumarin, a natural component of the plant; various fungi in the presence of moisture from coumarin to dicoumarol.

The toxic principle is dicoumarol which interferes with normal blood clotting by competitive inhibition of vitamin K 2,3-epoxide resulting in reduction of the concentrations of active forms of clotting factors II (prothrombin), VII, IX and X. The clinical pathological findings include significant changes in the clotting panel characterized by elevated PT, PPT and ACT.

Gross findings include multifocal hemorrhages (petechiae, ecchymosis and hematomas) in subcutaneous tissue, muscles and under the capsule of several organs. Histological findings include fatty change in liver, renal tubular degeneration, necrosis and hemorrhages (Jones *et al*., 1996; Puschner *et al*., 1998b).

## Reproductive system

The important plants which cause teratogenic effects or abortifacient potential are *Pinus* spp., *Veratrum* spp., *Lupine* spp., *Nicotiana* spp., *Conium maculataum* and hybrid sudan. Broomweed (*Gutierrezia* spp.) and Hoary alyssum (*Berteroa incana*) are reported to cause abortion in ruminants and equines, respectively. Carbon monoxide and nitrate do induce abortions in pigs and cattle, respectively, and are mentioned in other parts of this chapter.

#### *Pinus spp.*

Toxic principle is isocupressic acid which is a primary abortifacient compound. *Cupressus macrocarpa* and common

juniper (*Juniperus communis*) also contain high levels of isocupressic acid and induce abortion similar to *Pinus* spp. Toxin is present in green and dried needles and is water soluble. Cattle are the most susceptible species.

Abortion occurs mostly during the last trimester of pregnancy. Abortion usually occurs 2 days after pine needles have been fed but may occur up to 2 weeks after removed from source. Retained placenta is a common sequela of abortion. Live-born calves are weak and have poor viability. Parturition may be characterized by weak uterine contractions, incomplete dilation of the cervix and uterine hemorrhage. Metritis may occur. Gross findings are not specific. The observations in experimental studies conducted in pregnant cows include reduced number of trophoblastic giant cells in placentomes and more than normal number of necrotic luteal cells in corpora lutea (Jensen *et al.*, 1989; Stuart *et al.*, 1989; Gardner *et al.*, 1998). In experimental studies of cows exposed to pine needle tips both renal and neurological lesions were observed along with abortion, retention of placenta and endometritis. The renal lesions consisted of nephrosis characterized by tubular epithelial necrosis, proteinaceous and tubular casts in the tubular lumen, minimal inflammatory cell infiltration and congestion. The neurological lesions consisted of vacuolar changes in the neuropil of the basal ganglia, neuronal pyknosis and satelletosis in the cerebral cortex, diffuse perivascular and myelin edema which was prominent in the lumbar spinal cord. Focal skeletal myonecrosis of the large muscles (semimembranosus) was observed in animals which were paralyzed and recumbent. Suppurative endometritis limited to the mucosal surface was observed with no bacteria (Stegelmeier *et al.*, 1996). Diagnosis is made by evidence of consumption during gestation and clinical signs.

#### Hybrid sudan

Fetal malformations may occur when mares graze hybrid Sudan grass during the 20–50 days of gestation. Foals may be born with extreme flexion of the joints or ankylosis. Consumption of hybrid Sudan grass also may result in dystocia. Abortions are also reported associated with exposure (Prichard and Voss, 1967).

#### Lupines

Lupines are leguminous plants native to the western United States mostly in Rocky Mountain areas. Several quinolizidine alkaloids and piperidine alkaloids are isolated from *Lupine* spp. which are associated with the teratogenic action of these plants. Anagyrine is the most important teratogenic alkaloid which was experimentally been proved to induce teratogenic changes in cattle.

Ingestion of *Lupine* spp. results in a congenital syndrome called crooked calf syndrome which is characterized by arthrogryposis, scoliosis, torticollis and cleft palate. Some cases of abortions are also reported. Teratogenesis is observed when the plant is consumed by cows during 40–70 days of pregnancy. The crooked calf syndrome has been reproduced by the experimental feeding of the alkaloid, anagyrine the most teratogenic alkaloid of *Lupine* spp. Diagnosis is made by evidence of consumption during gestation, gross lesions and clinical signs (Panter *et al.*, 1998, 1999).

#### Veratrum spp.

The plant contains several alkaloids and the important teratogenic alkaloids include cyclopamine, veratrobasine, veratramine, cycloposine and jervine. Teratogenecity is reported commonly in sheep. The types of deformities are directly related to the stage of fetal development at the time of consumption. Teratogenic effect is manifested when the plant is consumed during 12–14 days of gestation. The most important deformity is the craniofacial effect. Consumption of the plant from days 0 to 10 may have no obvious effect. Days 12–30 of gestation are the most critical period and exposure during this period can lead to cleft palate and lips, syndactyly and brachygnathia. Consumption during days 12–14 of gestation results in cyclopia-type malformations which include hydrocephalus, displacement of nose and fusion of eyes. Experimental exposure during 30–36 days resulted in shortened metacarpals and metatarsals (Binns *et al.*, 1972; Keeler and Stuart, 1987). Diagnosis is made by correlating evidence of consumption, appropriate clinical signs and malformations.

#### Poison hemlock (Conium maculatum)

The toxic principle is a piperidine alkaloid. The most important toxic effect is teratogenecity. Common species affected is cattle, but can also affect pigs, sheep, goat and horse. The main teratogenic effects are arthrogrypotic skeletal malformations and cleft palate. This occurs when the plant is ingested by pregnant cows between days 40 and 100 of gestation. The skeletal lesions in cattle consist of torticollis, arthrogryposis, scoliosis and kyphosis. The cause of skeletal malformations and cleft palate is attributed to the lack of fetal movement during the critical stage of gestation. The maternal effect of poison hemlock is mortality and no significant pathological findings are observed (Keeler and Balls, 1978; Panter *et al.*, 1990, 1999). Differential diagnosis for teratogenic effects is *Lupine* species.

## Respiratory system

The most important toxicants which induce microscopic alterations in the respiratory system are ricin and the compounds which result in interstitial pneumonia.

### *Ricinus communis*

Ricin is the principle toxin and it is a phytotoxin (a lectin). All parts of the castor bean plant are toxic, the beans contain most ricin and need to be crushed or broken to release the toxic component. Ricin is 100 times more toxic parenterally than orally. The ricin molecule is composed of two glycoprotein chains A and B. One chain facilitates endocytosis, while the other chain, once in the cell, inhibits protein synthesis and causes cell death. Orally, ricin is readily absorbed from the stomach and intestine. Ricin is water soluble and not present in castor oil. Another phytotoxin in castor bean, ricinine, is reportedly goitrogenic. Common species affected are horses and dogs. Birds, cattle and pigs are also affected.

In dogs ingestion of castor bean causes severe GI clinical signs including vomiting with blood and diarrhea with blood and can lead to death (Albretsen *et al.*, 2000). Ingestion of castor bean/oral exposure of ricin results in catarrhal to hemorrhagic gastroenteritis. There may be petechial hemorrhages on the serosal surface of visceral organs and in subepicardium. Mesenteric lymph nodes are edematous. Hepatic and renal degenerative changes are reported. In birds it causes degeneration of hepatocytes and hemorrhage. In ducks there is ascending paralysis and the clinical signs appear similar to botulism (Dungworth, 1993).

Gross findings in inhalation experimental studies conducted in primates include edema of lungs; lungs do not collapse when the thoracic cavity is opened mottled red to purple discoloration. Microscopic findings include multifocal to coalescing areas of intra-alveolar fibrin, edema, and hemorrhage, acute alveolitis and necrosis of lower respiratory tract epithelium. Mild inflammation was also observed in the heart. Although it is suspected that ricin-induced pulmonary edema is due to increased pulmonary capillary endothelium permeability, the specific mechanism by which inhaled ricin crosses the respiratory epithelium to injure the vascular endothelium is not yet known (Wilhelmsen and Pitt, 1996). Diagnosis is based on the case history and pathological findings. Differential diagnosis includes other toxins which produce hemorrhages in the GI tract like arsenic and exposure to paraquat for pulmonary lesion.

### *Interstitial pneumonia*

Interstitial pneumonias in cattle have different names including acute bovine pulmonary emphysema and edema (ABPE), fog fever, atypical interstitial pneumonia (AIP) and cow asthma, the condition seems to occur predominantly in late summer or fall. The condition has an acute onset. Among the toxic etiologic causes, primary toxin is the amino acid L-tryptophan in lush pasture grasses, a compound which is converted to 3-methylindole by rumen microorganisms which is absorbed into the blood stream eventually reaching the lungs where the mixed function oxidase in the non-ciliated bronchiolar epithelial cells (Clara cells) convert them to a pneumotoxic compound which causes marked necrosis of the bronchiolar cells and pneumocytes. Other leading toxic causes of interstitial pneumonia are perilla mint and moldy sweet potatoes. Moldy sweet potato contaminated by pneumotoxic factor, 4-ipomeanol also produces the same clinical and pathological changes. Perilla mint, Stink weed, rape and kale (*Brassica* spp.) also produce similar clinical and pathological changes in the lung. The gross findings include enlarged pale lung with rubbery texture. Microscopic findings include alveolar and interstitial edema, emphysema with diffuse hyaline membrane formation in the alveolar lumen and necrosis of the alveolar epithelium. Those animals which survive for several days have proliferation of type II pneumocytes (Kerr and Linnabary, 1989; Dungworth, 1993). Diagnosis is by correlating history of exposure, clinical signs and pathological findings.

## Skin

This section consists of plants which produce skin lesions. The plants which produce primary photosensitization are St. Johnswort (*Hypericum perforatum*), buckwheat (*Fagopyrum esculentum*), spring parsley (*Cymopterus watsoni*), bishops weed (*Ammi majus*) and dutchmans breeches (*Thamnosma texana*), perennial rye grass (*Lolium perenne*) and Burr terfoil (*Medicago denticulata*). The other common compounds which produce photosensitization include phenothiazine, thiazides, some sulfonamides, tetracycline, acriflavins and methylene blue.

The toxic principle in St. Johnswort is hypericin, a fluorescent pigment. Susceptible species are mainly cattle, sheep, horses, goats, rabbits. Hypericin remains intact upon ingestion, is absorbed and passes through the liver and enter the general circulation and finally reach the skin leading to photosensitive reaction.

Toxicity in buckwheat is attributed to the naphthodianthrone derivative fagopyrin. All livestock with unpigmented skin are affected. The photodynamic agent in spring parsley, bishops weed and dutchmans breeches is psoralens. These plants also induce corneal edema and keratoconjunctivitis probably through the excretion of the compounds in the lacrimal secretion. The photodynamic substance in perennial rye grass is perloline.

Secondary hepatic photosensitization is due to hepatic injury and the plants include *Senecio*, *Crotalaria*, *Brassica* and *Heliotropium*. The other agents which can cause indirect photosensitization include blue green algae, neoplastic diseases, diseases which can induce diffuse, chronic and severe liver damage. The phylloerythrin which is the breakdown product of chlorophyll is removed by the liver and is excreted in the bile. When the liver or its ductal

system is injured leading to impairment of the excretory function, the phylloerythrin reaches the skin by the systemic circulation and cause photosensitization.

The common gross observations include edema and erythema, especially around the ears, face and eyelids leading to ulceration. In severe cases, inflammation may spread to unpigmented areas of the skin and vesicles may develop containing a yellowish fluid. Ruptured vesicles form a yellow or brown crusty scab. Erythema is followed by subdural edema and necrosis. Histopathological observations include dermatitis, necrosis and gangrene (Rowe, 1989; Jones *et al*., 1996). Diagnosis is made by identification of the plant material in the GI tract, evidence of consumption, appropriate clinical signs and pathological findings.

## Hairy vetch

Hairy vetch (*Vicia villosa*) is a legume that grows throughout United States and toxicity has been reported mostly from the midwestern states and California. The common species affected are cattle and horse. The gross pathological lesions include hemorrhage in heart, kidneys, omentum and intestinal mucosa. Dermatitis associated with hairy vetch is associated with pruritis. Lesions begin with alopecia of the udder, tail head, neck and later affect the face, trunk and the limbs leading to exudation, crusting and pruritis. The prominent histopathological findings include granulomatous inflammation predominantly in skin, liver, kidney and also heart, skeletal muscle, lymph node, intestine and urinary bladder. The inflammation is mostly around the vessels and consists of a mixture of lymphocytes, neutrophils, macrophages and eosinophils with and without multinucleate giant cells. In liver bile duct hyperplasia may also be observed (Anderson and Divers, 1983; Panciera *et al*., 1992; Woods *et al*., 1992). Diagnosis is made by correlating history of exposure, clinical signs and pathological findings.

## Urinary system

The most common plants which induce toxic pathological changes in the urinary system are Easter lily, Red maple, Oak, *Amaranthus*, *Rheum*, *Halogeton*, *Rumex* spp., *Solanum*, *Cestrum*, Brackenfern and Hybrid sudan grass.

### *Easter lilly*

Cats are the most common species affected. The aqueous extracts of leaves and flowers are proven to be nephrotoxic and pancreotoxic. The clinical pathological changes include an elevated creatinine and BUN with glucosuria, proteinuria with numerous tubular epithelial casts in urine sediment. The significant histopathological findings include acute necrosis of proximal convoluted tubules and degeneration of pancreatic acinar cells. The tubular epithelial cells show loss, degeneration and regeneration. Tubular lumen contains protein casts and cellular debris. Renal ultrastructurally changes include swollen mitochondria, megamitochondria, edema and lipidosis (Langston, 2002; Rumbeiha *et al*., 2004). Diagnosis is by correlating the clinical signs with histopathological examination and case history.

### *Oxalate-containing plants*

The common plants which contain toxic level of soluble oxalates are rhubarb (*Rheum rhaponticum*), halogeton (*Halogeton glomeratus*) and Grease wood (*Sacrobatus vermiculatus*), beets and dock (*Rumex* spp.) and lamb quarters (*Chenopodium* spp.).

The toxic principles are oxalic acid, sodium and potassium oxalates, which complex with calcium forming calcium oxalate and crystallize in the kidney when they are excreted. Sheep, cattle and swine are the common species affected. Hypocalcemia is observed due to formation of calcium oxalate. Increased BUN values are observed in chronic cases with nephritis. The gross lesions consist of radially arranged white streaks in the kidney and hemorrhages in the GI tract.

The common microscopic findings are hemorrhagic rumenitis in sheep associated with deposits of calcium oxalate in the walls of blood vessels, oxalate nephrosis characterized by irregular rhomboid crystals which are visible in sharply reduced or polarized light, protein casts in tubular lumen with varying degrees of renal tubular epithelial degeneration and necrosis (Dickie *et al*., 1978; Panciera *et al*., 1990).

In tropical and subtropical areas, certain grasses that are cultivated widely (genera of *Cenchrus*, *Panicum* and *Setaria*), accumulate large amounts of oxalate and have been associated with renal oxalate accumulation in cattle and sheep and with skeletal disease in the horse. Diagnosis is by evidence of consumption clinical signs and pathological findings.

### *Amaranthus spp.*

The toxic principles are unknown agents which cause perirenal edema and nephrosis. The most common species affected are cattle and swine. The significant clinical pathological findings include increased BUN, proteinuria, CPK and creatinine.

The most striking gross lesion is retroperitoneal edema in the perirenal connective tissue. Edema is often present in the ventral abdominal wall and per rectal area. Kidneys are normal or small in size and pale with subcapsular

petechiae. In calves free straw-colored fluid is observed in thoracic and peritoneal cavities. Histopathological findings include degeneration and necrosis of the tubular epithelium of the proximal tubules with interstitial edema, dilation of the renal tubules with protein casts and some may have oxalate crystals (Stuart *et al.*, 1975; Kerr and Kelch, 1998). Diagnosis is by evidence of consumption of the plant material with appropriate clinical signs and pathological findings.

### *Oak*

Oak (*Quercus* spp.) poisoning has been reported from many regions of the world, and more than 60 species of oak have been identified in North America. Tannins and their metabolites (digallic acid, gallic acid and pyrogallol) are responsible for the toxicity. High levels of toxic component are in young leaves and the shells of green acorns. Cattle and horses are the common species affected with reports more common in cattle.

Kidney is the target organ with pathological findings also in GI tract. Oak causes GI irritation which manifests in the early course of toxicosis, characterized by anorexia, constipation and colic. After a few days, constipation is followed by diarrhea, and fragments of acorns may be present within stools.

The gross findings include swollen pale kidney with petechial hemorrhage, perirenal edema, hemorrhage and ulcers in the GI tract (can extend from pharynx to the lower intestinal tract). The histopathological findings include degeneration and necrosis of tubular epithelium, regeneration of tubular epithelium, dilated tubules with erythrocytes, homogenous and granular casts and sloughed necrotic tubular epithelial cells and neutrophil infiltration. The renal interstitium has multifocal areas of hemorrhage and edema. GI lesions include hemorrhages in mesentery, stomach, small intestine and hemorrhage with ulcers in large intestine, especially in horses. Secondary lesions related to uremia and renal failure may also be observed in stomach and tongue. Oak toxicosis has high mortality due to renal failure (Anderson *et al.*, 1983; Plumlee *et al.*, 1998). Diagnosis is by evidence of consumption of the plant material with appropriate clinical signs and pathological findings.

### *Red maple (Acer rubrum)*

The most common species affected is equine. An unidentified toxin creates an acute hemolytic anemia associated with methemoglobinemia and/or Heinz body formation. Clinical pathological findings are hemolytic anemia and blood smears may show eccentrocytes, spherocytes, anisocytes and Heinz bodies. The gross findings include generalized icterus, splenomegaly, and enlarged liver with pale centrilobular areas, dark brown black discolored kidney, increased pleural and pericardial fluid, petechiae and ecchymosis in the serosal surfaces. The histopathological findings include hepatocyte degeneration in centrilobular areas, renal tubular epithelial degeneration with hemoglobin casts and erythrophagocytosis in spleen and liver. Pregnant mares may abort without showing any clinical signs (George *et al.*, 1982; Stair *et al.*, 1993). Diagnosis is by evidence of consumption of the plant material with appropriate clinical signs and pathological findings. Differential diagnosis includes nitrate toxicosis, equine infectious anemia and Babesiosis.

### *Onion (Allium)*

Dogs are the most common species affected. The toxic component of *Allium* spp. is *n*-propyl disulfide and its effects are on erythrocytes. The principal effects are related to hemolysis. This is believed to be secondary to oxidant-associated effects, and Heinz bodies may sometimes be evident. Discolored urine varying from port wine to almost black color is observed. Some animals may show icterus. Severe toxicoses may be lethal. No specific histopathological lesions are observed other than damage of the parenchymatous organs due to hemolytic anemia (Harvey and Rackear, 1985). Differential diagnosis includes zinc toxicosis, copper toxicosis, autoimmune hemolytic anemia, and hemolytic blood parasites and bacterial infections which cause hemolytic anemia. Diagnosis is by evidence of consumption with appropriate clinical signs and pathological findings.

### *Bracken fern (Pteridium aquilinum)*

Most common species affected are horse and cattle. Several toxic principles are recognized and poisoning in non-ruminants is due to thiaminase. In ruminants the toxins include a bone marrow toxin and the suspected carcinogen ptaquiloside which induces the bladder tumors in cattle. In horses it causes thiamine deficiency and leads to clinical signs of thiamine deficiency. The lesions in horses include enteritis, with some pericardial and epicardial hemorrhages. In sheep bracken fern poisoning is associated with progressive retinal degeneration and is called bright blindness. The condition is characterized by loss of rods and cons with reduction in width of the outer nuclear layer. The lesion is prominent in the tapetal region (Hirono *et al.*, 1993).

In cattle different clinical manifestations of the poisoning by bracken fern are reported. When large amounts of plants are consumed in a short period of time aplasia of the bone marrow develops and result in mortality. Thrombocytopenia, neutropenia and anemia develop and early myeloid cells are destroyed. Those animals consuming less quantity for longer period develop hematuria and is called enzootic hematuria. They also develop urinary

bladder tumors and squamous cell carcinoma in the GI tract. All these lead to death due to anemia and chronic wasting. The pathological findings include widespread petechial and ecchymotic hemorrhage in intestines, serosal surfaces of several internal organs, including urinary bladder, gall bladder, heart, subcutaneous tissue and muscles. Some animals develop abomasal ulcers. Hyperplasia and hemorrhage are observed in the urinary bladder and also ureter or renal pelvis. Chronic cystitis with hemangiomas develops which bleed resulting in hematuria. Adenocarcinomas, transitional cell carcinomas, squamous cell carcinomas, papillomas, fibromas and adenomas are reported in the urinary bladder, renal pelvis and ureters, related to exposure of bracken fern. Tumors in the GI tract are mostly squamous cell carcinomas located in pharynx, base of tongue, esophagus and rumen (Pamukcu *et al.*, 1976; Jones *et al.*, 1996; Gava *et al.*, 2002; Carvalho *et al.*, 2006). Diagnosis is by evidence of consumption of the plant material with appropriate clinical signs and pathological findings.

#### *Sorghum spp.*

In horses, especially females, a syndrome of "cystitis and ataxia" has been associated with the consumption of hybrid strain of *Sorghum* spp. Gross observations include edema and hemorrhage in the bladder mucosa with occasional ulceration of the mucosa. Histological findings include focal necrosis and ulceration of the urinary bladder mucosa, degeneration of axons and demyelination with gitter cells in cervical, thoracic, lumbar and sacral spinal cord segments. Fetal malformations associated with hybrid sudan is mentioned in the reproductive system section (Adams *et al.*, 1969; Morgan *et al.*, 1990).

## ZOOTOXINS

The toxic exposure from insects and reptiles is covered in this section. The clinical signs of exposure are very important in making conclusive diagnosis of most of these conditions and only few cases have gross or histopathological lesions suggestive of exposure to toxins. Most of the toxic exposures are severe and acute, with toxin entering the system resulting in mortality. The agents which are described in this section include hymenoptera, blister beetle, snakes, toad and spiders.

### Black blister beetle

Toxicosis is due to ingestion of blister beetle (*Epicauta* spp.) itself. Toxicity occurs primarily when beetles are present in alfalfa hay mostly in southwestern United States and occasionally in eastern and midwestern states of United States. The toxic principle is cantharidin, a bicyclic terpenoid, which is contained in the hemolymph, genitalia and other tissues of beetle. This is a very stable compound and remains toxic even in dead beetle. Ingested cantharidin causes irritation of oral and GI mucosa leading to colic. Horses are the most common species affected.

Clinical pathological findings include hemoconcentration, neutrophilic leukocytosis and hypocalcemia. Lesions are confined to GI tract, urinary tract and heart. Gross lesions are rare and may include ulceration and hyperemia in the entire GI tract and urinary bladder. Histopathological findings include ulceration and necrosis of the mucosal epithelium in the esophagus, stomach, urinary bladder and myocardial necrosis (Schoeb and Panciera, 1979; Helman and Edwards, 1997; Schmitz, 1989). Diagnosis is by clinical signs, pathological findings confirmed by analysis of urine, and gastric contents, or urine for cantharidin.

### Hymenoptera (bees, wasps) and ants

The toxins are not well characterized but may contain formic acid (in ants) which induces the pain. In acute cases the poison apparatus is observed in the wound by bees and certain wasps. Gross findings may include local edema and erythema. In dogs acute pruritic papular to facial nodular facial dermatitis are reported. Histopathological observations include eosinophilic folliculitis with collagen degeneration and mucinosis (Scott *et al.*, 2001). Fire ant bites in dogs cause erythema and pruritic swelling. Histopathology is characterized by vertically oriented linear band of full thickness necrosis of the dermis with edema and inflammatory cells predominated by eosinophils (Rakich *et al.*, 1993).

### Snakes

Most of the poisonous snakes in United States are of Crotalidae family which includes the rattlesnakes, water moccasins and copper heads. The most common snake of the Elapidae family seen in United States is the coral snake (*Micrurus euryxanthus*) which is distributed in southeast and southwestern United States. Crotalidae family produces venoms which are mostly necrolytic and hemolyzing. Hemorrhagins in crotalid venom are toxic to the vessels and hence cause hemorrhage and edema at the wound site, in addition to systemic hemorrhage and shock. Marked anemia is observed due to hemolysis and extravasation. Disseminated intravascular coagulation is observed in some cases. Coral snake venom is primarily neurotoxic and within a half hour neurotoxic effects may be noted. Coral snake venom causes local pain and swelling.

The rattlesnake bite in horses is mostly on or near the muzzle which results in head swelling, dyspnea and epistaxis. The most common complication is cardiac problems. The most common site of rattlesnake bite in dogs is the head. The most common finding is swelling at the bite area. The common initial clinical pathological changes include echinocytosis, thrombocytopenia, leukocytosis and prolonged ACT (Dickinson *et al*., 1996; Hackett *et al*., 2002). Generally edema and erythema along with fang marks (Crotalidae family) may be observed at the site of bite although it is difficult to identify due to thick hair coat in animals. These lesions may advance to necrotizing dermatitis with vasculitis. Major route of venom excretion is through the kidneys and hence kidney failure is observed in many cases of crotalid snake bites characterized by renal tubular necrosis with protein casts and hemorrhage and necrosis in the glomeruli.

### Spider

Spider bites are common in dogs. The most common spiders in United States are the brown recluse spider (*Loxosceles reclusa*), the black widow spider (*Latrodectus mactans*), the red widow (*Latrodectus bishopi*) and the common brown spider (*Loxosceles unicolor*). Brown recluse spider bite lesions are more common during the period of spring, fall and summer as they hibernate during winter. Brown recluse venom is cytotoxic and hemolytic. Several enzymes have been identified in the venom including lipases, hyaluronidase, alkaline phosphatase and sphingomyelinases. Sphingomyelinases are primarily responsible for both tissue necrosis and complement-dependent hemolysis. The pathogenesis is thought to involve intravascular coagulation locally at the site of the bite followed by necrosis and an influx of neutrophils. Endothelial damage and thrombosis of small capillaries have been demonstrated ultrastructurally as early as 3 h after envenomation.

Bites from brown recluse spiders are common at the face and forelegs and show considerable variation in clinical presentation. The early lesion is characterized by erythema, pruritis, pain, swelling and blister formation which may proceed to an indolent non-healing ulcer. In more severe cases, localized necrosis develops with a central area of deep blue to purple discoloration surrounded by a red rim of erythema. The lesion spreads in a gravity-dependent manner and eventually progresses to form a disfiguring dark black scar.

Grossly they appear as irregularly shaped, pale blue to blue-black mottled area of skin. Erythema with dermal and subcutaneous edema is also observed around the lesion. Histopathological findings include ulceration of the epidermis, necrosis and hemorrhage in the dermis (some times form cavitations) which may extend to the subcutaneous tissue with necrotizing vasculitis. Inflammatory cells are mixed and include neutrophils and macrophages and eosinophils may not be prominent. The vessels may contain fibrin thrombi, and the dermis may have collagen degeneration and edema (Gross *et al*., 1992). Differential diagnosis of the histopathological lesion includes other insect envenomation, snakebite, pythiosis, foreign body reactions or deep bacterial infections.

### Toads

The most common toad seen in United States is the giant tropical toad, *Bufo marinus* which produce toxins which include bufagins, bufotoxins, bufotenins and other compounds. Dogs and rarely cats are exposed to the toxin. Bufagin's and bufotoxin's action is described as digitalis-like, often resulting in ventricular fibrillation. The common clinical signs are related to cardiac and CNS. Profuse salivation, head shaking, pawing at mouth and wretching are the common initial signs. Other clinical signs include seizures, cardiac arrhythmia, dyspnea, vomiting and recumbency or collapse. No specific histopathological lesions are observed in exposure to these toxins. Toad poisoning is mostly reported from Florida and Texas (Roberts *et al*., 2000; Kahn, 2005).

## MISCELLANEOUS AGENTS

These agents include algae, citrus pulp, mushrooms, ethylene and propylene glycol.

### Algae

Toxic blooms of blue green algae in ponds and water reservoirs have been associated with acute, usually lethal toxicity in various species of domestic animals and humans. Algal blooms occur in the late summer or early fall due to the warm temperature. These toxic blooms of alga can be observed on top of water as a thick layer of blue, blue-green or green in color. Formation of the toxic bloom is promoted by fertilizer and animal waste runoff into these water reservoirs. Mostly ruminants are the affected species. Liver is the target organ in algal poisoning.

The toxins produced by blue green algae consist of primarily cyclic peptides (microcystins, nodularins) that target liver function and alkaloids (amatoxins) that target the nervous system and lipopolysaccharides that are potential irritants. The hepatic toxicity is commonly attributed to microcystin-LR which is produced by the blue-green alga *Microcystis aeruginosa*. The acute toxicity is attributed to cytoskeletal collapse due to aggregation of

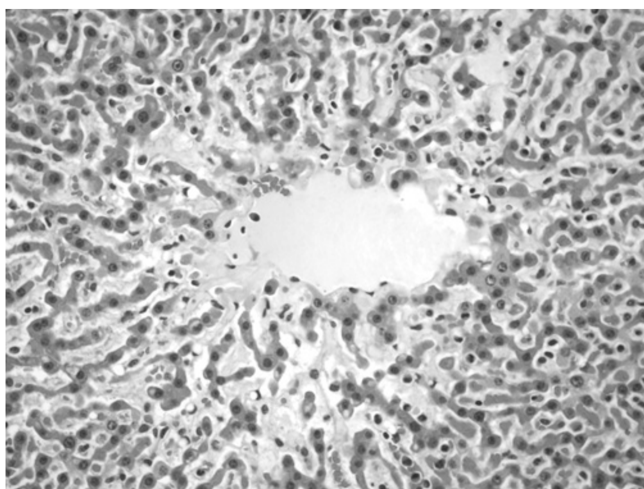

**FIGURE 90.5** Blue green algae poisoning, liver, bovine, centrilobular cord atrophy with dilated sinusoids and necrosis, H&E stain, 40×. This figure is reproduced in color in the color plate section. (Courtesy Dr. K Frazer, Philadelphia.)

actin filaments, microtubules and intermediate filaments within hepatocytes. The underlying pathogenesis involves rapid hyperphosphorylation of cytoskeletal proteins secondary to the potent inhibitory effects of this toxin on protein phosphatases 1 and 2A (Runnegar *et al.*, 1993; Guzman and Solter, 2002).

Grossly, liver is enlarged, hemorrhagic and friable and the gall bladder may have edema. Microscopic findings in acute toxicity are characterized by necrosis and degeneration of the hepatocytes primarily in the centrilobular areas and many of these hepatocytes are lost and replaced by erythrocytes (hemorrhage) (Figure 90.5). The coagulative necrosis and individualization of hepatocytes are a notable feature. Many cases have marked hemorrhage in the parenchyma (Frazier *et al.*, 1998; Puschner *et al.*, 1998a). Secondary (hepatogenous) photosensitization lesions also can develop due to the massive hepatic necrosis. Differential diagnoses for acute centrilobular hepatic necrosis in ruminants include aflatoxins, plant toxicants like *Cestrum* spp. and *Xanthium strumarium* spp.

## Citrus pulp

Citrus pulp has been used as cattle feed component and rarely do cause disease conditions. In a group of cattle fed with citrus pulp mortality was reported. The important gross findings included hemorrhages on the serosa of intestine and epicardium, lymphadenopathy, small intestinal hemorrhage and interstitial pneumonia. Histopathological findings included granulomatous inflammation with multinucleate giant cells and eosinophils in the heart, spleen, kidney, lymph nodes, liver, lung, pancreas and adrenal gland. The lesions and histopathological findings were similar to hairy vetch toxicosis and the pathogenesis is suspected to be due to a lectin in citrus pulp leading to a type IV hypersensitivity reaction (Saunders *et al.*, 2000).

Feeding of moldy citrus pulp which contained citrinin, a mycotoxin, has been reported to have resulted in an outbreak of pruritis, pyrexia and hemorrhagic syndrome in cows (Griffiths and Done, 1991).

## Ethylene glycol and propylene glycol

Intoxication with ethylene glycol is caused by consumption of antifreeze solution which contain up to 95% ethylene glycol. Mostly cats and dogs are the affected species but there are rare reports of intoxication in other species. The common clinical pathological findings in cats and dogs include neutrophilia, lymphopenia, azotemia, hyperphosphatemia, hypocalcemia, hyperglycemia and decreased whole blood bicarbonate. The common findings in urine analysis include proteinuria, glucosuria, hematuria, calcium oxalate and hippurate crystalluria, and the presence of renal epithelial cells, white blood cells and granular and cellular casts in the urine sediment (Thrall *et al.*, 1984).

Grossly the kidneys are firm with pale streaks at the corticomedullary junction. In some cases pulmonary edema and hyperemia of the gastric and intestinal mucosa are observed. The microscopic findings include marked renal interstitial fibrosis (in cases which survive for long), mild lymphocytic infiltration in the interstitium, atrophy, degeneration and necrosis and of the renal tubular epithelium with birefringent crystals, mineralization and glomerular atrophy in some cases. Microscopic demonstration of birefringent crystals in renal tubules using polarized light is pathognomonic for ethylene glycol toxicity in dogs and cats (Kelly, 1993; Jones *et al.*, 1996). In cats a hereditary disease called primary hyperoxaluria forms intraluminal birefringent oxalate crystals in the renal tubules (De Lorenzi *et al.*, 2005).

The antemortem diagnosis is by clinical pathological evaluation (increased anion and osmolal gaps, suggestive) colorimetric test kit, glycolic acid assay in serum and postmortem diagnosis is by pathological evaluation or chemical analysis of kidneys.

## Propylene glycol

Propylene glycol is a major component of soft-moist pet foods and is also used as a fungistat in pharmaceuticals, cosmetics and processed food. Experimental studies in cats have shown that propylene glycol induces Heinz body hemolytic anemia. This is relevant in cats with greater food intake like lactating queens and nursing kittens. The

histopathological findings in the cats dosed with propylene glycol included hepatic vacuolations in the periportal areas, intracellular aggregation of iron in liver and spleen (Christopher *et al.*, 1989). Mortality has been reported in a horse due to accidental iatrogenic oral administration of propylene glycol.

### Mushroom poisoning

Mushroom poisoning is commonly reported in small animals especially young dogs with few reports in horses. The most common mushroom is the *Amanita* spp. which contains amatoxins and is a thermostable toxin. Amatoxins are bicyclic octapeptides that are transported to the nucleus and inhibit RNA polymerase II, preventing DNA transcription, resulting in cessation of protein synthesis (Wieland, 1983; Tegzes and Puschner, 2002).

The common gross pathological findings include segmental congestion and hemorrhage in the mucosa of the small intestine and sometimes extending to the serosal surfaces serosa of distal ileum. Widespread necrosis and hemorrhage can be observed in the small intestine primarily in the posterior segments with necrosis of Peyer's patches in some cases. Hepatic necrosis is a prominent finding. There will be dissociation of hepatocytes, with degeneration of many with necrosis of random hepatocytes in all lobules (Figure 90.6). Edema and hemorrhage may be observed around central veins, with sparing of the portal tracts. The main lesion is nucleolar fragmentation in hepatocytes and enterocytes (Liggett and Weiss, 1989; Frazier *et al.*, 2000). Differential diagnosis includes other causes of hepatic necrosis like aflatoxicosis and exposure to other hepatotoxins. In large animals it should be differentiated from exposure to blue-green algae. Muscarinic/histaminic mushroom intoxications are reported in humans and are associated with no specific pathological lesions other than clinical signs associated with histamine release.

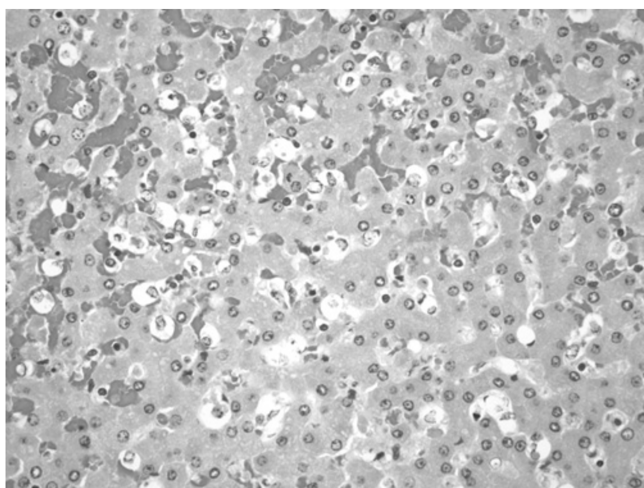

**FIGURE 90.6** Mushroom poisoning, liver, canine, hepatocyte dissociation and degeneration, H&E stain, 40×. This figure is reproduced in color in the color plate section. (Courtesy Dr. A Ligget, College of Veterinary Medicine, University of Georgia.)

## CONCLUSIONS

Domestic animals are exposed to a great number of toxins and most of these intoxications lead to marked alterations in biochemical profile of the body fluids, organs, tissues, cells and cellular organelles. These alterations are manifested as various pathological changes. Knowledge of the organs and systems affected in various intoxications will help clinicians to collect appropriate samples for both clinical pathological and histopathological investigations. With the advent of evidence-based medicine, the role of pathology in diagnosing toxic conditions is growing every day as pathological findings are the true reflections of structural and biochemical alterations of a toxic insult. Hence the clinical, gross and histopathological findings associated with toxicity are a great tool for etiological diagnosis of toxic exposure. The clinical and pathological findings related to experimental exposure of toxins in one species can be extrapolated in investigating natural cases of toxic exposure in multiple species (not in selective toxicity) of animals. Hence research in these areas will help clinicians to effectively use the data from these experiments to make a conclusive diagnosis and speed up therapeutic interventions especially in emergency medicine. Although we have several standardized *in vitro* testing methods for evaluation of toxic molecules, the histopathological changes associated with toxic exposure still remain the gold standard for assessing the toxic changes associated with their exposure. Though used routinely in preclinical toxicity evaluations of drug discovery, the new molecular pathology techniques will soon be used routinely for diagnosing clinical cases of toxic insults. Hence this branch of pathology plays an important role in diagnostic medicine. Finally, continued research in this area will increase the efficiency of clinical diagnosis for poisoning, and ultimately improve clinical practice.

CHAPTER

# 91

# Prevention and treatment of poisoning

*Camille DeClementi*

## INTRODUCTION

This chapter discusses prevention of poisoning, stabilization and care of the poisoned patient, decontamination techniques and antidotal therapies. Clinicians may find it beneficial to approach these patients no differently than any other patient. Using the same principles of history collection, physical examination and patient monitoring will help the clinician to concentrate on *treating the patient and not the poison*. Poisoning cases, like all cases, are often not predictable and oftentimes no antidote is available. A treatment plan should be developed based on the circumstances and progression of the individual case. Toxicant exposures often require immediate or urgent attention, so stabilization of the patient is the first priority. Once that has occurred, the clinician must decide if attempts at decontamination are needed. If an appropriate antidotal therapy is available and was not already given to assist with patient stabilization, it should then be administered.

In all instances, prevention of poisoning is preferable to treating a poisoning once it has occurred. Clients rely on their veterinarians to provide a great deal of information about their animal's well-being. Veterinarians are a great source of information on husbandry, disease prevention and safety. They are therefore the ideal source of information for clients on preventing poisoning as well.

## PREVENTION OF POISONING

Prevention of poisoning in household pets consists of controlling the animals' environment to decrease exposure to potentially dangerous substances. This requires animal caretakers to be diligent and knowledgeable of potential risks. While much of the advice offered to prevent poisoning will seem like common sense to many veterinarians, these guidelines are often unfamiliar to animal caretakers. Veterinarians are therefore encouraged to share this information with their clients.

Clients should be reminded to keep all veterinary and human medications, both prescription and over-the-counter (OTC), out of the reach of animals. Since some pets are able to climb onto high surfaces and open cabinets, medications are not adequately "out of reach" in those places. Owners should be instructed not to give their pets any medication, including their own, unless directed by their veterinarian. Clients may not realize that giving an OTC medication that they consider safe, like acetaminophen (APAP), could cause life-threatening illness in their pet. For example, treatment of alopecia in cats with topical minoxidil solution has led to pleural effusion, pulmonary edema and death (DeClementi *et al*., 2004). Clients should also store all other potentially hazardous products, including cleaning products, auto-care products, pesticides and insecticides, out of the reach of their animals. Garbage cans should be sealed with tamper-proof lids.

Animal caretakers should be urged to read all label information before using a product on an animal or in the animal's environment and to follow the label instructions exactly. Veterinarians should mention that it is often not safe to use a product on an animal species for which it is not intended. For example, using a concentrated permethrin flea product labeled for dogs could prove deadly if used on a cat (Richardson, 2000a).

Since many plants are poisonous, clients will want to be aware of the plants in an animal's environment, including those in outside areas. Additionally, they should be alert to any fluids leaking from vehicles and clean up leaks

immediately. One effective method to remove liquid is to allow clay cat litter to soak it up. The litter should then be swept up or vacuumed and disposed of in a manner that will prevent animal exposure. If a rodenticide or other bait is necessary in the home or yard, the product should be placed in an area that is completely inaccessible to non-target animals. The bait should be removed as soon as it is no longer needed. An animal's enclosure should be routinely checked, and unfamiliar or questionable items removed. Companion animals should be supervised, when possible, if they are outdoors, and a securely gated, confined area should be provided when animals are left unattended.

The guidelines for keeping household pets safe from poisoning are very similar to those for children, especially toddlers. Some pets may even be more at risk than children because, unlike children, they are commonly left unattended. They are also likely to chew open some containers, including those considered child-safe. The ASPCA website has additional information regarding poison prevention (www.aspca.org).

Decreasing the risk of exposure to toxicants is also important in large animals. Caretakers should be urged to purchase hay and feed from reputable suppliers, to examine the feed for recognizable contamination and to verify cleanliness and high quality. Feed should be stored in a clean, insect-free area at the appropriate moisture level to prevent damage and lessen the risk of contamination or mycotoxin growth (Osweiler, 2001).

Learning to identify poisonous plants and their potential effects is critical for large animal clients. Once poisonous plants have been recognized in an area, many strategies can be employed to limit exposure. The most effective strategy is to remove animals from poisonous plant-infested areas either by herding or fencing off those areas. If this is impossible, attempts should be made to reduce the poisonous plant populations via mechanical (burning or pulling), chemical (herbicides), biological (such as using the larvae of the cinnabar moth to control tansy ragwort) or other control methods. Since treatment with herbicides may increase palatability or toxicity in some plants, animals should not be allowed access to herbicide-treated areas until all plant material is dead and removed. Once the plant populations are controlled, good grazing management can be used to maintain the area in a condition that limits regrowth of the plants (Cheeke, 1998).

If grazing in contaminated areas cannot be avoided and plant numbers cannot be reduced, other techniques can be used. The stocking rates can be adjusted so that the animals have ample non-toxic forage available relative to the amount of poisonous plants present. Or the client may opt to graze a species of livestock on the area that is less susceptible to poisoning by the plants present. Another successful management practice is to graze livestock in the area only when the plants are at their lowest toxicity or when the plants are unpalatable and will likely not be eaten (Cheeke, 1998). For instance, only the seeds and two-leaf seedling stages of cocklebur (*Xanthium*) are toxic. Once the plant reaches the four-leaf seedling stage, it no longer presents a risk (Burrows and Tyrl, 2001). Avoiding certain plants during the times when livestock are most susceptible may also prevent poisoning. Cattle farmers, for example, can use timing as described above to prevent their calves from developing crooked calf disease. This disease is caused by the teratogenic alkaloids of many species of lupine plants. The fetus is only susceptible between days 40 and 70 of gestation. If pregnant cows are kept from grazing the plants during this time frame, the calves will not develop the disease (Cheeke, 1998).

Caretakers should avoid placing hungry animals onto ranges infested with poisonous plants. This is especially true when animals are released after being transported. Given that animals naïve to an area are more likely to be poisoned by indigenous plants than native animals, feeding prior to setting them out may help decrease exposure (Cheeke, 1998). Large animal enclosures and barns should also be kept free of other potential toxicants, including insecticides, pesticides, petroleum products and medicated feeds. Following label instructions is just as important for large animals as household pets. Medicated feeds, medications and insecticides should be used only on the labeled species. If a pour-on amitraz product intended for cattle is instead used on horses, fatal ileus may result (Gwaltney-Brant, 2004).

## STABILIZATION AND MONITORING

Toxicant exposures often require immediate or urgent attention. Television and movies have led the public to believe that every toxicant has an antidote; consequently animal caretakers may expect their veterinarian to provide one. Unfortunately, this expectation is far from reality. There are very few antidotes and when they do exist, they may be cost prohibitive or difficult to obtain. Therefore, it is critical for the clinician to concentrate on *treating the patient and not the poison*. Poisoning cases should be managed following the same principles of triage and patient stabilization as other emergencies. Decontamination and antidote administration, if available, should follow initial stabilization.

A detailed history should be taken after the patient is stabilized but the following questions should be asked on presentation. To what toxicant was the animal exposed? What amount? When did the exposure occur? Has the patient shown any effects? Have any treatments been performed (e.g. dilution, emesis or bathing)? Have other animals also been exposed?

As in any emergency case, initial evaluation and stabilization of the patient should address the basic ABCs (*a*irway, *b*reathing, *b*leeding, *c*ardiovascular, *c*irculation and level of *c*onsciousness). The clinician must assure that the patient has an adequate airway and is not having difficulty breathing. If needed, an endotracheal tube should be placed or a tracheostomy performed to establish a patent airway. If the patient is dyspneic, 100% oxygen should be delivered via oxygen cage, mask or nasal cannula (Mathews, 2006). Oxygen supplementation is contraindicated in a paraquat exposure (Oehme and Mannala, 2006). Stress and handling should be minimized in a dyspneic patient.

The patient should be checked for bruising and for signs of active bleeding from the nose, mouth, anus and vulva or penis. The mucous membrane color and capillary refill time should be evaluated. Pulse rate, rhythm and strength should be assessed. Electrocardiogram (ECG) and blood pressure monitoring should also be performed. If needed, an intravenous (IV) catheter should be placed and fluid therapy initiated. Attempts should be made to control life-threatening arrhythmias (Mathews, 2006).

The patient's level of consciousness should be determined. If the patient is actively seizing, diazepam, given as an IV bolus at a dosage of 0.5–1 mg/kg, is often the initial drug used for dogs and cats. If this is not effective, other medications including phenobarbital, pentobarbital and propofol may be useful. Inhalant anesthesia may also be used to control the seizure activity (Mathews, 2006). The reader is referred to a formulary or reference on emergency seizure control for recommendations on doses and drug choices for the species being treated. Since some diagnostic tests, including that for ethylene glycol, may give false results once injectable medications are administered, the clinician should obtain blood samples prior to administering these medications. Body temperature should be checked and thermoregulation initiated if needed.

Once the patient has been stabilized a more thorough clinical evaluation can be completed including complete history, physical examination and appropriate diagnostic testing (Cantilena, 2001), and a treatment plan developed. The signalment and health history of the patient is important in developing a treatment plan. If the patient is a nursing or pregnant female, for example, precautions will need to be taken to prevent exposure to the fetus or young. Or if the patient is taking a highly protein-bound medication, it is more at risk from an overdose of another protein-bound drug. If there is no known exposure to a toxicant but poisoning is suspected based on presentation and clinical findings, the questions in Table 91.1 may be helpful to reveal a cause (Mathews, 2006).

Next, a complete treatment plan should be developed. It should include what method, if any will be used to prevent further toxin absorption and if an antidotal therapy will be used. The plan should address any clinical signs not addressed in the initial stabilization. It should list what additional findings may yet develop and a plan of action for each. The plan should define how often the patient will be monitored and what indices will be evaluated. And it should determine what diagnostic tests are appropriate for the situation. The treatment plan may need to be updated as the case progresses.

**TABLE 91.1 History gathering questions**

- When was the patient last normal?
- How long have the signs been present?
- Were there any initial signs that are no longer present?
- Was the onset of the signs gradual or sudden?
- Are there other pets in the area? Are they affected?
- What was the location of the animal in the last few hours prior to development of signs? Was the animal supervised?
- Is the animal indoors or outdoors mostly?
- If the animal is outdoors, is it confined or does it roam?
- To what areas of the home or garage does the animal have access?
- Have any new foods or treats been introduced to the animal's diet?
- Any access to sugar-free products?
- Has there been any recent access to garbage?
- Has the animal chewed or destroyed anything recently?
- Are there any medications in the house (human, veterinary, prescription, OTC)?
- Could the animal have been exposed to illicit drugs?
- Are there children or teenagers in the household?
- Have there been any recent visitors who may have dropped medication?
- Are there any rodenticides or other baits being used in the home or yard?
- Could the animal have ingested any plants (indoors or outdoors)?
- Have any medications, herbal products or insecticides been administered to this or any other animals in the household recently?
- Are there any mushrooms growing in the yard?
- Is there a compost pile in the yard?
- Have any yard treatments been applied recently?
- Are there any livestock in the animal's environment?
- Have any livestock been recently euthanized or buried on the property?

Diagnostic testing will be governed by clinical findings, history and in a known exposure, expected effects. The clinician should perform baseline testing and repeat as required throughout the course of the treatment. Appropriate testing may include a packed cell volume (PCV) and total solids (TS) to identify dehydration or blood loss in cases of anticoagulant exposure or agents that may cause gastrointestinal (GI) ulceration. A complete blood count (CBC) may be needed to check for inflammation or secondary infections in cases where GI ulceration and perforation are possible, such as in exposures to cationic detergents, corrosive materials or non-steroidal anti-inflammatory drug (NSAID) medications. Monitoring the CBC is also indicated in exposures that may cause bone marrow suppression such as estrogen overdoses.

A full chemistry panel is often appropriate. Blood glucose should be monitored closely with exposures to sulfonylurea hypoglycemic agents and in exposures to the sugar-free sweetener xylitol in dogs (Dunayer, 2004). Monitoring the renal values, blood urea nitrogen (BUN) and serum creatinine is important in many exposures to identify dehydration and renal alterations if the patient was exposed to potential renal toxicants such as lilies in cats (Volmer, 1999), grapes and raisins in dogs (Eubig *et al.*, 2005), NSAIDs and ethylene glycol. In these cases, urinalysis is also indicated. Electrolytes should be monitored in cases where IV fluid therapy is required and in cases where the toxicant may lead to electrolyte abnormalities. For example, hypokalemia is a common effect in dogs that puncture albuterol inhalers (Vite and Gfeller, 1994).

Monitoring of acid–base status is important in some cases such as exposures to aspirin and ethylene glycol. The cardiovascular system will need to be monitored via ECG and evaluating blood pressure in exposures to certain agents such as pseudoephedrine and methylxanthines in chocolate. Other general testing including pulse oximetry, radiographs and ultrasound may be required depending on the toxicant. Specific tests, such as an ethylene glycol test or serum iron panel, may also be suitable depending on the situation.

In addition to these physiological parameters, the patient's clinical signs, vitals, behavior and mentation should be monitored frequently for the duration of the treatment and abnormalities addressed. The frequency and degree of monitoring will depend on the situation. The patient's attitude should be noted regularly. Respiratory and cardiovascular status should also be checked at regular intervals, especially in cases where these systems may be affected by the toxicant. Capillary refill time and mucous membrane color can be used to assess peripheral perfusion. Body temperature should be monitored if the toxicant, clinical findings or treatments may cause abnormalities. Appetite, hydration status, bowel movements and urinary output should also be noted (Mathews, 2006).

# DECONTAMINATION

Once the patient has been stabilized, decontamination should be considered to prevent additional exposure to the toxicant. Although the basics of decontamination are similar amongst species, the specific method of decontamination that is chosen in each case must be guided by the exposure circumstances and the species exposed. For all decontamination methods, consider sedation or anesthesia if the procedure will be very stressful for the patient but only if the health of the patient will allow. The handler should wear appropriate protective clothing including gloves, mask and eye gear to prevent personal exposure. Most exposures to toxicants can be broken down into ocular, dermal and oral exposures. Following are methods of decontamination for each of these exposure types.

## Ocular exposure

Ocular exposures may cause effects ranging from mild irritation to corrosive injury and blindness depending on the substance, the concentration, the exposure time and the sensitivity of the patient. With any ocular exposure, the eyes should be flushed repeatedly with tepid tap water or saline solution for a minimum of 20–30 min (Rosendale, 2002). An eyedropper can be used for smaller patients like birds or reptiles. With a larger patient, fill a plastic cup and slowly pour the contents over the ocular area. Patients can be given a mild sedative prior to flushing if needed and if the health of the patient will allow. If not sedated, the patient should be allowed to rest at regular intervals during the flushing to minimize stress. Fluorescein staining should be performed after flushing and again at 12–24 h after exposure to check for corneal ulceration. Additional treatment with ophthalmic and systemic medications may be necessary.

## Dermal exposure

Dermal exposure to a large variety of substances, including petroleum products, pesticides and insecticides, corrosive or irritating materials and substances that are sticky (tar, asphalt, sap and glue) may occur. Removal of such substances may be less stressful for the patient and safer for the handler if sedation is used. Sedatives should only be used if the health of the patient will allow. If not sedated, the patient should be allowed to rest at regular intervals to minimize stress.

In birds, dermal substances can be removed by using a water bottle to spritz the bird lightly with room temperature water. This procedure should be done in a warm environment to prevent chilling. The bird should be misted until the feathers no longer smell or feel of the product. If misting alone does not remove the product, and a soap is needed, a liquid dishwashing detergent (e.g. Dawn™) may be diluted in the bottle and applied. After removal of the substance, the bird should be rinsed via misting with plain water until all soap is removed. In cases of heavy exposure, birds may be bathed with liquid dishwashing detergent and rinsed well. After misting or bathing, the bird should be wiped with a dry towel and kept in a warm environment away from drafts until completely dry. The procedure for reptiles is similar.

For dermal exposures in mammals, bathing in a mild liquid dishwashing detergent and warm water is recommended. Baths may be repeated in order to remove the toxicant completely (Rosendale, 2002). The animal should then be rinsed well with warm water and towel dried, then kept in a warm environment until completely dry. For smaller patients, like cats, that resent being sprayed with water, the bucket technique may be helpful. Fill a bucket with warm soapy water and, while supporting the hind legs, immerse the patient up to the neck. Remove the patient and continue washing. Use a fresh bucket with plain warm water to rinse well.

If the patient has a sticky substance on its fur, feathers or skin, do not use solvents to remove it since these may be irritating or corrosive to the patient. Instead, to remove sticky substances from mammals, remove as much of the substance as possible by trimming the fur. Then work a small amount of vegetable oil, mineral oil, mayonnaise or peanut butter through the rest of the substance until it breaks down into "gummy balls". Afterward, wash with liquid dishwashing detergent as described above (Rosendale, 2002). For birds, do not trim the feathers, just use vegetable oil, mineral oil, mayonnaise or peanut butter and then mist as described above.

## Oral exposure

When a patient is exposed to a potentially dangerous substance by ingestion, the clinician has many options for decontamination including dilution, induction of emesis, lavage, removal via endoscopy or gastrotomy, use of adsorbents, cathartics and administration of enemas. Oftentimes the best treatment plan will include more than one of these methods.

### *Dilution*

Dilution with a small amount of milk or water is recommended in cases where irritants or corrosive materials have been ingested. A suggested dose is 2–6 ml/kg (Mathews, 2006) which would be approximately only 1–2 teaspoons in an average-sized cat. It is important to use only a small amount of liquid for dilution. Using excessive amounts could lead to vomiting and re-exposure of the esophagus to the damaging material (Rosendale, 2002). For birds and reptiles, juicy fruits and vegetables can be fed to accomplish dilution. Dilution is not recommended in patients who are at an increased risk for aspiration, including those who are obtunded (Rosendale, 2002) or actively seizing. Additionally, milk, yogurt and cottage cheese have been useful as demulcents in cases of oral irritation following ingestion of plants containing insoluble calcium oxalate crystals (*Philodendron* species, for example) (Means, 2004b).

### *Emetics*

Emetics are usually most effective if used within 2–3 h post-ingestion (Rosendale, 2002) but in some instances emesis may be effective even after that time frame. For instance, if a timed-released medication was ingested or if the substance ingested could coalesce to form a bezoar in the stomach, emesis may be effective later than 3 h after the ingestion. Chocolate (Albretsen, 2004) and chewable medications may form bezoars. If the patient has not eaten in the previous 2 h, feeding a small moist meal before inducing vomiting can increase chances of an adequate emesis. Emetics generally empty 40–60% of the stomach contents (Beasley and Dorman, 1990).

Dogs, cats, ferrets and potbelly pigs are examples of domestic animals that are able to vomit safely. Emetics should not be used in rodents, rabbits, birds, horses and ruminants. Rodents are unable to vomit (Plumb, 2005) and rabbits have a thin-walled stomach putting them at risk for gastric rupture if they vomit (Donnelly, 2004). It is not safe to induce emesis in birds, horses or cattle.

Induction of emesis is contraindicated with ingestion of alkalis, acids or other corrosive agents. When one of these products is swallowed, the protective epithelial lining of the esophagus may be damaged. This damage can leave the muscular layer of the esophagus exposed and at risk for ulceration, perforation and scarring if vomiting does occur (Beasley and Dorman, 1990). Emesis is not recommended after ingestion of petroleum distillates due to the risk of aspiration. Pre-existing conditions of the patient that can cause vomiting to be hazardous, such as severe cardiac disease or seizure disorder, must also be taken into account by the clinician when deciding whether to induce emesis. In all instances the attending veterinarian must weigh the benefits of emesis against the risks. Emesis should not be attempted if the animal has already vomited or is exhibiting clinical signs such as coma, seizures or recumbency, which make emesis hazardous. Additionally, if the patient has ingested a central nervous system (CNS) stimulant and is already agitated, the additional stimulation of vomiting could elicit seizures (Rosendale, 2002).

### *Hydrogen peroxide*

Hydrogen peroxide, at a 3% concentration, is a useful emetic when given orally. It is an ideal emetic for household use because the 3% concentration is used in many households for cuts and scrapes. Additionally, it is inexpensive and easy to administer. Hydrogen peroxide is thought to induce emesis via gastric irritation (Peterson, 2006). The dosage is 1–2 ml/kg (Beasley and Dorman, 1990) generally not to exceed 50 ml for dogs and potbelly pigs and 10 ml for cats and ferrets (Peterson, 2006). The dose can be administered with a syringe or turkey baster (Rosendale, 2002) or can be mixed with a small amount of milk or ice cream to entice voluntary ingestion. Vomiting usually occurs within

10–15 min and the dose can be repeated once if emesis is not initially successful. Walking or other gentle movement may be beneficial in initiating emesis. More concentrated solutions of hydrogen peroxide, as found in hair bleaching agents or other products, should not be utilized to induce emesis as they can lead to protracted, severe vomiting and significant irritation of the GI mucosa (Rosendale, 2002).

### *Apomorphine hydrochloride*

Apomorphine hydrochloride is often used in the clinical setting to induce emesis in dogs. Use of apomorphine is considered controversial in cats since an effective and safe dose has not been established (Plumb, 2005). Nonetheless many veterinarians, including the author, have used apomorphine effectively in cats with limited adverse effects (Rosendale, 2002). Apomorphine hydrochloride is a synthetic opiate that stimulates the dopamine receptors in the chemoreceptor trigger zone to cause emesis. The dosage is 0.04 mg/kg intravenously (IV) or intramuscularly (IM). Emesis is expected rapidly following IV administration but may take 5 min with IM administration. Apomorphine can also be used conjunctivally by crushing and dissolving a portion of a tablet in a few drops of water. The solution is then administered into the conjunctival sac at a dose of 0.25 mg/kg (Plumb, 2005). This route may be preferred since the eye can be rinsed after emesis has occurred to prevent additional systemic absorption and decrease the likelihood of adverse events. At doses used to induce emesis, adverse effects may include CNS depression and protracted vomiting. CNS stimulation and respiratory and cardiac depression may be seen with excessive doses (Plumb, 2005). The opiate antagonist, naloxone, can be used to reverse the CNS and respiratory effects, but will not block the emetic effect (Rosendale, 2002).

### *Xylazine hydrochloride*

Xylazine hydrochloride is a potent $\alpha_2$-adrenergic agonist used in the veterinary clinic setting primarily as a sedative. It has also been used, with some success, as an emetic in cats (Beasley and Dorman, 1990). Xylazine does not produce predictable emesis in dogs (Plumb, 2005). The recommended emetic dose in cats is 0.44 mg/kg IM. This dose is lower than the dose used for sedation in cats. Emesis is expected within 5 min of administration. Possible adverse effects include CNS and respiratory depression, hypotension and bradycardia (Plumb, 2005). These effects, as well as the emetic effects (Beasley and Dorman, 1990), can be reversed by giving an $\alpha_2$-adrenergic antagonist; either yohimbine at a dosage of 0.5 mg/kg IV or atipamezole at a dosage of 50 mcg/kg IM (Plumb, 2005).

### *Other emetics*

Other emetics have been recommended by various sources, including table salt, liquid dishwashing liquid, syrup of ipecac and powdered mustard. However, these are not as effective as those mentioned, and salt and syrup of ipecac may cause significant adverse effects. Salt (sodium chloride) has been associated with hypernatremia and CNS dysfunction (Beasley and Dorman, 1990) and there are concerns that syrup of ipecac can be cardiotoxic (Rosendale, 2002). Human pediatricians no longer routinely recommend syrup of ipecac for home use. Further, the American Association of Poison Control Centers reported in 2001 that the use of ipecac in human exposures has fallen by >95% over a 15-year period (Shannon, 2003).

### *Lavage*

Lavage is sometimes used in cases where emesis is contraindicated, not possible or has been unsuccessful. If the patient is agitated, seizing or recumbent or has other health concerns, such as recent abdominal surgery, that increase the risks associated with induction of emesis, lavage is an option. Lavage should also be considered in species, like rabbits and rodents, which are unable to vomit safely. Lavage is unlikely to remove as much ingested toxicant as emesis (Beasley and Dorman, 1990) and is associated with significant potential risks (Rosendale, 2002). For these reasons, it should not be chosen haphazardly as a decontamination method over emesis. Lavage should also not be used to remove caustic substances or volatile hydrocarbons for the same reasons emesis is contraindicated in such cases (Rosendale, 2002).

Gastric lavage can be used in small mammals to remove recently ingested toxicants. If the patient is a species with cheek pouches, the cheek pouches should be emptied gently with a finger or swab prior to the lavage. General anesthesia must be performed when performing gastric lavage unless the patient is comatose. In all instances, a cuffed endotracheal tube should be in place to prevent aspiration. Body temperature water (5–10 ml/kg) should be instilled via a large bore gastric tube with a fenestrated end, inserted to a length equal to the distance from the nose to the xiphoid cartilage (Beasley and Dorman, 1990). The head of the patient should be kept lower than the chest throughout the procedure. Gravity should be used to instill the water by holding the tube higher than the patient and then drained by moving the tube lower than the patient. The flushing process should be repeated multiple times (15–40) until the lavage fluid runs clear. With each flush, approximately the same amount of fluid instilled should be removed. Occlude the free end of the tube before removal to prevent aspiration (Rosendale, 2002). The initial washings should be saved for toxicological testing if needed (Peterson, 2006).

When both gastric and intestinal decontamination is considered necessary, enterogastric lavage can be considered. The procedure involves first performing gastric lavage and leaving the lavage tube in place. A retrograde

high enema is then performed until the enema fluid passes through the lavage tube and runs clear (Peterson, 2006). Administration of a preanesthetic dose of atropine has been recommended prior to performing enterogastric lavage to relax the smooth muscles of the GI tract (Rosendale, 2002). This procedure is labor intensive and carries the same, although intensified, risks as lavage and should only be considered in cases where the benefits clearly outweigh the risks of the procedure.

In humans, hypernatremia following lavage with normal saline and hyponatremia following lavage with water have been reported. Additionally, one human study showed that as much as 25% of the fluid used for lavage passed into the small intestine. Thus there is a concern that lavage may actually propel a toxicant into the small intestine where the absorptive surface area is greater. These risks should be limited by allowing the entire amount of fluid to drain out after each flush and by using only gravity to instill the water. Other risks associated with gastric lavage include esophageal or stomach damage or perforation, hypothermia and the accidental placement of the tube in the trachea and the instillation of fluid into the lungs (Rosendale, 2002).

A lavage technique can also be used in birds to remove recently ingested toxicants from the crop. To prevent injury to patient and handlers, anxious and fractious birds should be anesthetized prior to the procedure. If the patient is under general anesthesia, an endotracheal tube should be placed to protect the airway (Richardson *et al.*, 2001). The patient should be held with the head up and the mouth held open. The bird's head and neck should be extended to minimize esophageal damage. An appropriately sized feeding tube (soft plastic or rubber) is then passed into the crop. The crop should be palpated to assure correct placement. Then 10–20 ml/kg of warm saline is infused into the crop, the crop is massaged gently and the liquid is aspirated. The first washing can be kept for toxicological evaluation if needed. The cycle is repeated three or four times (Echols, 2005).

### *Adsorbents*

Adsorbents may be utilized in addition to or instead of emesis or lavage to prevent further systemic absorption of a toxicant. These agents act by adsorbing to a chemical or toxicant in the upper GI tract and facilitating its excretion via the feces. The most commonly used adsorbent is activated charcoal. In the past, kaolin–pectin (Kaopectate®) had also been recommended as an adsorbent and demulcent in some instances. Kaolin is a form of clay (hydrated aluminum silicate) and pectin is a purified carbohydrate derived from fruits. However, Kaopectate®, and most generic kaolin–pectin combinations, now contain bismuth subsalicylate as the active ingredient instead of kaolin and pectin. Some commercial activated charcoal products also contain kaolin (Vet-A-Mix, Toxiban®). Another clay bentonite (colloidal hydrated silica) is recommended in some literature. In most instances, activated charcoal is a superior absorbent to the clays. Burnt toast had been recommended in the past but is no longer considered to be an effective adsorbent (Beasley and Dorman, 1990).

Activated charcoal is composed of large porous particles that are able to adsorb and therefore trap a wide range of organic compounds within the GI tract. It is created from materials such as coal, wood, rye starch and coconut shells through a process using steam and acid treatments. The surface binding area of these products is quite large, in the range of 900–1500 $m^2/g$ (Rosendale, 2002). Charcoal tablets and capsules, found in pharmacies and used to control flatulence and bloating, are not likely to be as effective as the commercially prepared products (Buck and Bratich, 1986) as the concentration of the charcoal is often low and may have a smaller binding area.

The recommended dose of activated charcoal for all species of animals is 1–3 g/kg (or 1–3 mg/g) body weight (Buck and Bratich, 1986). There are many products on the market, including both liquid and powder forms. If using the powder formulation in dogs and cats, the total calculated dose of activated charcoal is mixed with 50–200 ml of warm tap water to make a slurry (Rosendale, 2002). In horses and ruminants, each gram of activated charcoal powder is mixed with 3–5 ml of water (Plumb, 2005). In symptomatic small animal patients and large animals, the activated charcoal liquid or prepared slurry is administered via stomach tube (Bailey and Garland, 1992). Small animals receiving activated charcoal via stomach tube should be sedated and have a cuffed endotracheal tube in place to prevent aspiration. In small animal patients where no clinical effects are present, activated charcoal can be given orally with a large syringe or can be mixed with a small amount of canned food or chicken broth and offered to the patient (Rosendale, 2002). Some patients, especially dogs, will voluntarily ingest the mixture. Many birds will regurgitate a portion of the activated charcoal dose given and some dogs and cats will vomit after administration.

Repeated doses of activated charcoal may be indicated in some instances such as cases where toxicants undergo enterohepatic recirculation. The first step in this process involves the toxicant being carried to the liver by either the portal vein after absorption from the GI tract or via the systemic circulation. Once in the liver the toxicant then enters the bile and is excreted into the GI tract where it is again available for absorption. Many toxicants are known to undergo this type of recycling, including ibuprofen, marijuana and digoxin.

Another instance where multiple doses of activated charcoal are appropriate is ivermectin toxicosis. Ivermectin is a substrate for the P-glycoprotein pump that transports some drugs across cell membranes. This pump is found in various cells including intestinal epithelial cells and brain

capillary endothelial cells. In the intestine, ivermectin enters the enterocyte by absorption from the GI tract. However, once in the cell, the P-glycoprotein pump acts to move the ivermectin across the membrane and back into the GI lumen. This cycling allows the ivermectin molecules to have multiple opportunities to bind with the repeated doses of activated charcoal. Loperamide, diltiazem and doxyrubicin are some other substrates of P-glycoprotein (Mealey, 2006).

When repeated doses are indicated, half the original dose should be given at 4–8 h intervals, often for 2–3 days (Peterson, 2006). It is important to mention that with medications that are excreted in the bile, activated charcoal can be of benefit regardless of the route the medication was administered. Thus if a patient received an overdose of injectable ivermectin subcutaneously, activated charcoal will still be a very valuable decontamination option. The ivermectin molecules will be carried to the GI tract by the bile and then be subject to the P-glycoprotein pump within the enterocytes.

The use of activated charcoal does carry some risks and it does not bind all compounds equally. Some chemicals that are not effectively adsorbed include: ethanol, methanol, fertilizer, fluoride, petroleum distillates, most heavy metals, iodides, nitrates, nitrites, sodium chloride and chlorate. Activated charcoal should not be given to animals that have ingested caustic materials since it is unlikely to bind them, it can be additionally irritating to the mucosal surfaces and make visualization of oral and esophageal burns difficult (Buck and Bratich, 1986). If ethylene glycol testing will be performed, activated charcoal should be administered after blood is collected, since propylene glycol found in many formulations can cause a false positive on this test. Additionally, the timing of the activated charcoal administration should be taken into account when deciding on dosing of other oral medications since the charcoal can also bind them. In APAP overdose in humans, for example, it is recommended that *N*-acetylcysteine (NAC) not to be administered orally until 3 h after activated charcoal (Plumb, 2005).

Administration of activated charcoal carries a significant risk of aspiration. If the patient does aspirate the charcoal, the prognosis is poor. Hence proper placement of the stomach tube and a protected airway is a must in symptomatic patients. The patient may also experience constipation and black bowel movements making it difficult to determine if melena is present. If the activated charcoal sits within the GI tract for a significant period of time, it may release the compound it has adsorbed, leading to systemic absorption and recurrence of the clinical signs. It is for this reason that activated charcoal is frequently administered with a cathartic. In fact, many commercially available preparations do contain a cathartic such as sorbitol.

Another possible adverse effect of activated charcoal administration is the development of hypernatremia. In humans, hypernatremia has been reported primarily in children when multiple doses of a charcoal–sorbitol mixture were administered. The hypernatremia is attributed to a water shift from the intracellular and extracellular spaces into the GI tract as a result of the osmotic pull of the sorbitol cathartic (Allerton and Strom, 1991). The ASPCA Animal Poison Control Center (APCC) has also received reports of elevated serum sodium following activated charcoal administration in dogs. Hypernatremia seems to be more often reported in small dogs receiving multiple doses of activated charcoal, but it has also been reported in large dogs and in cases receiving only a single dose. Furthermore, unlike the human reports, hypernatremia has also been noted in cases where no cathartic was present in the charcoal product given (APCC, unpublished data). Perhaps one of the other components of the product is also osmotically active. In these cases, the APCC has found that administration of a warm water enema is very effective at lowering the serum sodium and easing the resultant CNS effects.

### *Cathartics*

Cathartics enhance elimination of substances, including activated charcoal, by promoting their movement through the GI tract. Since activated charcoal only binds to toxicants by weak chemical forces, without cathartics the bound toxicant can eventually be released and reabsorbed (Rosendale, 2002). When used with activated charcoal, the cathartic should be given immediately following or mixed with the charcoal. Cathartics are contraindicated if the animal has diarrhea, is dehydrated, if ileus is present, or if intestinal obstruction or perforation is possible (Peterson, 2006).

There are bulk, osmotic and lubricant cathartics. The most commonly used bulk cathartic is psyllium hydrophilic mucilloid (e.g. Metamucil®). Psyllium is found in the ripe seed coatings of *Plantago* species. It absorbs water and swells in the intestine increasing bulk to induce peristalsis and decrease GI transit time. The dose in dogs is 1–2 tablespoons, and the dose in cats is 1–4 teaspoons (Plumb, 2005). Psyllium can also be used in birds by mixing ½ teaspoon with 60 ml of baby food to form a gruel, then administering by a dosing syringe or eyedropper (Richardson *et al.*, 2001).

Another bulking cathartic that can be used in dogs and cats is unspiced canned pumpkin. Dilute peanut butter, fruit or vegetables can also be used as bulking cathartic agents in birds and reptiles. Timothy hay can be utilized in rabbits. Bulking cathartics are also used to assist the passage of physical agents through the GI tract (Beasley and Dorman, 1990). Examples include small pieces of plastic, coins, button batteries and sand in horses (Plumb, 2005).

Osmotic cathartics have limited absorption from the GI tract so that they are able to pull electrolyte-free water

into the GI tract, thereby increasing the fluid volume and stimulating motility to hasten expulsion in the feces. There are saline and saccharide osmotic cathartics. Sorbitol is the most commonly used saccharide osmotic cathartic; it is the cathartic of choice and is frequently combined with activated charcoal in commercially prepared charcoal products. The dose is 1–2 ml/kg of a 70% solution (Peterson, 2006). Sorbitol can be utilized in mammals, birds and reptiles. The saline cathartics include sodium sulfate (Glauber's salts) and magnesium sulfate (Epsom salts). The recommended dose is 250 mg/kg. The use of magnesium sulfate has led to hypermagnesemia in some cases which presents as depression of the CNS and cardiovascular systems (Rosendale, 2002). Saline cathartics should not be used in patients with renal insufficiency or in birds or reptiles.

Of the lubricant cathartics, mineral oil is the most often used. Heavy mineral oil is preferred to light mineral oil since it is thought to carry less of a chance of systemic absorption and aspiration following oral administration. Mineral oil lubricates fecal material and the intestinal mucosa easing elimination and reduces absorption of water from the GI tract, increasing fecal bulk and cutting transit time (Plumb, 2005). Mineral oil is not recommended as a cathartic following activated charcoal administration as the mineral oil may render the charcoal less adsorptive (Buck and Bratich, 1986; Galey, 1992). Mineral oil has been recommended to bind lipid-soluble toxicants including metaldehyde, nitrate and cantharidin (Stair and Plumlee, 2004; Plumb, 2005) and is used to treat impaction in horses (Buck and Bratich, 1986). The recommended dose in horses is 2–4 l per 500-kg body weight (Brown and Bertone, 2001). Possible adverse effects include diarrhea and aspiration of the oil leading to lipid pneumonitis. Ensuring proper placement of the stomach tube and slow administration lessen the risk of aspiration (Plumb, 2005).

As mentioned above, hypernatremia attributed to sorbitol administration has been reported in humans. Because all cathartics alter the water balance in the GI tract, electrolyte abnormalities, especially hypernatremia, are a potential risk to their use. A patient's hydration status should be monitored frequently and fluids administered, IV or via an enema, as needed.

### *Enemas*

Enemas are also appropriate when elimination of toxicants from the lower GI tract is desired (Beasley and Dorman, 1990). Many extended-release or controlled-release medications are absorbed from the entire GI tract, including significant absorption from the colon (Buckley *et al.*, 1995). An enema is used to move those medications quickly through the colon and lessen additional systemic effects. The general technique is to use plain warm water or warm soapy water. Commercial phosphate enema solutions should be avoided due to the risk of electrolyte and acid–base disturbances (Beasley and Dorman, 1990). Enemas are not recommended for birds since they already have a rapid GI transit time. In reptiles, enemas may be useful since ingested materials often lag for prolonged periods in the colon.

In some cases, *endoscopy* or *gastrotomy* may be indicated to prevent further clinical effects. Endoscopy can be used to remove small objects such as pennies, lead paint chips and small batteries. Pennies, minted after 1982, contain a significant amount of zinc which can be released by the acidic environment of the stomach. Since zinc toxicosis can cause hemolytic anemia, it is prudent to remove the coin to prevent release and systemic absorption of the zinc (Richardson *et al.*, 2002). Coins can be removed via gastrotomy if endoscopy is not available. Gastrotomy is also used to prevent obstruction from expanding foreign objects. Uncooked yeast dough can rise in the warm environment of the stomach and produce an obstructive mass. In addition, as the dough rises, ethanol is released which can be absorbed from the stomach and lead to alcohol poisoning (Means, 2003). Expandable isocyanate-containing glues (i.e. Gorilla Glue™) can swell once ingested to fill the entire volume of the stomach. A gastrotomy is needed in these cases to remove the mass (Horstman *et al.*, 2003).

## ANTIDOTAL THERAPIES

If an antidote to the toxicant a patient has been exposed to exists, the appropriate time to administer it will depend on the situation. In some instances, the antidote will be crucial in stabilizing the patient. For example, atropine should be used immediately in cases of organophosphate (OP) toxicosis in which the patient has life-threatening bradycardia and bronchial secretions (Gwaltney-Brant, 2002). On the other hand, in some cases, administration of the antidote is best done later. This is true for vitamin $K_1$ being used in anticoagulant rodenticide exposures. In a recent exposure, decontamination first would be the most appropriate course of action. In an anticoagulant patient that is symptomatic, supportive measures like a blood transfusion should be started first since the vitamin $K_1$ will not be immediately lifesaving (Merola, 2002).

Unfortunately few antidotes exist. There is little economic incentive for pharmaceutical companies to seek approval for antidotal medications with only a small projected market (Post and Keller, 1999). Additionally, organizing clinical trials for antidotal medications is uniquely problematic. The US Food and Drug Administration (FDA) has offered incentives to develop antidotal therapies through the Orphan Drug Act. As a result, at least one antidotal therapy was released for veterinary

patients: fomepizole was approved for use in treating ethylene glycol intoxication (Cantilena, 2001). In situations where an antidote does exist, its use may be limited by its expense or availability.

Antidotes are generally divided into three groups, based on the mechanism by which they are protective. The groups are chemical antidotes, pharmacological antidotes and functional antidotes. Chemical antidotes act directly on the toxicant. They may decrease the toxicity of the agent or increase its excretion. Pralidoxime chloride, for example, does both; it binds to OP insecticide molecules making them unable to bind to their target and the pralidoxime–insecticide complex is then readily excreted (Mowry *et al.*, 1994).

Pharmacological antidotes antagonize the poison at the target site. Flumazenil, for example, has a high affinity for benzodiazepine receptors, thus it competes with benzodiazepines to reverse their depressive effects (Gwaltney-Brant, 2002). Functional antidotes act to lessen the symptoms of the poisoning. They have no interaction with the toxicant. An example of a functional antidote is the use of methocarbamol to control fasciculations and tremors associated with tremorgenic mycotoxins (Schell, 2000). Below are some examples of antidotal therapies available for use in veterinary medicine.

## Antidotes for amitraz: atipamezole and yohimbine

Amitraz, a synthetic formamidine pesticide, is used topically to control ticks, mites and lice on cattle, pigs and dogs, as well as to treat demodectic mange in dogs (Grossman, 1993). It is also available in a collar form (Preventic®) for tick control in dogs. The acaracide action of amitraz is not well understood, but it may have effects on the CNS of susceptible organisms. It also exhibits significant $\alpha$-2 adrenergic agonist activity (Plumb, 2005). This activity is believed to be responsible for the clinical signs associated with amitraz toxicosis including ataxia, CNS depression, hypotension, hyperglycemia, mydriasis, hypothermia, GI stasis and bradycardia (Grossman, 1993; Gwaltney-Brant, 2004). In dogs, toxicosis can occasionally result from exposure to a topical product but is more commonly due to ingestion of an amitraz-containing collar (Grossman, 1993; Gwaltney-Brant, 2004).

### *Atipamezole*

Atipamezole (Antisedan®) is an $\alpha$-2 adrenergic antagonist labeled for use as a reversal agent for the sedative medetomidine. It has been used successfully in the treatment of amitraz toxicosis to reverse CNS depression, bradycardia, GI stasis and hyperglycemia (Grossman, 1993; Gwaltney-Brant, 2004). The recommended dose in dogs is 50 mcg/kg IM (Plumb, 2005). The drug has a good margin of safety; dogs injected with 10 times the therapeutic dose did not have significant effects. Potential adverse effects of atipamezole administration include vomiting, diarrhea, hypersalivation, a brief period of excitation or apprehensiveness and tremors (Plumb, 2005). In cases where an amitraz collar was ingested and has not been retrieved from the GI tract, the atipamezole dose may need to be repeated each time signs recur until the collar is passed through the GI tract.

### *Yohimbine*

Yohimbine is another $\alpha$-2 adrenergic antagonist that has been used to counter the toxic effects of amitraz. The recommended dose in dogs is 0.1 mg/kg IV. Yohimbine has a short half-life (1.5–2 h in dogs), consequently the dose may need to be repeated. Potential adverse effects include temporary apprehension or CNS excitation, tremors, hypersalivation, elevated respiratory rate and hyperemic mucous membranes. Careful dosing is recommended, because tremors and seizures have been reported in dogs receiving five times the therapeutic dose (Plumb, 2005).

## Antidotes for anticholinesterase agents: atropine and pralidoxime

### *Atropine*

Atropine is used to counter the muscarinic effects of anticholinesterase (AChE) agents. Acetylcholine (ACh) is a neurotransmitter that transmits impulses at cholinergic nerve synapses and neuromuscular junctions. The enzyme AChE is responsible for the catabolism of ACh. AChE agents, which include the carbamate and OP insecticides, produce their effects by binding with AChE to disrupt the break down of ACh. The ACh accumulates within the synapse leading to over-stimulation of the end organ (Meerdink, 2004). There are two basic cholinergic receptor types: muscarinic and nicotinic. The muscarinic are the postganglionic parasympathetic receptors in smooth muscle, the heart and endocrine glands. Over-stimulation of these receptors leads to a complex of signs, often described as SLUDDE, which includes *s*alivation, *l*acrimation, *u*rinary incontinence, increased peristalsis and *d*iarrhea, increased bronchial secretions and *d*yspnea, miosis, nausea, *e*mesis and abdominal discomfort. Excessive stimulation of the nicotinic receptors, which are found in the skeletal muscles and autonomic ganglia, leads to tremors, and possibly seizures, potentially followed by muscle fatigue, weakness and paralysis (Meerdink, 1989).

Atropine competes with the accumulated Ach in the synapse to block only the muscarinic effects. Atropine does not block the nicotinic effects. The dosage used to counter AChE agents is: dogs and cats 0.2–2 mg/kg; cattle

0.5 mg/kg; horses 0.22 mg/kg. In all of those species, ¼ of the dose is given IV and the remainder intramuscularly (IM) or subcutaneously (SC) (Plumb, 2005). In some cases, administration of atropine may need to be repeated but great care should be exercised to prevent over-atropinization. Auscultation should be performed to monitor the patient for bradycardia and continued bronchial secretions, since these are the most life-threatening of the muscarinic signs. Additional atropine should only be given if these signs are present. The patient will not die from miosis or hypersalivation. Horses are quite susceptible to ileus caused by atropine administration, and a total dose of no more than 65 mg is recommended for a horse of average weight (Meerdink, 2004).

Atropine is not an effective antidote for other types of insecticides including pyrethroids. Because some of the signs of pyrethroid exposure, including tremors, seizures and hypersalivation, are also present with AChE agents, some veterinarians may erroneously administer atropine in these cases. Atropine is not only ineffective for pyrethroid toxicosis but in fact contraindicated, because it could exacerbate the CNS stimulatory effects and tachycardia that may be present in these cases. When presented with a suspected case of AChE exposure, the clinician can use a test dose of atropine to assist in making a preliminary diagnosis. The patient should be given the preanesthetic dose of atropine (0.02 mg/kg) IV. If this dose is able to produce typical anticholinergic signs such as mydriasis and tachycardia, then the patient has likely NOT been poisoned by an AChE agent (Fikes, 1990). If the patient truly had been poisoned by an AChE agent, the dose of atropine required to produce those effects would be at least 10 times higher (0.2 mg/kg).

### *Pralidoxime chloride*

Pralidoxime chloride (2-PAM) is used with atropine in the treatment of OP poisoning to relieve nicotinic signs such as tremors and muscle weakness (Fikes, 1990). 2-PAM reactivates the acetylcholinesterase enzyme (AChE) that has been inactivated by the OP. Normally acetylcholine (ACh) binds to the enzyme at the anionic binding site. OPs and carbamates bind nearby on the esteric site thus physically blocking the anionic site from ACh and inactivating the enzyme. 2-PAM is able to squeeze in via nucleophilic attack and bind to the anionic binding site. It then attaches to the OP forming a pralidoxime–OP complex. This complex detaches from the enzyme reactivating it and is then excreted in the urine (Fikes, 1990; Mowry *et al.*, 1994; Plumb, 2005). Please see Figure 91.1.

Administration of 2-PAM is most effective if given within 24 h of exposure (Plumb, 2005). If the OP remains attached to the AChE much longer, aging of the bond may occur so that it can no longer be broken by 2-PAM (Meerdink, 1989; Mowry *et al.*, 1994). There are instances when later administration is warranted. For example, in large OP exposures, pralidoxime may still be of some benefit if given within 36–48 h (Plumb, 2005). And 2-PAM may still be indicated even later if clinical signs have been present for an extended period of time (Fikes, 1992). Please see Table 91.2 for dosing information.

Treatment with 2-PAM should continue until the animal is asymptomatic. If no improvement is seen after 24–36 h following initiation of treatment, 2-PAM should be discontinued (Fikes, 1990). In acute feline chlorpyrifos toxicosis, cats with persistent tremors can be maintained on 1–2 times daily treatment for up to 4 weeks (Fikes, 1992). The typical presentation in these cats differs from the classical signs expected from other OPs. The onset may be delayed 1–5 days and the cats have neurological signs, including tremors, especially of the muscles of the back, neck and top of head, ataxia and seizures in addition to non-specific depression and anorexia which can persist 2–4 weeks (Fikes, 1992).

As indicated in Table 91.2, when given IV, administration of 2-PAM should be slow. Rapid IV administration can cause tachycardia, muscle rigidity, transient neuromuscular blockade and laryngospasm (Plumb, 2005). At therapeutic doses, 2-PAM is generally safe and has no significant adverse effects (Plumb, 2005). However, careful dosing is recommended. At high doses, 2-PAM may exhibit AChE activity including muscle weakness, ataxia, vomiting, hyperventilation, seizures, respiratory arrest and death. The LD50 in dogs is 190 mg/kg (Plumb, 2005).

Patients receiving 2-PAM should be monitored for hypersensitivity reactions (Plumb, 2005). 2-PAM is generally not recommended for carbamate toxicosis because AChE inhibition due to carbamates is rapidly reversible (Plumb, 2005), and 2-PAM has less affinity for carbamates than OPs (Meerdink, 2004). In addition, there is evidence that 2-PAM can reduce the protective effects of atropine in the treatment of one carbamate, carbaryl (Fikes, 1990). Since the drug is excreted by the kidneys, patients with underlying renal impairment should receive a decreased dose and be monitored closely for signs of toxicity (Plumb, 2005).

## Cyproheptadine HCl

Cyproheptadine HCl has been successful in treating serotonin syndrome in dogs and people (Gwaltney-Brant, 2002). Cyproheptadine is an antihistamine that is most commonly utilized in veterinary practice as an appetite stimulant for cats. It also is a potent serotonin antagonist (Plumb, 2005).

Serotonin is a neurotransmitter in the CNS. It also acts to promote platelet aggregation and as a stimulant on the smooth muscle of the respiratory, GI and cardiovascular systems. The term serotonin syndrome is used to describe

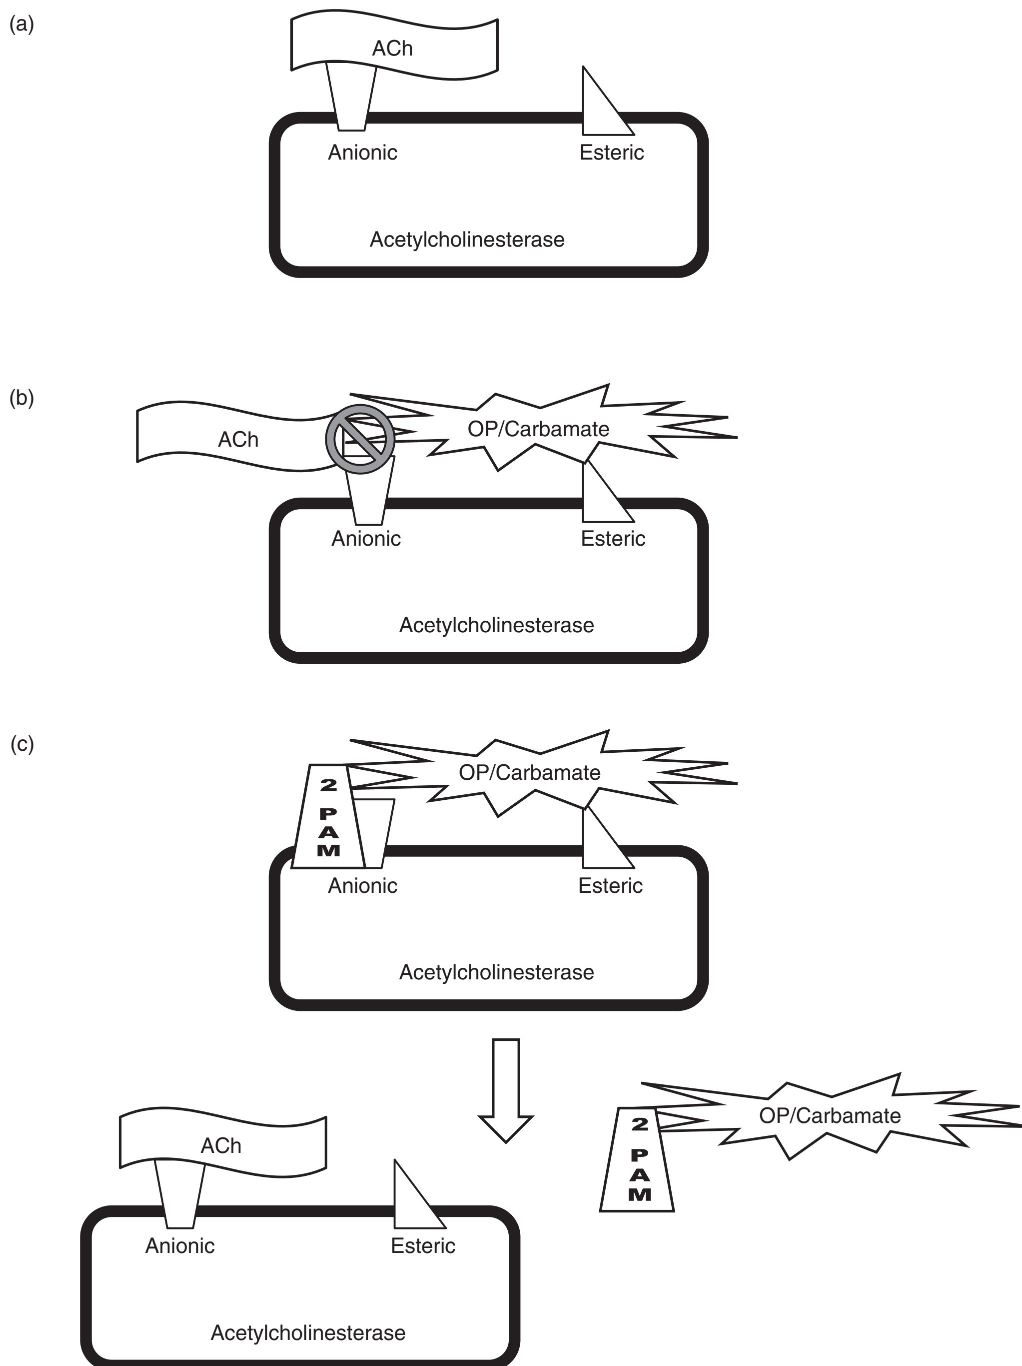

**FIGURE 91.1** Acetylcholinesterase binding and 2-PAM (Mowry et al., 1994). (a) ACh binds normally to the anionic site; (b) ACh cannot bind to the anionic site because the OP is blocking it; (c). 2-PAM slips in to bind to the site, forms 2-PAM-OP complex and detaches to reactivate the enzyme.

the characteristic signs which develop from excessive serotonin including autonomic, neuromuscular, behavioral and cognitive abnormalities (Gwaltney-Brant *et al.*, 2000). Excess serotonin may result from use or accidental overdose of medications that increase brain serotonin levels. These medications include selective serotonin reuptake inhibitors (SSRIs), like venlafaxine (Effexor®), paroxetine HCl (Paxil®) and fluoxetine HCl (Prozac®), as well as 5-hydroxytryptophan which is a serotonin precursor sold OTC as a dietary supplement. See Table 91.3 for a list of medications that carry a high potential of increasing brain serotonin levels (Gwaltney-Brant, 2002).

Dogs with serotonin syndrome typically have hyperthermia, central nervous abnormalities including tremors, seizures, ataxia, excitation or depression and hyperesthesia, and GI effects of vomiting, diarrhea and abdominal discomfort (Gwaltney-Brant, 2002). Death is possible if the signs are not controlled quickly. When used as a serotonin antagonist, the recommended dose of cyproheptadine in dogs is 1.1 mg/kg up to every 8 h until signs do

**TABLE 91.2 Pralidoxime dosing in OP treatment**

| Species | Dosing instructions |
|---|---|
| Dogs and cats | Pralidoxime works best when combined with atropine<br>Pralidoxime at 20 mg/kg, 2–3 times a day<br>Initial dose may be given either IM or slow IV<br>Subsequent doses may be given IM or SQ |
| Cattle | 25–50 mg/kg as a 20% solution IV over 6 min or as a maximum of 100 mg/kg/day as a CRI IV infusion |
| Horses | 20 mg/kg (may require up to 35 mg/kg) slow IV and repeat every 4–6 h |

**TABLE 91.3 Drugs with high serotonergic potential**

| | |
|---|---|
| Amitriptyline (e.g. Elavil®) | Lithium |
| Amphetamines (e.g. Adderall®) | Meperidine (e.g. Demerol®) |
| Clomipramine (e.g. Clomicalm®) | Moclobemide |
| Dexfenfluramine | Paroxetine (e.g. Paxil®) |
| Fenfluramine (e.g. Ponderal®) | Phenelzine |
| Fluoxetine (e.g. Prozac®) | Selegiline (e.g. Anipryl®) |
| Hydroxytryptophan | Sertraline (e.g. Zoloft®) |
| Imipramine (Tofranil®) | Tranylcypromine |
| Isocarboxazid | Tryptophan |
| | Venlafaxine (e.g. Effexor®) |

not recur (Gwaltney-Brant, 2006). The dose can be given orally if the patient is alert, not vomiting and activated charcoal was not given within 2 h. In those instances, the dose can be crushed, mixed with a small amount of saline and given per rectum. The drug should be discontinued after the first 2 doses if little or no improvement is noted (Gwaltney-Brant *et al.*, 2000). A similar dose of cyproheptadine has also been of some benefit in controlling vocalization and disorientation in some cases of baclofen toxicosis (Wismer, 2004).

## Digoxin immune Fab

Digoxin immune Fab fragments (e.g. Digibind® from Glaxo SmithKline) are a promising treatment for life-threatening digoxin toxicosis. The Fab fragments are used as a specific antidote for digoxin since they inactivate the drug by directly binding to it. The fragments are produced by first immunizing sheep with digoxin–human albumin complexes. In response, the sheep produce antibodies that are collected, purified and cleaved with papain into Fab fragments and Fc portions (Kittleson and Kienle, 1998). Digoxin immune Fab fragments are quite expensive, so their use may be cost prohibitive and they may be difficult to obtain. A local human hospital pharmacy may be willing to sell the product to the veterinary clinic if needed.

**TABLE 91.4 Plants containing cardiac glycosides**

| Plant species | Common name |
|---|---|
| *Acokanthera oblongifolia* | |
| *Adonis microcarpa* | Pheasant's eye |
| *Asclepias physocarpa* | Balloon cotton bush |
| *Byrophyllum tubiflorum* | Mother of millions |
| *Calotropis procera* | King's crown |
| *Carissa laxiflora* | |
| *Cerbera manghas* | Sea mango |
| *Convallaria majalis* | Lily of the valley |
| *Crytostegia grandioflora* | Rubber vine |
| *Helleboros* | |
| *Nerium oleander* | Oleander |
| *Thevetia neriifolia* | Yellow oleander |

Digoxin and other digitalis glycosides are thought to cause their effects by inhibition of the sodium–potassium ATPase pump (Na/K ATPase) through competition with potassium for binding sites (Kittleson and Kienle, 1998). Fab fragments can actually remove a digoxin molecule that is bound to the ATPase since their affinity for digoxin is much stronger than the affinity of digoxin for the Na/K ATPase target (Gwaltney-Brant, 2002). Fab fragments may also be used as an effective antidote for digitoxin toxicosis since they bind to it, though with less affinity than for digoxin. Moreover, sufficient cross reactivity exists with cardiac glycosides derived from *Bufo* toads and a wide variety of plants; consequently, Fab fragments may be effective at controlling toxicoses from these agents as well (Clark *et al.*, 1991; Gwaltney-Brant, 2002). Please see Table 91.4 for a list of plants containing cardiac glycosides that Fab fragments may be effective against.

The antidotal use of Fab fragments is indicated for treatment of potentially life-threatening cardiac glycoside toxicoses. Fab fragments should be considered when the patient has developed cardiac arrhythmias that are unresponsive to other antiarrhythmic therapy (Gwaltney-Brant, 2002). Ideally, the appropriate dose of Fab fragments is determined by using the patient's serum digoxin level. In some cases, the laboratory at a local human hospital may be willing to perform serum levels for the veterinarian. If a serum level can be obtained, the following formula is used to calculate the number of vials (Gwaltney-Brant, 2002). This formula assumes each vial will bind 0.5 mg of digoxin:

$$\text{Dose (number of vials)} = \text{Serum digoxin concentration (ng/ml)} \times \text{Body weight (kg)}/100$$

In cases where the cost of the calculated number of vials is prohibitive, if digoxin levels cannot be measured, or if the Fab fragments are being used to treat another cardiac

glycoside, treatment can be initiated with 1–2 vials and the patient observed for improvement. The reconstituted Fab fragments are administered over approximately 30 min. If the clinician feels the patient's clinical signs are immediately life threatening, the product can instead be given as a bolus. Fab fragments act quickly and dramatically. The patient's cardiac status is expected to begin improving within 20–90 min of administration and complete resolution of the clinical effects is usually seen within 4 h (Gwaltney-Brant, 2002). If significant improvement does not occur, additional vials may need to be given.

While monitoring the patient, it is important to note that the total serum digoxin concentration will be markedly increased with most commercial assays after Fab fragment administration. This occurs because previously tissue-bound digoxin binds to the Fab fragments, and the Fab–digoxin complexes then move into the blood to be excreted by the kidneys (Ward *et al.*, 1999). Since these patients have a compromised cardiovascular system as a result of the toxicosis, it is likely that renal perfusion is also compromised. These animals should be monitored carefully because decreased renal clearance of Fab–digoxin complexes may allow for dissociation of the toxin and recurrence of signs (Gwaltney-Brant, 2002).

The patient should also be monitored for hypokalemia. Elevated serum potassium is expected with cardiac glycoside toxicosis due to interference with the Na/K ATPase pumps. After administration of the Fab fragments, potassium moves quickly back into the cells leading to a significant drop in serum potassium levels. Serum potassium levels should be checked frequently within the first few hours and hypokalemia treated if needed (Gwaltney-Brant, 2002). The patient should also be monitored for anaphylaxis, fever and hypersensitivity reactions (Ward *et al.*, 1999).

## Antidotes for ethylene glycol: ethanol and fomepizole

### *Ethanol*

Ethanol can be used as an antidote for ethylene glycol poisoning. Ethylene glycol is found in many products at many concentrations. Most animal intoxications occur from ingestion of antifreeze since these products may have concentrations of ethylene glycol exceeding 90%. With intoxication, the GI, central nervous, cardiopulmonary and renal systems can be affected. Death is usually due to acute renal failure. The ethylene glycol itself does not cause the life-threatening clinical findings. It must be converted, primarily in the liver, to its more toxic metabolites including glycolic, glycoxalic and oxalic acids (Dalefield, 2004). The first step in the metabolism is conversion of the parent ethylene glycol molecule to glycoaldehyde via the enzyme alcohol dehydrogenase (ADH). Ethanol is also metabolized by ADH. It acts to block this conversion by competing for the enzyme, allowing time for ethylene glycol to be excreted unchanged in the urine (Mathews, 2006). Early intervention is very important to prevent the conversion to toxic metabolites. If a toxic dose was ingested and treatment is not initiated within a few hours of exposure, the patient's prognosis is grave.

**TABLE 91.5 Ethanol dosing in ethylene glycol treatment**

| | Intermittent dosing | CRI |
|---|---|---|
| Dogs | • Start with a 20% solution<br>• Give 5.5 ml/kg IV q4 h for 5 treatments<br>• Then give 5.5 ml/kg IV q6 h for 4 additional treatments | • Start with a 5% solution<br>• Give at CRI rate of 5.5 ml/kg/h until ethylene glycol test is negative |
| Cats | • Start with a 20% solution<br>• Give 5 ml/kg IV q6 h for 5 treatments<br>• Then give 5 ml/kg IV q8 h for 4 additional treatments | • Start with a 5% solution<br>• Give at CRI rate of 5 ml/kg/h |

The dosing recommendations for ethanol vary among authors. Intermittent dosing is possible but a constant rate infusion (CRI) is preferred to avoid high blood concentrations of the ethanol which can acerbate the potential clinical effects (Mathews, 2006). Please see Table 91.5 for examples of intermittent and CRI dosing recommendations for dogs and cats (Plumb, 2005). The ethylene glycol test by PRN Pharmaceutical Inc. can be used in dogs to determine when it is safe to discontinue ethanol treatment. The test measures serum concentrations $>50$ mg/dl. Since ethanol interrupts the metabolism of ethylene glycol, ethanol treatment should be continued until the test is negative indicating the parent ethylene glycol has been eliminated via the kidneys (Mathews, 2006). The test is not sensitive enough to be used in cats since they are significantly more sensitive to ethylene glycol intoxication than dogs and could develop life-threatening effects at serum concentrations $<50$ mg/dl. Treatment duration in cats should be based on clinical signs and laboratory findings; treatment may need to continue for more than 18 h (Mathews, 2006).

Ethanol is easy to obtain and is inexpensive. However, significant adverse effects will likely develop at the high doses required for treatment of ethylene glycol toxicosis including severe respiratory and CNS depression and metabolic acidosis. Since the signs of ethylene glycol intoxication mirror those effects, gauging patient progress can be challenging (Plumb, 2005).

### *Fomepizole*

Fomepizole, also called 4-methylpyrazole (4MP), is marketed as Antizol-Vet® by Jazz Pharmaceuticals as an antidote for ethylene glycol toxicosis in dogs. Recent studies

have found that 4MP can also be used in cats but must be used at higher doses to be effective (Connally *et al.*, 2002). 4MP is a synthetic ADH inhibitor that works similar to ethanol to prevent the conversion of ethylene glycol to its toxic metabolites. However, while ethanol acts by competing for the enzyme, 4MP forms a complex with ADH and its coenzyme (Connally *et al.*, 1996). Fomepizole is significantly more expensive than ethanol but has a therapeutic advantage because it causes fewer serious side effects (Gaddy, 2001). Dose-related CNS depression is the only adverse effect expected and tends to be mild if it develops. Cats are more at risk, because they require higher doses. Since 4MP has few serious risks, treatment is recommended in cases where exposure to ethylene glycol is suspected but not confirmed (Gwaltney-Brant, 2002).

4MP is excreted in the urine and accumulates over time depending on the dosage amount and frequency of administration. Since the drug accumulates, lower doses are given following the initial dose (Gaddy, 2001). In dogs, an initial dose of 20 mg/kg of the 5% reconstituted solution is given IV. At 12 and 24 h after the first dose, additional doses of 15 mg/kg are given. Finally, at 36 h after the first dose, a dose of 5 mg/kg is given. In cases where the patient has not fully recovered following the above doses or if an ethylene glycol test is positive, additional dosing of 3 mg/kg every 12 h is recommended (Gwaltney-Brant, 2002). This should continue until a negative ethylene glycol test indicates that the parent ethylene glycol has been eliminated via the kidneys.

The dosing schedule in cats is an initial dose of 125 mg/kg IV, then subsequent doses at 12, 24 and 36 h with 31.25 mg/kg (Plumb, 2005). Treatment in cats with either 4MP or ethanol must begin within 3 h post-ingestion of ethylene glycol or prognosis is grave. In dogs, fomepizole is most effective if given within 3–6 h of ethylene glycol ingestion; however some benefit was seen as late as 36 h post-ingestion. A late dose may prevent additional injury to the kidneys (Gwaltney-Brant, 2002). An ethylene glycol test can be used to determine if any parent ethylene glycol is still present.

## Flumazenil

Flumazenil, 1,4-imidazobenzodiazepine, is a benzodiazepine antagonist (Plumb, 2005). It is derived from the antibiotic anthramycin (Gwaltney-Brant, 2002) and blocks benzodiazepines by competition for the benzodiazepine receptor in the CNS (Plumb, 2005). Flumazenil has a higher affinity for the receptor than that of the benzodiazepines; as a result, it displaces receptor-bound benzodiazepines to reverse their depressive effects (Gwaltney-Brant, 2002).

Flumazenil has been used as a successful therapy for benzodiazepine toxicosis in dogs and cats (Wismer, 2002; Plumb, 2005). Please see Table 91.6 for a partial list of benzodiazepines that flumazenil may antagonize. It is also used to improve neurological signs in dogs with severe hepatic encephalopathy (Plumb, 2005). Flumazenil has been used in humans, with some success, to reverse ethanol and Tegretol-induced CNS depression. Consequently, it is reasonable to assume flumazenil also could be effective in small animal patients in such cases (Gwaltney-Brant, 2002).

**TABLE 91.6 Benzodiazepines**

| Generic name | Trade name |
|---|---|
| Alprazolam | Xanax® |
| Brotizolam | |
| Chlordiazepoxide | Librium® |
| Clobazam | |
| Clonazepam | Klonopin® |
| Clorazepate | |
| Diazepam | Valium® |
| Estazolam | |
| Flunitrazepam | Rohypnol® |
| Flurazepam | Dalmane® |
| Halazepam | |
| Lormetazepam | |
| Lorazepam | Ativan® |
| Medazepam | |
| Midazolam | Versed® |
| Nitrazepam | |
| Oxazepam | |
| Prazepam | |
| Quazepam | |
| Temazepam | |
| Triazolam | Halcion® |
| Zolazepam | |

The recommended flumazenil dose in dogs and cats is 0.01–0.02 mg/kg administered by rapid IV injection (Plumb, 2005). The medication rapidly crosses the blood–brain barrier, and a swift reversal of benzodiazepine-induced sedation is expected within 1–2 min (Gwaltney-Brant, 2002). The dose may need to be repeated multiple times, since flumazenil's half-life is shorter than most of the benzodiazepines. The half-life of flumazenil is only 1 h in humans (Plumb, 2005), but the half-life of diazepam in the dog is 6 h (Gwaltney-Brant, 2002). The patient should be monitored carefully for recurrence of signs and additional doses of flumazenil given as needed (Gwaltney-Brant, 2002). Repeat doses should not be given in asymptomatic patients. Flumazenil may act as a benzodiazepine agonist if administered at high doses despite its antagonist action at therapeutic doses (Gwaltney-Brant, 2002).

Flumazenil is a costly medication and carries the risk of significant adverse effects. It should be reserved for cases where the patient has life-threatening benzodiazepine induced clinical signs (Gwaltney-Brant, 2002). The drug should be given through a patent IV catheter, because extravascular leakage can cause extensive local tissue irritation and necrosis (Gwaltney-Brant, 2002). In humans,

vomiting, cutaneous vasodilation, vertigo, ataxia and blurred vision have been reported following flumazenil administration (Plumb, 2005). Seizures and death are also rarely reported in humans after treatment with flumazenil (ASHSP, 2003).

Flumazenil may lower the seizure threshold and is contraindicated in cases when seizures are anticipated. It also may increase intracranial pressure and should not be used in patients with head trauma (Gwaltney-Brant, 2002). Additionally, flumazenil is contraindicated in patients with life-threatening tricyclic antidepressant toxicosis and should be used only after careful consideration in cases of multiple drug overdosage (Plumb, 2005). Most human deaths and seizures associated with flumazenil followed use in cases of tricyclic antidepressant toxicosis (ASHSP, 2003) and mixed overdoses (Plumb, 2005).

## Methocarbamol

The skeletal muscle relaxant methocarbamol has proved to be very useful in the management of severe muscle fasciculations, tremors and seizures associated with a variety of toxicologic agents (Gwaltney-Brant, 2002). The exact mechanism by which methocarbamol works is unknown but it is thought to act centrally to block nerve impulses in the brain stem, spinal cord and subcortical levels of the brain ( Gwaltney-Brant, 2002; Plumb, 2005).

Methocarbamol has been used successfully in veterinary medicine to treat the following types of toxicoses: permethrin in cats (Richardson, 2000a), metaldehyde (Richardson *et al.*, 2003), strychnine (Gwaltney-Brant, 2002; Plumb, 2005) and tremorgenic mycotoxins (Schell, 2000). It is able to reduce the severity of tremors without causing the severe CNS depression often encountered when using a barbiturate medication (Gwaltney-Brant, 2002).

The dosage for dogs and cats is 55–220 mg/kg administered slowly IV at a rate of no more than 2 ml/min (Schell, 2000). Methocarbamol administration should be repeated if the signs recur; however, the total dose should not exceed 330 mg/kg in a 24-h period to avoid CNS and respiratory depression (Gwaltney-Brant, 2002; Richardson *et al.*, 2003). The dosage for horses is 15–25 mg/kg by slow infusion (Plumb, 2005). The drug should not be given SQ and extravasation of methocarbamol should be avoided as the solution can be irritating (Plumb, 2005).

In dogs and cats, adverse effects may include sedation, salivation, emesis, lethargy, weakness and ataxia. Slow administration of the drug can help to avoid salivation and emesis. Sedation and ataxia can be seen in horses following methocarbamol administration (Plumb, 2005). This medication is contraindicated in animals intended for food purposes and in patients hypersensitive to it (Plumb, 2005). The manufacturer lists known or suspected renal insufficiency as a contraindication to injectable methocarbamol therapy since the injectable product contains polyethylene glycol 300, which has been found to increase acidosis and urea retention in renal-impaired humans (Plumb, 2005). For this reason, veterinary patients treated with injectable methocarbamol should receive IV fluid support and have kidney values monitored if renal impairment is suspected or is a possible outcome of their clinical signs. For example, patients with prolonged tremors or seizures can release muscular myoglobin. The myoglobin is excreted by the kidneys and can lead to renal damage (Volmer, 2004).

## Naloxone HCl

Naloxone HCl (Narcan®) is an injectable opiate antagonist used to reverse the effects of opiate medications. It is able to reverse opioid agonist/antagonists such as butorphanol as well. This drug is also being investigated for treatment of other conditions like septic, hypovolemic and cardiogenic shock (Plumb, 2005).

Naloxone is a pure opiate antagonist, and it has no analgesic activity or other agonist effects (Plumb, 2005; Volmer, 2006). Although the exact mechanism for its activity is not fully understood, it is thought the drug acts as a competitive antagonist by binding to multiple opioid receptor sites. The drug apparently has its highest affinity for the $\mu$ receptor which makes it an ideal antagonist since most of the clinically useful opioids work by binding to the $\mu$ receptor (Plumb, 2005; Volmer, 2006).

Naloxone reverses most of the effects of opioids including analgesia and respiratory and CNS depression (Plumb, 2005). It does not reverse the emetic actions of apomorphine in dogs (Volmer, 2006). At high doses, naloxone increases dopamine levels and acts as a $\gamma$-aminobutyric acid (GABA) antagonist (Plumb, 2005).

Because orally administered naloxone is only minimally absorbed and the drug is destroyed rapidly in the digestive tract, an injectable formulation is preferred (Plumb, 2005). The onset of action is normally within 1–2 min when given IV and within 5 min when given IM (Plumb, 2005). The duration of action is usually 45–90 min but may be as long as 3 h (Plumb, 2005). Since the duration of action of naloxone may be shorter than the medication being reversed, additional doses may be required (Plumb, 2005).

The recommended dosage for dogs is 0.04 mg/kg IV, IM or SC. For cats, 0.02–0.04 mg/kg IV and for horses, 0.01–0.02 mg/kg IV (Plumb, 2005). In patients that have been intentionally given an opioid to treat a painful condition, abrupt reversal can lead to tachycardia, vasoconstriction and hypertension. In these cases, the unwanted CNS and respiratory depression can be reversed without reversing the analgesia. To achieve this, dilute 0.04–0.1 mg of naloxone in 5–10 ml of normal saline

and give slowly to effect by dosing 0.5–1 ml each minute (Mathews, 2006).

Naloxone is considered quite safe at therapeutic doses. Very high doses have been associated with seizures in a few patients perhaps due to GABA inhibition (Plumb, 2005). It is contraindicated in patients that are hypersensitive to it and should be used with caution in animals with pre-existing cardiac abnormalities due to the potential cardiovascular adverse effects (Plumb, 2005).

## N-acetylcysteine

NAC is used to prevent methemoglobinemia and hepatic necrosis in APAP toxicosis. APAP is metabolized in the liver primarily via glucuronidation and sulfation to non-toxic metabolites. Another minor pathway of metabolism does exist which yields a highly reactive metabolite, *N*-acetyl-para-benzoquinoneimine (NAPQI). NAPQI is produced through the P450 mixed function oxidase system and is normally inactivated through conjugation with glutathione. In a significant exposure, the glucuronidation and sulfation pathways become saturated, leading to increased production of NAPQI.

Initially the excess NAPQI will be detoxified through conjugation with glutathione. However, once glutathione stores in the liver are depleted, the NAPQI metabolite can lead to liver necrosis. NAPQI binds to hepatic cell membranes causing oxidative injury to the bi-lipid layer and potential cellular death and necrosis (Richardson, 2000b). Furthermore, depletion of glutathione in red blood cells (RBCs) allows oxidation of the hemoglobin to methemoglobin which is unable to carry oxygen (Aronson and Drobatz, 1996). While all species can develop both hepatic and RBC effects, dogs more commonly develop hepatic necrosis, whereas cats more commonly develop methemoglobinemia and Heinz body anemia (Taylor and Dhupa, 2000).

There are at least two mechanisms by which NAC prevents methemoglobinemia and hepatic necrosis from APAP. NAC binds directly with NAPQI rendering it inactive and therefore non-toxic. NAC is a precursor for glutathione production. It restores and maintains glutathione levels by increasing synthesis (Richardson, 2000b). NAC administration may also lead to increased serum sulfate which could re-establish the sulfation pathway to non-toxic metabolites (Aronson and Drobatz, 1996) (see Figure 91.2).

The therapeutic dose for dogs and cats is a loading dose of 140 mg/kg per os (PO) or IV (as a 5% solution), then 70 mg/kg PO or IV every 6 h for 7 treatments. The number of additional treatments varies between authors; some recommend up to 17 treatments (Plumb, 2005). Presently, both an injectable form and oral solution are on the market. When given orally, NAC can cause GI irritation, so proper dilution is important.

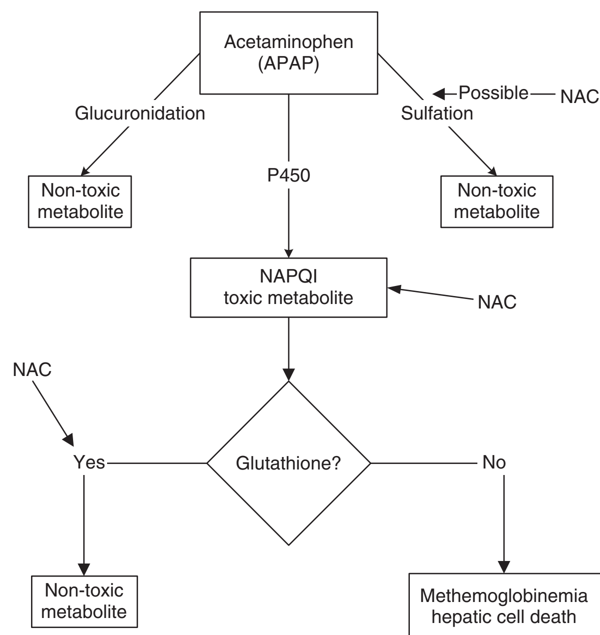

**FIGURE 91.2** Sites of NAC action in the metabolism of APAP.

## Pamidronate disodium

Pamidronate disodium (Aredia®) is a biphosphonate used in the treatment of hypercalcemia associated with malignancy and vitamin $D_3$ toxicity in dogs (Plumb, 2005). Vitamin $D_3$, also called cholecalciferol, is found in some rodenticides. Calcipotriene, which is an analog of cholecalciferol, is found in some human prescription topical antipsoriasis medications (e.g. Dovonex®) (Pesillo *et al.*, 2002). Since vitamin $D_3$ plays an important role in calcium and phosphorus homeostasis, oral exposure to these rodenticides or topical medications can lead to significant elevations in serum calcium and phosphorus levels. Vitamin $D_3$ enhances calcium and phosphorus absorption from the GI tract. In addition, it works with parathyroid hormone to promote calcium reabsorption in the kidney and mobilization of calcium from the bone via osteoclastic-mediated bone resorption (Rumbeiha *et al.*, 2000; Morrow, 2001).

Calcium maintains cell membrane stability and is a second messenger in several cellular responses (Pesillo *et al.*, 2002). Therefore, increasing serum calcium can cause many cellular effects including altered cell membrane permeability, a decrease in cellular energy production and cellular necrosis (Morrow, 2001). Patients poisoned by vitamin $D_3$ and its analogs often present with polyuria, polydipsia, vomiting, anorexia, lethargy, hypercalcemia and hyperphosphatemia (Pesillo *et al.*, 2002). If elevations in serum calcium and phosphorus concentrations go unchecked, the plasma calcium phosphorus product (Ca X P) can rise above 60 leading to soft tissue mineralization (Morrow,

2001). Mineralization of the kidneys and heart can lead to a life-threatening decrease in the function of these organs.

Pamidronate acts to decrease serum calcium levels by binding to hydroxyapatite crystals in the bone to prevent their dissolution and bone resorption. It also interrupts osteoclast activity and induces osteoclast apoptosis (Plumb, 2005). Some authors suggest pamidronate may decrease intestinal absorption of calcium as well (Pesillo *et al*., 2002).

The recommended dose of pamidronate is 1.3–2 mg/kg given as a slow IV infusion over several hours (Plumb, 2005). Pamidronate must be given in saline and should not mix with any IV fluid containing calcium (e.g. Ringer's). In most cases, a single dose will be effective in lowering calcium levels back to normal (Gwaltney-Brant, 2002). However, some patients may require an additional dose 5–7 days after the initial treatment (Morrow, 2001). Calcium levels should be monitored once daily for at least 10 days after they have returned to normal. Pamidronate is most effective if given within 24–36 h of the exposure, prior to development of soft tissue mineralization (Gwaltney-Brant, 2002).

Anemia, thrombocytopenia and granulocytosis have been reported in humans following pamidronate administration (Plumb, 2005). In dogs, hypersensitivity reactions, electrolyte abnormalities including hypomagnesemia and hypocalcemia, arrhythmias and renal toxicity are possible (Plumb, 2005). Slow infusion of the drug over at least 2 h may help in avoiding renal effects. Use of pamidronate in dogs with impaired renal function is controversial since it may confound renal injury (Gwaltney-Brant, 2002).

Pamidronate is expensive but its use may be more cost effective than using salmon calcitonin in vitamin $D_3$ toxicosis. Pamidronate lowers plasma calcium concentrations within 24–48 h of a single IV dose. Calcitonin requires dosing several times daily due to its short half-life. Additionally, with calcitonin therapy, saline diuresis and treatment with diuretics and corticosteroids must also be performed, requiring many days, sometimes multiple weeks, of hospitalization. In most cases treated with pamidronate, treatment can be performed on an out-patient basis once the calcium has returned to the normal range (Morrow, 2001; Pesillo *et al*., 2002). Pamidronate is also preferred to calcitonin since patients may become refractory to calcitonin treatment after 10 days of therapy (Rumbeiha *et al*., 2000; Morrow, 2001).

## Phytonadione (vitamin $K_1$)

Phytonadione, a naphthoquinone derivative identical to naturally occurring vitamin $K_1$, is used in the treatment of anticoagulant toxicosis resulting from anticoagulant rodenticides, the medication warfarin or moldy sweet clover (Plumb, 2005). All household pets, including pocket pets, may be exposed to anticoagulant rodenticides and the medication warfarin. Livestock and horses are more likely to be poisoned by the dicoumarol in moldy sweet clover, but they can also be exposed to rodenticides (Knight, 2004).

Anticoagulants block clotting factor activation. Vitamin $K_1$ is involved in the activation of precursor clotting factors into functional factors. During the activation, vitamin $K_1$ is converted to inactive vitamin $K_1$ epoxide. Normally, vitamin $K_1$ epoxide is reactivated by vitamin $K_1$ epoxide reductase. Anticoagulants work by inhibiting this enzyme and halting the recycling of vitamin $K_1$ (Merola, 2002). As a result, the number of active clotting factors decreases.

The vitamin $K_1$-dependent clotting factors are II, VII, IX and X. These factors are involved in all three pathways of the coagulation system: the extrinsic, intrinsic and common (Means, 2004a). Active bleeding is not expected for 3–7 days after the ingestion because the body has a reserve of active clotting factors. When these degrade naturally or are consumed, clinical signs are possible. If an external source of vitamin $K_1$ is provided, the factors will be activated normally (Merola, 2002).

Bleeding can occur anywhere within the body and the presenting clinical signs will relate to where the bleeding has occurred. The signs may be vague and non-specific. In dogs, dyspnea, coughing, lethargy and hemoptysis are commonly reported due to bleeding into the chest cavity (Merola, 2002). With moldy sweet clover poisoning in livestock, prolonged bleeding in some members following routine surgical procedures, like castration or dehorning, is often the first indication of a problem within the herd (Knight, 2004).

The dose for vitamin $K_1$ in household pets is 1.5–2.5 mg/kg orally twice daily. Pocket pets and other small patients can be given the injectable formulation orally if a suitable tablet size is not available. Small patients should be dosed at the high end of the range and larger patients (e.g. large breed dogs) should be started at the low end (Means, 2004a). Vitamin $K_1$ should be given with a fatty meal to enhance absorption. In dogs, giving the medication with canned food caused a 4–5 fold increase in bioavailability (Plumb, 2005).

Oral administration is preferred since the vitamin $K_1$ will be carried, via the portal circulation, directly to the liver where the activation of clotting factors occurs (Merola, 2002). Additionally, vitamin $K_1$ injections have been associated with anaphylactic reactions and hematoma formation (Plumb, 2005). However, IM administration is recommended by many authors for livestock, perhaps for ease of administration. The recommended dose for cattle, horses, swine, sheep and goats is 0.5–2.5 mg/kg IM (Knight, 2004; Plumb, 2005).

The length of vitamin $K_1$ administration depends on the toxicant. Warfarin exposures generally require a 14-day course. Second generation anticoagulant rodenticides

should be treated for 30 days except for bromadiolone which should be treated for 21 days (Means, 2004a). Moldy sweet clover poisoning should be treated for 1–2 weeks (Knight, 2004). In all cases, a prothrombin time (PT) should be checked 48–72 h after the course of vitamin $K_1$ is complete. If this test is abnormal, resume vitamin $K_1$ therapy for an additional 7 days (Merola, 2002).

Blood transfusions may be required in severely symptomatic patients, since it may take 6–12 h for the liver to produce active clotting factors following initiation of vitamin $K_1$ therapy (Plumb, 2005). Exercise restriction is indicated in all patients during this lag time to prevent active bleeding (Merola, 2002). Substituting vitamin $K_3$, menadione, is not recommended, as it is not as effective and is nephrotoxic in horses (Merola, 2002; Knight, 2004).

## CONCLUSION

Proper client education is crucial to poison prevention. However, when poisonings do occur, the clinician should concentrate on treating the patient and not the poison. The same principles of history collection, physical examination and patient monitoring that are used in other cases should be applied when managing a poisoning patient. Appropriate decontamination and antidotal therapies should be decided on after initial patient stabilization.

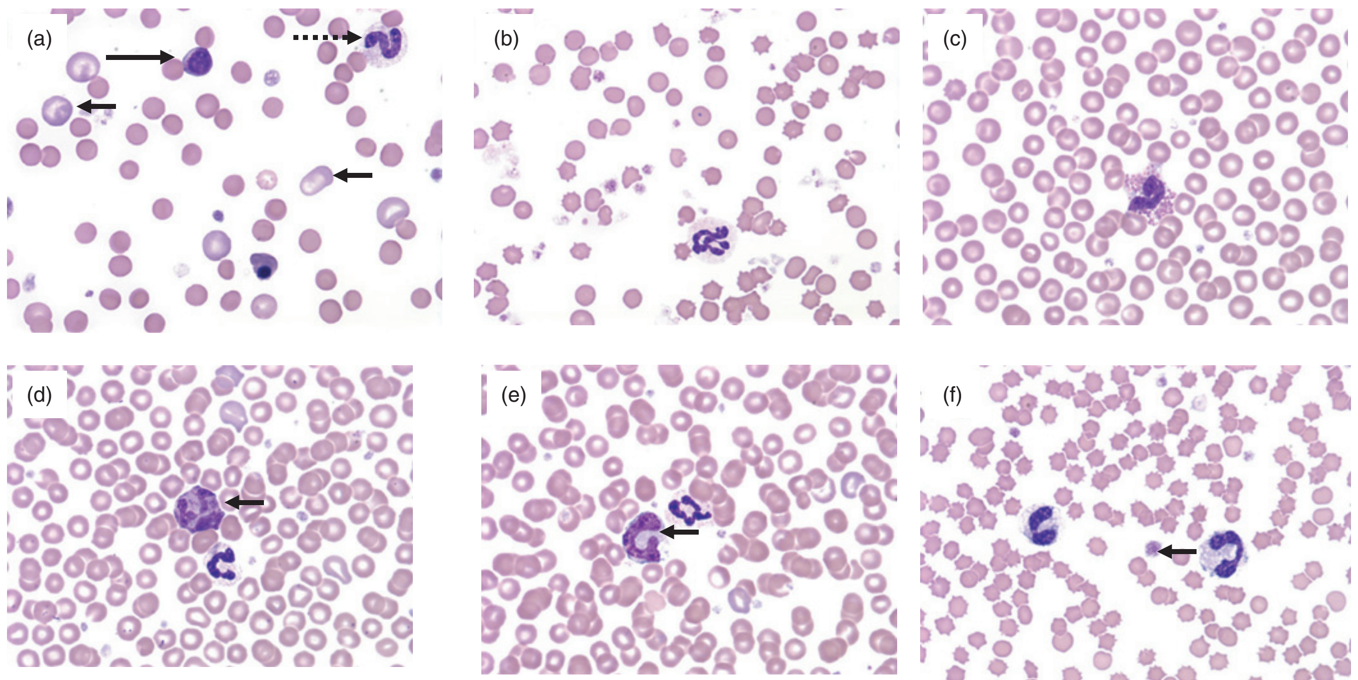
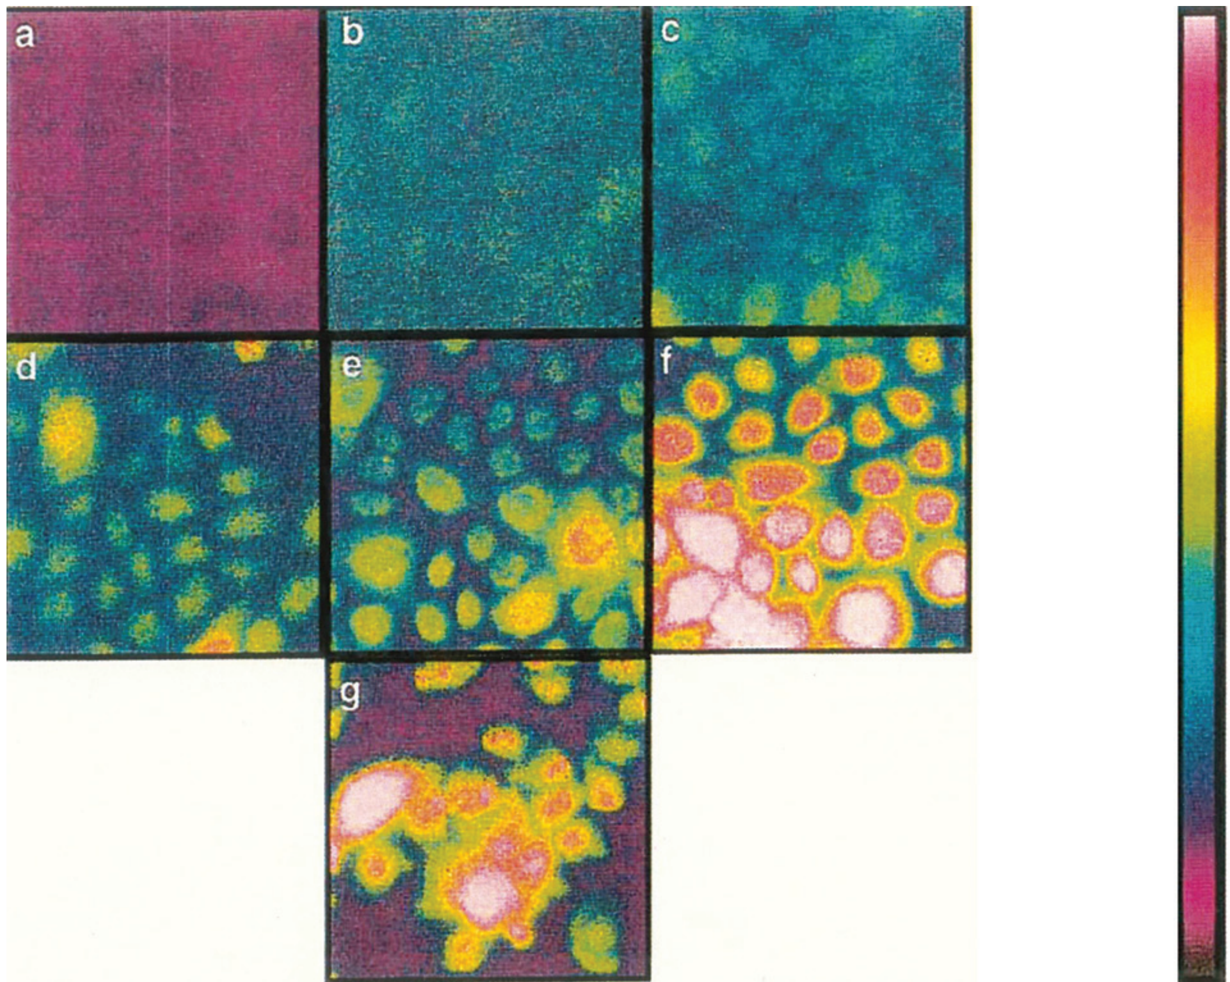
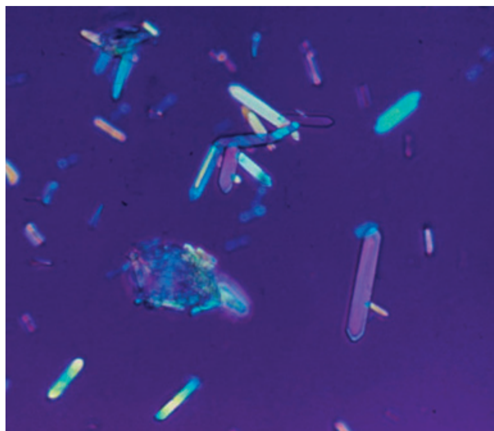
**CHAPTER 17 FIGURE 2** (a) Examples of erythroid precursors and granulocytic precursors (arrowheads) in the bone marrow of a dog. 60×, Diff-quik stain. Early erythroid precursors (arrow heads), late erythroid precursors (solid arrows) and granulocytic precursors (dotted arrows) are shown. (b) A mature megakaryocyte in the bone marrow of a dog is shown in the center of the picture. Erythroid and myeloid precursors are also noted (arrows). 60×, Modified Wrights stain.



**CHAPTER 17 FIGURE 3** *Normal and few abnormal erythrocyte and leukocyte morphology.* (a) Two large basophilic polychromatophilic erythrocytes or reticulocytes (small solid arrow) are present in the blood from a dog with IMHA. A normal neutrophil (dotted arrow), a metarubricyte and a lymphocyte (long arrow) are also present. 100×, Modified Wrights Stain. (b) Heinz bodies in the blood from a cat appearing as pale "spots" within erythrocytes with a modified Wrights stain, 100×. (c) Eosinophil with round granules in the blood from a dog. 100×, Modified Wrights stain. (d) Basophil (arrow) and neutrophil in the blood from a dog. 100×, Modified Wrights stain. (e) Monocyte (arrow) and neutrophil in the blood from a dog. 100×, Modified Wrights stain. (f) Toxic neutrophils in the blood from a cat demonstrating Döhle bodies, cytoplasmic vacuolation, and basophilia. A platelet (arrow) is also identified in the field 100×, Modified Wrights stain.



**CHAPTER 20 FIGURE 3** Changes in intracellular redox states of human cells after treatment with a tobacco extract. Cells (70% confluent) were treated with the tobacco extract for 24 h. After 24 h, medium was replaced with fresh medium containing 5 μm 2,7-dichlorofluorescein diacetate and fluorescence intensity was measured 5 m in later at 513 nm with a confocal laser scanning microscope. a, Control; b, 100 μg/ml; c, 150 μg/ml; d, 200 μg/ml; e, 250 μg/ml; f, 300 μg/ml; and g, 3 mM hydrogen peroxide (positive control).

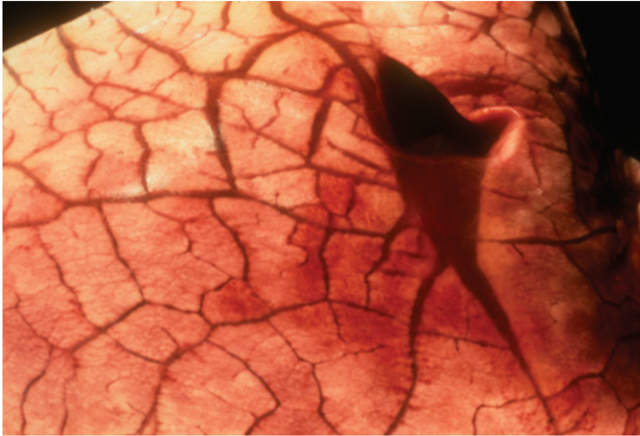


**CHAPTER 53 FIGURE 1** Calcium oxalate monohydrate crystals (polarized light) from a dog with EG toxicosis.

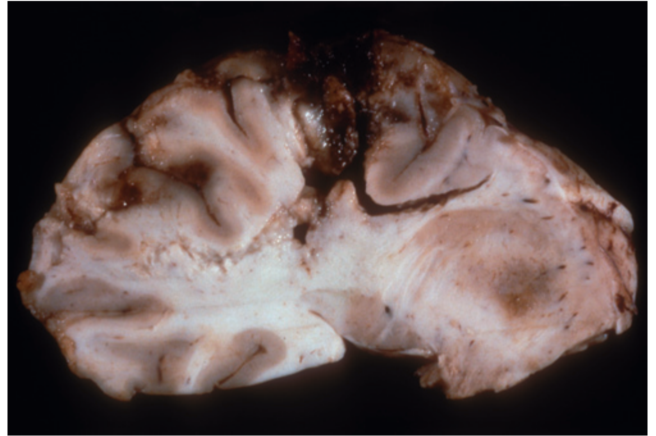
**CHAPTER 63 FIGURE 1** Late instar ETCs in nest.

**CHAPTER 64 FIGURE 1** An adult striped blister beetle (*E. vittata*). (Photo courtesy of James E. Appleby, University of Illinois.)

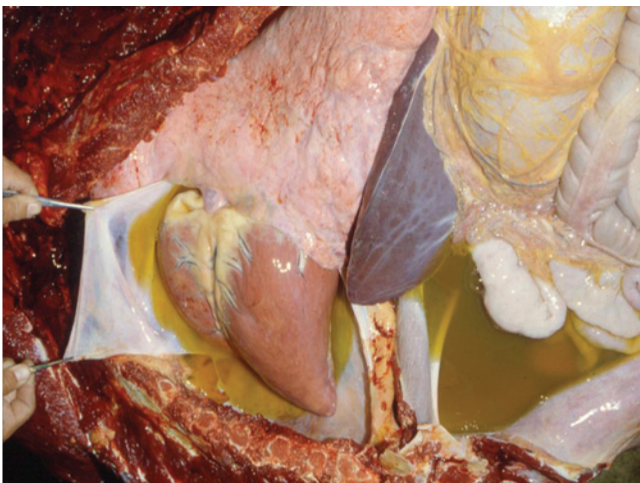
**CHAPTER 64 FIGURE 2** An adult blister beetle (*Epicauta*), with hemolymph droplets containing cantharidin. (Photo courtesy of Dr. Maria Eisner, Cornell University.)



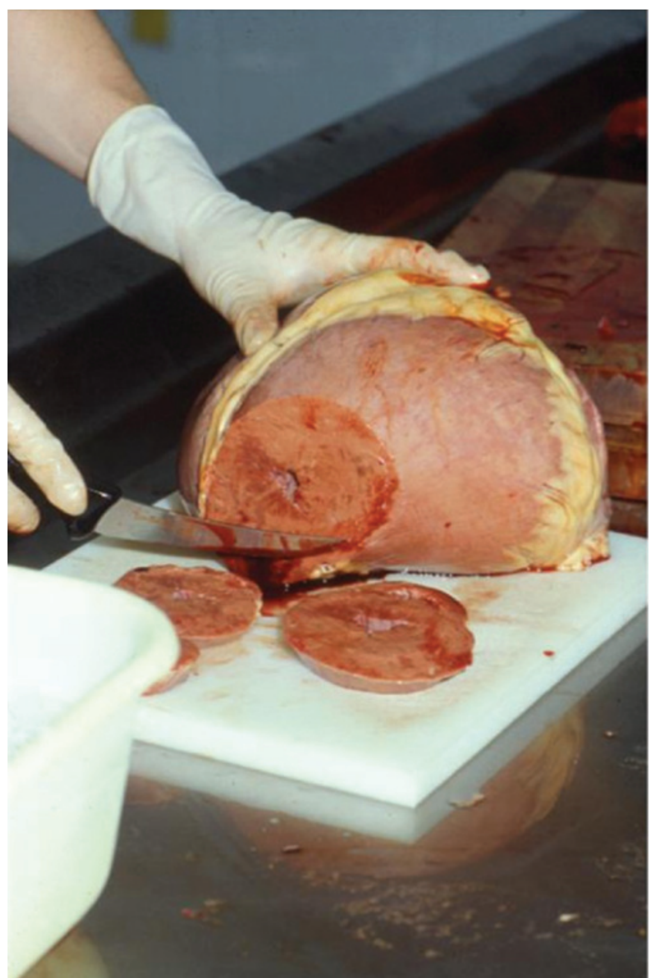
**CHAPTER 78 FIGURE 4** Lung from a pig fed fumonisin-containing culture material at a dose of 20 mg fumonisin $B_1$ per kg of body weight for 4 days. Pulmonary edema is characterized by severe widening of the interlobular septa (reprinted with permission from Smith and Constable, 2004).



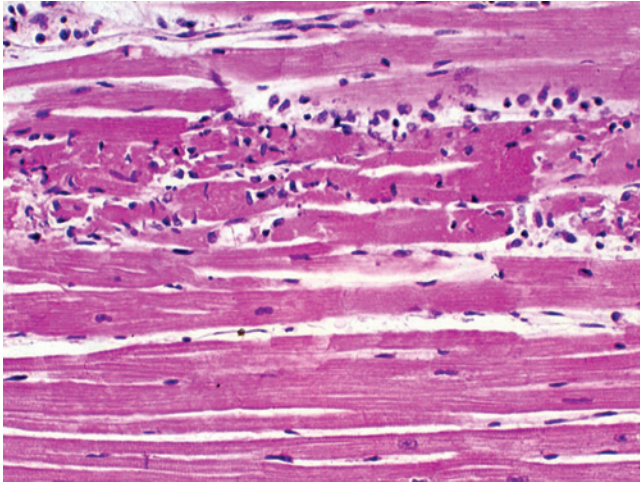
**CHAPTER 78 FIGURE 5** A cross-section of a cerebral hemisphere from a horse demonstrating liquefactive necrosis of the white matter typical of ELEM (reprinted with permission from Smith and Constable, 2004).



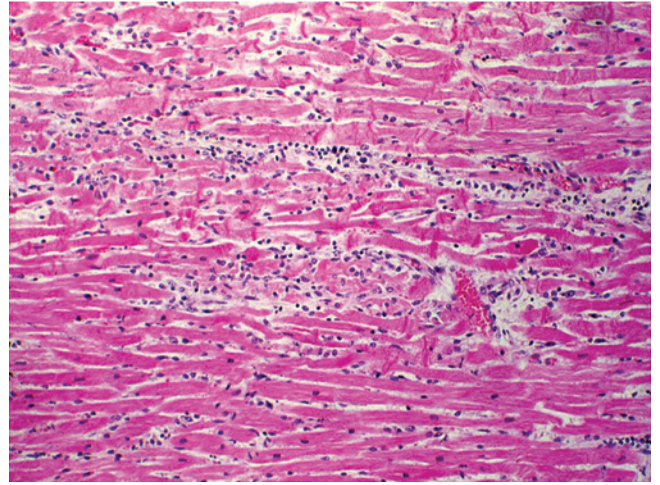
**CHAPTER 83 FIGURE 5** Thoracic and abdominal viscera from a mare that died 7 days following a single gavage dose of 1.65 mg monensin/kg body weight. Note the fluid accumulation in the body cavities and the pale areas and epicardial hemorrhages on the heart.



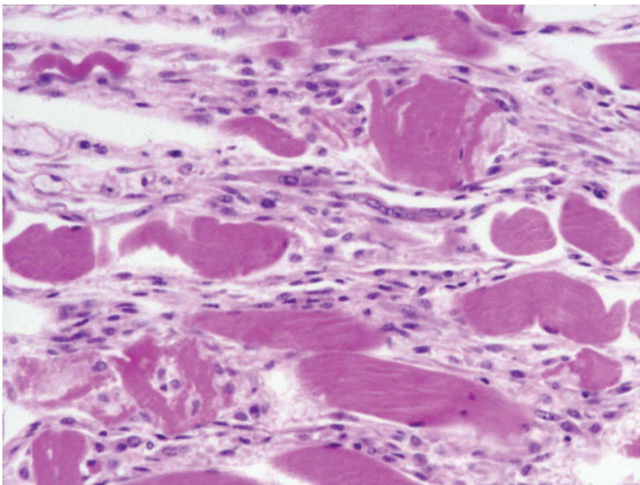
**CHAPTER 83 FIGURE 6** Diffuse pallor in cross sections of the heart from the same mare described in Figure 83.5 legend.



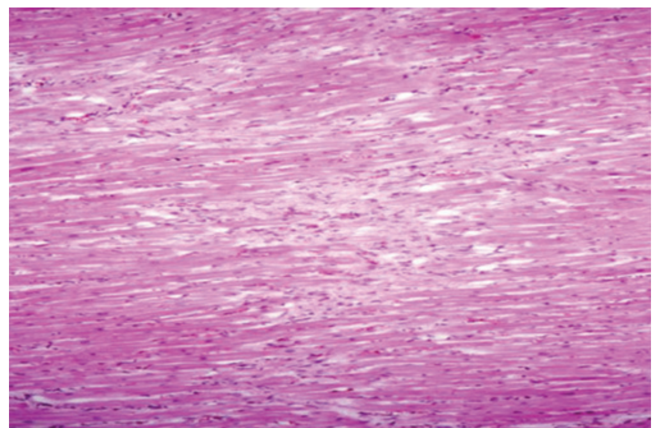
**CHAPTER 83 FIGURE 7** Early necrotic focus in the left ventricle of a gelding that died 20 h following gavage with 2.5 mg monensin/kg body weight. Necrotic muscle fibers have sparse infiltration of neutrophils and lymphocytes. H&E. Original magnification ×64.

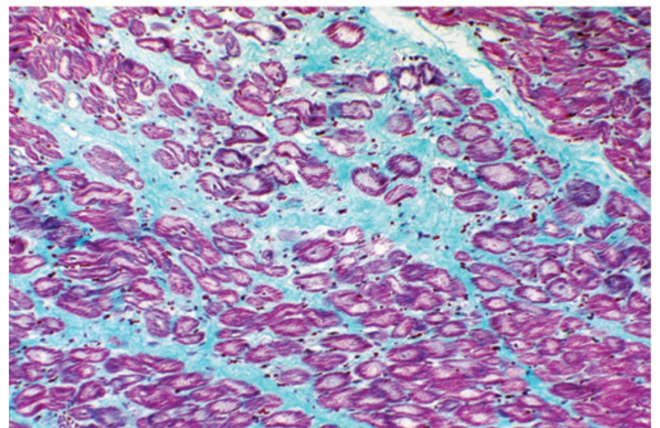


**CHAPTER 83 FIGURE 8** Larger foci of myofiber necrosis with contraction bands in the interventricular septum from a horse euthanized 72 h following a single oral dose of 1.65 mg monensin/kg body weight given by gavage. More cellular infiltrates with lymphocytes, macrophages, and few eosinophils are present. H&E. Original magnification ×10.

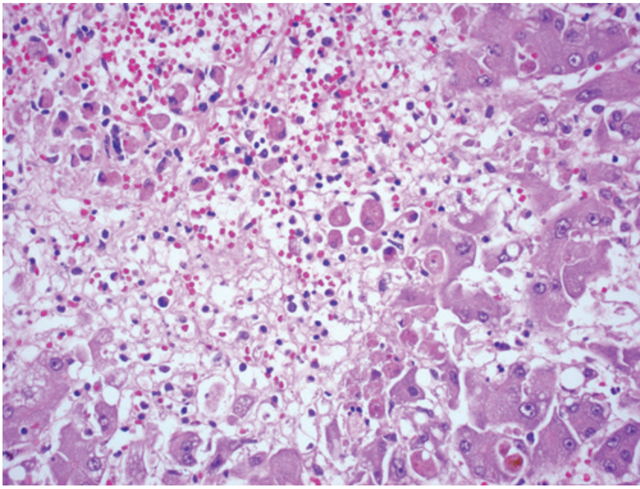


**CHAPTER 83 FIGURE 9** Skeletal muscle from a steer that died 6 days after a gavage dose of 39.8 mg monensin/kg body weight. Notice the fragmented and regenerating fibers. H&E. Original magnification ×80.

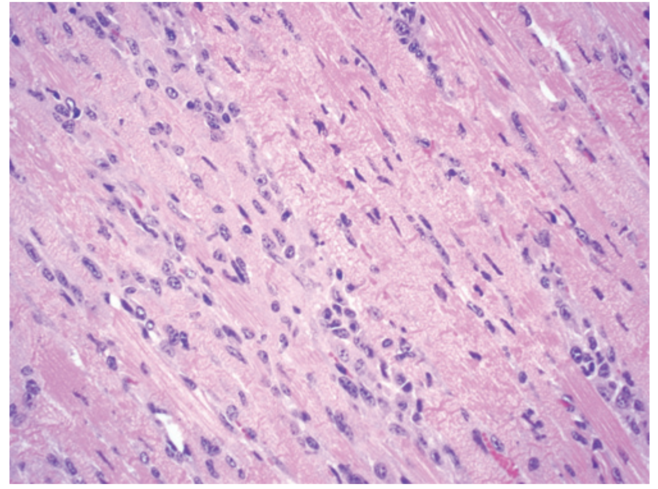




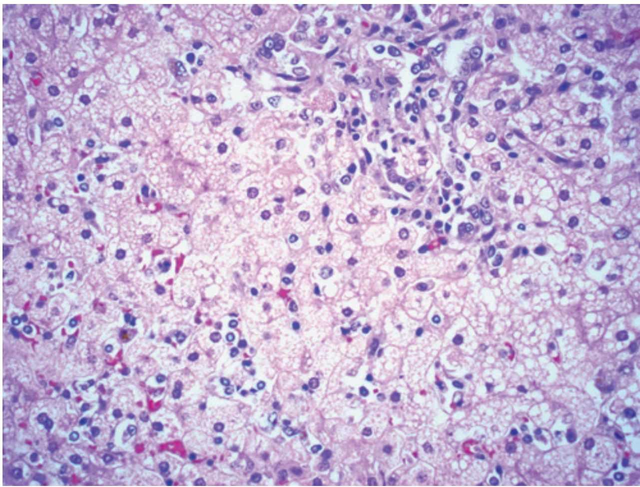
**CHAPTER 83 FIGURE 10** Hearts from animals that survived acute ionophore toxicity. Top: section of left ventricle with focal interstitial fibrosis from another steer, cohort of that described in Figure 83.9 legend, euthanized 28 days after a gavage dose of 39.8 mg monensin/kg body weight. H&E. Original magnification ×20. Bottom: interstitial fibrosis in the left ventricle from a gelding that survived a gavage dose of 2 mg monensin/kg body weight for 4 months. Masson's trichrome. Original magnification ×32.



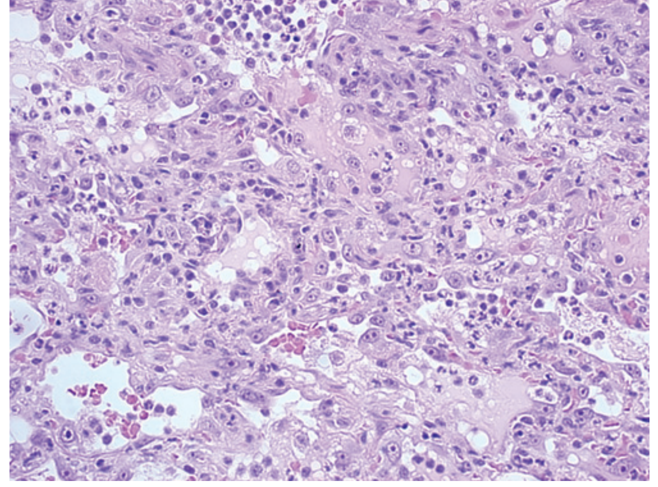
**CHAPTER 90 FIGURE 1** NSAID-induced toxicity, liver, canine, hepatocyte necrosis and degeneration in the centrolobular areas with marked biliary stasis, H&E stain, 403.



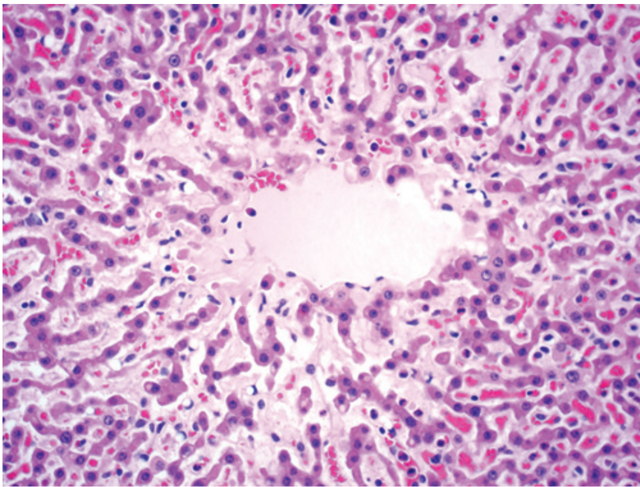
**CHAPTER 90 FIGURE 2** Monensin toxicity, heart, bovine, cardiac myocytes show degeneration and some areas myocytes replaced and infiltrated by lymphocytes and histiocytes, H&E stain, 40×. (Courtesy Dr. ME Hines, College of Veterinary Medicine, University of Georgia.)



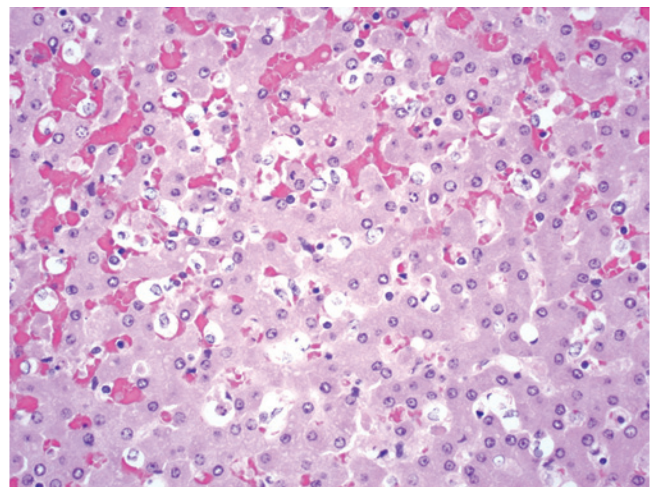
**CHAPTER 90 FIGURE 3** Aflatoxicosis, liver, canine, hepatocellular vacuolation with biliary hyperplasia, H&E stain, 40×. (Courtesy Dr. S Newman, College of Veterinary Medicine, University of Tennessee.)



**CHAPTER 90 FIGURE 4** Paraquat poisoning, lung, canine, diffuse interstitial pneumonia with type II pneumocyte hyperplasia, H&E stain, 40×. (Courtesy Dr. ME Hines, College of Veterinary Medicine, University of Georgia.)



**CHAPTER 90 FIGURE 5** Blue green algae poisoning, liver, bovine, centrilobular cord atrophy with dilated sinusoids and necrosis, H&E stain, 40×. (Courtesy Dr. K Frazer, Philadelphia.)



**CHAPTER 90 FIGURE 6** Mushroom poisoning, liver, canine, hepatocyte dissociation and degeneration, H&E stain, 40×. (Courtesy Dr. A Ligget, College of Veterinary Medicine, University of Georgia.)
