The impact of SLNB on the management of melanoma has been impressive. The results greatly facilitate accurate staging and play an important role in helping the clinician decide whether to perform completion lymph node dissection (CLND) or to offer adjuvant therapy. Several studies have demonstrated significant differences in survival and disease-free interval between SLN-negative patients and SLN-positive patients.^{43,44} One such study reported a 3-year disease-free survival rate of 88.5% in SLN-negative patients, compared with 55.8% in SLN-positive patients.⁴³

Surgical treatment of stage III melanoma *Completion lymph node dissection.* At present, CLND is recommended for management of the regional lymph node drainage basin in the presence of a positive SLN. Some clinical trial results do not appear to support this recommendation. For example, four randomized trials failed to demonstrate any overall survival benefit for patients randomly assigned to undergo elective lymph node dissection.⁴⁵⁻⁴⁸ It should be noted, however, that most of the patients in these studies did not have lymph node metastases, and thus, the trials did not have sufficient statistical power to detect a small survival benefit.⁴⁹ Other trial results, however, do support the recommendation for CLND in node-positive patients, including those of the World Health Organization Program Trial No. 14, which demonstrated that the 5-year survival rate in patients with occult nodal metastases detected at elective lymph node dissection was significantly better than that in patients who underwent delayed lymphadenectomy at the time when palpable nodal metastases developed (48% versus 27%).⁴⁷

Nonetheless, the impact of CLND on overall survival is still a matter for debate. The results of the first Multicenter Selective Lymphadenectomy Trial (MSLT-I) suggest that SLNB with immediate CLND if the SLN is positive improves disease-free survival but not overall survival.⁵⁰ In this trial, 1,973 patients were randomly assigned in a 4:6 ratio to undergo either (1) wide excision (WE) followed by nodal observation or (2) WE plus lymphatic mapping and sentinel lymph node biopsy (LM/SLNB) with immediate CLND if the SLN was positive. The two groups were comparable in regard to both patient variables (i.e., age and gender distribution) and lesion variables (i.e., location, thickness, and ulceration status). SLNs were analyzed by means of hematoxylin-eosin staining and immunohisto-

chemical staining. The incidence of wound complications at the primary site was comparable in the two groups, though surgical morbidity was significantly greater when SLNB was followed by CLND.⁵⁰ A planned interim analysis presented at the American Society of Clinical Oncology in 2005 demonstrated a significant difference in disease-free survival between the two groups (73% for WE followed by nodal observation versus 78% for WE plus LM/SLNB); however, the difference in overall survival was not statistically significant (86% for WE followed by nodal observation versus 87% for WE plus LM/SLNB).⁵¹ These data led some to suggest that a survival benefit might be gained by performing LM/SLNB followed by CLND in the event of a positive SLN, but this suggestion has not been widely accepted.⁵² A study now under way, the second Multi-center Selective Lymphadenectomy Trial (MSLT-II), will assess the therapeutic value of CLND against that of SLNB alone in patients who have a positive SLN.⁵¹

An important factor in considering whether to perform CLND after a positive SLNB is the likelihood of finding metastases in the remaining non-SLNs. In one series, 90 (14%) of 658 patients had a positive SLN, and only 18 (20%) of the 90 showed evidence of metastases in additional non-SLNs removed during CLND.⁵³ The number of positive nodes clearly has an impact on prognosis (as reflected by its inclusion in the current version of the AJCC's melanoma staging system³⁴), and this fact lends support to the argument for performing a CLND after a positive SLNB.

Another issue that has not yet been resolved is the extent of lymph node dissection required. One group, reviewing their experience with lymph node dissection before the use of SLNB, concluded that the extent of lymph node dissection was a more important concern with higher tumor burdens and a less important one with lower tumor burdens.⁵⁴ Patients with micrometastatic disease in an SLN are clearly different from patients with bulky nodal disease, and the potential benefits of aggressive lymph node dissection in either group must be carefully weighed against the morbidity of the procedure. Several studies are under way that should help address this issue, including MSLT-II.⁵⁵ The roles of lymphadenectomy and adjuvant interferon alfa-2b (IFN- α 2b) may be addressed by results from the Sunbelt Melanoma Trial.⁵⁶

Therapeutic lymph node dissection. Therapeutic lymph node dissection is performed in patients who show evidence of lymph node metastases on physical examination. Some of these patients will survive for extended periods; most will at least be rendered free of the signs and symptoms of nodal metastases.⁵⁷

Isolated limb perfusion. Most patients with in-transit metastases experience unfavorable outcomes, with 5-year survival rates ranging from 25% to 30%. Surgical excision to clear margins is the mainstay of therapy when the size and number of the lesions permit. Amputation is rarely necessary.

A therapeutic alternative to surgical excision for patients who have extensive in-transit metastases in an extremity is the technique known as isolated limb perfusion (ILP). The prime advantage of ILP is that it can achieve high regional concentrations of therapeutic agents while minimizing systemic side effects.⁵⁸ The arterial supply and the venous drainage are isolated, and a tourniquet may also be used to occlude superficial collateral veins. An oxygenated extracorporeal circuit is employed to circulate a chemotherapeutic agent (typically melphalan) for 1 to 1.5 hours. The temperature of the limb is usually elevated to 39° to 40° C.⁵⁹ In patients who have clinically positive nodes, therapeutic lymph node dissection is performed in the same setting, just before limb perfusion. The effect of ILP can be dramatic; for example, the rate of complete response with melphalan

is 54%.⁶⁰ Unfortunately, the beneficial effect is often short-lived, with recurrence rates reaching 50% within 1 to 1.5 years after ILP.⁶¹ In a 2004 series, the overall 5-year survival rate after ILP was 32%.⁶¹ Recurrence after ILP may be treated with surgical excision, though it has also been successfully treated with repeat ILP in patients with extensive disease.⁶²

Adjuvant therapy for stage IIB and III melanoma *Radiotherapy.* Radiotherapy has been used with some success after therapeutic lymph node dissection in patients with high-risk lesions, resulting in a decreased local recurrence rate⁶³ and a modest survival benefit⁶⁴ in comparison with historic controls. This modality is typically employed in stage III patients who have poor prognostic pathologic factors (e.g., positive surgical margins, multiple positive nodes, extracapsular spread, or vascular or perineural involvement).⁶⁵

Interferon therapy. Perhaps the most efficacious adjuvant agent tested to date is IFN- α 2b, which is currently approved by the United States Food and Drug Administration for adjuvant treatment of stage IIB and stage III melanoma. Although a trial reported in 1996 found that 1 year of high-dose IFN- α 2b therapy led to a prolonged relapse-free interval and improved overall survival,⁶⁶ subsequent trials and a meta-analysis did not confirm this overall survival benefit.⁶⁷ Furthermore, nearly all patients experience adverse effects (e.g., fatigue, neutropenia, headache, fever, and chills) with interferon therapy.⁶⁶

Treatment of stage IV melanoma *Metastasectomy.* There is a large body of literature supporting resection of metastases from melanoma. The following five factors are commonly cited as predictive of survival after metastasectomy: (1) the initial disease stage, (2) the disease-free interval after treatment of the primary melanoma, (3) the initial site of metastasis, (4) the extent of metastatic disease (single versus multiple sites), and (5) the ability to achieve complete resection.⁵⁷ In well-selected patients, this procedure can yield a reasonable likelihood of survival: a 1995 series reported a 5-year survival rate of 27% in all patients after pulmonary metastasectomy and a rate of 39% in patients with a single metastatic lesion.⁶⁸ More modest benefits have been observed after resection of metastases to the GI tract: a 1996 series reported a median survival of 44.5 months in patients in whom a complete resection was achieved, compared with a median survival of 4 weeks in those in whom complete resection could not be achieved.⁶⁹

The five aforementioned factors are of critical importance in patient selection for metastasectomy. To improve patient selection for curative procedures, surgeons often treat patients with a single-site asymptomatic metastasis by administering chemotherapy for 2 to 3 months before considering resection, the aim being to see whether the disease stabilizes or additional metastases develop.⁵⁷ If there is a response to treatment or the disease stabilizes with no evidence of further metastases, they proceed with resection.⁵⁷

It is extremely important to perform high-quality imaging before considering resection of metastases. The use of 18-fluorodeoxyglucose positron emission tomography (FDG-PET) may help detect occult metastatic disease more accurately. A 2004 comparison of FDG-PET with conventional imaging in patients with stage IV melanoma reported a sensitivity and specificity of 76% and 87% for conventional imaging, 79% and 87% for FDG-PET, and 88% and 91% for conventional imaging combined with FDG-PET.⁷⁰ With FDG-PET, as with any other imaging modality, appropriate use depends on a clear understanding of its capabilities and limitations.

Another important indication for metastasectomy is palliation; the vast majority of patients with stage IV melanoma will not be candidates for curative-intent metastasectomy. The goal of a palliative pro-

cedure is to control identifiable symptoms (e.g., GI bleeding or pain) caused by an advanced malignancy while minimizing morbidity.⁵⁷ A thorough discussion should be held among the surgeon, the patient, and the family to address the goals and expected outcomes of the procedure, as well as its potential morbidity.⁷¹

Chemotherapy. To date, the rates of objective response to chemotherapy for melanoma have been somewhat disappointing. Dacarbazine (DTIC) is the only currently approved chemotherapeutic agent for melanoma, and it offers no more than marginal therapeutic benefit, with moderate side effects.⁷² Various combination regimens—including BOLD (bleomycin, vincristine, lomustine [CCNU], DTIC), CVT (cisplatin, vincristine, DTIC), and CBDT (cisplatin, carmustine [BCNU], DTIC, tamoxifen)—have been employed, with response rates ranging from 9% to 55%.⁷² The oral alkylating agent temozolamide has been studied in stage IV melanoma patients; compared with DTIC, it yields a modest prolongation of survival, with an acceptable side-effect profile.⁷³

Melanoma vaccines. Several experimental melanoma vaccines are being investigated for possible use in advanced-stage melanoma. These agents use a variety of modalities to present melanoma antigens to host immune cells in an immunostimulatory context.⁷⁴⁻⁷⁶ There was considerable initial optimism regarding this approach, but a 2004 review of the experience at the National Cancer Institute found that the response rate for cancer vaccines was only 2.6%⁷⁷ (a figure comparable to the results obtained by others). The authors concluded that the use of cancer vaccines may still prove to be a viable strategy, but profound changes will be required to enhance the efficacy of these agents.

Immunotherapy. At present, immunotherapy is perhaps the most promising area of investigation with respect to the treatment of advanced melanoma. Immunotherapy has been defined in various ways, but in general, it can be thought of as a form of treatment based on the concept of modulating the immune system to achieve a therapeutic goal.⁷⁸ There are several different modalities that can be considered immunotherapy, including monoclonal antibody therapy and interferon-based therapy. For present purposes, we will focus on two modalities that are currently under active investigation: high-dose interleukin-2 (IL-2) therapy and adoptive cell transfer.

In initial studies, the response rates after high-dose IL-2 therapy for melanoma have ranged from 15% to 20%, with about half of the responding patients experiencing complete regression.⁷⁹ In those patients who do achieve a complete response, the effect is often durable.⁸⁰ Unfortunately, IL-2 immunotherapy is associated with severe side effects.

Adoptive cell transfer involves the administration of activated cytotoxic T lymphocytes (CTLs) that are generated against specific tumor types. These CTLs can be generated either by using specific tumor-associated antigens or by culturing lymphocytes with tumor cells. The objective is to encourage the selection of tumor-specific T lymphocytes that are capable of generating a strong immunologic response and thereby help break the body's immunologic tolerance of the tumor. Unfortunately, initial clinical trials of activated T cell transfer for other types of malignancy found that the transferred cells did not remain present in sufficient concentrations to yield a significant clinical effect.⁸¹ However, the addition of nonmyeloablative lymphodepleting chemotherapy, followed by autologous transfer of tumor-specific CTLs in conjunction with IL-2 administration, was shown to result in rapid clonal expansion of tumor-specific T lymphocytes *in vivo*, which was associated with a significant clinical response.⁸² In a 2005 study, transfer of a T cell receptor gene from a

patient with a significant antitumor response conferred impressive T cell responses.⁸³

Despite some advances in therapy, overall survival for patients with stage IV melanoma has not improved over the past 20 years. Overall 5-year survival remains lower than 5%, with a median survival of only 7.5 months.⁸⁴ The best hope for future improvements probably lies in the treatment of micrometastatic disease by means of targeted chemotherapy and immunotherapy.

Operative Technique

The inguinal nodes drain the anterior and inferior abdominal wall, the perineum, the genitalia, the hips, the buttocks, and the thighs. A superficial groin dissection removes the inguinal nodes, whereas a deep groin dissection incorporates the iliac and obturator nodes. Palpable nodes can be marked on the patient before operation.

SUPERFICIAL GROIN DISSECTION

The patient is placed in a supine position on the operating table, with the hip slightly abducted and with the hip and knee slightly flexed and supported by a pillow. A Foley catheter is inserted, and the skin is prepared and draped.

The femoral artery, the anterior superior iliac spine, the pubic tubercle, and the apex of the femoral triangle are marked. A diagonally oriented skin incision is made that extends from a point medial to

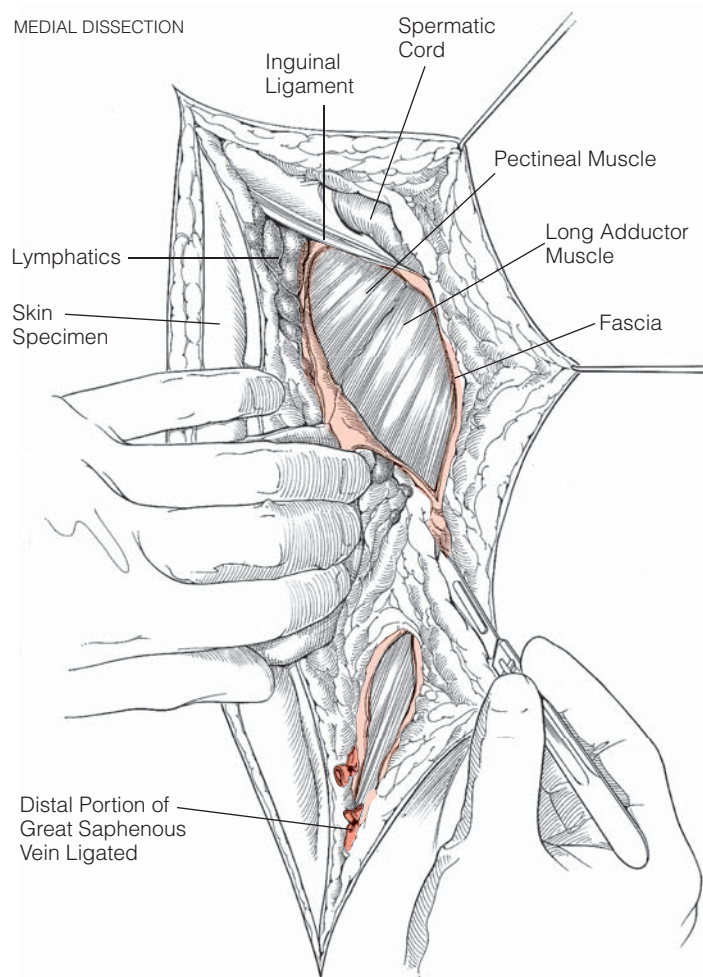

Figure 5 Superficial groin dissection. The incision is deepened to include the deep muscular fascia.

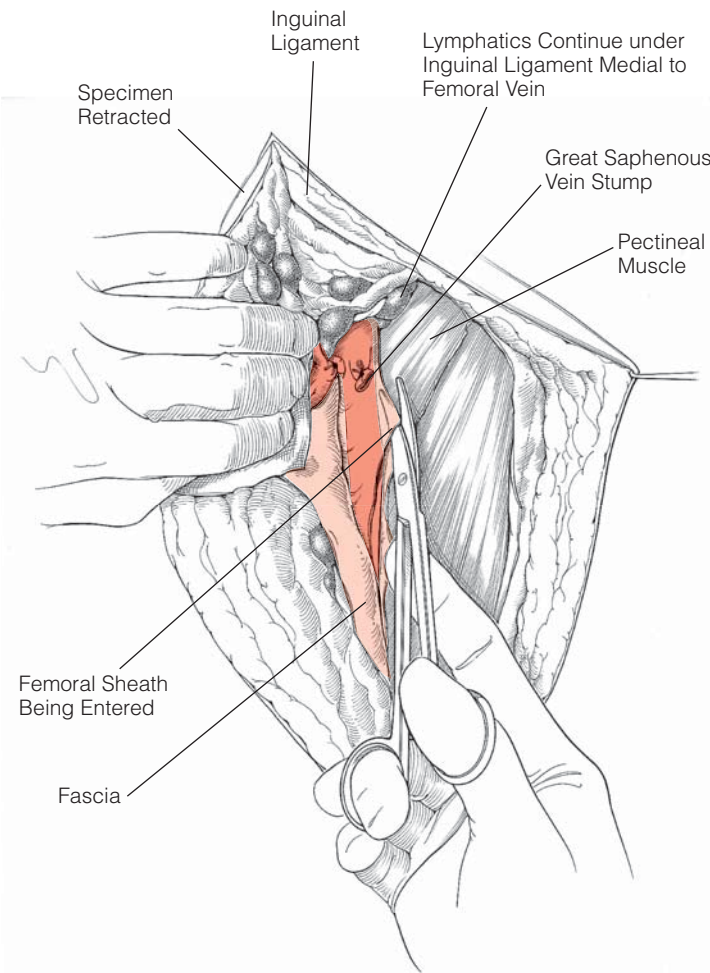

Figure 6 Superficial groin dissection. The investing fascia overlying the femoral nerve and vessels is removed.

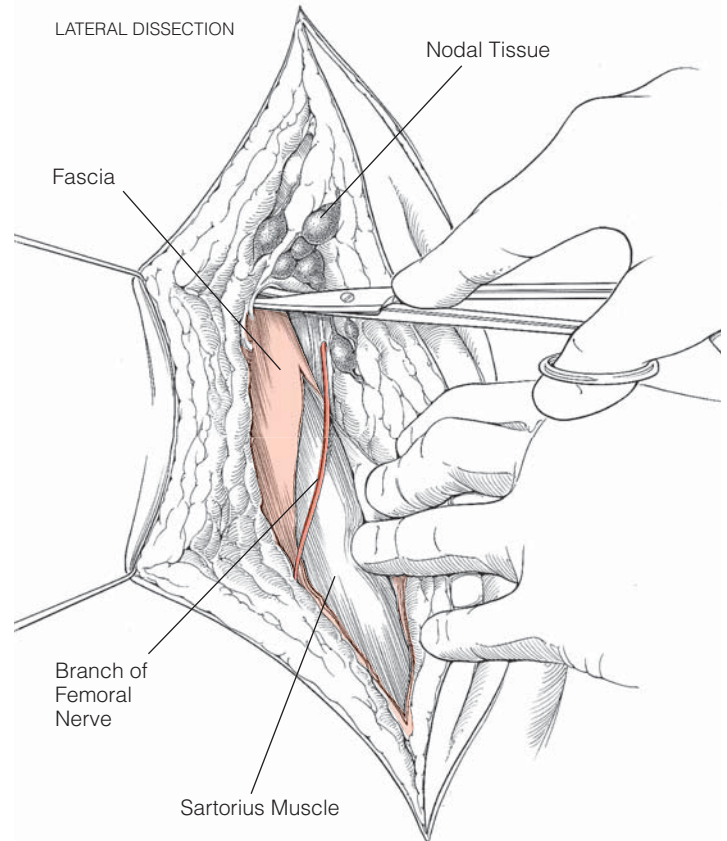

Figure 7 Superficial groin dissection. The groin dissection is continued on the lateral side.

the anterior superior iliac spine down to the apex of the femoral triangle; the incision is formed in the shape of an S so as not to cross the thigh flexion crease at a right angle. An incision oriented and shaped in this manner will cause the least possible interference with the musculocutaneous and cutaneous vascular territories of the skin, will minimize ischemia to the skin flaps, and will avoid a flexion contracture. Flaps are raised to allow identification of the medial border of the sartorius, the lateral border of the adductor longus, and the external oblique fascia on the lower abdominal wall.

Fat and nodal tissue are swept inferiorly off the external oblique aponeurosis, the spermatic cord, and the inguinal ligament [see Figure 5] and are reflected inferiorly. The fat and lymph nodes are then dissected from the femoral triangle, starting medially at the lateral edge of the adductor longus and proceeding laterally [see Figures 6 and 7]. The femoral vessels are left undisturbed. The saphenous vein is ligated and divided at the fossa ovalis [see Figure 8]; it is also ligated and divided as it exits the femoral triangle distally. The specimen is then dissected free from the femoral nerve. This step usually entails sacrificing branches of the lateral femoral cutaneous nerve, thereby resulting in numbness of the anterolateral thigh.

Cloquet's lymph nodes are located medial to the femoral vein under the inguinal ligament. These nodes are dissected out and submitted as a separate specimen. If Cloquet's nodes contain melanoma, the risk that iliac nodes will harbor melanoma is high, and a deep groin dissection should be performed (see below).

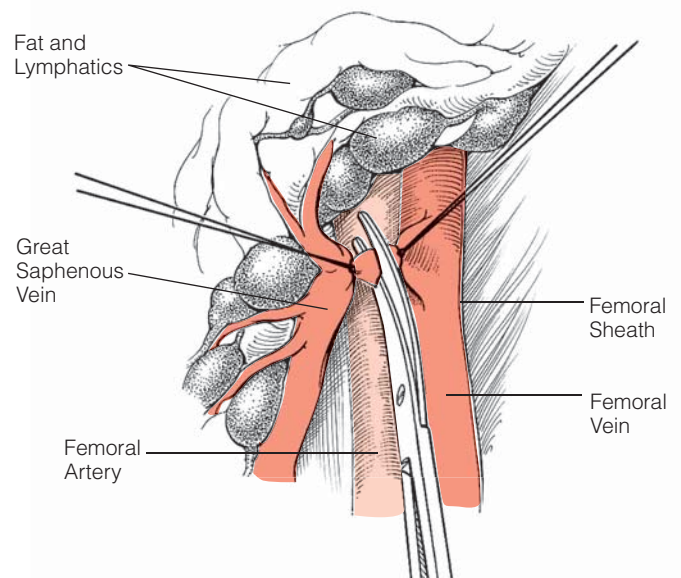

Figure 8 Superficial groin dissection. The great saphenous vein is ligated and divided.

DEEP GROIN DISSECTION

The inguinal ligament is divided, and the inguinal canal is further exposed by releasing the internal oblique abdominal muscle, the transversus abdominis, and the fascia transversalis and dissecting into the retroperitoneal space. The deep circumflex iliac vessels are ligated, and the peritoneum is separated from the preperitoneal fat and nodes by means of blunt finger dissection. Alternatively, rather than dividing the inguinal ligament, one may make a separate incision in the external oblique fascia parallel to and above the inguinal ligament.

Retractors are inserted to widen the retroperitoneal space, and the peritoneum and the abdominal viscera are retracted medially. The chain of lymph nodes, areolar tissue, and adventitial tissues along the

external iliac vessels is dissected; the dissection proceeds proximally to the origins of the internal iliac vessels (avoiding the ureter) and incorporates the nodes overlying the obturator foramen while carefully avoiding injury to the obturator nerve. The deep epigastric vessels are usually ligated at their origins from the external iliac artery and vein. The lymph node-bearing specimen is then removed as a unit, oriented, and marked with sutures for orientation and identification. The inguinal canal is reconstructed to prevent a hernia. Any defect medial to the femoral vessels under the ligament is sutured closed with Cooper's ligament. The sartorius is detached from the anterior superior iliac spine and is sutured to the midportion of the inguinal ligament to cover the femoral vessels. The skin and the subcutaneous tissues are then closed in layers over a soft suction drain.

5 BREAST PROCEDURES

Rena B. Kass, M.D., F.A.C.S., D. Scott Lind, M.D., F.A.C.S., and Wiley W. Souba, M.D., Sc.D., F.A.C.S.

The procedures used to diagnose, stage, and treat breast disease are rapidly becoming less invasive and more cosmetically satisfying while remaining oncologically sound. In particular, percutaneous core biopsy has largely replaced excisional breast biopsy for both palpable and nonpalpable breast lesions and has proved to be an equally accurate, less invasive, and less costly means of pathologic diagnosis.¹ Moreover, in clinically appropriate patients, sentinel lymph node biopsy (SLNB) has proved to be an accurate method of staging the axilla that reduces the incidence of many of the complications associated with traditional axillary node dissection.² Furthermore, breast conservation has largely supplanted mastectomy for definitive surgical treatment of breast cancer; randomized trials continue to demonstrate equivalent survival rates for the two therapies.³ Even in those cases where mastectomy is either required or preferred, advances in reconstructive techniques have been made that yield significantly improved outcomes after breast reconstruction.⁴ Finally, in an effort to eliminate the need for open surgical treatment of breast cancer, various percutaneous extirpative and ablative local therapies have been developed and are being evaluated for potential use in managing breast cancer in carefully selected patients.⁵

A more minimally invasive approach to breast disease will depend to a substantial extent on the availability of accurate and efficient imaging modalities. Adeptness with such modalities is rapidly becoming an essential part of the general surgeon's skill set. In this chapter, we describe selected standard, novel, and investigational procedures employed in the diagnosis and management of breast disease. The application of these procedures is a dynamic process that is shaped both by technological advances and by physicians' evolving understanding of the biology of breast diseases.

Breast Ultrasonography

Breast ultrasonography can be useful for evaluating palpable breast masses or mammographically indeterminate lesions; for carrying out postoperative and oncologic follow-up; for guiding aspiration and biopsy of lesions; and for facilitating intraoperative tumor localization, margin assessment, placement of catheters for partial-breast irradiation, and investigational tumor-ablating techniques.

In the office, breast ultrasonography has become a useful adjunct to the clinical breast examination, particularly in patients with radiographically dense mammograms: it defines breast lesions more clearly than physical examination does and thus can potentially reduce the number of unnecessary biopsies done for simple cysts or fibroglandular tissue presenting as a palpable nodularity. Whole-breast ultrasonography is not an effective screening tool and therefore should not be a substitute for annual mammography. The American College of Surgeons (ACS) and various surgical subspecialty organizations offer a multitude of courses, at varying skill levels, geared toward training general surgeons in the use of breast ultrasonography.

TECHNIQUE

Most real-time ultrasound imaging is performed with handheld probes generating frequencies between 7.5 and 12 MHz. The procedure is conducted with the patient supine, a pillow behind the shoulder, and the ipsilateral arm extended over the head for maximal spreading of the breast. Sonographic transmission gel is applied between the transducer and the skin to reduce air artifacts, and the transducer is pressed slightly against the skin to improve image quality. The selected breast area is imaged from the nipple outward in a radial pattern.

All lesions should be sonographically characterized with respect to margins, effect on adjacent tissue, internal echo pattern, compressibility, height-width ratio, and presence of shadowing versus posterior enhancement. Classically, simple cysts tend to be oval or lobulated, anechoic, and sharply demarginated; they typically demonstrate posterior enhancement. Benign solid lesions tend to be well circumscribed, hypoechoic, and wider than they are tall; they show homogeneous internal echoes and edge shadowing. Carcinomas are also hypoechoic masses, but they cross tissue planes and therefore tend to be taller than they are wide, with irregular borders; in addition, they can demonstrate heterogeneous interior patterns and broad acoustic shadowing [see *Figure 1*]. A lesion that has a single indeterminate characteristic on ultrasonography or that is clinically suspicious despite appearing benign on ultrasonography is an indication for core or open biopsy. Lesions should be characterized in at least two orthogonal planes, and the image should be saved for future reference.

Ductal Lavage

The majority of breast cancers originate from the epithelium of the mammary ducts. Ductal lavage is a method of recovering breast duct epithelial cells for cytologic analysis via a microcatheter that is inserted into the duct. Potential applications include identifying high-risk women, predicting risk with molecular markers, monitoring the effectiveness of chemopreventive agents, and delivering drugs directly into the ducts. At present, however, ductal lavage remains investigational, and its predictive value and clinical utility await further definition.⁶

TECHNIQUE

The breast duct epithelium may be sampled by means of either nipple fluid aspiration or ductal lavage. For the aspiration of nipple fluid, a topical anesthetic is first applied to the nipple, followed by a mild scrub with a dekeratinizing gel. Suction is then applied to the nipple while the breast is gently massaged. Aspirated fluid is sent for analysis. In ductal lavage, the breast and nipple are similarly prepared. The nipple duct orifice that yields fluid spontaneously or as a result of suction is cannulated, the duct is irrigated with saline, and the effluent is collected for cytologic analysis. Cannulation of the duct is possible in the majority of women. Both nipple fluid aspiration and ductal lavage are generally well tolerated. The former is simpler and less expensive, but the latter retrieves more cells.⁷

Figure 1 Breast ultrasonography. Shown are (a) a simple cyst that has smooth margins, is anechoic, and shows posterior enhancement; (b) a fibroadenoma that has smooth margins, is hypoechoic, and shows posterior shadowing; and (c) a mammary carcinoma that has irregular borders, is hypoechoic, and shows irregular posterior shadowing.

Ductoscopy

Advances in endoscopic technology have made visualization and biopsy of the mammary ducts possible. Mammary ductoscopy is a procedure in which a 0.9 mm microendoscope is employed to visualize the lining of the ductal system directly. It is currently being evaluated for use in three main areas: (1) evaluation of patients with pathologic nipple discharge,⁸ (2) evaluation of high-risk patients, and (3) evaluation of breast cancer patients to determine the extent of intraductal disease and perhaps reduce the rate of positive margins.⁹ At present, this investigational technology is available at only a few centers, and further study will be required to determine its precise role in the evaluation and management of breast disease.

TECHNIQUE

Ductoscopy can be performed either in the office or in the operating room with minimal discomfort. Before the procedure, a nipple block is usually performed with topical lidocaine cream, supplemented (if necessary) by intradermal injection of 1% lidocaine around the nipple-areola complex or intraductal instillation of lidocaine (or both). The breast is massaged to promote expression of nipple aspirate fluid, which facilitates identification of a ductal orifice. The duct is then gently dilated, and the ductoscope is advanced with the help of insufflation under direct visualization. Most ducts with pathologic discharge can readily be identified and dilated sufficiently to allow passage of the ductoscope.¹⁰ An outer air channel on the fiberscope permits instillation and collection of saline solution so that cells can be retrieved for ductal lavage.¹¹ Intraductal lesions can be percutaneously localized under direct endoscopic visualization for subsequent biopsy; alternatively, they may be amenable to endoscopic cytologic brushing or to the newly described technique of intraductal breast biopsy.¹⁰

The procedure is usually well tolerated. It should be noted that duct excision is still regarded as standard practice for pathologic discharge, regardless of endoscopic findings.

Breast Biopsy

Cytologic or tissue diagnosis of a palpable breast mass may be obtained by means of fine-needle aspiration (FNA) biopsy, core-needle biopsy (CNB), or open incisional or excisional biopsy. Currently, most solid lesions are initially diagnosed by means of

CNB, which is less invasive, less costly, and more expeditious than open biopsy while achieving comparable accuracy. In select circumstances, however, FNA biopsy and open biopsy may remain suitable options. All minimally invasive biopsy techniques are facilitated when guided by imaging modalities; such guidance enables the physician to perform a more directed biopsy that targets the lesion precisely while avoiding benign-appearing tissue, necrotic tissue, and adjacent structures (e.g., the chest wall, skin, and axillary vessels). Therefore, even when a lesion is palpable, ultrasound-directed biopsy is preferable to blind biopsy (though not absolutely necessary) and is recommended if the surgeon has a suitable ultrasound device in the office.

The choice of a specific biopsy technique should be individualized on the basis of the clinical and radiographic features of the lesion, the experience of the clinician, and the patient's condition and preference.

FINE-NEEDLE ASPIRATION BIOPSY

FNA biopsy permits the sampling of cells from the breast or the axillary region for cytologic analysis. It is particularly useful for sampling a clinically or sonographically suspicious axillary node and for evaluating cyst fluid that is bloody or that comes from an incompletely collapsed or recurrent cyst. In patients receiving anticoagulants, FNA biopsy is a reasonable alternative to CNB for evaluation of a solid lesion, in that there is less potential for hemorrhage if anticoagulation cannot be discontinued. Discrete masses discovered on physical examination may be either cystic or solid. A lesion that is shown by ultrasonography to be a simple cyst need not undergo FNA biopsy unless it is symptomatic.

Technique

The skin of the breast or axilla is prepared, and a local anesthetic is injected superficially via a 25-gauge needle. Although smaller needles may be used, a 21-gauge needle is optimal for FNA biopsy because it can be effectively used both for aspiration of potentially viscous fluid and for procurement of sufficient cellular material from solid masses. To generate adequate suction, a 10 ml or larger syringe should be used. As noted (see above), FNA biopsy ideally is performed under ultrasonographic guidance. If such guidance is unavailable, the lesion is held steady between the thumb and the index finger of the nondominant hand. Before the needle enters the skin, 1 ml of air is introduced into the biopsy

syringe. Then, without the application of suction, the needle is advanced into the lesion. Once the needle is in place, strong suction is applied.

If the lesion is cystic, all fluid is aspirated, at which point the mass should disappear. Ultrasonography can confirm the complete collapse of a cyst or help direct the needle to an undrained portion of the cyst. The fluid need not be sent for analysis unless it is bloody or is associated with a residual palpable mass or an incompletely collapsed cyst as seen on ultrasonography. If the fluid is to be sent for analysis, it is injected directly into the pathologic preservative. The patient is reexamined 4 to 8 weeks after successful aspiration. If the same cyst has recurred, aspiration should be repeated and the new aspirate sent for cytologic analysis.

If the lesion is solid, the needle is moved back and forth within the lesion along a 5 to 10 mm tract until tissue is visualized in the hub of the needle. (This oscillation of the needle along the same tract is the most effective way of obtaining a cellular, diagnostic specimen). Suction is released while the needle is still within the lesion, and the needle is then withdrawn. The contents of the needle are expelled onto prepared glass slides, spread into a thin smear, and fixed according to the preferences of the cytology laboratory. The syringe may be rinsed so that a cellblock can be prepared for further analysis. The lesion should be sampled twice to ensure that a sufficiently cellular sample has been obtained.

Interpretation of Results

Accurate interpretation of FNA requires substantial experience on the part of both the operator and the cytopathologist; only in a few select centers with expert breast cytopathologists has it remained the diagnostic procedure of choice for solid breast masses. Consequently, one must exercise considerable caution about using FNA biopsy rather than CNB as the sole means of confirming a cancer diagnosis before the initiation of definitive operative management or neoadjuvant therapy. FNA biopsy is unable to discriminate carcinoma in situ from invasive carcinoma and therefore incapable of establishing whether axillary node staging is needed. Furthermore, because of the smaller quantity of tissue extracted, FNA biopsy is a less reliable means of assessing receptor status than CNB is. Finally, in 1% to 2% of cases, FNA biopsy may yield false positive results,¹² potentially leading to an unnecessary cancer operation. For these reasons, it is recommended that malignancies identified by FNA biopsy be confirmed by means of CNB or open biopsy (preferably the former) before definitive therapy is provided.

Cytologic analysis that is diagnostic of a specific benign lesion (e.g., a fibroadenoma) may generally be relied on if it is in concordance with the clinical features of the lesion. However, a negative result from FNA biopsy does not exclude cancer: this procedure fails to diagnose as many as 40% of breast malignancies.¹² Cellular atypia, pathologic discordance, or a nondiagnostic FNA is an indication for tissue diagnosis.

CORE-NEEDLE BIOPSY

As noted (see above), CNB is the diagnostic procedure of choice for breast lesions. Like FNA biopsy, it is easily performed in an outpatient setting. Unlike FNA biopsy, CNB removes a narrow cylinder of tissue that is submitted for pathologic rather than cytologic analysis. Whenever feasible, CNB of both palpable and nonpalpable lesions is performed under ultrasonographic guidance, which permits real-time documentation of the needle's position within the lesion. For lesions not visualized on ultrasonography or for suspicious microcalcifications, stereotactic guidance may be employed instead. A preoperative diagnosis of malignancy

obtained via CNB enables the surgeon to perform a single-stage operative procedure. It may also help lower the positive margin rate for patients undergoing breast-conserving therapy, thereby reducing the need for reexcision and improving the cosmetic outcome.¹³

Various automatic, rotational, and vacuum-assisted devices may be employed to perform CNB; in what follows, we briefly discuss these devices [*see Technique, below*]. When CNB is performed with a 14-gauge needle, as is the case with Tru-Cut (Cardinal Health, Dublin, Ohio) devices and spring-loaded guns, up to 30% pathologic upgrading may be seen on subsequent surgical excision.¹ When CNB is done with a larger needle (8 to 11 gauge), as is the case with image-guided vacuum-assisted and rotational devices, a greater volume of tissue is delivered, and consequently, less pathologic upgrading is seen.¹⁴ With the vacuum-assisted core biopsy (VACB) devices currently available, it is possible to remove all radiographic evidence of the lesion. It is therefore common practice with all core biopsies to place a titanium clip or another surrogate marker at the biopsy site to facilitate future localization procedures. In addition, a clip should be placed at the biopsy site if the patient has a larger cancer for which neoadjuvant chemotherapy is required; some such lesions exhibit a complete clinical response to chemotherapy and thus are no longer radiographically visible at the time of definitive operative treatment. Two-view postbiopsy mammography should be performed to confirm accurate placement of the clip and adequate sampling of the lesion at the time of biopsy.

Technique

Palpation-guided biopsy In this setting, a manual Tru-Cut-type device or, more commonly, a spring-loaded semiautomatic biopsy gun is used to obtain the specimen. The skin is prepared, and a local anesthetic is infiltrated superficially via a 25-gauge needle. A nick is made in the skin with a No. 11 blade to permit easy entry of the biopsy needle (usually a 14-gauge needle). As with FNA biopsy (see above), the lesion is held steady in the nondominant hand while the biopsy needle is advanced into the periphery of the lesion. Next, the needle is manually advanced through the center of the lesion (if a manual device is used), or the gun is fired (if a spring-loaded device is used). Finally, the needle is withdrawn to retrieve the core. Four to five cores, each from a separate pass, should be obtained to ensure that the lesion is not undersampled. Pressure is applied over the lesion and the biopsy tract for 10 to 15 minutes to ensure adequate hemostasis. The nick in the skin is closed with an adhesive strip (e.g., Steri-Strip; 3M, St. Paul, Minnesota).

Ultrasound-guided biopsy This technique may be employed for both palpable and nonpalpable lesions. The lesion that is to undergo biopsy is centered on the screen of the ultrasound device. A local anesthetic is injected superficially, first along the anticipated biopsy tract and then both anterior and posterior to the lesion; this latter maneuver helps ensure that there is a safe distance between the lesion and the skin or the chest wall. A nick is made in the skin with a No. 11 blade. The biopsy needle is then inserted through the skin, with care taken to keep it in a plane parallel to the footplate of the ultrasound probe as it passes through the breast tissue. The biopsy itself can be either performed in a freehand manner or directed with a needle guide attached to the probe. The ideal final positions of the tip and shaft vary, depending on the particular biopsy device selected for the procedure [*see Figure 2*]. Regardless of which device is used, the tip and shaft of the needle should be visualized throughout the entire approach to

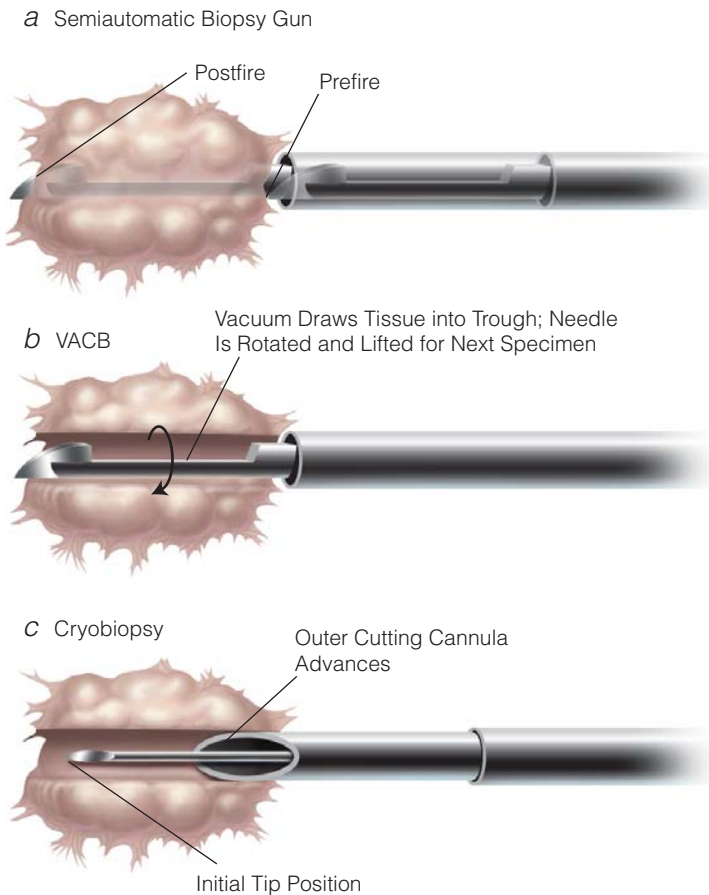

Figure 2 Core-needle biopsy. The positioning of the needle shaft and tip varies with the particular biopsy device being used. (a) For manual or semiautomatic guns that fire through the lesion, the position of the tip before firing should be at the edge of the lesion. Keeping the needle shaft parallel to the chest wall or the skin keeps these structures from being injured when the gun is fired or the core is manually obtained. (b) For most vacuum-assisted devices, multiple cores can be obtained through a single placement of the device within the breast. For diagnostic biopsies performed under ultrasonographic or stereotactic guidance, the needle may be placed in the center of the lesion and rotated up to 360° in specified intervals. (c) For cryobiopsy, the tip of the needle should be advanced through the center of the lesion toward the far edge of the lesion before firing. This step stabilizes the lesion. The outer cutting and rotating cannula is then fired over the inner needle.

and biopsy of the lesion. Prefire and postfire images should be obtained that show the needle in proximity to and within the lesion, respectively. Four to five good cores are required for adequate sampling. Once the biopsy is complete, pressure is applied over the lesion and the biopsy tract, and a Steri-Strip is placed. To facilitate closure of larger entry sites, a single subcuticular stitch may be used.

Brisk bleeding may occur during and immediately after the procedure, but it usually can be controlled by the application of direct pressure. Patients are restricted from engaging in strenuous activity for 24 hours after biopsy. Bruising may result, but it typically resolves within days. Other potential complications include hematoma, fat necrosis, a palpable lump, and infection; however, such events are uncommon. Most patients receiving oral anticoagulants can be switched to a subcutaneous alternative that can be stopped on the morning of the procedure.

Semiautomated gun biopsy. When a spring-loaded semiautomatic biopsy gun is used, the tip of the needle should abut the lesion in such a way that the biopsy trough will be in the lesion after the device is fired. Ideally, the repeat passes should sample different portions of the lesion and avoid any necrotic areas that have been visualized.

Vacuum-assisted core biopsy. Vacuum-assisted rotational cutting devices employ a 7- to 11-gauge probe with a distal sampling trough and an inner rotating cutter. The sampling trough can be placed either in the center of the lesion or directly under it. The probe is attached to a vacuum system, which draws the target tissue into the trough. Once the tissue has been drawn into the trough, the inner rotating cutter is advanced and cuts a core from it. The tissue core is then delivered by the vacuum system through the barrel of the probe and into a proximal collection chamber. The probe can be rotated up to 360° and can retrieve multiple samples through a single insertion in the skin. The larger tissue volumes obtained with these rotational VACB devices have reduced the incidence of atypical ductal hyperplasia or ductal carcinoma in situ (DCIS) upgrades on subsequent excisional biopsies.⁵

Cryoassisted core biopsy. In a cryobiopsy, a thin (19-gauge) solid needle is placed in the middle of the targeted tissue. The tip is then cooled to approximately -10° C, a temperature that freezes the tissue to the needle but does not cause tissue necrosis. An outer rotating cutting cannula (10 gauge) is then advanced over the inner localizing needle. The device is removed from the breast, and the single specimen is removed. As with the semiautomatic biopsy gun, multiple passes into the breast are still required. However, the local anesthetic effect of the cooling process, the ability of the device to spear and stabilize a lesion, and the absence of a firing gun-type action make cryobiopsy advantageous, particularly for a mobile lesion that lies close to the skin or the chest wall.

Stereotactic-guided biopsy Lesions that are visible only on mammography—including small solid lesions, asymmetric densities, and suspicious groups of microcalcifications—can often be targeted and subjected to core biopsy under stereotactic guidance.¹⁵ This outpatient procedure commonly makes use of a mounted VACB gun, similar to the handheld VACB device previously described (see above). Stereotactic biopsy is appropriate for lesions that are clearly visible on digital images and identifiable on stereotactic projections. Lesions that lie close to the chest wall or in the subareolar region may not be amenable to stereotactic biopsy and are often best approached via open biopsy with needle localization (see below). Likewise, lesions in thinly compressible breasts may not be amenable to stereotactic biopsy, because firing of the needle may result in a through-and-through injury to the breast. Certain stereotactic systems may not be suitable for patients who are unable to lie prone or are morbidly obese. It should be kept in mind that stereotactic biopsy is a diagnostic procedure and is not intended for therapeutic purposes. On the whole, it is safe, and the complication rate is acceptably low.

Depending on the system being employed, the patient either lies prone on the stereotactic table or sits upright. With the breast compressed craniocaudally or mediolaterally, stereotactic digital imaging is then performed to visualize the targeted lesion and calculate its location in three dimensions, and a suitable probe insertion site is identified. The skin is prepared, and a small amount of buffered 1% lidocaine with epinephrine is administered. The skin at the insertion site is punctured with a No. 11 blade, the probe is manually advanced to the prefire site, and the position of the probe is

confirmed by means of stereotactic imaging. The device is then fired, repeatedly cutting, rotating, and retrieving samples until the desired amount has been removed. Targeted removal of suspicious microcalcifications is confirmed with specimen mammography.

Once the biopsy is complete, an inert metallic clip is deployed into the biopsy site through the probe for future localization; deployment and positioning are initially confirmed by stereotactic imaging. The biopsy device is then removed, the edges of the skin incision are approximated with Steri-Strips, and a compressive bandage is applied. Typically, 1 g of tissue (equivalent to approximately 10 to 12 samples with an 11-gauge probe) is sufficient for diagnosis. Once the procedure is over and the breast has been released from compression, a two-view mammography should be obtained to verify that the clip was accurately placed and to document that the targeted lesion was adequately sampled.

Interpretation of Results

CNB is a highly accurate diagnostic tool: the false-negative rate is only 1% to 2%,¹⁶ which is comparable to that of open wire-localized biopsy. When pathologic evaluation reveals fibroadenoma, microcalcifications within benign fibrocystic tissue, or other comparably benign pathologic conditions, there is no need for any special follow-up, and routine screening mammography may be resumed. However, when biopsy of the targeted mass lesion fails to yield a mass diagnosis or a biopsy specimen from group of clustered calcifications is devoid of microcalcifications on pathologic review, the discordant result should be viewed with some suspicion and should be considered an indication for open biopsy. Subsequent excisional biopsy is also indicated when CNB reveals atypical hyperplasia, radial scar, lobular carcinoma in situ (LCIS), or papilloma. The rationale is that the excisional biopsy may result in a pathologic upgrade to cancer. For example, open biopsy after a CNB indicative of atypical ductal hyperplasia may reveal DCIS in approximately 40% of patients when CNB was performed with a 14-gauge automated gun. The use of larger (e.g., 11-gauge) core biopsy devices has reduced the frequency of this finding to approximately 20%,¹⁷ but it has not eliminated the need for excision. False positive results are rare with CNB; therefore, a diagnosis of malignancy may be believed, and a one-stage definitive surgical procedure may then be planned without further biopsy.

Touch Preparation of Cores

For an immediate but preliminary diagnosis, cytologic touch preparation of fresh cores may be performed in the office.¹⁸ The tissue is blotted to remove any gross blood, the core is gently smeared along a glass slide, and the slide is then immediately fixed in 70% ethanol. A layer of cells is left on the surface of the slide for cytologic evaluation, while the core is preserved for permanent evaluation. This procedure has a diagnostic accuracy of nearly 90%. Although the false-negative rate is approximately 25%, an immediate diagnosis is obtained in 75% of patients.¹⁸ Like all preliminary diagnoses, touch preparation diagnoses should be treated with caution until the final results of histopathologic evaluation are available.

PERCUTANEOUS EXCISIONAL BIOPSY

In some instances, patient preference may dictate complete removal of a mass regardless of its benign appearance. As an alternative to open biopsy (see below), percutaneous excision of small masses may be performed.¹⁹⁻²¹ This procedure can be performed in an outpatient setting with the patient under local anesthesia. Some of the devices used for percutaneous excision are vacuum assisted and remove the mass as multiple cores, whereas others

deliver large intact samples in a single pass [see Figure 3]. Although such approaches clearly show promise for future surgical treatment of breast cancer, these percutaneous devices are currently approved by the U.S. Food and Drug Administration (FDA) only for excision of benign masses. Lesions found to be harboring cancer should undergo subsequent open surgical reexcision. Excision of lesions that are close to the skin or the chest wall or are larger than 2 to 3 cm in diameter may prove technically challenging with percutaneous techniques; open excisional biopsy [see Open Biopsy, below] may be preferable for such lesions.

CRYOABLATION

Patients with a biopsy-proven fibroadenoma who want their mass removed but desire an alternative to open or percutaneous surgical excision may be candidates for cryoablation, which destroys targeted tissue by alternately freezing and thawing it. Intracellular ice formation, osmotic injury, and ischemic injury are all believed to contribute to the mechanism of tissue destruction.

Figure 3 Percutaneous excisional biopsy. This procedure may be performed by means of several different methods. (a) One approach is to employ a vacuum-assisted device, which is placed with the trough under the lesion and the shaft parallel to the posterior aspect of the lesion. The needle is then lifted anteriorly as it is rotated first 45° degrees clockwise, then back to the center position (0°), and finally 45° counterclockwise to remove the entire lesion in multiple cores. (b) Another option is to employ an electrosurgical device such as the Ovation (Rubicon Medical, Inc., Redwood City, California), which circumscribes the mass with a cutting wire loop while concurrently deploying a retractable plastic bag that encapsulates the lesion and retracts it through the skin en bloc. (c) A third option is to employ a device such as the Intact Breast Lesion Excision System (Intact Medical Corp., Natick, Massachusetts), which circumscribes the mass with radiofrequency wand and delivers it en bloc.

Figure 4 Cryoablation. The needle is placed through the center of the lesion, and argon gas is delivered to create a local temperature of -40°C . The resulting iceball is well visualized by ultrasonography.

Because of the natural analgesic effect of cold, cryoablation is generally a well-tolerated procedure that can be performed in an outpatient setting. Clinically, resorption of the fibroadenoma increases over time, with 12-month follow-up studies reporting 73% to 97% reductions in lesion volume. Despite the occasional residual disease noted when cryoablation is used to treat larger masses, both hospital-based and community-based studies have reported that patient satisfaction rates are higher than 90% with this procedure.²²

Technique

A 12-gauge cryoprobe is inserted into the center of the lesion under ultrasonographic guidance. If the lesion is in close proximity to the chest wall or the skin, it should first be isolated by injecting normal saline. To freeze the lesion, inert argon gas is delivered through the tip of the probe in such a way as to create a local temperature of -40°C or lower. An iceball is thereby formed that is well visualized by ultrasonography [see Figure 4]. In a tightly coupled system, helium is then delivered to thaw the lesion. For adequate necrosis to occur, two freeze-thaw cycles must be performed; the exact specifications of these cycles depend on the size of the lesion.

OPEN BIOPSY

The vast majority of open breast biopsies are now performed with either local anesthesia alone or local anesthesia with I.V. sedation.

Technique

Various options for incisions are available [see Figure 5]. If the pathology is unclear, the incision is placed directly over the lesion to minimize tunneling through breast tissue. The incision should be long to ensure that the mass, together with a small rim of grossly normal tissue, can be excised as a single specimen and be oriented so that it can be included within any future lumpectomy or mastectomy incision should the lesion prove malignant. Resection of overlying skin is not necessary unless the lesion is extremely superficial. Historically, surgeons performing open biopsies have generally employed curvilinear incisions placed within the resting

lines of skin tension [see Figure 5a, 5b]. Currently, however, some surgeons are advocating the use of radial incisions, particularly for medial, lateral, and inferior lesions.¹³ If a previous CNB proved the lesion to be benign (e.g., fibroadenoma) but the patient still favors excision, it is acceptable to move the incision to a circum-areolar position or another less visible site.

For diagnostic biopsies, the surgeon should orient the specimen, and the pathologist should ink all margins. Meticulous hemostasis should be achieved before closure to prevent the formation of hematomas that could complicate subsequent definitive oncologic resection. A cosmetic subcuticular skin closure is preferred.

NEEDLE (WIRE)-LOCALIZATION BREAST BIOPSY

Lesions that are not amenable to stereotactic core biopsy may be excised by means of needle (wire)-localization breast biopsy (NLBB). Such lesions include those that are close to the chest wall or under the nipple, as well as those occurring in a thin breast, where firing the needle may cause it to pass through the opposite side of the breast. Radiographic evidence of a radial scar is also an indication for NLBB: a core pathologic diagnosis of such a scar would ultimately necessitate open excision. Finally, reexcision is required when stereotactic or ultrasound-guided CNB reveals lesions determined to be high risk on pathologic evaluation (e.g., atypical hyperplasia, LCIS, papilloma, carcinoma, or lesion whose pathologic status is discordant with radiographic findings). In these circumstances, wire localization may be performed on the residual lesion, a clip placed at the time of CNB, or another surrogate marker (see below). To bracket a more extensive area of calcifications, multiple wires may be placed, especially if previous CNB revealed atypia or malignancy in the area.

Technique

The lesion to be excised is localized by inserting a thin needle and a fine wire under mammographic or ultrasonographic guidance immediately before operation. To facilitate incision placement, images should be sent to the OR with the wire entry site indicated on them. The incision is placed as directly as possible over the mass to minimize tunneling through breast tissue. With superficial lesions, the wire entry site is usually close to the lesion and thus may be included in the incision. With some deeper lesions, the wire entry site is on the shortest path to the lesion and so may still be included in the incision. Once the incision is made, a block of tissue is excised around and along the wire in such a way as to include the lesion [see Figure 6a, b]. This process is easier and involves less excision of tissue if the localizing wire has a thickened segment several centimeters in length that is placed adjacent to or within the lesion. The wire itself can then be followed into breast tissue until the thick segment is reached, at which point the excision can be extended away from the wire to include the lesion in a fairly small tissue fragment.

With many lesions, the wire entry site is in a fairly peripheral location relative to the position of the lesion, which means that including the wire entry site in the incision would result in excessive tunneling within breast tissue. In such cases, the incision is placed over the expected position of the lesion [see Figure 6c], the dissection is extended into breast tissue to identify the wire a few centimeters away from the lesion itself, and the free end of the wire is pulled up into the incision. A generous block of tissue is then excised around the wire. Intraoperative ultrasonography may be useful for identifying the tip of the needle and facilitating excision, particularly in the case of a deep lesion or biopsy site in a large breast.

Radiography should be performed intraoperatively on all wire-localized biopsy specimens to confirm excision of the lesion. If the

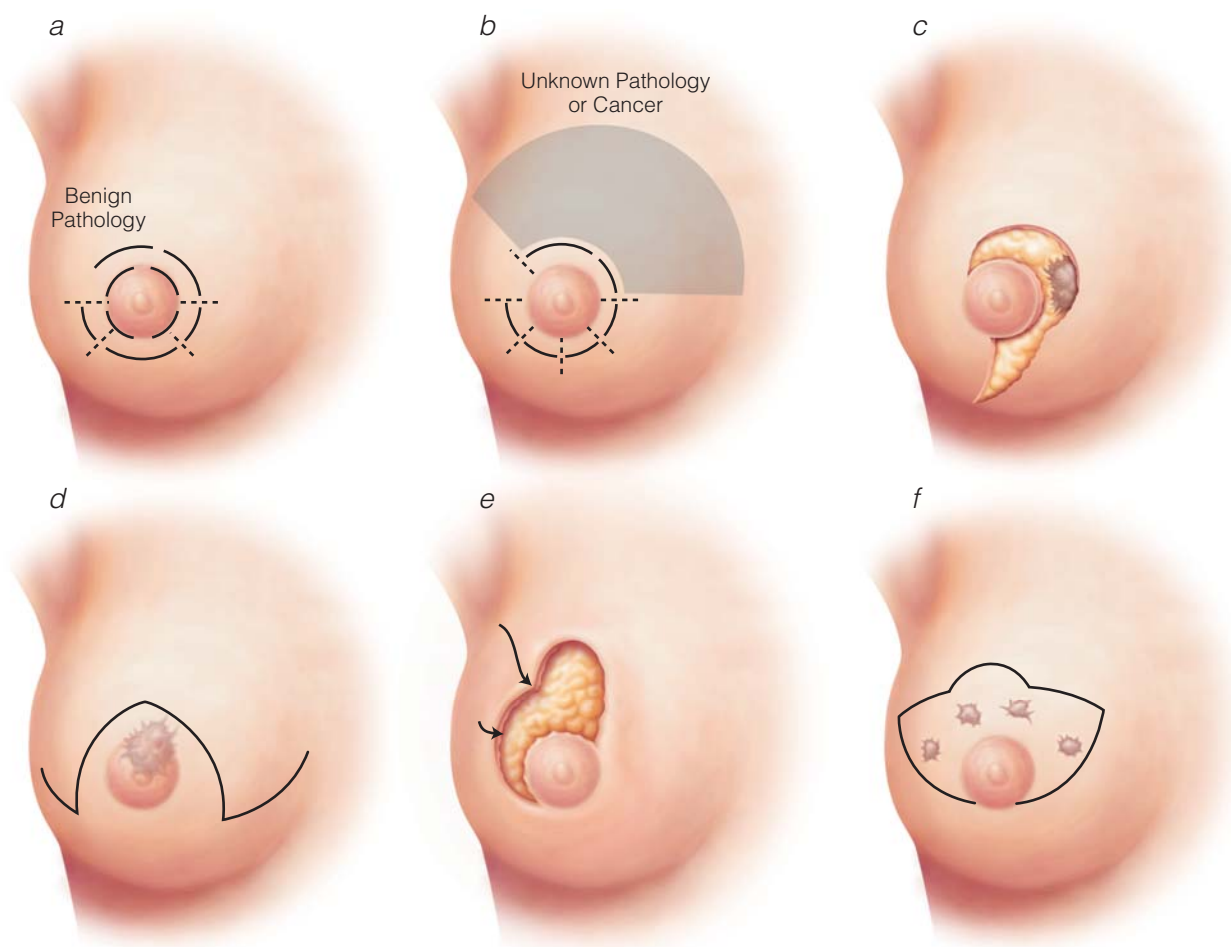

Figure 5 Open biopsy. (a) For biopsy-proven benign masses, a circumareolar incision generally provides excellent cosmesis and a well-hidden scar. If the lesion is too far from the nipple, curvilinear incisions are traditionally employed instead. Alternatively, medial, lateral, and inferior incisions may be placed in a radial fashion. (b) For lesions of unknown pathology, incisions should be placed directly over the lesion and should be oriented so that they will be included within a subsequent mastectomy incision if margins prove positive and mastectomy is indicated. As with benign lesions, either curvilinear incisions or radial incisions may be employed. Circumareolar incisions should be avoided in this setting because reexcision to provide clear margins, as is indicated in the case of malignancy, can necessitate excision of a portion of the nipple-areola complex and can commit the surgeon to a mastectomy. In cases where reexcision is indicated, avoidance of incisions in the so-called no man's land may improve cosmesis, in that it allows future reconstructive efforts to include advancement of the nipple-areola complex if desired. Various oncoplastic incisions may be employed as alternatives for (c) medial, (d) central, or (e, f) superior lesions.

lesion was missed, another tissue sample may be excised if the surgeon has some idea of the likely location of the missed lesion. If, however, the surgeon suspects that the wire was dislodged before or during the procedure, then the incision should be closed, and repeat localization and biopsy should be performed later. In addition to wire dislocation or transection, wire localization is occasionally associated with vasovagal reactions. Alternatives to wire localization include hematoma ultrasound-guided (HUG) excision (see below), carbon marking,²³ use of methylene blue dye,²⁴ and placement of radioactive seeds.²⁵

Hematoma ultrasound-guided excision In patients who have undergone CNB, particularly those who have undergone VACB, the hematoma at the biopsy site can often serve as a physiologic marker that accurately guides intraoperative localization [see Figure 7].^{26,27} This procedure, referred to as HUG excision, renders wire placement unnecessary and can facilitate operative schedul-

ing. The hematoma is localized in two planes, and 1 cm margins are marked off around the lesion; dissection is then continued down toward the chest wall in a block fashion. Excision of the hematoma can be confirmed by ultrasonography of the specimen *ex vivo*, as well as direct visualization of the hematoma in the gross specimen.

Terminal Duct Excision

Terminal duct excision is the procedure of choice in the surgical treatment of pathologic nipple discharge.²⁸ The goal is to excise the discharging duct with as little additional tissue as possible. To this end, the surgeon should carefully note the precise position of the offending duct at the time of the initial examination.

OPERATIVE TECHNIQUE

The patient is instructed to refrain from manually expressing her discharge for several days before operation. After local anes-

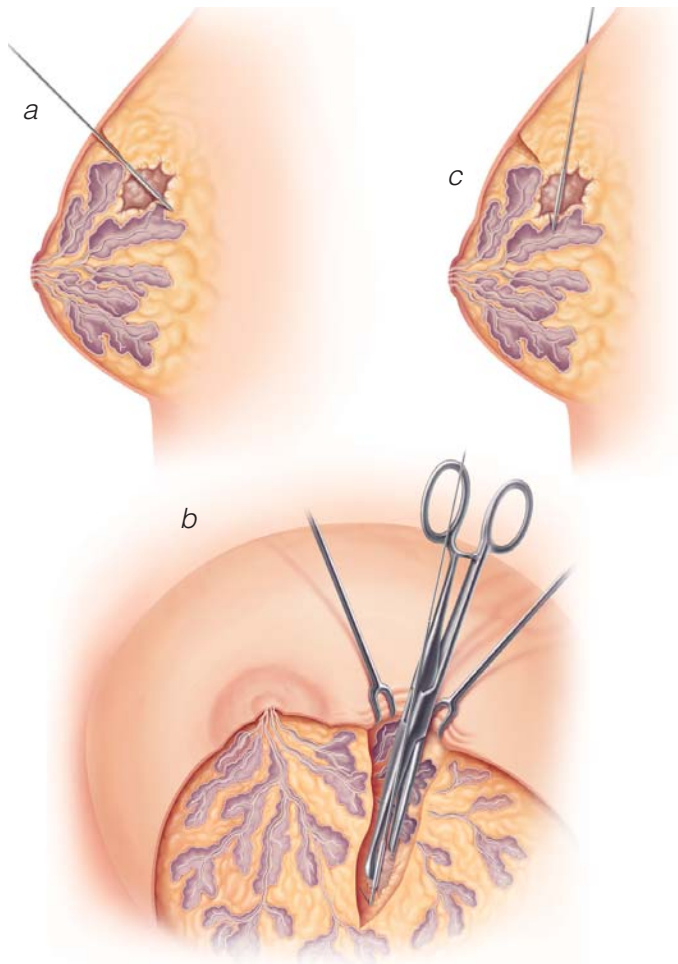

Figure 6 Needle-localization breast biopsy. (a) The mammographic abnormality is localized preoperatively. The relation between the wire, the skin entry site, and the lesion is noted by the surgeon. The skin incision is placed over the expected location of the mammographic abnormality. (b) The tissue around the wire is removed en bloc with the wire and sent for specimen mammography. Tunneling and piecemeal removal are to be avoided. (c) It is sometimes necessary to insert the localizing wire from a peripheral site to localize a deep or central lesion. The incision should be placed directly over the expected location of the lesion, not over the wire entry site. The dissection is extended into breast tissue to identify the wire a short distance from the lesion. The free end of the wire is pulled into the wound, and the biopsy is performed as previously described.⁵⁶

thetia (with or without sedation) is administered, the surgeon attempts to express the discharge. If this attempt is successful, the edge of the nipple is grasped with a forceps, and a fine lacrimal duct probe (000 to 0000) is gently inserted into the discharging duct. A radial incision is made within the areola at the same clock position as is occupied by the draining duct [see Figure 8]; this incision is preferred to a circumareolar incision because it is believed to preserve more nipple sensation and function.²⁹ The nipple skin flap is raised, and the duct containing the wire is excised with a margin of surrounding tissue from just below the nipple dermis to a depth of 4 to 5 cm within the breast tissue. The electrocautery should be employed with particular caution in the superficial portions of the dissection to prevent devascularization of the nipple-areola complex. If it is not possible to pass the lacrimal duct probe into the discharging duct or it is unclear which duct has resulted

in the pathologic discharge, the entire subareolar duct complex must be excised from immediately beneath the nipple dermis to a depth of 4 to 5 cm within the breast tissue. The breast tissue should be reapproximated beneath the nipple to prevent retraction of the nipple or indentation of the areola.

Surgical Options for Breast Cancer

There are several surgical options for primary treatment of breast cancer; indications for selecting among them are reviewed elsewhere [see 3:1 Breast Complaints]. It should be emphasized that for most patients, partial mastectomy (lumpectomy) to microscopically clear margins coupled with axillary staging and radiation therapy yields long-term survival equivalent to that associated with mastectomy and axillary staging. Currently, indications for mastectomy include patient preference, the inability to achieve clean margins without unacceptable deformation of the breast, the presence of disease in multiple quadrants (multicentric disease), previous chest wall irradiation, pregnancy, the presence of severe collagen vascular disease (e.g., scleroderma), and the lack of access to a radiation therapy facility.

Partial Mastectomy

Partial mastectomy—also referred to as wide local excision or lumpectomy—involves excision of all cancerous tissue to microscopically clear margins. Although 1 cm margins are the goal, many surgeons consider 2 mm margins to be adequate for reducing the risk of local recurrence.³⁰ Hence, reexcision is indicated whenever margins are either positive or too close (< 2 mm). Partial mastectomy is commonly performed with the patient under local anesthesia, with or without sedation. The addition of an axillary staging procedure (a common event) usually necessitates general anesthesia, but in select circumstances, local or epidural anesthesia may suffice.

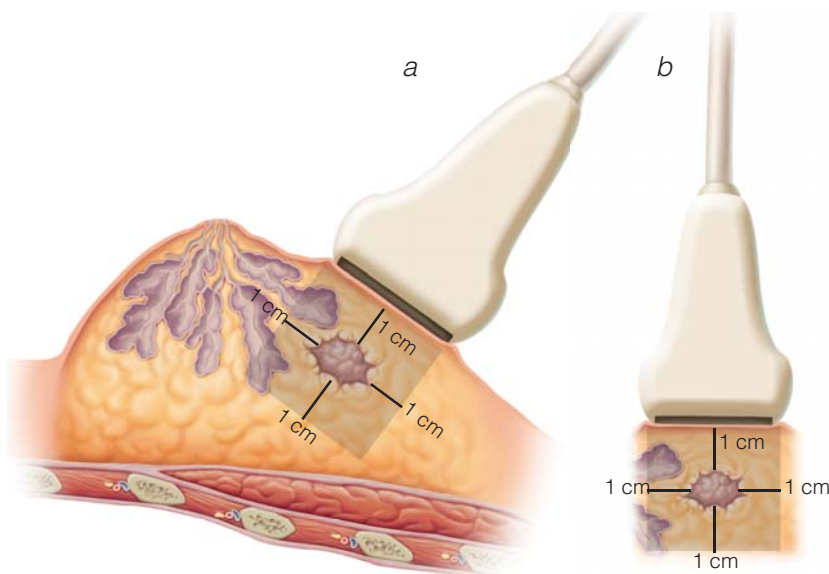

OPERATIVE TECHNIQUE

An incision is placed directly over the lesion to minimize tunneling through breast tissue; it should be oriented so as to be included within a subsequent mastectomy incision if margins prove positive. As with open biopsy (see above), curvilinear incisions have been the standard, but radial incisions are now being advocated by some surgeons, particularly for upper outer, medial, lateral, and inferior lesions. A radial incision facilitates excision of tumors that extend in a ductal distribution, preserves the contour of the breast, and permits easier reexcision if margins prove positive [see Figure 5b]. With current oncologic techniques,^{31,32} lesions in the central, medial, or superior portions of the breast can be resected with minimal cosmetic deformity [see Figure 5c, d, e, f]. Resection of a portion of the overlying skin is not necessary unless the lesion is extremely superficial.

To obtain clear margins, a 1 to 1.5 cm margin of normal-appearing tissue should be removed beyond the edge of the palpable tumor or, if excisional biopsy has already been performed, around the biopsy cavity. In the case of nonpalpable lesions diagnosed by means of CNB, wire localization is performed, and 2 to 3 cm of tissue should be excised around the wire to obtain an adequate margin. Intraoperative ultrasonography may reduce the rate of positive margins by allowing visualization of the tumor edge or the previous biopsy site.³³

The specimen should be oriented by the surgeon and the margins inked by the pathologist; this orientation is useful if reexcision is required to achieve clean margins. Reexcision of any close (< 2

Figure 7 Hematoma ultrasound-guided excision. (a) The hematoma is localized in two planes with intraoperative ultrasonography, and 1 cm margins are marked off around it. Dissection then proceeds down toward the chest wall in a block fashion. Excision of the hematoma is confirmed by ultrasonography of the specimen *ex vivo* (b), as well as by direct visualization of the hematoma in the gross specimen.^{26,27}

mm) margins may be performed during the same surgical procedure if the specimen margins are assessed immediately by the pathologist. If the specimen was not oriented, the entire biopsy cavity should be reexcised. Surgical clips may be left in the lumpectomy site to help the radiation oncologist plan the radiation

boost to the tumor bed or to direct partial-breast irradiation. In the closure of the incision, hemostasis should be meticulous: a hematoma may delay adjuvant therapy. Deep breast tissue should be approximated only if such closure does not result in significant deformity of breast contours. A cosmetic subcuticular closure is preferred. Wearing a support bra worn during the day and the night can reduce shearing of fragile vessels.¹³

ACCELERATED PARTIAL-BREAST IRRADIATION WITH BALLOON CATHETER

Historically, whole-breast irradiation has been the standard treatment to reduce the risk of local recurrence after breast-conserving therapy (BCT). Long-term follow-up of patients who have received BCT demonstrates, however, that only 1% to 3% of recurrences within the breast arise at a significant distance from the primary cancer site (i.e., in other breast quadrants); the remainder develop near the original biopsy site.^{30,34} This approach provides the rationale for the approach known as accelerated partial-breast irradiation (APBI), in which a shortened course of high-dose radiation is delivered to the tissue surrounding the lumpectomy cavity (the region theoretically at greatest risk). Several different APBI techniques have been developed, including placement of interstitial catheters, use of a localized external beam, single-dose intraoperative treatment, implantation of radioactive beads or seeds, and insertion of a balloon catheter into the lumpectomy site. Although long-term follow-up has not been carried out, the short-term results reported for some APBI techniques indicate that in most centers, recurrence rates have been low, with good cosmesis and only mild chronic toxicity.³⁵

The technique of APBI can be illustrated by considering the MammoSite Radiation Therapy System (Cytac Corp., Palo Alto, California), in which a balloon catheter is inserted into the surgical cavity after lumpectomy to provide partial-breast irradiation (see below). Although the catheter may also be inserted at the time of the original operation, it is preferable to wait for final pathologic evaluation to confirm clear margins; if the catheter is inserted and margins are found to be positive, it will have to be replaced (a costly process). Postoperative insertion may be done either percutaneously under ultrasonographic guidance or by means of an open technique. Once the catheter is in place, a radiation source (iridium 192) is delivered into the balloon via a high-dose rate remote afterloader.

Figure 8 Terminal duct excision. (a) A radial incision is made within the areola. (b) The involved duct is identified by means of blunt dissection and removed along with a core of breast tissue. (c) If no single duct is identified, the entire subareolar ductal complex is excised from immediately beneath the nipple dermis to a depth of 4 to 5 cm within breast tissue.^{28,29}

Technique

For safe and effective delivery of radiotherapy through the MammoSite balloon catheter, the lumpectomy cavity must be able to conform its shape to that of an ovoid or spherical catheter without significant air pockets, able to accommodate a volume of at least 30 ml (the volume of the smallest available balloon), and able to maintain a minimum distance of 7 mm from the skin with the catheter in place. In addition, if a percutaneous technique is being considered, the surgeon should be comfortable with ultrasonography (which will be employed for initial visualization of the lumpectomy cavity). If the above criteria seem reasonably attainable, one may proceed with a percutaneous approach [see *Figure 9*].

Percutaneous approach A site peripheral to the scar is chosen as the entry site for the balloon catheter, and a local anesthetic is injected along the proposed catheter tract. A trocar (supplied with the insertion kit) is inserted into the cavity via the peripheral entry site, then removed. The shape of the cavity is visualized by means of ultrasonography, and a catheter of appropriate shape (ovoid or spherical) and volume (30 to 65 ml) is advanced through the newly formed tract. Saline is then infiltrated to inflate the catheter balloon to the maximum volume that the cavity can accommodate. The cavity is then reimaged to confirm that the catheter is an adequate distance (7 mm) from the skin. If the distance is inadequate, the balloon volume is reduced. If it is not possible to keep the catheter at least 7 mm from the skin while maintaining a balloon volume of at least 30 ml, conversion to an open approach is indicated.

Open approach The cavity is reopened through the original skin incision. Occasionally, a thick rind may form around the residual seroma; this rind may be excised to reduce tension and increase the volume of the cavity. If necessary, the anterior skin may be excised in the form of an ellipse to provide improved anterior coverage of the catheter, and the subcutaneous tissue may be pulled together over the catheter and the cavity to help ensure adequate coverage and sufficient distance from the skin. A peripheral site is chosen for insertion of the catheter. After the skin is closed, ultrasonography is employed to confirm that the distance from the skin is adequate. A topical antibiotic is applied at the insertion site; no anchoring stitch is necessary. Correct positioning of the catheter is confirmed by a postplacement treatment-planning CT scan that is evaluated by the radiation oncologist.

Minimally Invasive Tumor-Ablating Techniques

The next step in the evolving application of minimally invasive techniques to breast cancer is to determine whether ablative local therapies can safely substitute for standard surgical extirpation. Cryotherapy, laser ablation, radiofrequency ablation (RFA), and focused ultrasound ablation have all been studied as means of eradicating small breast cancers.³⁶ In most of these techniques, a probe is placed percutaneously into the breast lesion under imaging guidance, and tumor cell destruction is achieved by means of either heat or cold.

Cryotherapy has been successfully used in the treatment of nonresectable liver tumors. It kills tumor cells by disrupting the cellular membrane during multiple freeze (−40° C)/thaw cycles. Unfortunately, early study results reveal that in the treatment of breast cancer, the degree of tumor destruction achieved with cryotherapy is inconsistent.

Laser ablation causes hyperthermic cell death by delivering

energy through a fiberoptic probe. Because of the precise targeting required, it has proved difficult to ensure complete tumor destruction with this technique as well.

RFA is a minimally invasive thermal ablation technique in which frictional heat is generated by intracellular ions moving in response to alternating current. It appears to be the most promising ablative method for small breast cancers. Like cryotherapy, RFA has also been extensively used to treat liver tumors. The RFA probe is percutaneously placed in the tumor under imaging guidance, and a star-shaped set of electrodes is deployed from the tip of the probe to deliver heat at a temperature of 95° C. Postprocedural MRI may help confirm complete tumor destruction after RFA and other ablative techniques.

To date, experience with ablative breast therapies has been limited, and long-term follow-up has not been carried out. There is some evidence that patients who have small, well-defined, unifocal cancers without extensive intraductal components may have greater success with these techniques.³⁶ Most of the initial studies of ablative breast therapies involved subsequent surgical excision to obtain histologic evidence of cell death. Unfortunately, when ablative therapies are used alone, the benefits of pathologic assessment of the specimen, including evaluation of margin status, are lost. Clearly, minimally invasive ablative approaches to breast cancer are technically feasible, and they do appear to offer some potential advantages; however, it remains to be determined to what extent they are oncologically appropriate.

Lymphatic Mapping and SLN Biopsy

The pathologic status of the axillary nodes is the single most important prognostic factor for outcome after treatment of breast cancer. The growing recognition of the morbidity of traditional axillary dissection (lymphedema and sensory deficits), together with the increased capability of mammography to detect smaller, potentially node-negative invasive breast cancers, has given rise to the development of SLNB as an axillary staging procedure. SLNB is a minimally invasive means of identifying the first node or nodes draining the breast and hence the first node or nodes to which tumor may spread. In experienced hands, a negative SLNB reliably predicts a tumor-free axilla (false-negative rate, 5% to 9%); therefore, when such a result is obtained, no further nodes need be removed and the patient can spared the morbidity of a traditional axillary node dissection.³⁷⁻³⁹ Surgeons competent in SLNB should be able to identify the sentinel lymph node (SLN) with at least 90% accuracy and a false-negative rate lower than 5%.⁴⁰ It is recommended that surgeons first learning the technique use axillary dissection as a backup for the first 20 procedures to gain experience in identifying the SLN. Currently, axillary dissection is recommended for patients who have a positive SLN; however, prospective, randomized trials are required to determine the extent to which this step is necessary in SLN-positive patients.

The most common method of identifying the SLN involves injection of both a vital blue dye and a radionuclide.⁴¹⁻⁴⁴ The radionuclide is first injected into the subareolar lymphatic plexus, either preoperatively or, in some centers, intraoperatively.⁴¹ Because the breast and its overlying skin drain to the same few SLNs,⁴³ peritumoral, intradermal, and subareolar injection are all acceptable approaches; subareolar injection has the advantage of being expeditious and accurate in cases of multicentric (as well as unicentric) disease.⁴⁴ The vital blue dye is then injected, commonly in the subareolar plexus, and the breast is massaged for 5 minutes to stimulate lymphatic flow. Lymph nodes that are “hot” (i.e., radioactive), blue, or both, as well as palpable nodes, are removed

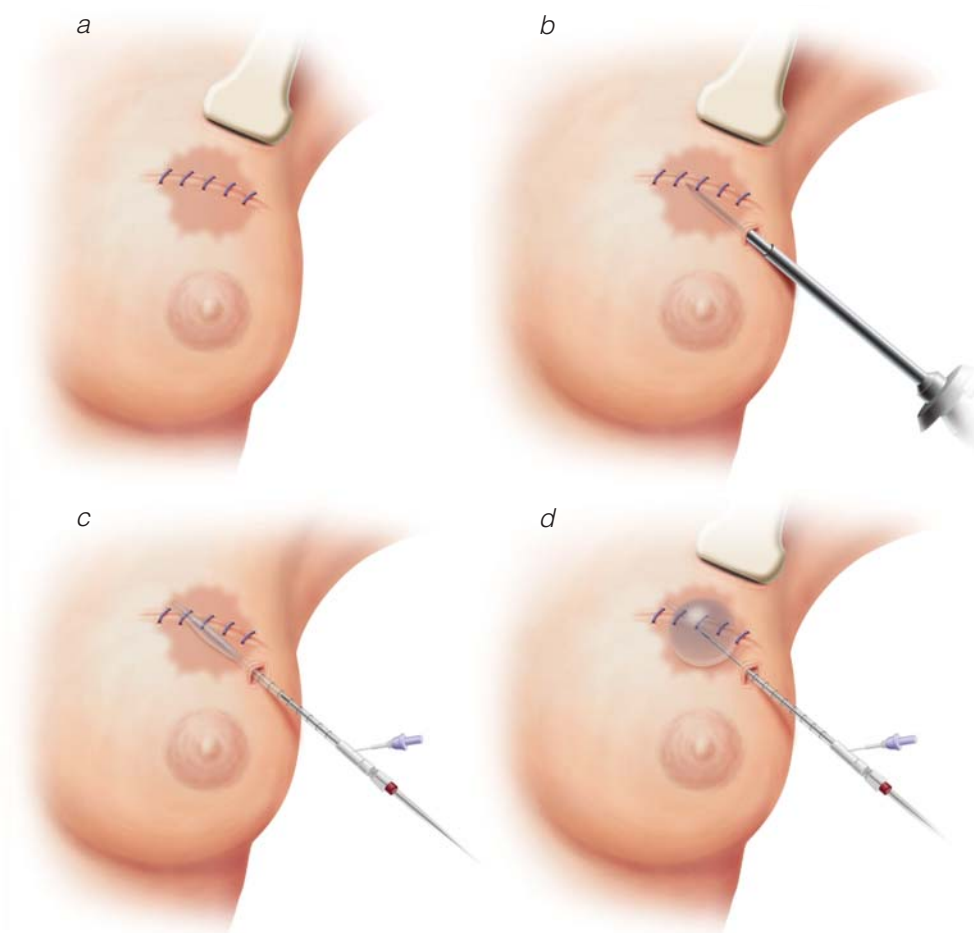

Figure 9 Accelerated partial-breast irradiation with balloon catheter. (a) The lumpectomy cavity is evaluated by means of ultrasonography. (b) The trocar is inserted through a separate entry site under ultrasonographic guidance. (c) The uninflated balloon catheter is advanced through the trocar path. (d) Under ultrasonographic visualization, the balloon is inflated with saline or contrast material. An anterior distance of at least 7 mm between the catheter and the chest wall or skin is confirmed.

for evaluation by frozen-section analysis or touch-print cytology. The technique of SLNB is described in greater detail elsewhere [see 3:6 *Lymphatic Mapping and Sentinel Lymph Node Biopsy*].

SLNB has also been employed in DCIS patients, but in general, its use should be limited to patients with extensive DCIS who are undergoing mastectomy (in the event of occult invasive disease). Some investigators recommend SLNB for patients with extensive DCIS who are undergoing BCT (in whom CNB may have missed an area of invasion),⁴⁵ though others caution against this practice.^{46,47} Results from the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-27 trial suggest that in patients undergoing neoadjuvant therapy, SLNB may be performed either before or after therapy, with no significant differences in identification and false-negative rates⁴⁸; however, this suggestion is not universally accepted.⁴⁹ Contraindications to SLNB include the presence of clinically positive axillary nodes, previous axillary surgery, and pregnancy or lactation. Large or locally advanced breast cancers commonly give rise to a positive SLN but are not a contraindication to the procedure, in that some patients may still be spared the morbidity of a full axillary dissection.

Axillary Dissection

Before the advent of SLNB, axillary dissection was routinely performed in breast cancer patients: it provided prognostic information that guided subsequent adjuvant therapy, it afforded excellent local control, and it may have contributed a small overall survival benefit.

Axillary dissection includes resection of level I and level II lymph nodes [see *Figure 10a*].⁵⁰ The superior border of the dissec-

tion is formed by the axillary vein; the lateral border of the dissection is formed by the latissimus dorsi; the medial border is formed by the pectoral muscles and the anterior serratus muscle; and the inferior border is formed by the tail of the breast. Level II nodes are easily removed by retracting the pectoralis major and the pectoralis minor medially; it is not necessary to divide or remove the pectoralis minor. Level III nodes are not removed unless palpable disease is present.

Axillary dissection, either alone or in conjunction with lumpectomy or mastectomy, usually calls for general anesthesia, but it may be performed with thoracic epidural anesthesia. To facilitate identification and preservation of motor nerves within the axilla, the anesthesiologist should refrain from using neuromuscular blocking agents. In the absence of neuromuscular blockade, any clamping of a motor nerve or too-close approach to a motor nerve with the electrocautery will be signaled by a visible muscle twitch.

STRUCTURES TO BE PRESERVED

There are a number of vascular structures and nerves passing through the axilla that must be preserved during axillary dissection [see *Figure 10b*]. These structures include the axillary vein and artery; the brachial plexus; the long thoracic nerve, which innervates the anterior serratus muscle; the thoracodorsal nerve, artery, and vein, which supply the latissimus dorsi; and the medial pectoral nerve, which innervates the lateral portion of the pectoralis major.

The axillary artery and the brachial plexus should not be exposed during axillary dissection. If they are, the dissection has been carried too far superiorly, and proper orientation at a more inferior position should be established. In some patients, there

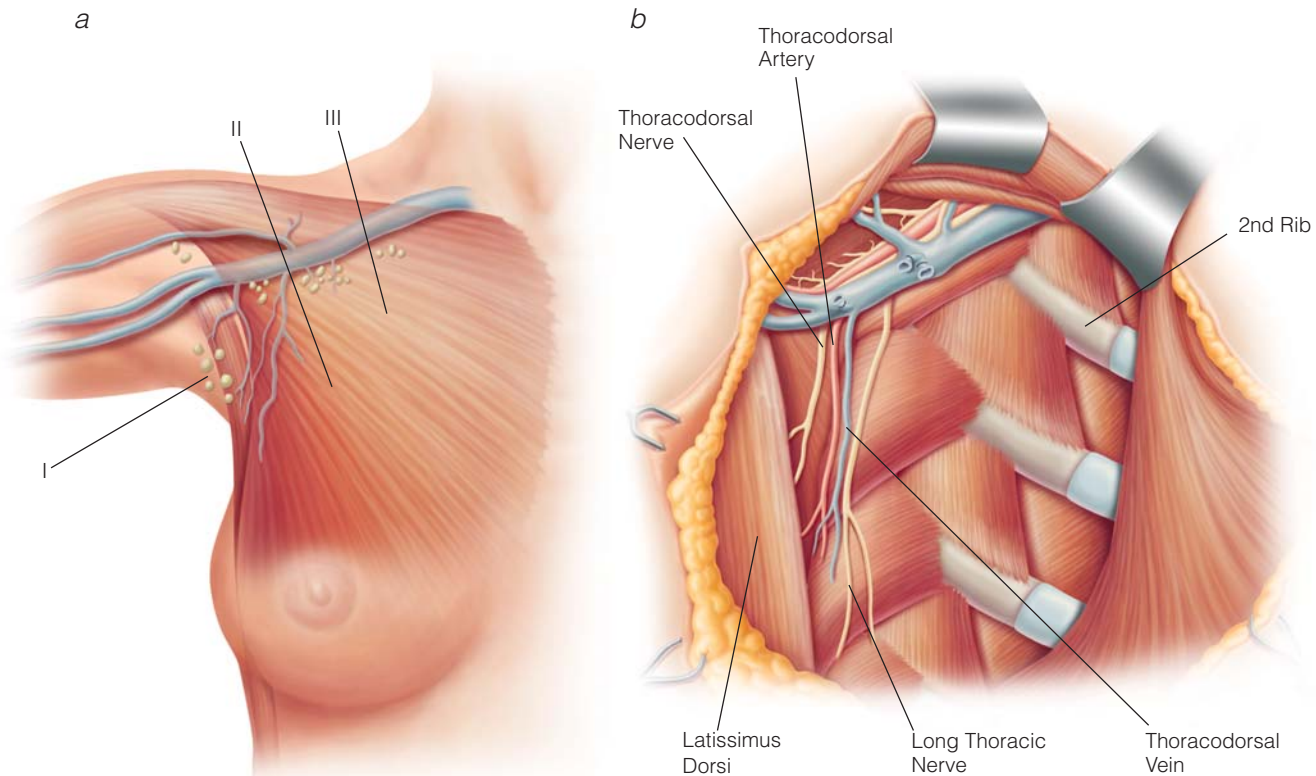

Figure 10 Axillary dissection.⁵⁰ (a) Shown are axillary lymph node levels in relation to the axillary vein and the muscles of the axilla (I = low axilla, II = midaxilla, III = apex of axilla). (b) Shown is a view of the structures of the axilla after completion of axillary dissection.

may be sensory branches of the brachial plexus superficial (and, rarely, inferior) to the axillary vein laterally near the latissimus dorsi; injury to these nerves results in numbness extending to the wrist. To prevent this complication, the axillary vein should initially be identified medially, under the pectoralis major. Medial to the thoracodorsal nerve and adherent to the chest wall is the long thoracic nerve of Bell. The medial pectoral nerve runs from superior to the axillary vein to the undersurface of the pectoralis major, passing through the axillary fat pad and across the level II nodes; it has an accompanying vein whose blue color may be used to identify the nerve. If a submuscular implant reconstruction [see Breast Reconstruction after Mastectomy, *below*] is planned, preservation of the medial pectoral nerve is especially important to prevent atrophy of the muscle.

The intercostobrachial nerve provides sensation to the posterior portion of the upper arm. Sacrificing this nerve generally leads to numbness over the triceps region. In many women, the intercostobrachial nerve measures 2 mm in diameter and takes a fairly cephalad course near the axillary vein; when this is the case, preservation of the nerve will not interfere with node dissection. Sometimes, however, the nerve is tiny, has multiple branches, and is intermingled with nodal tissue that should be removed; when this is the case, one should not expend a great deal of time on attempting to preserve the nerve. If the intercostobrachial nerve is sacrificed, it should be transected with a knife or scissors rather than with the electrocautery, and the ends should be buried to reduce the likelihood of postoperative causalgia.

OPERATIVE TECHNIQUE

The incision for axillary dissection should be a transverse or curvilinear one made in the lower third of the hair-bearing skin of the axilla. For cosmetic reasons, it should not extend anteriorly

onto the pectoralis major; however, it may be extended posteriorly onto the latissimus dorsi as necessary for exposure. Skin flaps are raised to the level of the axillary vein and to a point below the lowest extension of hair-bearing skin, either as an initial maneuver or after the initial identification of key structures.

The key to axillary dissection is obtaining and maintaining proper orientation with respect to the axillary vein, the thoracodorsal bundle, and the long thoracic nerve. After the incision has been made, the dissection is extended down into the true axillary fat pad through the overlying fascial layer. The fat of the axillary fat pad may be distinguished from subcutaneous fat on the basis of its smoother, lipomalike texture. There may be aberrant muscle slips from the latissimus dorsi or the pectoralis major; in addition, there may be an extremely dense fascial encasement around the axillary fat pad. It is important to divide these layers early in the dissection. The borders of the pectoralis major and the latissimus dorsi are then exposed, which clears the medial and lateral borders of the dissection.

The axillary vein and the thoracodorsal bundle are identified next. As discussed (see above), the initial identification of the axillary vein should be made medially, under the pectoralis major, to prevent injury to low-lying branches of the brachial plexus. Sometimes, the axillary vein takes the form of several small branches rather than a single large vessel. If this is the case, all of the small branches should be preserved.

The thoracodorsal bundle may be identified either distally at its junction with the latissimus dorsi or at its junction with the axillary vein. The junction with the latissimus dorsi is within the axillary fat pad at a point two thirds of the way down the hair-bearing skin of the axilla, or approximately 4 cm below the inferior border of the axillary vein. Occasionally, the thoracodorsal bundle is bifurcated, with separate superior and inferior branches entering the latis-

simus dorsi; this is particularly likely if the entry point appears very high. If the bundle is bifurcated, both branches should be preserved. The thoracodorsal bundle may be identified at its junction with the latissimus dorsi by spreading within axillary fat parallel to the border of the muscle and looking for the blue of the thoracodorsal vein. Identification is also facilitated by lateral retraction of the latissimus dorsi. The long thoracic nerve lies just medial to the thoracodorsal bundle on the chest wall at this point and at approximately the same anterior-posterior position. It may be identified by spreading tissue just medial to the thoracodorsal bundle, then running the index finger perpendicular to the course of the long thoracic nerve on the chest wall to identify the cordlike nerve as it moves under the finger. Once the nerve is identified, axillary tissue may be swept anteriorly away from the nerve by blunt dissection along the anterior serratus muscle; there are no significant vessels in this area.

The junction of the thoracodorsal bundle with the axillary vein is 1.5 to 2.0 cm medial to the point at which the axillary vein crosses the latissimus dorsi. The thoracodorsal vein enters the posterior surface of the axillary vein, and the nerve and the artery pass posterior to the axillary vein. There are generally one or two scapular veins that branch off the axillary vein medial to the junction with the thoracodorsal vein. These are divided during the dissection and should not be confused with the thoracodorsal bundle.

The axillary vein and the thoracodorsal bundle having been identified, the pectoralis major is retracted medially at the level of the axillary vein, and the latissimus dorsi is retracted laterally to place tension on the thoracodorsal bundle. Once this exposure is achieved, the axillary fat and the nodes are cleared away superficial and medial to the thoracodorsal bundle to the level of the axillary vein. Superiorly, dissection proceeds medially along the axillary vein to the point where the fat containing level II nodes crosses the axillary vein. To improve exposure, the fascia overlying the level II extension of the axillary fat pad should be incised to release tension and expose the lipomalike level II fat. As noted [see Structures to Be Preserved, *above*], the medial pectoral nerve passes onto the underside of the pectoralis major in this area and should be preserved. One or more small venous branches may pass inferiorly from the medial pectoral bundle; particular attention should be paid to preserving the nerve when ligating these venous branches.

The next step in the dissection is to reflect the axillary fat pad inferiorly by dividing the medial attachments of the axillary fat pad along the anterior serratus muscle. Care must be taken to preserve the long thoracic nerve. Because there are no significant vessels or structures in the tissue anterior to the long thoracic nerve, this tissue may be divided sharply, with small perforating vessels either tied or cauterized. Finally, the axillary fat is freed from the tail of the breast with the electrocautery or a knife.

There is no need to orient the axillary specimen for the pathologist, because treatment is not affected by the anatomic level of node involvement. A closed suction drain is placed through a separate stab wound. (Some practitioners prefer not to place a drain and simply aspirate postoperative seromas as necessary.) A long-acting local anesthetic may be instilled into the axilla—a particularly helpful practice if the dissection was done as an outpatient procedure.

Mastectomy

The goal of a mastectomy is to remove all breast tissue—including the nipple, the areola, and the pectoral fascia—while leaving viable skin flaps and a smooth chest wall for application of prosthesis. This should be the objective whether the mastectomy

is performed for cancer treatment or for prophylaxis. Skin-sparing mastectomy (SSM) performed in conjunction with immediate reconstruction is discussed elsewhere [see Breast Reconstruction after Mastectomy, *below*]. Proper skin incisions and good exposure are the key components of a well-performed mastectomy. Mastectomy usually calls for general anesthesia, but it may be performed with thoracic epidural anesthesia or local anesthesia in select circumstances.

OPERATIVE TECHNIQUE

The traditional mastectomy incision is an elliptical one that is placed either transversely across the chest wall or at an upward angle toward the axilla. It should be fashioned in such a way as to include the nipple-areola complex and any incision from a previous biopsy [see *Figure 11a*]. Ideally, the upper and lower skin flaps should be of similar length so that there is no redundant skin on either flap. The outline of the incision may be established by using the following five steps.

1. The lateral and medial end points are marked.
2. The breast is pulled firmly downward.
3. To define the path of the upper incision, a straight line is drawn from one end point to the other across the upper surface of the breast.
4. The breast is pulled firmly upward.
5. To define the path of the lower incision, a straight line is drawn from one end point to the other across the lower surface of the breast.

The outlined incision is then checked to confirm that it can be closed without either undue tension or redundant skin. Dog-ears or lateral skin folds can be prevented by extending the incision medially or laterally to remove all the skin that contributes to the forward projection of the breast. The closure should be fairly snug intraoperatively while the arm is extended; significant slack will be created when the arm is returned to the patient's side. The medial and lateral end points of the incision may be adjusted upward or downward to include any previous biopsy incisions.

As noted [see Partial Mastectomy, *above*], there is increasing acceptance of the use of radial and oncoplastic incisions for BCT. In a small percentage of women, persistently positive margins may dictate conversion from BCT to mastectomy. In large-breasted women with excess breast skin, traditional elliptical incisions can easily incorporate any previous radial or superior-pole oncoplastic incisions that may have been performed [see *Figure 11b*]. In smaller-breasted women, however, sigmoid, modified Wise, or other oncoplastic mastectomy incisions may be needed to incorporate previous lumpectomy incisions [see *Figure 11c*].

Once the incision is made, the next step is to create even and viable flaps. In most patients, there is a fairly well defined avascular plane between subcutaneous fat and breast tissue. This plane is identified by pulling the edges of the incision upward with skin hooks and beginning a flap that is 8 to 10 mm thick. After an initial release of the skin edge, the desired plane is developed by applying firm tension downward on the breast tissue and away from the skin at a 45° angle. The fine fibrous attachments between breast tissue and subcutaneous fat (Cooper's ligaments) are then divided with the electrocautery or a blade, and crossing vessels are coagulated or ligated as they appear. To protect both arterial supply to and venous drainage from the skin flap, one must refrain from excessive ligation or cauterization of vessels on the flap. For most women, flap viability is not an issue. For diabetics, smokers, and other patients with diffuse small vessel disease, however, it is a serious consideration. In such patients, flaps should be no longer than necessary with no

Figure 11 Mastectomy incisions. (a) Elliptical incisions incorporate traditional lumpectomy incisions. (b) In large-breasted women with excess breast skin, traditional ellipses can easily incorporate previous radial and superior-pole oncoplastic incisions. (c) In smaller-breasted women, sigmoid, modified Wise, or other oncoplastic mastectomy incisions may be needed to incorporate previous radial lumpectomy incisions.

excess tension, and extra care should be taken to preserve flap vessels. Patients should be warned that even with these measures, there may be some skin necrosis along the incision. Such necrosis is best treated with gradual debridement of the eschar.

Flaps are raised superiorly to the clavicle, medially to the sternum, inferiorly to the inframammary fold, and laterally to the border of the latissimus dorsi. The pectoral fascia is incised both superiorly and medially. Inferiorly, the fascia of the abdominal muscles is not divided. The pectoralis major, the abdominal muscles, and the anterior serratus muscle form the deep border of the dissection. The

pectoral fascia is removed with the breast specimen and may be separated from the muscle with either the electrocautery or a blade.

In a simple mastectomy, the dissection proceeds around the lateral edge of the pectoralis major but stops before entering the axillary fat pad (unless the procedure is being done in conjunction with SLNB). A single closed suction drain is placed through a separate lateral stab wound in such a way that it extends under the lower flap and a short distance upward along the sternal border of the dissection.

A modified radical mastectomy essentially consists of an axillary node dissection added to a simple mastectomy. At the lateral edge of the dissection, the border of the latissimus dorsi is exposed, as is the lateral border of the pectoral muscle. Retraction of these two muscles provides excellent exposure for the axillary dissection [see Axillary Dissection, *above*]. Some surgeons prefer to remove the breast from the chest wall first, whereas others leave the breast attached to provide tension for the axillary dissection. Upon completion of the procedure, two closed suction drains are placed, one in the axilla and another under the lower flap and extending to the midline.

After either a simple or a modified radical mastectomy, the skin is closed and a dressing applied according to the surgeon's preference. Early arm mobilization is encouraged.

Breast Reconstruction after Mastectomy

The vast majority of women undergoing mastectomy are candidates for breast reconstruction and should be offered a plastic surgery consultation before undergoing definitive surgical treatment. Reconstruction is covered by insurance and may be done either at the time of the mastectomy (immediate reconstruction) or as a delayed procedure (delayed reconstruction). Regardless of when it is done, reconstruction does not interfere with detection of recurrent disease. Immediate breast reconstruction does not significantly delay subsequent adjuvant therapy, and if it is done through a skin-sparing incision (see below), it may contribute to a more natural cosmetic outcome. Options for reconstruction include implants with tissue expansion, the transverse rectus abdominis myocutaneous (TRAM) flap, the latissimus dorsi myocutaneous flap, and various free flaps. Patient preference and lifestyle, the availability of suitable autologous tissue, and the demands imposed by additional cancer therapies are variables that can influence the timing and choice of the optimal reconstructive technique [see *Figure 12*].

Patients who definitely need radiation therapy after mastectomy are at higher risk for complications after reconstruction. Whereas most physicians recommend delayed reconstruction in such cases, a small percentage of these patients undergo immediate reconstruction, incurring higher risk in the process. If the need for postmastectomy radiation therapy is unclear at the time of mastectomy (i.e., final pathology results are not available), a delayed-immediate reconstruction may be performed. An expander is placed at the time of SSM to preserve the breast skin envelope, and the definitive reconstructive plan is formulated once the final pathologic results have become available and the need for radiation therapy has been determined.⁵¹

SKIN-SPARING MASTECTOMY

SSM, which consists of resection of the nipple-areola complex, any existing biopsy scar, and the breast parenchyma, followed immediately by breast reconstruction, has become an increasingly popular approach for women requiring mastectomy.⁵² With this approach, the inframammary fold is preserved, and a generous skin envelope remains after reconstruction; cosmetic results are thereby optimized. In addition, SSM is oncologically safe and is

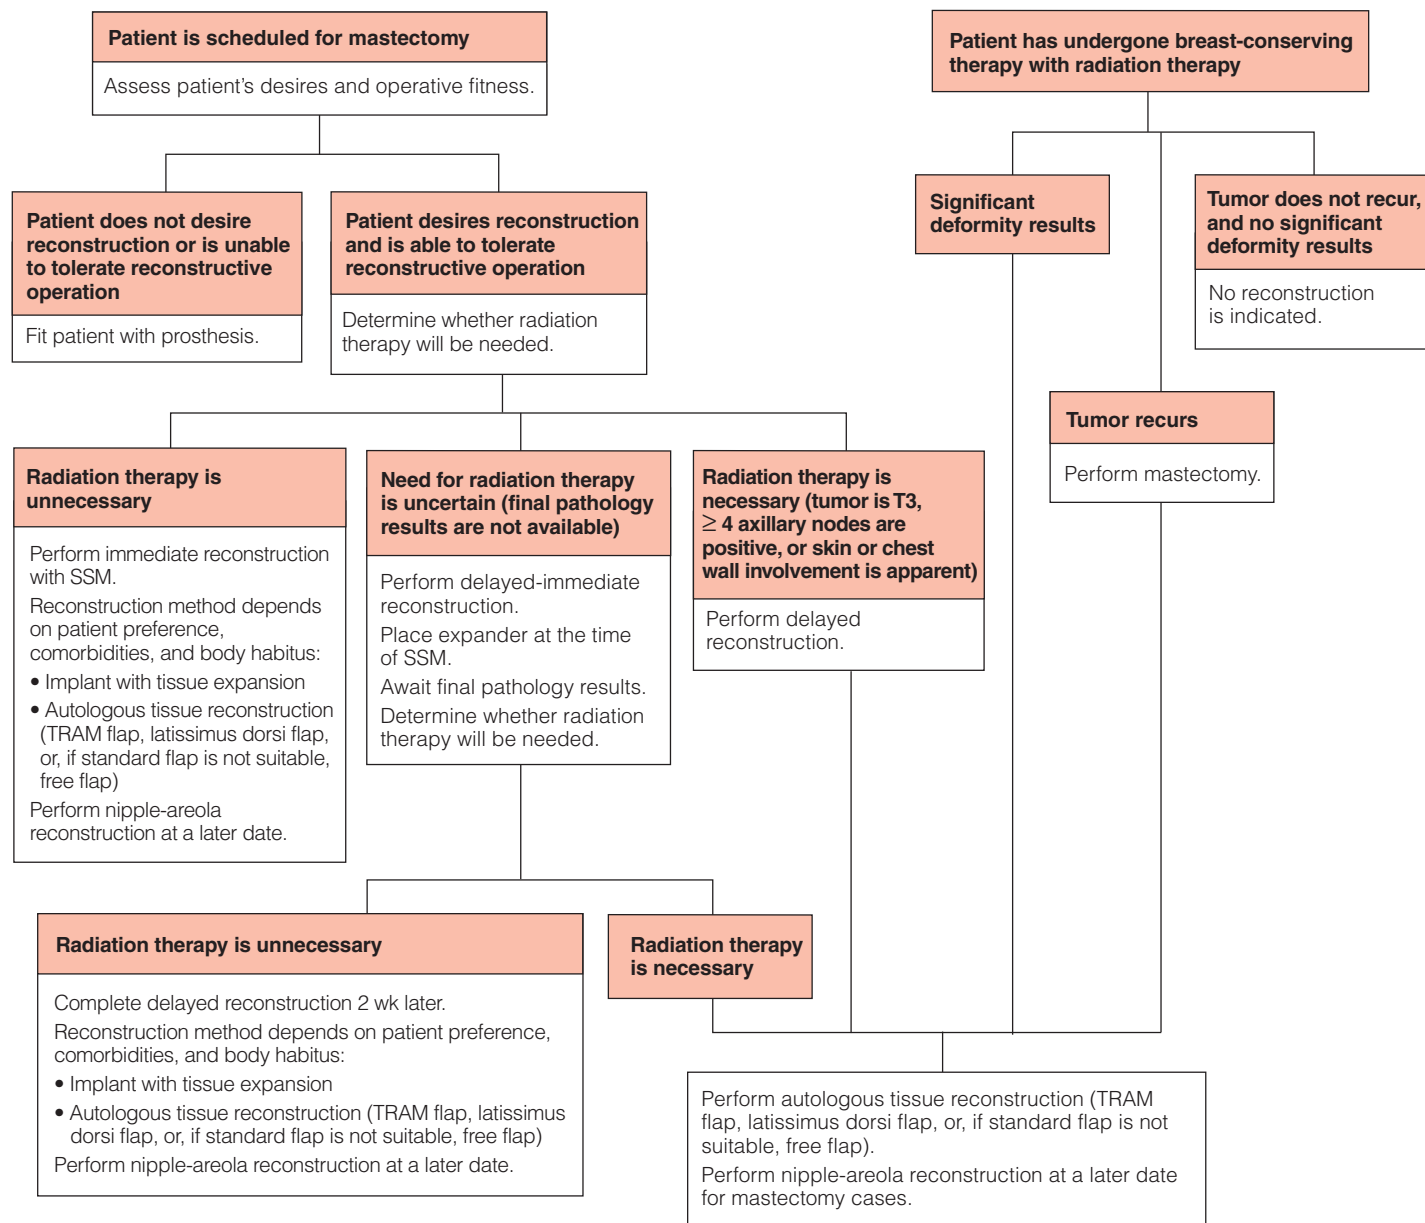

Figure 12 Algorithm outlines the major steps in breast reconstruction after mastectomy.

not associated with an increased incidence of local recurrence.⁵³ The recurrences that do occur typically develop below the skin flaps and thus are easily detectable; deep recurrences beneath the reconstruction are comparatively uncommon.

The incision for SSM with immediate reconstruction should be planned in collaboration with the plastic surgeon [see Figure 13], and the inframammary fold should be marked preoperatively with the patient in a sitting position. Several options are available for SSM. For CNB-diagnosed tumors that are not superficial, a circumareolar incision may be employed, with a lateral extension for exposure if necessary. Different incisions may be used if it proves necessary to incorporate previous incisions or to remove skin anterior to superficial tumors. A separate axillary incision may be useful when axillary dissection or SLNB is being performed. Select patients may be candidates for newer techniques that spare the nipple, the areola, or both; however, these techniques are still under investigation, and long-term follow-up is required to determine their utility and applicability. CNB sites generally are not

included in the excised skin segment, the surgeon may opt to excise them through a separate skin ellipse. Intraoperatively, flaps are created in a circular fashion to optimize exposure. Although optimal cosmesis is part of the rationale for SSM, cosmetic considerations should never be allowed to compromise the extent of the dissection in any way.

RECONSTRUCTION OPTIONS

Prosthetic Implants

The simplest method of reconstruction is to place a saline- or silicone-filled implant beneath the pectoralis major. Even after SSM, the pectoralis major is usually so tight that expansion of this muscle and the skin is necessary before an implant that matches the opposite breast can be inserted. Serial expansions are performed on an outpatient basis until an appropriate size has been attained. A second operative procedure is then required to exchange the expander for a permanent implant. A nipple and an areola are constructed at

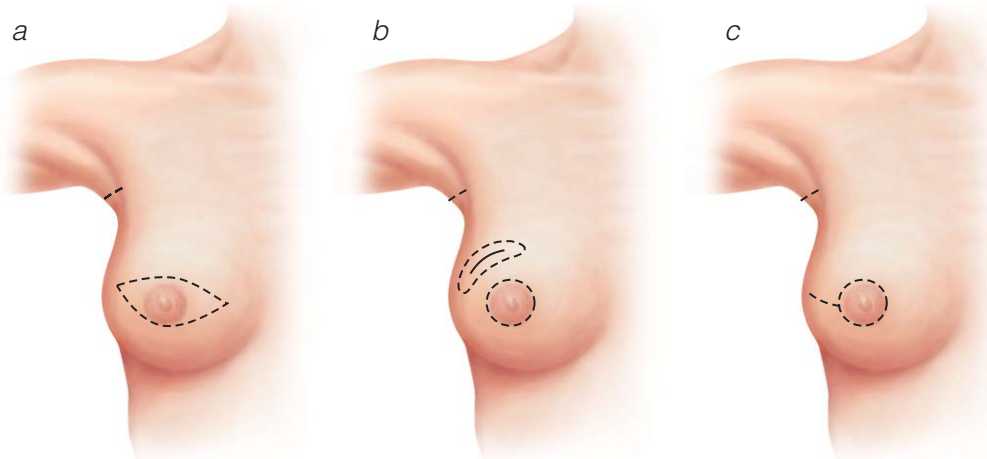

Figure 13 Skin-sparing mastectomy. Shown is the recommended placement of a circumareolar incision for SSM. A lateral extension can provide further exposure for flap development or axillary staging. Separate incisions may be used to excise previous lumpectomy incisions or to gain access to the axilla.

a later date. AlloDerm (LifeCell Corp., Branchburg, New Jersey), an acellular dermal matrix derived from human cadaver skin, may be sewn to the pectoralis muscle and the inframammary fold to reinforce the lower pole of the breast.⁵⁴ This measure may reduce post-operative pain and improve cosmesis, as well as facilitate immediate implant placement in smaller-breasted women.

The major advantages of implant reconstruction are reduced operating time, faster recuperation, and a reasonably good cosmetic outcome. The cosmetic result may deteriorate over time as a consequence of capsule formation or implant migration, and the implant may have to be replaced after each decade of use.

Autologous Tissue

An alternative approach to reconstruction is to transfer vascularized muscle, skin, and fat from a donor site to the mastectomy defect. The most commonly used myocutaneous flaps are the TRAM flap [see Figure 14] and the latissimus dorsi flap [see Figure 15]. Use of the free TRAM flap is advocated by certain centers and may be a preferred option for patients who smoke or are diabetic or obese.

The major advantage of autologous tissue reconstruction is that it generally yields a superior cosmetic result that remains stable over time; in addition, the reconstructed breast has a softer, more natural texture than a breast that has undergone implant reconstruction.

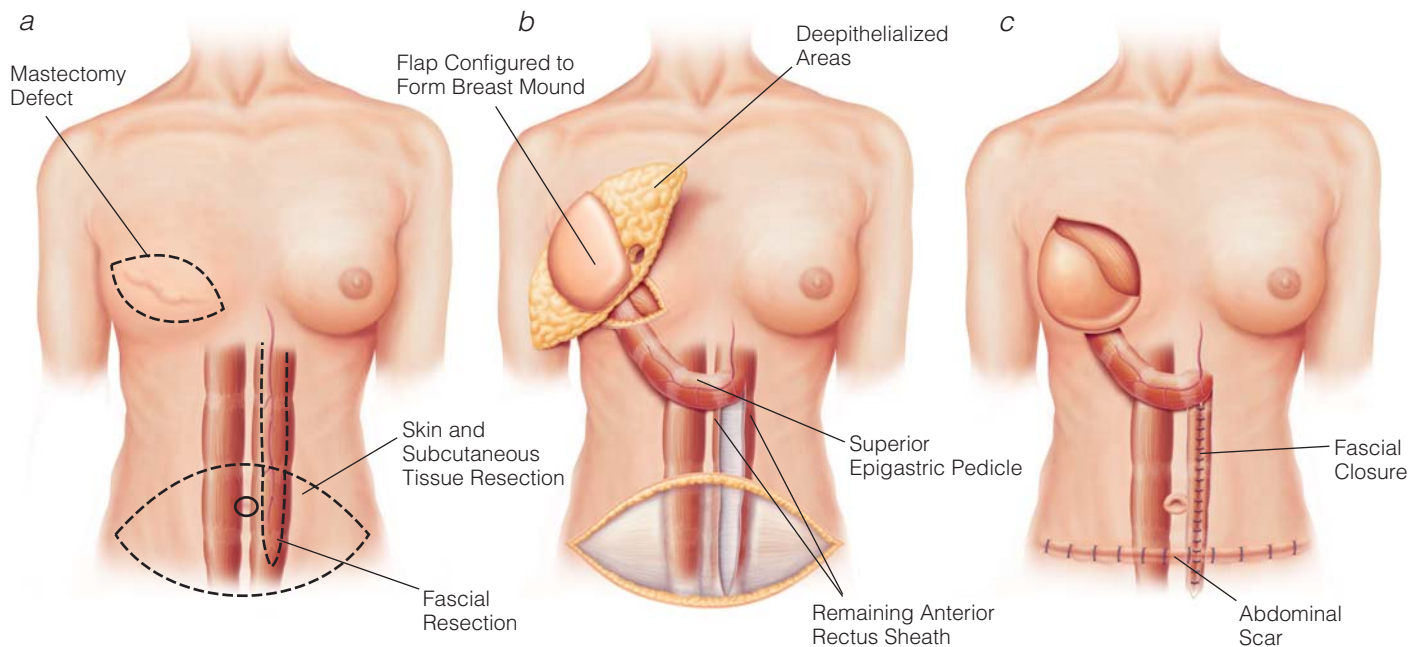

Figure 14 Breast reconstruction after mastectomy: TRAM flap. (a) The infraumbilical flap is designed. The TRAM flap is tunneled subcutaneously into the chest wall cavity. Blood supply to the flap is maintained from the superior epigastric vessels of the rectus abdominis. (b) Subcutaneous fat and deepithelialized skin are positioned under the mastectomy flaps as needed to reconstruct the breast mound. (c) The fascia of the anterior rectus sheath is approximated to achieve a tight closure of the abdominal wall defect and to prevent hernia formation. The umbilicus is sutured into its new position.

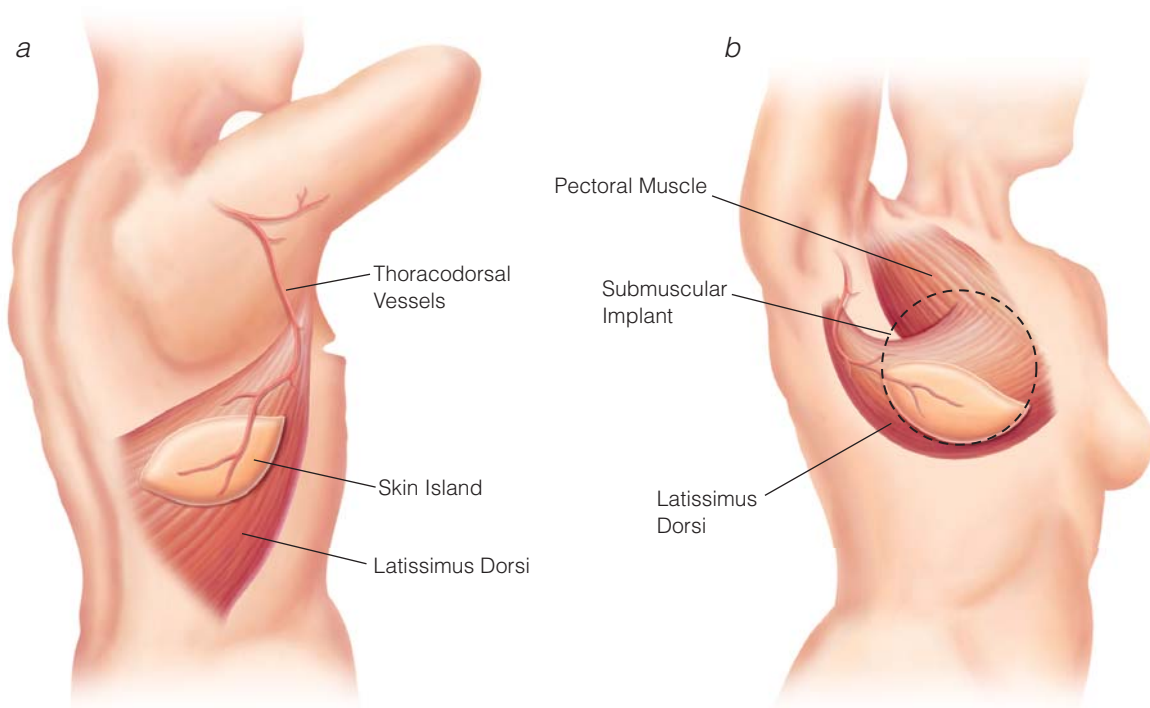

Figure 15 Breast reconstruction after mastectomy: latissimus dorsi myocutaneous flap with submuscular implant. With this flap, addition of an implant is often required to provide the reconstructed breast with adequate volume and projection. (a) The myocutaneous flap is elevated; it is important to maintain the blood supply to the flap from the thoracodorsal vessels. The flap is tunneled subcutaneously to the mastectomy defect. (b) The latissimus dorsi is sutured to the pectoralis major and the skin of the inframammary fold, so that the implant is completely covered by muscle.

tion. The main drawbacks are the magnitude of the surgical procedure (involving both a prolonged operating time and longer inpatient hospitalization), the potential need for blood transfusion, and the pain and loss of muscle function that arise at the donor site. Smokers and patients with significant vascular disease may not be ideal candidates for autologous tissue reconstruction. Partial necrosis of the transferred flap may create firm areas; on rare occasions, complete necrosis and consequent loss of the flap can occur.

A number of factors are considered in choosing between the TRAM flap and the latissimus dorsi flap. In a TRAM flap reconstruction, the contralateral rectus abdominis is transferred along with overlying skin and fat to create a breast mound. This procedure yields a flatter abdominal contour but calls for a long transverse abdominal incision and necessitates repositioning of the umbilicus. The major advantages of TRAM flap reconstruction are that it provides enough tissue to match most contralateral breasts and that it offers the option of performing bilateral TRAM flap procedures in healthy candidates who want bilateral reconstruction. Patients who have undergone abdominal procedures that compromise the TRAM flap's vascular supply are not ideal candidates for TRAM reconstruction. Postoperative discomfort is greater with TRAM flap reconstruction than with other flap reconstructions because of the extent of the abdominal portion of the procedure.

In a latissimus dorsi myocutaneous flap reconstruction, the ipsilateral latissimus dorsi is transferred along with overlying skin and fat to create a breast mound. The operative technique for the latissimus dorsi flap reconstruction is complex, requiring intraoperative changes in patient position (unless the oncologic surgeon is willing to perform the mastectomy with the patient in a lateral decubitus position). Patients who have undergone irradiation of the breast, the chest wall, or the axilla (including irradiation of the thora-

codorsal vessels) may not be eligible for this procedure. A major advantage of the latissimus dorsi flap is that its donor site is associated with less postoperative discomfort than the abdominal donor site of the TRAM flap. In addition, transfer of the latissimus dorsi results in substantially less functional impairment than transfer of the rectus abdominis. One major drawback is that in many women, the latissimus dorsi is not bulky enough to provide symmetry with the contralateral breast; consequently, to match the size of the opposite breast, the flap must be supplemented with an implant. Thus, the drawback of the implant's limited lifespan is added to the drawbacks associated with autologous tissue reconstruction.

Free-flap reconstruction options are used primarily when other autologous and implant reconstruction options are not available, do not provide sufficient tissue volume, or have failed. They are more complex procedures, requiring microvascular anastomoses and carrying a higher risk of total flap loss. The two most commonly employed free-flap options are the free TRAM flap and the free gluteus flap.

Donor-site morbidity—including postoperative pain, wound-healing complications, decreased abdominal muscle strength, and hernia formation—is a prime disadvantage of either pedicled or free TRAM flap reconstruction. As a result, muscle-sparing alternatives to autogenous breast reconstruction have been developed, such as the deep inferior epigastric perforator (DIEP) flap.⁵⁵ In this approach, free flaps are used that comprise skin and fat alone, without the rectus abdominis. Avoidance of muscle sacrifice in the abdomen ultimately translates into greater patient satisfaction, but careful patient selection is essential to optimize outcomes. The disadvantages of the DIEP flap include the considerable technical expertise and long operating time required, as well as the greater potential for flap loss (because this flap has a more tenuous blood supply than the standard TRAM flap).

6 LYMPHATIC MAPPING AND SENTINEL LYMPH NODE BIOPSY

Seth P. Harlow, M.D., David N. Krag, M.D., F.A.C.S., Douglas S. Reintgen, M.D., F.A.C.S., Frederick L. Moffat, Jr., M.D., F.A.C.S., and Thomas G. Frazier, M.D., F.A.C.S.

Breast cancer and melanoma are among the most common malignancies treated by U.S. surgeons. In 2003, it was estimated that there were 54,200 new cases of melanoma and 212,600 new cases of breast cancer in the United States.¹ The incidence of melanoma has been rising rapidly in the past few decades, and the incidence of breast cancer is also likely to keep rising as the baby-boomer generation ages.

Over the past 20 years, significant strides have been made in the management of these two diseases from the standpoint of both surgical and adjuvant treatment. For both patients with melanoma and those with breast cancer, adjuvant therapies for high-risk lesions have been shown to have a positive impact on recurrence rates and overall survival. In melanoma, the administration of adjuvant interferon alfa-2b to patients with T4 (> 4.0 mm deep) primary tumors or nodal metastases has led to lower recurrence rates and longer overall survival.² In breast cancer, there is a much more extensive body of experience with adjuvant chemotherapy and hormone therapy for optimization of survival in high-risk patients.^{3,4} In both diseases, the presence or absence of lymph node metastases is highly predictive of patient outcome and is the most important prognostic factor for disease recurrence and cancer-related mortality. Surgical management of the regional lymph nodes will continue to be an important component of therapy for patients with these malignancies.

Progress in the management of regional lymph nodes in melanoma and in breast cancer has taken different routes to what is likely to be the same destination—namely, the use of lymphatic mapping and sentinel lymph node (SLN) biopsy in clinically node-negative patients. The development of intraoperative lymphatic mapping and selective lymphadenectomy has made it possible to map lymphatic flow from a primary tumor to the initial draining node or nodes (i.e., the SLN or SLNs) in the regional nodal basin. The pathologic status of the SLN is known to be concordant with the pathologic status of the nodal basin as a whole. Integration of these techniques, along with increasingly detailed and sophisticated pathologic examination of the SLN, into the surgical treatment of melanoma and breast cancer offers the potential for more conservative operations, lower morbidity, and more accurate disease staging.

Lymphatic Mapping and SLN Biopsy for Melanoma

RATIONALE

Assessment of Nodal Status

There are several established factors for predicting the risk of metastatic disease in melanoma patients. These factors must be taken into account to ensure that patients are appropriately stratified into different risk groups and hence can receive appro-

priate treatment. The presence of lymph node metastases is the single most powerful predictor of recurrence and survival in melanoma patients: 5-year survival is approximately 40% lower in patients who have lymph node metastases than in those who do not. This finding suggests that many melanoma patients are likely to benefit from accurate nodal staging.

Elective lymph node dissection Until the latter part of the 1990s, elective lymph node dissection (ELND) was the mainstay of the surgeon's armamentarium for nodal staging of melanoma patients. ELND removes clinically negative nodes, as opposed to therapeutic node dissections, which are done for nodes with gross tumor involvement. Opinions are divided as to whether ELND actually extends survival or whether it is solely a staging procedure. Two prospective, randomized trials failed to demonstrate better survival in melanoma patients treated with ELND than in patients undergoing wide local excision (WLE) alone as primary surgical therapy.^{5,6} Retrospective studies from large databases, however, suggested that there may be subpopulations of patients who do benefit from ELND. The Intergroup Melanoma Trial was the first randomized study to show enhanced survival in patient subgroups after surgical treatment of clinically occult metastatic melanoma.⁷ The benefit was found in patients with melanomas 1.1 to 2.0 mm thick and patients younger than 60 years.⁸

Adjuvant therapy for high-risk melanoma Three national prospective, randomized trials sponsored by the Eastern Cooperative Oncology Group (ECOG) investigated the use of adjuvant interferon alfa-2b in patients with high-risk melanoma. The first trial, ECOG 1684,² was the impetus for the Food and Drug Administration's approval of interferon alfa-2b, in that it was the first study to demonstrate that this agent was an effective adjuvant therapy for patients with high-risk melanoma. Patients eligible for ECOG 1684 had either thick primary melanomas (> 4.0 mm thick) or nodal metastases. ECOG 1684 and a subsequent trial, ECOG 1694,⁹ reported significant overall survival benefits for patients receiving adjuvant interferon alfa-2b; a third trial, ECOG 1690,¹⁰ did not, though it did show an improvement in disease-free survival for the treated group.

Given the results from the Intergroup Melanoma Trial and the three ECOG trials, one can make a strong argument that when the risk of nodal metastases reaches a certain defined level, a nodal staging procedure should be performed. Because of the morbidity associated with a negative ELND, lymphatic mapping and SLN biopsy has become the de facto procedure of choice for nodal staging in melanoma patients.

Lymphatic mapping and selective lymphadenectomy SLN biopsy in melanoma was first described in 1992 by Morton

and associates,¹¹ who outlined a procedure of intraoperative lymphatic mapping and selective lymphadenectomy in which a vital blue dye was injected into the skin around the site of the primary melanoma. These investigators showed that the SLN is the first node in the lymphatic basin into which the primary melanoma consistently drains (though not necessarily the closest to the primary lesion). They harvested the SLN separately from the remainder of the regional nodes, and they found that the pathologic status of the SLN was highly accurate at predicting the pathologic status of the entire nodal basin, which was surgically removed in all of the patients studied. These findings suggested that melanoma patients could be accurately staged with procedures that were far less extensive than complete nodal dissections.

PREOPERATIVE EVALUATION

Selection of Patients

The risk of nodal metastases in melanoma patients depends on a number of factors, including primary tumor thickness, presence of ulceration, primary tumor location, and patient sex. Any patient with invasive melanoma (Clark level II or higher) is at some risk for nodal metastasis; however, before recommending SLN biopsy, the surgeon should determine what the relative risk

of nodal metastasis is with respect to the cost and morbidity of the procedure.

Patients with intermediate-thickness melanomas (1.0 to 4.0 mm) are the ones likely to gain most from SLN biopsy: the risk of nodal metastases in the absence of systemic disease is believed to be highest in this group. In patients with melanomas between 0.76 and 1.0 mm thick, the risk of nodal metastasis is less than 6%, but the procedure can certainly be justified in this population on the basis of its low morbidity. In patients with thin melanomas (< 0.76 mm), several prognostic factors have been shown to identify higher risk, including primary tumor depth of Clark level III or higher, ulceration, the presence of regression, male sex, and axial location.¹² Patients with thin melanomas and multiple risk factors may be at high enough risk to warrant SLN biopsy.

In patients with thick melanomas (> 4.0 mm), the risk of occult systemic metastases is as high as 70%, and that of occult nodal metastases ranges from 60% to 70%. The high risk of systemic disease was the main reason why ELND was not recommended for such patients in the past. Now that these patients have access to effective adjuvant therapy, however, they should be offered lymphatic mapping and SLN biopsy as a staging procedure. Among patients with thick melanomas, those with negative nodes survive longer than those with microscopic nodal dis-

Choice of Radiocolloid and Vital Blue Dye for Lymphatic Mapping

Choice of Radiocolloid

Little work has been done to determine which radiocolloid is best suited to either preoperative or intraoperative mapping. The ideal radiocolloid for intraoperative SLN mapping would have small particles (< 100 nm) that are uniformly dispersed, would be highly stable, and would have a short half-life that would not complicate the handling of the excised specimen. Technetium-99m (^{99m}Tc)-labeled compounds, being gamma emitters, satisfy most of these requirements. In a direct comparison between filtered (0.1 μm filter) ^{99m}Tc-labeled sulfur colloid (TSC) and ^{99m}Tc-labeled antimony trisulfide colloid (T-ATC), which has a particle size of 3 to 30 nm, filtered TSC was transported more quickly to the nodal basin and emitted less radiation to the liver, the spleen, and the whole body.⁹⁸ Unfiltered TSC contains relatively large particles (100 to 1,000 nm), and some investigators have found it to migrate more slowly from the injection site; however, other investigators have found it to be slow to flow through the first SLN to higher secondary nodes, which is actually an advantage.

A comparison between Tc-labeled human serum albumin (T-HSA), Tc-labeled stannous phytate, and T-ATC with respect to lymphoscintigram quality showed that T-ATC provided the best images for preoperative lymphoscintigraphy.⁹⁹ In an animal study comparing T-HSA with TSC, TSC was actually concentrated in the SLN over a period of 1 to 2 hours, whereas T-HSA passed rapidly through the SLN.¹⁰⁰ As a result, TSC yielded higher activity ratios at intraoperative mapping, improved the success rate of localization, made the technique easier, and thus was a superior reagent for this application.

The Sydney Melanoma Unit (SMU) prefers the use of T-ATC because this agent seems to have smaller, more uniform particles that rapidly migrate into the lymphatic channels but still are appropriately trapped and retained by the SLN. At SMU, use of T-ATC allows injection of the radiocolloid and imaging to be performed on the day before operation. SMU investigators find that hot spots in the regional basin are maintained even when 24 hours have elapsed from the time of injection. The radioactivity in the basin over the hot spot (i.e., the SLN) is decreased because four half-lives of technetium have been expended and because some of the radiocolloid has passed through, but the ex vivo activity ratio is not substantially affected. In the United States, T-ATC has been removed from the market and is unavailable for clinical use. Currently, TSC (filtered or unfiltered) is the agent favored by most surgeons in the United States.

Choice of Vital Blue Dye

Several vital blue dyes have been investigated with an eye to their potential applicability to cutaneous lymphatic mapping. Among these are methylene blue (American Regent, Shirley, NY); isosulfan blue, 1% in aqueous solution (Lymphazurin; United States Surgical Corp., Norwalk, CT); patent blue-V (Laboratoire Guerbet, France); Cyalume (American Cyanamid Co., Bound Brook, NJ); and fluorescein dye. All substances tested were known to be nontoxic in vivo and were injected intradermally as provided by the supplier. In a feline study, patent blue-V and isosulfan blue were the most accurate in identifying the regional lymphatic drainage pattern.¹⁰¹ These dyes entered the lymphatics rapidly, with minimal diffusion into the surrounding tissue. Their bright-blue color was readily visible and allowed easy identification of the exposed lymphatics.

Isosulfan blue has worked extremely well for intraoperative SLN mapping. In some patients with thin skin, the afferent lymphatics can be seen through the skin after the injection of isosulfan blue. In addition, when the dye enters the SLN, it stains the node a pale blue, thus clearly distinguishing the SLN from the surrounding non-SLNs. The other dyes have largely been abandoned as unsatisfactory because they diffuse too rapidly into surrounding tissue and are not retained by the lymphatic channels in sufficient concentrations to stain the SLN. The fluorescent dyes fluorescein and Cyalume are readily visualized, but a dark room is necessary for optimal visualization; moreover, because of the diffusion of these dyes into surrounding tissue, the background fluorescence is unacceptably high. Methylene blue is relatively poorly retained by the lymphatic vessels and thus stains the SLN too lightly.

Use of vital blue dyes rarely causes complications but has been associated with severe allergic reactions in the literature.¹⁹ Blue dye can be retained at the primary tumor site for more than 1 year. The color gradually fades with time; however, the patient can be left with a permanent tattoo if the injected dye is not removed with the wide excision or the lumpectomy. Fortunately, in the head and neck area, where a permanent tattoo would be unacceptable, the richness of the cutaneous lymphatics allows rapid clearance of the blue dye from the skin and subcutaneous tissues. A small amount of residual blue dye may be left behind after wide excision, but this typically disappears rapidly and poses no real problem. All patients report the presence of dye in the urine and stool during the first 24 hours. In some cases, the dye can interfere with transcutaneous oxygen monitoring during anesthesia.

ease.¹³ Accordingly, some medical oncologists simply observe T4 patients unless nodal disease is documented.

The extent of any operation done at the primary site before SLN biopsy may affect the success of the biopsy procedure. In patients who have had large areas of tissue undermining or have undergone reconstruction with a rotational flap or Z-plasty, the normal lymphatic channels may be disrupted, and such disruption may render SLN biopsy inaccurate. Nevertheless, there have been reports of SLN biopsy being performed successfully after previous WLE, which suggests that many of these patients may be salvageable for accurate nodal staging if their primary tumors have been widely excised.¹⁴ These patients may have more SLNs in more regional nodal basins than patients in whom the primary tumor has not been resected with curative intent, but at present, there is no unequivocal evidence that previous WLE of the primary lesion increases the risk of postoperative nodal relapse.^{15,16}

OPERATIVE PLANNING

Positioning and Anesthesia

Patients should be prepared to undergo wide excision of the primary melanoma site (where indicated) and SLN biopsy during the same operative session. Depending on the location of the primary lesion, it may be possible to perform the two procedures with the patient in a single position; however, it often happens that the patient must be moved to a different position to afford the surgeon adequate access to the different locations. The choice of anesthesia varies, depending on the size and location of the wide excision and the likely depth of the SLNs. In selected cases, local anesthesia may be appropriate, but for many lesions, general or regional anesthesia is preferable.

OPERATIVE TECHNIQUE

Although the technical details of lymphatic mapping and SLN biopsy for melanoma vary from institution to institution, the reported results of the different approaches have been very similar. Proper performance of these procedures requires close collaboration between the surgeon, the nuclear radiologist, and the pathologist, with each member playing a critical role in the process.

Step 1: Injection of Radiolabeled Tracer and Lymphoscintigraphy

On the day of the procedure, patients report to the nuclear medicine suite for injection of the radiolabeled tracer and preoperative lymphoscintigraphy. It is crucial to have a mechanism in place by which the location of the primary melanoma site and the desired dose of the tracer can be reliably communicated to the nuclear radiologist. Some melanoma biopsy sites are difficult to locate, particularly if multiple skin biopsies have already been performed.

A radiolabeled agent is then selected; the most common choices are technetium-99m (^{99m}Tc)-labeled sulfur colloid (TSC) and ^{99m}Tc-labeled antimony trisulfide colloid (T-ATC) [see *Side-bar Choice of Radiocolloid and Vital Blue Dye for Lymphatic Mapping*]. The dose of the tracer and the volume of the injectate are largely determined by the location and size of the primary tumor site but generally can be kept to 0.5 mCi or less and 1 ml or less, respectively. Injections are made intradermally around the circumference of the lesion or biopsy site, and dynamic scans are taken 5 to 10 minutes after injection. The location of the SLN can be marked on the skin by the radiologist to assist the surgeon; however, this location may vary slightly with changes in patient position and should therefore be confirmed by the surgeon with the gamma probe in the operating room. All regional basins at risk should be marked, along with any in-transit nodes

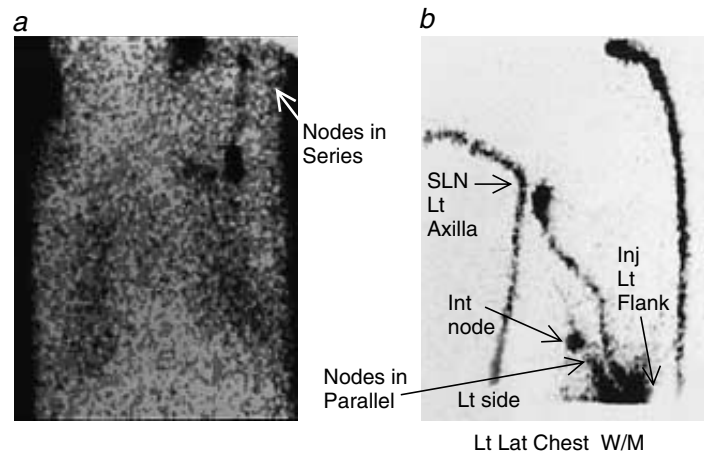

Figure 1 Lymphatic mapping and SLN biopsy for melanoma. In-transit nodal areas are identified in 5% of melanoma patients; this is the reason why preoperative lymphoscintigraphy is performed for primary sites on either the upper or the lower extremity. In a patient with a melanoma on the left hand (a), the injection site and the left hand are raised above the head, and cutaneous lymphatic flow into an epitrochlear node can be seen. This in-transit node then emits a lymphatic vessel flowing to the left axilla. By definition, the SLN is the first node in the chain that receives primary lymphatic flow. The epitrochlear node and any axillary nodes are nodes in series. Hence, the epitrochlear node is the SLN and thus is the only node that must be harvested. In a patient with a primary melanoma on the left flank (b), there are two separate afferent lymphatics, one leading to an SLN in the left axilla and the other leading to an in-transit node on the left flank. These are nodes in parallel in that they both receive primary lymphatic flow from the skin site. Hence, the two nodes are equally at risk for metastatic disease, and both are considered SLNs and must be harvested.

that are identified [see *Figure 1*], to allow accurate nodal staging. Lymphoscintigraphy is also useful in that it provides a good estimate of the number of SLNs the surgeon can expect to find at operation.

The timing of tracer injection in relation to the surgical procedure is not critically important. Activity in the SLNs usually reaches its maximum 2 to 6 hours after injection; waiting longer to carry out the procedure may increase the labeling of secondary nodes. There have, however, been several reports of SLN procedures being accurately performed 16 to 24 hours after tracer injection.¹⁷ Because of the short half-life of technetium (6 hours), delaying procedures for this amount of time may reduce the radioactivity at the injection site and lower the background interference, but because TSC is retained in the SLN dendritic cells, the SLNs can still be easily identified.

Step 2: Intraoperative Lymphatic Mapping and Identification of SLN

It is our practice to review the lymphoscintigram when the patient arrives in the OR, then evaluate him or her with the gamma probe before deciding on positioning; access to nodal basins may be difficult in certain positions. Probe evaluation begins by defining the diffusion zone around the primary tumor site, where SLN identification is not possible. The area between this diffusion zone and the possible nodal drainage sites is then mapped for possible in-transit nodes by means of a systematic but expeditious evaluation for radioactive “hot spots.” The gamma probe is moved in a linear fashion between the diffusion zone and the nodal basin. It is

then shifted medial or lateral to the previous line, and the process is repeated until the entire area is evaluated. The location of a radioactive hot spot is confirmed by identifying a discrete location where the radioactive counts are higher than the counts found in the tissue 1 to 2 cm more proximal to the injection site (the background skin count). The counts from the hot spot and the background are recorded. The hot-spot site is marked on the skin to allow more direct dissection to the SLN.

Concomitant use of a vital blue dye [see *Sidebar Choice of Radiocolloid and Vital Blue Dye for Lymphatic Mapping*] is favored by many surgeons. The blue dye is complementary to the radiolabeled tracer; the combination of the two marking agents improves the chances of identifying the SLN and facilitates node retrieval. The blue dye is injected into the dermis immediately adjacent to the melanoma. For lesions on an extremity, the dye may be injected along the proximal margin of the lesion or biopsy site; for lesions on other areas, it should be injected circumferentially. The general recommendation is to wait 5 to 10 minutes after injecting the dye before initiating SLN retrieval.

To minimize the dissection required for node resection, the incision for the SLN biopsy should be made through the hot spot identified by the gamma probe. The incision should also be situated so that it can be incorporated into a longer incision should the finding of a positive SLN necessitate performance of a completion lymph node dissection (CLND). The gamma probe is placed in a sterile sheath and used again after the incision is made to guide further dissection. If blue dye was used, the surgeon can visually follow the blue lymphatic channels to the blue-stained SLN.

An SLN is defined as either (1) the most radioactive node in the basin or (2) a node that either is stained blue or clearly has a blue-stained lymphatic vessel entering it. When an SLN is removed, the ex vivo radioactivity count in the node is recorded. This count is then used as a reference for determining which, if any, of the remaining nodes in that basin (some of which may be potential SLNs) should be removed. In our view, if the radioactivity count in the hottest remaining node in the basin is less than 10% of the ex vivo count in the hottest SLN, none of the remaining nodes should be considered SLNs, and none should be removed.¹⁸ Any nodes whose radioactivity counts exceed this 10% threshold, however, should be removed.

A final count of the SLN biopsy bed is then taken to document that all significantly radiolabeled SLNs have been accounted for and removed. In addition, the tissues are examined for blue-stained lymphatic channels or lymph nodes regardless of radioactivity; as noted, blue staining confers SLN status even if the node is not radioactive. Finally, when it appears that all relevant SLNs have been removed, as confirmed by the final bed count, the tissues are palpated for grossly suspicious nodes. Firm tumor-involved nodes with obstructed afferent lymphatics may divert lymph flow to non-SLNs, and such diversion is a significant cause of false negative SLN biopsy results.

Once an SLN is identified, it should be dissected out with as little trauma to the surrounding tissues as possible. Lymphatic channels to the node should be identified and either tied or clipped to reduce the risk of postoperative seroma formation. Because the gamma probe can localize SLNs with great accuracy, routine dissection of motor nerves is not required; however, knowledge of the likely location of the motor nerves is critical for preventing inadvertent injury to these structures during dissection.

Step 3: Pathologic Evaluation of SLN

The optimal extent of pathologic evaluation of SLNs in patients with melanoma has been the subject of some debate. SLN biopsy

allows pathologists to focus their efforts on one node or a small number of nodes, and this focus has led to a process of ultrastaging. Currently employed methods include serial sectioning, immunohistochemical (IHC) staining for melanoma-associated antigens (e.g., S-100 and HMB-45), and reverse transcriptase polymerase chain reaction (RT-PCR) for identification of messenger RNA (mRNA) transcripts of the enzyme tyrosinase. It is clear that these techniques can improve identification of node-positive patients, but it is not yet clear what their prognostic value may be with respect to determining patient outcome and guiding further therapy. Additional study in this area is required to resolve this issue.

COMPLICATIONS

Complications of SLN biopsy are quite uncommon. Allergic reactions to the blue dyes occur in fewer than 1% of patients but can range in severity from mild urticaria to anaphylaxis; thus, the surgical team and the anesthesia team should always be prepared for this uncommon but potentially serious problem.¹⁹ Motor nerve injury is rare. In a series of 30 patients who had head and neck melanomas with SLN drainage to the parotid region, there were no injuries to the facial nerve when the SLN was removed without nerve dissection.²⁰ Similar results have been reported for nodes in the posterior triangle of the neck and the spinal accessory nerve, as well as for axillary nodes and the long thoracic and thoracodorsal nerves. The incidence of wound complications is quite low (1.7% wound complication rate; 3.0% seroma rate), as is the incidence of postbiopsy lymphedema (0.7%). In the Sunbelt Melanoma Trial, the complication rate in 2,120 patients undergoing SLN biopsy was 4.6%, compared with 23.2% in 444 patients undergoing CLND.²¹

OUTCOME EVALUATION

Studies of SLN biopsy in melanoma patients have demonstrated consistently good technical success and high pathologic accuracy with a variety of different techniques. There have been three studies in which SLN biopsy was done with confirmatory CLND of all lymph node basins in which SLNs were identified.^{11,22,23} When the results of these studies are considered together, the pathologic false negative rate for SLN biopsy in clinically node-negative melanoma patients is about 6%. The pathologic accuracy rate (i.e., the rate at which the pathologic status of the SLN is the same as that of the entire nodal basin) is 98%.

Several trials have prospectively followed patients treated with SLN biopsy and subsequent observation if the SLN was negative.²⁴⁻²⁷ These trials reported similar rates of technical success (94%–98%) and of node positivity (12% to 16%). The rates of first relapse in the regional nodes in these patients were similar as well (range, 3.8%–8%; mean, 4.4%), a finding that is consistent with the rates of false negative SLNs in the series in which CLND was performed. These studies also found that the pathologic status of the SLNs was the most important predictor of disease-free survival and overall survival, a result that further underscores the accuracy of the procedure and the importance of nodal staging in predicting melanoma outcomes.

The available data suggest that lymphatic mapping is applicable to all primary body sites, including the head and the neck (the most technically demanding sites).^{17,28} The best results are achieved with a combination mapping approach that employs both a vital blue dye and a radiocolloid. The procedure is associated with slightly higher false negative rates in patients with head and neck melanoma than in those with melanoma of the trunk or extremities (10% versus 1% to 2%). Nevertheless, the false negative rates with head and neck melanoma are still low enough to justify offering lymphatic mapping to patients—especially given

that the only alternative method of obtaining the nodal staging information is CLND, a procedure that carries a much higher morbidity.

Lymphatic Mapping and SLN Biopsy in Breast Cancer

RATIONALE

Assessment of Nodal Status

In early breast cancer, as in melanoma, the pathologic status of the regional lymph nodes is the most important predictor of outcome. The presence of regional lymph node metastases in breast cancer reduces 5-year survival by 28% to 40%.^{29,30} Prognostic factors related to primary tumor characteristics have consistently been shown to be inferior to nodal status as predictors of disease outcome. In addition, regional lymph node dissection in the setting of breast cancer is superior to observation and at least equivalent to irradiation for regional disease control in clinically node-negative patients.³¹ There is some evidence that adequate regional disease control may confer a small survival benefit.³²

Invasive breast cancer has a relatively high rate of nodal metastasis in clinically node-negative patients. The risk of metastasis is clearly related to the size of the primary tumor, but it is significant (15% or higher) even in patients with early (T1a) lesions.^{33,34} The primary nodal drainage basin for the breast is the ipsilateral axilla; however, drainage to extra-axillary sites (e.g., the internal mammary lymph node chain, the supraclavicular nodes, and the intramammary nodes) is also reported. Other potential sites of lymphatic drainage notwithstanding, the recommended surgical procedure for evaluating the regional lymph nodes in clinically node-negative breast cancer patients has been level I and II axillary lymph node dissection (ALND). Such dissections are, however, associated with a significant risk of long-term morbidity, primarily related to the risk of lymphedema in the affected arm. For this reason, SLN biopsy was developed and investigated as a possible substitute for standard ALND in the treatment of breast cancer.

PREOPERATIVE EVALUATION

Selection of Patients

All clinically node-negative patients with a diagnosis of invasive breast cancer are potential candidates for SLN biopsy. Ideal candidates are those patients with unifocal lesions who have no history of previous axillary surgery or prior cancer treatment. Performing an SLN biopsy after a previous excisional biopsy is technically feasible; however, SLN biopsy may be easier if the lesion is still in place. Patients who have undergone extensive breast procedures (e.g., breast reduction, placement of breast implants, or multiple open biopsies) may have significant alterations in the lymphatic pathways, which may compromise the accuracy of SLN biopsy. Patients with multifocal tumors or inflammatory cancer also are generally poor candidates for SLN biopsy, though there is some evidence suggesting that using periareolar injection sites may allow the procedure to be performed accurately in patients with multifocal disease.³⁵ The use of SLN biopsy in patients who have received preoperative chemotherapy has been reported in only a very modest number of cases.³⁶⁻³⁸

OPERATIVE PLANNING

Positioning and Anesthesia

Patients should be placed in the supine position, with all potential nodal sites within the operative field. Preoperative lym-

phoscintigraphy may help the surgeon identify SLNs located in extra-axillary sites (e.g., the internal mammary chain). Although SLN biopsy may be performed with the patient under local anesthesia, we favor general anesthesia for this procedure, particularly when it is done in conjunction with the breast excision.

OPERATIVE TECHNIQUE

Step 1: Injection of Radiolabeled Tracer and Lymphoscintigraphy

In the United States, the radiocolloid most commonly employed for SLN biopsy in breast cancer patients is TSC, which may be used either unfiltered or filtered (< 220 nm) [see *Sidebar Choice of Radiocolloid and Vital Blue Dye for Lymphatic Mapping*]. The ^{99m}Tc dose generally ranges from 0.45 to 1.0 mCi, and the injectate volume ranges from 4 to 8 ml. TSC is injected directly into the breast parenchyma in four to eight locations around the primary tumor site or the biopsy cavity. Because there are fewer lymphatic vessels in the breast parenchyma than in the dermis, it takes longer for the tracer to be transported in sufficient quantity to the SLNs than it does in the setting of melanoma. A minimum of 30 minutes is generally necessary before lymphoscintigraphy is performed or the patient is brought to the OR [see *Figure 2*].

When the lesion is palpable, injection is guided by the size, shape, and location of the mass. When the lesion is not palpable, injection is guided by ultrasonography or needle-wire localization. If an excisional biopsy was previously performed, the tracer should be injected into the breast parenchyma rather than into the biopsy cavity; it will not diffuse out of the cavity. This is best done under ultrasonographic guidance. In addition, injections should not be made into the retromammary fat or the pectoral fascia, because doing so would lead to wide diffusion of tracer throughout the chest area, which would make nodal identification very difficult.

As in melanoma, the timing of SLN biopsy after tracer injection is not of critical importance. Good results have been obtained with injection-to-biopsy intervals ranging from 30 minutes to 24 hours. The usual recommendation is to wait 1 to 2 hours.

Figure 2 Lymphatic mapping and SLN biopsy for breast cancer. Whereas flow of the radiocolloid to the SLN takes 5 to 10 minutes for melanoma mapping, it takes 30 to 40 minutes for breast cancer mapping. In addition, the primary site is usually closer to the regional basin in breast cancer than it is in melanoma, and shine-through from the primary site may be a problem. Invariably, the lumpectomy or mastectomy is performed first, followed by axillary SLN harvesting.

Comment Several alternative routes of tracer injection have been investigated for SLN biopsy in breast cancer patients, primarily in response to the difficulties sometimes associated with peritumoral injection (e.g., delayed tracer uptake and wide diffusion zones that can overlap the nodal basins). These routes include intradermal or subdermal injection in the area overlying the tumor, subareolar injection, and periareolar injection. The rationale for the development of these alternatives is that there is significant overlap between the lymphatic vessels of the breast skin and those of the breast parenchyma. Multiple studies have confirmed that the use of these injection routes yields high localization rates and results in accurate removal of SLNs that reflect the pathologic nodal status of individual patients. A notable deficiency of these techniques, however, has been the low reported rate of tracer migration to nodes outside the axilla, particularly to the internal mammary lymph node chain. This result is thought to be attributable to a unique set of lymphatic channels deep in the breast parenchyma, separate from the overlying skin, that drain to the internal mammary chain.

Another injection route that has been described is intratumoral injection. This technique employs a very small volume of injectate, thereby avoiding much of the injection-site diffusion issues associated with peritumoral injection. Intratumoral injection gives the radiolabeled tracer access to the deeper lymphatic vessels and identifies SLN drainage to the extra-axillary nodal sites significantly more frequently than even peritumoral injection does.

The various tracer-injection methods have not been directly compared; thus, at present, the optimal route of injection can only be inferred by comparing studies from different institutions. The potential importance of the extra-axillary sites is not entirely clear, but it appears that these sites may be the sole locations of metastatic disease in as many as 20% of the node-positive patients from whom they are removed.^{39,40} Most patients in whom SLNs are found outside the axilla have additional SLNs in the axillary basin.

Step 2: Intraoperative Lymphatic Mapping and Removal of SLN

Intraoperative mapping of SLNs is done in essentially the same fashion for breast cancer as for melanoma. Our approach begins by performing a primary survey of the potential nodal sites with the handheld gamma detector. First, the radiotracer injection-site diffusion zone is defined [see Figure 3]. The points at which the probe's audio output peaks are marked circumferentially on the skin surrounding the injection site. Within this zone, the probe is unable to identify an SLN.

Next, as in a melanoma survey, the probe is placed close to the skin and moved away from the diffusion zone in a linear manner. As the probe moves further from the injection site, the radioactivity counts decrease. If there is an SLN beneath the area being evaluated, a discrete radioactive hot spot will be identified. The location of the hot spot is marked on the skin, and the remainder of the primary survey is completed, focusing on detecting any additional SLNs. All potential nodal sites (including the supraclavicular and infraclavicular nodes, the internal mammary chain, intramammary sites, and the upper abdomen) are carefully assessed, and finally, the axilla is evaluated. By routinely assessing the other potential sites before the axilla, the surgeon can ensure that they are not overlooked and can confirm that each patient has been optimally evaluated.

Once the hot spots have been identified and marked, the radioactivity counts over each hot spot are recorded, as well as a background count from an area between the hot spot and the injection site, about 2 to 3 cm from the hot spot. If there is indeed a

Figure 3 Lymphatic mapping and SLN biopsy for breast cancer. The diffusion zone of radioactivity around the injection site is circled on the breast. The hot spot in the axilla is marked (HS) as well.

radioactive SLN below the marked hot spot, the background count should be significantly lower than the hot-spot count.

Next, after the primary survey and counts have been recorded, 5 ml of vital blue dye is injected into the breast parenchyma around the tumor or the biopsy cavity. The breast is gently massaged for 5 to 10 minutes to enhance transport of the dye to the SLNs. A small incision is made at the hot-spot location marked on the skin. The gamma probe is placed in a sterile sheath and inserted into the wound, and the “line of sight” to the point of maximal radioactivity, along which dissection proceeds to the hot node or nodes, is identified. During the dissection, the surgeon looks for blue-stained lymphatic channels and nodes [see Figure 4]. Most of the time, the radiocolloid and the vital blue dye identify the same SLNs. The SLNs are then carefully removed, and the lymphatic vessels entering them are tied off whenever possible.

Once the SLNs have been excised, the ex vivo radioactivity count for each one is recorded, as is the presence or absence of blue dye in either the node itself or the lymphatic vessels entering it. The ex vivo count of the excised node is then used as a guide for

Figure 4 Lymphatic mapping and SLN biopsy for breast cancer. A small incision is made in the axilla on the basis of the hot-spot location. The SLNs identified are both radioactive and stained blue.

Figure 5 Lymphatic mapping and SLN biopsy for breast cancer. In touch-imprint cytology, slides are touched to tissue from a “hot” specimen, and cells on the section or the margin are exfoliated onto the slide for cytologic preparation. Shown are (a) permanent histology of an infiltrating ductal carcinoma extending down to an inked margin and (b) a touch preparation demonstrating bizarre malignant cells from the sampling of the margin. The advantages of this technique are that the entire margin can be sampled and that tissue is not lost in the cryostat.

determining the completeness of radioactive SLN removal. As in melanoma, if the remaining radioactivity in the nodal basin is more than 10% of that in the hottest node removed, there may be SLNs still in place that should be sought out and, if found, removed. If the residual radioactivity in the nodal basin is less than 10% of that in the hottest node, the remaining nodes should not be removed. These guidelines apply equally to SLN biopsy in extra-axillary locations. The remaining nodes in the nodal basin should also be evaluated for blue staining of the nodes themselves or of the lymphatic channels entering them; any nodes meeting these criteria should be removed and labeled as SLNs.

Finally, before the SLN procedure is completed, the remaining nodes in the basin should be palpated. If a firm, hard tumor-replaced node is identified, it should be removed and categorized as an SLN. As in melanoma, the presence of a tumor-replaced node can increase the risk of a false negative SLN biopsy.

Step 3: Pathologic Evaluation of SLN

Pathologic SLN evaluation in breast cancer patients has two main aspects. The first is intraoperative evaluation of the SLN when the pathologic status of the node is being used to determine the need for axillary dissection; the second is permanent evaluation of the nodes to determine whether micrometastatic disease is present.

Two techniques are commonly employed for intraoperative evaluation of SLNs: frozen-section analysis and touch-imprint cytology. Frozen-section histopathology is available in most hospitals, and all surgical pathologists have some experience with it. This technique has a drawback, however, in that it sometimes uses up a large portion of the SLN, leaving a remnant that is insufficient for permanent paraffin-embedded sections. In addition, the sectioning of radioactive nodes on a cryostat raises radiation-safety issues for the pathologists.

Studies of frozen-section techniques of evaluating SLNs for metastatic breast cancer report false negative rates of 27% and 32%.^{41,42} When 60 frozen sections are made from each SLN, the

false negative rate can be reduced to about 5%,^{41,43} but at the cost of 45 to 60 minutes of operating time and loss of tissues for permanent histopathologic evaluation. In comparison, touch-imprint cytology consumes much less time and tissue, is far more accurate (false negative rate, 0.8%),⁴⁴ and does not contaminate the cryostat. It has also been applied to the evaluation of lumpectomy margins [see Figure 5]. The chief limitation of the touch-imprint method is that for optimal results, it requires a pathologist who is highly skilled in the cytologic evaluation of lymph nodes. Some centers use rapid immunohistochemical (IHC) analysis for cytokeratin staining to detect tumor cells in touch-imprint or frozen-section specimens, anticipating that detection of such cells can thereby be improved, particularly in patients with invasive lobular or well-differentiated ductal carcinomas.

Techniques used to date for permanent pathologic evaluation of SLNs in the setting of breast cancer include (1) serial sectioning of the nodes with routine hematoxylin-eosin (H&E) staining, (2) cytokeratin IHC staining [see Figure 6], and (3) RT-PCR detection of mRNA transcripts specific for epithelial cells. Each of these techniques is more sensitive in detecting tumor cells in the SLNs than routine H&E analysis of bivalved nodes. There is, however, some controversy surrounding their use, centering on the clinical relevance of a positive result. Some of these techniques (i.e., IHC and RT-PCR) are sensitive enough to identify single tumor cells in SLNs, but it is not clear whether such individual cells are actually capable of forming metastases. In the current staging system for breast cancer, metastases large enough to be seen on H&E sections are the benchmark for nodal staging. Metastases 2 mm in size or larger are known to have a negative impact on survival⁴⁵; however, it is not certain that the same can be said of smaller metastatic lesions. In 1999, the College of American Pathologists issued a consensus statement recommending that the staging of SLNs be based on routine histologic evaluation of the nodes cut at approximately 2 mm intervals.⁴⁶ Routine use of cytokeratin IHC staining should not be adopted as standard until its significance is demonstrated in clinical trials.

COMPLICATIONS

The complications of SLN biopsy in breast cancer patients are similar to those seen in melanoma patients. There is a minor

Figure 6 Lymphatic mapping and SLN biopsy for breast cancer. Cytokeratin immunohistochemical staining finds metastatic cells in 9.4% of breast cancer patients whose SLNs are histologically negative on routine examination.

Table 1 SLN Identification by Nodal Basin at Different Injection Sites^{39,41,50-52,54-95}

Nodal Basin	Injection Location			
	Peritumoral*	Intradermal/Subdermal†	Periareolar/Subareolar‡	Intratumoral§
Axilla	92.0% (range, 86%–100%)	96.4% (range, 93%–100%)	98.4% (range, 94.2%–100%)	92.0% (range, 88%–96%)
Internal mammary chain	4.9% (range, 0%–25.3%)	0.6% (range, 0%–4%)	0%	18.4% (range, 13%–43%)
Other	0.6% (range, 0%–8.4%)	0%	0%	4.3% (range, 0%–33.1%)

*28 trials; 5,924 patients. †11 trials; 1,872 patients. ‡5 trials; 486 patients. §5 trials; 669 patients.

(< 1%) risk of allergic reactions to the blue dye. There is a small risk of sensory or motor nerve injury or lymphedema whenever an axillary node procedure is performed; this risk is substantially reduced, though not entirely eliminated, with SLN biopsy.⁴⁷ With an internal mammary SLN biopsy, there is a risk of pneumothorax from unintended opening of the parietal pleura. This risk is very small with careful technique, however, and the problem can almost always be corrected by closing the wound around a rubber catheter inserted through a small stab incision and removing it at the end of a positive pressure breath given by the anesthesiologist. Surgical site infections occur in fewer than 1% of cases, and small seromas occur in about 10%.

OUTCOME EVALUATION

The first report of SLN biopsy in breast cancer, published in 1993, described the use of the gamma-probe localization technique for SLN identification.⁴⁸ A second report, published the following year, described the use of the vital blue dye technique for this purpose.⁴⁹ Since these initial reports, many single-center and multicenter studies have been published that achieved remarkably similar results using either or both of these techniques.

The early studies of SLN biopsy tended to use either a radiolabeled tracer or a vital blue dye alone. The first trial in which the two agents were used together was published in 1996.⁵⁰ This study documented an improvement in SLN localization and a 0% false negative rate, albeit in a small series of patients. Subsequent multicenter trials incorporating larger study groups yielded more reliable indications of the applicability of these techniques to the overall surgical community. In one such study, surgeons from 11 centers performed SLN biopsies and confirmatory axillary dissection in clinically node-negative patients with invasive breast cancer.⁵¹ The overall success rate for identifying and removing an SLN was 93%, the pathologic accuracy rate for predicting the presence

of nodal metastases from the SLNs removed was 97%, and the pathologic false negative rate was 11.4%. A subsequent multicenter trial, using a combination of blue-dye staining and the gamma-probe technique in most patients, reported an SLN retrieval rate of 88% and a pathologic false negative rate of 7.2%.⁵² A third trial, using the gamma-probe technique, reported an SLN retrieval rate of 87% and a pathologic false negative rate of 13%.⁵³ A fourth, using both blue-dye staining and the gamma-probe technique, reported an SLN retrieval rate of 86% and a pathologic false negative rate of 4%.⁵⁴

The numerous single-institution reports on SLN biopsy have made use of a variety of techniques. The technical variable of greatest interest has been the route by which the radiolabeled tracer is injected into the breast. The routes evaluated include peritumoral injection (as in the early studies), superficial injection into the dermis of the skin overlying the tumor site, periareolar or subareolar injection, and, most recently, intratumoral injection.

We have reviewed the literature on the use of different routes of injection and the associated rates of SLN localization by nodal basin, node positivity rates, and false negative rates. This review included those studies in which a radiolabeled tracer was used for SLN identification (either by lymphoscintigraphy or by intraoperative gamma probe localization) and in which the location of the SLN basins and the pathologic status of the SLNs could be ascertained [see Tables 1, 2, and 3]. Data on 8,951 patients were reviewed.^{39,41,50-52,54-95} The results of our review indicated that all of the approaches have acceptable SLN retrieval rates but that the rates are slightly higher with the more superficial ones (i.e., the dermal, subareolar, and periareolar techniques). There are, however, significant differences in the locations of the SLN basins identified with the different methods: with the superficial injection techniques, drainage is essentially confined to the axillary basin, whereas with the deeper injection techniques, as many as 22% of patients

Table 2 SLN Pathologic Positive Rates by Nodal Basin at Different Injection Sites^{39,41,50-52,54-95}

Nodal Basin	Injection Location			
	Peritumoral*	Intradermal/Subdermal†	Periareolar/Subareolar‡	Intratumoral§
Axilla	34.0% (range, 21%–50%)	35.2% (range, 18.2%–51.3%)	26.2% (range, 23.1%–42.1%)	37.8% (range, 12.7%–43.7%)
Internal mammary chain	21.2% (range, 0%–29.2%)	0%	0%	13% (range, 4.2%–25.9%)
Other	NA	0%	0%	3.4%

*28 trials; 5,924 patients. †11 trials; 1,872 patients. ‡5 trials; 486 patients. §5 trials; 669 patients.

Table 3 False Negative SLN Identification Rates at Different Injection Sites^{39,41,50-52,54-95}

Injection Location	Evaluable Patients (No.)	False Negative Rate
Peritumoral*	3,909	6.0%
Intradermal/subdermal†	1,734	6.5%
Periareolar/subareolar‡	19	0%
Intratumoral§	126	5.2%

*28 trials; 5,924 patients. †11 trials; 1,872 patients. ‡5 trials; 486 patients. §5 trials; 669 patients.

are found to have nodal basins outside the axilla. Approximately 16% to 21% of the extra-axillary SLNs will be found to have metastatic disease if removed. The clinical ramifications of these findings are that some patients may be understaged if the extra-axillary sites are not evaluated, and such understaging may affect the recommendations for systemic adjuvant therapy. What impact this possibility might have on tumor recurrence rates and patient survival is unknown at present; to resolve the uncertainty would require a large prospective, randomized trial.

To date, the only prospective, randomized trial of SLN biopsy in breast cancer is that of Veronesi and coworkers.⁹⁶ In this trial, a total of 516 evaluable patients were randomly assigned to undergo either SLN biopsy with confirmatory axillary dissection (257 patients) or SLN biopsy with axillary dissection done only if the biopsy yielded positive results (259 patients). At a median follow-up point of 46 months, no significant survival differences were reported, and there were no regional nodal recurrences in either arm. Admittedly, the study size was quite small. Other, larger trials that will have greater statistical power to evaluate the safety of SLN biopsy when completed are the National Surgical Adjuvant Breast and Bowel Project (NSABP) B32 trial and the American College of Surgeons Oncology Group (ACOSOG) Z0010 trial. Another ongoing study is the ACOSOG Z0011 trial, the aim of which is to evaluate the effectiveness of SLN biopsy as the sole surgical procedure in patients with pathologically positive SLNs.

Training and Credentialing

Credentialing criteria for new operative procedures have traditionally been under the jurisdiction of local hospital credentialing committees. When new technology becomes available, adequate training is essential, both to ensure that surgeons can perform the new procedures competently and to address medicolegal liability concerns. The American College of Surgeons (ACS) has a committee (the Committee on Emerging Surgical Technology and Education) that monitors this activity. With some new techniques (e.g., laparoscopic cholecystectomy and image-guided breast biopsy), hospitals have required surgeons to attend formal training courses and to have their first cases proctored by surgeons with experience in the new technique before they are allowed to perform the procedure on their own.

National organizations continue to struggle with the problem of educating and credentialing surgeons to perform new procedures. This problem takes on increasing urgency as medicolegal issues

proliferate, as other specialists begin to move into areas once generally considered to be the domain of surgeons (e.g., radiologists performing breast biopsies), and as new technical developments promise to revolutionize surgical care. In an effort to address this problem as it bears on lymphatic mapping, the ACS, in association with the Moffitt Cancer Center, initiated a program designed to investigate how best to train teams (comprising surgeons, nuclear medicine physicians, radiologists, and pathologists) in the new technology. This formal training course is a 2-day session composed of didactic lectures, live surgery (including extensive surgeon-audience interaction during the procedure), and a hands-on laboratory. The program offers mentoring of initial cases as registrants go back to their institutions, maintains national registries on the Internet so that different experiences can be compared, and, finally, facilitates the participation of other university and community physicians in national protocols. Further information may be obtained from the Center for Minimally Invasive Surgical Techniques (888-456-2840; www.slnmapping.org). Participation in programs such as this one provides a certain degree of protection against medicolegal risk as new technology and procedures are introduced.

Another avenue of training that has been available to surgeons is participation in clinical trials such as the NSABP B32 trial. Previous experience with SLN biopsy is not a requirement for participation in this trial, and all participating surgeons are required to undergo a training process to gain experience with the procedure and familiarity with the specifics of the protocol. The techniques used in this trial represented a combination of common methods designed to maximize the efficacy of the procedure. The training phase included distribution of a detailed training manual, the opportunity to view a video of the procedure, and a site visit by a protocol-designated core trainer to explain the specifics of the procedure.

Radiation Exposure Guidelines and Policies

The amount and type of radioactivity injected in the course of lymphatic mapping and SLN biopsy are relatively limited. Typically, from 0.4 to 1.2 mCi of ^{99m}Tc is injected. This agent is a pure gamma emitter with a short half-life (6 hours); thus, the risks of potentially harmful beta radiation are avoided. The total radiation dose used is quite small—only about 5% of that used in common nuclear scanning techniques (e.g., bone scans). It has been estimated that a maximum of 0.45 Gy could be absorbed at the injection site. Of hospital workers, the surgeon is exposed to the highest levels of radiation. A study from Walter Reed Army Medical Center found that the hands of surgeons performing lymphatic mapping and SLN biopsy were exposed to an average of 9.4 ± 3.6 mrem per operation.⁹⁷ Therefore, on the basis of skin dosage recommendations set by the Nuclear Regulatory Commission, a surgeon would have to perform more than 5,000 SLN procedures a year to incur more than the minimal level of risk.

The low risk notwithstanding, proper handling of radioactive specimens is recommended. All such specimens should be handled as little as possible for at least 24 to 48 hours and should be appropriately labeled. Each institution performing these procedures should develop guidelines for handling and processing specimens in accordance with their own institution's radiation safety policies.

7 SURFACE RECONSTRUCTION PROCEDURES

Joseph J. Disa, M.D., F.A.C.S., Eric G. Halvorson, M.D., Himansu R. Shah, M.D.

General Technical Issues in Plastic Surgical Wound Repair

The key to achieving optimal results in wound closure is correct approximation of the wound edges.¹ Because remodeling scars contract downward, it is essential that the edges be maximally everted to prevent the development of a depression at the closure site.² Such eversion can easily be accomplished either with carefully placed simple sutures or with vertical or horizontal mattress sutures. It is also important that closure be performed in layers so as to eliminate dead space. Accurate realignment of wound edges is especially critical with facial injuries. In the case of a defect involving the vermilion border of the lip, it is very helpful to mark the exact position of the lip margin with a marking pen. For a full-thickness laceration of the lip, the mucous membrane should be repaired first with absorbable suture material. The muscle layer should then be repaired with absorbable suture material. Skin closure is performed last. Placement of the initial suture at the vermilion border facilitates accurate alignment; a mismatch of more than 1 mm will be visible from a conversational distance.

Fundamental to any plastic surgical wound repair is good suturing technique. Careful handling of tissues and placement of sutures facilitates optimal wound healing and minimizes scar formation. A curved cutting needle is typically used to repair skin. With the surgeon's forearm fully pronated, the point of the needle is passed through the skin and the dermis at right angles to the skin surface. As the forearm is supinated, the curve of the needle causes the point to penetrate the dermis on the opposite side of the wound. At every step, it is vital to cause as little tissue trauma as possible. Gentle pressure on the skin with a closed Adson forceps or a skin hook will achieve eversion of the wound margins and allow proper suture placement without crushing the skin edge. Excessive pressure on the forceps can lead to ischemia of the wound edge and diminish the quality of wound healing.

Plastic surgical repair of an open wound may involve any of the following types of sutures: (1) simple interrupted sutures, (2) vertical mattress sutures, (3) horizontal mattress sutures, (4) subcuticular continuous sutures, (5) half-buried horizontal mattress sutures, or (6) continuous over-and-over sutures [see Figure 1]. No single suturing technique is ideal for all contexts; clearly, individual surgeons have differing preferences depending on the clinical situation or on personal choice. In general, however, simple, subcuticular, and continuous sutures are preferred because they tend to produce less wound edge ischemia and ultimately result in better scars. Whichever technique is employed, the mechanism of trauma will have some influence on the cosmetic outcome: crush or shear injuries, such as those that occur in falls or motor vehicle accidents, result in less favorable scars than those caused by sharp lacerations, such as glass or knife cuts.

Simple interrupted sutures are useful for closing simple wounds without excess tension. Subcuticular continuous sutures are useful for approximating wound edges without tension after the dermis has been approximated with buried deep dermal sutures.

Continuous over-and-over sutures are used for much the same purposes as simple sutures. They can be placed more quickly than interrupted sutures because knots are needed only at the beginning and the end; however, it is harder to distribute tension evenly over a nonlinear wound with a continuous over-and-over suture. When it is not possible to achieve a tension-free environment in which the dermis is properly apposed with buried sutures, mattress sutures may be preferred. These sutures generally provide better eversion of wound edges in areas where significant tension is present (e.g., on the lower extremities or over bony prominences); however, they tend to induce more wound edge ischemia and thus must be placed carefully. Half-buried mattress sutures are commonly employed for anchoring flaps and skin grafts, particularly at the corners.

The type of suture material used depends on personal preference to some extent; however, for the face, permanent suture material (e.g., 5-0 or 6-0 nylon) is generally preferred. Needle marks can be prevented by removing sutures earlier rather than later [see Table 1].

After a suture is placed, care should be taken to tie the knot properly. The knot should be brought to one side of the wound, and the tension should be adjusted so that the skin edges are apposed without compromising the blood supply. The optimal distance between sutures varies depending on the anatomic site undergoing repair; however, on the face, sutures should be approximately 3 to 4 mm apart and be placed 2 mm from the wound edge. Besides sutures, both staples and adhesive strips are currently used for wound closure. Whereas the former are commonly employed for lacerations of the scalp, where cosmetic outcome is of less importance, the latter are commonly employed when the wound is superficial and the edges can be easily approximated with little tension. Adhesive glues can also be used for superficial wounds; they are especially useful in children and in patients whose wounds are located in areas where a durable protective barrier is desired (e.g., the axilla or the groin).

Skin Grafts

Skin grafts are generally used to cover large open wounds that are not infected [see 3:3 *Open Wound Requiring Reconstruction*]. Healing requires a well-vascularized bed. Use of a skin graft is contraindicated in the presence of any of the following: (1) gross infection, (2) cortical bone denuded of periosteum, (3) a tendon denuded of paratenon, (4) cartilage denuded of perichondrium, and (5) heavily contaminated or irradiated areas (a relative rather than absolute contraindication).

CLASSIFICATION

Skin grafts are divided into two categories on the basis of thickness: (1) split-thickness (or partial-thickness) grafts and (2) full-thickness grafts. A full-thickness graft contains the entire epidermis and dermis, whereas a split-thickness graft contains the epidermis

Figure 1 Shown are types of sutures used in plastic surgical wound repair. (a) Simple interrupted sutures. An equal bite of tissue is taken on each side of the wound; to ensure eversion of skin edges, a significant amount of deeper tissue is incorporated. (b) Vertical mattress sutures. Bites are taken either (1) first close to the wound and then distant from it or (2) vice versa. Bites on either side of the wound must be equally spaced from the skin edges. (c) Horizontal mattress sutures. As with vertical mattress sutures, all bites are equally spaced from the skin edges. (d) Subcuticular continuous suture. All bites, except for entrance and exit bites, are within the dermis at the same level; the suture should enter and exit the dermis at right angles. (e) Half-buried horizontal mattress sutures. These are similar to standard horizontal mattress sutures except that tissue opposite the side where the stitch enters the skin is grasped in the subcuticular level; thus, the needle passes into and out of the epidermis at only two locations. (f) Continuous over-and-over suture. This resembles a simple suture except that it is continuously passed through the wound until the desired terminus is reached.

but only part of the dermis [see Figure 2]. Split-thickness grafts are further subdivided into thin and thick split-thickness grafts.

Full-thickness skin grafts can be harvested from anywhere on the body, but they are most frequently taken from the upper eyelid, the buttocks, the arms, the groin, and the postauricular and supraclavicular areas. Because of their higher elastin content, such grafts are associated with more primary contraction than split-thickness grafts are; however, they are less often associated with secondary contraction. Full-thickness skin grafts are less likely to become hyperpigmented than split-thickness skin grafts are. Because primary closure of the donor site is required, the size of a full-thickness graft is limited by the dimensions of the site from which it comes.

Split-thickness skin grafts can be harvested from any of a number of broad, flat areas of the body, including the thigh, the buttocks, the back, the abdomen, the chest, and the posterior neck. In general, split-thickness grafts are more readily available than full-thickness grafts; in addition, they have better survival rates because plasmic imbibition (the process by which a skin graft is nourished by the underlying tissue) is more effective with thinner grafts. The main disadvantages of split-thickness grafts vis-à-vis full-thickness grafts are the increased secondary contraction and the higher incidence of hyperpigmentation.

OPERATIVE TECHNIQUE

Full-Thickness Grafts

The recipient site is adequately debrided, and the defect is measured. An outline of the defect is made on the graft site. If the graft is circular, it may have to be converted to an ellipse for smooth clo-

Table 1 Optimal Timing of Suture Removal after Wound Closure

Closure Site	Optimal Suture Removal Time (days after closure)

sure [see Figure 3a]. An incision is made around the outline with a No. 10 or 15 blade. The edges of the graft are elevated with skin hooks. Meticulous dissection is performed in such a way that as little subcutaneous tissue as possible is included with the graft [see Figure 3b]. Once the graft is harvested, any subcutaneous tissue is sharply removed (a step known as defatting the graft). The graft is then wrapped in a saline-soaked sponge until ready for use.

The graft is properly positioned and secured with absorbable sutures [see Figure 3c]. A tie-over bolster dressing is applied—typ-

ically, Xeroform (Kendall Healthcare, Mansfield, Massachusetts) wrapped around cotton soaked with mineral oil or saline [see Figure 3d]. The donor site is then closed, either in two layers (for thicker donor sites, such as the groin) or in a single layer (for thinner donor sites, such as the eyelid).

Split-Thickness Grafts

A split-thickness graft may be harvested with a Humby knife, a Weck blade, or a power-driven dermatome. Currently, a power-driven dermatome is the most popular choice.

Harvesting and placement of a split-thickness skin graft is a relatively simple technique; however, attention to detail is necessary to optimize graft take. The key to how well a skin graft takes is the quality of the recipient bed; the relevant contraindications should be kept in mind (see above).

The recipient wound is debrided until a uniform bleeding surface is encountered. Extra care should be taken to debride areas of nonviable tissue because the graft will not take in such areas. Meticulous hemostasis is crucial because hematoma is the most common cause of graft loss. The defect is then measured [see Figure 4a], and the donor site is marked to indicate an appropriately sized graft. If the donor site is hairy, it is shaved before the graft is harvested. Any preparation solution remaining on the donor site is cleaned off, and mineral oil (or, as some surgeons prefer, water) is applied to lubricate the skin.

Next, the dermatome is prepared by inserting the blade and securing it by tightening the screws [see Figure 4b]. The graft thickness is determined by the calibration gauge, which, for most split-thickness grafts, is typically set at 14 (a setting equivalent to 0.014 in., or approximately 0.356 mm). As another method of setting the desired thickness, the edge of most No. 15 scalpels should just fit into the space created between the dermatome device and the

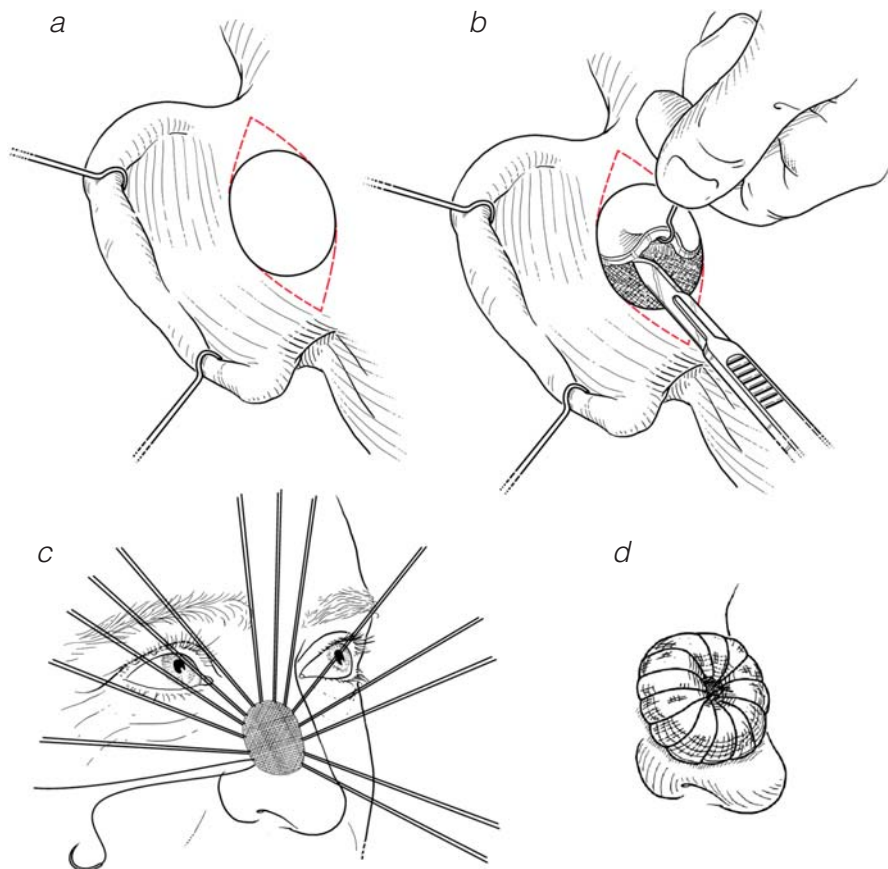

Figure 3 Skin grafts: full thickness. (a) A retroauricular full-thickness skin graft is outlined; conversion to an elliptical shape may facilitate closure. (b) The graft is elevated with skin hooks, with care taken to include as little subcutaneous tissue as possible. (c) The graft is sutured in place. (d) A tie-over bolster dressing is applied to maintain pressure on the graft and ensure good contact between it and the recipient bed.

Figure 4 Skin grafts: split thickness. (a) Shown is a cheek defect after excision of a melanoma in situ. (b) A dermatome is used to harvest the graft. It is set to obtain a specific thickness of skin; 0.014 in. (0.356 mm) is a common setting. (c) The graft is harvested by applying steady pressure to the skin with the dermatome while advancing it forward. The assistant retracts the skin to optimize contact between blade and skin. (d) The skin is gently removed from the dermatome. If necessary, it can be meshed to increase its size.

blade. The skin surface is smoothed with gentle but steady traction to facilitate the harvest. Using an assistant to apply traction on the skin in all directions is very helpful [see Figure 4c]. The dermatome is turned on and placed so that it engages the skin at a slight angle [see Figure 4d]. It is then slowly advanced until an adequate amount of skin is harvested. Once harvested, the graft can be applied to the recipient area either with or without meshing.

Meshing a skin graft can be advantageous, first, because it allows a smaller graft to cover a larger area, and second, because it provides interstices through which fluid can drain in exudative environments. Meshed grafts generally take longer to heal than nonmeshed grafts do because the interstices must contract and fill with scar tissue; in addition, meshed grafts often heal with a cobblestone appearance. There are two basic types of graft meshers, those that contain grooved meshing boards and those that do not. Expansion ratios range from 1.5:1 to 3:1. The desired ratio is selected by choosing either the appropriate meshing board or the appropriate cutting blade, depending on the type of mesher used. In most circumstances, an expansion ratio of 1.5:1, which increases surface area by 50%, is sufficient. On rare occasions, an expansion ratio of 3:1 is needed, depending on the availability of donor sites in relation to the requirements of the recipient area. The graft

to be meshed is placed with the dermis side up on the grooved side of the meshing board. The meshing board is rolled through the mesher, and the meshed graft is ready for final placement over the recipient site.

The skin graft is secured to the recipient bed either with absorbable suture material or with staples [see Figure 5a]. A bolster dressing, made of Xeroform and of cotton soaked in saline or mineral oil, is applied over the graft. The bolster is fixed in place either by tying sutures over it (for broad, flat areas such as the trunk or the face) [see Figure 5b] or by wrapping gauze or an elastic bandage (or both) around it (for curved areas such as the extremities). Alternatively, a vacuum-assisted closure device (e.g., VAC; Abdominal Dressing System; Kinetic Concepts, Inc., San Antonio, Texas) can be placed over a graft covered with Xeroform or a similar non-stick gauze.³ Such a device is particularly helpful when the wound bed has an irregular surface, which can result in tenting of the graft and consequent graft loss. Although some clinical studies have found vacuum-assisted closure to be superior to conventional bolsters, this method does have disadvantages, including higher cost, greater complexity, and immobility resulting from attachment to the device. With a graft on an extremity, splinting may be necessary for immobilization. The donor site is then dressed with an

Figure 5 Skin grafts: split thickness. (a) The skin graft is sutured in place. Care is taken to trim all excess skin and to ensure that the graft is in complete contact with the bed. (b) A tie-over bolster dressing is applied. (c) The donor site is dressed. In this case, calcium sodium alginate is applied to the bed, followed by a bio-occlusive dressing. The dressing is left intact until reepithelialization occurs (typically, 7 to 10 days).

occlusive dressing (e.g., OpSite; Smith & Nephew, Hull, United Kingdom) or a semioclusive dressing (e.g., Xeroform) until reepithelialization occurs [see Figure 5c].

POSTOPERATIVE CARE

The postoperative fate of a skin graft is largely determined by the circumstances of the wound (especially the presence or absence of infection) and the technical execution of the grafting procedure.⁴ Successful healing of skin grafts requires immobilization of the recipient site for 5 to 7 days. Immobilization can be accomplished with tie-over bolsters; on extremities, skin grafts can be further immobilized with plaster casts. Proper immobilization is critical for graft survival because it prevents shearing in the plane between the graft and the wound bed. After 5 to 7 days of immobilization, the graft is inspected, and either a gauze dressing (e.g., Xeroform) or a lubricating antibiotic ointment is applied for another 5 to 7 days. Because grafted skin lacks oil glands, a non-irritating moisturizer should then be applied to the graft for several months thereafter, until the graft is capable of maintaining a more normal level of skin moisture without the moisturizer.

Grafts that are treated by closed methods (i.e., tie-over bolsters) are carefully observed for evidence of infection. Developing erythema or suppuration is an indication for immediate removal of the bolster dressing and inspection of the graft. On infrequent occasions, a graft may be threatened by infection; in such cases, the graft may be saved by switching to an open method of graft care with wet dressings changed three or four times a day.

Nonmeshed grafts may form a hematoma or seroma that will prevent the graft from taking. Accumulated fluid should be evacuated by puncturing the graft or by rolling cotton-tipped swabs over it until the fluid escapes from under its edges. Survival of the entire graft is possible if fluid is meticulously evacuated within the first few days after graft placement; plasmic imbibition will keep the graft viable over this period.

Meshed grafts are not subject to the problem of fluid accumulation, nor are they as vulnerable as nonmeshed grafts to the shear forces that can prevent graft survival. For meshed grafts, the postoperative goal is to prevent desiccation, because they are more exposed to the environment. After the initial dressing change, gauze dressings (e.g., Xeroform) should be placed over the graft and changed once a day. After 2 weeks, the dressings can be discontinued, but the graft should be kept well lubricated with either a skin cream or cocoa butter.

Meshed grafts that are placed over wounds at high risk for infection may be managed postoperatively with wet dressings changed three times a day. The dressing changes will not interfere with graft take and will maximize graft survival in the face of heavy bacterial contamination.

Extremities that are recipient sites for skin grafts should always be maintained above heart level for a minimum of 1 week postoperatively. Lower extremities with skin grafts should remain elevated for a minimum of 10 days to 2 weeks, particularly when the graft is below the knee. Patients should also be mobilized in a progressive manner, beginning with brief periods of limb dangling. Premature ambulation of patients with lower-extremity skin grafts can result in loss of the skin graft despite an early appearance of complete graft take.

Donor sites of split-thickness grafts heal by epithelialization. They are best managed by coverage with a gas-permeable polyurethane film dressing (e.g., OpSite). This dressing retains moisture underneath, which favors rapid reepithelialization. It is also impermeable to bacteria. The addition of calcium sodium alginate under

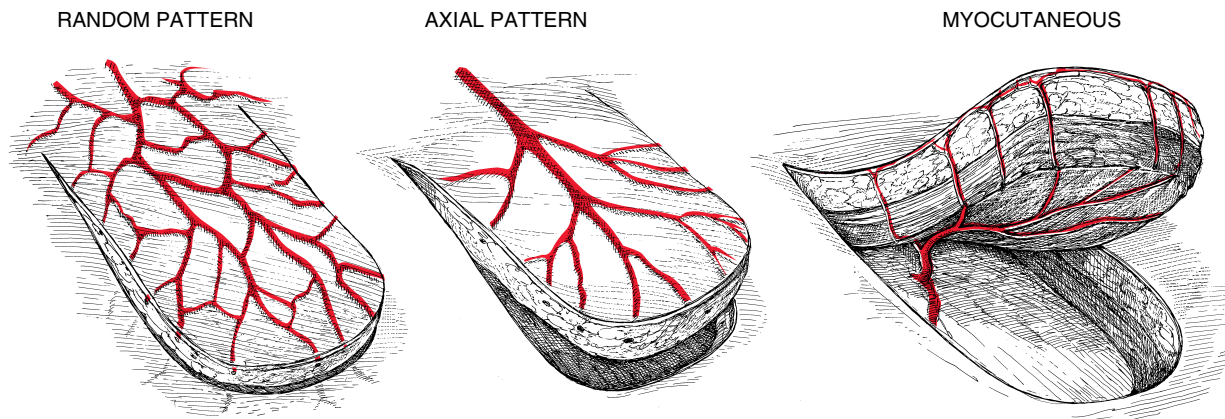

Figure 6 Local flaps. A random-pattern skin flap (left) is supplied by a subdermal plexus of small vessels that do not have an axial orientation. An axial-pattern skin flap (center) is designed parallel to the axis of a known major subcutaneous artery. It can have a greater length:width ratio because its blood supply is more reliable. A myocutaneous flap (right) derives the blood supply of its skin component from vertical perforators from the underlying muscle. The skin can be completely isolated over the muscle as an island.

the OpSite facilitates the absorption of the fluid that tends to collect there, thus further simplifying donor site management.⁵

Local Flaps

CLASSIFICATION

Flaps are classified according to the types of tissue that they contain, their blood supply [see Figure 6], and the method by which they are moved from the donor to the recipient site.

Tissue Contents

Flaps commonly consist of skin and subcutaneous tissue alone. However, they may also consist of skin combined with muscle, fascia, or bone; in these cases, the flaps are called myocutaneous, fasciocutaneous, or osteocutaneous, respectively. If a flap composed of skin and subcutaneous tissue that contains a known major artery (an axial-pattern, or arterialized, skin flap [see Blood Supply, below]) is raised at the donor site and remains attached only by the vascular pedicle, it is termed an island flap. The same flap is termed a free flap if the vascular pedicle is severed, the flap is transferred to a distant recipient site, and its circulation is restored by microvascular anastomoses.

Blood Supply

The earliest flaps in common use were skin flaps that had what is known as a random-pattern type of circulation [see Figure 7a], in which blood is supplied by the subdermal capillary plexus rather than by a named vessel.⁶ The precarious nature of the blood supply of such flaps severely limited flap design and resulted in a preoccupation with suitable length:width ratios. Greater length:width ratios became possible after the empirical discovery that a more vigorous circulation develops in flaps raised in stages (the delay phenomenon).⁷

The next flaps to come into common use had an axial-pattern type of circulation, in which a sizable artery coursed directly to a specific cutaneous territory [see Figure 7b]. The groin was the first region where this arrangement was carefully described, and it remains a useful source of flaps for selected applications. Because longer flaps can be made in areas where the blood supply has an axial pattern, the length:width ratio and the delay phenomenon became less important issues.⁸ Identification of an axial-pattern

blood supply to a given graft allows so-called islanding of the graft from the donor site except for the vascular connection, which is preserved. Such island flaps have greater mobility than flaps with a less attenuated attachment to the donor site.

A third type of flap was based on the myocutaneous blood supply, a network of vessels that perforate muscles vertically and supply the overlying skin [see Figures 7c, d]. These vessels are not necessarily the exclusive supply to the skin in a specific region, but they are able to support the skin entirely when other sources of blood supply are eliminated. Investigation of the body musculature showed that there were at least five basic patterns of blood supply to muscle, distinguished by the existence of and balance between primary pedicles and secondary sources of blood supply [see Figure 8]. Some muscles can be rotated or transposed as myocutaneous flaps on the basis of either their dominant or their secondary blood supply (e.g., the pectoralis major and the latissimus dorsi). Some muscles have two dominant supplies and can be transposed on either one (e.g., the rectus abdominis). Other muscles do not reliably support skin territories supplied by minor pedicles (e.g., the gracilis).

Other patterns of cutaneous blood supply are now well recognized. Fasciocutaneous flaps with high length:width ratios can be reliably raised on the trunk, arms, and legs. The blood supply of deep fascia appears to consist of both a deep and a superficial fascial plexus. These vessels connect both to perforating vessels from the underlying muscles and to the subcutaneous tissue vessels above them.⁹ At least three types of fasciocutaneous flaps may be distinguished on the basis of the fascial blood supply to the skin [see Figure 9].¹⁰

In some areas, fascia supplies overlying subcutaneous tissue and skin more directly. Such a blood supply is most evident in the extremities, where direct branches from major vessels course through intermuscular septa to reach the deep fascia and supply the overlying skin and subcutaneous tissue. The forearm is a clinically important donor site because thin septocutaneous flaps fed by the radial artery can be raised as either pedicled or free flaps. Other examples of fasciocutaneous flaps include the lateral arm septocutaneous flap, fed by the profunda brachii artery; the scapular flap, fed by the circumflex scapular artery [see Figure 7d]; the fibular osteofasciocutaneous flap, fed by the peroneal artery; and the anterolateral thigh flap, fed by the descending branch of the lateral circumflex femoral artery.

Method of Movement to Recipient Site

Local flaps may be called either rotation, advancement, or transposition flaps, depending on how they are moved to reach their recipient sites.

A more complete characterization of flaps is achieved by combining all of the descriptive categories mentioned. For example, a muscle and skin flap that is rotated to cover an adjacent soft tissue defect is termed a myocutaneous rotation flap, and a skin and bone flap used to reconstruct a distant composite defect is termed an osteocutaneous free flap.

OPERATIVE TECHNIQUE

In all forms of plastic surgery, it is essential to cause as little tissue trauma as possible when raising a flap. Using skin hooks rather than forceps is helpful in this regard. The flap is marked and incised, and elevation is begun, first with a scalpel and then, at the base of the flap, with a blunt scissors to prevent injury to the blood supply. The electrocautery should be used judiciously in the elevation of skin flaps: although cauterization causes less bleeding, skin flaps often rely on the subdermal plexus for perfusion, and this plexus can be damaged by electrocautery dissection. Close attention to atraumatic technique throughout the procedure will result

in less edema in the flap and, therefore, less circulatory compromise. Hemostasis is essential; in small flap procedures, bipolar coagulation controls bleeding with minimal damage to the flap's blood supply. Two-layer closure is recommended, with absorbable suture material in the deeper layer to decrease the tension and fine nylon for skin closure.

The recommendations just mentioned apply to local flap procedures in general. In what follows, we describe several different types of local flaps that are useful for the purposes of the general surgeon, and we summarize key technical points specific to each.

Transposition Flaps

A flap that is moved laterally into the primary defect is called a transposition flap. The essential concept in the design of such a flap is to ensure that the flap is long enough to cover the entire defect, so that the transfer can be done without tension [see Figure 10].

The skin is marked and incised with a scalpel, and dissection is carried through the subcutaneous fat. The flap is retracted with a skin hook, and dissection is performed with a blunt scissors until the flap is elevated sufficiently to allow it to be transposed into the defect without tension. The secondary defect is closed primarily; alternatively, depending on the location of the donor area and the

Figure 7 Local flaps. (a) The blood supply of random-pattern skin flaps is limited; only small flaps (e.g., thenar flaps, shown here), are consistently reliable. (b) Shown is an axial-pattern skin flap. (c) The skin and subcutaneous tissue of a myocutaneous flap can exist as a complete island because the blood supply is derived from vertical muscular perforators. (d) Shown are a large free flap of scapular area skin and the entire latissimus dorsi. The subscapular vessels that connect the two will supply both components of the flap after microvascular anastomoses.

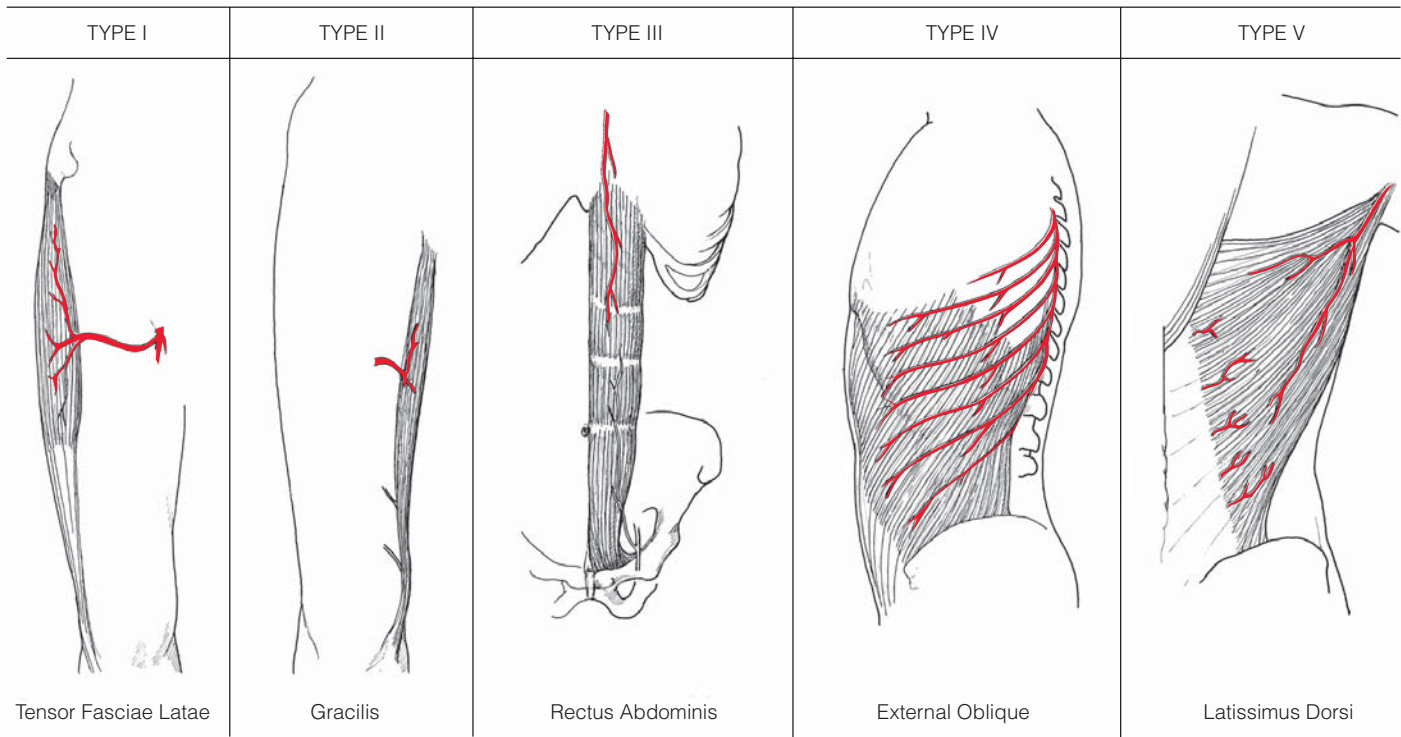

Figure 8 Local flaps. Schematized are the five basic patterns of blood supply to muscle. Individual muscles are classified on the basis of the dominance, number, and size of the vessels that supply them. Type I is supplied by a single dominant pedicle. Type II is supplied by one dominant vessel and several much smaller vessels. Type III is supplied by two dominant pedicles. Type IV is supplied by multiple vessels of similar size. Type V is supplied by one dominant pedicle and several smaller segmental vascular pedicles.

degree of skin tension present there, a skin graft may be indicated. As with any local flap, wide undermining of the surrounding tissues may be necessary for closure of the defect and the donor site. Closure is then performed in two layers.

Bilobed flap A bilobed flap is a transposition flap consisting of two lobes of skin and subcutaneous tissue based on a common

pedicle [see *Figure 11*]. It is often used to correct nasal defects involving the lateral aspect, the ala, or the tip. The keys to a successful bilobed flap are (1) accurate design and (2) wide undermining of the surrounding tissue in the submuscular plane to allow a smooth transposition. The primary lobe is usually at an angle of 45° or less to the defect; the secondary lobe is designed to achieve closure of the donor defect and is substantially smaller

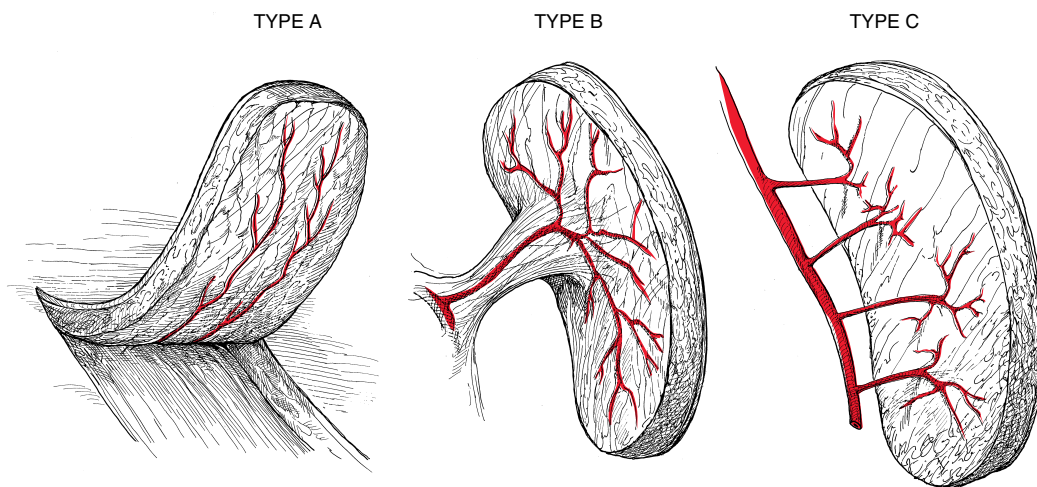

Figure 9 Local flaps. At least three types of fasciocutaneous flaps exist, categorized by blood supply configuration. Type A is supplied by multiple small, longitudinal vessels coursing with the deep fascia. These flaps must retain a base of a certain width and cannot be raised as islands (e.g., longitudinally oriented flaps of skin and fascia on the lower leg). Type B is supplied by a single major vessel within the fascia (e.g., scapular flap). Type C is supplied by multiple perforating segments from a major vessel coursing through intermuscular septa (e.g., forearm flaps).

Figure 10 Local flaps: transposition flap. After excision of the defect, a transposition flap of adequate length is designed and elevated in the subcutaneous plane. The flap is moved laterally into the defect and inset. It may be necessary to excise a dog-ear of excess skin at the tip of the flap harvest site.

than the primary lobe. The angle between the two is 90° to 100° . Both flaps are raised simultaneously in the submuscular plane. Wide undermining of the area (also in the submuscular plane) minimizes tension. The primary lobe of the bilobed flap is transposed into the initial defect, the secondary lobe is transposed into the donor defect left by the primary lobe, and the defect left by the secondary lobe is closed primarily. Closure is accomplished with 5-0 or 6-0 nylon.

Rhomboid flap (Limberg flap) A rhomboid flap is a transposition flap that is designed in a specific geometric fashion [see Figure 12]. The initial defect is converted to a rhomboid, with care taken to plan the flap in an area with minimal skin tension. The rhomboid must be an equilateral parallelogram with angles of 60° and 120° ; this design allows the surgeon to excise less tissue than would be needed for an elliptical flap. One face of the rhomboid constitutes the first side of the flap (YZ). The short diagonal of the rhomboid is then extended outward for a distance equal to its own length. This extension should be oriented along relaxed skin tension lines, perpendicular to the line of maximum extensibility; it constitutes the second side of the flap (XY). Next, a line parallel and equal in length to YZ is drawn from X to outline the third side of the flap. Correct orientation of the rhomboid is vital for achieving flap repair with minimal tension, particularly with respect to the line of maximum extensibility: it is along this base line that maximum tension results when the donor defect is closed. Once the flap has been correctly designed and

elevated, it is transposed into the defect. Closure is done in two layers.

Rhomboid flaps work best on flat surfaces (e.g., the upper cheek, the temporal region, and the trunk). Extra attention to flap design is necessary when an attempt is made to close a defect over a convex surface with a rhomboid flap; improper flap design leads to excessive tension and potential flap necrosis.

Rotation Flaps

A flap that is rotated into the defect is called a rotation flap.^{11,12} This type of flap is commonly used to repair a defect on the scalp, where large flaps must be designed to overcome the inelasticity of scalp tissue. A rotation flap takes the form of a semicircle of which the defect occupies a wedge-shaped segment [see Figure 13]. The original defect is converted to a triangular shape (ABC). One side of the triangular defect (AC) is extended to a point (D) that will serve as the pivot point for the flap. The distance between A and D should be at least 50% greater than that between A and C. A semicircular line extending from C to D is then defined.

The flap is incised with a scalpel, elevated, and rotated. As with all local skin flaps, wide undermining of the surrounding tissue may be necessary to allow tension-free rotation and wound closure. The flap is secured with a two-layer closure; the secondary defect may be closed primarily. Sometimes, a so-called back cut is required to gain adequate rotation. The most common technical error with rotation flaps is improper design: a flap that is too small will not cover the defect adequately.

Figure 11 Local flaps: bilobed flap. A flap with two lobes is created, with the first lobe the same size as the defect and the second lobe substantially (~50%) smaller than the first. The flap is elevated in the submuscular plane. Wide undermining at this level is necessary for tension-free transposition. The first lobe covers the initial defect, and the second covers the defect from the first. The second lobe is placed in an area of loose skin, and its area of origin is closed primarily.

Figure 12 Local flaps: rhomboid (Limberg) flap. (a) The defect is converted to a rhomboid, with all four sides of equal length and angles of 60° and 120°. An extension XY is made that is the same length as the short diagonal of the rhomboid, and a line of equal length is drawn from X paralleling YZ. (b) The flap is oriented so that XY follows the relaxed skin tension lines (RSTL) and YZ the line of maximum extensibility (LME). (c) The flap is inset.

Advancement Flaps

Advancement flaps are moved directly forward into a defect without either rotation or lateral movement. The single-pedicle advancement flap is a rectangular or square flap of skin and subcutaneous tissue that is stretched forward. The flap is oriented with respect to the local skin tension, with care taken to plan the advancement in an area where the skin is extensible. A rectangular defect is created, and the flap is elevated in an area of loose skin and advanced to cover the defect [see Figure 14]. When closure is

performed, some excess skin (dog-ears) at the base of the flap (Burow's triangles) may have to be excised.

V-Y advancement flap The V-Y advancement flap is a modification of a basic advancement flap [see Figure 15]. The use of a V-Y advancement flap eliminates the need to revise the dog-ears that sometimes result with rotation flaps. When possible, the flap should be oriented in accordance with the line of maximum extensibility. Its length should be 1.5 to 2 times that of the defect in the direction of the closure.

Incisions are made completely through skin. As with other flaps, skin hooks are used to retract the skin flap, and blunt scissors dissection is then performed. The point of the V on the flap is the area where tightness is most frequently encountered; this area may have to be released to facilitate advancement. Care must be taken not to undermine the advancing flap excessively; doing so may impair or interrupt the blood supply to the flap and result in necrosis. Once adequately advanced, the flap is sutured at the advancing edge and at the base of the Y.

Z-Plasty

When reconstruction is indicated for small, localized scars, soft tissue coverage is generally sufficient. With such coverage, there is no threat of breakdown leading to exposure of important structures; instead, the reconstructive problem is generally functional. An example is a flexion crease contracture, which is commonly seen after a burn injury. A local procedure that rearranges the existing tissue can relieve the tension by making more tissue available in one direction, even though the amount of tissue in the area is not actually increased.

The Z-plasty [see Figure 16] is an example of such tissue rearrangement.¹³ Two triangular flaps are designed so that they have in common a central limb aligned in the direction along which additional length is desired. For example, the limb may be placed along the line of a contracture. Two lines, approximately equal in length to the central limb, are drawn from either end of the limb, diverging from it at equal angles varying from 30° to 90°. The degree of lengthening obtained is determined by the size of this angle [see Table 2]. In theory, maximal length gain is achieved by using the largest angle possible, but in practice, the maximum usable angle is determined by the limits of skin elasticity. A 60° angle, which is commonly used, will result in a 75% gain in length along the central limb. Triangular flaps are elevated, and the fibrous tissue band responsible for the contracture is divided. The triangular flaps are transposed and inset, yielding increased length in the desired direction, with the original Z rotated 90° and reversed.

Although Z-plasty is conceptually simple, it is not necessarily easy: experience is necessary for the surgeon to realize the limita-

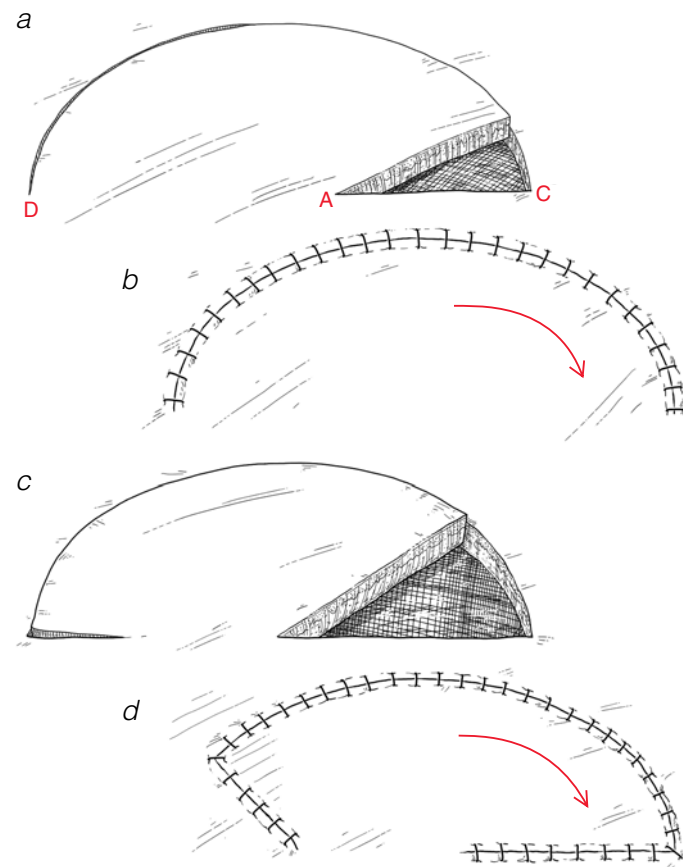

Figure 13 Local flaps: rotation flap. (a) The defect is converted into a wedge. One side (AC) is extended to a pivot point D, so that AD is at least 50% longer than AC. A semicircle from C to D is defined. (b) The flap is elevated, rotated, and inset. (c, d) If there is too much tension, a back cut may be necessary to release the flap and allow rotation. Care is taken not to make the back cut excessively long; to do so could devascularize the flap.

tions of technique and appreciate the subtleties of proper design. Important considerations in the use of Z-plasty include appropriate determination of the length of the central limb and correct orientation of the limbs so that the new central limb formed after transposition is parallel to skin tension lines. Multiple Z-plasties may be useful for some localized scars.

POSTOPERATIVE CARE

Local Flaps

The postoperative care of local flaps is not complex. Flap healing is supported by adequate nutrition and maintenance of a normal hemodynamic state, including normal blood volume. Tension must not be placed on the flap. Tension can develop in flaps on the trunk as a result of changes in patient position or in flaps on the limbs as a result of loss of immobilization. Generally, the tip of any local flap is not only its most valuable portion but also its most vulnerable area. At the tip, the blood supply is the most precarious, and the detrimental effects of tension are magnified. Unfortunately, no pharmacologic agents are of proven benefit in preventing necrosis of a flap with failing circulation. Any flap necrosis that might develop should be minimized by preventing infection of the necrotic tissue. Necrotic tissue must therefore be debrided after the extent of tissue loss becomes clear. Portions of the flap that are undergoing demarcation but do not appear actively infected can be protected by the application of a topical antibiotic (e.g., silver sulfadiazine cream).

Extremities that are recipient sites for flaps, like those that are recipient sites for skin grafts, should be immobilized and elevated after the operation until satisfactory wound healing has occurred.

Free Flaps

Survival of free flaps, unlike that of local flaps, tends to be an all-or-none phenomenon. Careful postoperative monitoring of flap circulation is essential because flap failure is likely to be the result of a problem at the vascular anastomoses. Flaps are usually monitored for 7 days. However, the most critical time for free-flap monitoring is the first 6 to 8 hours because the majority of vascular crises usually occur within this period. Early detection and aggressive investigation of such crises generally allow a flap to be salvaged. Maintenance of normal blood volume, treatment of hypothermia, and avoidance of pressors are particularly important in the early

Figure 14 Local flaps: direct advancement flap. (a) A flap whose shape corresponds to that of the defect is elevated in the subcutaneous plane and advanced into the defect. (b) Excision of Burow's triangles (excess skin at the flap base) may be necessary to permit advancement.

Figure 15 Local flaps: V-Y advancement flap. (a) A V-shaped flap is created whose length is 1.5 to 2 times that of the defect. With subcutaneous connections to the skin preserved (because these constitute the blood supply to the flap), the flap is advanced into the defect. (b) The V incision is converted to a Y as the base is closed primarily.

Figure 16 Local flaps: Z-plasty. (a) The central limb of the Z is placed along the line of contracture. Incisions diverging from the scar at a 60° angle will yield an increase of approximately 75% in the direction of the central limb. (b) The flaps are transposed. (c) The length has been increased in the desired direction, and the original Z design has been rotated 90° and reversed.

postoperative period to prevent vascular spasm. Spasm causes flaps to appear pale and to exhibit a significant temperature drop.

Free flaps exhibit venous engorgement when placed in a dependent position up to several weeks postoperatively. Such engorgement is generally not dangerous, though patients with free flaps below the knee should be gradually mobilized in the same fashion as patients with skin grafts in this location. These patients should also keep the lower extremity elevated for at least 10 to 14 days.

Free flaps in the head and neck area require that the patient's head motion be restricted somewhat for the first few days. It is important that electrocardiographic leads and tracheostomy tube ties not compress the external jugular vein if it was used as a recipient vessel for anastomosis. If central lines are used after operation, they should be placed on the contralateral side of the neck.

Free flaps should be monitored on an hourly basis during the early postoperative period. Most free flaps include an exposed skin island, which facilitates evaluation of the flap circulation. The flap is observed for color and for capillary refill—the most important indicators of flap viability. A pale flap generally indicates arterial insufficiency; however, this is not always the case, because certain

Table 2 Z-Plasty: Incision Angle and Degree of Lengthening Theoretically Possible

donor sites, such as the abdomen, are relatively light in color under normal circumstances, which means that a flap from one of these sites may appear pale while still having an adequate arterial supply. Flaps with venous insufficiency are characteristically blue in color and exhibit rapid capillary refill. In such flaps, brisk capillary refill often precedes the blue discoloration, and it is cause for concern when observed. Bleeding from the edges of a flap is common in the presence of venous hypertension.

If a skin island is exposed, Doppler ultrasonography should reveal the presence of a triphasic arterial pulse. The site of this pulse should be marked with a suture or with permanent ink to facilitate monitoring by nursing staff. A trained ear can distinguish between triphasic, biphasic, and monophasic pulses, which (in that order) indicate increasing degrees of arterial compromise from arterial thrombosis or increasing venous hypertension.

Surface temperature probes can be used to monitor free flaps that have a skin island. The advantages of this method are simplicity and reliability. One probe is placed on the flap and another on a nearby area to serve as a control. The flap surface temperature is generally about 1.0° to 2.5° C lower than the control temperature. A progressive widening of this temperature difference is ominous and calls for critical assessment of the flap circulation. The absolute temperature of the flap probe is also significant: a flap temperature higher than 32° C indicates healthy circulation, whereas a temperature between 30° and 32° C indicates marginal circulation and a temperature lower than 30° C often indicates a vascular problem. In a healthy flap, temperature fluctuations may be caused by a dislodged probe, an exogenous heat source (e.g., a

lamp), cooling of one of the probes from an oxygen mist mask, or cleaning of the flap skin with alcohol (which results in a precipitous drop in skin temperature).

To confirm the presence of an anastomotic problem, flap circulation is assessed directly by a full-thickness puncture of the flap skin with a 20-, 22-, or 25-gauge needle. If flap circulation is healthy, a drop of bright-red blood should appear at the puncture site within a few seconds, and another drop should appear each time the previous drop is wiped away by an alcohol swab. The failure of blood to appear or the delayed appearance of a clear, serous ooze instead of blood is an indication of arterial insufficiency. Vigorous, dark bleeding confirms a venous problem. Flaps that are pale as a result of vascular spasm are difficult to assess because their bleeding response to needle puncture is poor despite intact anastomoses. As a rule, clinical judgment of flap viability on the basis of all these methods of flap monitoring will be highly predictive. If, however, some uncertainty exists, surgical exploration should be undertaken because the entire flap may be in jeopardy.

Free flaps without skin islands are more difficult to monitor accurately. Muscle flaps can be followed in much the same way as skin free flaps by inserting needle temperature probes directly into the muscle belly. A healthy muscle free flap is red in color and typically has a serous ooze between the interstices of the overlying meshed skin graft. A flap with an arterial problem quickly becomes dry and dark in appearance. A muscle flap with a venous problem becomes dark and engorged with blood and exhibits bleeding from its surface and perimeter. A muscle free flap can be punctured with a needle to assess the quality of the bleeding if its circulatory status is unclear.

Fascial free flaps covered with skin grafts are more difficult to assess. They tend to transmit body core temperature readily because they are quite thin; therefore, needle temperature probes are generally unreliable. It is often possible in these cases either to observe the arterial pulsations in the flap directly or to monitor them with a conventional Doppler device.

Some free flaps are completely buried beneath the skin. Others, such as intraoral skin free flaps, are equally difficult to monitor postoperatively. Specialized transplants (e.g., jejunal transplants) are particularly vulnerable to short periods of anoxia and are not likely to be salvageable by the time a problem is recognized. Alternative methods of monitoring buried free flaps are being developed and are being used with increasing frequency. One example is the implantable Doppler monitor. This device is placed in direct contact with the artery or vein distal to the anastomosis to obtain a continuous Doppler signal.¹⁴

1 DYSPHAGIA

Ahmad S. Ashrafi, M.D., F.R.C.S.C., and R. Sudhir Sundaresan, M.D., F.A.C.S., F.R.C.S.C.

Dysphagia may be defined as difficulty in transferring a food bolus from the mouth to the stomach. It may be associated with abnormalities in the oral, the pharyngeal, or the esophageal phase of swallowing. Unlike the term globus, which describes a painless sensation of fullness in the neck or throat, the term dysphagia implies actual interference with the swallowing mechanism [see *Sidebar The Swallowing Mechanism*]. Dysphagia may be classified as oropharyngeal or esophageal. Whereas oropharyngeal dysphagia (i.e., dysphagia resulting from abnormalities in the oral or the pharyngeal phase of swallowing) usually implies a functional disturbance in the swallowing mechanism, esophageal dysphagia may result from a discrete mechanical obstruction or from an esophageal motility disorder.

The exact prevalence of dysphagia is difficult to determine, but it is estimated that 35% of persons older than 50 years complain of dysphagia at least once a week. It is important to keep in mind, however, that the changes in swallowing physiology associated with aging rarely lead to true dysphagia. Esophageal dysphagia arises primarily from intrinsic diseases of the esophagus; oropharyngeal dysphagia frequently occurs as part of a neurologic, metabolic, myopathic, or infectious syndrome.¹

In what follows, we review the diagnostic and therapeutic decision-making approaches employed in assessing patients with dysphagia. Although it is important that surgeons have a working knowledge of all causes of dysphagia, our focus here is on evaluation of conditions that give rise to esophageal dysphagia. We mention surgical management options but do not address them in detail; the operative procedures performed to treat the various clinical entities that cause dysphagia are described more fully elsewhere [see 4:4 *Open Esophageal Procedures*, 4:5 *Minimally Invasive Esophageal Procedures*, and 4:7 *Video-Assisted Thoracic Surgery*].

Clinical Evaluation

Evaluation of a patient with dysphagia must be performed in a systematic manner. Assessment begins with obtaining a detailed history, followed by physical examination. Except in the case of acute caustic ingestion, for which direct flexible esophagoscopy is the first line of assessment, the barium swallow, a readily available and noninvasive test, should be the first investigative tool. The barium swallow is a cost-effective, rapid, and easily available test that provides a “road map” of the esophagus and the lesion and yields a tremendous amount of information before endoscopic assessment. Additional diagnostic information can be obtained by means of fiberoptic esophagoscopy, manometry, 24-hour pH study, and, occasionally, bronchoscopy and endoscopic ultrasonography (EUS). Further diagnostic imaging, in the form of computed tomography and positron emission tomography

(PET), is particularly valuable in assessing patients with esophageal cancer.

OROPHARYNGEAL DYSPHAGIA

Oropharyngeal dysphagia is usually associated with symptoms that originate in the oropharynx, including inability to chew food, drooling, coughing during a meal, and nasal regurgitation of solids or liquids. In general, if a patient experiences dysphagia within 1 second of swallowing, an oropharyngeal origin is likely. A variety of different conditions are capable of causing oropharyngeal dysphagia. The common causes can be grouped into three broad categories: (1) generalized (systemic) conditions, (2) intrinsic functional disturbances, and (3) conditions that give rise to fixed mechanical obstruction [see *Table 1*]. Overall, the most common cause of oropharyngeal dysphagia is a cerebrovascular accident (CVA).

ESOPHAGEAL DYSPHAGIA

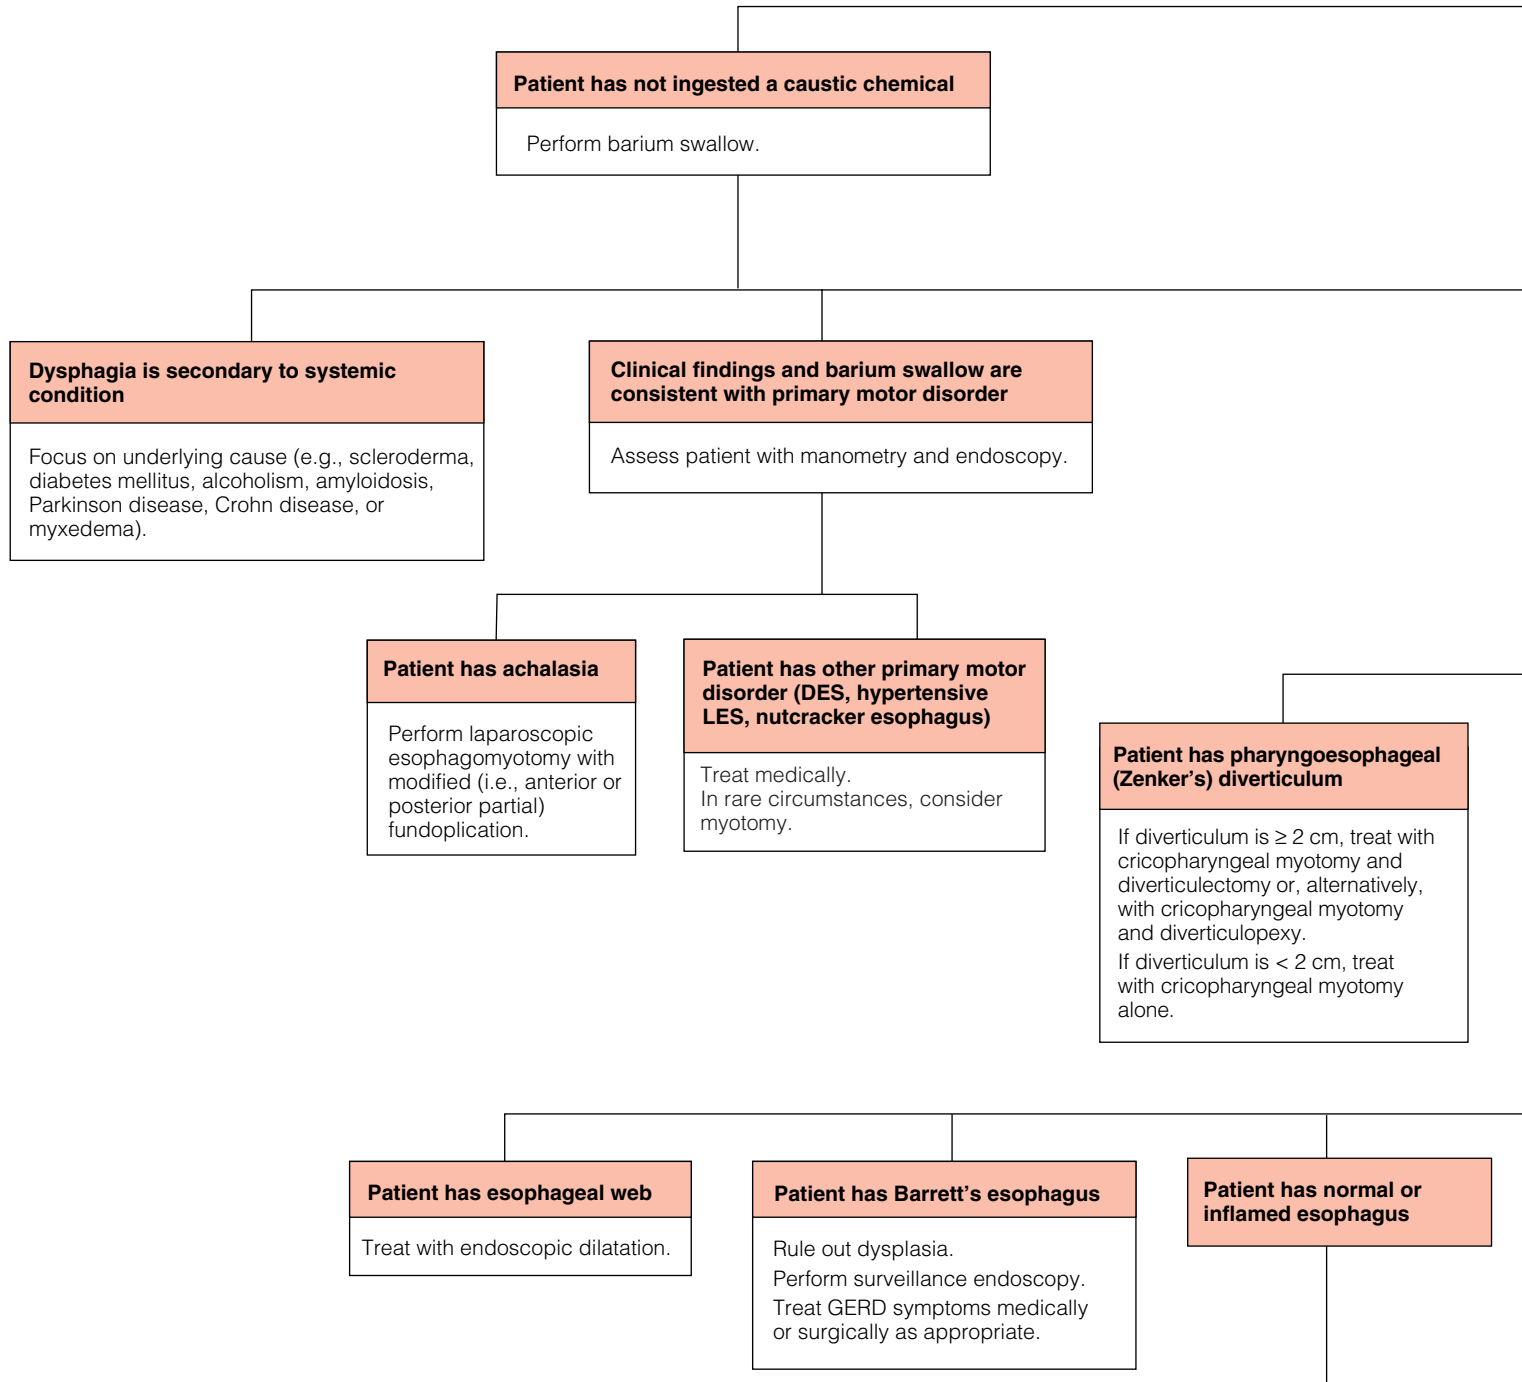

Esophageal dysphagia causes symptoms that are referable to the chest or the abdomen. In approximately 75% of cases, the patient's perception of the location of the obstructive site corresponds to the actual anatomic site of the lesion.² In addition to dysphagia, patients may experience associated symptoms, such as chest pain (with a character and a radiation pattern resembling those of coronary artery disease [CAD]), retrosternal burning, and regurgitation of undigested food.³

As a general rule, if the swallowing difficulty gradually progresses from solids to liquids, the dysphagia probably has a mechanical cause. Patients who have mechanical obstruction usually complain of dysphagia without pain and can relieve their symptoms only by regurgitating or by altering their diet. If significant weight loss and

The Swallowing Mechanism

Swallowing consists of both a voluntary phase (comprising the oral phase and the first part of the pharyngeal phase) and an involuntary phase (comprising the latter part of the pharyngeal phase and the esophageal phase). The voluntary phase starts with mastication and ends with the positioning of an appropriately sized food bolus in the back of the oropharynx via tongue retraction. The involuntary phase starts with the opening of the glossopalatal gate and the propulsion of the bolus into the pharynx, beyond the upper esophageal sphincter. Once in the esophagus, the food bolus is propelled into the stomach by primary and secondary esophageal peristaltic waves. The lower esophageal sphincter relaxes, allowing the food to be delivered into the stomach. The brain-stem swallowing center, located in the medulla and the pons, provides involuntary control of swallowing. Although swallowing begins in the oropharynx and is initially voluntary, the subsequent reflex mechanisms are based on peripheral input from the oropharyngeal innervation and are involuntary.

Evaluation of Dysphagia

Patient presents with difficulty in swallowing

Obtain complete history.
Perform thorough examination.

Patient has ingested a caustic chemical

Perform direct flexible esophagoscopy.
Ensure adequate airway, breathing, and circulation.
Place patient on NPO regimen.
Give I.V. antibiotics.
Initiate total parenteral nutrition.
Perform barium swallow in 2–3 wk.

Barium swallow reveals esophageal diverticular disease

Treat according to anatomic level of diverticulum.

Barium swallow suggests fixed mechanical obstruction

Assess patient with endoscopy.

Follow up for stricture. Steroids are not helpful for stricture prophylaxis. If stricture develops, treat with endoscopic dilatation. If stricture is tight and cannot be dilated, perform esophageal resection.

Patient has midesophageal diverticulum

Lesions result from periesophageal inflammation and are frequently asymptomatic; dysphagia is rare. If there are no significant symptoms, they need not be treated, and therapy focuses on underlying inflammatory condition.

Patient has epiphrenic diverticulum

Assess patient with manometry and endoscopy.
If symptoms are absent or mild, manage conservatively.
If significant symptoms are present, manage surgically with myotomy, diverticulectomy, and partial fundoplication.

Patient has peptic stricture

Treat with endoscopic dilatation, and perform brush biopsy to rule out malignancy.

Patient has Schatzki's ring

If lesion is asymptomatic, no treatment is required.
If lesion is symptomatic, treat with endoscopic dilatation and medical (or, if necessary, surgical) therapy for GERD.

Patient has esophageal cancer

Perform esophagoscopy for pathologic diagnosis.
Rule out distant metastatic disease with CT or PET. EUS may aid in locoregional staging.
Treat surgically according to stage of disease.
If cancer is localized and patient is medically fit, perform esophagectomy.

Give PPIs.
Consider manometry and 24-hr pH study.
Consider antireflux surgery.

Table 1 Common Causes of Oropharyngeal Dysphagia

Generalized conditions	CVA Myasthenia gravis
Intrinsic functional disturbances	Cricopharyngeal achalasia Zenker's diverticulum
Conditions producing fixed mechanical obstruction	Neoplasm Webs Previous surgical treatment Previous radiation therapy

anorexia develop and symptoms are progressing rapidly, esophageal cancer is the likely cause of the dysphagia.

If, however, the patient has dysphagia for both liquids and solids, an underlying esophageal motor disorder is probably responsible. Patients who have motor disorders that cause dysphagia often develop certain unusual maneuvers to relieve their difficulty, including repeated swallowing, raising the arms over the head or assuming different positions during swallowing, and the Valsalva maneuver. Such patients also frequently complain of other associated symptoms (e.g., chest pain).

Physical examination is not as helpful as a detailed history. Clues that may help identify malignant conditions include the development of head and neck lymphadenopathy, the presence of an oropharyngeal mass, the appearance of subcutaneous lumps (suggestive of cutaneous metastasis), and the occurrence of clinical features associated with abdominal organ metastasis (jaundice, ascites, hepatomegaly). Muscle weakness, fatigability, and other neurologic deficits detected on physical examination may suggest a CVA or myasthenia gravis as the cause of dysphagia. Like oropharyngeal dysphagia, esophageal dysphagia may be caused by a number of different generalized conditions, intrinsic functional disturbances, or conditions that give rise to fixed mechanical obstruction [see Table 2].⁴

Workup and Management of Specific Causes of Dysphagia

SECONDARY MOTOR DISORDERS RESULTING FROM SYSTEMIC CONDITIONS

In patients with secondary motility disorders, the esophageal motor disturbance is a manifestation of a systemic condition; thus, organs other than the esophagus are also involved. The classic examples of systemic conditions that give rise to esophageal motility disorders are scleroderma, diabetes mellitus, and alcoholism. Patients who have one or more of these conditions may present with varying degrees of dysphagia, and their evaluation usually entails functional and structural evaluation of the esophagus.

Treatment is aimed at the underlying cause. Patients with scleroderma exhibit atrophy and sclerosis of distal esophageal smooth muscle with fragmentation of connective tissue. Consequently, primary peristalsis is absent, and the lower esophageal sphincter (LES) is hypotensive or virtually absent. Patients usually present with gastroesophageal reflux and heartburn. Because they also lack secondary peristalsis, there is no mechanism for clearing the refluxed acid back to the stomach, and as a result, patients are pre-

disposed to ulcerative esophagitis and peptic stricture [see Disorders Producing Fixed Mechanical Obstruction, Peptic Stricture, below].

Other causes of secondary esophageal motility disturbance resulting in dysphagia are amyloidosis, Parkinson disease, Crohn disease, and myxedema.

INTRINSIC FUNCTIONAL DISTURBANCES

Primary Motor Disorders

Achalasia The majority of patients with achalasia present with dysphagia for liquids

and solids. Most describe a long-standing history of swallowing difficulty, with or without associated weight loss. Other presenting symptoms include regurgitation, chest pain, heartburn, and coughing or choking spells. Typically, patients will have developed coping mechanisms to deal with the problem (e.g., changing position during eating, drinking liquids to “wash down” the food, and practicing repetitive swallowing and chewing).

A barium x-ray with fluoroscopy will show absent peristalsis and a dilated esophagus. Other findings include a tapered narrowing in the distal esophagus (a so-called bird’s beak [see Figure 1]) and, occasionally, an epiphrenic diverticulum [see Esophageal Diverticula, below]. Because the study is dynamic, failure of LES relaxation must be watched for as it is performed. Over time, the esophagus can dilate significantly, to the point where it takes on a sigmoid shape.

Although some radiologists will declare a diagnosis of achalasia solely on the basis of barium x-rays and fluoroscopy, upper GI endoscopy is essential to rule out fixed mechanical obstruction (long-standing achalasia is a risk factor for squamous cell cancer of the esophagus because of chronic stasis and retention esophagitis) or so-called pseudoachalasia (a motility disorder resulting from a carcinoma on the underside of the cardia that extends proximally within the wall of the esophagus). The key diagnostic test in the setting of suspected achalasia is esophageal manometry. Characteristic manometric features of achalasia include aperistalsis and incomplete relaxation of the LES; the LES pressure may be either high or normal.

A detailed discussion of the management of achalasia is beyond the scope of this chapter. Briefly, medical management offers virtually no benefit. Pneumatic dilatation offers subjective improve-

Table 2 Common Causes of Esophageal Dysphagia

Figure 1 Shown are proximal dilatation and classic bird's-beak narrowing consistent with achalasia in a 22-year-old woman being evaluated for dysphagia.

ment in more than two thirds of patients; however, the result is durable in only a minority of cases, and the procedure carries a 4% to 5% risk of rupture. Laparoscopic esophagomyotomy with anterior (Dor) fundoplication (or, as some surgeons prefer, posterior partial fundoplication) [see 4:5 *Minimally Invasive Esophageal Procedures*] probably represents the current standard of care.

Diffuse esophageal spasm

Diffuse esophageal spasm (DES) is a motility disorder of unknown etiology that gives rise to dysphagia and chest pain. The dysphagia is non-progressive and is encountered with both liquids and solids.

The chest pain is nonexertional but may respond to nitroglycerin.

A barium x-ray may show the classic corkscrew appearance [see *Figure 2*], but this finding is nondiagnostic. The diagnosis is established by manometry; the key finding is the periodic occurrence of simultaneous high-amplitude contractions with intervening periods of normal peristalsis. The presence of these intervals of normal peristalsis is important for distinguishing DES from nutcracker esophagus [see *Nutcracker Esophagus, below*]. An elaborate workup is often necessary to clarify the basis of the chest pain and rule out the possibility of CAD.

Once CAD has been ruled out, management is primarily medical and consists of reassurance, nitrates, and calcium channel blockers. Botulinum toxin injection and extended esophagomyotomy have been used to treat DES, with some success, but in general, surgery does not have an established role in this setting.

Hypertensive lower esophageal sphincter Hypertensive LES is a rare motility disorder of unknown etiology. Although it

can occur in isolation, it is usually seen in association with achalasia, nutcracker esophagus, or DES. Patients present with dysphagia for liquids and solids. Manometric evaluation shows a mean LES resting pressure higher than 45 mm Hg in midrespiration. Treatment is primarily medical, but balloon dilatation has been employed to relieve persistent dysphagia.

Nutcracker esophagus Nutcracker esophagus is an esophageal motility disorder of unknown etiology that affects women more often than men. Patients usually present with chest pain but may have associated dysphagia as well. Manometry typically shows peristaltic waves with significantly elevated amplitude (> 180 mm Hg). Barium x-rays are usually normal. Treatment is similar to that of DES and is primarily medical.

Esophageal Diverticula

Esophageal diverticula account for fewer than 5% of all cases of dysphagia. They may be classified into two broad categories: true and false. True diverticula include all layers of the esophageal

wall, whereas false diverticula include only the mucosal layer. True diverticula develop as a result of a periesophageal inflammatory process that places traction on the esophageal wall (and thus are also referred to as traction diverticula), whereas false diverticula are manifestations of an underlying motor dysfunction (and thus are also referred to as pulsion diverticula). Esophageal diverticula may also be classified into three categories on the basis of the anatomic level at which they occur: pharyngoesophageal (Zenker's), midesophageal, and epiphrenic. A few patients will exhibit

Figure 2 Shown is classic corkscrew appearance of esophagus in a middle-aged man presenting with dysphagia and intermittent chest pain.

Figure 3 Shown is a large pharyngoesophageal pouch (Zenker's diverticulum) in an elderly patient with dysphagia, regurgitation of old retained food, and recurrent pneumonia.

diffuse intramural diverticulosis, a rare condition characterized by the development of multiple 1 to 5 mm outpouchings in association with esophageal inflammation and fibrosis. These outpouchings are believed to be dilated esophageal mucous glands resulting from chronic inflammation. Dysphagia is the most common presenting complaint for this condition, though one third of patients complain of gastroesophageal reflux.

Pharyngoesophageal diverticula Zenker's diverticula are the most common esophageal diverticula. These pulsion diverticula result from pharyngocricopharyngeal incoordination that leads to herniation of the mucosa in Killian's triangle (the posterior midline of the lower pharynx, between the oblique muscle fibers of the inferior pharyngeal constrictor and the transverse fibers of the cricopharyngeus). Dysphagia is the most common symptom, but patients may also complain of halitosis, regurgitation of undigested food, throat discomfort, a palpable neck mass, a gurgling noise during swallowing, and recurrent aspiration pneumonia.

The best initial diagnostic tool is a barium swallow [see Figure 3], which will establish the diagnosis and also may help diagnose any associated problems (e.g., gastroesophageal reflux disease [GERD] and hiatal hernia). Performing upper GI endoscopy without first obtaining a barium study is a potentially disastrous maneuver: because the endoscope will preferentially enter the pouch rather than the true esophageal lumen, there is a significant risk of inadvertent esophageal perforation. Endoscopy does play a role in assessing the esophageal mucosa, but it is best performed at the time of operation.

The fundamental component of surgical treatment is relief of the functional obstruction at the cricopharyngeus (via cricopharyngeal myotomy) [see 4:4 *Open Esophageal Procedures*]. Once this is done, diverticula larger than 2 cm should be excised; smaller diverticula can generally be managed with myotomy alone. Diverticulopexy is another option for dealing with the pouch.

Midesophageal diverticula Midesophageal diverticula are true (i.e., traction) diverticula that are caused by periesophageal inflammation. The usual cause is granulomatous inflammation of the subcarinal lymph nodes

resulting from tuberculosis or fungal infection (typically, histoplasmosis). These diverticula are frequently asymptomatic and are often found incidentally during evaluation for some other disorder. Dysphagia does occur but is a rare symptom; the clinical manifestations are usually related to the underlying inflammatory disease or to associated complications (e.g., infection, bleeding, or fistulization to the airway). If the diverticula are not symptomatic, they need not be treated, and the therapeutic focus is on the underlying problem that prompted the evaluation.

Epiphrenic diverticula Epiphrenic diverticula are acquired pulsion diverticula that arise in the distal 10 cm of the esophagus [see Figure 4]. Although these diverticula are usually associated with other esophageal motor disorders

(e.g., achalasia, DES, and hypertensive LES), they occasionally occur in the absence of any underlying esophageal dysfunction. If symptoms are absent or mild, conservative management is appropriate. If significant symptoms (e.g., dysphagia) are present, however, surgical management—usually entailing myotomy, diverticulectomy, and modified fundoplication—is indicated. Before operation, patients should undergo a thorough functional assessment with manometry.

Figure 4 Shown is a giant epiphrenic diverticulum in an elderly woman with progressive dysphagia and weight loss, in whom cancer was initially suspected.

DISORDERS PRODUCING
FIXED MECHANICAL
OBSTRUCTION

Esophageal Webs

A web is a localized narrowing of the esophagus caused by intraluminal extension of the mucosa and part of the submucosa of the esophageal wall. Webs may be either congenital or, more commonly, acquired, usually secondary to conditions such as iron deficiency anemia, pemphigoid, and ulcerative colitis (among others). The main presenting symptom is dysphagia, the severity of which is proportional to the degree of obstruction. Treatment usually consists of simple endoscopic dilatation [see 5:18 *Gastrointestinal Endoscopy*] after careful verification of the nature of the lesion.

Peptic Stricture

GERD is a very common problem. The majority of patients will present with heartburn and regurgitation. Although the associated hypomotility observed in some GERD patients can account for some of the dysphagia, it is important to consider (and, if possible, rule out) more significant complications, such as peptic stricture, Barrett's esophagus, and carcinoma.

Peptic stricture represents the end stage of ulcerative esophagitis, in which the healing of circumferential ulceration results in

annular fibrosis. Proton pump inhibitors (PPIs) have proved highly effective in controlling GERD symptoms and enhancing the healing of esophageal ulcers; as a result of their widespread use, peptic stricture is now an infrequent complication.

Peptic strictures may occur at any age, and there is usually an antecedent history of GERD. The symptoms are progressive but unlike those of a malignant process, in that the dysphagia usually dates back several years and weight loss is usually absent. Typically, a patient with a peptic stricture describes gradually worsening dysphagia, initially for solids and eventually for liquids as well. If the patient has dysphagia for liquids before solids or has dysphagia for both liquids and solids, an associated motility disorder must be suspected. Strictures induced by reflux are located in the distal esophagus at the squamocolumnar junction [see Figure 5]; the presence of strictures in other parts of the esophagus raises the possibility of causes other than acid-peptic injury. The best initial diagnostic testing approach consists of a barium swallow [see Figure 5] followed by upper GI endoscopy, which shows ulcers and a concentric stenosis (which is usually short).

Management of GERD patients with peptic strictures is controversial. One approach consists of dilatation of the stricture [see 5:18 *Gastrointestinal Endoscopy*] in conjunction with high-dose PPI therapy. An important component of this approach is the performance of a brush biopsy at the time of dilatation to rule out a malignancy. If the stricture recurs, then dilatation with an antireflux procedure [see 4:4 *Open Esophageal Procedures and 4:5 Minimally Invasive Esophageal Procedures*] is indicated. In the rare cases in which the stricture cannot be dilated, esophageal resection [see 4:4 *Open Esophageal Procedures and 4:7 Video-Assisted Thoracic Surgery*] must be considered.

Schatzki's Ring

Schatzki's ring is a concentric, symmetrical narrowing at the squamocolumnar junction that arises from the development of submucosal annular fibrosis and is usually accompanied by a small hiatal hernia.⁵ The exact cause is unknown, though there is a strong correlation with GERD. Dysphagia is usually for solids and is proportional to the diameter of the ring. Barium swallow establishes the diagnosis [see Figure 6], and esophagoscopy is recommended to confirm it.

For asymptomatic patients, no specific treatment is needed. For patients who present with food impaction, emergency treatment, involving rigid esophagoscopy and removal of the food bolus, is indicated. Definitive treatment entails dilatation of the ring in conjunction with medical therapy for GERD. If the ring proves refractory to this approach, dilatation plus antireflux surgery (fundoplication) [see 4:4 *Open Esophageal Procedures and 4:5 Minimally Invasive Esophageal Procedures*] may be indicated.

Chemical Ingestion

Alkali are commonly found in household cleaning agents, mostly in the form of sodium or potassium hydroxide (NaOH, KOH). The majority of alkali-related injuries occur accidentally in children; however, such injuries also occasionally occur in adults as part of a suicide attempt. The magnitude and site of the injury are directly relat-

Figure 5 Barium swallow shows severe ulcerative esophagitis, annular fibrosis (stricture), and evidence of acquired esophageal shortening. Shortness of narrowed segment suggests benign underlying cause.

Figure 6 Shown is Schatzki's ring in a middle-aged man with severe reflux symptoms and recent-onset dysphagia.

ed to the length of the contact time between the offending substance and the esophageal mucosa. Injury can occur at any level, but the most common site is the distal esophagus; the proximal esophagus, where the transit time is very short, is frequently spared. The inflammation and injury eventually lead to submucosal scar formation, which in turn leads to stricture formation and dysphagia.

Figure 7 Barium swallow from a 22-year-old patient who ingested toilet cleaner shows long, stringlike lumen from midesophagus to stomach. Dilatation was impossible in this case, and thus, management included esophageal resection with colonic interposition.

A careful endoscopic examination is an essential initial step. The scope should be advanced under direct vision to the proximal injury site; if severe injury is observed, the scope should not be advanced any further. A barium swallow should be done in the first month after injury to detect any stricture that may have formed and to determine its location, severity, and length. Serial barium swallows are helpful in following patients to monitor healing after caustic injury [see Figure 7].

At one time, it was common to administer steroids prophylactically to patients with caustic injuries to the esophagus as a strategy for preventing stricture formation. A 1990 study, however, found that this practice had no beneficial effect on healing and stricture formation rates in children,⁶ and thus, steroids currently are not widely used in this setting. Strictures are treated by endoscopic dilatation as necessary [see 5:18 *Gastrointestinal Endoscopy*]. The ultimate solution for a tight, nondilatable stricture [see Figure 7] is esophageal resection [see 4:4 *Open Esophageal Procedures* and 4:7 *Video-Assisted Thoracic Surgery*].

Esophageal Cancer

The incidence of esophageal adenocarcinoma is rising at an alarming rate. Dysphagia is the presenting symptom in more than 90% of esophageal cancer patients. Dysphagia caused by cancer

is usually gradual in onset and starts with solids, then progresses to include liquids. Other nonspecific presenting symptoms of esophageal cancer are odynophagia, regurgitation, and pain in the

Figure 8 Shown is classic appearance of midesophageal squamous cell carcinoma. Mucosal irregularity is apparent within lesion, along with proximal dilatation and shouldering at upper and lower borders. Bronchoscopy confirmed penetration of tumor into airway mucosa.

neck, abdomen, or back. Fistulization of an esophageal tumor into the airway will result in ongoing aspiration (the so-called swallow-cough sequence) and pulmonary sepsis. Weight loss occurring in association with dysphagia is strongly suggestive of esophageal cancer and should prompt appropriate investigation.

A complete history and physical examination should be carried out, followed by a barium swallow. Characteristic features of esophageal cancer on barium x-ray include narrowing, mucosal irregularity, the presence of a mass, and, occasionally, a so-called shouldered stricture [see *Figure 8*]. Esophagoscopy is essential for establishing a pathologic diagnosis by means of biopsy, brushings, and washings.

Treatment is determined by the stage of the disease. In a medically fit patient with localized esophageal cancer, esophagectomy is indicated [see *4:4 Open Esophageal Procedures and 4:7 Video-Assisted Thoracic Surgery*]. Traditionally, CT scanning of the neck, the chest, the abdomen, and the pelvis has been performed to rule out distant metastatic disease. More recently, PET scanning has also been used for this purpose. EUS, if available, may also aid in locoregional staging. For lesions in the upper third or the middle third of the esophagus, bronchoscopy is necessary to rule out direct tumor invasion of the airway.

2 CHEST WALL MASS

John C. Kucharczuk, M.D., F.A.C.S.

Evaluation of Chest Wall Mass

Chest wall masses arise from a variety of different causes. The chest wall contains a number of distinct tissues, including skin, fat, muscle, bone, cartilage, lymphatic vessels, and fascia. Each of these component tissues can give rise to either a benign or a malignant primary chest wall mass. In addition, the chest wall is also in intimate proximity to a number of organs (e.g., the breast, the lung, the mediastinum, and the pleura) that may give rise to a chest wall mass through extension of a malignancy or infection. Finally, because of its large surface area, the chest wall can be the site of a secondary mass caused by metastasis from a distant malignancy (e.g., carcinoma or sarcoma) [see Table 1].

Chest wall masses, whether primary or secondary, are relatively uncommon in clinical practice. Accordingly, many surgeons lack a solid working knowledge of the causes, evaluation, treatment, and natural history of these lesions. Often, this unfamiliarity leads to inappropriate selection of diagnostic studies, unnecessary delays in treatment, and considerable frustration for patient and surgeon alike. In what follows, I outline a focused clinical approach aimed at streamlining the evaluation and treatment of patients with chest wall masses. Appropriate diagnostic studies and operative planning are discussed, and specific causes of chest wall masses are reviewed.

Clinical Evaluation

HISTORY AND PHYSICAL EXAMINATION

Initial evaluation of a patient with a chest wall mass begins with a careful history that notes the symptoms associated with the mass and records the history of its growth. Previously obtained radiographs, if available, are reviewed to determine how rapidly the mass has been growing. A complete physical examination is performed to rule out other sites of disease and to identify any comorbid medical conditions that may affect the patient's candidacy for resection. If the mass is palpable, its size and its salient characteristics (i.e., hard versus soft and fixed versus mobile) are noted. By itself, physical examination will not establish whether the lesion is benign or malignant.

Investigative Studies

DIAGNOSTIC IMAGING

At presentation, most patients with chest wall masses have already undergone chest radiography and computed tomography. In the case of a primary chest wall mass, magnetic resonance imaging is useful for further characterization of the lesion. MRI allows precise delineation of tissue planes and major adjacent neurovascular structures¹; however, as

a stand-alone test, it cannot differentiate between benign and malignant chest wall lesions.

In general, given that neither physical examination nor diagnostic imaging can reliably distinguish benign from malignant chest wall masses, it is important to move quickly to tissue diagnosis. With very unusual tumors, it is often necessary to consult a highly specialized pathologist to make the diagnosis and an oncologist to assist in treatment planning.

BIOPSY

Whether a tissue diagnosis is needed before initiation of definitive therapy depends on the size and characteristics of the lesion. If the lesion is small (< 3 cm), regardless of whether it is believed to be benign or malignant, excisional biopsy is performed as both diagnosis and treatment. If the lesion is larger (≥ 3 cm) and its resection will lead to significant morbidity and necessitate extensive reconstruction, a preoperative tissue diagnosis is obtained.

Whether fine-needle aspiration (FNA) is useful for tissue diagnosis in this setting remains a subject of debate. FNA is a simple procedure that can be performed in the office during the initial patient evaluation, and several studies suggest that it is an effective technique for assessing chest wall masses.² Nevertheless, in routine clinical practice, cytologic analysis of a fine-needle aspirate from a primary chest wall mass frequently yields nondiagnostic results, and additional tissue is often requested. In such cases, a core-needle biopsy or an incisional biopsy is performed. Both techniques provide tissue for histologic evaluation, and both must be performed in such a way that the biopsy tract will be completely excised at the time of definitive surgical treatment. As a rule, in patients with a known primary malignancy and a secondary chest wall mass, I perform FNA. In patients with a primary chest wall mass larger than 3 cm and no underlying diagnosis, I proceed directly to incisional biopsy for diagnosis.

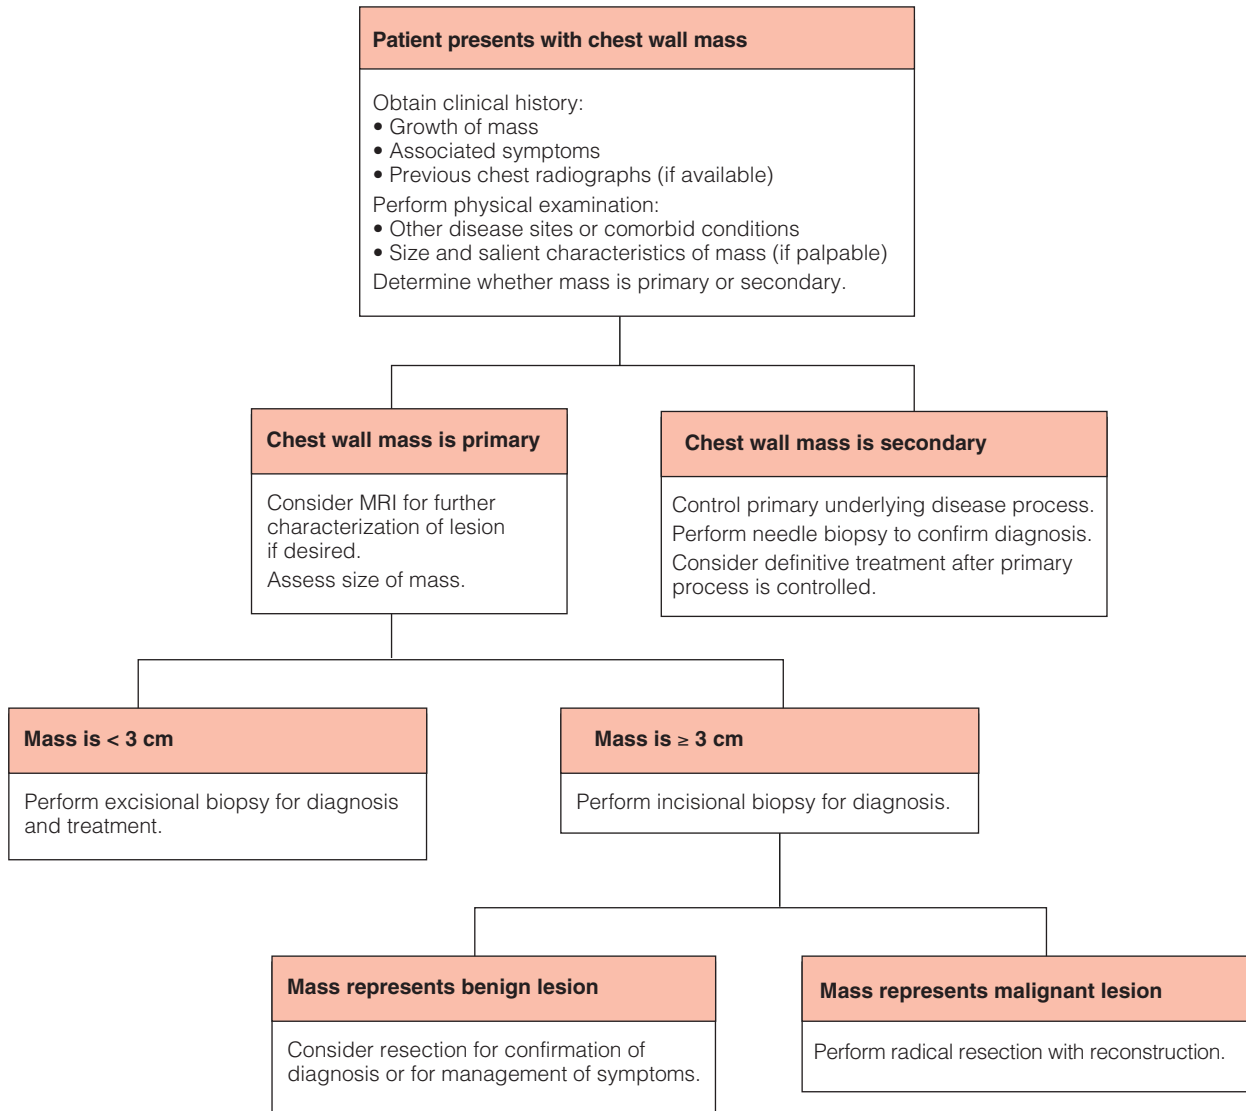

Table 1 Classification of Primary and Secondary Chest Wall Masses

Primary masses of chest wall	Benign
	Infectious masses Soft tissue neoplasms Bone and cartilage neoplasms
Secondary masses of chest wall	Malignant
	Soft tissue neoplasms Bone and cartilage neoplasms Tumor invasion from contiguous organs Metastasis from distant organs

Evaluation of Chest Wall Mass

Management

PRIMARY BENIGN MASSES OF CHEST WALL

Infectious Masses

Sternal infection Primary sternal osteomyelitis may be seen in intravenous drug abusers but is otherwise rare. Much more common is osteomyelitis occurring after median sternotomy. Approximately 1% to 3% of median sternotomies for cardiac procedures are complicated by sternal wound infection.³ Risk factors include diabetes, the use of bilateral internal mammary arteries, and reoperation.⁴ Patients with poststernotomy osteomyelitis present with pain, drainage, and, often, a palpable mass overlying the incision. In most cases, the infection is not confined to the sternum but extends deeply into the mediastinum as well. The diagnostic study of choice is CT scanning of the chest, which will determine the extent of mediastinal soilage.

After CT, the patient is taken to the operating room for wide drainage and sternal debridement. A number of different techniques have been employed to treat these infections; of these, aggressive surgical debridement of the infected area with flap closure yields the best overall clinical outcomes [see 4:6 Chest Wall Procedures].⁵

The patient who presents with a pulsating sternal mass after sternotomy represents a special case. Such patients have a pseudoaneurysm of the underlying aorta and are at risk for exsanguination. They should undergo an emergency CT angiogram or aortogram to confirm the diagnosis and then be taken directly to the OR, where they are placed on cardiopulmonary bypass through femoral cannulation and cooled to a hypothermic state before the sternum is opened.

Sternoclavicular joint infection Sternoclavicular joint (SCJ) infections present as painful palpable masses overlying the joint [see Figure 1]. These infections are often associated with I.V. drug abuse, infected indwelling subclavian catheters, or trauma. Most patients also have an underlying risk factor (e.g., diabetes or hepatic or renal insufficiency) or a history of sepsis. The diagnosis

Figure 1 Sternoclavicular joint infections present as painful palpable masses overlying the joint.

Figure 2 CT scan shows typical appearance of SCJ infection, including fluid collection around the joint and tissue stranding.

is made on the basis of the history, the physical examination, and CT scanning of the chest (with particular attention paid to the SCJ). Typical CT findings include tissue stranding and a collection around the joint [see Figure 2].

Treatment consists of wide resection of the SCJ and the proximal third of the clavicle, as well as debridement of the manubrium [see 4:6 Chest Wall Procedures].⁶ Often, the proximal portion of the first rib is involved and also must be resected. Immediate reconstruction is performed by rotating a pectoralis muscle flap into the resection cavity. After operation, I.V. antibiotics are administered for 6 weeks. Most patients require intensive postoperative physical therapy to restore strength, function, and mobility in the upper extremity.

Osteomyelitis of rib Osteomyelitis of a rib presents as a painful, swollen mass overlying an infected segment of rib. Often, a draining sinus tract is present. The diagnosis is made on clinical grounds. A CT scan of the chest is obtained to rule out an underlying intrathoracic condition (e.g., empyema).

Treatment consists of resection of the infected bone and soft tissue coverage of the defect [see 4:6 Chest Wall Procedures]. Care must be taken to avoid contamination of the underlying pleural cavity during rib resection.

In children, the diagnosis is made on clinical grounds and may be facilitated by the use of ultrasonography, which demonstrates obliteration of the intermuscular planes adjacent to the infected rib and pericostal edema.⁷ Again, a CT scan is usually obtained to rule out other underlying pleura-based abnormalities. As with adults, the range of pathologic organisms that may be recovered is quite wide.

Benign Neoplasms

Benign neoplasms of the chest wall may be divided into those arising from soft tissue and those arising from bone and cartilage [see Table 2].

Soft tissue neoplasms Benign soft tissue neoplasms of the chest wall usually present as slowly growing, painless masses. On examination, the lesions usually are soft and freely movable. Plain radiographs and a CT scan of the chest are obtained. The CT

Table 2 Primary Benign Chest Wall Neoplasms by Tissue of Origin

Benign soft tissue neoplasms	Lipoma Fibroma Hemangioma Granuloma Neurofibroma Elastoma Desmoid
Benign bone and cartilage neoplasms	Osteochondroma Chondroma Fibrous dysplasia Eosinophilic granuloma

scan shows a homogeneous mass, with no necrosis and no infiltration of associated soft tissue or destruction of associated bone. Small soft tissue lesions (< 3 cm) are completely removed by means of excisional biopsy, which provides definitive diagnosis and treatment. Larger lesions (\geq 3 cm) undergo incisional biopsy first to rule out a malignant soft tissue neoplasm. If the lesion is confirmed as benign, it is resected with close negative margins to minimize the size of the surgical defect. If it is determined to be malignant, an aggressive wide excision is performed with immediate reconstruction [see 4:6 Chest Wall Procedures].

Desmoid tumors deserve special mention, in that they are borderline neoplasms.⁸ These tumors generally arise in the muscle and fascia around the shoulder. Although they are histologically benign, they can infiltrate adjacent structures and exhibit a high tendency for local recurrence. Desmoid tumors are best treated by means of radical surgical excision. In patients with positive surgical margins, the recurrence rate is 89%, whereas in those with negative margins, the recurrence rate is less than 20%.⁹

Bone and cartilage neoplasms Osteochondromas are the most common bone tumors overall. These lesions are benign cartilaginous neoplasms that may occur in any bone that undergoes enchondral bone formation; essentially, they are hamartomas of the growth plate. The knee is the most common site of occurrence. In the chest, osteochondromas arise in the metaphyseal regions of the anterior ribs. Most are asymptomatic and are found when screening chest radiographs reveal an eccentric growth pattern at the costochondral junction. The diagnosis is made on the basis of a characteristic pattern on plain x-rays. In children, osteochondromas are followed; in postpubescent and adult patients, they are resected to confirm the diagnosis and rule out malignancy.

Chondromas are the next most common benign neoplasms of the chest wall. They occur along the costochondral junctions between the anterior ribs and the sternum. Unfortunately, it is not possible to distinguish between benign and malignant cartilage neoplasms on the basis of clinical or radiographic findings; therefore, excision is required for diagnosis. Excision results in a significant surgical defect that usually necessitates complex reconstruction, including the use of prosthetic material to provide rigid structure and soft tissue coverage [see 4:6 Chest Wall Procedures].

Fibrous dysplasia usually presents as a painless cystic bone lesion that is found incidentally on a screening chest x-ray. Replacement of the medulla by fibrous tissue creates a characteristic radiolucent appearance. These lesions are treated conservatively and are simply followed. Local resection is indicated if pain develops or if the lesion is seen to be enlarging on serial x-rays.

PRIMARY MALIGNANT MASSES OF CHEST WALL

Like benign chest wall neoplasms, malignant chest wall neoplasms may be divided into those arising from soft tissue and those arising from bone and cartilage [see Table 3].

Soft Tissue Neoplasms

Sarcomas are the primary malignant soft tissue neoplasms of the chest wall. Most of the published series addressing soft tissue sarcoma of the chest wall have included small numbers of patients and have also addressed lesions arising in bone and cartilage. The largest surgical series of patients with soft tissue sarcomas of the chest wall was published in 1991.¹⁰ This study included 149 patients who had undergone resection at the Memorial Sloan-Kettering Cancer Center in New York. The overall 5-year survival rate was 66%. Unfortunately, the study also included 32 patients with desmoid tumors, which are not histologically classified either as sarcomas or as malignant neoplasms. In 2005, a large retrospective study from a single institution in Brazil reported on 55 patients who underwent surgical treatment of soft tissue sarcomas of the chest wall.¹¹ Nearly 53% of the lesions were fibrosarcomas. With wide surgical resection, the disease-free survival rate was 75% at 5 years and 64% at 10 years. The histologic grade of the tumor and the type of surgical resection performed were found to be independent prognostic factors for disease-free survival. These findings are consistent with those of other studies that suggest that age, gender, symptoms, and lesion size do not have a significant impact on survival.¹²

Sarcomas of the chest wall can be quite sizable [see Figure 3]. They are painless in about 50% of patients. The typical clinical finding is a hard, fixed mass. No calcifications are visible on CT chest scans, but bone invasion is common. The standard treatment is wide surgical excision. Currently, the data are not sufficient to warrant recommendation of neoadjuvant therapy, which has become routine in managing soft tissue sarcomas of the extremities. In 2001, the University of Texas M. D. Anderson Cancer Center reported its multidisciplinary experience with primary chest wall sarcomas.¹³ The retrospective review included patients with sarcomas of soft tissue, cartilage, and bone, as well as desmoid tumors. Nevertheless, the cumulative 5-year survival rate was 64%, which is about the rate to be expected from surgery alone.

Bone and Cartilage Neoplasms

A solitary plasmacytoma is a unique chest wall mass that is caused by a localized collection of monoclonal plasma cells. His-

Table 3 Primary Malignant Chest Wall Neoplasms by Tissue of Origin

Figure 3 Shown is the appearance of a chest wall sarcoma on physical examination. Such lesions can be quite large.

tologically, the plasma cells are identical to those seen in patients with multiple myeloma; however, in a plasmacytoma, unlike multiple myeloma, these cells are confined to a single site. Patients generally present with pain and often have pathologic rib fractures. When soft tissue becomes involved, a palpable mass becomes evident. The role of surgery is limited to obtaining tissue for diagnosis via FNA, core-needle biopsy, or a small incisional biopsy. Tissue is sent for analysis by flow cytometry, which confirms the clonal nature of the cells.¹⁴ Definitive local radiotherapy is the treatment of choice for solitary bone plasmacytoma.¹⁵ Although local control is achieved in more than 90% of patients with radiation therapy alone, about 50% of patients progress to multiple myeloma within 2 years and require systemic treatment.¹⁶

Chondrosarcomas are the most common primary malignant tumors of the chest wall. They are found along the anterior sternal boarder or the costochondral arches and are substantially more common in males than in females. Pain is typically a presenting complaint. CT scanning is the primary imaging study; however, there are no distinguishing radiographic characteristics that establish a definitive diagnosis.¹⁷ Complete surgical resection with adequate surgical margins and immediate reconstruction is the treatment of choice [see 4:6 *Chest Wall Procedures*]. A 2004 study from the Mayo Clinic reported a 5-year survival rate of 100% and a recurrence rate of less than 10% in patients with adequate surgical margins.¹⁸ In contrast, patients with inadequate surgical margins had a 50% 5-year survival rate and a 75% local recurrence rate.

Ewing sarcoma is an aggressive primary malignant bone tumor that occurs in children and adolescents. It is more common in boys than in girls and usually develops between the ages of 10 and 20 years. Ewing sarcoma was initially distinguished from osteosarcoma on the basis of its sensitivity to radiation. The origin of Ewing sarcoma remains unclear, but there appear to be several tumors that share the same genetic translocation; these lesions are referred to as the Ewing family of tumors.¹⁹

The initial role of surgery in managing primary Ewing sarcoma of the chest wall consists of obtaining tissue for diagnosis. With smaller rib lesions, this may be done by means of an excisional biopsy. Generally, Ewing sarcoma is best managed with a

multimodality approach that includes preoperative chemotherapy followed by complete resection of residual disease.²⁰ A 2003 review of three multi-institutional trials from the Pediatric Oncology Group suggests that in patients with Ewing sarcoma and closely related primitive neuroectodermal tumors of the chest wall, the likelihood of achieving a complete resection is improved by employing neoadjuvant chemotherapy followed by delayed resection.²¹ The definitive resection is undertaken after four cycles of chemotherapy. If the resection is complete and the pathologic margins are negative, no radiation therapy is administered. Avoidance of radiation therapy may be particularly important in pediatric and adolescent patients, who are at significant (10% to 30%) risk for a radiation-induced malignancy over their lifetime.²²

Askin tumors are members of the Ewing family of tumors. They are small round cell tumors of the thoracopulmonary region that arise from the same primordial stem cell. They are best managed by means of diagnostic biopsy, preoperative chemotherapy, and complete surgical resection.²³

Synovial sarcomas are very uncommon, but they occasionally arise on the trunk, where they present as palpable chest wall masses. Although these tumors are referred to as synovial cell sarcomas, this term is a misnomer, in that the lesions do not arise from synovial cells or joint cavities. The name originally derived from the tumors' resemblance to developing synovial tissue under light microscopy; however, synovial sarcomas are now known to arise from primitive mesenchymal cells.²⁴ The most important prognostic factor is tumor size.²⁵ The limited data available at present suggest that although neoadjuvant chemotherapy may elicit an objective response, it apparently has no detectable beneficial effect on survival.²⁶ The current therapeutic recommendation is aggressive surgical resection. If the tumor is very large or margins are positive, postoperative adjuvant treatment is indicated.

SECONDARY MASSES OF CHEST WALL

The secondary chest wall masses of surgical interest arise as direct extensions of a malignancy in a contiguous organ. The breast and the lung are the most common primary sites. The initial evaluation centers on the underlying disease, not the chest wall mass. For example, a patient with a chest wall mass resulting from direct invasion by a primary lung cancer should undergo a staging workup to determine the extent of the disease. If the patient is a stage-appropriate candidate for resection and is medically fit for surgery, he or she should undergo pulmonary resection with en bloc chest wall resection.²⁷ After resection, the patient should be referred for four cycles of postoperative chemotherapy. The interventional intent is cure, and the outcomes are stage specific.

Unfortunately, most women who present with a chest wall mass arising from a breast neoplasm have a local recurrence. From a technical standpoint, resection with reconstruction is feasible in this setting; however, it is unclear whether it offers any real benefit. In a study from the Memorial Sloan-Kettering Cancer Center, 38 women underwent extensive chest wall resection for recurrent breast cancer.²⁸ The operative mortality was 0%, but the 5-year survival rate was only 18%, and by 5 years, 87% of the patients had local recurrences. Currently, chest wall resection for locally recurrent breast cancer must be considered on a case-by-case basis.

3 PARALYZED DIAPHRAGM

Bryan F. Meyers, M.D., F.A.C.S., and Benjamin D. Kozower, M.D.

Evaluation of Elevated Hemidiaphragm

Paralysis of the diaphragm is an unusual and challenging clinical problem that may occur either in isolation or as part of a systemic disease. It can be caused by a number of disorders and should be considered in the differential diagnosis whenever a chest radiograph shows an elevated hemidiaphragm. At one time, diaphragmatic paralysis was generally considered to be a benign condition, but it is now clear that many patients experience various pulmonary, cardiac, and gastrointestinal symptoms. The symptoms reported are typically nonspecific, and the correct diagnosis is often difficult to make.

It is helpful to remember that the clinical manifestations of diaphragmatic paralysis are usually explained by the pathophysiology. Interruption of the phrenic nerve anywhere between the neck and the diaphragm results in paralysis of the ipsilateral hemidiaphragm [see Discussion, Diaphragmatic Anatomy, below]. Because the diaphragm is a continuous muscular sheet, one might suppose that paralysis of one side would adversely affect the other. Actually, the two sides of the diaphragm function independently: tension from one side is not distributed to the other across the central tendon.¹ Bilateral diaphragmatic paralysis is rarely encountered by the thoracic surgeon. When it does occur, it is usually a manifestation of neuromuscular or systemic disease.

The functional effects of hemidiaphragmatic paralysis are similar to but less striking than those of bilateral paralysis [see Discussion, Normal Diaphragmatic Function, below].² An elevated hemidiaphragm compresses the hemithorax and results in a restrictive pattern of lung disease. In the seated position, the patient's vital capacity and total lung capacity decrease by approximately 20%; in the supine position, vital capacity decreases by nearly 40%.³ Ventilation and perfusion of the lower lobe are also reduced on the affected side. Mismatching may widen the alveolar-arterial oxygen difference and produce mild hypoxemia.⁴ Generally, adults with healthy lungs tolerate these changes well; however, patients who are obese or have underlying lung disease are more likely to be symptomatic.

Diaphragmatic paralysis is frequently described in the literature in conjunction with eventration of the diaphragm. Eventration is a condition in which all or a portion of one hemidiaphragm is permanently elevated while retaining its continuity and its normal attachments to the costal margins. Although eventration and unilateral paralysis are technically different, they often give rise to the same physiologic disturbances and radiographic findings.

Clinical Evaluation

HISTORY

In adults, the clinical presentation of unilateral paralysis of the diaphragm is highly variable. Right and left hemidiaphragmatic paralysis seem to occur with equal frequency and usually cause little or no respiratory

compromise. Patients may sleep in a semirecumbent position or in the lateral decubitus position with the affected hemidiaphragm down. Most patients have few respiratory symptoms at rest, but some complain of dyspnea, cough, or chest pain with exertion [see Figure 1]. Patients with left-side paralysis may experience GI complaints resulting from compression of the stomach [see Figure 2]. In addition, patients may suffer from recurrent pneumonia, bronchitis, or cardiac arrhythmias.

Bilateral diaphragmatic paralysis, on the other hand, is poorly tolerated. Patients with this condition depend more on their accessory muscles of respiration, avoid the supine position, and are more prone to chronic respiratory failure.⁵

In children, diaphragmatic paralysis may cause severe respiratory distress. Compared with adults, children have weaker intercostal muscles, a more compliant chest wall, and a more mobile mediastinum. Accordingly, children must depend on their diaphragms to achieve adequate tidal volumes. Unilateral diaphragmatic paralysis in a child usually necessitates mechanical ventilation; bilateral paralysis is often fatal without prompt ventilatory support.

Common Causes of Diaphragmatic Paralysis

As noted (see above), bilateral diaphragmatic paralysis is usually a manifestation of a systemic disease, such as a neuromuscular junction disorder, an immunologic phenomenon, or a myopathy. Because thoracic surgeons rarely treat these conditions, the ensu-

Figure 1 Shown is a postoperative radiograph from a 55-year-old woman who underwent left upper lobectomy. Because the tumor was directly adherent to the phrenic nerve, a 2 cm portion of the left phrenic nerve was resected along with the tumor. Recovery was uneventful, and the only late symptom was mild dyspnea with exertion.

Evaluation of Elevated Hemidiaphragm

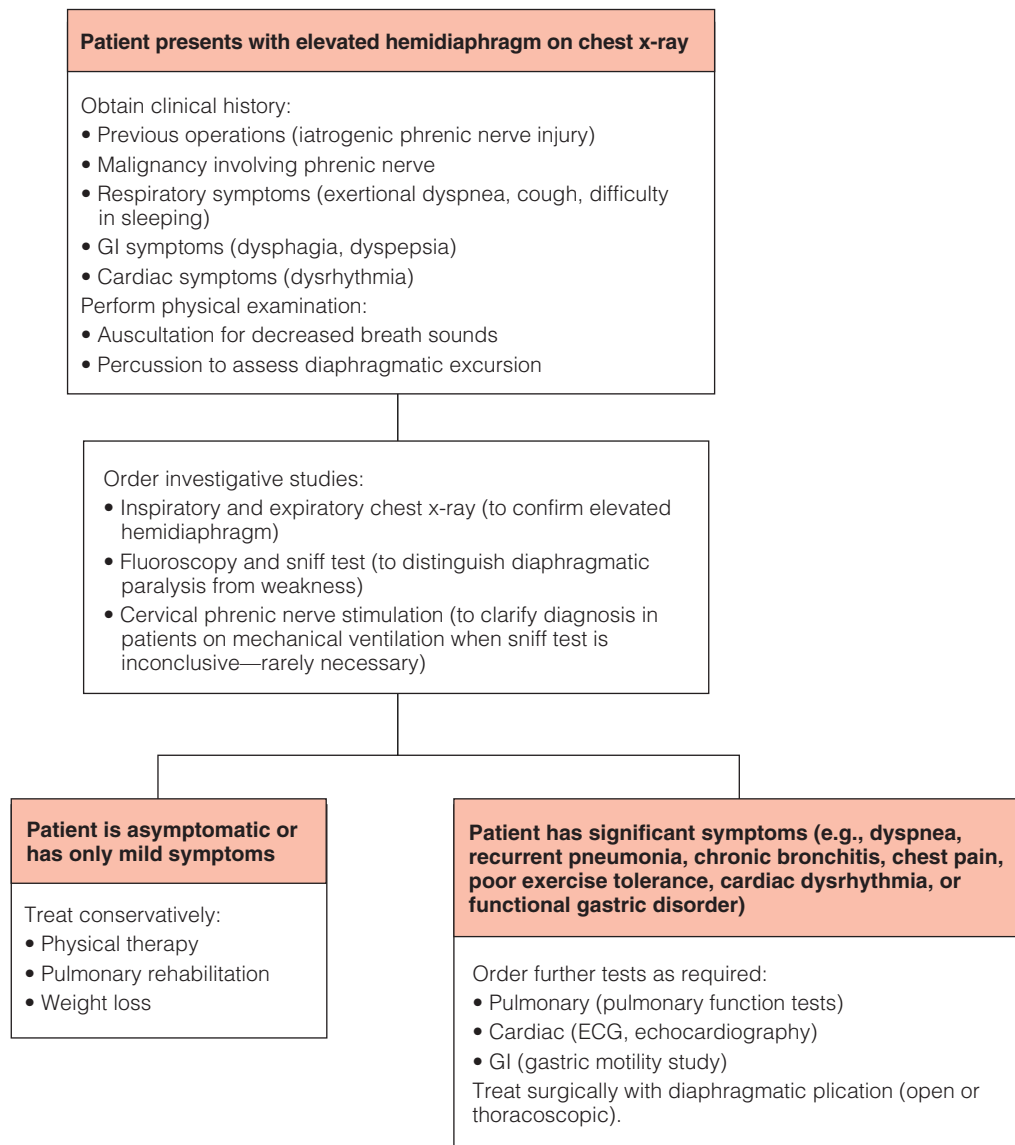

Figure 2 Shown is a postoperative radiograph of a 70-year-old man who underwent left upper lobectomy for removal of a peripheral 3 cm lesion. The phrenic nerve was injured with the electrocautery during mediastinal lymph node dissection. The radiograph shows permanent elevation of the left hemidiaphragm with gastric bloating 3 years after operation. The patient is neither dyspneic nor dyspeptic and does not require surgical intervention.

ing discussion focuses on conditions associated with isolated diaphragmatic paralysis [see Table 1]. The two most common causes of unilateral diaphragmatic paralysis are (1) iatrogenic injury after a cardiothoracic or cervical procedure and (2) malignancy.

Injury to phrenic nerve Common mechanisms of phrenic nerve injury during cardiac procedures include stretching, crushing, transection, and hypothermia. During the mid-1980s, topical ice slush was frequently employed in cardiopulmonary bypass procedures, and this practice dramatically increased the incidence of phrenic nerve injury. After cooling jackets replaced topical ice slush in this setting, the incidence of elevated hemidiaphragms fell from 23% to 2%.^{6,7} It has been suggested that harvesting the internal mammary artery may contribute to phrenic nerve injury, but a def-

inite connection between the two has not been established.

The outcome of phrenic nerve injury incurred during cardiac surgery has been well studied. In many cases, the injured phrenic nerves recover; typical recovery times for diaphragmatic function range from 6 months to 2 years.^{6,8} In 20% of cases, however, the injury is permanent [see Figure 3]. Although morbidity is usually minimal, bilateral diaphragmatic paralysis after cardiac surgery has occasionally resulted in death. It should be kept in mind that diaphragmatic paralysis after cardiac surgery is a more serious problem in children than in adults. In pediatric patients, phrenic nerve injury usually results in respiratory distress, which may prevent weaning from mechanical ventilation.⁹

In current usage, the term iatrogenic phrenic nerve injury refers to either (1) unintentional injury to the nerve during an operation or (2) intentional resection of the nerve to permit complete excision of a chest neoplasm. In the past, however, phrenic nerve injury was sometimes deliberately induced to elevate or disable a hemidiaphragm for therapeutic purposes, either permanently or temporarily. Therapeutic phrenic nerve paralysis was originally achieved by crushing the nerve at the level of the diaphragm with a surgical clamp; subsequently, temporary paralysis was achieved by exposing the phrenic nerve in the neck and infiltrating the area around it with local anesthetics. This technique was employed in the treatment of pulmonary tuberculosis and was occasionally performed to elevate a hemidiaphragm and help obliterate a difficult pleural space problem. It must be emphasized that in current practice, therapeutic phrenic nerve paralysis is of historic interest only. It is never necessary, and it is no longer considered appropriate or beneficial.

Malignancy involving phrenic nerve Neoplastic involvement of the phrenic nerve accounts for one third of cases of diaphragmatic paralysis.¹⁰ Bronchogenic carcinomas are the lesions that most commonly affect the phrenic nerve, and paralysis is usually secondary to mediastinal lymph node involvement or direct mediastinal invasion by central tumors. Other mediastinal tumors that may affect the phrenic nerve include thymomas, lymphomas, and germ cell tumors. It is reassuring to note that in patients with unilateral diaphragmatic paralysis of no clear origin, malignancy turns out to be the cause in fewer than 5% of cases. Although patients with unexplained diaphragmatic paralysis are unlikely to have an occult malignancy, they are also unlikely to recover their diaphragmatic function.¹⁰

PHYSICAL EXAMINATION

Patients with diaphragmatic paralysis may be asymptomatic or may present with some of the nonspecific clinical findings mentioned (see above). Physical examination usually reveals decreased breath sounds on the affected side, a mediastinal shift during inspiration, or a scaphoid abdomen. Percussion may demonstrate an elevated hemidiaphragm with decreased excursion on inspiration.

Investigative Studies

In the majority of cases, an asymptomatic person is referred to the surgeon because a chest radiograph demonstrates an elevated hemidiaphragm. It is important to remember that there is a broad differential diagnosis for an elevated hemidiaphragm and that diaphragmatic paralysis is relatively rare [see Table 2].

Workup usually begins with inspiratory and expiratory chest

Table 1 Causes of Isolated Diaphragmatic Paralysis

- Idiopathic paralysis
- Phrenic neuropathy

 - Herpes zoster
 - Poliomyelitis
 - Amyotrophic lateral sclerosis

Figure 3 Shown are three chest radiographs of a 25-year-old man with residual anterior mediastinal mass after treatment for germ cell tumor. (a) Preoperative view shows normal diaphragmatic positioning bilaterally. (b) Immediate postoperative view demonstrates an elevated right hemidiaphragm, attributed to stretch injury and electrothermal injury caused by dissection of mass from the vicinity of the phrenic nerve at the right hilum. (c) Late view, 3 months after operation, reveals gradual restoration of normal diaphragm positioning. Patient is asymptomatic.

radiographs. However, fluoroscopic examination is the most practical method of assessing the movement of the diaphragm. The excursion of the domes of the diaphragm averages 3 to 5 cm and may range from 2 to 10 cm.¹¹ The examination is typically performed with the patient standing, but it is more sensitive when the patient is supine because the effect of gravity is removed. In a patient with unilateral paralysis, the paralyzed hemidiaphragm moves upward with rapid inspiration and downward with expiration. This paradoxical motion passively follows changes in intrapleural and intra-abdominal pressure.

The so-called sniff test is then performed to confirm that the abnormal diaphragm excursion is the result of paralysis rather than of weakness. During this test, the patient inhales forcefully and rapidly through the nose with the mouth closed. A sharp and brief downward motion in both hemidiaphragms is the normal response when paralysis is absent. If an entire hemidiaphragm exhibits a paradoxical upward motion greater than 2 cm, however, diaphragmatic paralysis is likely.¹² The diagnosis of diaphragmatic paralysis may be difficult to make in patients with severe chronic obstructive pulmonary disease, in whom normal hemidiaphragms move very little. The sniff test may also be inconclusive in weak, debilitated patients, who often are incapable of producing a forceful sniff. In patients who are undergoing mechanical ventilation and in whom the diagnosis remains in doubt after a

sniff test, a definitive diagnosis can be made by employing cervical phrenic nerve stimulation in conjunction with electromyographic measurement of phrenic nerve latency.¹³ This final test is rarely necessary.

Management

CONSERVATIVE VERSUS SURGICAL TREATMENT

Treatment is individualized and depends on the degree to which the patient is incapacitated. Most healthy adults with isolated diaphragmatic paralysis are asymptomatic or suffer only from mild exertional dyspnea. The vast majority of these patients do not require surgical treatment and are best treated conservatively (e.g., with physical therapy, pulmonary rehabilitation, and counseling on weight loss, if necessary). Just as many patients with normal lung function can tolerate major pulmonary resections, most patients who are otherwise fit can tolerate unilateral diaphragmatic paralysis without the need for surgical intervention.

Operative management may, however, be indicated for children and for adults who have significant symptoms (e.g., dyspnea, recurrent pneumonia, chronic bronchitis, chest pain, poor exercise

tolerance, cardiac arrhythmias, or functional disorders of the stomach).¹⁴ The classic treatment is diaphragmatic plication, which may be performed either via a thoracotomy or thoracoscopically. Plication of the diaphragm was first performed in 1947 to treat congenital eventration of the diaphragm, and the basic principles of the procedure have changed little since then.¹⁵

PLICATION OF DIAPHRAGM

Open

A standard diaphragmatic plication is performed through a posterolateral thoracotomy in the eighth intercostal space. The lung and the mediastinum are examined to exclude any unsuspected pathologic conditions. The uncut diaphragm is plicated with four to six parallel rows of heavy nonabsorbable sutures. The stitches are placed in an anterolateral-to-posterolateral direction, and each row takes several bites of the diaphragm to form pleats. The sutures are tied only after all the rows have been placed. When all of the sutures are placed and tied, the diaphragm should be tight, and much of the plicated tissue should lie within the central tendon.

Open diaphragmatic plication is an effective procedure for treating diaphragmatic paralysis. In a study of 17 patients who underwent plication for exertional dyspnea,¹⁶ no major complications were reported during a mean hospital stay of 11 days. At 6 months' follow-up, patients exhibited significant improvements with respect to dyspnea score, forced vital capacity (FVC), total lung capacity (TLC), functional residual capacity (FRC), and arterial oxygenation. Furthermore, the subjective and objective improvements were maintained for at least 5 years. In a subsequent series from the United Kingdom, similar results were observed at a mean follow-up of 10 years: 14 of 15 patients were satisfied with their plication and had returned to work.¹⁷ In addition, FVC, forced expiratory volume in 1 second (FEV₁), FRC, and TLC improved by 12%, 15%, 26%, and 13%, respectively.

Research has also been performed on changes in respiratory mechanics after diaphragmatic plication. In 1980, one group noted that plication was more successful for hemiparalysis than for bilateral diaphragmatic paralysis.¹⁸ These clinical results subsequently led another group to hypothesize that normal functioning of the contralateral hemidiaphragm might be required to derive significant benefit from diaphragmatic plication.¹⁹ These investigators demonstrated that plication for unilateral paralysis improved the strength of the normal contralateral hemidiaphragm, so that the contralateral hemidiaphragm functioned as a better pressure generator and thus made a greater contribution to breathing. However, they found that bilateral plication for bilateral paralysis did not yield significant improvements with respect to diaphragmatic function, lung compliance, or work of breathing.

There was a small improvement in tidal volume after bilateral plication, but this was probably attributable to improved rib cage efficiency secondary to diaphragmatic fixation.

These findings may explain why bilateral plication has been more beneficial for adults than it has been for children,²⁰ who depend more on the diaphragmatic contribution to respiration. In infants, the small improvement in rib cage efficiency may not be large enough to allow them to be weaned from mechanical ventilation. In children with hemidiaphragmatic paralysis, however, plication is essential for improving diaphragmatic efficiency and preventing complications associated with long-term mechanical ventilation.²⁰

Thoracoscopic

In 1996, a thoracoscopy-assisted approach to diaphragmatic plication was first described. The goal was to achieve an equivalent degree of plication by less invasive means.²¹ Three patients were treated in this fashion. The procedure made use of a double-lumen endotracheal tube, two thoracoscopic ports, and a 5 cm minithoracotomy. The diaphragm was invaginated and stitched with two rows of continuous sutures. The results were excellent, and the average hospital stay was 8 days. All three patients showed significant improvements in FVC and FEV₁: FVC improved by 9% to 22%, and FEV₁ improved by 11% to 14%. These improvements were maintained for a minimum of 17 months.

Since this first description, several reports of successful diaphragmatic plication with a purely thoracoscopic approach (using three or four ports) have been published.^{14,22} These case reports documented symptomatic improvement and reduced length of stay (4 days); however, they did not document significant improvements in FVC or FEV₁. Thoracoscopic diaphragmatic plication appears to be the surgical method of the future, but larger series with longer follow-up periods are needed. The main contraindication to thoracoscopic plication is extensive pleural adhesions from inflammatory reactions or previous operations.

SURGICAL PROPHYLAXIS AFTER PHRENIC NERVE INJURY

Phrenic Nerve Repair versus Prophylactic Plication

An area of investigation that, to date, has not been sufficiently explored is the potential role of prophylactic procedures in cases where one is confident that a phrenic nerve has been injured during an operation and wishes to reverse or at least mitigate the effect of the injury.

If the injury resulted from sharp dissection, so that the entire nerve is present but divided, one may elect to repair the nerve. On occasion, we have invited colleagues from plastic surgery to perform microsurgical anastomoses between the cut ends of the severed nerves, but we have never attempted a formal analysis of this practice. Such a repair would not, of course, be feasible in a case where the phrenic nerve was resected in the course of excision of an attached invasive tumor.

If the nerve was resected or was injured beyond hope of recovery, one may reasonably consider plicating the diaphragm during the same operation so as to minimize the impact of the diaphragmatic paralysis without having to perform another operation later. This strategy has not yet been studied in the surgical literature, but it should be kept in mind for the rare instances of phrenic nerve resection or injury during pulmonary or mediastinal resection.

PACING OF DIAPHRAGM

Although pacing of the diaphragm requires an intact phrenic nerve and thus is not useful in cases of classic diaphragmatic

Table 2 Differential Diagnosis of Elevated Hemidiaphragm on Chest Radiograph

Volume loss (atelectasis, lobar collapse, hypoplasia)
Splinting

Abdominal disease (dilated viscera, abscess)
Single-lung transplantation for pulmonary fibrosis

paralysis, it is an established mode of ventilatory support with which the thoracic surgeon should be familiar. The two main indications for diaphragmatic pacing are central alveolar hypoventilation and high cervical spinal cord injury; less common indications are intractable hiccups and end-stage chronic obstructive pulmonary disease. Central alveolar hypoventilation is a form of sleep apnea resulting from failure of the respiratory drive itself rather than from an anatomic obstruction. It is also known as Ondine's curse (from the German myth about the water nymph Ondine, who, finding that her mortal husband had been unfaithful, placed a fatal curse on him so that he would only breathe while awake).²³ The underlying cause is impaired sensitivity of the brain's respiratory control center to alterations in oxygenation. The clinical result is persistent hypoventilation with sleep apnea and the development of pulmonary hypertension.

The use of electricity to induce diaphragmatic contraction was first suggested by Hufeland in 1783.²⁴ Besides an intact phrenic nerve and a functioning diaphragm, diaphragmatic pacing also

requires normal lungs with the ability to oxygenate and ventilate in response to diaphragmatic movement; severe restrictive lung disease and major chest wall deformities are contraindications to pacing. In addition, it is crucial that the patient be cooperative and motivated and have adequate support from nursing staff and family.

Phrenic nerve pacing involves the use of an extracorporeal generator with an antenna that transmits radiofrequency signals to a subcutaneous radio receiver; the receiver then translates the radiofrequency signal into direct current, which is delivered through electrodes to the phrenic nerves. The electrodes are placed on the phrenic nerves via bilateral anterior thoracotomies or neck incisions. Several different commercial pacing systems are available, but they all work according to the same basic concept.

Phrenic nerve pacing remains a relatively rare procedure. The largest series published to date included 165 patients, of whom 27% were paced on a full-time basis and 63% on a part-time basis.²⁵ Phrenic nerve pacing met the ventilatory requirements of 47% of the patients and was partially successful in 36%.

Discussion

Diaphragmatic Anatomy

For the purposes of discussion, the diaphragm may usefully be divided into left and right hemidiaphragms. In anatomic terms, the diaphragm is a dome-shaped muscle that can be described as having both muscular and tendinous components. The muscular portion of the diaphragm is divided into three parts, each of which originates from one of the three structural elements forming the lower thoracic aperture: the pars lumbalis diaphragmatis (originating from the lumbar spine), the pars costalis diaphragmatis (from the ribs), and the pars sternalis diaphragmatis (from the sternum). The pars lumbalis is the most powerful region of the diaphragm.²⁶ All three parts insert into a central aponeurosis known as the central tendon. This tendon has a cloverleaf shape, with one leaf directed anteriorly and two leaves directed laterally (one into each hemithorax).

The diaphragm possesses three major apertures, which allow passage of the inferior vena cava, the esophagus, and the aorta. The caval orifice is located in the right portion of the central tendon, typically at the level of T8. Diaphragmatic contraction stretches this orifice and may facilitate the return of blood to the heart during inspiration. The right phrenic nerve and some lymphatic vessels also pass through this orifice. The esophageal hiatus is located behind the central tendon at the level of T10. This aperture, unlike the other two, is ventrally framed by muscle. The aortic opening is anterior to T12, between the crura and behind the median arcuate ligament. The aortic opening also allows passage of the azygos vein, the thoracic duct, and lymphatic channels as they descend from the thorax into the abdomen.

The arterial supply to the cranial surface of the diaphragm consists of the pericardiophrenic, musculophrenic, and superior phrenic arteries. The posterior aspect of the diaphragm is supplied by small direct branches from the aorta. The caudal surface of the diaphragm is supplied by the inferior phrenic arteries, which arise from the aorta or the celiac trunk; these arteries are much larger than the superior phrenic arteries. Occasionally, the right inferior phrenic artery originates from the right renal artery.²⁷ The venous drainage from the diaphragm mirrors the arterial supply.

The left and right phrenic nerves arise from the C3–C5 nerve roots and travel a distance of 30 to 40 cm between their cervical origin and their termination on the surface of the diaphragm. A firm understanding of the anatomy of the phrenic nerves is crucial for the thoracic surgeon because iatrogenic injury during operation is a leading cause of diaphragmatic paralysis. Both nerves originate on the middle scalene muscle and cross to the anterior scalene muscle, where they descend within an investment of fascia. At the base of the neck, the left phrenic nerve crosses the thoracic duct, descending into the thorax on the anterior surface of the left subclavian artery. It then travels between the left common carotid and subclavian arteries, crosses in front of the vagus nerve, and passes lateral to the aortic arch, where it descends along the pericardium to a point just above the diaphragm. At the thoracic inlet, the right phrenic nerve is located behind the innominate vein and usually crosses in front of the internal mammary artery. It descends to the right of the innominate vein and the superior vena cava before reaching the pericardium, anterior to the lung. Finally, the right phrenic nerve descends along the inferior vena cava toward the diaphragm. Both phrenic nerves branch just proximal to the diaphragm, and small terminal branches innervate the muscle.

Normal Diaphragmatic Function

The diaphragm is the most important respiratory muscle. During inspiration, the diaphragm contracts and moves caudally in a pistonlike fashion. This motion forces the abdominal contents down and forward, increasing the vertical dimension of the chest cavity. In addition, the ribs lift the lateral aspect of the diaphragm during inspiration, causing the transverse diameter of the thorax to increase. As the diaphragm contracts, pleural pressure decreases, facilitating lung inflation. Normal diaphragmatic function accounts for 75% of air movement during normal respiration and is responsible for 60% of minute volume in the supine position. Diaphragmatic excursion averages about 1 cm during normal tidal breathing, but it can increase to 10 cm during forced inspiration and expiration.²⁸

4 OPEN ESOPHAGEAL PROCEDURES

John Yee, M.D., F.R.C.S.C., and Richard J. Finley, M.D., F.A.C.S., F.R.C.S.C.

The remarkable developments in diagnosis, imaging, and surgical treatment of esophageal diseases over the past 15 years have resulted in markedly better patient outcomes: the morbidity and mortality associated with surgery of the esophagus have been substantially reduced. In particular, the operative techniques employed to treat esophageal disease have advanced considerably, as a result of an improved understanding of esophageal anatomy and physiology and the successful introduction of minimally invasive approaches to the esophagus [see 4:5 *Minimally Invasive Esophageal Procedures*]. For a number of diseases (e.g., achalasia), minimally invasive procedures have proved to be as effective as their open counterparts while causing less postoperative morbidity. The growing stature of minimally invasive approaches does not, however, diminish the importance of the equivalent open approaches. In this chapter, we describe common open operations performed to excise Zenker's diverticulum, to manage complex gastroesophageal reflux disease (GERD), and to resect esophageal and proximal gastric tumors.

General Preoperative Considerations

METHODS OF PATIENT ASSESSMENT

The functional results achieved with esophageal procedures become more predictable when the approach to preoperative patient evaluation is precise and reproducible. The ciné barium swallow remains the most cost-effective method for initial evaluation of esophageal anatomy and function. It should be employed before endoscopy because the results may direct the endoscopist's attention to particular areas of concern. For example, a finding of abnormal angulation or strictures indicates that the endoscopist should either use a pediatric-caliber endoscope or exercise more caution in passing a standard adult endoscope. In addition, endoscopic examination alone is often insufficient for assessing esophageal motility disorders or defining the complex anatomy of a paraesophageal hiatal hernia.

Endoscopic ultrasonography (EUS) is an extension of the visual mucosal examination. The information it can provide about the extension of mass lesions beyond the confines of the esophageal wall is helpful in planning surgical resection. In addition, EUS can differentiate benign stromal tumors from cystic or malignant neoplasms on the basis of characteristic echogenicity patterns. The combination of EUS and computed tomography permits highly precise anatomic assessment of esophageal neoplasms, definition of the extent of local invasion, and identification of regional metastases.

Functional imaging with photodynamic or vital staining allows accurate diagnosis of dysplastic or malignant mucosal lesions in their earliest stages. Positron emission tomography (PET) yields similar results by localizing metabolically active tissue regionally or at distant sites. The combination of morphologic data from high-resolution CT and functional data from PET is particularly effective for identifying occult metastases that would preclude curative resection for esophageal cancer.

Esophageal manometry, 24-hour esophageal pH testing, and

nuclear studies for assessment of esophageal and gastric transit provide functional data that can facilitate the diagnosis and treatment of GERD, achalasia, and other disorders of the esophagus. They are useful complements to standard investigations (e.g., ciné barium swallow and endoscopy).

Complete preoperative investigation of all patients, even those with classic histories and physical findings, is mandatory. The data from anatomic and functional testing allow the surgeon to plan the operation more appropriately and effectively (e.g., deciding on the need for esophageal lengthening in patients with paraesophageal hernias or choosing between a complete and a partial fundoplication in patients with hernias associated with varying degrees of esophageal dysmotility).

OPTIMIZATION OF PATIENT HEALTH STATUS

Patients with obstructing esophageal diseases are often elderly, debilitated, and malnourished. Although months of insufficient nutrition cannot be corrected in the space of a few hours, anemia, dehydration, and electrolyte abnormalities can be mitigated by means of intravenous support and appropriate laboratory monitoring. If esophageal obstruction prevents oral intake, endoscopic dilation of the stricture, accompanied by either nasogastric intubation or percutaneous endoscopic gastrostomy (PEG) [see 5:18 *Gastrointestinal Endoscopy*], is indicated; the patient should then be able to resume at least a liquid diet. If weight loss has exceeded 10%, enteral nutrition, comprising at least 2,000 kcal/day of a high-protein liquid diet, should be administered for at least 10 days before the operation. Cardiovascular, renal, hepatic, and respiratory function should be documented and optimized. If the patient is aspirating, the esophagus should be evacuated and the patient should be given nothing by mouth until after the operation. Aspiration pneumonia should always be corrected preoperatively.

Cricopharyngeal Myotomy and Excision of Zenker's Diverticulum

PREOPERATIVE EVALUATION

Patients who are candidates for cricopharyngeal myotomy usually present with difficulty initiating swallowing, cervical dysphagia or odynophagia [see 4:1 *Dysphagia*], and a history of pulmonary aspiration. These symptoms of cricopharyngeal dysfunction may or may not be associated with a Zenker's diverticulum. Ciné contrast studies may reveal poor pharyngeal contractility, pulmonary or nasal aspiration, abnormalities of the upper esophageal sphincter, pharyngeal pouches, or other structural abnormalities in the distal esophagus. Barium is the usual contrast agent, but if aspiration is suspected, a nonionic contrast agent can be used instead to prevent pneumonitis.

Zenker's diverticulum is a pulsion diverticulum that arises adjacent to the inferior pharyngeal constrictor, between the oblique fibers of the posterior pharyngeal constrictors and the cricopharyngeus muscle. This mucosal outpouching results from a transient incomplete opening of the upper esophageal sphinc-

Figure 1 Cricopharyngeal myotomy and excision of Zenker's diverticulum. A soft roll is placed behind the shoulders to extend the neck. The head is turned to the side opposite the incision. The cricoid cartilage is palpated and marked. The skin is incised obliquely along the sternocleidomastoid muscle, as shown, or transversely in a skin crease at the level of the cricoid.

ter. The diverticulum ultimately enlarges, drapes over the cricopharyngeus, and dissects behind the esophagus into the prevertebral space. The pouch usually deviates to one side or the other; accordingly, the side on which the deviation occurs must be determined by means of a barium swallow so that the appropriate operative approach can be selected. Esophageal motility studies may show either incomplete upper esophageal relaxation on swallowing or poor coordination of the upper esophageal relaxation phase with pharyngeal contractions. Upper GI endoscopy is performed preoperatively to exclude the presence of a pharyngeal or esophageal carcinoma and to assess the upper GI anatomy. If there is evidence of GERD, proton pump inhibitors (PPIs) are given.

In symptomatic patients (e.g., those with dysphagia, nocturnal cough, or recurrent pneumonia from aspiration), surgical therapy is indicated regardless of whether a pouch is present or how large it may be. Such treatment involves correcting the underlying cricopharyngeal muscle dysfunction with a cricopharyngeal myotomy. If there is a diverticulum larger than 2 cm, it should be excised in addition to the cricopharyngeal myotomy. Alternatively, the diverticulum may be managed via endoscopic obliteration of the common wall between the pharyngeal pouch and the esophagus with either a stapler or a laser. Cricopharyngeal incoordination may be temporarily relieved by injecting botulinum toxin into the cricopharyngeus.

OPERATIVE PLANNING

The patient is placed on a clear fluid diet for 2 days before the operation. With the patient under general anesthesia, the trachea is intubated with a single-lumen endotracheal tube. Cricoid pressure is applied to prevent aspiration of diverticular contents. A soft

roll is placed behind the shoulders to extend the neck. The patient is placed in a 20° reverse Trendelenburg position, and the legs are wrapped with pneumatic calf compressors to prevent deep vein thrombosis (DVT). With the endotracheal tube placed to the left side of the mouth, a preliminary flexible esophagogastroscopy is performed to empty the diverticulum of all food and to examine the esophagus and the stomach. The scope is then brought back up into the oropharynx and moved into the pouch. The location of the diverticulum (on the left or the right side) is confirmed by turning off the room lights and noting which side is transilluminated by the gastroscope.

OPERATIVE TECHNIQUE

Step 1: Incision and Dissection of Pharyngeal Pouch

The patient lies with the head turned away from the side on which the incision is made. The cricoid cartilage is palpated and marked. A 4 cm skin incision is made, either obliquely along the sternocleidomastoid muscle [see Figure 1] or transversely in a skin crease at the level of the cricoid. The platysma is divided in the same line. Self-retaining retractors are inserted. The anterior border of the sternocleidomastoid muscle is incised throughout its length. The omohyoid muscle and the sternohyoid and sternothyroid muscles are retracted [see Figure 2]. The sternocleidomastoid muscle is retracted laterally to expose the carotid sheath and the internal jugular vein. The middle thyroid vein is ligated and divided, and the thyroid gland and the trachea are retracted medially by the assistant's finger to minimize the risk of injury to the underlying recurrent laryngeal nerve. There is no need to encircle the esophagus or to dissect in the tracheoesophageal groove. The deep cervical fascia is divided. The inferior thyroid artery is divided as laterally as possible. The carotid sheath is retracted laterally, and

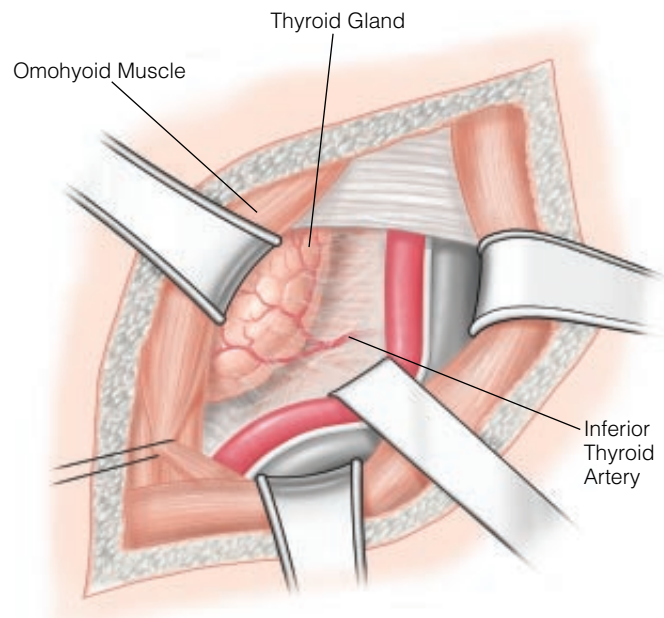

Figure 2 Cricopharyngeal myotomy and excision of Zenker's diverticulum. The sternocleidomastoid is incised along the anterior border so as to expose the omohyoid muscle and the sternohyoid and sternothyroid muscles, which are retracted. The thyroid gland and the trachea are retracted medially by the assistant's finger, and the inferior thyroid artery is ligated and divided laterally to avoid injury to the recurrent laryngeal nerve.

Figure 3 Cricopharyngeal myotomy and excision of Zenker's diverticulum. (a) The diverticulum is dissected away from the esophagus, and an esophageal myotomy is started approximately 3 cm below the cricopharyngeus. The myotomy is continued proximally through the cricopharyngeus, and the muscle around the diverticulum is freed. (b) A linear stapler is placed at the base of the sac and pressed firmly against the esophagoscope. The stapler is fired, and the diverticulum is excised.

dissection is carried down to the prevertebral fascia [see Figure 2]. The endoscope placed in the diverticulum is palpated, and the pouch is dissected away from the cervical esophagus up as far as the pharygoesophageal junction. The flexible endoscope is then removed from the pouch and advanced into the thoracic esophagus so that it can be used as a stent for the cricopharyngeal myotomy. Dissection of the pharyngeal pouch is then completed.

Step 2: Myotomy

The esophageal myotomy is started approximately 3 cm below the cricopharyngeus on the posterolateral esophageal wall [see Figure 3a]. The esophageal muscle is divided down to the mucosa, which is recognizable from its bluish coloration with the submucosal plexus overlying it. The esophageal muscle is dissected away from the mucosa with a right-angle dissector and divided with a low-intensity diathermy unit. The myotomy is then continued proximally through the cricopharyngeus and up into the muscular wall of the hypopharynx for 2 cm if there is no diverticulum present. The hypopharynx is distinguished by a pronounced submucosal venous plexus. The muscle is then swept off the mucosa for 120°.

Step 3: Freeing or Excision of Diverticulum

If there is a diverticulum less than 2 cm in diameter, the cricopharyngeus is transected and the muscularis around the diverticulum is freed. The myotomy is extended onto the hypopharynx for 2 cm. The diverticulum may be suspended to the back wall of the pharynx. It should not be sutured to the prevertebral fascia, because the passage of sutures through the diverticulum can contaminate the fascia, leading to an increased risk of fascial infection.

If the diverticulum is more than 2 cm in diameter, it is excised with a linear stapler loaded with 2.5 mm staples, which is placed at the base of the sac and pressed firmly against the esophagoscope [see Figure 3b]. Particular care must be taken at this point so as not

to injure the recurrent laryngeal nerve. The stapler is fired, and the diverticulum is excised. The staple line is cleaned with an antiseptic solution, and the incision is filled with saline. The esophagus is insufflated with air to determine whether mucosal leakage has occurred, and the esophagoscope is removed; any mucosal leaks found are closed with fine absorbable sutures. In the absence of a stapler, the best way of excising the sac is to make a series of short incisions through the neck of the sac with scissors, suturing the edges after each cut with absorbable monofilament sutures (the so-called cut-and-sew technique). The esophagoscope ensures that the esophageal lumen is not narrowed.

Step 4: Drainage and Closure

Once hemostasis has been achieved, a short vacuum drain is placed through the skin into the retroesophageal space. The platysma is repaired with absorbable sutures, and the skin is closed with a subcuticular absorbable suture. Nasogastric intubation is unnecessary. Prokinetic agents and PPIs are administered to prevent gastroesophageal reflux. A water-soluble contrast study is done on the day of the operation. If the results are normal, the patient is started on a liquid diet, and the drain is removed on postoperative day 1, when the patient is discharged.

COMPLICATIONS

The main complications associated with cricopharyngeal myotomy are recurrent laryngeal nerve trauma (occurring in 0.5% of cases), fistulas (1%), hematoma formation, infection (2%), aspiration, and recurrence (4%). Hematomas and infections must be drained promptly. Fistulas usually close once the prevertebral space is drained and the associated infection controlled. Aspiration is the most serious complication after cricopharyngeal myotomy. Gastroesophageal reflux may contribute to oropharyngeal dysphagia. Division of the upper esophageal sphincter in a patient with an incompetent esophagogastric junction may lead to massive tracheobronchial aspiration. Therefore, documented gastroesophageal reflux, gas-

troesophageal regurgitation, and severe distal esophagitis may be relative contraindications to cricopharyngeal myotomy until the lower esophageal sphincter defect has been remedied with an anti-reflux operation.

OUTCOME EVALUATION

Of patients with a Zenker's diverticulum, at least 90% experience excellent results from surgical treatment. Of patients without a Zenker's diverticulum, one third experience excellent results, another third show moderate improvement, and the remaining third show no improvement.¹ Patients with poor pharyngeal contractility in conjunction with normal upper esophageal sphincter function show little improvement with cricopharyngeal myotomy. Patients with oropharyngeal dysphagia secondary to neurologic involvement who have intact voluntary deglutination, adequate pulsion of the tongue, and normal phonation may show improvement with cricopharyngeal myotomy. Appropriate selection of patients for cricopharyngeal myotomy leads to better surgical outcomes.

Transthoracic Hiatal Hernia Repair

Unlike most operations on the esophagus, which are extirpative procedures, hiatal hernia repair with fundoplication is a reconstructive procedure, the aim of which is to restore a high-pressure zone at the esophagogastric junction that prevents reflux but also permits comfortable swallowing. Currently, this repair is often accomplished via minimally invasive approaches; however, such approaches may be hampered by significant perceptual and motor limitations, such as loss of stereopsis, reduced tactile feedback, and decreased range of motion for the instruments. The degree of tension on the hiatal repair sutures, the quality of the crural tissue itself, and the caliber of the esophageal hiatus after repair all must be assessed. In certain patients, laparoscopic reconstruction of a competent gastroesophageal high-pressure zone may be very difficult and may demand a degree of tactile sensitivity that is not yet achievable via video laparoscopy.

The long-term success of antireflux surgery, whether done via the transthoracic approach or by means of laparoscopy, depends on three factors: (1) a tension-free repair that maintains a 4 cm long segment of esophagus in the intra-abdominal position, (2) durable approximation of the diaphragmatic crura, and (3) correct matching of the fundoplication technique chosen to the peristaltic function of the esophagus. The transthoracic approach should be considered whenever the standard abdominal approaches to hiatal hernia repair carry an increased risk of failure or complication—for example, in patients who have a foreshortened esophagus associated with a massive hernia and an incarcerated intrathoracic stomach, patients with severe peptic strictures of the esophagus, patients in whom the hiatal hernia coexists with an esophageal motility disorder or morbid obesity, and patients who have undergone multiple previous abdominal operations. The transthoracic repair is particularly useful when a previous open abdominal procedure has failed. In this situation, the reasons for such failure, whether technical or tissue-related, should be assessed so that a compensatory strategy can be devised.

PREOPERATIVE EVALUATION

Symptomatic Evaluation

All patients being considered for fundoplication to treat GERD must undergo a comprehensive evaluation to determine whether there is indeed an anatomic substrate for their symptoms and what

the most appropriate form of repair is. Specifically, a history of heartburn and effortless regurgitation should be sought. Dysphagia and odynophagia are not typically associated with hiatal hernia unless there is a significant paraesophageal component. Persistent dysphagia may reflect the presence of a stricture or a neoplasm [*see 4:1 Dysphagia*]. Reflux-induced esophageal spasm may present with occasional episodes of cervical dysphagia, but the transient nature of the symptoms easily differentiates this condition from dysphagia caused by a fixed obstruction. Chest pain that radiates toward the back after meals and is relieved by nonbilious vomiting may indicate the presence of an incarcerated intrathoracic stomach that is hindering the emptying of the paraesophageal component. Atypical chest pain from cholelithiasis, peptic ulcer, or coronary artery disease may confound the diagnosis.

Imaging

Radiographic investigation should begin with a ciné barium swallow, which will yield valuable information regarding the length of the esophagus, its peristaltic function, and the integrity of the mucosal surface. The gastric views can be used for qualitative assessment of distal emptying. Any paraesophageal component will be clearly demonstrated, along with any associated organoaxial volvulus. A simple barium swallow often yields the most useful information for managing the complex problem of recurrent hiatal hernia and a slipped Nissen fundoplication.

Next, esophagogastrosopy should be performed to examine the mucosa for the presence of esophagitis, Barrett's mucosa, stricture, or malignancy. The locations of any lesions observed, along with the position of the squamocolumnar junction, should be carefully documented in terms of their distance from the incisors. All strictures must undergo cup or brush biopsy to rule out an occult malignancy. The presence of severe esophagitis raises the possibility of acquired shortening of the esophagus secondary to transmural inflammation and contraction scarring. Every effort should be made to measure the length of the esophagus accurately.

Dilation

If a stricture is found during esophagoscopy, a decision must be made about whether to attempt esophageal dilation. This procedure carries the risk of perforation and should be performed only after careful consideration. If the stricture is diagnosed at the time of the initial endoscopic examination, it is advisable to perform only the brush biopsy at this point, deferring dilation to a subsequent visit. Delaying dilation gives the surgeon time to reassess the anatomy depicted on the barium swallow, to decide whether wire-guided dilation is necessitated by angulation of the esophagus, to obtain informed consent, to assemble the requisite equipment, and to plan sedation for what is often an uncomfortable procedure. If a malignancy is suspected at the time of the initial endoscopic examination, dilation should be avoided. In this situation, repair is impossible; thus, if iatrogenic perforation of a malignant stricture occurs, the surgeon will have to attempt emergency resection in an inadequately prepared patient in whom proper staging is unlikely to have been completed.

The standard flexible adult esophagoscope is approximately 32 French in caliber. In advancing the scope into the stricture, only very gentle pressure should be necessary. As a rule, a mild stricture that is not associated with steep angulation of the esophagus will readily accept passage of the endoscope and will be amenable to subsequent blind dilation with Hurst-Maloney bougies.

After successful passage, the scope is removed, and sequential insertion of progressively larger dilators (starting at 32 French) into the stricture is attempted. The weight of the dilator alone should be

sufficient to effect its passage, with little or no forward force applied. Although the patient will be able to swallow comfortably only after satisfactory passage of a dilator at least 48 French in caliber, it is essential never to try to force passage. To this end, the surgeon must take careful note of the subtle signs of increasing resistance transmitted through the dilator. Sequential dilation should be stopped whenever significant resistance is encountered or blood streaks appear on the dilator. Sudden pain during dilation is an ominous sign and calls for immediate investigation with a swallow study using a water-soluble contrast agent (e.g., Gastrografin; Schering AG, Berlin, Germany). Subcutaneous emphysema in the neck or mediastinal air on a plain chest radiograph may also indicate an injury to the esophagus. Perforation must be definitively ruled out before the patient can be discharged.

Highly stenotic strictures that do not allow the passage of a standard adult endoscope may be associated with a distorted and a steeply angulated esophagus. In such cases, the use of a pediatric endoscope may permit directed placement of a guide wire through the stricture; fluoroscopy is a useful adjunct for this purpose. A series of progressively larger Savary-Gillard dilators may then be passed over the guide wire to enlarge the lumen and allow subsequent endoscopic biopsy. As a rule, much less tactile feedback is available during wire-guided dilation than during passage of standard Maloney-Hurst bougies. Increased pressure is required to pass the Savary-Gillard dilators because of the resistance caused by the wire passing through the dilator itself. It is essential that the wire be well lubricated and not be allowed to dislodge proximally between the sequential insertions of progressively larger dilators. The caveats that apply to blind dilation also apply to wire-guided dilation.

Patients whose esophagus can be dilated to 48 French and who are candidates for antireflux surgery may undergo subsequent intraoperative dilation to 54 to 60 French. Patients who cannot be dilated to 48 French and fail to achieve comfortable swallowing should be classified as having a non-dilatable stricture and should be considered for transhiatal esophagectomy [see Resection of Esophagus and Proximal Stomach, *below*].

Functional Evaluation

Esophageal manometry permits quantitative assessment of peristalsis, a capability that is critically important for determining which type of fundoplication is most suitable for reconstructing a nonoccluding high-pressure zone at the esophagogastric junction. Stationary pH tests measure the capacity of the esophagus to clear acid, its sensitivity to instilled acid, the relationship of reflux episodes to body position, and the correlation between changes in esophageal pH and the subjective symptoms of heartburn. Ambulatory 24-hour pH testing allows further quantification of reflux episodes with respect to duration, frequency, and association with patient symptoms.

OPERATIVE PLANNING

The transthoracic hiatus hernia repair may be completed with either a partial fundoplication (as in the 240° Belsey Mark IV procedure) or a complete fundoplication (as in the 360° Nissen procedure). Acquired shortening of the esophagus may necessitate lengthening of the esophagus by means of a Collis gastroplasty, in which the portion of the gastric cardia along the lesser curvature and directly contiguous to the distal esophagus is fashioned into a tube [see Operative Technique, Step 6a, *below*].

A thoracic epidural catheter is placed for regional analgesia. General anesthesia is administered, and flexible esophagoscopy is

performed by the operating team. Insufflation should be done with as little air as is practical, particularly in the case of large paraesophageal hernias. The extent of the pathologic condition is documented and the absence of malignancy verified. The stomach is decompressed with suction, and the endoscope is removed. An orogastric tube is placed while the patient is supine.

Tracheal intubation is performed with either a standard single-lumen endotracheal tube or a double-lumen tube. The former requires that the ventilated left lung be retracted cephalad with moist packs during the procedure; the latter allows lung isolation and is preferred by some surgeons. A Foley catheter is placed; central venous access generally is not required. Subcutaneous heparin is administered for DVT prophylaxis, and pneumatic calf compression devices are applied. Antibiotic prophylaxis is provided [see 1:2 *Prevention of Postoperative Infection*].

The patient is positioned for a left thoracotomy. The table is flexed to distract the ribs. An axillary roll is placed to protect the right brachial plexus. The right leg is bent at hip and knee while the left leg is kept straight. Pillows are placed between the legs, and all pressure points are padded. The arms are positioned so that the humeri are at right angles to the chest and the elbows are bent 90°.

OPERATIVE TECHNIQUE

Step 1: Incision and Entry into Chest

A standard left posterolateral thoracotomy is performed. The latissimus dorsi is divided. The serratus fascia is incised, but the muscle itself can generally be preserved. For most patients, the sixth interspace is the most appropriate incision site for exposing the hiatus. The seventh interspace can also be used, particularly if the patient is tall or has a hyperextended chest as a result of chronic pulmonary disease. The paraspinal muscles are elevated away from the posterior aspect of the adjacent ribs, and a 1 cm segment of the rib below the selected interspace is resected to facilitate exposure. The chest is then entered, and the lung and the pleural space are thoroughly inspected. The leaves of the retractor are spread slowly over the course of the next several minutes so as not to cause iatrogenic rib fractures.

Step 2: Mobilization of Esophagus and Excision of Hernia Sac

The inferior pulmonary ligament is divided with the electrocautery to the level of the inferior pulmonary vein [see *Figure 4*]. The mediastinal pleura overlying the esophagus is longitudinally incised to expose the esophagus from the level of the carina to the diaphragm. Particular care is taken to avoid injury to the vagi. Vessels supplying the esophagus and arising from the adjacent aorta are cauterized and divided. A few larger vessels may have to be ligated with 2-0 silk. The esophagus is encircled just below the inferior pulmonary vein with a wide Penrose drain [see *Figure 4*]. The two vagi are mobilized and carried with the esophagus. (The right vagus is located along the right anterior border of the descending aorta and can easily be missed.)

The esophagus is then elevated, and mobilization is circumferentially completed in the direction of the diaphragm, starting from the level of the carina. In cases of giant paraesophageal hernia or reoperation for a failed repair, the stomach will have a large intrathoracic component. Dissection continues inferiorly to separate the sac from the pericardium anteriorly and the aorta posteriorly. The right pleura is closely approximated to the esophagus for 2 to 5 cm above the diaphragm; in the presence of a substantial hiatal hernia and its sac, it may be difficult to identify. The right pleura should be gently dissected away from the sac without entry into

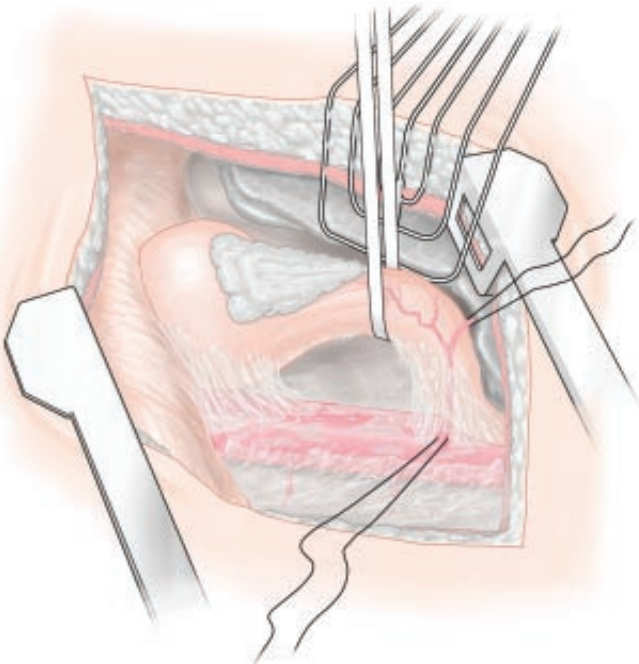

Figure 4 Transthoracic hiatal hernia repair. The lung is retracted, and the inferior pulmonary ligament is divided to the level of the inferior pulmonary vein. The mediastinal pleura overlying the esophagus is incised to expose the esophagus from the level of the carina to the diaphragm. The esophagus and both vagi are encircled just below the inferior pulmonary vein with a Penrose drain. Vessels supplying the esophagus and arising from the adjacent aorta are ligated and divided.

the right chest. This can generally be done with a small sponge on a stick. If a tear occurs, it should be closed with absorbable suture material to prevent accumulation of blood and fluid on the right side during the operation.

Dissection is continued inferiorly to expose the right and left crura. The left crus is generally more robust and is certain to be easily seen with this exposure. Its medial fibers may be attenuated and may blend into the hernia sac superiorly. The sac should be incised 1 cm above the muscle fibers because the muscle alone will not hold sutures well for the subsequent repair. Skeletonization of the crural muscle must be avoided; it is the fibroconnective tissue that provides the most tensile strength. The hernia sac is dissected away from the left crus in an anterior-to-posterior direction. The right crus is generally less robust than the left. In the case of a previous failed repair, the right crus may be very difficult to see, being obscured from the operator's view by the intrathoracic stomach. Dissection of the right crus is best accomplished in a posterior-to-anterior direction.

Once the sac is circumferentially freed from the crura, dissection proceeds cephalad along the esophagus. To minimize the risk of vagal injury, the sac should be incised parallel to the esophagus.

Step 3: Division of Phrenoesophageal Membrane and Gastrohepatic Ligament

The esophagus is retracted anteriorly to expose the posteriorly located phrenoesophageal membrane, which is then divided to yield entry into the lesser sac. The remainder of the phrenoesophageal membrane is elevated with a right-angle clamp as it courses anteriorly, yielding a view of the spleen below. The esophagus and the stomach are thus completely mobilized from the left crus. The esophageal branch of the left phrenic artery, visible near the left vagus, is divided near the crus.

The uppermost portion of the gastrohepatic ligament is found along the undersurface of the right crus. It is divided with the electrocautery. Belsey's artery, a communicating branch between the left gastric artery and the inferior phrenic artery, lies in this area and may have to be ligated directly. It is vital to divide the gastrohepatic ligament down to the level of the left gastric artery. The caudate lobe of the liver must be clearly visible beneath the right crus. This opening is essential for subsequent passage of the fundoplication wrap behind the esophagus.

Step 4: Mobilization of the Stomach

The highest short gastric arteries are ligated between ties to permit mobilization of the fundus. Excessive traction must be avoided to prevent splenic injury. Three or four vessels are usually divided. The esophagogastric junction is elevated well into the chest, and any organoaxial rotation of the stomach is released as the short gastric vessels are divided. It is crucial that ligation be limited to the vessels along the greater curvature. Inadvertent ligation of the vessels along the lesser curvature can easily occur, especially if there was a previous operation. Loss of blood supply from the branches of the left gastric artery along the lesser curvature will lead to ischemia of the Collis gastroplasty tube and will predispose to either leakage at the staple line or subsequent stricture formation.

In the case of a redo repair, the previous fundoplication often will have slipped down onto the cardia or even onto the body of the stomach. Generally, the inner aspect of the previous fundoplication can be freed from the esophagus without any difficulty; rarely will any major dissection have been done in this area during the original operation. The vagi will be found within the wrap and should be specifically visualized. Because of scarring, it may be difficult to see the point at which the previous fundoplication attaches to itself. Not uncommonly, a serosal tear develops on the fundus as the wrap is undone. Any areas of concern can be reinforced

Figure 5 Transthoracic hiatal hernia repair. The esophagogastric junction is mobilized by dividing the phrenoesophageal ligament and some short gastric vessels. No. 1 silk sutures are passed through the exterior aspect of the right crus (with care taken to avoid the adjacent inferior vena cava) and through the left crus (with care taken to avoid the spleen).

with a simple stitch of 4-0 silk. Mobilization is complete when the fundus is restored to its original anatomic position and the greater curvature can be followed down to the left gastroepiploic artery.

Step 5: Closure of Crura

Because the right crus is often quite attenuated, it is crucial to incorporate an adequate amount of tissue into the repair. An Allis or Babcock clamp is placed at the apex of the hiatus and into the central tendon so that both crura can be placed under tension. The esophagus is retracted anteriorly, and a No. 1 silk suture is passed through the most posterior aspect of the left crus, with care taken to avoid the adjacent spleen [see Figure 5]. A notched spoon retractor is placed through the hiatus and into the abdomen behind the left crus. The spleen is thus protected while the suture is brought through the left crus.

Next, the suture is brought out through the right crus, with care taken to prevent injury to the aorta or entry through the right pleura. Three to five crural repair stitches are then placed at 1 cm intervals, from posterior to anterior. The sutures should be staggered slightly so that the needle entry points are not all in a straight line; this measure helps prevent longitudinal shredding of the muscle fibers when the sutures are placed under tension. The sutures are held together with hemostats but left untied at this point in the operation.

Placement of traction on the last suture should close the defect while still allowing easy passage of one finger along the esophagus. The final decision on whether to tie this last suture or to cut it out is made later, after construction of the fundoplication. It is better to err on the side of an overly narrow opening; removing a suture is easier than having to place an extra one at a time when exposure is less than optimal.

Step 6: Assessment of Esophageal Length and Removal of Anterior Fat Pad

After placement of the crural stitches, an assessment of the esophageal length is made. Ideally, the stomach can easily be reduced into the abdomen without placing tension on the thoracic esophagus. When esophageal foreshortening is found, a Collis gastroplasty is performed [see Step 6a, below].

If an esophageal stricture is present, the assistant performs dilation by passing a tapered bougie orally while the surgeon supports the esophagus. The anteriorly located esophageal fat pad is removed in anticipation of the gastroplasty, with care taken not to injure the vagi located on either side [see Figure 6].

Step 6a: Collis Gastroplasty

In a Collis gastroplasty for a short esophagus, a stapler is used to form a 4 to 5 cm neoesophagus out of the proximal stomach, thereby effectively lengthening the esophagus and transposing the esophagogastric junction more distally. A large-caliber Maloney bougie (54 French for women, 56 French for men) is placed in the esophagus to prevent narrowing of the lumen as the stapler is fired. The bougie is advanced well into the stomach so that its widest portion rests at the esophagogastric junction. The bougie is held against the lesser curvature, and the fundus is retracted away at a right angle to the esophagus with a Babcock clamp. A 60 mm gastrointestinal anastomosis (GIA) stapler loaded with 3.5 mm staples is applied immediately alongside the bougie on the greater curvature side [see Figure 7a] and fired, simultaneously cutting and stapling the cardia. The staple line is oversewn with nonabsorbable 4-0 monofilament suture material on both sides [see Figure 7b]. Two metal clips are placed to mark the distal extent of the gastroplasty tube, denoting the new esophagogastric junction.

Figure 6 Transthoracic hiatal hernia repair. The anterior fat pad is removed from the esophagus with sharp dissection, with care taken to avoid injury to the vagi.

Step 7: Fundoplication and Reduction of Wrap into Abdomen

The fundus is passed posteriorly behind the esophagus and brought up against the anterior stomach, with care taken to avoid torsion of the fundal wrap. The fundus is then wrapped either over the lower 2 cm of the esophagus, if no gastroplasty was done, or over a 2 cm length of the gastroplasty tube while the bougie is in place. The seromuscular layer of the fundus is approximated to that of the esophagus or the gastroplasty tube and that of the adjacent anterior stomach with two interrupted 2-0 silk sutures [see Figure 8]. When tied, the wrap should still be loose enough to accommodate a finger alongside the esophagus. The fundoplication sutures are again oversewn with a continuous seromuscular nonabsorbable monofilament suture. Two clips are placed at the superior aspect of the wrap. These, along with the previously placed clips, help confirm both the length and the location of the wrap on chest x-ray.

Once the fundoplication is complete, the dilator is removed and the wrap is reduced into the abdomen. Two mattress sutures of 2-0 polypropylene are placed to secure the top of the fundoplication to the underside of the diaphragm. The crural sutures are then sequentially tied, from the most posterior one to the most anterior. When the final suture is tied, one finger should still be able to pass through the hiatus alongside the esophagus.

Step 8: Drainage and Closure

A nasogastric tube is passed into the stomach and secured. Hemostasis is verified, and a single thoracostomy tube is placed. The wound is closed in layers. A chest x-ray is performed to verify the position of the tubes and the location of the clips marking the wrap. The patient is then extubated in the OR and transported to the recovery area.

POSTOPERATIVE CARE

Patients typically remain in the hospital for 5 days. The nasogastric tube is left on low suction and removed on postoperative day 3. Patients then begin liquid oral intake, advancing to a full fluid

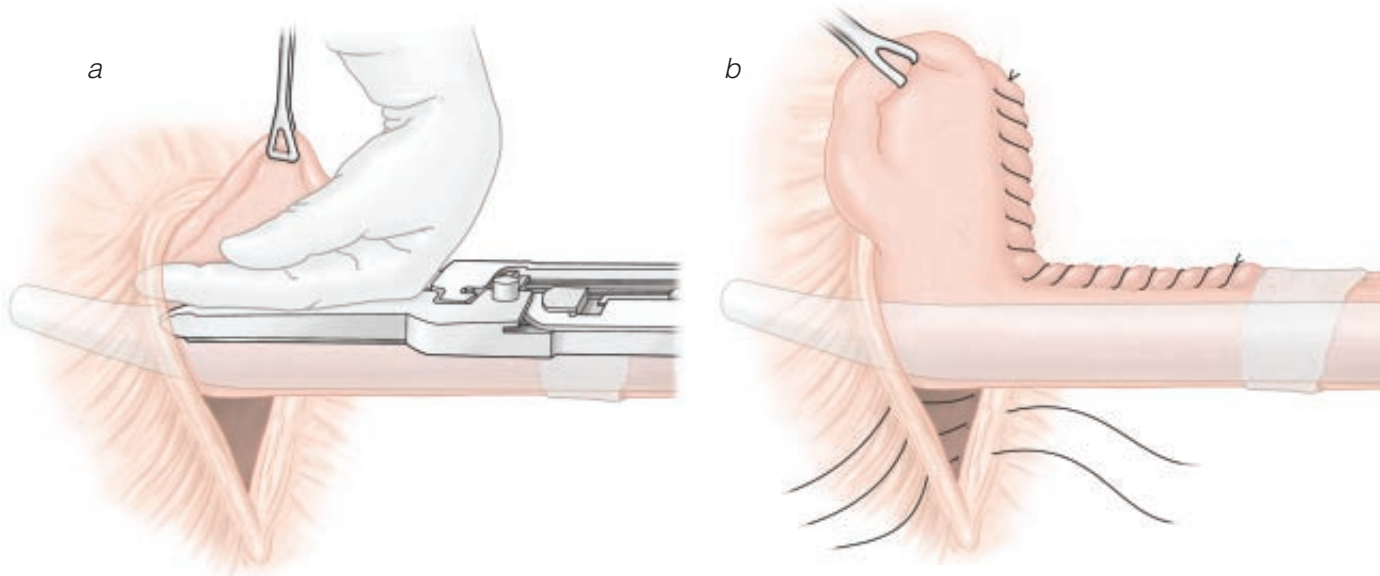

Figure 7 Transthoracic hiatal hernia repair. (a) If esophageal foreshortening is present, a Collis gastroplasty is performed. A 54 French Maloney bougie is inserted through the esophagogastric junction. A 4 to 5 cm neoesophagus is formed with a 60 mm GIA stapler loaded with 3.5 mm staples. (b) Both the fundal staple line and the lesser curvature staple line are oversewn with nonabsorbable monofilament suture.

diet as tolerated. Early ambulation is encouraged to prevent respiratory complications. Judicious use of analgesics and antiemetics minimizes nausea and vomiting. The thoracostomy tube is removed as drainage subsides. The epidural and Foley catheters are generally removed later the same day. A barium swallow is performed on postoperative day 5 to verify the position of the wrap, to ensure that there is no significant esophageal obstruction, and to provide a qualitative impression of gastric emptying. Gastroparesis secondary to vagal nerve dysfunction may be apparent.

Once patients can tolerate a soft solid diet, they are discharged home with instructions about the gradual resumption of a normal diet at home. Large meals and carbonated beverages should be avoided in the early postoperative period.

COMPLICATIONS

The root causes of the complications arising after transthoracic hiatal hernia repair are often technical; thus, the best prevention, in most cases, is meticulous surgical technique. Mobilization of the stomach with ligation of short gastric vessels may result in injury to the spleen. Injury to the vagi predisposes to gastric dysfunction, early satiety, and so-called gas-bloat syndrome. Poor crural approximation increases the chances that the repair will fail. Dehiscence allows upward migration of the wrap into the chest or the development of a paraesophageal hernia. The gastroplasty may leak at the staple line. Overzealous dissection along the lesser curvature can devascularize the cardia and cause ischemic stenosis of the gastroplasty tube. Torsion of the fundus results in perforation and sepsis. Excessive distraction of the ribs can lead to pain and splinting with subsequent atelectasis or pneumonia. Inadequate mobilization of the fundus may place excessive tension on the wrap and promote later disruption and recurrent reflux. A slipped Nissen can result when the wrap is inadequately fixed to the esophagus or the gastroplasty tube and the stomach telescopes through the intact fundoplication to assume an hourglass configuration. This event leads to varying degrees of heartburn, regurgitation, and dysphagia because the proximal pouch tends to empty slowly and remain distended after meals. A wrap that is too tight or too long results in persistent dysphagia.

Recurrent heartburn and regurgitation call for evaluation with contrast studies and esophagoscopy. The barium swallow is the most useful test for assessing whether the repair has failed. If there is an anatomic condition that is responsible for recurrent symptoms (e.g., slipping of the fundoplication or disruption of the crural repair), reoperation is usually necessary; continued medical treatment of symptoms related to a structural failure invariably proves to be of little use. A barium swallow may also identify gastroparesis secondary to vagal nerve injury. Nuclear transit studies for gastric emptying will help confirm this diagnosis. Dysphagia that is not

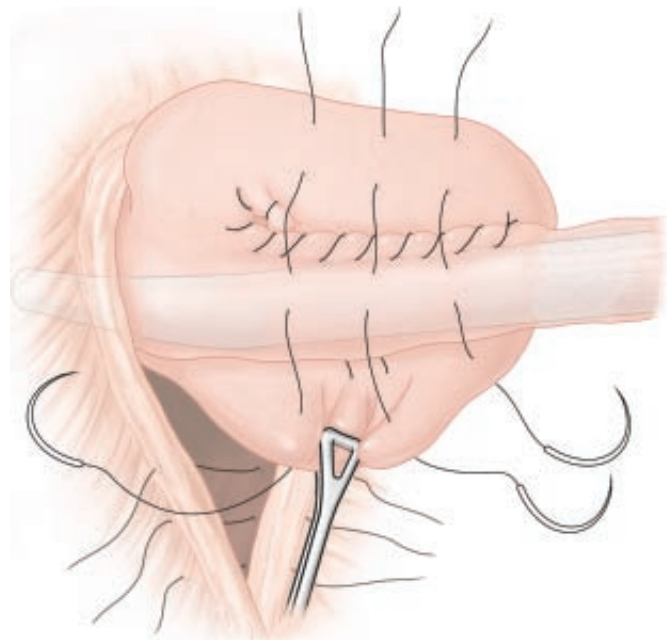

Figure 8 Transthoracic hiatal hernia repair. The fundus is passed behind the esophagus and sewn to the neoesophagus and the anterior stomach over a 2 cm length with interrupted 2.0 silk sutures.

related to recurrent reflux, ulceration, or stricture usually responds to dilation; reoperation is not required if the barium swallow shows contrast flowing through the esophagus and an intact wrap beneath the diaphragm. Given that patients with longstanding reflux are at higher risk for dysplasia and esophageal adenocarcinoma, it is important to perform endoscopy to rule out malignancy.

OUTCOME EVALUATION

Transthoracic hiatal hernia repair yields good to excellent results in more than 85% of patients undergoing a primary repair. Approximately 75% of patients who have previously undergone hiatal hernia repair experience symptomatic improvement.²

Resection of Esophagus and Proximal Stomach

In the remainder of the chapter, we describe the standard open techniques for resection of the esophagus and the esophagogastric junction. Transhiatal esophagectomy is commonly performed to treat end-stage benign esophageal disease and carcinomas of the cardia and the lower esophagus. Esophageal resection through a combined laparotomy–right thoracotomy approach is ideal for cancers of the middle and upper esophagus. The gastric conduit may be anastomosed to the cervical esophagus either high in the right chest (as in an Ivor-Lewis esophagectomy) or in the neck (as in a transhiatal esophagectomy). The left thoracoabdominal approach is rarely used but may be indicated for resection of the distal esophagus and the proximal stomach in the case of a bulky tumor that is locally aggressive.

PREOPERATIVE EVALUATION

Thorough preoperative preparation is essential for good postoperative outcome. Smoking cessation and a graded regimen of home exercise will help minimize postoperative complications and encourage early mobilization. Schematic diagrams have proved useful for educating patients and shaping their expectations about quality of life and ability to swallow after esophagectomy. Illustrations, by emphasizing the anatomic relations, greatly facilitate discussion of potential complications (e.g., hoarseness from recurrent laryngeal nerve injury, pneumothorax, anastomotic leakage, mediastinal bleeding, and splenic injury).

Potential postoperative problems (e.g., reflux, regurgitation, early satiety, dumping, and dysphagia) must be discussed before operation. Such discussion is particularly relevant for patients undergoing esophagectomy for early-stage malignant tumors or for high-grade dysplasia in Barrett's mucosa. These patients generally have no esophageal obstruction and may be completely asymptomatic; accordingly, their expectations about postoperative function may be quite different from those of patients with profound dysphagia secondary to near-complete esophageal occlusion. Support groups in which patients with upcoming operations can contact patients that have already undergone treatment have proved to be highly beneficial to all parties. Realistic expectations improve the chances of a satisfactory outcome.

Evaluation of Operative Risk

Preoperative assessment should include a thorough review of the patient's cardiopulmonary reserve and an estimate of the level of operative risk [see *ECP:4 Risk Stratification, Preoperative Testing, and Operative Planning*]. Spirometry, arterial blood gas analysis, and exercise stress testing should be considered. Even when a transhiatal esophagectomy without thoracotomy is planned, patients should be assessed with an eye to whether they can tolerate a laparotomy and a thoracotomy, in case the latter is made necessary by findings that

become apparent only at the time of operation. Thoracic epidural analgesia should be administered for pain control. If an Ivor-Lewis or thoracoabdominal approach is taken, a double-lumen endotracheal tube should be placed for separate lung ventilation.

Imaging

Contrast esophagography, esophagoscopy with biopsy, and contrast-enhanced CT of the chest and the upper abdomen are required before esophagectomy. The esophagogram identifies the location of the tumor and may indicate whether it extends into the proximal stomach. Esophagoscopy allows direct assessment of the mucosa, precise localization of the tumor, and collection of tissue for histologic study. Retroflexion views of the stomach, after distention with air, are particularly important if proximal gastric invasion is suspected, in which case esophagogastrectomy with reconstruction of alimentary continuity by means of intestinal interposition may be required. In cases of midesophageal cancer, a bronchoscopy is mandatory to rule out airway involvement. The carina and the proximal left mainstem bronchus are the sites that are most at risk for local invasion.

Contrast-enhanced CT scans of the chest and abdomen are standard. Thoracic and abdominal CT scans yield information on the extent of any celiac or mediastinal adenopathy, the degree of esophageal thickening, and the possibility of invasion of the adjacent aorta or tracheobronchial tree. The lung parenchyma is assessed for metastatic nodules, as are the liver and the adrenal glands. When the distal extent of tumor cannot be defined as a result of near-complete obstruction on endoscopy, a prone abdominal CT can help differentiate a tumor at the gastric cardia from a collapsed but normal stomach. If the obstruction is not complete, the stomach can be distended with air (through either the ingestion of effervescent granules or the passage of a small-bore nasogastric tube) to improve visualization. A prone CT also yields improved imaging of the gastrohepatic and celiac lymph nodes by allowing the stomach to fall away from these adjacent structures. Metastatic cancer in the celiac lymph nodes portends a very poor prognosis and is a contraindication to resection.

PET scanning is useful for the detection of occult distant metastases that preclude curative resection. Suspicious areas should undergo needle biopsy or laparoscopic or thoracoscopic assessment. Similarly, pleural effusions [see *4:8 Pleural Effusion*] must be tapped for cytologic evaluation. Invasion of mediastinal structures and the presence of distant metastases are contraindications to transhiatal esophagectomy.

At present, EUS, though quite sensitive for detection of paraesophageal adenopathy, is incapable of differentiating reactive lymph nodes from nodes invaded by malignancy. CT and PET have limitations, and thus, locoregional involvement may not be recognized before resection is attempted. In patients who are marginal candidates for surgical treatment and in whom metastatic disease is suspected, thoracoscopy and laparoscopy have been advocated for histologic evaluation of mediastinal lymph nodes, pleural or peritoneal abnormalities, and celiac nodes. Although this approach adds to the cost of investigation, it can save the patient from having to undergo a major operation for what would later prove to be an incurable condition.

Neoadjuvant Therapy

Patients with esophageal cancer who are candidates for resection may benefit from neoadjuvant chemotherapy and concurrent radiation therapy. In particular, patients with good performance status and bulky disease should be considered for such therapy. To date, no randomized trials have conclusively demonstrated a sur-

vival benefit with this approach, but several series have documented a 20% to 30% rate of complete response with no viable tumor found at the time of resection. After chemoradiation, patients are restaged with a barium swallow and CT. PET scanning after treatment may yield spurious results, in that inflammatory conditions can mimic the increased tracer uptake seen in malignant tissue. Microscopic disease cannot be assessed, and scarring from radiation may further confound the situation by preventing tracer uptake in areas that actually harbor malignancy.

If there are no contraindications to surgical treatment, resection is scheduled 2 to 3 weeks after the completion of neoadjuvant therapy. This interval allows time for patients to return to their baseline activity level and for any induced hematologic abnormalities to be corrected. Previous chemoradiation therapy does not make transhiatal esophagectomy significantly more difficult or complicated. Many tumors are downstaged and less bulky at the time of resection. In centers with experience in this approach, the rates of bleeding and anastomotic leakage remain low.

OPERATIVE PLANNING

Transhiatal Esophagectomy

In transhiatal esophagectomy, the stomach is mobilized through a short upper midline laparotomy, the esophagus is mobilized from adjacent mediastinal structures via dissection through the hiatus without the use of a thoracotomy, and the stomach is transposed through the posterior mediastinum and anastomosed to the cervical esophagus at the level of the clavicles. The main advantages of this approach are (1) a proximal surgical margin that is well away from the tumor site, (2) an extrathoracic esophagogastric anastomosis that is easily accessible in the event of complications, and (3) reduced overall operative trauma. Single-center studies throughout the world have shown transhiatal esophagectomy to be safe and well tolerated, even in patients who may have significantly reduced cardiopulmonary reserve. Long-term survival is equivalent to that reported after transthoracic esophagectomy.

Although transhiatal esophagectomy has been used for resection of tumors at any location in the esophagus, it is best suited for resection of tumors in the lower esophagus and at the esophagogastric junction. It should also be considered the operation of choice for certain advanced nonmalignant conditions of the esophagus. Nondilatable strictures of the esophagus may occur as an end-stage complication of gastroesophageal reflux. Intractable reflux after failed hiatal hernia repair may not be amenable to further attempts at reconstruction of the esophagogastric junction and thus may call for esophagectomy. Because of the high cervical anastomosis, a transhiatal esophagectomy is less likely to predispose to postoperative reflux and recurrent stricture formation than a transthoracic esophagectomy would be. Achalasia may result in a sigmoid megaesophagus and dysphagia that cannot be managed without removal of the esophagus. Transhiatal esophagectomy permits complete removal of the thoracic esophagus and, in the majority of patients, restoration of comfortable swallowing without the need for a thoracotomy.

Generally, patients are admitted to the hospital on the day of the operation. Thoracic epidural analgesia is administered, both intraoperatively and postoperatively, and appropriate antibiotic prophylaxis is provided [see 1:2 *Prevention of Postoperative Infection*]. Heparin, 5,000 U subcutaneously, is given before induction, and pneumatic calf compression devices are applied. A radial artery catheter is placed to permit continuous monitoring of blood pressure. Central venous access is rarely required. General anesthesia is administered via an uncut single-lumen endotracheal tube.

Flexible esophagoscopy is performed (if it was not previously performed by the surgical team). A nasogastric tube is placed before final positioning and draping.

The patient is placed in the supine position with a small rolled sheet between the shoulders. The arms are secured to the sides, and the head is rotated to the right with the neck extended. The neck, the chest, and the abdomen are prepared as a single sterile field. The drapes are placed so as to expose the patient from the left ear to the pubis. The operative field is extended laterally to the anterior axillary lines to permit placement of thoracostomy tubes as needed. A self-retaining table-mounted retractor is used to facilitate upward and lateral traction along the costal margin.

Ivor-Lewis Esophagectomy

At many institutions, Ivor-Lewis esophagectomy is preferred because it provides excellent direct exposure for dissection of the intrathoracic esophagus, in that it combines a right thoracotomy with a laparotomy. This procedure should be considered when there is concern regarding the extent of esophageal fixation within the mediastinum. One advantage of Ivor-Lewis esophagectomy is that an extensive local lymphadenectomy can easily be performed through the right thoracotomy. Any attachments to mediastinal structures can be freed under direct vision. Whether any regional lymph node dissection is necessary is highly controversial; no significant survival advantage has yet been demonstrated. Long-term survival after Ivor-Lewis resection is equivalent to that after transhiatal esophagectomy.³

The main disadvantages of the Ivor-Lewis procedure are (1) the physiologic impact of the two major access incisions employed (a right thoracotomy and a midline laparotomy) and (2) the location of the anastomosis (in the chest, at the level of the azygos vein). Incision-related pain may hinder deep breathing and the clearing of bronchial secretions, resulting in atelectasis and pneumonia. Complications of the intrathoracic anastomosis may be hard to manage. Although the anastomotic leakage rate associated with Ivor-Lewis esophagectomy has typically been 5% or lower—and thus substantially lower than the rate cited for the cervical anastomosis after transhiatal esophagectomy—intrathoracic leaks are much more dangerous and difficult to handle than intracervical leaks. In many cases, drainage of the leak will be incomplete and empyema will result. Reoperation may prove necessary to manage mediastinitis.

Left Thoracoabdominal Esophagogastricectomy

The left thoracoabdominal approach is indicated for resection of the distal esophagus and the proximal stomach when removal of the stomach necessitates the use of an intestinal substitute to restore swallowing. If the proximal stomach must be resected for adequate resection margins to be obtained, then the distal stomach may be anastomosed to the esophagus in the chest. This operation is frequently associated with significant esophagitis from bile reflux, and dysphagia is common. Consequently, many surgeons prefer to resect the entire stomach and the distal esophagus and then to restore swallowing with a Roux-en-Y jejunal interposition anastomosed to the residual thoracic esophagus.

OPERATIVE TECHNIQUE

Transhiatal Esophagectomy

Transhiatal esophagectomy is best understood as consisting of three components: abdominal, mediastinal, and cervical. The abdominal portion involves mobilization of the stomach, pyloromyotomy, and placement of a temporary feeding jejunostomy.

Step 1: incision and entry into peritoneum A midline laparotomy is performed from the tip of the xiphoid to the umbilicus. The peritoneum is opened to the left of the midline so that the falciform and the preperitoneal fat may be retracted en bloc to the right. Body wall retractors are placed at 45° angles from the midline to elevate and distract both costal margins. The retractors are placed so as to lift up the costal margin gently and open the wound. The abdomen is then inspected for metastases.

Step 2: division of gastrohepatic ligament and mobilization of distal esophagus The left lobe of the liver is mobilized by dividing the triangular ligament, then folded to the right and held in this position with a moist laparotomy pad and a deep-bladed self-retaining retractor. Next, the gastrohepatic ligament is divided. Occasionally, there is an aberrant left hepatic artery arising from the left gastric artery [see Figure 9]. The peritoneum over the right crus is incised, and the hiatus is palpated; the extent and mobility of any tumor may then be assessed. The peritoneum over the left crus is similarly divided, and the esophagus is encircled with a 2.5 cm Penrose drain. Traction is applied to draw the esophagogastric junction upward and to the right; this measure facilitates exposure of the short gastric arteries coursing to the fundus and the cardia.

Step 3: mobilization of stomach The greater curvature of the stomach is inspected and the right gastroepiploic artery palpated. The lesser sac is generally entered near the midpoint of the greater curvature. The transition zone between the right gastroepiploic arcade and the short gastric arteries is usually devoid of blood vessels. A moist sponge is placed behind the spleen to elevate it and facilitate subsequent control of the short gastric vessels.

Dissection then proceeds along the greater curvature toward the pylorus. The omentum is mobilized from the right gastroepiploic artery. Vessels are ligated between 2-0 silk ties, and great care is exercised to avoid placing excessive traction on the arterial arcade. A 1 cm margin is always maintained between the line of dissection and the right gastroepiploic artery. Venous injuries, in particular, can occur with injudicious handling of tissue. The ultrasonic scalpel is particularly efficient and effective for mobilization of the stomach; again, this instrument must be applied well away from the gastroepiploic arcade. Dissection is continued rightward to the level of the pylorus. It should be noted that the location of the gastroepiploic artery in this area may vary; often, it is at some unexpected distance from the stomach wall. Posterior adhesions between the stomach and the pancreas are lysed so that the lesser sac can be completely opened.

The assistant's left hand is then placed into the lesser sac to retract the stomach gently to the right and place the short gastric vessels on tension. The Penrose drain previously placed around the esophagus facilitates exposure by retracting the cardia to the right. Dissection along the greater curvature proceeds cephalad. The vessels are divided well away from the wall of the stomach to prevent injury to the fundus. Clamps should never be placed on the stomach. A high short gastric artery is typically encountered just adjacent to the left crus. Precise technique is required to prevent injury to the spleen. The Penrose drain [see Step 2, above] is exposed as the peritoneum is opened over the left crus. Mobilization of the proximal stomach and liberation of the distal esophagus are thereby completed.

Once the stomach has been completely mobilized along the greater curvature, it is elevated and rotated to the right [see Figure

Figure 9 Transhiatal esophagectomy. The duodenum is mobilized, and the gastrohepatic and gastrocolic omenta are divided.

Figure 10 Transhiatal esophagectomy. After the stomach has been completely mobilized along the greater curvature, it is elevated and rotated to the right. The left gastric vessels are suture-ligated and divided. A 1 cm margin of the diaphragmatic crura is taken in continuity with the esophagogastric junction, providing ample clearance of the tumor and improved exposure of the lower mediastinum.

10]; the left gastric artery and associated nodal tissues can then be visualized via the lesser sac. The superior edge of the pancreas is visible, and the remaining posterior attachments of the stomach are divided along the hiatus and the left crus. These may be quite extensive if there has been a history of pancreatitis or preoperative radiation therapy.

If the operation is being done for malignant disease, a final determination of resectability can be made at this point. Tumor fixation to the aorta or the retroperitoneum can be assessed. Celiac and paraortic lymph nodes can be palpated and, if necessary, sent for biopsy. The left gastric artery and vein are then ligated proximally, either through the lesser sac or directly through the divided gastrohepatic ligament. All nodal tissue is dissected free in anticipation of subsequent removal en bloc with the specimen.

Step 4: mobilization of duodenum and pyloromyotomy

The duodenum is mobilized with a Kocher maneuver. Careful attention to the superior extent of this dissection is critical. Adhesions to either the porta hepatis or the gallbladder must be divided to ensure that the pylorus is sufficiently freed for later migration to the diaphragmatic hiatus.

Gastric drainage is provided by a pyloromyotomy. Two figure-eight traction sutures of 2-0 cardiovascular silk are placed deeply through both the superior and the inferior border of the pylorus; traction is then placed on these sutures to provide both exposure and some degree of hemostasis. The pyloromyotomy is begun 2 to 3 cm on the gastric side of the pylorus. The serosa and the muscle are divided with a needle-tipped electrocautery to expose the submucosa; generally, these layers of the stomach are robust, making the proper plane easy to find.

Dissection is extended toward the duodenum with the aid of a fine-tipped right-angle clamp. The duodenal submucosa, recognizable by its fatty deposits and yellow coloration, is exposed for approximately 0.5 cm. The duodenal submucosa is usually much more superficial than expected, and accidental entry into the duodenum often occurs just past the left edge of the circular muscle of the pylorus. Releasing the tension on the traction sutures helps the surgeon visualize the proper depth of dissection. Should entry into the lumen occur, a simple repair using interrupted fine monofilament (4-0 or 5-0 polypropylene) sutures to close the mucosa is performed. Small metal clips are applied to the knots of the traction sutures before removal of the ends; these clips serve to indicate the level of the pyloromyotomy on subsequent radiographic studies.

Step 5: feeding jejunostomy Placement of a standard Weitzel jejunal feeding tube approximately 30 cm from the ligament of Treitz completes the abdominal portion of the transhiatal esophagectomy.

Step 6: exposure and encirclement of cervical esophagus

The cervical esophagus is exposed through a 6 cm incision along the anterior edge of the left sternocleidomastoid muscle [see Figure 1] that is centered over the level of the cricoid cartilage. The platysma is divided to expose the omohyoid, which is divided at its tendon. The strap muscles are divided low in the neck. The esophagus and its indwelling nasogastric tube can be palpated.

The carotid sheath is retracted laterally, and blunt dissection is employed to reach the prevertebral fascia. The inferior thyroid artery is ligated laterally; the recurrent laryngeal nerve is visible just

deep and medial to this vessel. No retractor other than the surgeon's finger should be applied medially: traction injury to the recurrent laryngeal nerve will result in both vocal cord palsy and uncoordinated swallowing with aspiration. In particular, metal retractors must not be used in this area. The tracheoesophageal groove is incised close to the esophageal wall while gentle finger traction is applied cephalad to elevate the thyroid cartilage toward the right. This measure usually suffices to define the location of the nerve.

The esophagus is then encircled by passing a right-angle clamp posteriorly from left to right while the surgeon's finger remains in the tracheoesophageal groove. The tip of the clamp is brought into the pulp of the fingertip. The medially located recurrent laryngeal nerve and the membranous trachea are thereby protected from injury. The clamp is brought around, and a narrow Penrose drain is passed around the esophagus [see Figure 11]. Blunt finger dissection is employed to develop the anterior and posterior planes around the esophagus at the level of the thoracic inlet.

Step 7: mediastinal dissection Some authors describe this portion of the procedure as a blunt dissection, but in fact, the vast majority of the mediastinal mobilization is done under direct vision. Narrow, long-handled, handheld, curved Harrington retractors are placed into the hiatus and lifted up to expose the distal esophagus. Caudal traction is placed on the esophagus, allowing excellent visualization of the hiatus and the distal esophagus. Long right-angle clamps are used to expose these attachments. Vascularity in this area is often minimal, and hemostasis can easily be achieved with either the electrocautery or the ultrasonic

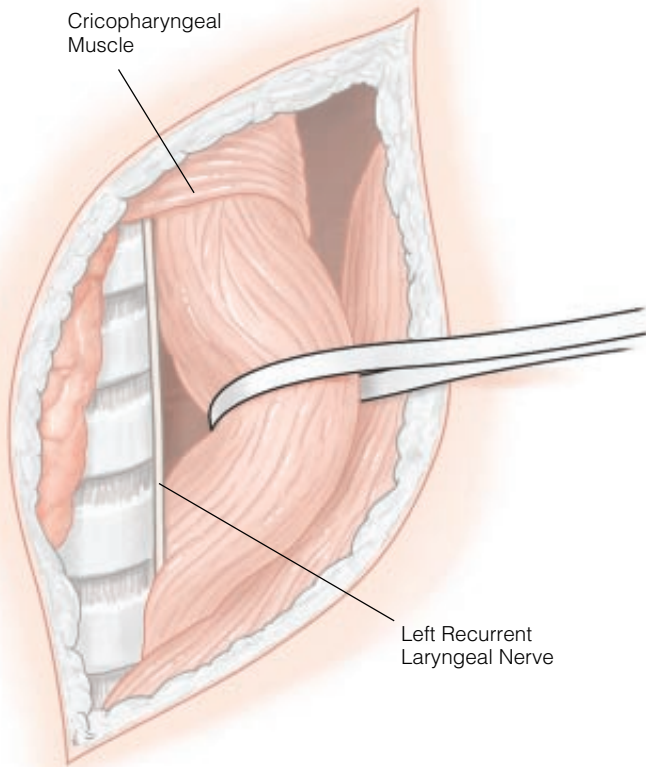

Figure 11 Transhiatal esophagectomy. Once the cervical esophagus is exposed through an incision along the left sternocleidomastoid muscle, strap muscles are divided and retracted, and the cervical esophagus is dissected away from the left and right recurrent laryngeal nerves.

Figure 12 Transhiatal esophagectomy. The plane posterior to the esophagus is developed by placing the surgeon's right hand into the hiatus along the prevertebral fascia. A moist sponge stick is placed through the cervical incision posterior to the esophagus, and the posterior plane is completed.

scalpel. The left crus can be divided to facilitate exposure. Paraesophageal lymph nodes are removed either en bloc or as separate specimens. Dissection is continued cephalad with the electrocautery and a long-handled right-angle clamp. The two vagi are divided, and the periesophageal adhesions are lysed. Mobilization of the distal esophagus under direct vision is thus completed up to the level of the carina.

Three specific maneuvers are now carried out. First, the plane posterior to the esophagus is developed [see Figure 12]. The surgeon's right hand is advanced palm upward into the hiatus, with the fingers closely applied to the esophagus. The volar aspects of the fingers run along the prevertebral fascia, elevating the esophagus off the spine. A moist sponge stick is placed through the cervical incision, also posterior to the esophagus. The sponge is advanced toward the right hand, which is positioned within the mediastinum. As the sponge is advanced into the right palm, the posterior plane is completed. A 28 French mediastinal sump is then passed from the cervical incision into the abdomen along the posterior esophageal wall and attached to suction. Any blood loss from the mediastinum is collected and monitored.

Second, the anterior plane is developed [see Figure 13]. This is often much more difficult than developing the posterior plane because the left mainstem bronchus may be quite close to the esophagus. Again, the surgeon's right hand is placed through the hiatus, but it is now palm down and anterior to the esophagus. The

fingertips enter the space between the esophagus and the left mainstem bronchus. The hand is gently advanced, and the airway is displaced anteriorly. A blunt curved suction handle is employed from above as a substitute finger. It is advanced along the anterior aspect of the esophagus through the cervical incision. The right hand guides the tip of the suction handle beneath the bronchus. Lateral displacement of the handle allows further mobilization of the bronchus away from the esophagus. Completion of the anterior and posterior planes usually results in a highly mobile esophagus.

Third, the lateral attachments of the upper and middle esophagus are divided. Upward traction is applied with the Penrose drain previously placed around the cervical esophagus, allowing further dissection at the level of the thoracic inlet. Lateral attachments are pushed caudally into the mediastinum, and traction applied to the esophagus from below allows these attachments to be visualized inferiorly through the hiatus, then isolated with long right-angle clamps and divided with the electrocautery. Caution must be exercised so as not to injure the azygos vein. Dissection on the right side must therefore be kept close to the esophagus. Once the last lateral attachment is divided, the esophagus is completely free and can be advanced into the cervical wound.

Close monitoring of arterial blood pressure is maintained throughout. Transient hypotension may occur as a result of mediastinal compression and temporary impairment of cardiac venous return as the surgeon's hand or retractors are passed through the hiatus. Vasopressors are never required for management: simple

Figure 14 Transhiatal esophagectomy. The esophagus is divided in the neck and delivered into the abdomen. Retractors are placed in the hiatus, and any vessels entering into the esophagus are clipped and divided. The vagi are also clipped and divided.

repositioning of the retractors or removal of the dissecting hand usually results in prompt restoration of normal BP. Placement of the patient in a slight Trendelenburg position is often helpful.

Step 8: proximal transection of esophagus and delivery into abdomen The nasogastric tube is retracted to the level of the cricopharynx, and the esophagus is divided with a cutting stapler 5 to 6 cm distal to the muscle. The esophagus is then removed via the abdomen [see Figure 14]. Retractors are placed in the hiatus, and the mediastinum is inspected for hemostasis. The sump is removed. Both pleurae are inspected. The lungs are inflated so that it can be determined which pleural space requires thoracostomy drainage. The mediastinum is packed with dry laparotomy pads from below. A narrow pack is placed into the thoracic inlet from above. Chest tubes are then placed as required along the inframammary crease in the anterior axillary line. The drainage from these tubes should be closely monitored throughout the rest of the operation to ensure that any bleeding from the mediastinal dissection does not go unnoticed.

Step 9: excision of specimen and formation of gastric tube The gastric fundus is grasped, and gentle tension is applied along the length of the stomach. The esophagus is held at right angles to the body of the stomach, and the fat in the gastrohepatic ligament is elevated off the lesser curvature; all lymph nodes are thus mobilized. A point approximately midway along the lesser curvature is selected. The blood vessels traversing this area from the right gastric artery are ligated to expose the lesser curvature. The distal resection margin is then marked; it should be 4 to 6 cm from the esophagogastric junction, extending from the selected point on the lesser curvature to a point medial to the fundus. A 60

Figure 13 Transhiatal esophagectomy. The anterior plane is developed by placing the surgeon's right hand through the hiatus anterior to the esophagus. The fingertips enter the space between the esophagus and the left mainstem bronchus, to be met by a blunt suction handle passed downward through the cervical incision. The lateral attachments of the esophagus are divided from above downward as far as the aortic arch.

mm GIA stapler loaded with 3.5 mm staples is then used to transect the proximal stomach, proceeding from the lesser curvature toward the fundus [see Figure 15]. Resection of the cardia along with the adjacent portion of the lesser curvature effectively converts a J-shaped stomach into a straight tube.

For maximizing the length of the gastric tube, there are several technical points that are critical. Tension must be maintained on the stomach as the stapler is serially applied cephalad. The stapler should be simply placed on the stomach and fired: no attempt should be made to telescope tissue into the jaws, because to do so would effectively reconstitute the curve of the stomach and diminish its upward reach. Typically, three staple loads are required.

The specimen is removed, and frozen section examination is done on the distal margin. The completed staple line is then oversewn with a continuous Lembert suture of 4-0 polypropylene. Once again, tension is maintained along the stomach to prevent any foreshortening of the lesser curvature. The use of two separate sutures, each reinforcing half of the staple line, is helpful in this regard.

Step 10: advancement of stomach into chest or neck

The mediastinal packs are removed, and hemostasis is verified in the chest. The stomach is inspected as well. The ends of any short gastric vessels that were divided with the ultrasonic scalpel are now tied so that subsequent manipulation does not precipitate bleeding. The stomach is oriented so that the greater curvature is to the patient's left. There must be no torsion. The anterior surface of the fundal tip should be marked with ink so that proper orientation of the stomach can be confirmed after its passage into the neck. The stomach can usually be advanced through the posterior mediastinum without any traction sutures or clamps. The surgeon's hand is placed palm down on the anterior surface of the stomach, with the fingertips about 5 cm proximal to the tip of the fundus. The hand is then gently advanced through the chest, pushing the stomach ahead of itself. The tip of the fundus is gently grasped with a Babcock clamp as it appears in the neck. To prevent trauma at this most distant aspect of the gastric tube, the clamp should not be ratcheted closed.

No attempt should be made to pull the stomach up into the neck: the position of the fundus is simply maintained as the surgeon's hand is removed from the mediastinum. Further length in the neck can usually be gained by gently readvancing the hand along the anterior aspect of the stomach. This measure uniformly distributes tension along the tube and ensures proper torsion-free orientation in the chest. The stomach is pushed up into the neck rather than drawn up by the clamp.

A useful alternative approach for positioning the gastric tube involves passing a large-bore Foley catheter through the mediastinum from the neck incision. The balloon is inflated, and a 50 cm section of a narrow plastic laparoscopic camera bag is tied onto the catheter just above the balloon. The gastric tube is positioned within the bag, and suction is applied through the catheter, creating an atraumatic seal between the stomach and the surrounding plastic bag. As the bag is drawn upward through the neck with gentle traction on the Foley catheter, the stomach advances through the mediastinum. A small dry pack is placed in the neck behind the fundus to prevent retraction into the chest. The stomach is not secured to the prevertebral fascia in any way.

The feeding jejunal tube is brought out the left midabdomen through a separate stab incision. The hiatus is inspected for hemostasis, as is the splenic hilum. It may be necessary to reconstitute the hiatus with one or two simple sutures of 1-0 silk placed through the crura. These sutures must be placed with care to

ensure that injury to the gastroepiploic arcade does not occur at this late point in the procedure. The hiatus is narrowed, but not so much that three fingers cannot be easily passed alongside the gastric conduit. This reconstitution will help prevent herniation of other abdominal contents alongside the gastric conduit. The liver is returned to its anatomic position, thus also preventing any subsequent herniation of bowel into the chest. The pyloromyotomy is generally found at the level of the diaphragm. The laparotomy is then closed in the usual fashion. The viability of the fundus in the neck incision is checked periodically as the abdominal portion of the procedure is completed.

Step 11: cervical esophagogastric anastomosis The construction of the esophagogastric anastomosis is the most important part of the entire operation: any anastomotic complication will greatly compromise the patient's ability to swallow comfortably. Accordingly, meticulous technique is essential.

A seromuscular traction suture of 4-0 polyglactin is placed through the anterior stomach at the level of the clavicle and drawn upward, thus elevating the fundus into the neck wound and greatly facilitating the anastomosis. The pack behind the fundus is then removed.

The site of the anterior gastrotomy is then carefully selected: it should be midway between the oversewn lesser curvature staple line and the greater curvature of the fundus (marked by the ligated ends of the short gastric vessels). The staple line on the cervical esophagus is removed, and the anterior aspect of the esophagus is grasped with a fine-toothed forceps at the level of the planned gastrotomy. A straight DeBakey forceps is then applied across the full width of the esophagus to act as a guide for division. The esophagus is cut with a new scalpel blade at a 45° angle so that the anterior wall is slightly longer than the posterior wall; the

Figure 15 Transhiatal esophagectomy. A gastric tube is formed by stapling along the lesser curvature of the stomach from the junction of the right and left gastric vessels to the top of the fundus. This staple line is oversewn with a continuous 3-0 suture, with care taken not to foreshorten the gastric tube.

anterior wall then forms the hood of the anastomosis. The fine-toothed forceps is used to maintain orientation of the esophagus throughout. Two full-thickness stay sutures of 4-0 Vicryl are placed, one at the midpoint of the anterior cut edge of the esophagus and one at the corresponding location posteriorly. The posterior stitch is placed from inside the lumen, and the needle is left on the suture for later use.

A 2 cm gastrotomy is then performed with a needle-tipped electrocautery using cutting current. The incision is obliquely oriented, with the cephalad extent proceeding slightly medially. The needle from the stay suture previously placed on the posterior wall of the esophagus is then passed the full thickness of the cephalad aspect of the gastrotomy [see Figure 16a]. Traction on this untied suture brings the esophagus toward the stomach. A 45 mm endoscopic stapler loaded with 3.5 mm staples is used to form the back wall of the anastomosis. The thicker portion of the device (the cartridge) is advanced cephalad into the esophagus, with the narrower portion (the anvil) in the gastric lumen [see Figure 16b]. The tip of the stapler should be aimed toward the patient's right ear. Tension is applied to the stay suture holding the esophagus and stomach together so as to bring tissue into the jaws of the device. The portion of the fundus extending beyond the stapler is then rotated medially to ensure that the new staple line is well away from the one previously placed along the lesser curvature. This is a crucial point: crossing of the two staple lines may create an ischemic area that can give rise to a large leak in the postoperative period.

The stapler is then closed, holding the esophagus and stomach together, but not yet fired. The position of the nasogastric tube should be maintained just at the level of the cricopharynx during the construction of the anastomosis. This positioning keeps the tube out of the operative field and protects it from being entrapped by the jaws of the stapler; it also facilitates subsequent passage of the tube into the gastric conduit once the posterior wall of the anastomosis is complete. Two suspension sutures are placed on either side of the closed stapler, one toward the tip and the other near the heel of the jaws. These four sutures alleviate any potential tension on the staple line by approximating the muscular layer of the esophagus to the seromuscular layer of the stomach. The suspension sutures are tied, and the stapler is fired, thereby completing the posterior portion of the anastomosis [see Figure 16c].

The anterior portion of the anastomosis is closed in two layers. The inner layer consists of a continuous 4-0 polydioxanone suture placed as full-thickness inverting stitches, and the second layer consists of interrupted seromuscular Lembert sutures [see Figure 17]. The lateral and medial corners of the anastomosis, where the staple line meets the handsewn portion, merit extra attention. These corners are quite fragile, and excessive traction may result in dehiscence progressing cephalad along the staple line in a zipperlike fashion. The inner layer should therefore be started at each corner, incorporating the last 5 mm of the staple line. Once several stitches have been placed from the two corners, the nasogastric tube can be passed through the anastomosis. The nasogastric tube is properly positioned when the most distal black marker is at the nares. The inner layer is then completed as the two sutures are tied at the midpoint.

Step 12: drainage, closure, and completion x-ray A small Penrose drain is placed in the thoracic inlet below the anastomosis and brought out through the inferior end of the neck incision. The drain is secured, and the incision is irrigated. The strap muscles are not reapproximated but are merely attached loosely to the underside of the sternocleidomastoid muscle with two interrupted 4-0 polyglactin sutures. The platys-

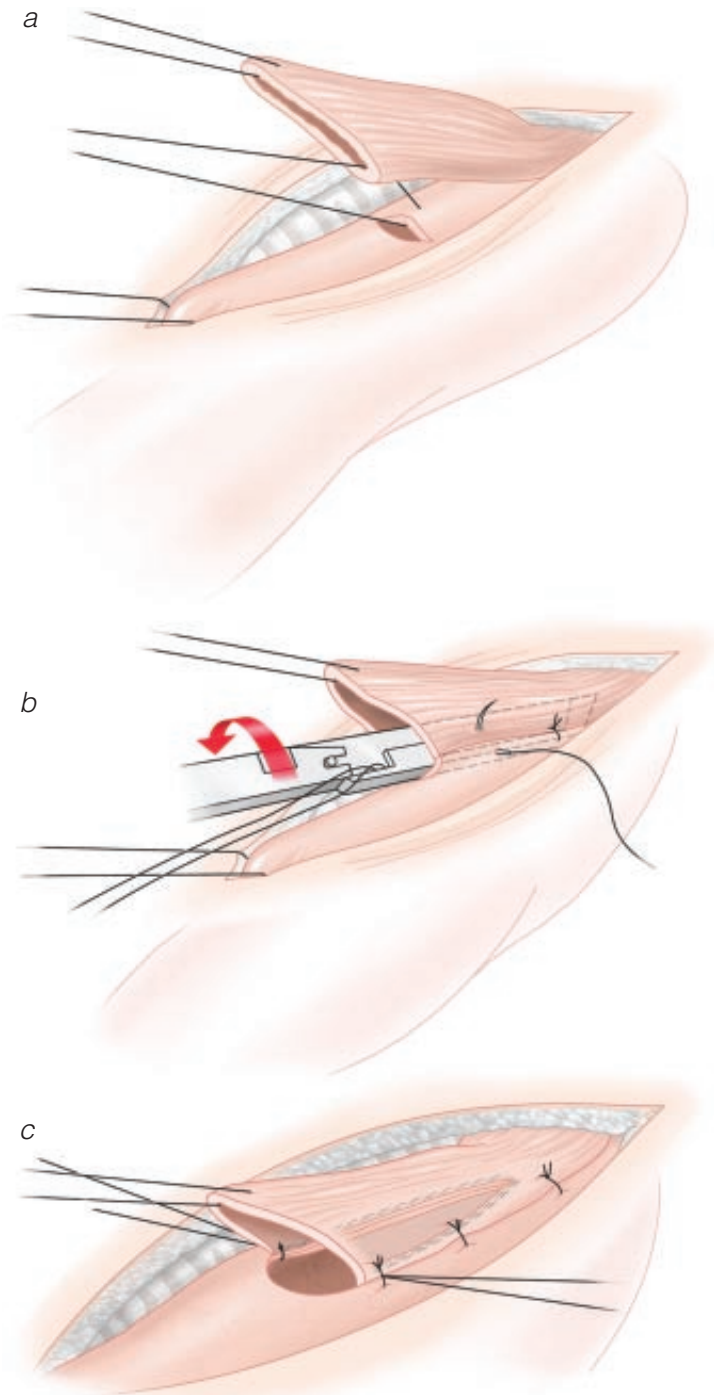

Figure 16 Transhiatal esophagectomy. (a) After the proximal end of the stomach tube is delivered into the neck, the esophagus is cut at a 45° angle so that the anterior wall is longer than the posterior wall. A gastrotomy is placed between the oversewn lesser curvature staple line and the greater curvature of the fundus. A full-thickness suture is placed through all layers of the esophagus and all layers of the gastrotomy. (b) An endoscopic GIA stapler is used to form the back wall of the anastomosis. The thicker portion of the device (the cartridge) is advanced cephalad into the esophagus, with the narrower portion (the anvil) in the gastric lumen. The tip of the stapler should be aimed toward the patient's right ear. The staple line must be well away from the lesser curvature staple line. Two suspension sutures are placed on either side of the closed stapler, one toward the tip and the other near the heel of the jaws. (c) The stapler is fired to complete the posterior portion of the anastomosis.

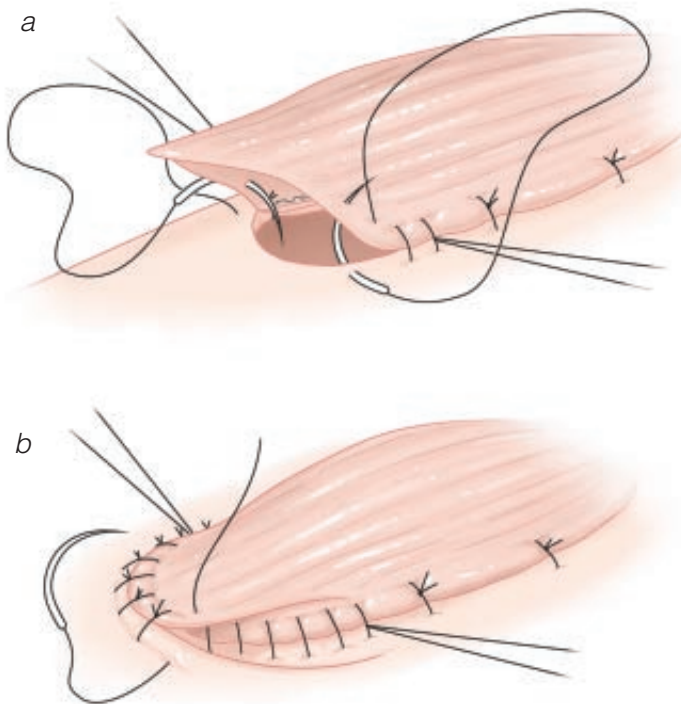

Figure 17 Transhiatal esophagectomy. The anterior portion of the anastomosis is completed with (a) an inner layer consisting of a continuous 4-0 polydioxanone suture and (b) an outer layer consisting of interrupted sutures.

ma is reconstituted with interrupted 4-0 polyglactin sutures. The nasogastric tube is secured.

A chest x-ray is obtained in the OR to verify the position of the drains and the absence of any abnormal collections in the chest. Patients are extubated in the OR and transported to the anesthetic recovery area. Extubation should be carried out only when the health care team is confident that subsequent reintubation is unlikely to be necessary. Emergency reintubation after a cervical anastomosis is hazardous, in that vigorous neck extension may threaten the suture line. Once patients are awake and alert, which is usually 3 to 4 hours after the operation, they are taken to the general ward. As a rule, admission to an intensive care unit is not required unless there are substantial comorbidities or intraoperative concerns. To prevent excessive traction on the anastomosis, the neck should be maintained in a flexed position with two pillows placed behind the head.

In certain patients, a stapled anastomosis may be impractical. In patients with a bull-neck habitus, for example, a partial sternal split may be required for adequate exposure of the cervical esophagus, and a handsewn true end-to-end anastomosis may be necessary. In addition, patients who have previously undergone antireflux surgery may have a relatively short gastric tube that will necessitate an end-to-end reconstruction.

Patients should, if possible, begin walking the morning after the operation. An incentive spirometer should be constantly within arm's length of the patient, and hourly use of this device should be encouraged. The nasogastric tube is removed on postoperative day 3, and the patient is allowed ice chips in the mouth. The thoracic epidural catheter is removed the afternoon after the chest tube is removed. The diet is gradually advanced so that a soft diet is begun on postoperative day 5 or 6. A barium swallow is performed on postoperative day 6 in preparation for hospital discharge on day 7 or 8.

Ivor-Lewis Esophagectomy

Steps 1 through 5 Esophagoscopy is performed to confirm the location of the tumor. Steps 1, 2, 3, 4, and 5 of an Ivor-Lewis esophagectomy are virtually identical to the first five steps (i.e., the abdominal portion) of a transhiatal esophagectomy. Once complete mobilization of the stomach is verified, the pylorus is manually advanced to the level of the diaphragm to ensure that it is not being tethered by the duodenum or the greater omentum. The stomach is then placed back into the anatomic position, and the laparotomy is closed.

Step 6: exposure and mobilization of esophagus The patient is shifted to the left lateral decubitus position and re-draped. Single-lung ventilation is instituted, and the chest is entered through a right fifth or sixth interspace thoracotomy. The inferior pulmonary ligament is divided, and the lung is retracted cephalad. The esophagus is mobilized from the level of the diaphragm to a point above the azygos vein [see Figure 18], which is typically divided with a vascular stapler. The pleura overlying the esophagus is divided to the level of the thoracic inlet, superior to the azygos vein. The esophagus is encircled with a Penrose drain in the retrotracheal region. The pleura is then divided to the level of the diaphragm, with care taken to stay close to the right bronchus and the pericardium and avoid injury to the thoracic duct. The soft tissue between the esophagus and the aorta posteriorly and between the esophagus and the trachea or the pericardium anteriorly is dissected free and maintained en bloc with the esophagus. Periesophageal and subcarinal nodes are thereby mobilized [see Figure 18b].

Step 7: excision and removal of specimen The hiatus is incised and the abdomen entered. The stomach is drawn up into the chest, with care taken not to place excessive traction on the gastroepiploic pedicle. The esophagus is divided with a stapler proximally at least 5 cm away from any grossly evident tumor. A margin is sent for frozen section examination. The distal resection margin is completed in a similar manner, and the esophageal specimen is removed from the operative field [see Figure 19]. The gastric staple line is oversewn, and the stomach is positioned in the posterior mediastinum.

Step 8: intrathoracic esophagogastric anastomosis The site of the esophagogastric anastomosis should be about 2 cm above the divided azygos vein. Several interrupted sutures are used to secure the transposed stomach to the adjacent pleura. The staple line on the esophagus is removed, and a gastrotomy is performed in preparation for a side-to-side functional end-to-end anastomosis [see Figure 20]. With the aid of full-thickness traction sutures, the esophagus is positioned along the surface of the stomach and well away from the oversewn staple line defining the gastric resection margin. The posterior aspect of the anastomosis is completed with an endoscopic GIA stapler as described earlier [see Transhiatal Esophagectomy, Step 11, above, and Figures 16 and 17]. A nasogastric tube is passed, and the anterior wall is completed in two layers. The first layer consists of a full-thickness continuous 3-0 polydioxanone suture; the second consists of interrupted absorbable sutures approximating the seromuscular layer of the stomach to the muscular layer of the esophagus.

Two alternative methods of anastomosis are sometimes used: (1) a totally handsewn end-to-side anastomosis and (2) a totally stapled end-to-end anastomosis. The latter technique involves opening the previously placed gastric staple line and advancing the handle of an end-to-end anastomosis (EEA) stapler through

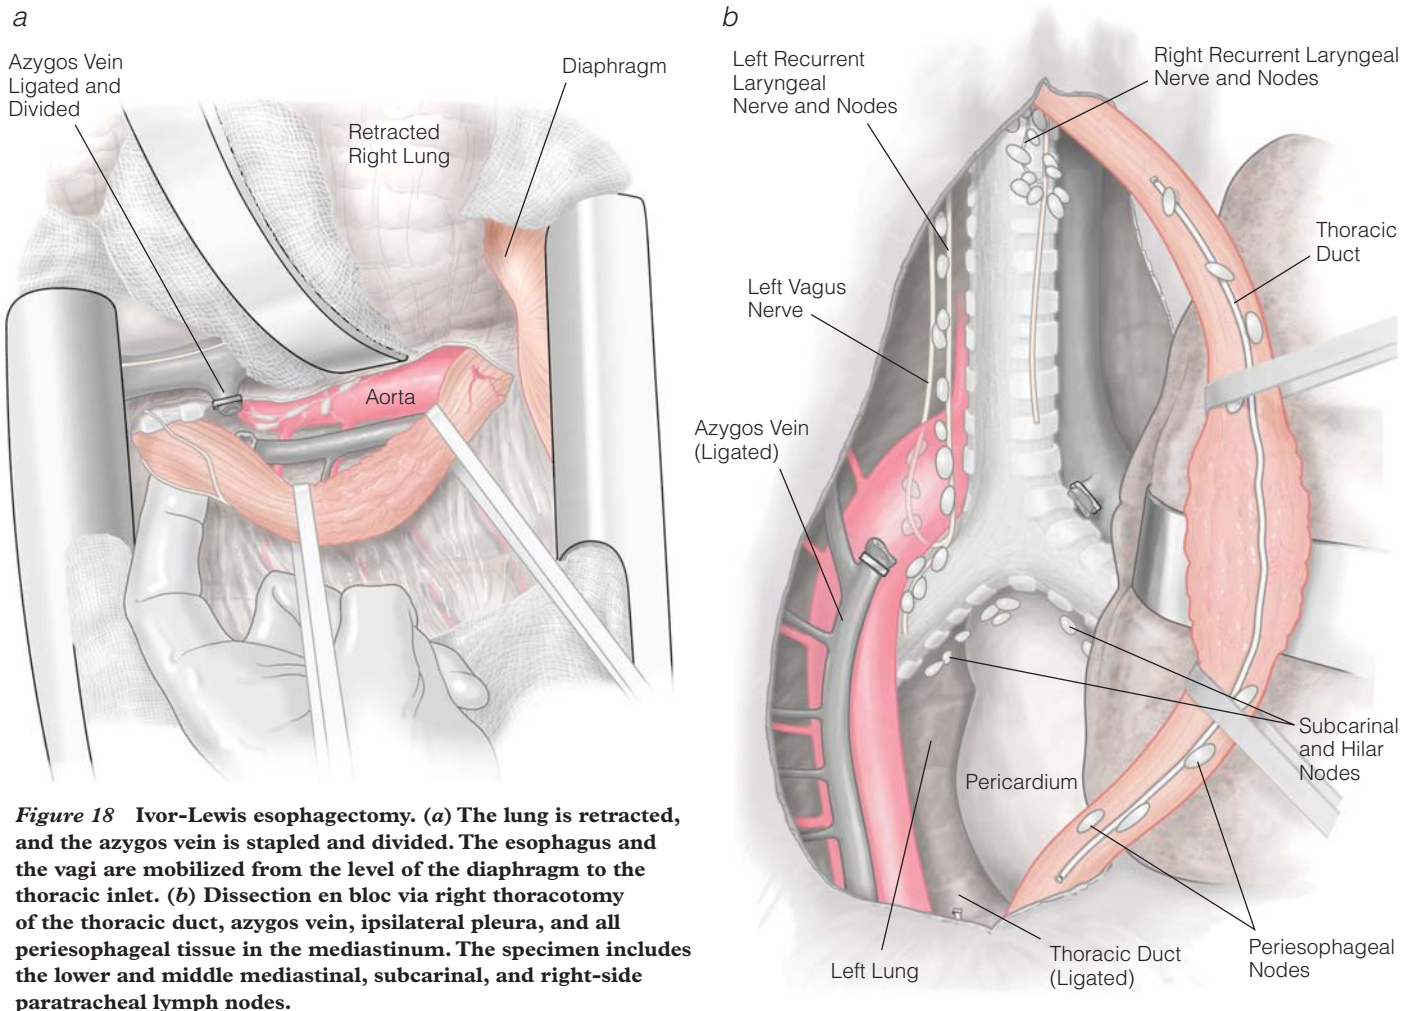

Figure 18 Ivor-Lewis esophagectomy. (a) The lung is retracted, and the azygos vein is stapled and divided. The esophagus and the vagi are mobilized from the level of the diaphragm to the thoracic inlet. (b) Dissection en bloc via right thoracotomy of the thoracic duct, azygos vein, ipsilateral pleura, and all periesophageal tissue in the mediastinum. The specimen includes the lower and middle mediastinal, subcarinal, and right-side paratracheal lymph nodes.

the stomach. The proximal esophagus is dilated sufficiently to accommodate at least a 25 mm head. The anvil is placed into the distal esophagus and secured with a purse-string suture. The tip of the stapler is brought out through the apical wall of the stomach and attached to the anvil. The stapler is then fired to create the end-to-end anastomosis, and the gastrotomy is closed. The advantages of this technique are its relative simplicity and the theoretical security of a completely stapled anastomosis; the main potential disadvantage is the risk of postoperative dysphagia resulting from an overly narrow anastomotic ring.

After completion of the anastomosis, the stomach is inspected for any potential redundancy or torsion in the chest. To prevent torsion, the stomach is anchored to the pericardium with nonabsorbable sutures. The diaphragmatic hiatus is then inspected: it should allow easy passage of two fingers into the abdomen alongside the transposed stomach. Interrupted sutures may be used to approximate the edge of the crura to the adjacent stomach wall, thereby preventing any later herniation of abdominal contents into the pleural space.

Step 9: drainage and closure Two chest tubes are placed through separate stab incisions. The tip of the posterior drain is positioned alongside the stomach at the level of the anastomosis. Fine gut sutures secured to the adjacent parietal pleura will help maintain the position of the tube. The thoracotomy is then closed in the standard fashion.

Patients should begin walking on postoperative day 1. The naso-

gastric tube is generally removed on postoperative day 3. Oral intake is not begun at this point; feeding is accomplished via the temporary jejunostomy. A barium contrast study is performed approximately 5 to 7 days after the operation. If there is no anastomotic leakage, oral intake is initiated and advanced as tolerated. The chest tubes are removed only after the reinstatement of oral intake. Patients are generally discharged from the hospital by postoperative day 8 to 10.

Left Thoracoabdominal Esophagogastrectomy

Step 1: incision and entry into peritoneum The patient is placed in the right lateral position, with the hips rotated backward about 30°. An exploratory laparotomy is performed through an oblique incision extending from the tip of the sixth costal cartilage to a point about halfway between the sternum and the umbilicus. The peritoneal cavity is carefully examined to rule out peritoneal and hepatic metastases. The region of the cardia is palpated and the mobility of the tumor assessed. If there is minor involvement of the crura or the tail of the pancreas, resection may still be possible; however, if the tumor is firmly fixed or there are peritoneal or hepatic metastases, resection should be abandoned. A feeding jejunostomy, an esophageal stent, or both may be inserted to improve swallowing and allow nutrition.

Step 2: assessment of gastric involvement and incision of diaphragm The extent to which the tumor involves the stom-

Figure 19 Ivor-Lewis esophagectomy. The esophagus and the proximal stomach are divided and stapled at least 5 cm away from the gross tumor.

ach determines whether a total gastrectomy or a proximal gastrectomy is indicated along with the distal esophagectomy. If no metastases are found, the incision is extended and the chest is opened with a left posterolateral incision through the sixth interspace. If the thoracic component of the tumor appears to be resectable, the costal margin is divided. It is advisable to remove a 1 to 2 cm segment of the costal margin to facilitate repair of the diaphragm at the end of the operation and reduce postoperative costal margin pain. The diaphragm is incised radially [see Figure 21]. Branches of the pericardiophrenic artery are suture-ligated, and the sutures are left long so that they can be used as diaphragmatic retractors. Alternatively, a circumferential incision may be made about 2 cm from the costal margin to reduce the risk of postoperative diaphragmatic paralysis.

Step 3: division of pulmonary ligament and mobilization of esophagus and stomach The pulmonary ligament is divided, and the mediastinal pleura is incised over the esophagus as far as the aortic arch. The esophagus is mobilized above the tumor and is retracted by a Penrose drain [see Figure 21]. The esophageal vessels are carefully dissected, ligated, and divided. The tumor is mobilized; the plane of the dissection is kept close to the aorta on the left, and if necessary, the right parietal pleura is taken in continuity with the lesion. About 1 cm of the crura is taken in continuity with the tumor to provide good local clearance. The stomach is then mobilized in much the same way as in a transhiatal esophagectomy [see Figure 9].

Step 4: assessment of pancreatic involvement and hepatic viability The lesser sac is opened through the greater omentum so that it can be determined whether the primary tumor involves the distal pancreas. If so, it is reasonable to resect the distal pancreas, the spleen, or both in continuity with the stomach; if not, the short gastric vessels are ligated and divided, with the spleen preserved. The lesser omentum is detached from the right side of

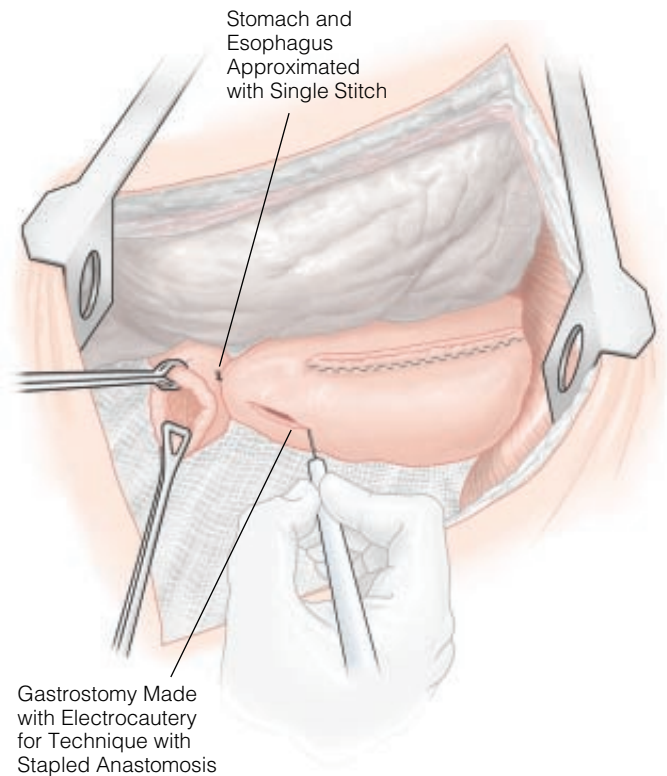

Figure 20 Ivor-Lewis esophagectomy. The transposed stomach is sutured to the adjacent pericardium, and a gastrostomy is carried out halfway between the lesser curvature staple line and the greater curvature. The anastomosis is completed as in a transhiatal esophagectomy [see Figures 16 and 17].

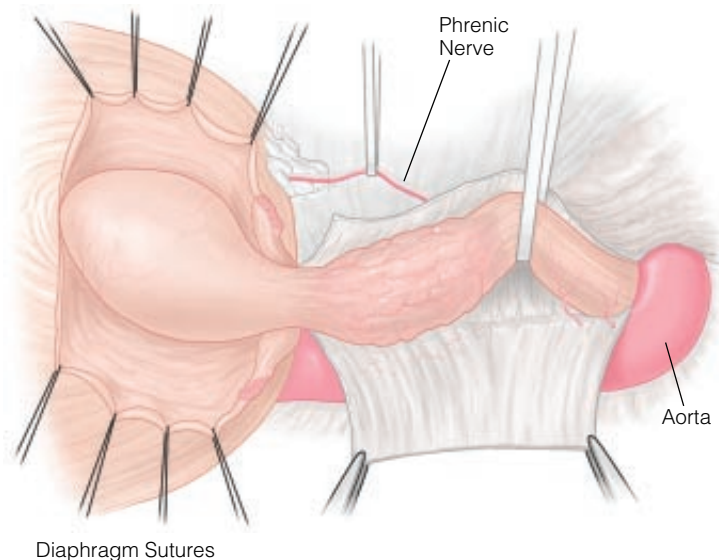

Figure 21 Left thoracoabdominal esophagogastrectomy. The diaphragm is incised radially. The branches of the pericardial phrenic artery are suture-ligated, and the sutures are left long to be used as diaphragmatic retractors. The pulmonary ligament is divided, and the esophagus is mobilized above the tumor and retracted with a Penrose drain. The esophageal vessels are ligated and divided. The tumor and the esophagus are mobilized off the aorta down to the hiatus; 1 cm of the diaphragmatic crura is taken in continuity with the tumor to provide local clearance. The stomach is then mobilized in much the same way as in a transhiatal esophagectomy [see Figure 9].

Figure 22 Left thoracoabdominal esophagogastrctomy: proximal esophagogastrctomy with esophagogastrctomy. If the tumor can be completely resected by removing the proximal stomach, a proximal esophagogastrctomy is carried out.

the esophagus and the hilum of the liver, then divided down to the area of the pylorus, with the right gastric artery and vein preserved. There is often a hepatic branch from the left gastric artery running through the gastrohepatic omentum. If this hepatic branch is of significant size, a soft vascular clamp should be placed on the artery for 20 minutes so that the viability of the liver can be assessed. If the liver is viable, the artery is suture-ligated and divided.

Step 5: division of greater omentum and short gastric vessels The greater omentum is divided, with care taken to preserve the right gastroepiploic artery and vein. These two vessels are suture-ligated and divided well away from the stomach. Ligation and division of the short gastric vessels allow complete mobilization of the greater curvature of the stomach. Dissection is extended downward as far as the pylorus. The stomach is turned upward, and the left gastric vessels are exposed through the lesser sac [see Figure 10]. The lymph nodes along the celiac axis and the left gastric artery are swept up into the specimen, and the gastric vessels are either suture-ligated or stapled and divided.

Step 6: choice of partial or total gastrectomy At this time, the surgeon determines whether the whole stomach must be resected to remove the gastric part of the cancer or whether a partial (i.e., proximal) gastrectomy will suffice.

Proximal esophagogastrctomy with esophagogastrctomy. If the surgeon decides that resection of the proximal stomach will remove all of the tumor while leaving at least 5 cm of tumor-free stomach, a proximal esophagogastrctomy is performed [see Figure 22]. A gastric tube is fashioned with a linear stapler [see Transhiatal Esophagectomy, Step 9, above, and Figure 15]. The staple line is oversewn with inverting 3-0 sutures. Because the vagus nerves are divided and gastric stasis may result, a pyloromyotomy is performed, much as in a transhiatal esophagectomy.

The proximal gastric resection margin is covered with a sponge and turned upward over the costal margin. The stomach tube is then brought up through the hiatus and into the thorax behind the proximal esophageal resection margin. The margin should be at least 10 cm from the proximal end of the esophagogastric cancer. If the esophageal resection margin is not adequate, the stomach tube is mobilized and brought to the left neck, then anastomosed to the cervical esophagus through a left neck incision; alternatively, the left colon is interposed between the gastric stump and the cervical esophagus. If the resection margin is adequate, the tip of the stomach tube is sewn to the posterior wall of the esophagus [see Figure 23].

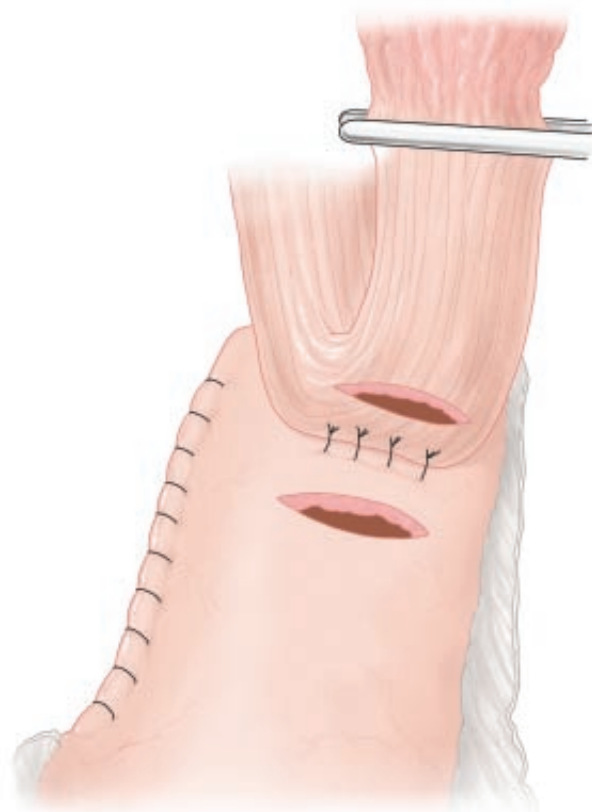

Figure 23 Left thoracoabdominal esophagogastrctomy: proximal esophagogastrctomy with esophagogastrctomy. The esophagus is sewn to the tip of the stomach tube, halfway between the lesser curvature suture line and the greater curvature. An anastomosis is then fashioned with the stapling technique used in transhiatal esophagectomy [see Figures 16 and 17].

The anastomosis is then performed with the stapling technique previously described for transhiatal esophagectomy [see Figures 16 and 17]. A nasogastric tube is passed down into the gastric remnant. The tube is sewn to the pericardium and the endotheracic fascia to prevent anastomotic dehiscence.

Total gastrectomy with Roux-en-Y esophagojejunostomy. If the surgeon decides that a total gastrectomy is necessary, the right gastroepiploic and right gastric vessels are suture-ligated and divided distal to the pylorus. The duodenum is divided just distal to the pylorus with a linear stapler. The staple line is inverted with interrupted 3-0 nonabsorbable sutures and covered with omentum to prevent duodenal stump blowout.

The esophagus is then mobilized up to the level of the inferior pulmonary vein. Two retaining sutures are placed in the esophageal wall. A monofilament nylon purse-string suture is placed around the circumference of the proximal esophagus in preparation for stapling. A No. 24 Foley catheter with a 20 ml balloon is advanced into the esophagus and gently inflated to distend the esophageal lumen. The resected specimen is sent to the pathologist for examination of the margins.

A jejunal interposition is then fashioned by using the Roux-en-Y technique. One or two jejunal arteriovenous arcades are divided to mobilize enough jejunum to allow anastomosis to the thoracic esophagus [see Figure 24]. After removal of the Foley catheter, a 25 or 28 mm EEA stapler is passed through the jejunum into the esophagus, fired, and removed. The jejunum is anchored to the pericardium and the proximal esophagus. The duodenal loop is anastomosed to the jejunum at least 45 to 50 cm distal to the esophagojejunal anastomosis to minimize bile reflux [see Figure 24]. The blind end of the jejunal loop is then stapled closed.

After careful irrigation of the chest, the first step in the closure is to repair the diaphragm around the hiatus. The gastric or jejunal interposition is sewn to the crura with interrupted nonabsorbable sutures. The remainder of the diaphragm is closed with interrupted nonabsorbable 0 mattress sutures. A chest tube is placed into the pleural space close to but not touching the anastomosis. The final sutures in the peripheral part of the diaphragm are placed but are not tied until the ribs are brought together with pericostal sutures. The left lung is reexpanded. The costal cartilages are not approximated but are left to float free. If the ends of the costal margin are abutting, another 2 cm of costal cartilage should be removed to reduce postoperative pain. Thoracic and abdominal skin layers are closed with a continuous absorbable suture. The skin and the subcutaneous tissue are closed in the usual fashion.

POSTOPERATIVE CARE

As a rule, patients are not routinely admitted to the ICU after esophagectomy; however, individual practices depend on the distribution of skilled nursing and physiotherapy personnel. Early ambulation is the mainstay of postoperative care. As a rule, patients are able to walk slowly, with assistance, on postoperative day 1. Patient-controlled epidural analgesia is particularly useful in facilitating good pulmonary toilet and minimizing the risk of atelectasis or pneumonia.

The nasogastric tube is removed on postoperative day 3; jejunostomy tube feedings are gradually started at the same time. Once bowel function normalizes, patients are allowed small sips of liquids. Chest tubes are removed as pleural drainage subsides. By postoperative day 6, most patients have progressed to a soft solid diet. Dietary education is provided, focusing primarily on eating smaller and more frequent meals, avoiding bulky foods (e.g., meat and bread) in the early postoperative period, and taking measures

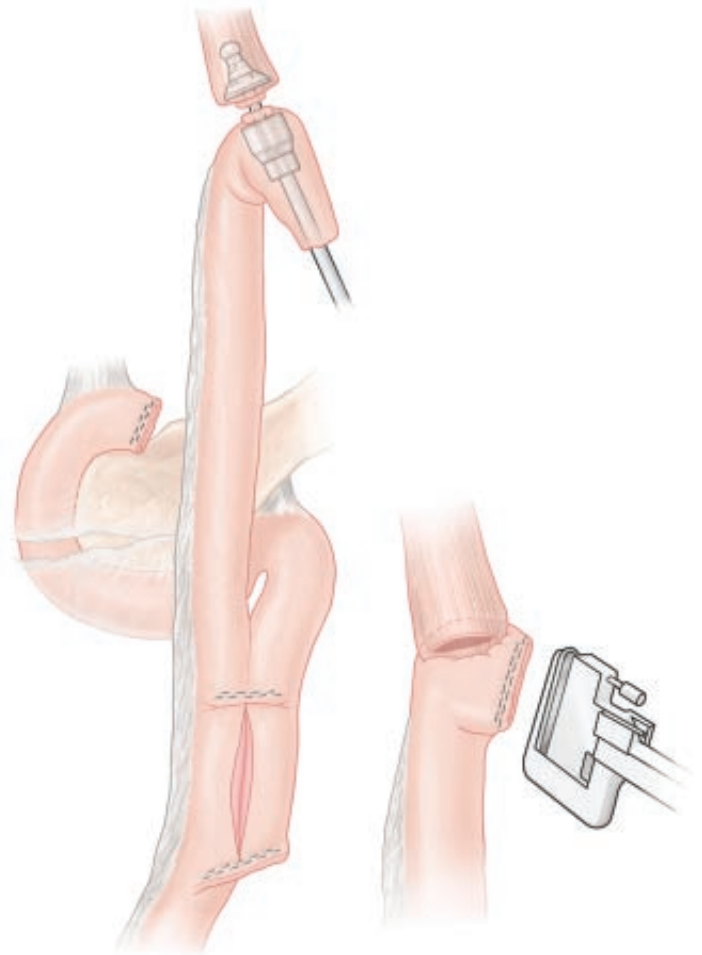

Figure 24 Left thoracoabdominal esophagogastrectomy: total gastrectomy with Roux-en-Y esophagojejunostomy. A jejunal interposition is fashioned with the Roux-en-Y technique. One or two jejunal arteriovenous arcades are divided to mobilize enough jejunum for anastomosis to the thoracic esophagus. A 25 or 28 mm EEA stapler is passed through the jejunum into the esophagus. The jejunum is anchored to the pericardium and the proximal esophagus. The duodenal loop is anastomosed to the jejunum at least 45 to 50 cm distal to the esophagojejunal anastomosis. The blind end of the jejunal loop is then stapled closed.

to minimize postprandial dumping. Patients are also taught how to care for their temporary feeding jejunostomy. Consumption of caffeine and carbonated beverages is usually limited during the first few weeks after discharge.

A barium swallow is performed on postoperative day 7 to verify the integrity of the anastomosis and the patency of the pyloromyotomy. Patients are usually discharged on postoperative day 7 or 8. The feeding jejunostomy is left in place until the first postoperative evaluation, which usually takes place 2 to 3 weeks after the operation. The feeding tube is removed during that visit if oral intake and weight are stable.

COMPLICATIONS OF ESOPHAGECTOMY

Pulmonary Impairment

Atelectasis and pneumonia should be considered preventable complications of esophagectomy. Patients with recognized preoperative impairment of pulmonary reserve should be considered for transhiatal esophagectomy. Existing pulmonary function can be

optimized through incentive spirometry, use of bronchodilators, and physical rehabilitation. Chronic nocturnal aspiration from esophageal obstruction should be watched for in the preoperative patient; the head of the bed should be elevated 30° to 45° as a preventive measure. Effective pain control is essential to prevent postoperative atelectasis. Routine use of patient-controlled thoracic epidural analgesia should be considered. Deep breathing, early ambulation, and chest physiotherapy encourage the clearing of bronchial secretions. Certain patients will require nasotracheal aspiration or bronchoscopy for pulmonary toilet.

Tracheobronchial Injury

On rare occasions, lacerations of the membranous trachea or the left mainstem bronchus occur during esophagectomy. When such injuries occur during transthoracic resection, management is relatively simple, thanks to the already excellent operative exposure. Direct suture repair and tissue reinforcement with adjacent pleura or a pedicle of intercostal muscle provide safe closure in almost all cases. When tracheobronchial injuries occur during transhiatal esophagectomy, they are less obvious but no less urgent. This rare complication arises during mediastinal dissection. Typically, the anesthetic team notes a loss of ventilatory volume, and the surgeon may detect the smell of inhalational agents in the operative field. Bronchoscopy should be promptly performed to identify the site of the injury. The uncut endotracheal tube is then advanced over the bronchoscope and past the site of the laceration to restore proper ventilation. High tracheal injuries can usually be repaired by extending the cervical incision and adding a partial sternotomy. Injury to the carina or the left mainstem bronchus must be repaired via a right thoracotomy.

Bleeding

Hemorrhage should be rare during esophagectomy. In routine situations, blood loss should amount to less than 500 ml. The blood supply to the esophagus consists of small branches coming from the aorta, which are easily controlled and generally constrict even if left untied. Splenic injuries sometimes occur during mobilization of the stomach. The resultant hemorrhage can be immediate or delayed; blood loss may be significant, and splenectomy is usually required. Precise dissection around the left gastric artery is vital: the bleeding vessels may retract, and attempts at control may result in injury to the celiac artery or its hepatic branches. Similarly, peripancreatic vessels may be difficult to control if inadvertently injured during the Kocher maneuver.

Bleeding that arises during the mediastinal stage of the transhiatal esophagectomy generally subsides with packing if it derives from periesophageal arterial branches. Brisk loss of dark blood usually signifies injury to the azygos vein. The first step in addressing such injuries is to pack the mediastinum quickly so as to allow the anesthetic team to stabilize the patient and restore volume. Chest tubes are immediately placed to allow detection of any free hemorrhage into the pleural space. Precise localization of the bleeding site may then follow. Injury to the azygos vein may be addressed via an upper sternal split; however, when the exposure is poor, the surgeon should not hesitate to proceed to a full sternotomy. Bleeding from the subcarinal area is usually bright red and may involve bronchial arteries or small periesophageal vessels arising from the aorta, both of which can usually be controlled through the hiatus with a long-handled pistol-grip clip applicator or electrocautery.

Laryngeal Nerve Injury

Injury to the recurrent laryngeal nerve is a major potential complication of transhiatal esophagectomy. Traction neuropraxia may

be temporary and require no specific treatment. Permanent injury will lead to hoarseness and impaired protection of the airway during deglutition. Pneumonia from chronic aspiration is a major problem. Meticulous protection of the nerve during the cervical stage should minimize the incidence of this complication. If laryngeal nerve injury becomes apparent in the postoperative period, early medialization of the affected cord should be performed by an otolaryngologist.

Of particular concern is the risk of bilateral nerve injury after a transthoracic esophagectomy with a cervical esophagogastric anastomosis (i.e., a so-called three-hole esophagectomy). Any dissection of the upper esophagus performed through the right chest should be done as close to the esophagus as possible to avoid placing traction on the right recurrent laryngeal nerve; the subsequent left cervical dissection may put the left recurrent laryngeal nerve at risk for damage. Bilateral paralysis of the vocal cords is very poorly tolerated and has a devastating impact on quality of life.

Chylothorax

Thoracic duct injuries typically present by postoperative day 3 or 4. Dyspnea and pleural effusion may be noted if thoracostomy tubes are not in place. Thoracentesis yields an opaque, milky fluid. In patients who already have a chest drain in place, there is typically a high volume of serous drainage in the first 2 postoperative days. As enteral nutrition is established and dietary fat reintroduced, the fluid assumes a characteristic milky appearance. In most cases, the gross appearance is diagnostic, and there is rarely a need to confirm the diagnosis by measuring the triglyceride level. A thoracostomy drain is placed to monitor the volume of the chyle leak. Chest x-rays should be obtained to verify complete drainage of the pleural space and full expansion of the lung.

Patients with chylothorax should be converted to fat-free enteral nutrition. Persistent drainage exceeding 500 ml/8 hr is an indication for early operation and ligation of the thoracic duct; high-volume chyle leaks are unlikely to close spontaneously. Prolonged loss of chyle causes significant electrolyte, nutritional, and immunologic derangements that may prove fatal if allowed to progress. Accordingly, patients with persistent chyle leakage should undergo operation within 1 week of diagnosis. A feeding tube is placed in the duodenum before operation if a jejunostomy tube is not already in place. Jejunal feeding with 35% cream at a rate of 60 to 80 ml/hr is maintained for at least 4 hours before operation. Feeding is continued even during the procedure: the enteral fat stimulates a brisk flow of chyle and greatly facilitates visualization of any thoracic duct injury.

Right-side chyle leaks are approached via either a thoracotomy or video-assisted thoracoscopy. The magnification and excellent illumination associated with thoracoscopy are partially counterbalanced by the constraints imposed by port placement and limited tissue retraction. The inferior pulmonary ligament is divided, and the posterior mediastinum is inspected for extravasation of milky fluid. Any visible sources of chyle leakage can be controlled with clips or suture ligatures. In some cases, mass ligation of the thoracic duct at the level of the diaphragm, incorporating all the soft tissue between the aorta and the azygos vein, may be required.

Left-side leaks can be difficult to manage. The subcarinal area is typically involved; this is the level at which the thoracic duct crosses over from the right. Exploration should begin on the left side. If the leak cannot be visualized, a right-side approach may be necessary to control the thoracic duct as it first enters the chest.

Anastomotic Leakage

The consequences of anastomotic complications after esophagectomy vary considerably in severity, depending on their loca-

tion and cause. The cervical anastomotic leaks that may develop after transhiatal esophagectomy are generally simple to treat. Leaks in the early postoperative period are usually related to technical factors (e.g., excessive tension across the anastomosis). A nonviable stomach may not give rise to obvious signs, and thus, any possibility of ischemia in the transposed stomach must be addressed promptly. Tachycardia, confusion, leukocytosis, cervical wound drainage, and neck tenderness may or may not be present.

The morbidity of an open cervical wound is not high—certainly lower than that of an untreated leak. Accordingly, any clinical suspicion of a leak should prompt a diagnostic contrast swallow study using dilute barium. Large leaks are manifested as persistent collections of contrast material outside the esophagus. Although such leaks rarely extend into the pleural space, any fluid in the chest must be drained so that its nature can be determined. The neck wound is opened by removing the sutures and performing gentle digital exploration of the prevertebral space behind the esophagus as the finger is advanced into the mediastinum; this is usually done at the bedside and requires little, if any, patient sedation.

Saline-moistened gauze packing is changed three or four times a day. Prolonged or copious cervical drainage may call for supplemental deep wound aspiration with a Yankauer suction handle. Administering water orally during aspiration facilitates removal of any necrotic debris. A fetid, malodorous breath associated with sanguineous discharge from the nasogastric tube and purulent fluid in the opened neck incision are ominous signs that should prompt early esophagoscopy. Diffuse mucosal ischemia may indicate the presence of a nonviable stomach; reoperation with completion gastrectomy and proximal esophagostomy is required to treat this rare catastrophic complication.

Generally, leaks that occur more than 7 days after operation are small and are related to some degree of late ischemic disruption along the anastomosis. They can usually be managed by opening the cervical wound at the bedside and packing the site with gauze. Oral diet is advanced as tolerated. It may be noted that the volume of the leak is markedly greater or less depending on the position of the head during swallowing. Accordingly, before discharge, patients are taught how to temporarily adjust their swallowing as well as how to manage their dressing changes. Applying gentle pressure to the neck wound and turning the head to the left may help the patient ingest liquids with minimal soiling of the open neck incision. Dysphagia, even with an opened neck incision, should be treated by passing tapered esophageal dilators orally between 2 and 4 weeks after surgery. When a bougie at least 48 French in caliber can be passed through the anastomosis, the patient can usually swallow comfortably. The size of the leak often decreases after dilation as food is allowed to proceed preferentially into the stomach. To maximize the diameter of the anastomosis and reduce the likelihood of a symptomatic stricture, subsequent dilations should be scheduled at 2-week intervals for the next few months.

When a routine predischarge barium swallow after transhiatal esophagectomy raises the possibility of an anastomotic leak in an asymptomatic patient, the question arises of whether the wound should be opened at all. For small, contained leaks associated with preferential flow of contrast material into the stomach, observation alone may suffice in selected cases. Patients must be closely watched for fever or other signs of major infection. Given the quite low morbidity of cervical wound exploration, the surgeon should not hesitate to drain the neck if the patient's condition changes.

The incidence of anastomotic leakage is low after Ivor-Lewis resection, but the consequences are significant. Leaks presenting early in the postoperative period are usually related to technical

problems and are difficult to manage; those presenting later are generally related to some degree of ischemic tissue loss. Patients who have received radiation therapy or are nutritionally depleted may be especially vulnerable to problems with anastomotic healing. A contrast swallow with dilute barium is the best method of evaluating the anastomosis. Leaks may be manifested either as a free flow of contrast into the pleural space or as a contained fluid collection.

Small leaks that drain immediately into properly placed thoracostomy tubes can usually be managed by giving antibiotics and withholding oral intake. Local control of infection generally results in spontaneous healing. Anastomotic disruptions that are large or are associated with a major pleural collection typically necessitate open drainage with decortication; percutaneous drainage may be considered as a preliminary approach in selected patients. Persistent soiling of the mediastinum and the pleural space is fatal if untreated.

Early esophagoscopy is strongly advised to evaluate the viability of the gastric remnant. Ischemic necrosis of the stomach necessitates reexploration, decortication, takedown of the anastomosis, gastric debridement, return of any viable stomach into the abdomen, closure of the hiatus, and proximal diversion with a cervical esophagostomy. Repair or revision of the anastomosis in an infected field is certain to fail and should never be considered. In certain cases, diversion via a cervical esophagostomy and a completion gastrectomy may be required.

Late Complications

At every postoperative visit, symptoms of reflux, regurgitation, dumping, poor gastric emptying, and dysphagia must be specifically sought: these are the major quality-of-life issues for post-esophagectomy patients.⁴ Reflux and regurgitation may complicate any form of alimentary reconstruction after esophagectomy, though cervical anastomoses are less likely to be associated with symptomatic reflux than intrathoracic anastomoses are. Reflux symptoms generally respond to dietary modifications, such as smaller and more frequent meals. Regurgitation is usually related to the supine position and thus tends to be worse at night; elevating the bed and avoiding late meals may suffice for symptom control. Dumping is exacerbated by foods with high fat or sugar content. Dysphagia may be related to narrowing at the anastomosis or, in rare instances, to poor emptying of the transposed stomach. Anastomotic strictures are most commonly encountered as a sequel to a postoperative leak. There may be excessive scarring at the anastomosis, associated with local distortion or angulation. Specific tests for gastric atony include nuclear medicine gastric emptying studies using radiolabeled food. A simple barium swallow may indicate an incomplete pyloromyotomy as a cause of poor gastric emptying; balloon dilation often corrects this problem.

Any form of anastomotic leak will increase the incidence of late stricture. Dysphagia may be treated by means of progressive dilation with Maloney bougies. This procedure is performed in the outpatient clinic and often does not require sedation or any other special patient preparation. Complications are rare if due care is exercised during the procedure. As noted [*see Transthoracic Hiatal Hernia Repair, Preoperative Evaluation, Dilation, above*], it is essential that the caliber of the dilators be increased gradually and that little or no force be applied in advancing them. The appearance of blood on a withdrawn dilator signals a breach of the mucosa; further dilation should be done cautiously lest a transmural injury result. Comfortable swallowing, of liquids at least, is usually achieved after the successful passage of a 48 French bougie. It is preferable, however, to advance dilation until at least

a 54 French bougie can be passed with ease. For late strictures that are particularly difficult to dilate, endoscopic examination and histologic evaluation may be required to rule out a recurrent tumor. CT of the chest should also be performed whenever there is unexplained weight loss or fatigue late after esophagectomy.

The Savary system of wire-guided dilators has been particularly helpful in the management of tight or eccentric strictures. Patients are generally treated in the endoscopy suite. Temporary sedation with I.V. fentanyl and midazolam is required. Fluoroscopy is used to confirm proper placement of a flexible-tip wire across the stricture. Serial wire-guided dilation can then be performed with confidence and increased patient safety.

OUTCOME EVALUATION

Transhiatal Esophagectomy

A 1999 study from the University of Michigan presented data on 1,085 patients who underwent transhiatal esophagectomy without thoracotomy, of whom 74% had carcinoma and 26% had nonmalignant disease.⁵ Transhiatal esophagectomy was completed in 98.6% of the patients; the remaining 1.4% were converted to a transthoracic esophagectomy as a result of either thoracic esophageal fixation or bleeding. Previous chemotherapy or radiation therapy did not preclude performance of a transhiatal esophagectomy. Nine patients experienced inordinate intraoperative blood loss; three died as a result. The overall hospital mortality was 4%. The overall 5-year survival rate for patients undergoing transhiatal esophagectomy is approximately 20% for adenocarcinoma of the cardia and the esophagus and 30% for squamous cell carcinoma of the esophagus.

The stapled anastomosis described earlier [see Operative Technique, Transhiatal Esophagectomy, Step 8, *above*] reflects numerous refinements introduced at the University of Michigan. The endoscopic GIA stapler has a low-profile head that is ideally suited to the tight confines of the neck, enabling the surgeon to fashion a widely patent side-to-side functional end-to-end anastomosis with three rows of staples along the back wall. The rate of anastomotic stricture is markedly lower with this anastomosis than

with a totally handsewn anastomosis. As regards postoperative function, stomach interposition through the posterior mediastinum after transhiatal esophagectomy is associated with low rates of aspiration and regurgitation. Esophageal reflux and esophagitis—commonly seen with intrathoracic esophagogastric anastomoses—are usually not clinically significant problems with this approach. Patients are advised to elevate the head of their bed and to continue taking PPIs for about 3 months after the operation. Approximately one third will require esophageal dilation for dysphagia after the operation. Some 7% to 10% experience postvagotomy dumping symptoms, which in most cases can be controlled by simply avoiding high-carbohydrate foods and dairy products.

Ivor-Lewis Esophagectomy

Ivor-Lewis esophagectomy is associated with anastomotic leakage rates and operative mortalities of less than 3%.^{3,6} Approximately 5% of patients will require anastomotic dilation. Again, patients are advised to elevate the head of the bed and to continue taking PPIs. In some patients, the gastric interposition rotates into the right posterolateral thoracic gutter, resulting in postprandial gastric tension and rendering them more susceptible to aspiration. Compared with transhiatal esophagectomy, extended transthoracic esophagectomy is associated with higher pulmonary morbidity and operative mortality but also with a superior 3-year survival rate.⁷

Left Thoracoabdominal Esophagogastrrectomy

Left thoracoabdominal esophagogastrrectomy is also associated with anastomotic leakage rates and operative mortalities of less than 3%.⁸ Approximately 5% of patients will require esophageal dilation. Reconstructions involving anastomosis of the distal stomach to the esophagus are associated with a high incidence of delayed gastric emptying and bile gastritis and esophagitis. Of all the operations we have described, this one results in the lowest postoperative quality of life. Accordingly, most surgeons prefer to carry out a total gastrectomy. Swallowing is restored with a Roux-en-Y jejunal interposition.

5 MINIMALLY INVASIVE ESOPHAGEAL PROCEDURES

Marco G. Patti, M.D., F.A.C.S.

During the 1970s and the 1980s, operations for benign esophageal disorders were often withheld or delayed in favor of less effective forms of treatment in an effort to prevent the postoperative discomfort, the long hospital stay, and the recovery time associated with open surgical procedures. For instance, pneumatic dilatation became first-line therapy for achalasia, even though surgical management had been shown to be clearly superior.¹

In the first part of the 1990s, it became clear that treatment of benign esophageal disorders with minimally invasive procedures yielded results comparable to those of treatment with traditional operations while causing minimal postoperative discomfort, reducing the duration of hospitalization, shortening recovery time, and permitting earlier return to work.^{2,3} Consequently, minimally invasive surgery was increasingly considered as first-line treatment for achalasia, and laparoscopic fundoplication was considered more readily and at an earlier stage in the management of gastroesophageal reflux disease (GERD).

Since then, minimally invasive esophageal procedures have continued to evolve, thanks to better instrumentation and improved surgical expertise. In addition, with greater experience and longer follow-up periods, it has become possible to analyze techniques and their results more rigorously. For instance, whereas a few years ago a left thoracoscopic Heller myotomy was considered the procedure of choice for achalasia, the current procedure of choice is a laparoscopic Heller myotomy with partial fundoplication, which has proved to be better at relieving dysphagia and controlling postoperative reflux.⁴⁻⁷ Similarly, whereas total fundoplication and partial fundoplication were initially considered equally effective in treating GERD,⁸ total fundoplication is now viewed as clearly superior for this purpose and should be used whenever feasible.⁹

In this chapter, I focus on minimally invasive approaches to the treatment of abnormal gastroesophageal reflux and esophageal motility disorders. The standard open counterparts of these operations are described elsewhere [see 4:4 *Open Esophageal Procedures*].

Laparoscopic Nissen Fundoplication

PREOPERATIVE EVALUATION

All patients who are candidates for a laparoscopic fundoplication should undergo a preoperative evaluation that includes the following: (1) symptomatic evaluation, (2) an upper GI series, (3) endoscopy, (4) esophageal manometry, and (5) ambulatory pH monitoring.

Symptomatic Evaluation

The presence of both typical symptoms (heartburn, regurgitation, and dysphagia) and atypical symptoms of GERD (cough, wheezing, chest pain, and hoarseness) should be investigated, and

symptoms should be graded with respect to their intensity both before and after operation. Nonetheless, a diagnosis of GERD should never be based solely on symptomatic evaluation. Many authorities assert that the diagnosis can be made reliably from the clinical history,¹⁰ so that a complaint of heartburn should lead to the presumption that acid reflux is present; however, testing of this diagnostic strategy demonstrates that symptoms are far less sensitive and specific than is usually believed.¹¹ For instance, a study from the University of California, San Francisco (UCSF), found that of 822 consecutive patients referred for esophageal function tests with a clinical diagnosis of GERD (based on symptoms and endoscopic findings), only 70% had abnormal reflux on pH monitoring.¹² Heartburn and regurgitation were no more frequent in patients who had genuine reflux than in those who did not; thus, symptomatic evaluation, by itself, could not distinguish between the two groups.

The response to proton pump inhibitors (PPIs) is a better predictor of abnormal reflux. For example, in the UCSF study just cited, 75% of patients with GERD reported a good or excellent response to PPIs, compared with only 26% of patients without GERD.¹² Similarly, a study involving multivariate analysis of factors predicting outcome after laparoscopic fundoplication concluded that a clinical response to acid suppression therapy was one of three factors predictive of a successful outcome, the other two being an abnormal 24-hour pH score and the presence of a typical primary symptom (e.g., heartburn).¹³

Upper Gastrointestinal Series

An upper GI series is useful for diagnosing and characterizing an existing hiatal hernia. The size of the hiatal hernia helps predict how difficult it will be to reduce the esophagogastric junction below the diaphragm. In addition, large hiatal hernias are associated with more severe disturbances of esophageal peristalsis and esophageal acid clearance.¹⁴ Esophagograms are also useful for determining the location, shape, and size of a stricture and detecting a short esophagus.

Endoscopy

Endoscopy is typically the first test performed to confirm a symptom-based diagnosis of GERD. This approach has two pitfalls, however. First, even though the goal of endoscopy is to assess the mucosal damage caused by reflux, mucosal changes are absent in about 50% of GERD patients.¹² Second, major interobserver variations have been reported with esophageal endoscopy, particularly for low-grade esophagitis.¹⁵ In one study, for instance, 60 (24%) of 247 patients with negative results on pH monitoring had been diagnosed as having grade I or II esophagitis.¹² Accordingly, I believe that endoscopy is most valuable for excluding gastric and duodenal pathologic conditions and detecting the presence of Barrett's esophagus.

Esophageal Manometry

Esophageal manometry provides useful information about the motor function of the esophagus by determining the length and resting pressure of the lower esophageal sphincter (LES) and assessing the quality (i.e., the amplitude and propagation) of esophageal peristalsis. In addition, it allows proper placement of the pH probe for ambulatory pH monitoring (5 cm above the upper border of the LES).

Ambulatory pH Monitoring

Ambulatory pH monitoring is the most reliable test for the diagnosis of GERD, with a sensitivity and specificity of about 92%.¹⁶ It is of key importance in the workup for the following four reasons.

1. It determines whether abnormal reflux is present. In the UCSF study mentioned earlier,¹² pH monitoring yielded normal results in 30% of patients with a clinical diagnosis of GERD, thereby obviating the continuation of inappropriate and expensive drugs (e.g., PPIs) or the performance of a fundoplication. In addition, pH monitoring prompted further investigation that in a number of cases pointed to other diseases (e.g., cholelithiasis and irritable bowel syndrome).
2. It establishes a temporal correlation between symptoms and episodes of reflux. Such a correlation is particularly important when atypical GERD symptoms are present because 50% of these patients experience no heartburn and 50% do not have esophagitis on endoscopy.¹⁷
3. It allows staging on the basis of disease severity. Specifically, pH monitoring identifies a subgroup of patients characterized by worse esophageal motor function (manifested by a defective LES or by abnormal esophageal peristalsis), more acid reflux in the distal and proximal esophagus, and slower acid clearance. These patients more frequently experience stricture formation and Barrett metaplasia and thus might benefit from early antireflux surgery.¹⁸
4. It provides baseline data that may prove useful postoperatively if symptoms do not respond to the procedure.

OPERATIVE PLANNING

The patient is placed under general anesthesia and intubated with a single-lumen endotracheal tube. Abdominal wall relaxation

is ensured by the administration of a nondepolarizing muscle relaxant, the action of which is rapidly reversed at the end of the operation. Adequate muscle relaxation is essential because increased abdominal wall compliance allows increased pneumoperitoneum, which yields better exposure. An orogastric tube is inserted at the beginning of the operation to keep the stomach decompressed; it is removed at the end of the procedure.

The patient is placed in a steep reverse Trendelenburg position, with the legs extended on stirrups. The surgeon stands between the patient's legs. To keep the patient from sliding as a result of the steep position used during the operation, a bean bag is inflated under the patient, and the knees are flexed only 20° to 30°. A Foley catheter is inserted at the beginning of the procedure and usually is removed in the postoperative period. Because increased abdominal pressure from pneumoperitoneum and the steep reverse Trendelenburg position decrease venous return, pneumatic compression stockings are always used as prophylaxis against deep vein thrombosis.

The equipment required for a laparoscopic Nissen fundoplication includes five 10 mm trocars, a 30° laparoscope, a hook cautery, and various other instruments [see Table 1]. In addition, we use a three-chip camera system that is separate from the laparoscope.

OPERATIVE TECHNIQUE

In all patients except those with very poor esophageal motility—for whom partial fundoplication [see Laparoscopic Partial (Guarner) Fundoplication, *below*] is preferable—we advocate performing a 360° wrap of the gastric fundus around the lower esophagus as described by Nissen, but we always take down the short gastric vessels to achieve what is called a floppy fundoplication. This type of wrap is very effective in controlling gastroesophageal reflux.^{19,20} The operation can be divided into nine key steps as follows.

Step 1: Placement of Trocars

Five 10 mm trocars are used for the operation [see Figure 1]. Port A is placed about 14 cm below the xiphoid process; it can also be placed slightly (2 to 3 cm) to the left of the midline to be in line with the hiatus. This port is used for insertion of the scope. Port B is placed at the same level as port A but in the left midclavicular line. It is used for insertion of the Babcock clamp; insertion of a grasper to hold the Penrose drain once it is in place surrounding the esophagus; or insertion of the clip applier, the ultrasonic coagulating shears, or both to take down the short gastric vessels. Port C is placed at the same level as the previous two ports but in the right midclavicular line. It is used for insertion of the fan retractor, the purpose of which is to lift the lateral segment of the left lobe of the liver and expose the esophagogastric junction. I do not divide the left triangular ligament. The fan retractor can be held in place by a self-retaining system fixed to the operating table. Ports D and E are placed as high as possible under the costal margin and about 5 to 6 cm to the right and the left of the midline so that they are about 15 cm from the esophageal hiatus; in addition, they should be placed so that their axes form an angle of 60° to 120°. These ports are used for insertion of the graspers, the electrocautery, and the suturing instruments.

Troubleshooting If the ports are placed too low in the abdomen, the operation is made more difficult. If port C is too low, the fan retractor will not retract the lateral segment of the left lobe of the liver well, and the esophagogastric junction will not be exposed. If port B is too low, the Babcock clamp will not reach the esophagogastric junction, and when the ultrasonic coagulating

shears or the clip applicator is placed through the same port, it will not reach the upper short gastric vessels. If ports D and E are too low, the dissection at the beginning of the case and the suturing at the end are problematic.

Other mistakes of positioning must be avoided as well. Port C must not be placed too medially, because the fan retractor may clash with the left-hand instrument; the gallbladder fossa is a good landmark for positioning this port. Port A must be placed with extreme caution in the supraumbilical area: its insertion site is just above the aorta, before its bifurcation. Accordingly, I recommend initially inflating the abdomen to a pressure of 18 mm Hg just for placement of port A; increasing the distance between the abdominal wall and the aorta reduces the risk of aortic injury. I also recommend directing the port toward the coccyx. Once port A is in place, the intraperitoneal pressure is reduced to 15 mm Hg. A Hasson cannula can be used in this location, particularly if the patient has already had one or more midline incisions. Maintaining the proper angle (60° to 120°) between the axes of the two suturing instruments inserted through ports D and E is also important: if the angle is smaller, the instruments will cover part of the operating field, whereas if it is larger, depth perception may be impaired. Finally, if a trocar is not in the ideal position, it is better to insert another one than to operate through an inconveniently placed port.

If the surgeon spears the epigastric vessels with a trocar, bleeding will occur, in which case there are two options. The first option is to pull the port out, insert a 24 French Foley catheter with a 30 ml balloon through the site, inflate the balloon, and apply traction with a clamp. The advantage of this maneuver is that the vessel

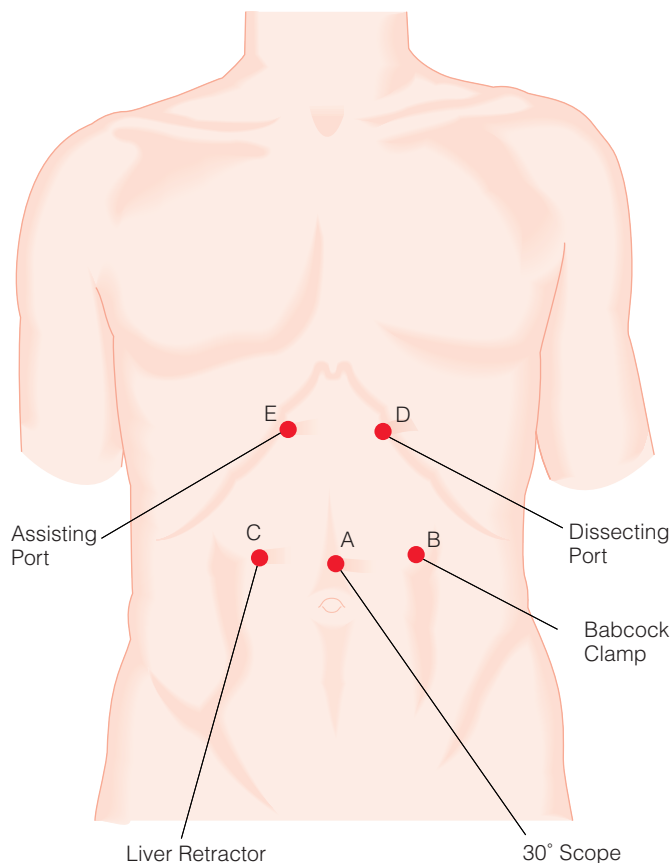

Figure 1 Laparoscopic Nissen fundoplication. Illustrated is the recommended placement of the trocars.

need not be sutured; the disadvantage is that the surgeon must then choose another insertion site. At the end of the case, the balloon is deflated. If some bleeding is still present, it must be controlled with sutures placed from outside under direct vision. The second option is to use a long needle with a suture, with which one can rapidly place two U-shaped stitches, one above the clamp and one below. The suture is tied outside over a sponge and left in place for 2 or 3 days.

Step 2: Division of Gastrohepatic Ligament; Identification of Right Crus of Diaphragm and Posterior Vagus Nerve

Once the ports are in place, the gastrohepatic ligament is divided. Dissection begins above the caudate lobe of the liver, where this ligament usually is very thin, and continues toward the diaphragm until the right crus is identified. The crus is then separated from the right side of the esophagus by blunt dissection, and the posterior vagus nerve is identified. The right crus is dissected inferiorly toward the junction with the left crus.

Troubleshooting An accessory left hepatic artery originating from the left gastric artery is frequently encountered in the gastrohepatic ligament. If this vessel creates problems of exposure, it may be divided; in my experience, doing so has not caused problems. When dissecting the right crus from the esophagus, the electrocautery should be used with particular caution. Because the monopolar current tends to spread laterally, the posterior vagus nerve may sustain damage simply from being in proximity to the device, even when there is no direct contact. The risk of neuropraxia can be reduced by using the cut mode rather than the coagulation mode when the electrocautery is close to the nerve. The cut mode has problems of its own, however, and is not recommended in most laparoscopic procedures. A better alternative is to use the ultrasonic coagulating shears.

Step 3: Division of Peritoneum and Phrenoesophageal Membrane above Esophagus; Identification of Left Crus of Diaphragm and Anterior Vagus Nerve

The peritoneum and the phrenoesophageal membrane above the esophagus are divided with the electrocautery, and the anterior vagus nerve is identified. The left crus of the diaphragm is dissected downward toward the junction with the right crus.

Troubleshooting Care must be taken not to damage the anterior vagus nerve or the esophageal wall. To this end, the nerve should be left attached to the esophageal wall, and the peritoneum and the phrenoesophageal membrane should be lifted from the wall by blunt dissection before they are divided.

Step 4: Creation of Window between Gastric Fundus, Esophagus, and Diaphragmatic Crura; Placement of Penrose Drain around Esophagus

The esophagus is retracted upward with a Babcock clamp applied at the level of the esophagogastric junction. Via blunt and sharp dissection, a window is created under the esophagus between the gastric fundus, the esophagus, and the diaphragmatic crura. The window is enlarged with the ultrasonic coagulating shears, and a Penrose drain is passed around the esophagus. This drain is then used for traction instead of the Babcock clamp to reduce the risk of damage to the gastric wall.

Troubleshooting The two main problems to watch for during this part of the procedure are (1) creation of a left pneumothorax and (2) perforation of the gastric fundus.

A left pneumothorax is usually caused by dissection done above the left crus in the mediastinum rather than between the crus and the gastric fundus. This problem can be avoided by properly dissecting and identifying the left crus.

Perforation of the gastric fundus is usually caused by pushing a blunt instrument under the esophagus and below the left crus without having done enough dissection. Care must be exercised in taking down small vessels from the fundus when the area behind the esophagus is approached from the right: the anatomy is not as clear from this viewpoint, and perforation can easily occur. Sometimes, perforation is caused by the use of a monopolar electrocautery for dissection. An electrocautery burn can go unrecognized during dissection and manifest itself in the form of a leak during the first 48 hours after operation.

Step 5: Division of Short Gastric Vessels

The ultrasonic coagulating shears or the clip applier is introduced through port B. A grasper is introduced by the surgeon through port D, and an assistant applies traction on the greater curvature of the stomach through port E. Dissection begins at the level of the middle portion of the gastric body and continues upward until the most proximal short gastric vessel is divided and the Penrose drain is reached.

Troubleshooting Again, there are two main problems to watch for during this part of the procedure: (1) bleeding, either from the gastric vessels or from the spleen, and (2) damage to the gastric wall.

Bleeding from the gastric vessels is usually caused by excessive traction or by division of a vessel that is not completely occluding with clips on both sides. Vessels up to 5 mm in diameter can be taken down with the ultrasonic coagulating shears; this process requires about half of the amount of time needed when only clips are used. The lower blade has a sharp, oscillating inferior edge that must always be kept in view to prevent damage to other structures (e.g., the pancreas, the splenic artery and vein, and the spleen). Damage to the gastric wall can be caused by a burn from the electrocautery used to dissect between vessels or by traction applied via the graspers or the Babcock clamp.

Step 6: Closure of Crura

The diaphragmatic crura are closed with interrupted 2-0 silk sutures on a curved needle; the sutures are tied intracorporeally. Exposure is provided by retracting the esophagus upward and toward the patient's left with the Penrose drain. The lens of the 30° laparoscope is angled slightly to the left by moving the light cable of the scope to the patient's right. The first stitch should be placed just above the junction of the two crura. Additional stitches are placed 1 cm apart, and a space of about 1 cm is left between the uppermost stitch and the esophagus.

Troubleshooting Care must be taken not to spear the posterior wall of the esophagus with either the tip or the back of the needle. So as not to limit the space available for suturing, the bougie is not placed inside the esophagus during this part of the procedure.

Step 7: Insertion of Bougie into Esophagus and through Esophagogastric Junction

The esophageal stethoscope and the orogastric tube are removed, and a 56 French bougie is inserted by the anesthesiologist and passed through the esophagogastric junction under laparoscopic vision. The crura must be snug around the esophagus

but not too tight: a closed grasper should slide easily between the esophagus and the crura.

Troubleshooting The most worrisome complication during this step is perforation of the esophagus. This can be prevented by lubricating the bougie and instructing the anesthesiologist to advance the bougie slowly and to stop if any resistance is encountered. In addition, it is essential to remove any instruments from the esophagogastric junction and to open the Penrose drain; these measures prevent the creation of an angle between the stomach and the esophagus, which can increase the likelihood of perforation. The position of the bougie can be confirmed by pressing with a grasper over the esophagus, which will feel full when the bougie is in place.

Step 8: Wrapping of Gastric Fundus around Lower Esophagus

The gastric fundus is gently pulled under the esophagus with the graspers. The left and right sides of the fundus are wrapped above the fat pad (which lies above the esophagogastric junction) and held together in place with a Babcock clamp introduced through port B. (The Penrose drain should be removed at this point because it is in the way.) Usually, three 2-0 silk sutures are used to secure the two ends of the wrap to each other. The first stitch does not include the esophagus and is used for traction; the second and the third include a bite of the esophageal muscle. The bougie is passed into the stomach after the first stitch to assess the size of the wrap. If the wrap seems at all tight, the stitch is removed and repositioned more laterally. Two coronal stitches are then placed between the top of the wrap and the esophagus, one on the right and one on the left. Finally, one additional suture is placed between the right side of the wrap and the closed crura.

To avoid the risk of injuring the inferior vena cava at the beginning of the dissection, some surgeons use a different method—the so-called left crus approach.¹⁹ In this approach, the operation begins with identification of the left crus of the diaphragm and division of the peritoneum and the phrenoesophageal membrane overlying it. The next step is division of the short gastric vessels, starting midway along the greater curvature of the stomach and continuing upward to join the area of the previous dissection. When the fundus has been thoroughly mobilized, the peritoneum is divided from the left to the right crus, and the right crus is dissected downward to expose the junction of the right and left crura. With this technique, the vena cava is never at risk. In addition, the branches of the anterior vagus nerve and the left gastric artery are less exposed to danger. This technique can be very useful, particularly for management of very large paraesophageal hernias and for second antireflux operations [see Reoperation for GERD, below].

Troubleshooting To determine whether the wrap is going to be floppy, the surgeon must deliver the fundus under the esophagus, making sure that the origins of the short gastric vessels that have been transected are visible. Essentially, the posterior wall of the fundus is being used for the wrap. If the wrap remains to the right of the esophagus without retracting back to the left, then it is floppy, and suturing can proceed. If not, the surgeon must make sure that the upper short gastric vessels have been transected. If tension is still present after these maneuvers, it is probably best to perform a partial wrap [see Laparoscopic Partial (Guarner) Fundoplication, below].

Damage to the gastric wall may occur during the delivery of the fundus. Atraumatic graspers must be used, and the gastric fundus must be pulled gently and passed from one grasper to the other.

Sometimes, it is helpful to push the gastric fundus under the esophagus from the left. The wrap should measure no more than 2 to 2.5 cm in length and, as noted, should be done with no more than three sutures. The first stitch is usually the lowest one; it must be placed just above the fat pad where the esophagogastric junction is thought to be.

If the anesthesiologist observes that peak airway pressure has increased (because of a pneumothorax) or that neck emphysema is present (because of pneumomediastinum), the pneumoperitoneum should be reduced from 15 mm Hg to 8 or 10 mm Hg until the end of the procedure. Pneumomediastinum tends to resolve without intervention within a few hours of the end of the procedure. Small pneumothoraces (usually on the left side) tend to resolve spontaneously, rendering insertion of a chest tube unnecessary. Larger pneumothoraces (> 20%), however, call for the insertion of a small (18 to 20 French) chest tube.

Step 9: Final Inspection and Removal of Instruments and Ports from Abdomen

After hemostasis is obtained, the instruments and the ports are removed from the abdomen under direct vision.

Troubleshooting If any areas of oozing were observed, they should be irrigated and dried with sponges rolled into a cigarette-like shape before the ports are removed. In addition, if some grounds for concern remain, the oozing areas should be examined after the pneumoperitoneum is decreased to 7 to 8 mm Hg to abolish the tamponading effect exerted by the high intra-abdominal pressure.

All the ports should be removed from the abdomen under direct vision so that any bleeding from the abdominal wall can be readily detected. Such bleeding is easily controlled, either from inside or from outside.

COMPLICATIONS

A feared complication of laparoscopic Nissen fundoplication is esophageal or gastric perforation, which may result either from traction applied with the Babcock clamp or a grasper to the esophagus or the stomach (particularly when the stomach is pulled under the esophagus) or from inadvertent electrocautery burns during any part of the dissection. A leak will manifest itself during the first 48 hours. Peritoneal signs will be noted if the spillage is limited to the abdomen; shortness of breath and a pleural effusion will be noted if spillage also occurs in the chest. The site of the leak should always be confirmed by a contrast study with barium or a water-soluble contrast agent. Optimal management consists of laparotomy and direct repair. If a perforation is detected intraoperatively, it may be closed laparoscopically.

About 50% of patients experience mild dysphagia postoperatively. This problem usually resolves after 4 to 6 weeks, during which period patients receive pain medications in an elixir form and are advised to avoid eating meat and bread. If, however, dysphagia persists beyond this period, one or more of the following causes is responsible.

1. A wrap that is too tight or too long (i.e., > 2.5 cm).²¹
2. Lateral torsion with corkscrew effect. If the wrap rotates to the right (because of tension from intact short gastric vessels or because the fundus is small), a corkscrew effect is created.
3. A wrap made with the body of the stomach rather than the fundus. The relaxation of the LES and the gastric fundus is controlled by vasoactive intestinal polypeptide and nitric oxide^{22,23}; after fundoplication, the two structures relax simultaneously

with swallowing. If part of the body of the stomach rather than the fundus is used for the wrap, it will not relax as the LES does on arrival of the food bolus.

4. Choice of the wrong procedure. In patients who have severely abnormal esophageal peristalsis (as in end-stage connective tissue disorders), a partial wrap is preferable. A 360° wrap may cause postoperative dysphagia and gas bloat syndrome.

If the wrap slips into the chest, the patient becomes unable to eat and prone to vomiting. A chest radiograph shows a gastric bubble above the diaphragm, and the diagnosis is confirmed by means of a barium swallow. This problem can be prevented by using coronal sutures and by ensuring that the crura are closed securely.

Paraesophageal hernia may occur if the crura have not been closed or if the closure is too loose. In my opinion, closure of the crura not only is essential for preventing paraesophageal hernia but also is important from a physiologic point of view, in that it acts synergistically with the LES against stress reflux. Sometimes, it is possible to reduce the stomach and close the crura laparoscopically. More often, however, because the crural opening is very tight and the gastric wall is edematous, laparoscopic repair is impossible and laparotomy is preferable.

POSTOPERATIVE CARE AND OUTCOME EVALUATION

Postoperative care and outcome evaluation of laparoscopic Nissen fundoplication are considered elsewhere in conjunction with the discussion of partial fundoplication [see Laparoscopic Partial (Guarner) Fundoplication, Postoperative Care and Outcome Evaluation, *below*].

Laparoscopic Partial (Guarner) Fundoplication

PREOPERATIVE EVALUATION AND OPERATIVE PLANNING

Preoperative evaluation and operative planning are essentially the same for partial (Guarner) fundoplication as for Nissen fundoplication. This operation should be performed only in patients with the most severe abnormalities of esophageal peristalsis: it is less effective than a 360° wrap for long-term control of reflux.⁹ In addition, laparoscopic partial fundoplication may be performed after laparoscopic Heller myotomy for achalasia [see Laparoscopic Heller Myotomy with Partial Fundoplication, *below*].²⁴

OPERATIVE TECHNIQUE

The first seven steps in a Guarner fundoplication are identical to the first seven in a Nissen fundoplication. The wrap, however, differs in that it extends around only 240° to 280° of the esophageal circumference. Once the gastric fundus is delivered under the esophagus, the two sides are not approximated over the esophagus. Instead, 80° to 120° of the anterior esophagus is left uncovered, and each of the two sides of the wrap (right and left) is separately affixed to the esophagus with three 2-0 silk sutures, with each stitch including the muscle layer of the esophageal wall. The remaining stitches (i.e., the coronal stitches and the stitch between the right side of the wrap and the closed crura) are identical to those placed in a Nissen fundoplication.

POSTOPERATIVE CARE

Currently, my average operating time for a laparoscopic fundoplication is approximately 2 hours. I start patients on a soft mechanical diet on the morning of postoperative day 1 and usually discharge them after 23 to 48 hours. The recovery time usually ranges from 10 to 14 days.

OUTCOME EVALUATION

The initial results of laparoscopic fundoplication obtained in the early 1990s indicated that the operation was effective in controlling reflux but that postoperative dysphagia occurred more often than had been anticipated.⁸ Many experts thought that this problem could be avoided by tailoring the fundoplication to the strength of esophageal peristalsis as measured by esophageal manometry.⁸ Accordingly, partial fundoplication (240°) was recommended for patients with impaired peristalsis, and total fundoplication (360°) was recommended for those with normal peristalsis. The short-term results of this tailored approach were promising.⁸ Gradually, however, it became evident that partial fundoplication was not as durable as total fundoplication⁹ and that total fundoplication did not pose a special problem for patients with weak peristalsis.²⁵

Long-term follow-up of patients operated on in accordance with the tailored approach at UCSF between October 1992 and December 1999 indicated that the promising short-term results reported earlier⁸ were not maintained over time.²⁰ After a mean follow-up period of 70 months, 56% of the patients who underwent partial fundoplication had recurrent reflux as documented by pH monitoring, compared with only 28% of those who underwent total fundoplication. (These figures probably overestimate the real incidence of postoperative reflux, in that most of the patients studied had heartburn and very few were asymptomatic.) In addition, more of the patients in the partial fundoplication group needed acid-suppressing medication (25% versus 8%) or a second operation (9% versus 3%). The incidence of postoperative dysphagia, however, was the same in the two groups, which indicated that the completeness of the wrap played no role in causing this largely transient complication. These findings suggest that the initial problems with postoperative dysphagia were primarily attributable to unknown technical factors that were largely eliminated from the procedure as surgeons garnered more experience with it. As a result, total fundoplication is currently considered the procedure of choice for patients with GERD, regardless of the strength of their esophageal peristalsis.

Laparoscopic Heller Myotomy with Partial Fundoplication

Minimally invasive surgical procedures for primary esophageal motility disorders (achalasia, diffuse esophageal spasm, and nutcracker esophagus) yield results that are comparable to those of open procedures but are associated with less postoperative pain and with a shorter recovery time.²⁶ Today, laparoscopic Heller myotomy with partial fundoplication has supplanted left thoracoscopic myotomy as the procedure of choice for esophageal achalasia.^{4,7} Long-term studies demonstrated that even though left thoracoscopic myotomy led to resolution of dysphagia in about 85% to 90% of patients, it had the following four drawbacks.

1. Gastroesophageal reflux developed postoperatively in about 60% of patients because no fundoplication was performed in conjunction with the myotomy.⁴ With the laparoscopic approach, in contrast, a partial fundoplication can easily be performed, which prevents reflux in the majority of patients^{4,5} and corrects many instances of preexisting reflux arising from pneumatic dilatation.⁴ A prospective, randomized, double-blind clinical trial that compared Heller myotomy alone with Heller myotomy and Dor fundoplication clearly demonstrated that the addition of a fundoplication is essential: the incidence of postoperative reflux (as measured by pH monitoring) was 47.6% in patients who underwent myotomy alone but only 9.1% in those

- who underwent myotomy and Dor fundoplication.²⁷
2. The extension of the myotomy onto the gastric wall (clearly the most critical and challenging part of the operation) proved difficult because of poor exposure, with the consequent risk of a short myotomy and persistent dysphagia. With the laparoscopic approach, in contrast, excellent exposure of the esophagogastric junction is easily achieved, and the myotomy can be extended onto the gastric wall for about 2 to 2.5 cm.⁴
3. Double-lumen endotracheal intubation and single-lung ventilation were required, with the patient in the right lateral decubitus position. In contrast, the setting for a laparoscopic myotomy (the same as that for a laparoscopic fundoplication) is much easier for the patient, the anesthesiologist, and the OR personnel. In addition, most surgeons have by now acquired substantial experience with laparoscopic antireflux procedures and thus are more familiar and comfortable with laparoscopic exposure of the distal esophagus and the esophagogastric junction.
4. The average postoperative hospital stay was about 3 days because of the chest tube left in place at the time of the operation and the discomfort arising from the thoracic incisions. After a laparoscopic Heller myotomy, the hospital stay is only 1 or 2 days; there is no need for a chest tube, and patients are more comfortable.

Because of these drawbacks, left thoracoscopic myotomy is now largely reserved for patients with achalasia who have undergone multiple abdominal operations (which may rule out a laparoscopic approach). A laparoscopic Heller myotomy and Dor fundoplication is considered the procedure of choice for achalasia.

PREOPERATIVE EVALUATION

All candidates for a laparoscopic Heller myotomy should undergo a thorough and careful evaluation to establish the diagnosis and characterize the disease.²⁸

An upper GI series is useful. A characteristic so-called bird's beak is usually seen in patients with achalasia. A dilated, sigmoid esophagus may be present in patients with long-standing achalasia. A corkscrew esophagus is often seen in patients with diffuse esophageal spasm. Endoscopy is performed to rule out a tumor of the esophagogastric junction and gastroduodenal pathologic conditions.

Esophageal manometry is the key test for establishing the diagnosis of esophageal achalasia. The classic manometric findings are (1) absence of esophageal peristalsis and (2) a hypertensive LES that fails to relax appropriately in response to swallowing.

Ambulatory pH monitoring should always be done in patients who have undergone pneumatic dilatation to rule out abnormal gastroesophageal reflux. In addition, pH monitoring should be performed postoperatively to detect abnormal reflux, which, if present, should be treated with acid-reducing medications.²⁸

In patients older than 60 years who have experienced the recent onset of dysphagia and excessive weight loss, secondary achalasia or pseudoachalasia from cancer of the esophagogastric junction should be ruled out. Endoscopic ultrasonography or computed tomography can help establish the diagnosis.²⁹

OPERATIVE PLANNING

Patient preparation (i.e., anesthesia, positioning, and instrumentation) is identical to that for laparoscopic fundoplication.

OPERATIVE TECHNIQUE

Many of the steps in a laparoscopic Heller myotomy are the same as the corresponding steps in a laparoscopic fundoplication. The

Figure 2 Laparoscopic Heller myotomy with partial fundoplication. The proposed myotomy line is marked on the surface of the esophagus.

ensuing description focuses on those steps that differ significantly.

Either a Dor or a Guarner fundoplication [see Laparoscopic Partial (Guarner) Fundoplication, *above*] may be performed in conjunction with a Heller myotomy. The Dor fundoplication is an anterior 180° wrap. Its advantages are that (1) it does not require posterior dissection and the creation of a window between the esophagus, the stomach, and the left pillar of the crus; (2) it covers the exposed esophageal mucosa after completion of the myotomy; and (3) it is effective even in patients with GERD.³⁰ Its main disadvantage is that achieving the proper geometry can be difficult, and a wrong configuration can lead to dysphagia even after a properly performed myotomy.³¹ The advantages of the Guarner fundoplication are that (1) it is easier to perform; (2) it keeps the edges of the myotomy well separated; and (3) it might be more effective than a Dor procedure in preventing reflux. Its main disadvantages are that (1) it requires more dissection for the creation of a posterior window and (2) it leaves the esophageal mucosa exposed.

Steps 1 through 6

Steps 1, 2, 3, 4, 5, and 6 of a laparoscopic Heller myotomy are essentially identical to the first six steps of a laparoscopic fundoplication. Steps 4 and 6, however, are necessary only if a posterior partial fundoplication is to be performed. Care must be taken not to narrow the esophageal hiatus too much and push the esophagus anteriorly.

Step 7: Intraoperative Endoscopy

The esophageal stethoscope and the orogastric tube are removed, and an endoscope is inserted. The endoscopic view allows easy identification of the squamocolumnar junction, so that the myotomy can be extended downward onto the gastric wall for about 2 cm distal to this point. In addition, if possible mucosal

perforation is a concern, the esophagus can be covered with water from outside while air is insufflated from inside; bubbling will be observed over the site of any perforation present.

At the beginning of a surgeon's experience with laparoscopic Heller myotomy, intraoperative endoscopy is a very important and helpful step; however, once the surgeon has gained adequate experience with this procedure and has become familiar with the relevant anatomy from a laparoscopic perspective, it may be omitted.

Troubleshooting The most worrisome complication during intraoperative endoscopy is perforation of the esophagus. This complication can be prevented by having the procedure done by an experienced endoscopist who is familiar with achalasia.

Step 8: Initiation of Myotomy and Entry into Submucosal Plane at Single Point

The fat pad is removed with the ultrasonic coagulating shears to provide clear exposure of the esophagogastric junction. A Babcock clamp is then applied over the junction, and the esophagus is pulled downward and to the left to expose the right side of the esophagus. The myotomy is performed at the 11 o'clock position. It is helpful to mark the surface of the esophagus along the line through which the myotomy will be carried out [see Figure 2]. The myotomy is started about 3 cm above the esophagogastric junction. Before it is extended upward and downward, the proper submucosal plane should be reached at a single point; in this way, the likelihood of subsequent mucosal perforation can be reduced.

Troubleshooting The myotomy should not be started close to the esophagogastric junction, because at this level the layers often are poorly defined, particularly if multiple dilatations or injections of botulinum toxin have been performed. At the preferred starting point, about 3 cm above the esophagogastric junction, the esophageal wall is usually normal. As a rule, I do not open the entire longitudinal layer first and then the circular layer; I find it easier and safer to try to reach the submucosal plane at one point and then move upward and downward from there. In the course of the myotomy, there is always some bleeding from the cut muscle fibers, particularly if the esophagus is dilated and the wall is very thick. After the source of the bleeding is identified, the electrocautery must be used with caution. The most troublesome bleeding comes from the submucosal veins encountered at the esophagogastric junction (which are usually large). In most instances, gentle compression is preferable to electrocautery. A sponge introduced through one of the ports facilitates the application of direct pressure.

Step 9: Proximal and Distal Extension of Myotomy

Once the mucosa has been exposed, the myotomy can safely be extended [see Figure 3]. Distally, it is extended for about 2 to 2.5 cm onto the gastric wall; proximally, it is extended for about 6 cm above the esophagogastric junction. Thus, the total length of the myotomy is typically about 8 cm [see Figure 4].

Troubleshooting The course of the anterior vagus nerve must be identified before the myotomy is started. If this nerve crosses the line of the myotomy, it must be lifted away from the esophageal wall, and the muscle layers must then be cut under it. In addition, care must be taken not to injure the anterior vagus nerve while removing the fat pad. Treatment with botulinum toxin occasionally results in fibrosis with scarring and loss of the normal

Figure 3 Laparoscopic Heller myotomy with partial fundoplication. The myotomy is extended proximally and distally.

anatomic planes; this occurs more frequently at the level of the esophagogastric junction.

If a perforation seems possible or likely, it should be sought as described earlier [see Step 7, above]. Any perforation found should be repaired with 5-0 absorbable suture material, with interrupted sutures employed for a small perforation and a continuous suture for a larger one. When a perforation has occurred, an anterior fundoplication is usually chosen in preference to a posterior one because the stomach will offer further protection against a leak.

Step 10 (Dor Procedure): Anterior Partial Fundoplication

Two rows of sutures are placed. The first row (on the left side) comprises three stitches: the uppermost stitch incorporates the gastric fundus, the esophageal wall, and the left pillar of the crus [see Figure 5], and the other two incorporate only the gastric fundus and the left side of the esophageal wall [see Figure 6]. The gastric fundus is then folded over the myotomy, and the second row (also comprising three stitches) is placed on the right side between the fundus and the right side of the esophageal wall, with only the uppermost stitch incorporating the right crus [see Figures 7 and 8]. Finally, two additional stitches are placed between the anterior rim of the hiatus and the superior aspect of the fundoplication [see Figure 9]. These stitches remove any tension from the second row of sutures.

Troubleshooting Efforts must be made to ensure that the fundoplication does not become a cause of postoperative dysphagia. Accordingly, I always take down the short gastric vessels, even though some authorities suggest that this step can be omitted.^{5,29} In addition, the gastric fundus rather than the body of the stomach should be used for the wrap, and only the uppermost stitch of the right row of sutures should incorporate the right pillar of the crus.³⁰

Figure 4 Laparoscopic Heller myotomy with partial fundoplication. The myotomy is approximately 8 cm long, extending distally for about 2 to 2.5 cm onto the gastric wall and proximally for about 6 cm above the esophagogastric junction.

Figure 5 Laparoscopic Heller myotomy with anterior partial fundoplication (Dor procedure). The uppermost stitch in the first row incorporates the fundus, the esophageal wall, and the left pillar of the crus.

Step 10 (Guarner Procedure): Posterior Partial Fundoplication

Alternatively, a posterior 220° fundoplication may be performed. The gastric fundus is delivered under the esophagus, and each side of the wrap (right and left) is attached to the esophageal wall, lateral to the myotomy, with three sutures [see Figure 10].

Figure 6 Laparoscopic Heller myotomy with anterior partial fundoplication (Dor procedure). The second and third stitches in the first row incorporate only the fundus and the left side of the esophageal wall.

Figure 7 Laparoscopic Heller myotomy with anterior partial fundoplication (Dor procedure). The uppermost stitch in the second row incorporates the fundus, the esophageal wall, and the right crus.

Step 11: Final Inspection and Removal of Instruments and Ports from Abdomen

Step 11 of a laparoscopic Heller myotomy is identical to step 9 of a laparoscopic Nissen fundoplication.

COMPLICATIONS

Delayed esophageal leakage, usually resulting from an electrocautery burn to the esophageal mucosa, may occur during the first 24 to 36 hours after operation. The characteristic signals are chest pain, fever, and a pleural effusion on the chest x-ray. The diagno-

sis is confirmed by an esophagogram. Treatment options depend on the time of diagnosis and on the size and location of the leak. Early, small leaks can be repaired directly. If the site of the leak is high in the chest, a thoracotomy is recommended; if the site is at the level of the esophagogastric junction, a laparotomy is preferable, and the stomach can be used to reinforce the repair. If the damage to the esophagus is too extensive to permit repair, a transhiatal esophagectomy [see 4:4 *Open Esophageal Procedures*] is indicated.

Dysphagia may either persist after the operation or recur after a symptom-free interval. In either case, a complete workup is necessary, and treatment is individualized on the basis of the specific cause of dysphagia. Reoperation may be indicated [see Reoperation for Esophageal Achalasia, below].

Abnormal gastroesophageal reflux occurs in 7% to 20% of patients after operation.^{4,5} Because most patients are asymptomatic, it is essential to try to evaluate all patients postoperatively with manometry and prolonged pH monitoring. Reflux should be treated with acid-reducing medications.

POSTOPERATIVE CARE

I do not routinely obtain an esophagogram before initiating feeding. Patients are started on a soft mechanical diet on the morning of postoperative day 1, and this diet is continued for the rest of the first week. Patients are discharged after 24 to 48 hours and are able to resume regular activities in 7 to 14 days.

OUTCOME EVALUATION

The results obtained to date with laparoscopic Heller myotomy and partial fundoplication are excellent and are generally comparable to those obtained with the corresponding open surgical procedures: dysphagia is reduced or eliminated in more than 90% of patients.^{4,7} Laparoscopic treatment clearly outperforms balloon dilatation and botulinum toxin injection in the treatment of achalasia. Its high success rate has caused a shift in practice, to the

Figure 8 Laparoscopic Heller myotomy with anterior partial fundoplication (Dor procedure). The second and third stitches in the second row incorporate only the fundus and the right side of the esophageal wall.

Figure 9 Laparoscopic Heller myotomy with anterior partial fundoplication (Dor procedure). Two final stitches are placed between the superior portion of the wrap and the anterior rim of the hiatus.

point where most referring physicians currently regard surgery as the preferred treatment.³²

Left Thoracoscopic Myotomy

PREOPERATIVE EVALUATION

Preoperative evaluation is essentially the same as that for laparoscopic Heller myotomy.

OPERATIVE PLANNING

The patient is placed under general anesthesia and intubated with a double-lumen endotracheal tube so that the left lung can be deflated during the procedure. As for a left thoracotomy, the patient is placed in the right lateral decubitus position over an inflated bean bag. The instrumentation is similar to that for a laparoscopic Nissen or Guarner fundoplication. Instead of conventional trocars, four or five thoracoports with blunt obturators are employed, because insufflation of the thoracic cavity is not required. The myotomy can be performed with a monopolar hook cautery, bipolar scissors, or an ultrasonic scalpel. A 30° scope and a 45° scope are essential for thoracoscopic procedures. In addition, an endoscope is used for intraoperative endoscopy.

OPERATIVE TECHNIQUE

Step 1: Placement of Thoracoports

Five ports are usually placed [see Figure 11]. Port A, used for the 30° scope, is inserted in the sixth intercostal space about 3.5 to 5 cm behind the posterior axillary line. Port B, used for the lung retractor, is placed in the third intercostal space about 1.25 to 2.5 cm anterior to the posterior axillary line. Port C, used for insertion of a grasper, is placed in the sixth intercostal space in the anterior axillary line. Port D, used for insertion of the instrument employed for the myotomy, is placed in the seventh intercostal space in the midaxillary line. Port E is placed in the eighth intercostal space between the anterior axillary line and the midaxillary line. This

port is optional: it is needed in about 30% of cases to allow the surgeon to obtain further exposure of the esophagogastric junction through retraction of the diaphragm.

Troubleshooting A common mistake is to insert port A too anteriorly. This port must be placed well beyond the posterior axillary line to provide the best angle for the 30° scope. Often, the other ports are placed one or two intercostal spaces too high. This mistake hampers the performance of the most delicate portion of the operation, the myotomy of the distal portion of the esophagus and the stomach.

Sometimes, chest wall bleeding occurs as a consequence of port insertion. This bleeding will obscure the operating field and therefore must be stopped before the intrathoracic portion of the procedure is begun. This is accomplished either by using the cautery from the inside or by applying a stitch from the outside if an intercostal vessel has been damaged.

Step 2: Retraction of Left Lung and Division of Inferior Pulmonary Ligament

Once the ports are in place, the deflated left lung is retracted cephalad with a fan retractor introduced through port B. This maneuver places tension on the inferior pulmonary ligament, which is then divided. After the ligament is divided, the fan retractor can be held in place by a self-retaining system fixed to the operating table.

Troubleshooting Before the inferior pulmonary ligament is divided, the inferior pulmonary vein must be identified to prevent a life-threatening injury to this vessel. If oxygen saturation decreases, particularly in patients with lung disease, the retractor should be removed and the lung inflated intermittently.

Step 3: Division of Mediastinal Pleura and Dissection of Periesophageal Tissues

The mediastinal pleura is divided, and the tissues overlying the esophageal wall are dissected until the wall of the esophagus is vis-

Figure 10 Laparoscopic Heller myotomy with posterior partial fundoplication (Guarner procedure). Each side of the posterior 220° wrap is attached to the esophageal wall with three sutures.

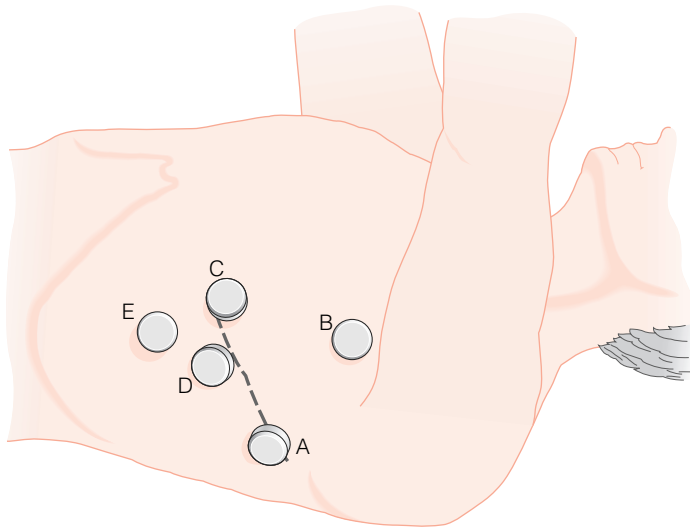

Figure 11 Left thoracoscopic myotomy. Illustrated is the recommended placement of the thoracoports.

ible. This maneuver varies in difficulty depending on the width of the space between the aorta and the pericardium (which sometimes is very small) and on the size and shape of the esophagus. Large (sigmoid) esophagi tend to curve to the right, which makes identification of the wall difficult. If the esophagus is not immediately apparent, it can be easily identified in the groove between the heart and the aorta by means of transillumination provided by an endoscope [see Figure 12].

Troubleshooting The endoscope placed inside the esophagus at the beginning of the procedure plays an important role. In the early stages of the procedure, it allows identification of the esophagus via transillumination. When the light intensity of the 30° scope is turned down, the esophagus appears as a bright structure. In addition, tilting the tip of the endoscope brings the esophagus into view as it is lifted from the groove between the aorta and the heart.

Step 4: Initiation of Myotomy and Entry into Submucosal Plane at Single Point

As in a laparoscopic Heller myotomy, it is helpful to mark the surface of the esophagus along the line through which the myotomy will be carried out. The myotomy is started halfway between the diaphragm and the inferior pulmonary vein. Again, the proper submucosal plane should be reached at a single point before the myotomy is extended upward and downward.

Troubleshooting Troubleshooting for this step is essentially the same as that for step 8 of a laparoscopic Heller myotomy, with the exception that here the myotomy is started 4 to 5 cm (rather than 3 cm) above the esophagogastric junction.

Step 5: Proximal and Distal Extension of Myotomy

Once the mucosa has been exposed, the myotomy can safely be extended proximally and distally [see Figure 13]. I usually extend the myotomy for about 5 mm onto the gastric wall, without adding an antireflux procedure.^{3,4} Typically, the total length of the myotomy is about 6 cm for patients with achalasia.

Troubleshooting Proximally, the myotomy is extended all the way to the inferior pulmonary vein only in cases of vigorous achalasia (high-amplitude simultaneous contractions associated

with chest pain in addition to dysphagia) or diffuse esophageal spasm; otherwise, it is limited to the distal 5 to 6 cm of the esophagus. If a longer myotomy is needed, the lung is displaced anteriorly and the myotomy extended to the aortic arch.

Distally, the myotomy is continued for 5 mm past the esophagogastric junction. The endoluminal view provided by the endoscope is useful for assessing the location of the esophagogastric junction. Often, the stomach is distended by the air insufflated by the endoscope and pushes the diaphragm upward, thereby limiting the view of the esophagogastric junction. If sucking air out of the stomach does not resolve this problem, an additional port (i.e., port E) may be placed in the eighth intercostal space, and a fan retractor may be introduced through this port to push the diaphragm down.

Because the myotomy of the gastric wall is the most challenging part of the operation, good exposure is essential. It is at this level that an esophageal perforation is most likely to occur. The

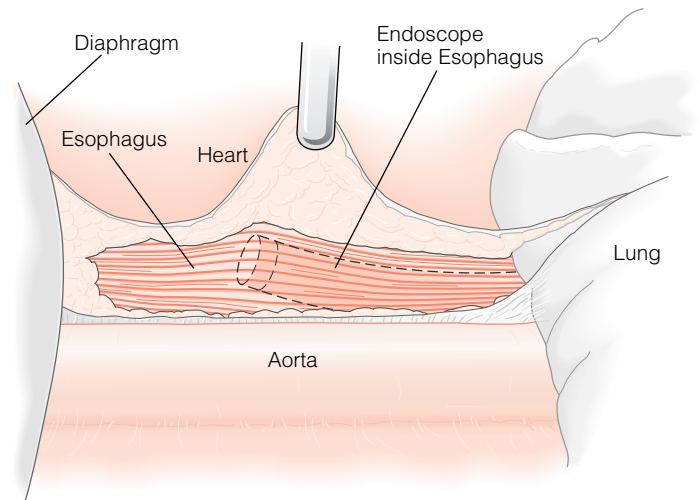

Figure 12 Left thoracoscopic myotomy. The esophagus may be identified by means of transillumination from the endoscope.

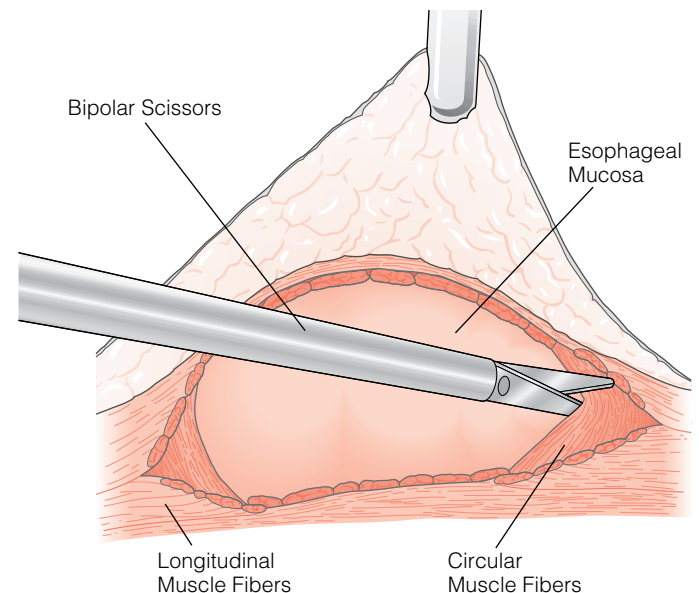

Figure 13 Left thoracoscopic myotomy. Shown are the distal and proximal extensions of the myotomy.

risk is particularly high in patients who have undergone pneumatic dilatation or injection of botulinum toxin, both of which may lead to the replacement of muscle layers by scar tissue and the consequent loss of the regular planes. Perforations recognized in the OR can be repaired by thoracoscopic intracorporeal suturing or, if this fails, by thoracotomy and open repair. The gastric fundus can be used to buttress the repair. If it is unclear whether a perforation has occurred, the esophagus should be covered with water and air insufflated through the endoscope as described earlier [see Laparoscopic Heller Myotomy with Partial Fundoplication, Operative Technique, Step 7, above].

Step 6: Insertion of Chest Tube and Removal of Thoracoports

A 24 French angled chest tube is inserted under direct vision through port D or port E. The ports are removed under direct vision, and the thoracic wall is inspected for bleeding.

COMPLICATIONS

As with laparoscopic Heller myotomy, delayed esophageal leakage is a common postoperative complication, and treatment options are similar.

If the myotomy is not extended far enough onto the gastric wall, residual dysphagia occurs. To prevent this problem, the distal extent of the myotomy should be assessed by means of endoscopy with the goal of including 5 mm of the gastric wall. Patients with residual dysphagia must be evaluated by means of esophageal manometry, which will document the extent of the residual high-pressure zone and the pressure within it. The myotomy can be easily extended by a laparoscopic approach, and a Dor fundoplication can be added.

If, on the other hand, the myotomy is extended too far onto the gastric wall, abnormal gastroesophageal reflux occurs. Some patients present with heartburn; others are asymptomatic. It is essential to evaluate patients postoperatively with manometry and prolonged pH monitoring. Mild reflux can be treated with acid-reducing medications, particularly in elderly patients. In younger patients, abnormal reflux should be corrected with a laparoscopic partial fundoplication (e.g., Dor fundoplication).

POSTOPERATIVE CARE

Patients are started on a liquid diet the morning of postoperative day 1; on postoperative day 2, they are started on a soft mechanical diet, which is continued for the rest of the first week. I do not routinely obtain an esophagogram before starting feedings. The chest tube is removed after 24 hours if the lung is fully expanded and there is no air leak. Patients are discharged after 48 to 72 hours and are able to resume regular activities in 7 to 10 days.

OUTCOME EVALUATION

The results obtained with thoracoscopic myotomy are generally comparable to those obtained with open surgical procedures. In a 1999 study from UCSF,⁴ 26 (87%) of the first 30 patients with achalasia who were treated in this fashion experienced good or excellent results [see Table 2]. Currently, however, this procedure is rarely used to treat esophageal achalasia: laparoscopic Heller myotomy and Dor fundoplication is now the treatment of choice.³²

Right Thoracoscopic Myotomy

A right thoracoscopic myotomy extending from the diaphragm to the thoracic inlet is the preferred procedure for patients who have nutcracker esophagus or diffuse esophageal spasm involving the entire length of the esophagus but whose LES function is nor-

Table 2 Results of Thoracoscopic Myotomy in 30 Patients with Achalasia⁴

Results	Patients (% of Total)
Excellent (no dysphagia)	21 (70)
Good (dysphagia < once/wk)	5 (17)
Fair (dysphagia > once/wk)	3 (10)
Poor (persistent dysphagia)	1 (3)

mal. On the whole, this procedure is technically simpler than a left thoracoscopic myotomy: because there is no need to go through the esophago-gastric junction, perforation, postoperative dysphagia, and abnormal gastroesophageal reflux are largely prevented.

PREOPERATIVE EVALUATION

Preoperative evaluation of patients being considered for right thoracoscopic myotomy is essentially the same as that of patients being considered for left thoracoscopic myotomy.

OPERATIVE PLANNING

Operative planning is similar to that for a left thoracoscopic myotomy. The double-lumen tube is used to deflate the right lung rather than the left, and the patient is placed in the left lateral decubitus position over an inflated bean bag, as for a right thoracotomy. The instrumentation is identical except for the endovascular 30 mm stapler used to transect the azygos vein. A thoracotomy tray should be kept ready in case an emergency thoracotomy is necessary to control bleeding.

OPERATIVE TECHNIQUE

Step 1: Insertion of Thoracoports

Only port B is inserted where it would be for a left thoracoscopic myotomy. All the other ports are inserted one intercostal space higher because the myotomy need not be extended all the way to the stomach but must be extended to the thoracic inlet. Usually, only four ports are placed; however, an additional port may be placed in the fourth intercostal space in the anterior axillary line to facilitate the proximal extension of the myotomy.

Step 2: Dissection of Periesophageal Tissues and Division of Azygos Vein

The periesophageal tissues above and below the azygos vein are dissected away from the esophagus. A tunnel is created between the azygos and the esophagus with a dissector or a right-angle clamp. The vein is then transected with an endovascular 30 mm stapler. (Alternatively, the azygos is spared and simply lifted off the esophagus with umbilical tape.)

Troubleshooting Dissection of the azygos vein is the most critical part of this procedure. I find it easier to transect the azygos vein than to keep the vein lifted away from the esophagus and perform the myotomy under it.

Steps 3, 4, and 5

Steps 3, 4, and 5 of a right thoracoscopic myotomy are virtually identical to steps 4, 5, and 6 of a left thoracoscopic myotomy, with a few minor exceptions. Once the submucosal plane is reached, the myotomy is extended distally to the diaphragm and

proximally to the thoracic inlet. The endoscope plays a less critical role than in a left thoracoscopic myotomy because the esophagus is easily identified and because the myotomy is not extended through the esophagogastric junction. Instead, a 52 to 56 French bougie is placed inside the esophagus; this facilitates division of the circular fibers and separates the edges of the myotomy nicely.

COMPLICATIONS

A delayed esophageal leak is the most common postoperative complication. It should be handled as described earlier [*see Laparoscopic Heller Myotomy with Partial Fundoplication, Complications, above*].

POSTOPERATIVE CARE

The postoperative course of patients who have undergone this procedure is usually identical to that of patients operated on for achalasia.

OUTCOME EVALUATION

Long-term follow-up has confirmed the excellent results initially obtained for diffuse esophageal spasm with either a thoracoscopic or a laparoscopic approach.^{26,33} The results for nutcracker esophagus, however, have been disappointing: a number of patients have experienced postoperative dysphagia and recurrent chest pain. In my view, the optimal treatment of nutcracker esophagus remains uncertain. The results of operative management are less predictable with nutcracker esophagus than with other esophageal disorders, and chest pain often is not alleviated.³³

Reoperation for GERD

At the UCSF Swallowing Center, an increasing number of patients are being seen for evaluation and treatment of foregut symptoms after laparoscopic antireflux surgery. These patients are treated as follows.

PREOPERATIVE EVALUATION

Some degree of dysphagia, bloating, and abdominal discomfort is common during the first 6 to 8 weeks after a fundoplication. If these symptoms persist or heartburn and regurgitation occur, a thorough evaluation (with barium swallow, endoscopy, esophageal manometry, and pH monitoring) is carried out with the aim of answering the following three questions:

1. Are the symptoms attributable to persistent gastroesophageal reflux?
2. Are the symptoms attributable to the fundoplication itself?
3. Can the cause of the failure of the first operation be identified and corrected by a second operation?

Many patients report heartburn after a fundoplication. It is often assumed that this symptom must be the result of a failed operation and that acid-reducing medications should be restarted. In most cases, however, this assumption is mistaken: postoperative pH monitoring yields abnormal results in only about 20% of patients.³⁴ The value of manometry lies in its ability to document the changes caused by the operation at the level of the LES and the esophageal body. The pH monitoring assesses the reflux status and determines whether there is a correlation between symptoms and actual episodes of reflux. If abnormal reflux is in fact present, the therapeutic choice is between medical therapy and a second operation.

Other patients complain of dysphagia arising *de novo* after the operation. This symptom is usually attributable to the operation itself and may occur in the absence of abnormal reflux. In addition

to manometry and pH monitoring, a barium swallow is essential to define the anatomy of the esophagogastric junction. A study from the University of Washington³⁵ found that the anatomic configurations observed could be divided into three main types: (1) type I hernia, in which the esophagogastric junction was above the diaphragm (subdivided into type IA, with both the esophagogastric junction and the wrap above the diaphragm, and type IB, with only the esophagogastric junction above the diaphragm); (2) type II hernia, a paraesophageal configuration; and (3) type III hernia, in which the esophagogastric junction was below the diaphragm and there was no evidence of hernia but in which the body of the stomach rather than the fundus was used for the wrap. In 10% of patients, however, the cause of the failure could not be identified preoperatively.³³

Some patients present with a mix of postprandial bloating, nausea, and diarrhea. These symptoms may be the result of damage to the vagus nerves. Radionuclide evaluation of gastric emptying often helps quantify the problem.

OPERATIVE PLANNING

Patient preparation (i.e., anesthesia, positioning, and instrumentation) for a reoperation for reflux is identical to that for the initial laparoscopic fundoplication.

OPERATIVE TECHNIQUE

I routinely attempt a second antireflux operation laparoscopically, but if the dissection does not proceed smoothly, I convert to a laparotomy. To provide a stepwise technical description that would be suitable for all reoperations for reflux is impossible because the optimal procedure depends on the original approach (open versus laparoscopic), the severity of the adhesions, and the specific technique used for the first operation (total or partial fundoplication). The key goals of reoperation for reflux are as follows.

1. To dissect the wrap and the esophagus away from the crura. This is the most difficult part of the operation. The major complications seen during this part of the procedure are damage to the vagus nerves and perforation of the esophagus and the gastric fundus.
2. To take down the previous repair. The earlier repair must be completely undone and the gastric fundus returned to its natural position. If the short gastric vessels were not taken down during the first procedure, they must be taken down during the second.
3. To dissect the esophagus in the posterior mediastinum so as to have enough esophageal length below the diaphragm and avoid placing tension on the repair.
4. To reconstruct the cardia. The same steps are followed as for a first-time repair. If, after extensive esophageal mobilization, the esophagogastric junction remains above the diaphragm (short esophagus), esophageal lengthening can be accomplished by adding a thoracoscopic Collis gastroplasty to the fundoplication. To date, however, I have never found this step to be necessary.

COMPLICATIONS

Because the risk of gastric or esophageal perforation or damage to the vagus nerves is much higher during a second antireflux operation, the surgeon must be ready to convert to a laparotomy if the dissection is too cumbersome or the structures are not properly identified. Most perforations are recognized and repaired intraoperatively. Leaks manifest themselves during the first 48 hours. Peritoneal signs are noted if the spillage is limited to the abdomen; shortness of breath and a pleural effusion are noted if spillage also

occurs in the chest. The site of the leak should always be confirmed by means of a contrast study with barium or a water-soluble agent. Perforation is best handled with laparotomy and direct repair of the leak.

OUTCOME EVALUATION

Whereas the success rate is around 80% to 90% for a first antireflux operation, it falls to 70% to 80% for a second such operation. In my view, a second operation should be attempted by an expert team only if medical management fails to control heartburn or pneumatic dilatation has not relieved dysphagia.

Reoperation for Esophageal Achalasia

Laparoscopic Heller myotomy improves swallowing in more than 90% of patients. What causes the relatively few failures reported is still incompletely understood. Typically, a failed Heller myotomy is signaled either by persistent dysphagia or by recurrent dysphagia that develops after a variable symptom-free interval following the original operation.

A complete workup (routinely including barium swallow, endoscopy, manometry, and pH monitoring) is required before treatment is planned. In addition, it is my practice to review the video of the first operation to search for technical errors that might have been responsible for the poor outcome. Such errors typically fall into one of the following three categories.

1. A myotomy that is too short either distally or proximally. If the myotomy is too short distally, a barium swallow shows persistent distal esophageal narrowing and manometry shows a residual high-pressure zone. If the myotomy is too short proximally, it will be apparent from the barium swallow.
2. A constricting Dor fundoplication. Often, manometry and pH monitoring yield normal results, but a barium swallow shows slow passage of contrast media from the esophagus into the stomach. In one study from UCSF,³¹ problems with Dor funduplications occurred in four (4%) of 102 patients. Analysis of the video records of the first operations showed that in three of the four patients, all the stitches in the right suture row had incorporated the esophagus, the right pillar of the crus, and the

stomach, thereby constricting the myotomy. In one patient, the short gastric vessels had not been taken down, and the body of the stomach rather than the fundus had been used for the fundoplication.

3. Transmural scarring caused by previous treatment. In patients treated with intrasphincteric injection of botulinum toxin, transmural fibrosis can sometimes be found at the level of the esophagogastric junction. This unwelcome finding makes the myotomy more difficult and the results less reliable.

There are two treatment options for persistent or recurrent dysphagia after Heller myotomy: (1) pneumatic dilatation and (2) a second operation tailored to the results of preoperative evaluation. In a 2002 study,³⁶ pneumatic dilatation was successfully used to treat seven of 10 patients who experienced dysphagia postoperatively; of the remaining three patients, two required a second operation and one refused any treatment.

In the UCSF study just cited,³¹ however, pneumatic dilatation was effective in only one of the eight patients in whom it was tried. That patient was the one with a short distal myotomy; none of the four patients with dysphagia resulting from a poorly constructed Dor fundoplication derived any benefit. In two patients who had a short proximal myotomy, the myotomy was successfully extended to the inferior pulmonary vein through a left thoroscopic approach. Of the four patients with a constricting Dor fundoplication, two underwent a second operation during which the Dor was taken down, and one of these two had a second myotomy. Currently, both patients are free of dysphagia; however, they experience abnormal reflux and are being treated with acid-reducing medications.

Reoperation for achalasia is a technically challenging procedure. It is of paramount importance to avoid perforating the exposed esophageal mucosa during the dissection. A small hole can be repaired, but a larger laceration might necessitate an esophagectomy. This option should always be discussed with the patient before the operation.

Overall, about 10% of patients have some degree of dysphagia after a Heller myotomy. Pneumatic dilatation, a second operation, or both should always be tried before a radical procedure such as esophagectomy is decided on.

6 CHEST WALL PROCEDURES

Seth D. Force, M.D.

Chest wall procedures are an important component of any thoracic surgeon's practice. The approach to these procedures is somewhat different from the approach to esophageal or pulmonary resections and requires specific knowledge of thoracic musculoskeletal anatomy, as well as of the different types of autologous and artificial grafts available for chest wall reconstruction. Broadly, chest wall procedures may be divided into those performed to treat congenital chest wall disease and those done to treat acquired disease. In what follows, I describe the major surgical techniques in both categories and review the pitfalls that may accompany them.

Procedures for Congenital Chest Wall Disease

Congenital chest wall defects arise from abnormal development of the sternum, the costal cartilages, and the ribs. Such defects include pectus excavatum (funnel chest), pectus carinatum (pigeon chest), cleft sternum, and Poland syndrome (absence of the breast and the underlying pectoralis muscle and ribs). Of these, pectus excavatum is by far the most common, accounting for more than 90% of all congenital chest wall procedures; accordingly, the ensuing discussion focuses on the surgical aspects of pectus excavatum repair.

REPAIR OF PECTUS EXCAVATUM

Preoperative Evaluation

Because pectus excavatum occurs in varying degrees of severity, patients may seek surgical treatment for any of a number of different reasons, such as shortness of breath, early fatigue with exercise, or simple dissatisfaction with their appearance. Thus, one of the most important tasks for surgeons treating pectus excavatum is determining which patients are candidates for operative management. In an attempt to facilitate this determination, the Congenital Heart Surgery Nomenclature and Database Project has developed a classification system for pectus excavatum, in which a deformity less than 2 cm in depth is classified as mild, a deformity 2 to 3 cm in depth is classified as moderate, and a deformity greater than 3 cm in depth is classified as severe.¹ A computed tomography-based index has also been devised, in which the transverse chest diameter is divided by the anteroposterior diameter; an index greater than 3.2 is considered indicative of severe disease.²

These classification attempts notwithstanding, the precise indications for surgery remain unclear. Many studies have attempted to show that the depressed sternum leads to pulmonary compromise, but for the most part, these studies have had small sample sizes and have employed differing measures of lung function, both of which have made accurate comparisons difficult. In one study that included 25 United States Air Force personnel with symptomatic pectus excavatum, lung volumes were comparable to those in normal persons, but there was a significant difference in

maximum voluntary ventilation.³ In a study that compared 37 patients who had undergone surgical repair of pectus excavatum both with normal persons and with persons who had uncorrected deformities, no differences in physical working capacity among the three groups were noted.⁴ Other studies have reported improvements in exercise tolerance and regional ventilation and perfusion after surgical repair of pectus excavatum.^{5,6} On the other hand, some investigators have reported decreases in pulmonary function in symptomatic patients after corrective surgery. One group attributed this result to overly aggressive resection in very young patients that led to growth restriction of the chest wall; accordingly, they recommended delaying surgical repair until 6 to 8 years of age.⁷

Severe pectus excavatum has also been reported to cause cardiac dysfunction secondary to sternal compression of the right ventricle. Several early studies found stroke volume and cardiac output to be lower in exercising upright patients than in supine patients.^{8,9} However, improvement in cardiac function after pectus excavatum repair has not been universally documented. In one study, first-pass radionuclide angiocardiology failed to show any improvements in left ventricular function after repair of pectus excavatum.¹⁰ At present, there is no consensus on the cardiopulmonary benefits of pectus excavatum repair, and the major reasons for surgical treatment are still patient discomfort and dissatisfaction with appearance.

Operative Technique

A number of different procedures have been employed to treat pectus excavatum, but for present purposes, I focus on (1) the Ravitch procedure (and variations thereof) and (2) the Nuss procedure. For historical reasons, the turnover technique, originally described by Judet and Judet¹¹ and later employed by Wada,¹² warrants a brief mention. Wada's series included 199 patients whose deformities were corrected with a version of this technique; good results were achieved in 63% of patients, and there were only three instances of partial sternal necrosis. Today, however, the turnover technique is rarely used because of the good results that can be achieved with techniques that do not carry a risk of sternal necrosis. It is usually reserved for extreme cases of pectus excavatum, which often include deformities of the sternum in addition to abnormalities of the costal cartilages.

Ravitch procedure Repair of pectus excavatum is based on the principle that the deformity is secondary to abnormal growth of the costal cartilages. Accordingly, correction involves (1) resection of the abnormal cartilages, (2) a transverse anterior sternal osteotomy to allow anterior displacement of the sternum, and (3) sternal fixation to prevent posterior displacement after the repair. Most of the variations in the Ravitch procedure have to do with the use of different sternal fixation techniques.

Step 1: initial incision and exposure. Either a midline incision or a

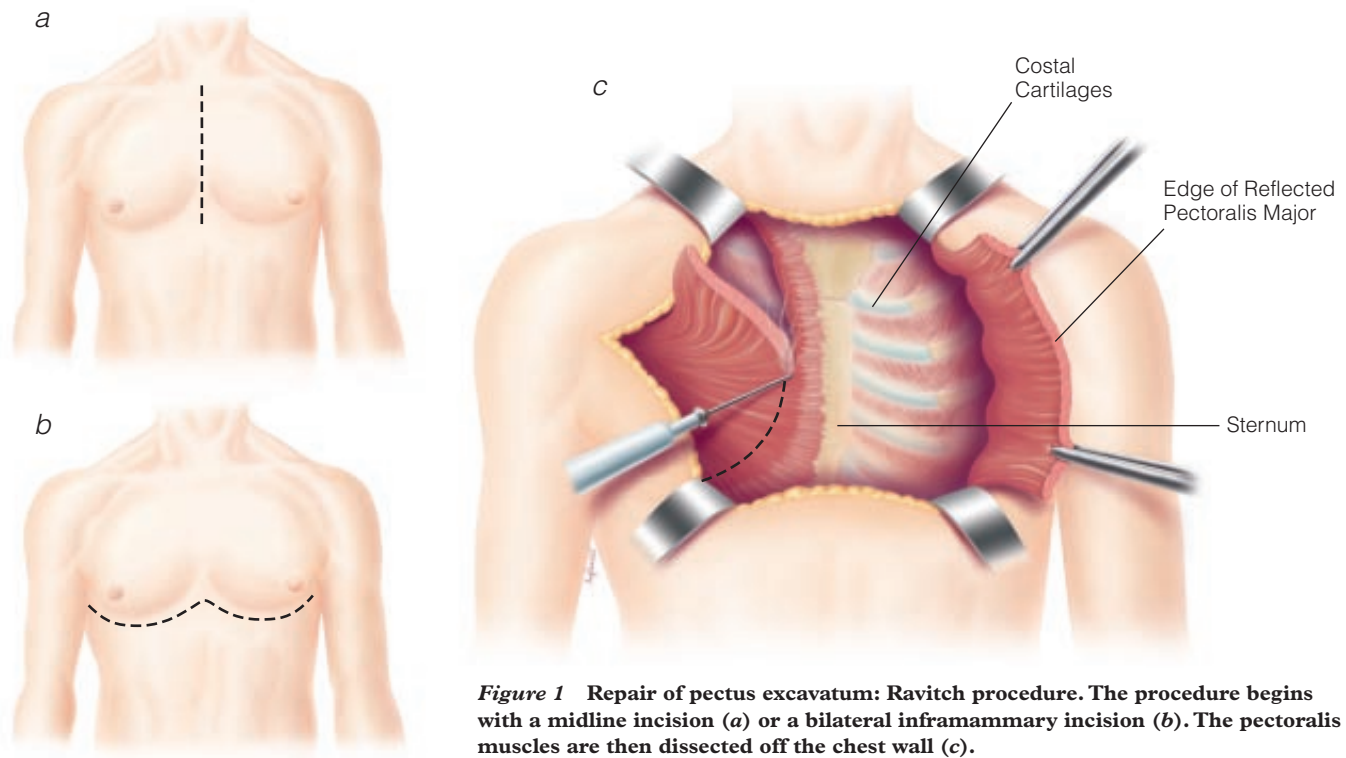

Figure 1 Repair of pectus excavatum: Ravitch procedure. The procedure begins with a midline incision (a) or a bilateral inframammary incision (b). The pectoralis muscles are then dissected off the chest wall (c).

bilateral inframammary incision is made [see Figure 1a, b]; the latter incision yields superior cosmetic results, especially in female patients, but necessitates the elevation of large subcutaneous skin flaps to the level of the angle of Louis or the sternal notch superiorly and to the xiphoid process inferiorly. The pectoralis muscles are then mobilized from the chest wall, beginning medially and proceeding laterally until the costal cartilages are exposed [see Figure 1c].

Step 2: resection of abnormal cartilages. For each abnormal costal cartilage, the anterior perichondrium is scored with the electrocautery along the length of the cartilage, and the cartilage is dissected from the perichondrium with a periosteal elevator [see Figure 2a].

The posterior plane between the cartilage and the perichondrium is then developed in one area, and the cartilage is divided with a scalpel between the jaws of a right-angle clamp [see Figure 2b]. The cut end of the cartilage is grasped with a clamp, and the rest of the cartilage is dissected from the perichondrium. Once the correct plane is established, the dissection can be facilitated by gently pushing the perichondrium off the cartilage with a finger. The entire cartilage should be removed from the sternum to the rib, with every attempt made to maintain the integrity of the perichondrium. During this part of the procedure, the xiphoid process is also detached from the sternum. The extent of cartilage removal depends on the individual defect present but usually includes the third rib.

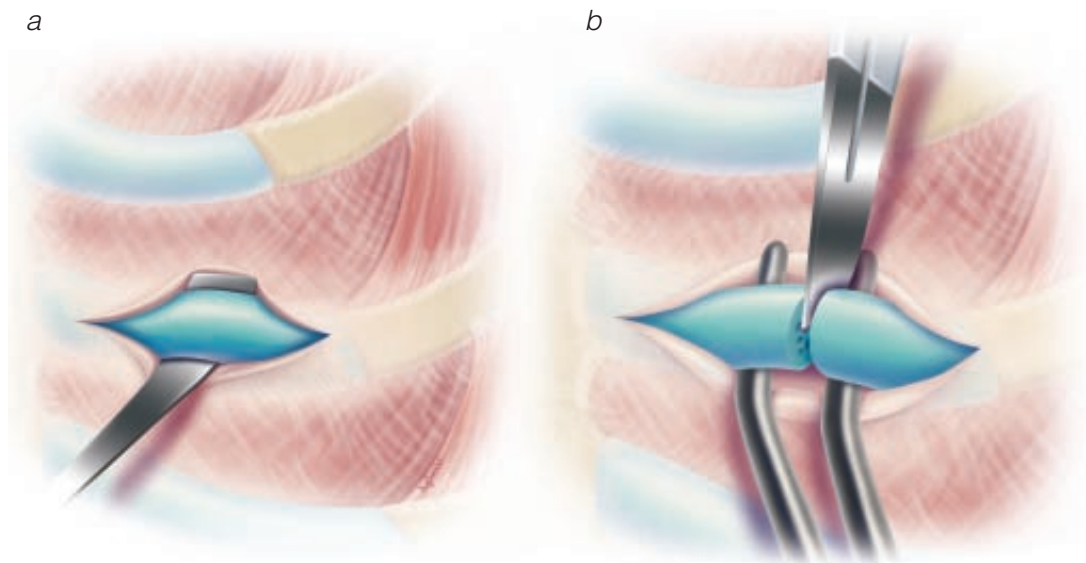

Figure 2 Repair of pectus excavatum: Ravitch procedure. (a) The anterior perichondrium is opened, and the abnormal cartilage is dissected free with a periosteal elevator. (b) The cartilage is divided.

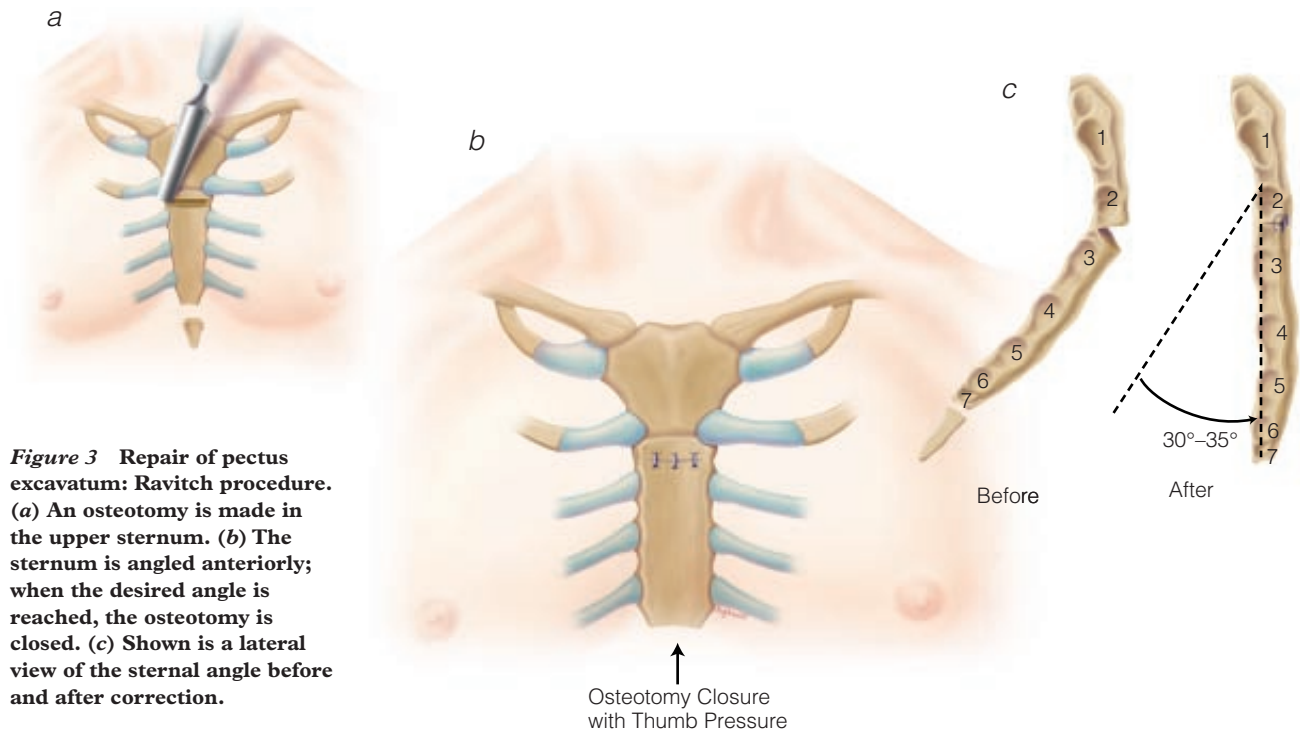

Figure 3 Repair of pectus excavatum: Ravitch procedure. (a) An osteotomy is made in the upper sternum. (b) The sternum is angled anteriorly; when the desired angle is reached, the osteotomy is closed. (c) Shown is a lateral view of the sternal angle before and after correction.

Step 3: sternal osteotomy. An osteotomy is made in the upper anterior table of the sternum with either a periosteal elevator or a small reticulating bone saw [see Figure 3a], and the posterior table of the sternum is fractured. The sternum can then be angled anteriorly. When the desired angle is reached, the osteotomy is closed with three interrupted nonabsorbable sutures or with microplates and screws [see Figure 3b, c]. At this point, rotational sternal defects can be corrected by making anterior and posterior lateral osteotomies on either side of the sternum and then closing the osteotomies with sutures or microplates.

Step 4: sternal fixation. Sternal fixation can be accomplished by any of several means. Posterior sternal support can be achieved by placing a Kirschner wire or retrosternal bar that is secured to the periosteum of the rib and left in place for approximately 3 months after operation [see Figure 4]. Alternatively, the sternum can be supported with a piece of polypropylene mesh or with two polypropylene sutures sutured to the xiphoid process and then brought around the right and left second ribs.¹³

Step 5: closure and drainage. The pectoralis muscles are reapproximated in the midline, closed suction drains are placed in the subcutaneous flaps, and the subcutaneous layer and the skin are closed. To prevent seroma formation, one closed suction drain may be placed posterior to the pectoralis muscles and another between the pectoralis muscles and the subcutaneous layer; the right pleural space may then be opened anteriorly and a right pleural tube placed through a separate incision.¹⁴

Nuss procedure Minimally invasive repair of pectus excavatum, also referred to as the Nuss procedure, has gained popularity over the past decade.

Step 1: configuration of bar. The patient is placed in the supine position with the arms abducted, and marks are made on either side of the chest at spots that correspond to the deepest point of

the defect. The bar that will be used for the repair is shortened to a length equivalent to the measured distance between the two midaxillary lines minus 1 cm. A complex series of bends are then placed in the bar to match its contours to those of the patient's deformity.

Step 2: initial incisions and creation of intrathoracic tunnel. Incisions are made in the right and left midaxillary lines at the level of the marks, and a subcutaneous flap is raised from each incision and extended to the defect. A Crawford vascular clamp or a

Figure 4 Repair of pectus excavatum: Ravitch procedure. Sternal fixation is accomplished through placement of a retrosternal bar.

Figure 5 Repair of pectus excavatum: Nuss procedure. Incisions are made on either side of the chest. A Crawford vascular clamp is inserted through the right intercostal space and advanced along the sternum and out the left intercostal space.

Lorenz pectus introducer is then placed through the right intercostal space under thoracoscopic visualization and advanced along the posterior sternum and out the corresponding left intercostal space [see Figure 5].

Step 3: placement and fixation of bar. An umbilical tape is pulled through the anterior mediastinum and attached to the bar, which is then gently pulled, with the concave side up, through the intercostal space. A Lorenz pectus bar rotator is employed to flip the bar over, and the ends of the bar are positioned in the subcutaneous space [see Figure 6]. Occasionally, for proper alignment, the bar may have to be removed and rebent, or stabilizers may have to be placed alongside it. When the bar is correctly positioned, it is sutured to the chest wall musculature with an absorbable suture on one end and a permanent suture on the other.

The bar is usually left in place for 2 years. Excellent results have been reported.¹⁵ Significant complications include bar displacement necessitating reoperation (9.2% of procedures), pneumothorax (4.8%), infection (2%), and pleural effusion (2%). Rare complications include cardiac injury, thoracic outlet syndrome (TOS), pericarditis, and sternal erosion caused by the bar.

Figure 6 Repair of pectus excavatum: Nuss procedure. (a) The pectus bar is pulled into the tunnel opened by the vascular retractor, then flipped to provide the desired chest contour. (b) The ends of the bar are then sutured to the chest wall musculature.

Outcome Evaluation

In general, the results of pectus excavatum repair are good, and the overall complication rate is low. In one study, 90% of 76 patients operated on over a 30-year period experienced excellent outcomes, and only one patient required reoperation for a recurrent defect.¹⁴ The incidence of complications (pleural effusions, pneumonia, and wound seromas) was 14%.¹⁴ In another study, no operative deaths occurred in more than 800 repairs, and only a few cases of serious infections and bleeding were reported.¹⁶ Other investigators have reported rare complications arising from the migration of sternal support bars and wires.¹⁷

REPAIR OF PECTUS CARINATUM

Surgical repair of pectus carinatum resembles surgical repair of pectus excavatum in several respects. The same skin incision is employed, and the pectoralis major muscles are elevated in a similar manner. Subperichondrial resection of the abnormal cartilages is then carried out, usually extending to the second costal cartilage. Next, a generous V-shaped osteotomy is made in the upper portion of the sternum at the point of maximal protrusion, which is usually near the insertion of the second cartilage. Occasionally, a second osteotomy is required near the caudal end of the sternum to facilitate elevation of the manubrium and depression of the sternum. Finally, the osteotomy is closed with nonabsorbable monofilament sutures, drains are placed, and soft tissue is closed as in a pectus excavatum repair.

The results of pectus carinatum repair are generally comparable to those of pectus excavatum repair. Most patients experience good outcomes, and operative morbidity is low.

Procedures for Acquired Chest Wall Disease

TRANSAXILLARY FIRST RIB RESECTION FOR THORACIC OUTLET SYNDROME

Preoperative Evaluation

TOS results from compression of the subclavian blood vessels or the brachial plexus as these structures exit the bony thorax. Symptoms may be primarily vascular (e.g., arm swelling or loss of pulse) or neurogenic (e.g., pain and paresthesias). The workup for TOS includes a detailed physical examination, as well as imaging and nerve conduction studies.

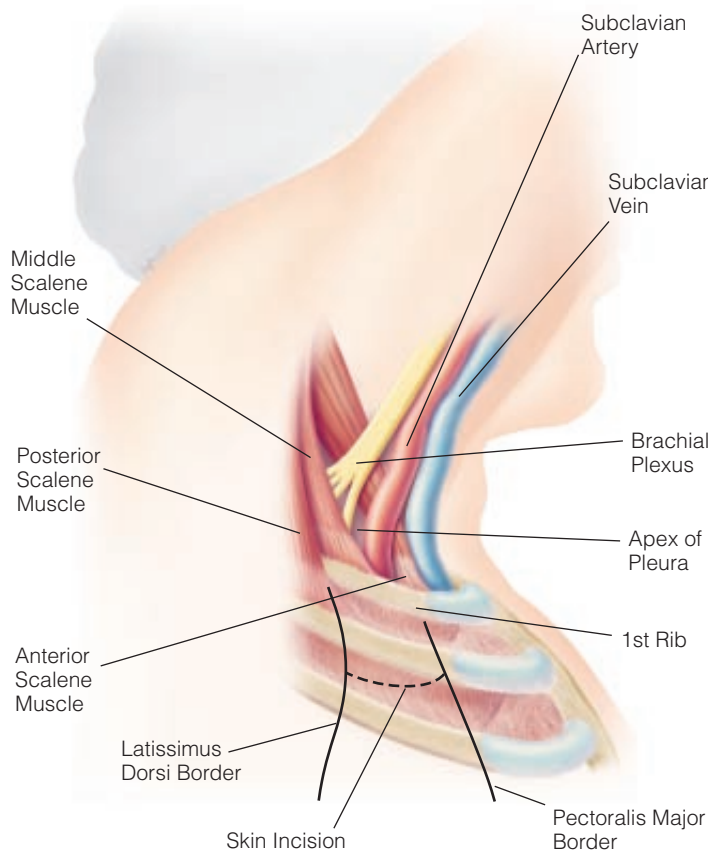

Figure 7 Transaxillary first rib resection. Shown are the transaxillary incision and the thoracic outlet anatomy.

Operative Planning

Surgical treatment of TOS typically involves resection of the first rib, which widens the thoracic outlet and relieves the neurovascular impingement. First rib resection can be accomplished

via several different approaches, including posterior, supraclavicular, infraclavicular, transthoracic, and transaxillary. I focus here on the transaxillary approach, which provides good exposure of the first rib and allows the surgeon to avoid the subclavian blood vessels and the brachial plexus. Regardless of the specific surgical approach followed, any surgeon embarking on a first rib resection must have a detailed knowledge of the thoracic outlet to keep from injuring the neurovascular structures in the area.

Operative Technique

The patient is placed in the lateral decubitus position, and the affected arm is kept at a 90° angle either by an arm holder or, alternatively, by an assistant. Care must be taken not to hyperabduct or hyperextend the shoulder. The arm, the axilla, and the chest are prepared and draped into the sterile field.

Step 1: initial incision and exposure An incision is made just below the axillary hair line and extended from the pectoralis major to the latissimus dorsi [see Figure 7]. The subcutaneous tissue is incised down to the chest wall with the electrocautery, with care taken to stay perpendicular to the axis of the chest. Dissection is then begun along the chest wall and carried toward the first rib. The intercostal brachial nerve is identified where it exits between the first and second ribs. This nerve should be spared: dividing it leads to numbness of the upper inner biceps region.

Step 2: dissection and division of anterior portion of first rib When the first rib is encountered, it is dissected from the periosteum with a periosteal elevator. Dissection is continued anteriorly along the rib until just past the subclavian vein, at which point a right-angle clamp can be passed around the rib in the subperiosteal plane. A Gigli saw or a first rib cutter is then used to divide the anterior portion of the rib [see Figure 8a].

Next, the first rib is retracted inferiorly to permit visualization of the anterior scalene muscle, which is then divided at its attachment to the rib. To prevent thermal injury to the phrenic nerve, a scalpel rather than an electrocautery is used to divide the muscle [see Figure 8b]. Care should also be taken not to injure the subcla-

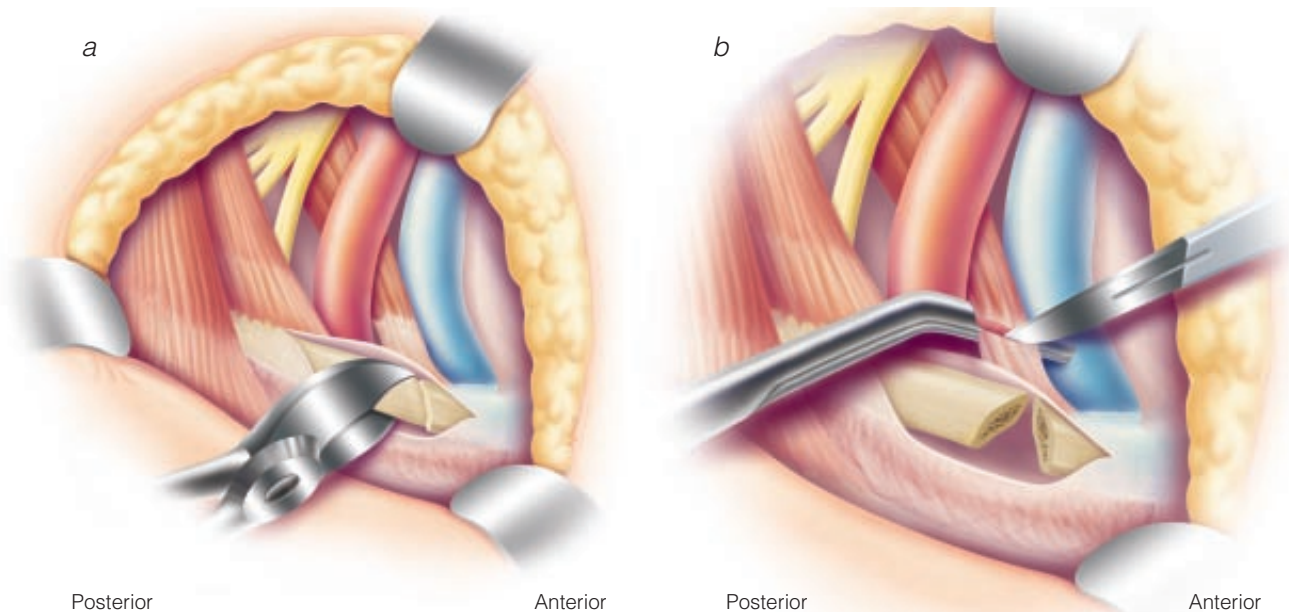

Figure 8 Transaxillary first rib resection. (a) The anterior portion of the first rib is cut. (b) The anterior scalene muscle is then divided.

Figure 9 Chest CT reveals a large pulmonary and chest wall mass.

vian vein and artery, which lie anterior and posterior to the anterior scalene muscle, respectively. As an alternative, the anterior scalene muscle may be divided before the anterior portion of the rib is cut.

Step 3: dissection and division of posterior portion of first rib The subperiosteal dissection is continued posteriorly, freeing the first rib from the pleura, the subclavian vessels, and the brachial plexus. The posterior portion of the rib is then divided with a first rib cutter as close as possible to the articulation of the rib with the transverse process. Every effort should be made to keep from injuring the C8 and T1 nerve roots.

Step 4: closure The incision is closed without drainage. If the pleura was inadvertently entered, air may be aspirated from the chest with a red rubber tube, which is removed before the subcutaneous tissue is closed. One authority recommends further neurolysis of the C7 to T1 nerve roots and the middle and lower trunks of the brachial plexus, as well as resection of the anterior and middle scalene muscles up into the neck.¹⁸

Complications

Surgical complications include injuries to the subclavian vein and artery (leading to massive blood loss), the brachial plexus, the phrenic nerve, the long thoracic nerve, and the thoracic duct.

Outcome Evaluation

The long-term results of first rib resection appear to be independent of the exposure technique employed. Good results, defined as relief of major symptoms, have been reported in as many of 90% of patients in the first year and in as many as 70% of patients 5 to 10 years after operation. There continues to be considerable debate over the preferred surgical approach, but to date, no studies have shown any one approach to have significant advantages over any of the others.

CHEST WALL RESECTION

Chest wall resection has become a critical component of the thoracic surgeon's armamentarium. It may be performed to treat either benign conditions (e.g., osteoradionecrosis, osteomyelitis, and benign neoplasms) or malignant disease.

Preoperative Evaluation

Preoperative imaging studies may include chest x-ray, chest CT

[see Figure 9], and magnetic resonance imaging if vertebral involvement is suspected. The other preoperative tests ordered are much the same as those required for any other large thoracic procedure, including pulmonary function testing, nutritional assessment, and cardiac stress testing in patients who are older or have a history of cardiac disease.

Operative Planning

Operative planning for chest wall resection should include establishing the extent of the resection, weighing options for chest wall stabilization, and deciding on the method of tissue coverage to be employed. A multidisciplinary approach, involving the participation of a neurosurgeon and a plastic surgeon, may be required.

The technique of chest wall resection is essentially the same for benign conditions as for malignant ones and is mainly dependent on the location of the lesion. For malignant tumors of the chest wall, a 5 cm margin, or at least resection of one uninvolved rib above and below the tumor, is required. Additionally, any involved skin and any biopsy site must be resected along with the chest wall specimen. For infection or osteoradionecrosis, the resection must include all nonviable skin and underlying bone; if it does not, skin and muscle flaps may not heal properly. Any destroyed lung tissue may also have to be resected along with the chest wall specimen. In addition, recurrent cancer must be ruled out before the operation can proceed. A particular challenge is posed by breast cancer patients who have already had muscle flaps for breast reconstruction; in these patients, tissues other than muscle (e.g., omentum) may be required for tissue coverage after chest wall resection.

Standard Chest Wall Resection

In cases in which a concomitant lung resection is required, the

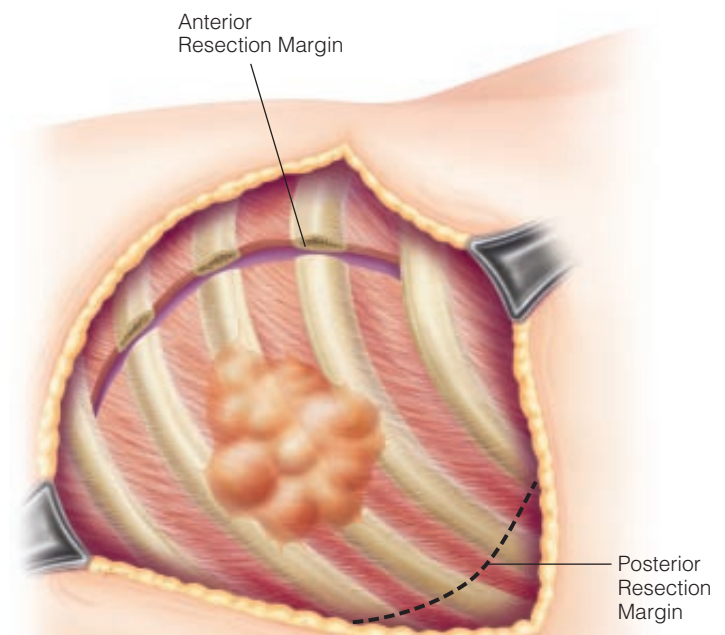

Figure 10 Chest wall resection. The anterior and posterior margins of the required resection are determined. The anterior margin is completed first.

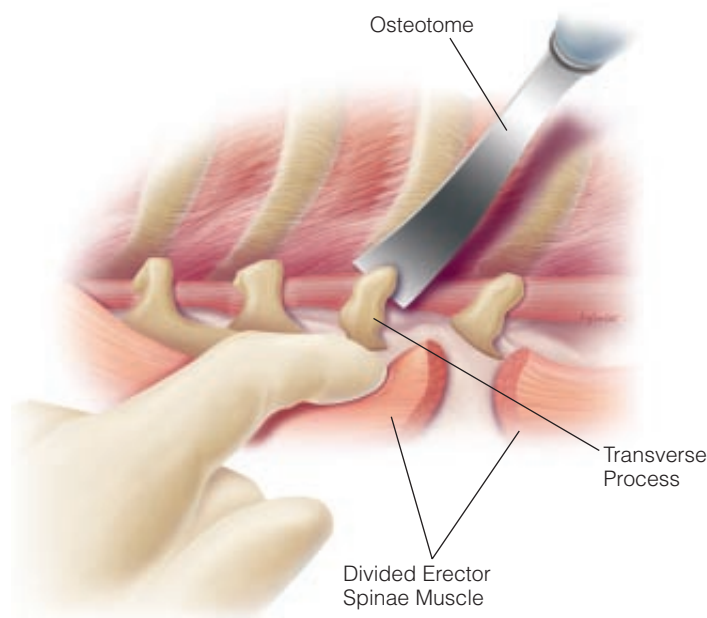

Figure 11 Chest wall resection. Depicted is disarticulation of the rib from the transverse process.

chest wall resection is usually performed first; this measure renders the lung more mobile and facilitates the pulmonary resection. The lateral decubitus position is the best choice for most combined lung–chest wall procedures, whereas the supine position is preferable for isolated anterior chest wall procedures. If a larger chest wall resection is expected, every attempt should be made to spare major muscle groups so that these muscles can be used later to cover any prosthetic material used in reconstruction.

Operative technique *Step 1: initial incision and exposure.* The usual incision is a standard posterolateral thoracotomy incision through the fifth interspace.

Step 2: determination of extent of required chest wall resection. As soon as the pleura is opened, the surgeon should palpate the tumor to evaluate the extent of chest wall involvement, which determines the extent of the resection. Removal of uninvolved ribs may make reconstruction of the chest wall more complicated. For example, posterior resections that do not require removal of the fifth rib are protected by the scapula, so that reconstruction is unnecessary. If the fifth rib is removed, however, the tip of the scapula will tend to become stuck under the sixth rib with shoulder movement; this is very uncomfortable for the patient, and chest wall reconstruction will therefore be required at the time of resection.

At this point, the surgeon should also rule out diffuse pleural disease before proceeding with resection. In some cases, the tumor can be removed by means of extrapleural dissection, without any need for chest wall resection. If there is any suspicion of chest wall involvement, however, chest wall resection is mandatory because leaving any tumor behind guarantees a recurrence.

The extent of the chest wall resection is marked with the electrocautery on the outside of the thoracic cavity. At least one grossly uninvolved rib should be included both above and below the tumor.

Step 3: completion of anterior boundary of resection. Initially, the periosteum over the lowest rib to be resected is scored, and a periosteal elevator is used to separate the intercostal bundle from

the rib. Alternatively, the intercostal bundle can be doubly ligated and divided at the anterior resection margin. Once the intercostal vessels are cleared from the lowest rib, the electrocautery is used to divide the pleura below the rib toward the anterior boundary of the resection. The rib is then divided with a rib cutter, with care taken to ensure a margin of at least 5 cm from the tumor [see Figure 10]. Next, the intercostal bundle of the next higher rib is ligated and divided, the intercostal muscle is divided with the electrocautery, and the rib is cut with a rib cutter in the same manner as the previous rib. This process is repeated until the anterior boundary of resection is completed. A subperiosteal plane is then developed over the highest rib to be resected, the adjacent intercostal bundle is separated from the rib, and the parietal pleura is divided with the electrocautery.

Step 4: completion of posterior boundary of resection. If the tumor margin does not involve the vertebrae, the posterior portion of the chest wall resection is identical to the anterior portion [see Step 3, above]. If, however, the tumor appears to encroach on the head of the rib or the transverse process, it will be necessary to disarticulate the rib from the transverse process or, in the latter situation, remove the transverse process entirely.

Disarticulation of the rib from the transverse process is performed by dissecting the paraspinal ligament and erector spinae muscles away from the spine with the electrocautery, thereby exposing the joint between the head of the rib and the transverse process. The ligaments attaching the rib to the transverse process are then incised with the electrocautery, and an osteotome is inserted into the joint, which is then levered anteriorly and posteriorly to disarticulate the rib from the transverse process [see Figure 11]. The intercostal neurovascular bundle must be ligated and divided at this point: failure to do so will result in bleeding and possibly in leakage of cerebrospinal fluid. If bleeding occurs, it can be controlled with bipolar electrocauterization and temporary packing with a hemostatic agent. The hemostatic agent must not be left in place permanently, because it may expand or result in a neural foramen hematoma, and either of these events can lead to spinal cord compression and significant neurologic injury. If at any time the surgeon feels uncomfortable about ongoing intercostal bleeding or a possible CSF leak, intraoperative neurosurgical consultation should be obtained. In cases in which the tumor involves the transverse process, this structure must be removed from the vertebral body with an osteotome and a mallet or with a first rib cutter. If the tumor has invaded the vertebral body and resection is still being considered, neurosurgical consultation should be obtained. Generally, if the tumor involves more than one quarter of the vertebral body or extends into multiple vertebral levels, it is considered unresectable.

Step 5: lung resection (if required). Once the posterior chest wall margin has been completed, the lung resection (if required) is performed. The entire lung–chest wall specimen is then submitted for pathologic examination, and histopathologic margins are obtained both on the lung and on the chest wall. If the chest wall margins are positive, the involved area must be trimmed back and a new margin submitted.

Step 6: chest wall reconstruction. Chest wall reconstruction is required for all anterior defects and for posterior defects that involve any rib lower than the fourth rib. Reconstruction can be performed either with polypropylene or Gore-Tex (W. L. Gore and Associates, Flagstaff, Arizona) mesh or with a polypropylene–methylmethacrylate sandwich. The latter is employed when rigid recon-

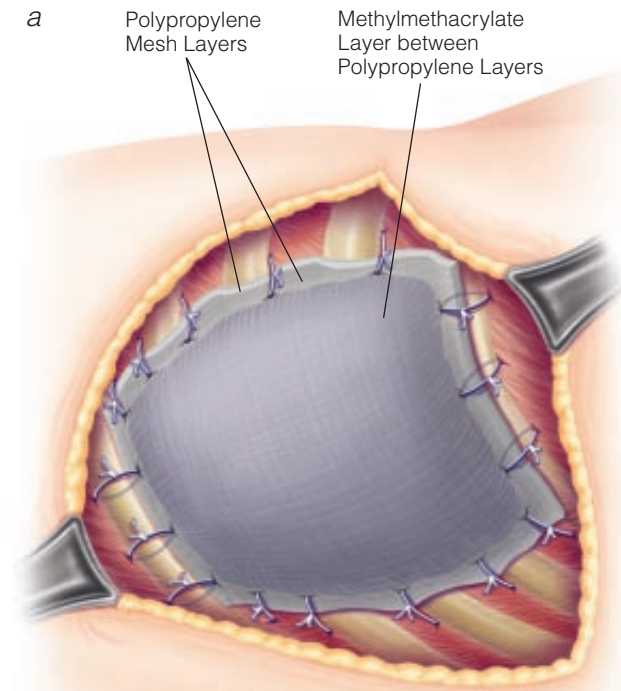

Figure 12 Chest wall resection. (a) A polypropylene-methylmethacrylate sandwich is created by spreading a layer of methylmethacrylate cement between two pieces of polypropylene mesh. When sufficiently hardened, the sandwich is sutured to the ribs. (b) Photograph shows a polypropylene-methylmethacrylate sandwich sutured in place.

struction is warranted (as in anterior reconstruction); it not only provides added protection of pleural and mediastinal structures but also creates a better cosmetic effect by recreating the shape of the chest wall.

To create the polypropylene-methylmethacrylate sandwich, two pieces of polypropylene mesh are cut to the size of the defect. A thin layer of methylmethacrylate cement is spread on one of the mesh pieces, and the other piece is then applied over the methylmethacrylate layer. As this sandwich begins to harden, it is molded to the contours of the chest wall, with care taken to protect the patient's skin against injury from the heat given off by the hardening cement. When the sandwich is sufficiently hardened, it is sewn to the ribs with 0 polypropylene sutures [see Figure 12a]. The sutures may be passed around the uppermost and lowermost ribs and may be placed directly through the anterior and posterior margins [see Figure 12b]. If rib disarticulation was required to complete the posterior margin, holes may be drilled in the transverse processes and the sutures passed through these holes; alternatively, the sandwich may be sutured to the paraspinal ligament.

If polypropylene or Gore-Tex mesh is used without cement, it should be cut to a size smaller than that of the defect. Thus, the mesh will effectively be stretched when it is sutured to the chest wall, and any laxity in the reconstruction will thereby be alleviated.

Step 7: closure and drainage. The serratus anterior and the latissimus dorsi are closed in the standard fashion, as are the subcutaneous and skin layers. With the exception of pleural tubes, drains are not routinely used. Special attention should be paid to postoperative analgesia: patients who have undergone extensive resections often experience considerable pain and are therefore prone to atelectasis and pneumonia. Epidural analgesia should be employed routinely in such cases.

Troubleshooting If chest wall infection is a possibility (as with osteoradionecrosis or osteomyelitis), alternative reconstructive techniques are required to obviate concerns about superinfection

resulting from the use of synthetic material. In particular, radiation injury may involve all layers of the chest wall, necessitating very large resections [see Figure 13a]. Muscle or omental flaps with split-thickness skin grafts may be required for coverage; thus, preoperative consultation with an experienced plastic surgeon is advisable. A particular concern is what to use to reconstruct the chest wall. Various tissues (e.g., fascia lata and ribs) have been employed, but an easier substitute that works quite well is an absorbable synthetic mesh (e.g., Vicryl). The mesh is sewn to the ribs as previously described [see Step 6, above], and the tissue flap is placed on top of the mesh, followed by a skin graft [see Figure 13b, c]. Alternatively, some authors recommend the use of muscle or myocutaneous flaps without rigid chest wall reconstruction after resection, particularly in infected fields.¹⁹

Outcome evaluation The results achieved after major chest wall resection have generally been excellent. One study reviewed 200 patients who underwent resection and reconstruction over a 25-year period.²⁰ The reconstructions ranged from relatively straightforward two-rib resections to more complex forequarter amputations. The indications for resection were lung cancer (38%), osteoradionecrosis (29%), chest wall tumor (27%), and osteomyelitis (16%). Immediate reconstruction was performed in 98% of patients. The major muscle flaps utilized were latissimus dorsi (20%), rectus abdominis (17%), pectoralis major (16%), and serratus anterior (9%). Free flaps were utilized in only 9% of cases, and split-thickness skin grafts were required in 12% of patients. Reconstruction was performed with Prolene mesh (25%), Marlex mesh (11%), Vicryl mesh (6%), or a polypropylene-methylmethacrylate sandwich (6%). Operative mortality was 7%, and major morbidity occurred in 24% of patients. Most of the morbidity was accounted for by pneumonia (14%) and acute respiratory distress syndrome (6%).

Manubrial and Clavicular Resection

Resection of the manubrium or the clavicle may be necessary if

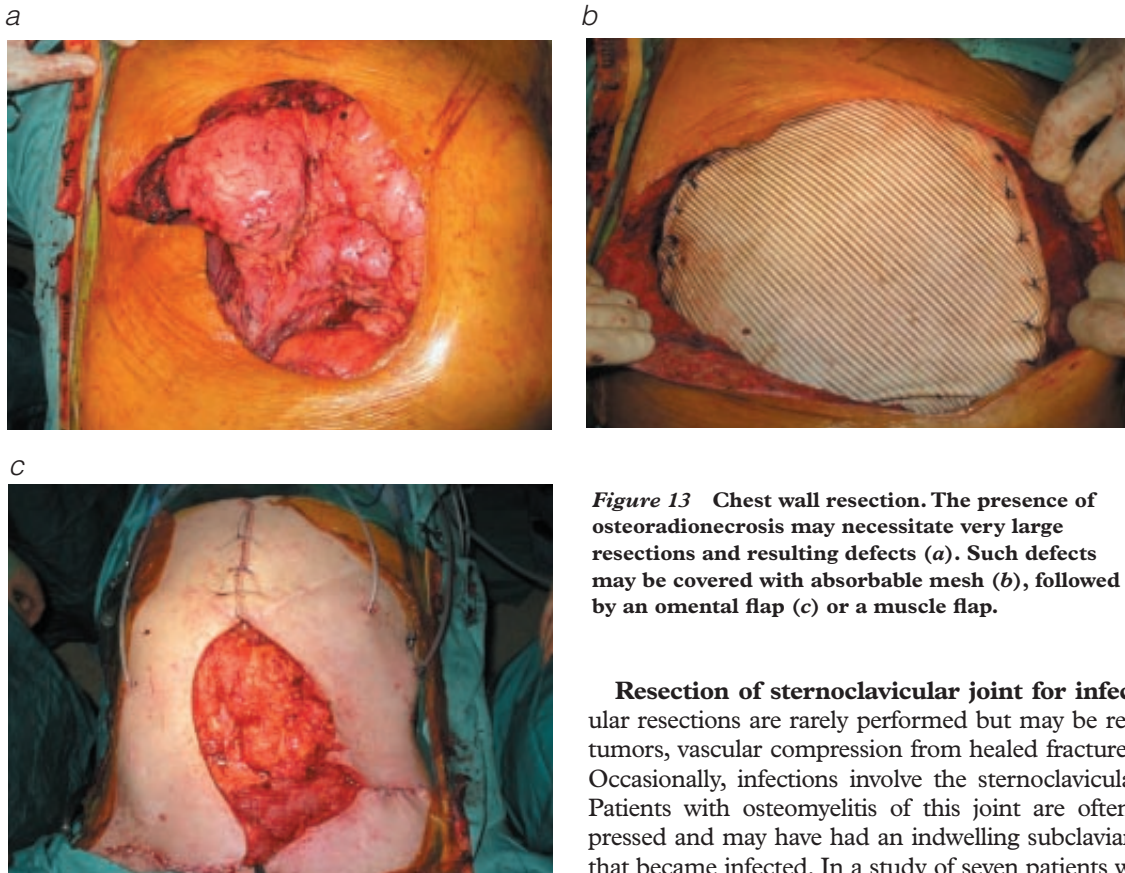

Figure 13 Chest wall resection. The presence of osteoradionecrosis may necessitate very large resections and resulting defects (a). Such defects may be covered with absorbable mesh (b), followed by an omental flap (c) or a muscle flap.

these structures become infected or involved with tumors. Clavicular and manubrial resections follow the same operative approach as other chest wall resections. Specifically, attention must be paid to how much bone to resect, how to reconstruct the defect, and how to provide tissue coverage.

Resection of sternoclavicular joint for infection Clavicular resections are rarely performed but may be required to treat tumors, vascular compression from healed fractures, or infection. Occasionally, infections involve the sternoclavicular joint (SCJ). Patients with osteomyelitis of this joint are often immunosuppressed and may have had an indwelling subclavian vein catheter that became infected. In a study of seven patients who underwent SCJ resection for infection, five of six patients initially treated with antibiotics and simple drainage experienced recurrences, whereas six of six patients treated with resection of the joint and pectoralis muscle advancement flaps were cured. None of the patients experienced problems with arm mobility in the course of long-term follow-up.²¹

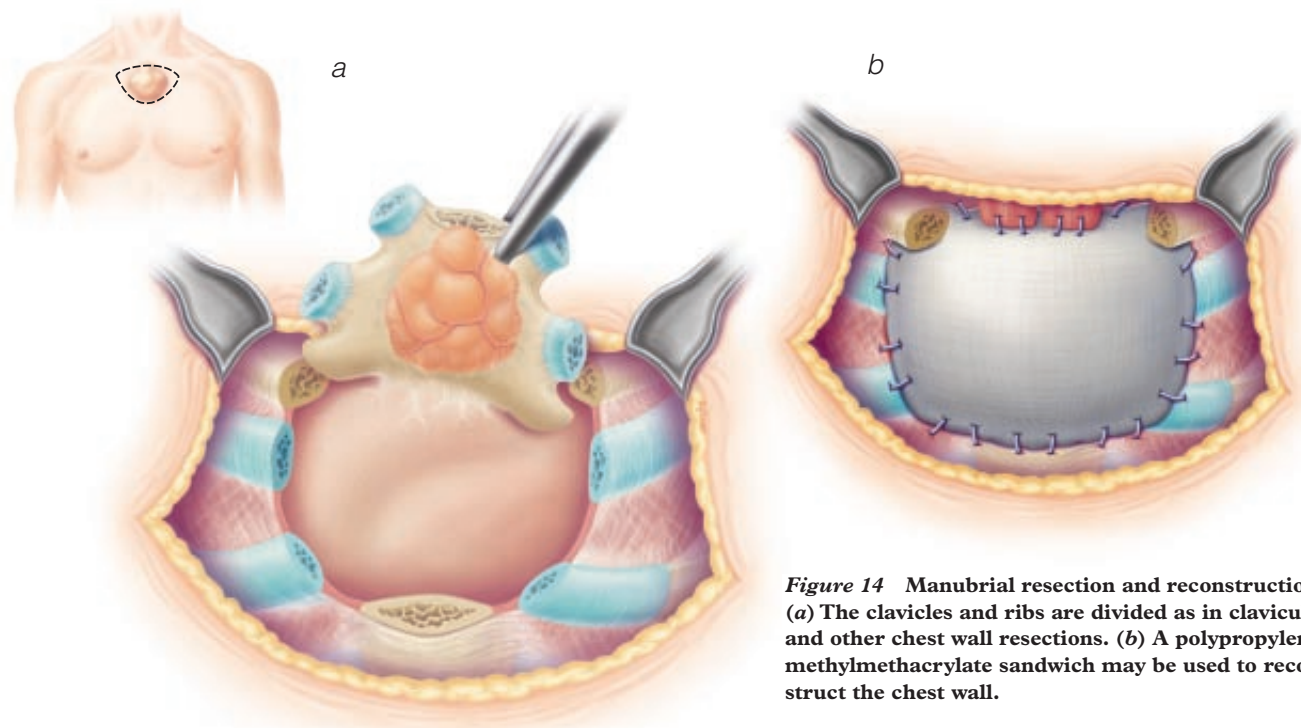

Figure 14 Manubrial resection and reconstruction. (a) The clavicles and ribs are divided as in clavicular and other chest wall resections. (b) A polypropylene-methylmethacrylate sandwich may be used to reconstruct the chest wall.

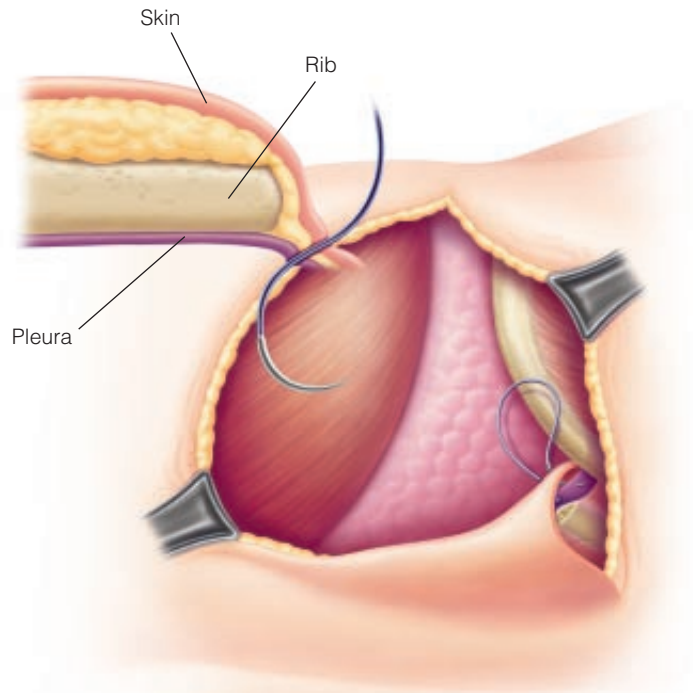

Figure 15 Open chest drainage (Eloesser flap). Once the ribs have been resected, the skin overlying the thoracostomy is marsupialized to the parietal pleura to permit packing and open pleural drainage.

Operative technique. An incision is made that extends along the distal clavicle and curves down onto the manubrium. The soft tissue is divided with the electrocautery down to the clavicle and the manubrium. The muscular attachments of the pectoralis major and the sternocleidomastoid muscle are dissected off the clavicle and the manubrium with a periosteal elevator. Dissection in the subperiosteal plane is then continued circumferentially around the distal clavicle, with special care taken to keep from injuring the subclavian vessels that lie deep to the clavicle. A Gigli saw is passed around the clavicle with a right-angle clamp and used to divide the distal clavicle. The distal cut end of the clavicle is grasped with a penetrating towel clamp and bluntly dissected away from the deep tissue toward the manubrium. Any pockets of infection encountered should be cultured, drained, and debrided.

At this point, a large separation in the SCJ, caused by the infection, should be apparent. Resection of a small portion of the manubrium is usually required to remove all of the infected bone. Once the tissue deep to the manubrium has been dissected, a small band retractor is placed beneath the manubrium, and an oscillating sternal saw is used to resect the lateral portion of the manubrium, adjacent to the SCJ. Alternatively, a rongeur may be used to debride infected bone from the manubrium. All tissue should be sent for culture.

Severe infections may necessitate more extensive resection of bone or soft tissue, but if the infection is caught early, simple resection of the SCJ is generally curative. In more extensive resections, muscle flap coverage may be required, but in simple SCJ resections, good results can be obtained by using only deep closed suction drainage, followed by multilayer closure of the wound. To prevent any recurrent osteomyelitis, antibiotics should be continued for several weeks after resection.

Resection of manubrium for cancer Manubrial resections may be required for rare cases of primary or metastatic cancers.

Operative technique. Because of the relative paucity of tissue overlying the manubrium, cancers in this area may involve the dermis. In such cases, it may be necessary to resect skin along with the specimen. Alternatively, if the skin is not involved, an upper midline incision may be employed. The incision is carried down circumferentially to the chest wall, with care taken to maintain a 2 to 3 cm margin from the tumor. The clavicles and ribs are divided in the same fashion as for chest wall and clavicular resections [see Figure 14a]. Associated structures (e.g., the thymus) can be resected along with the manubrium; these tumors rarely involve the innominate vein.

A polypropylene-methylmethacrylate sandwich is useful for reconstruction of this area of the chest wall [see Figure 14b]. The patch is secured to the remaining ribs and clavicles with 0 polypropylene sutures. Coverage is then provided with a pectoralis major

a

b

Figure 16 Open chest drainage (Eloesser flap). (a) Photograph shows a right Eloesser flap 8 months after creation. (b) Photograph shows an Eloesser flap that was closed with a muscle flap.

advancement flap or, if skin was excised, a pedicled pectoralis myocutaneous flap. A pleural drain may be placed if either pleural space was entered, but this measure is not routinely employed.

Open Chest Drainage (Eloesser Flap)

Open drainage procedures are usually included in discussions of treatment of empyema, but they really represent a type of chest wall resection. Open drainage techniques for empyema were first described in the late 1800s by Poulet and subsequently by Schede. Graham, who headed the Army Empyema Commission during World War I, is credited with the observation that ensuring pleural-pleural symphysis was the key to preventing the often fatal complication of pneumothorax.²² Indications for open chest drainage include postpneumonectomy empyema or bronchopleural fistula, long-standing empyema in a patient who cannot undergo decortication, and chronic bronchopleural fistula in a high-risk patient.

Operative technique The technique currently employed by most thoracic surgeons follows Symbas's modification of Eloesser's open drainage technique.²³ This procedure has come to be known as the Eloesser flap. Preoperative chest CT is essential for identifying the exact location of the empyema, which determines the placement of the incision.

Step 1: initial incision and exposure. The patient is placed in the decubitus position, and a 6 to 8 cm incision is made over the area corresponding to the most dependent area of the infected cavity. Symbas employed a U-shaped incision; however, a simple linear incision can also be used with good results. The subcutaneous tissue and muscle are then divided down to the chest wall with the electrocautery.

Step 2: resection of ribs and creation of thoracostomy. The pleural

space is opened with the electrocautery, any pus present is drained, and the chest cavity is manually and visually explored. Next, 6 to 8 cm segments of two or three adjacent ribs are resected according to the same principles employed for other chest wall resections. The resulting thoracostomy is large enough to permit drainage and packing. The skin overlying this thoracostomy is then marsupialized to the thickened parietal pleura with absorbable sutures [see Figure 15]. If the pleura does not possess sufficient integrity to hold the sutures, they can be placed through the periosteum of the ribs.

Step 3: packing and drainage. The wound is irrigated with normal saline and packed with saline-moistened gauze. Postoperatively, a chest x-ray should be obtained to rule out pneumothorax, and twice- to thrice-daily packing is initiated. Packing is continued on an outpatient basis, and the wound is monitored. The wound will begin to close over the next several weeks. If the empyema or bronchopleural fistula has not healed by the time the wound starts closing, the thoracostomy will have to be revised. In some cases, this can be accomplished merely by manually dilating the opening in the operating room; in others, the entire thoracostomy must be revised. In either case, the goal is to maintain a large enough opening to allow adequate packing.

Step 4: closure of thoracostomy. Once the lung and the pleural space have healed, the thoracostomy is closed. The procedure for closing the thoracostomy depends on the size and nature of the remaining defect [see Figure 16a]. For small defects, simple closure of the skin will suffice. For larger defects or residual spaces in the pleura, however, muscle flap closure will be required [see Figure 16b]. Improvements in radiographic techniques and greater emphasis on early intervention for empyemas have significantly reduced the need for open chest drainage; however, this technique can still be valuable in the appropriate clinical situation.

7 VIDEO-ASSISTED THORACIC SURGERY

Raja M. Flores, M.D., Bernard Park, M.D., and Valerie W. Rusch, M.D., F.A.C.S.

The technique of thoracoscopy was first described in 1910 by Jacobeus, a Swedish physician who used a cystoscope to examine the pleural space.¹ Although thoracoscopy was initially performed for diagnostic purposes, it later evolved into a therapeutic procedure. During the 1930s and 1940s, it was used to lyse intrapleural adhesions after collapse therapy for tuberculosis. During the 1950s, when effective antituberculous chemotherapy became available, thoracoscopy fell into disuse in the United States²; however, it remained popular in Europe, where it was employed in diagnosing and treating problems such as pleural effusion, empyema, traumatic hemothorax, persistent air leak after pulmonary resection, and spontaneous pneumothorax.³⁻⁵ During the 1970s and 1980s, a few North American surgeons revived the practice of thoracoscopy, both to manage pleural disease and to perform small peripheral lung biopsies in patients with diffuse pneumonitis.

In the first stages of its revival, thoracoscopy was often performed with open endoscopes that were originally designed for other procedures (e.g., mediastinoscopes).^{6,7} As optics and lighting systems improved, smaller-caliber endoscopes were created specifically for thoracoscopic applications⁸; however, these instruments were limited, in that only one person could visualize the operative field at a given time. In 1991, the application of video technology to thoracoscopy revolutionized the procedure because it allowed several persons to see the operative field simultaneously and to operate together as they would during an open procedure. In addition, the development of endoscopic instruments, particularly endoscopic staplers, enabled surgeons to perform major operations using minimally invasive techniques. The impact of this new technology was so profound that within a 2-year period, traditional thoracoscopic techniques were abandoned in favor of video-assisted thoracic surgery (VATS).^{9,10}

In what follows, therefore, we focus on current VATS procedures rather than on traditional thoracoscopic techniques. There are numerous accepted diagnostic and therapeutic indications for VATS [see *Table 1*]. Accordingly, there are numerous operations that can be performed by VATS; we describe the most important of these, with the exception of esophageal myotomy and fundoplication, which are covered elsewhere [see *4:5 Minimally Invasive Esophageal Procedures*]. In addition, we describe the application of telerobotics to VATS lobectomy.

A major force that drives surgeons to perform VATS procedures has been patient demand. Unfortunately, the application of VATS has not always been accompanied by careful evaluation of outcomes. Feasibility has sometimes been confused with success. Although VATS appears to have beneficial effects in terms of cosmesis and postoperative pain in the short term, it has not yet been proved to have beneficial effects on pulmonary function and a return to normal activity in the long term.^{11,12} It is therefore the responsibility of thoracic surgeons to perform these procedures selectively rather than indiscriminately, either in settings where the effectiveness of VATS is clearly proved or, where the role of VATS

has not been fully established, within the context of well-designed clinical trials.

In particular, questions remain about the oncologic soundness of some VATS procedures. It appears that levels of cytokines and other acute-phase reactants are lower with minimally invasive procedures than with the corresponding open procedures.^{13,14} However, it remains to be determined whether this decrease will ultimately result in decreased tumor growth or reduced recurrence rates. Rigorous evaluation is needed to determine how VATS may be most appropriately and safely employed in cancer patients.

Operative Planning

POSITIONING AND PORT PLACEMENT

Patient preparation and positioning are much the same for most VATS procedures. As a rule, the lateral decubitus position offers the best exposure, and it permits easy conversion to a thoracotomy if necessary. There are occasional exceptions to this rule, however, and in such cases the choice of position is dictated by the procedure planned. For instance, if a cervical mediastinoscopy or a Chamberlain procedure is being performed for lung cancer staging and the pleura must be examined to rule out the presence of metastases, the patient can be left in the supine position and the videothoracoscope introduced through the parasternal incision or a separate inferior incision.¹⁵

Port placement, the use of so-called access incisions (utility thoracotomies), and instrumentation may vary from one procedure to the next. In approximately 20% of patients undergoing VATS, intraoperative conversion to a standard thoracotomy will be necessary for any of several reasons, including extensive pleural adhesions and pulmonary lesions that cannot be located thoracoscopically or that necessitate a more extensive resection than can be accomplished endoscopically. With experience, one can learn to predict the likelihood of such conversion in a given case. It is important to discuss this possibility with the patient before operation and to obtain informed consent to conversion. Any patient who is likely to require conversion to a thoracotomy or who may be undergoing lobectomy or pneumonectomy should receive the cardiopulmonary evaluation that is usual for such procedures before VATS is performed.

ANESTHESIA AND MONITORING

VATS procedures are performed with the patient under general anesthesia. Very limited operations (e.g., pleural biopsies) can be done with a single-lumen endotracheal tube in place, but most procedures should be performed with single-lung ventilation using a double-lumen endotracheal tube or a bronchial blocker. The degree of intraoperative monitoring needed depends on the extent of the planned procedure and on the patient's general medical condition. Standard monitoring techniques (including pulse oximetry) are al-

ways used, but arterial lines are placed selectively. A central venous catheter or a Swan-Ganz catheter is inserted only when the patient's baseline cardiac status demands precise hemodynamic monitoring. A Foley catheter is inserted at the beginning of all VATS procedures to monitor urine output because it is not always possible to predict how long the operation will take or whether conversion to thoracotomy will prove necessary.

INSTRUMENTATION

Instrumentation for VATS comprises (1) video equipment, (2) endoscopes and thoracoports, (3) staplers, (4) thoracic instruments (e.g., lung clamps and retractors) modified for endoscopic use, and (5) various devices for tissue cauterization, including lasers. Because immediate conversion to thoracotomy is occasionally necessary, a basic set of thoracotomy instruments should be an integral part of a VATS instrument tray.¹⁶

Video Equipment

Minor variations in lighting and optics aside, the basic components of all video systems used for thoracoscopy are similar: a large-screen (21 in.) video monitor, a xenon light source, a video recorder, and a printer for still photography, mounted together on a cart. A second video monitor, also mounted on a cart, is connected by cable to the main monitor and is placed across from it at the head of the operating table. Thus, both the surgeon and the first assistant are able to look directly at a video display without having to turn away from the surgical field. Alternatively, a single monitor can be placed at the head of the operating table. The only additional item of equipment necessary for laparoscopy is an insufflator. Therefore, to maximize cost-efficiency, hospitals acquiring video monitors and endoscopes should coordinate the choice of this expensive equipment among the specialties using it, including thoracic surgery, general surgery, gynecology, and urology. Hospitals performing many endoscopic procedures may find it advisable to dedicate one or more rooms to video endoscopic surgery and to mount video equipment on the ceilings or walls.

Endoscopes and Thoracoports

Some procedures are performed with a forward-viewing (0°) rigid scope; however, 30° angled scopes are useful for visualizing the sulci and the superior and posterior mediastinum and provide better overall visualization of the pleural space. In addition to the standard 10 mm thoroscopes, there are 5 mm thoroscopes whose resolution is nearly as good. The scope is attached to the light source by a light cable and is coupled to the video-monitor system by a camera cable [see Figure 1]. Although camera cables can be sterilized, it is best to cover the camera head and cable with a clear plastic bag so that the cable can remain in the OR at all times. Videoscopes are now available in which the camera chip is located at the tip of the scope rather than in the connecting camera cable; these are replacing the endoscopes previously used because they provide a sharper image. For complex procedures (e.g., VATS lobectomy), we currently use a 30° rotating scope, which allows better orientation and visualization around structures such as the pulmonary artery and bronchus. Flexible thoroscopes, which look like a short, heavy version of a flexible bronchoscope but have a more rigid distal end, are also available. Some surgeons feel that flexible thoroscopes enhance their ability to visualize the entire pleural space, but these devices are very expensive and continue to be premium purchases for most hospitals.

Originally, thoracoscopy made use of trocar cannulas designed for laparoscopy to access the pleural space. However, these devices are too long and have sharp ends that can injure the lung. Because

Table 1 Indications and Contraindications for VATS Procedures

Diagnostic indications

- Undiagnosed pleural effusion
- Indeterminate pulmonary nodule
- Undiagnosed interstitial lung disease
- Pulmonary infection in the immunosuppressed patient
- To define cell type in known thoracic malignancy
- To define extent of a primary thoracic tumor
- Nodal staging of a primary thoracic tumor
- Diagnosis of intrathoracic pathology to stage a primary extrathoracic tumor
- Evaluation of intrapleural infection

Therapeutic indications

- Lung
 - Spontaneous pneumothorax
 - Bullous disease
 - Lung volume reduction
 - Persistent parenchymal air leak
 - Benign pulmonary nodule
 - Resection of pulmonary metastases (in highly selected cases)
 - Resection of primary lung tumor (in highly selected cases)
- Mediastinum
 - Drainage of pericardial effusion
 - Excision of bronchogenic or pericardial cyst
 - Resection of selected primary mediastinal tumors
 - Esophageal myotomy
 - Facilitation of transhiatal esophagectomy
 - ? Resection of primary esophageal tumors
 - ? Thymic resection
 - Ligation of thoracic duct
- Pleura
 - Drainage of a multiloculated effusion
 - Drainage of an early empyema
 - Pleurodesis

Contraindications

- Extensive intrapleural adhesions
- Inability to sustain single-lung ventilation
- Extensive involvement of hilar structures
- Preoperative induction chemotherapy or chemoradiotherapy
- Severe coagulopathy

patients undergoing thoracoscopy are under general anesthesia and have a double-lumen endotracheal tube in place, the cannulas need not maintain an airtight seal, as they do in laparoscopy. Accordingly, thoracoports, which are shorter than laparoscopy cannulas and have a corkscrew configuration on the outside that stabilizes them within the chest wall, are routinely used. The trocar is simply a blunt-tip obturator that facilitates passage of the cannula through the chest wall [see Figure 2a]. Thoracoports are available in several sizes (5, 10.5, 12, and 15 mm in diameter) to accommodate various instruments.

Staplers

Endoscopic staplers that cut between two simultaneously applied triple rows of staples (gastrointestinal anastomosis [GIA] staplers) are available in lengths of 30 and 60 mm and in staple depths of 2.0, 2.5, 3.5, and 4.8 mm [see Figure 2b]. Like their counterparts designed for open procedures, they are disposable multicartridge instruments. The endoscopic GIA stapler with 2.0 and 2.5 mm staples is designed for division of pulmonary vessels. Some surgeons are reluctant to use it on hilar vessels because if the

Figure 1 Shown is a forward-viewing (0°) rigid scope that can be used for either laparoscopy or thoracoscopy. A detachable camera cable is clipped onto the eyepiece of the scope for video endoscopy. The camera cable can be sterilized or enclosed within a plastic sheath if it is used frequently.

stapler fails mechanically (e.g., cuts without applying both staple lines properly), life-threatening hemorrhage can ensue. Endoscopic staplers that do not cut (transverse anastomosis [TA] staplers) are also available.

Some advocate using two applications of the endovascular stapling device to minimize the risk of transecting the vessel as a consequence of a stapling misfire. In this approach, the stapler is first fired proximally with the knife removed, leaving six rows of staples in place. Next, the stapler is fired again more distally with the cutting mechanism intact to transect the vessel, leaving a total of nine rows of staples on the patient side and three rows of staples on the specimen side.

Endoscopic GIA staplers have revolutionized surgeons' ability to perform minimally invasive pulmonary resections. These devices are highly reliable and provide excellent hemostasis and closure of air leaks. There are also stapler cartridges that buttress

the staple line with prosthetic materials (e.g., Gore-Tex; W. L. Gore, Boulder, Colorado) to reduce postoperative air leakage in patients with emphysematous lung tissue.

Although they have been largely supplanted by endoscopic GIA staplers, standard stapling instruments can also be used during some VATS procedures. They are unnecessary for most pulmonary wedge resections but may be helpful for more complex procedures (e.g., lobectomies). Standard GIA staplers and articulated rotating TA staplers (Roticulator; AutoSuture, Norwalk, Connecticut) are the most practical devices for VATS because they can be inserted and positioned through an access incision.

Instruments

Various types of Pennington and Duval clamps are available [see Figure 2c]. Sponge sticks modified by the introduction of various curves and a line of DeBakey-type teeth on the end can also be

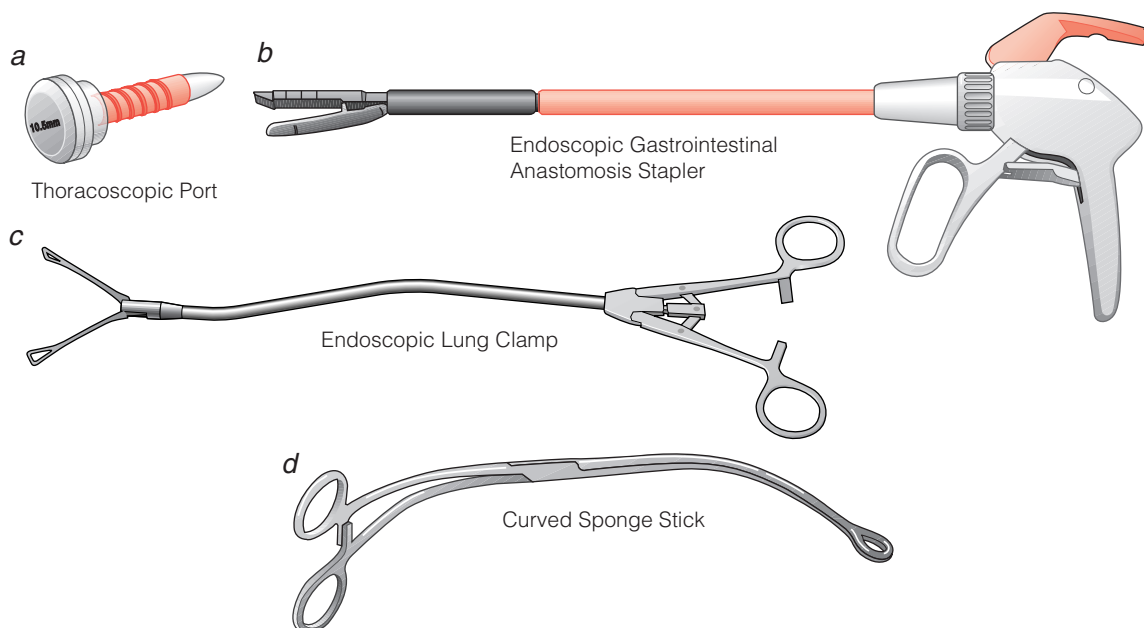

Figure 2 Shown are instruments commonly used during VATS. Modified trocar cannulas, called thoracoports (a), facilitate access to the pleural space. They are shorter than the cannulas used in laparoscopy and have a corkscrew configuration on the outside that maintains their position on the chest wall. The trocar is a blunt-tipped plastic obturator that facilitates passage of the cannula through the chest wall. A thin plastic diaphragm stabilizes the position of the instruments or can be removed to facilitate access to the pleural space. Endoscopic GIA staplers that make incisions between two triple rows of staples (b) can be inserted through these ports. Like staplers designed for open procedures, endoscopic GIA staplers are disposable multifire instruments that hold three replacements of the staple cartridge. Another instrument that can be inserted through these ports is the nondisposable endoscopic lung clamp (c), which is available in various shapes with serrations at the end or along the full length of the clamp. Finally, the port allows insertion of curved sponge sticks (d), which have been modified for endoscopic use as lung clamps or lymph node holders.

Figure 3 Shown are retractors used for VATS. Vein retractors are best suited for gentle retraction of hilar or mediastinal structures, such as the vessels, bronchi, esophagus, and lymph nodes. The tip of the disposable vein retractor (a) can be extended from or withdrawn into the shaft to allow insertion of the retractor through a 12 mm port. The most useful retractor for general purposes is the fan retractor (b). A knob on the end of the handle opens and closes the fan, allowing the retractor to be inserted through a port and opened for retraction in the pleural space.

used as lung clamps or lymph node holders [see Figure 2d]. Several retractors have been developed for endoscopic surgery. One such device is a modified Finochietto retractor with long, narrow blades, which is particularly helpful for retracting the chest wall soft tissues in an access incision. Others are the disposable vein retractor [see Figure 3a], the tip of which can be withdrawn into the straight instrument shaft, and the fan retractor, which can be opened and closed like a fan by turning a knob on the end of the retractor [see Figure 3b]. Of these, the fan retractor is the most useful general retractor for thoracoscopic procedures. Vein retractors are best suited for gentle retraction of hilar or mediastinal structures (e.g., vessels, bronchi, esophagus, or lymph nodes).

In major VATS procedures (e.g., VATS lobectomy), the soft tissues of the access incision may be retracted by means of a cerebellar (or Weitlaner) retractor. This measure allows the surgeon to encircle the hilar vascular structures by using two instruments simultaneously through the same incision. A Harken clamp is useful, in that it is long enough to reach behind a vascular structure

and pass a monofilament suture to the tip of the instrument. A polyp forceps is an excellent instrument for holding and retracting lymph nodes during a mediastinal lymph node dissection (MLND). Because polyp forceps have a slightly curved configuration and a blunt tip, they can also be used to dissect around hilar vessels.

Although biopsy forceps have been specifically created for laparoscopy and thoracoscopy, those used for mediastinoscopy are, in fact, well suited for thoracoscopy. Because laparoscopy instruments were developed before thoracoscopy instruments, many types of grasping forceps are available; however, most are too traumatizing for thoracic surgery. DeBakey forceps, modified for endoscopic use, are the gentlest type available. Various curved and right-angle dissecting clamps, needle holders, and scissors have been developed [see Figure 4]. In addition, standard thoracotomy instruments can be inserted through a minithoracotomy incision and used just as they would be in an open procedure.

Devices for Tissue Cauterization

Most scissors have an electrocautery attachment that permits simultaneous cutting and cauterizing. The neodymium:yttrium-aluminum-garnet (Nd:YAG) laser is sometimes applied to VATS resection of pulmonary lesions. This is done by inserting the YAG laser-fiber through angled or straight handpieces [see Figure 5]. Laser-assisted pulmonary resection is helpful in removing lesions on the flat surface of the lung, where a stapler cannot be easily applied.¹⁷

The argon beam electrocoagulator (ABC) (ConMed Corporation, Utica, New York) is a noncontact form of electrocautery that provides superb hemostasis on raw surfaces (e.g., denuded pulmonary parenchyma or the chest wall after pleurectomy) and helps seal air leaks from the surface of the lung.¹⁸ The standard disposable ABC handpiece used for open procedures is narrow enough to pass through a thoracoport and thus may be used for VATS. The optional Bend-a-Beam handpiece is extremely useful in VATS lobectomy because it allows the surgeon to shape the shaft of the instrument for easier coagulation of hard-to-reach areas.

Figure 4 Various right-angle (a) and curved (b) dissecting clamps are available. On the angled model shown (a), the knob close to the handle rotates the shaft of the clamp 360°. Many types of endoscopic scissors (c) are also available. Some scissors incorporate an attachment for an electrocautery so that the surgeon can cut and cauterize simultaneously.

Figure 5 Shown is an angled handpiece through which an yttrium-aluminum-garnet (YAG) laser can be placed during VATS. The handpiece is narrow enough to be used during thoracoscopy as well as during open procedures.

Instrumentation for videothoracoscopy continues to evolve, especially as minimally invasive cardiac surgical procedures become commonplace. Nevertheless, to put together the best set of instruments, it still is necessary to combine disposable and nondisposable instruments from different manufacturers and to borrow instruments originally designed for other procedures. Rather than create separate instrument trays for different VATS procedures, it is best to maintain a single standard tray that includes the basic instruments required for most operations and to add instruments as needed. Again, this tray should also include the instruments needed for conversion to thoracotomy.

Basic Operative Technique

VATS procedures include both true videothorascopies and video-assisted procedures that are really a cross between videothorascopies and standard thoracotomies. Because VATS procedures are still evolving, there is no firm consensus among surgeons with respect to the number, size, and location of incisions.

The basic videothoracoscopy techniques have been well described.¹⁹ The primary strategy is to place the instruments and the thoracoscope so that all are oriented in the same direction, facing the target disease within a 180° arc [see Figure 6]; this positioning prevents mirror imaging. The incisions should also be placed widely distant from each other so that the instruments do not crowd one another.

For most procedures, the videothoracoscope is inserted through a thoracoport placed between the midaxillary and the

posterior axillary line at the seventh or eighth intercostal space. Instruments are introduced through two thoracoports: one is placed at approximately the fifth intercostal space in the anterior axillary line, and the other is placed at the fifth space, parallel to and about 2 to 3 cm away from the posterior border of the scapula [see Figure 6a]. If the procedure is converted to a thoracotomy, the two upper incisions can be incorporated into the thoracotomy incision and the lower incision can be used as a chest tube site. When a patient is being operated on for an apical lesion (e.g., bullae causing a spontaneous pneumothorax) [see Figure 6b], the camera port can be placed at the fifth or sixth intercostal space, and the two instrument ports may also be moved higher, with one in the axilla and the other higher on the posterior chest wall at approximately the third intercostal space. Depending on the location of the lesion being removed, a fourth port incision may be helpful to permit the introduction of additional instruments.

When the lung must be palpated so that a small or deep-seated lesion can be located or when complex video-assisted procedures are being performed, a small (4 cm) intercostal incision is added to the three port incisions. This utility thoracotomy, or access incision, is usually placed in the midaxillary line or in the auscultatory triangle. An infant Finochietto retractor or a Weitlaner retractor is used to retract the soft tissues without actually spreading the ribs [see Figure 7].

These basic concepts regarding incision placement are modified as necessary to accommodate the procedure being performed and the location of the lesion being removed (see below).

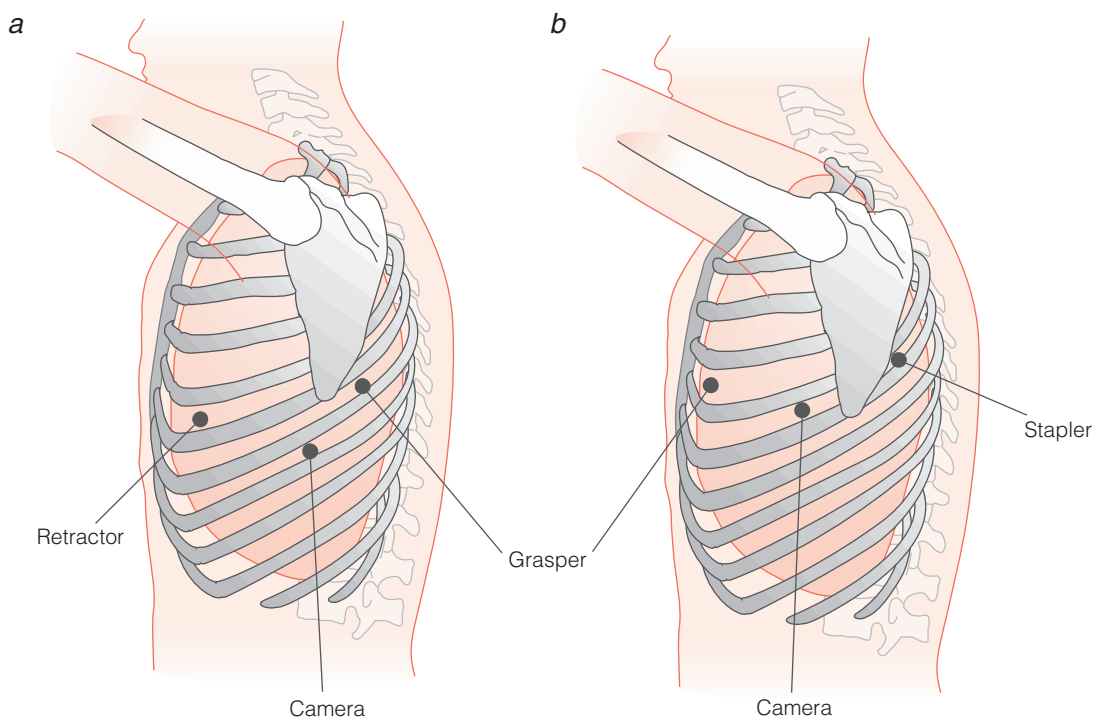

Figure 6 Basic operative technique. Shown is the typical positioning of instruments and the video camera for patients undergoing VATS for a lesion in the superior segment of the left lower lobe of the lung. Instruments are introduced through two port incisions made anteriorly at approximately the fifth intercostal space in the anterior axillary line and posteriorly parallel to and 2 to 3 cm away from the border of the scapula (a). For patients undergoing thoracoscopy for apical bullous disease in the left upper lobe of the lung, the camera port can be placed at the fifth or sixth intercostal space; one instrument port can be inserted in the axilla and the other port inserted higher on the posterior chest wall at approximately the third intercostal space (b).

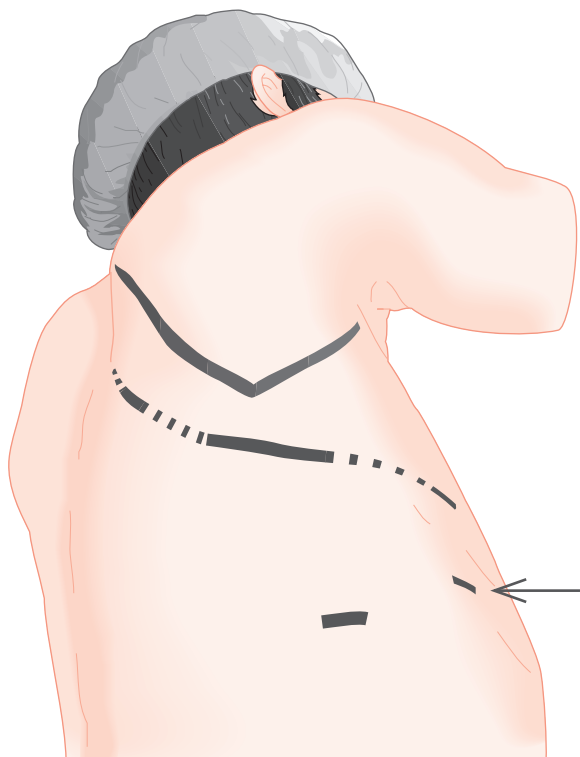

Figure 7 Basic operative technique. Shown are the incisions used for common VATS procedures. The thoracoscope is inserted through the bottom incision. Anterior and posterior incisions are used for the introduction of instruments. Only one additional low anterior incision (arrow) is needed for thoracoscopic pleural procedures. If necessary, a so-called utility thoracotomy (dotted line) can be added at the fifth intercostal space. The tip of the scapula is outlined. These incisions can be incorporated into a standard thoracotomy incision if the VATS procedure is converted to an open procedure.

VATS Procedures for Pleural Disease

OPERATIVE TECHNIQUE

A double-lumen endotracheal tube is inserted and the patient is placed in the lateral decubitus position. Two 1.5 cm incisions are made, one for the videothoracoscope and one for the instruments. The videothoracoscope is inserted through a 10.5 mm thoracoport at the seventh or eighth intercostal space in the midaxillary line; the instruments are inserted through a port placed a couple of interspaces higher in the anterior axillary line. If a talc poudrage is performed, both incisions are reused for placement of chest tubes, with a right-angle tube inserted on the diaphragm through the lower incision and a straight tube advanced up to the apex of the pleural space through the upper incision. The addition of a diaphragmatic chest tube helps prevent loculated basilar fluid collections after a talc pleurodesis. If a thoracotomy is subsequently performed, the upper port site is incorporated into the anterior aspect of the incision and the lower site can be reused as a chest tube site. Proper placement of port incisions is especially important in patients with suspected malignant mesothelioma because of the propensity of this tumor to implant in incisions and needle tracks.^{8,20,21}

Once the videothoracoscope has been inserted, pleural biopsies are obtained under direct vision by introducing a biopsy forceps through a port placed in the upper incision. (The mediastinoscopy biopsy forceps are well suited to this task.) Pleural fluid is evacu-

ated with a Yankauer or pool-tip suction device. Fibrinous debris can be removed by irrigating the pleural space with a pulsating water jet lavage device designed for debridement of orthopedic wounds. This technique is particularly useful for the debridement and drainage of loculated fibrinopurulent empyemas.²² At the end of the procedure, intercostal blocks are performed by using a mediastinoscopy aspiration needle, and talc can be insufflated for pleurodesis, if indicated. All of these instruments are introduced sequentially through the upper incision.²³

An alternative approach is to make a single incision in the midaxillary line at the sixth or seventh intercostal space and to use an operating thoracoscope that incorporates a biopsy forceps. This approach has the advantage of requiring only one incision; however, it does not allow as much latitude in draining or debriding the pleural space. Moreover, the biopsy forceps in an operating thoracoscope is of a smaller caliber than a mediastinoscopy biopsy forceps and thus cannot obtain as large a biopsy specimen.

TROUBLESHOOTING

In patients with loculated effusion, thoracoport placement must sometimes be modified. The preoperative chest computed tomographic scan and chest x-ray should help ensure that the ports are placed in areas where the lung is not adherent to the chest wall.

In some cases, the pleural space is obliterated by adhesions or tumor. This event occurs most frequently in patients who have had severe inflammatory disease (e.g., pneumonia, empyema, or tuberculosis) or extensive pleural malignancy (e.g., locally advanced malignant mesothelioma). In these circumstances, the anterior thoracoport incision can be extended to a length of 5 to 6 cm, the underlying rib section can be resected, and the parietal pleura can undergo biopsy directly; a full thoracotomy is not required. If thoracotomy is subsequently warranted for therapeutic reasons (e.g., for pleurectomy, decortication, or extrapleural pneumonectomy for mesothelioma), this small incision can be incorporated into the thoracotomy incision.

VATS Pulmonary Wedge Resection

VATS pulmonary wedge resection has become a standard approach to diagnosing small indeterminate pulmonary nodules, especially those not technically amenable to transthoracic needle biopsy.^{24,25} It is also an accepted method of diagnosing pulmonary infiltrates of uncertain origin, particularly in immunocompromised patients in whom transbronchial biopsy is either unsafe or inappropriate.^{26,27}

The role of VATS wedge resection is less well defined in the management of primary lung cancers. It is an appropriate compromise operation for primary lung cancers in patients with cardiac or pulmonary function status that rules out lobectomy. However, it remains a highly controversial approach to the treatment of pulmonary metastases.²⁸ In an often-quoted 1993 study,²⁹ patients with CT-documented pulmonary metastases underwent first thoracoscopic resection and then thoracotomy in the same setting. Many additional lesions, both benign and malignant, were found at thoracotomy that had been missed by VATS. The study was terminated early because of the failure of thoracoscopy to identify these lesions. One criticism of the study is that the preoperative CT scans were not comparable to the spiral (helical) CT scans currently available and therefore probably missed many pulmonary nodules that modern scanning methods would have identified.

A 2000 nonrandomized multicenter study of patients undergoing VATS metastasectomy for colon cancer suggested that minimal residual disease not identified by helical CT and not resected

by VATS may not affect survival significantly.³⁰ This conclusion, however, is completely at odds with all of the previously published surgical literature on pulmonary metastasectomy performed via thoracotomy. Improved survival in patients with pulmonary metastases appears to be directly linked to the ability to remove all gross tumor, and VATS does not allow the careful bimanual palpation that is critical to detecting pulmonary metastases that are too small or too deep to be visible endoscopically.³⁰⁻³² Accordingly, most centers reserve VATS for diagnosis rather than treatment of pulmonary metastases. Until a well-designed prospective, randomized trial is conducted with survival as an end point, the standard of care remains thoracotomy and metastasectomy.

Anecdotal reports of port-site recurrence have also raised concerns about VATS as a treatment method in patients with malignancies. However, a 2001 study of 410 patients from a prospective

VATS database at the Memorial Sloan-Kettering Cancer Center (MSKCC) found only one case of port-site recurrence.³³ The authors concluded that the incidence of such recurrences can be kept low if surgical oncologic principles are respected. At MSKCC, these principles include (1) reserving VATS for lesions that can be widely excised; (2) conversion to an open thoracotomy for definitive or extensive operations; and (3) meticulous technique for extraction of specimens from the pleural space, with small specimens removed directly through a thoracoport and larger specimens removed in specimen bags.

OPERATIVE TECHNIQUE

Once general anesthesia has been induced and a double-lumen endotracheal tube inserted, the patient is placed in the full lateral decubitus position. Ventilation to the lung being operated on is stopped as soon as the patient is rotated into the lateral decubitus position, so that the lung will be thoroughly collapsed by the time the videothoracoscope is inserted into the pleural space. Small subpleural pulmonary nodules are most easily identified in a fully atelectatic lung because they protrude from the surrounding collapsed pulmonary parenchyma, which is softer.^{19,20} Most pulmonary wedge resections are performed as true videothoroscopic procedures using just three port incisions placed in the triangulated manner already described [see Basic Operative Technique, above].

The pulmonary nodules to be removed are grasped with an endoscopic lung clamp (Pennington or Duval) inserted through one instrument port, and wedge resection is done with repeated applications of an endoscopic stapler inserted through the opposite port.^{24,34} As the resection is performed, it is often helpful to introduce the stapler through each of two instrument ports to obtain the correct angle for application to the lung [see Figure 8]. To prevent tumor implantation in the chest wall, small specimens (usually those resected with three or fewer stapler applications) are removed via the thoracoport. Larger specimens are placed in a disposable plastic specimen retrieval bag, which is then brought out through a very slightly enlarged anterior thoracoport incision.

When the wedge resections have been completed, intercostal blocks are performed under direct vision with a mediastinoscopy aspiration needle, and a single chest tube is inserted through the inferior port after the videothoracoscope is withdrawn.³⁵ The videothoracoscope can be placed through the anterior incision to check the position of the chest tube and to confirm reinflation of the lung after the double-lumen endotracheal tube is unclamped. The remaining incisions are then closed with sutures.

TROUBLESHOOTING

Four techniques may be used to locate pulmonary nodules that are either too deep or too small to be easily visible on simple inspection of the lung. All of these should be used in conjunction with a high-quality preoperative chest CT scan to identify the lung segment in which the nodule is located.

First, an endoscopic lung clamp may be gently run across the surface of the lung as an extension of digital palpation.^{20,36} With some patience and experience, one can achieve considerable success with this technique. Second, ultrasonographic examination of the collapsed lung may be used to locate deep pulmonary nodules; at present, however, this approach appears to have lost favor.³⁷ Third, CT-guided needle localization may be used preoperatively if a nodule is likely to be difficult to locate. Localization is accomplished by injecting methylene blue or by inserting a barbed mammography localization needle, which is then cut off at the skin exit site and later retrieved thoracoscopically.³⁸ Needle

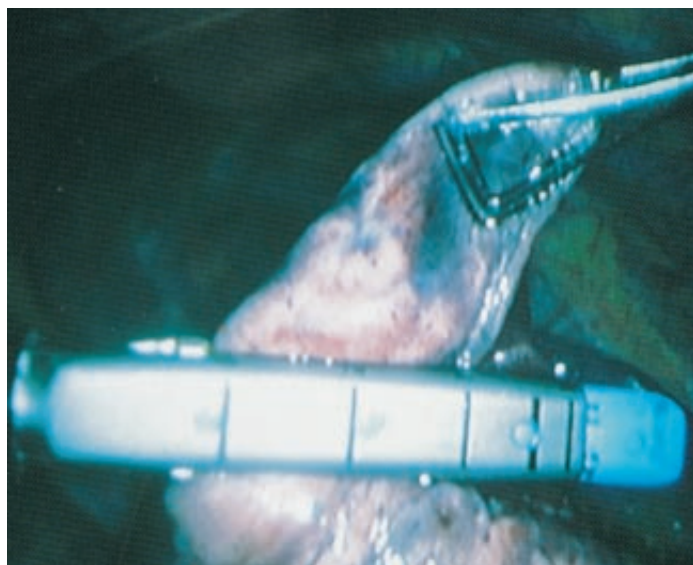

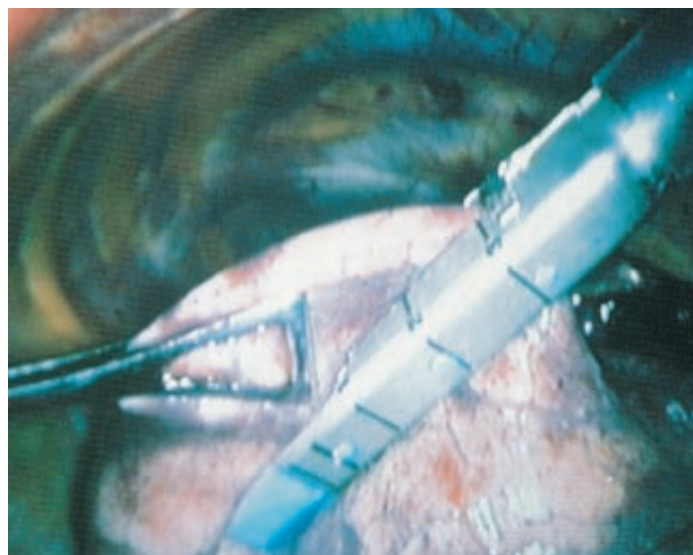

Figure 8 VATS pulmonary wedge resection. A double-lumen endotracheal tube is used to render the lung partially atelectatic. The pulmonary nodule is lifted upward with a lung clamp, and an endoscopic GIA stapler is applied to the lung underneath (top). During the wedge resection, the lung clamp and the stapler are alternately inserted through opposite ports to obtain the correct angle for performance of the wedge resection (bottom).

localization techniques are effective, but they are also costly and time-consuming and hence are not used by most surgeons. Finally, if careful endoscopic examination of the lung does not reveal the location of a nodule, an access incision is added to the videothoracoscopy.^{24,39} Each lobe of the lung is sequentially rotated up to this non-rib-spreading utility thoracotomy for direct digital palpation. This technique almost always allows identification of a nodule when other techniques fail. As the endoscopist gains experience with these techniques, conversion to thoracotomy solely for the purpose of locating a pulmonary nodule is rarely necessary.⁴⁰

Pulmonary nodules located on the broad surface of the lung may not be amenable to a wedge resection with an endoscopic stapler. Such nodules can be removed by means of electrocauterization, just as in an open thoracotomy. An extension is placed on the handle of the electrocautery, which is then introduced into the pleural space through either a port or an access incision. Another approach is to resect the pulmonary nodule with a laser in either a contact or a noncontact mode. The potassium-titanyl-phosphate (KTP)/YAG laser is particularly suited to this task because it is capable of both cutting and coagulation. To minimize bleeding and air leakage, raw pulmonary surfaces can be cauterized with either the Nd:YAG laser or the ABC.¹⁷ Numerous types of absorbable sealant patches or materials are also available to control air leaks from areas of raw pulmonary parenchyma.

Occasionally, after a wedge resection, it is necessary to suture together the pleural edges over an area of raw pulmonary parenchyma. The suturing can be done directly through a non-rib-spreading access incision or through port sites. In the latter case, the ports are removed and a 3-0 polypropylene suture is passed through the anterior port site with a standard needle holder. A second needle holder is introduced via the posterior port site and used in place of a forceps to pick up and reposition the needle as it is passed through the lung. The surgeon and the first assistant work together to oversee the lung, in contrast with the normal practice for an open procedure, in which the surgeon uses a needle holder and a forceps to place the sutures.

VATS Procedures for Spontaneous Pneumothorax and Bullous Disease

OPERATIVE TECHNIQUE

VATS is now frequently performed for the management of recurrent spontaneous pneumothorax and for bullous disease.^{41,42} The approach is similar to that followed in a wedge resection, with three or four port sites being utilized. The videothoracoscope is inserted at the fifth intercostal space in the midaxillary line, and two other port sites are added at the fourth intercostal space in the anterior and posterior axillary lines.

In patients with spontaneous pneumothorax, the responsible bulla (which is usually apical in location) is identified, and wedge resection is done with an endoscopic stapler.^{43,44} Bullae can be excised by applying the stapler across the base of the area of bullous disease. They can also be ablated with the ABC or the Nd:YAG laser, then suture-plicated if necessary; however, this approach may not be as successful over the long term.^{45,46}

Taking note of the lower rate of recurrence, the shorter hospital stay, and the relative cost-effectiveness, some surgeons advocate performing VATS for the first episode of spontaneous pneumothorax.^{47,48} To justify this approach in patients with primary spontaneous pneumothorax, however, well-designed clinical trials rather than retrospective reviews will be required.

TROUBLESHOOTING

The placement of port incisions should be determined by the location of the bullae. Because bullous disease is generally apical, port sites are correspondingly higher than for the average wedge resection (i.e., at the fourth and sixth intercostal spaces rather than at the fifth or sixth and eighth spaces). The precise placement should, however, be determined by pinpointing the disease site or sites on the preoperative chest x-ray and CT scans.

The main problem after resection for bullous disease is prolonged leakage of air from the staple line. This problem can be minimized by applying commercially available sleeves made of bovine pericardium or Gore-Tex over the arms of the stapler to reinforce the staple line and by performing some form of pleu-

Figure 9 VATS procedures for spontaneous pneumothorax and bullous disease. Limited apical pleurectomy is a useful alternative to chemical pleurodesis in young patients with spontaneous pneumothorax because these patients may need to undergo thoracotomy later in life. Shown is an outline of the pleural resection (a) performed in this procedure. The pleura is grasped at the inferior border with forceps and lifted in the avascular layer in a cranial or ventral direction (b). A T-shaped incision is made in the pleura at the level of the subclavian artery or the truncus brachiocephalicus. The dissection of the pleural flap thus created is extended in either the ventral or the parasternal direction and in either the apical or the mediastinal direction (c).

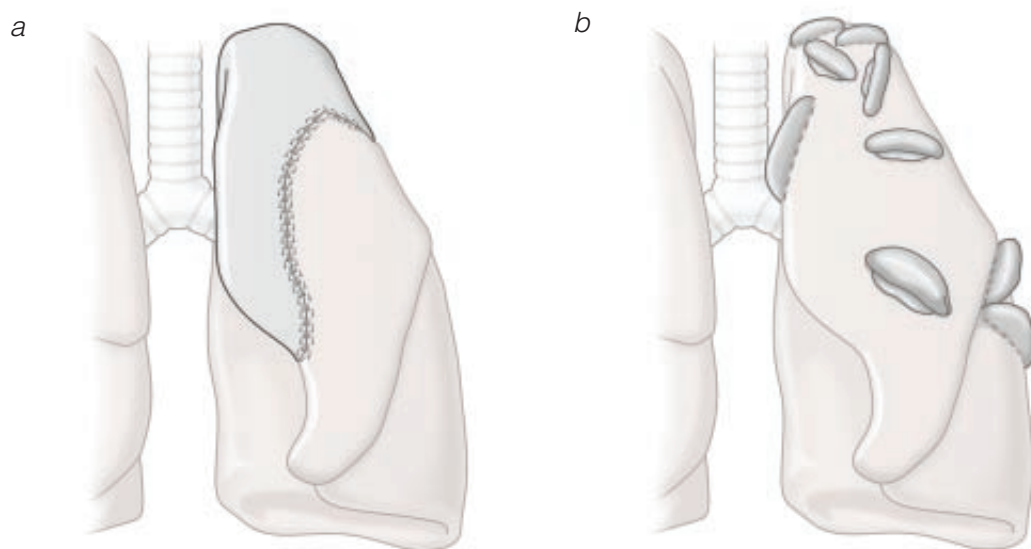

Figure 10 VATS lung volume reduction surgery. Thoracoscopic lung volume reduction can be accomplished through either (a) resection or (b) plication without cutting.

rodesis. Mechanical pleurodesis is done with a small gauze sponge passed through a port site. Some surgeons scarify the pleura by cauterizing it with the ABC or the Nd:YAG laser, but this is not as successful as mechanical pleurodesis. Chemical pleurodesis by talc poudrage is an appropriate option for older patients with emphysema and bullous disease but is unwise in young patients with spontaneous pneumothorax, who might require a thoracotomy later in life.⁴⁹ Another option in younger patients is a limited apical pleurectomy [see Figure 9]. Special angulated instruments and blunt dissectors have been designed for this procedure; however, a parietal pleurectomy is also easily performed with combinations of standard blunt and sharp instruments.⁵⁰

VATS Lung Volume Reduction Surgery

OPERATIVE TECHNIQUE

VATS may also be applied to the performance of lung volume reduction surgery (LVRS). If unilateral LVRS is planned, the patient is placed in the lateral decubitus position and port placement is similar to that for a patient undergoing a wedge resection of the upper lobe. Most patients undergoing LVRS, however, benefit from bilateral LVRS. For this procedure, the patient is placed in the standard supine bilateral lung transplant position, with shoulder rolls placed vertically in an I fashion behind the back and with the arms positioned above the head. The camera port is placed in the anterior axillary line at the sixth interspace. A lung compression clamp is placed on the area that will be resected. A Gore-Tex–reinforced stapler is then inserted into the chest and fired sequentially until the desired area is excised [see Figure 10a].

Another approach used to help buttress the tenuous staple line in emphysematous lung tissue is lung plication [see Figure 10b].⁵¹ In this method, the defunctionalized, bullous lung tissue is stapled to itself to form a plicated autologous buttress [see Figure 11]. Because the diseased bullous lung is not cut, the risk of postoperative air leakage is minimized.

TROUBLESHOOTING

A major cause of morbidity and mortality with this procedure is the occurrence of air leaks, which sometimes are large enough to compromise ventilation significantly. Thus, once LVRS has been done on one side, the lung is reexpanded and any air leaks

carefully assessed. If the leak is small, the other side is operated on in the same setting; if the leak is large, the contralateral procedure is put off to a later date. The use of fibrin glue or another commercially available pneumostatic sealant along the staple line should be considered to minimize postoperative air leakage.

VATS Lobectomy and Pneumonectomy

Although VATS lobectomy is much less frequently performed than VATS pulmonary wedge resection, standard techniques have been developed for it.⁵² VATS pneumonectomy, on the other hand, is less well accepted. Both operations are done as video-assisted procedures using a utility thoracotomy, which facilitates insertion of standard thoracotomy instruments, extraction of the resected specimen from the pleural space, and performance of the technically complex aspects of the procedure, including dissection of the hilar vessels and the mediastinal lymph nodes.

A 1998 retrospective study addressing the adequacy of VATS lobectomy as an oncologic procedure reported on 298 patients who underwent VATS lobectomy with MLND for primary non–small cell lung cancer.⁵³ On the basis of a 70% 4-year survival rate for stage I tumors, the investigators concluded that outcome after VATS lobectomy is comparable to that after open thoracotomy. At 5 years, however, survival rates after VATS are inferior, stage for stage, to the rates generally reported after thoracotomy. Such differences could reflect either inaccurate staging or true oncologic differences between VATS and thoracotomy; additional prospective studies are needed to clarify these issues.

Although VATS lobectomy has not been proved to be oncologically sound in the long term, there is good evidence that it is safe in acute settings.⁵⁴ Therefore, it should certainly be performed to treat benign diseases (e.g., bronchiectasis).⁵⁵ As with all minimally invasive procedures, conversion to open thoracotomy is indicated if technical issues require it. Some authors advocate VATS lobectomy for low-grade malignancies (e.g., carcinoids) as well.⁵⁶ It must be recognized, however, that although carcinoids have a lower malignant potential than non–small cell lung cancer, they are still malignancies and must be treated appropriately for optimal long-term outcome.

Two approaches to lobectomy have been developed. One involves sequential anatomic ligation of the hilar structures, much as in a standard lobectomy,^{57,58} and the other involves mass ligation of the

Figure 11 VATS lung volume reduction surgery. Shown are the key steps in the plication method of LVRS. (a) The apex of the lung area selected for plication is drawn to one side over a lung plication clamp, and the retractable guidebar of the clamp is extended into position. (b) The clamp is rotated 180° to fold the lung over itself. (c) The guidebar is retracted, a stapler is positioned with its jaws around the folded lung (but not yet closed), and the plication clamp is removed. (d) Shown is a cross-section of the folded lung after the stapler has been positioned but before the clamp has been removed. The stapler is then fired to complete the plication.

pulmonary vessels and the bronchus. Both approaches require at least two port incisions in addition to the utility thoracotomy incision. The sequential anatomic ligation approach has been well described and follows sound surgical oncologic principles.⁵⁷ Accordingly, it is our preferred method of performing VATS lobectomy. It must be remembered, however, that VATS lobectomy is a procedure for which there is no accepted uniform definition. In a survey aimed at defining the criteria used by minimally invasive thoracic surgeons for VATS lobectomy,¹⁴ the length of the utility incision ranged from 4 to 10 cm, the number of incisions ranged from three to five, and the use of rib spreading was variable. In an effort to standardize the approach at our own institution (MSKCC), we define a VATS lobectomy as an anatomic dissection that is performed entirely under thoracoscopic visualization, proceeds in an anterior-to-posterior fashion, employs a 4 cm utility incision, involves absolutely no rib spreading, and uses two thoracoscopy ports (one for the camera and one for retraction). Our definition also includes nodal evaluation (either sampling or dissection) of levels 4, 7, and 9 on the right and levels 5, 6, 7, and 9 on the left.

OPERATIVE TECHNIQUE

Lobectomy (Sequential Anatomic Ligation)

Positioning and port placement Correct positioning and port placement are essential for a successful VATS lobectomy. The patient is placed in the maximally flexed lateral decubitus position to prevent the hip from impeding downward movement of the thoracoscope. Tilting the hip posteriorly, especially in obese patients, greatly increases the range of movement of the thoracoscope. After the initi-

ation of single-lung ventilation, the camera port is placed at the eighth interspace in the anterior axillary line (for right-side lesions) or in the posterior axillary line (for left-side lesions). The posterior port is then placed where the lower lobe edge touches the diaphragm (at the ninth or 10th interspace) along the anterior border of the paraspinous muscle. A retractor is placed through the posterior port, and the upper lobe is retracted laterally to allow visualization of the superior pulmonary vein. The utility incision (no longer than 4 cm) is placed directly over the superior pulmonary vein for upper lobectomies (at approximately the third or fourth interspace) and one interspace lower for middle and lower lobectomies. A Weitlaner (or cerebellar) retractor is used to retract the soft tissues, and there is no need for rib spreading. A rotating 30° videothoracoscope is always used for these procedures.

Right-side resections *Right upper lobe.* The superior pulmonary vein is dissected from the overlying pleura via the access incision with long Metzenbaum scissors and DeBakey forceps, much as in an open lobectomy. A Harken clamp is passed behind the superior pulmonary vein after clear identification of the middle lobe vein. The superior pulmonary vein is encircled with a monofilament tie and retracted upward via the utility incision. An empty sponge stick is then placed through the utility incision, and the upper lobe is retracted posteriorly. An endovascular stapler is placed through the posterior port and, with the suture as a guide, passed behind the superior pulmonary vein.

Once the pulmonary vein has been divided, the anterior and apical segmental branches of the pulmonary artery are visualized. The level 10 lymph nodes are removed. A Harken clamp is passed

around the anterior and apical pulmonary arterial branches, and a monofilament suture is passed around them and brought out through the utility incision. The endovascular stapler is passed through the posterior port and used to transect the vessels. Transection of the truncus artery branch exposes the right upper lobe bronchus. Dissection is performed to separate the ongoing pulmonary artery from the bronchus. A monofilament suture is passed around the bronchus and brought out through the utility incision. An endoscopic GIA stapler with 4.8 mm staples is placed through the posterior port, and the right upper lobe bronchus is transected. This step exposes the branch of the pulmonary artery to the posterior segment of the right upper lobe, which is transected in the same manner through the posterior port.

Once all the structures to the upper lobe have been divided, the fissure is assessed. A lung clamp placed through the posterior port is used to retract the middle and lower lobes inferiorly, and a second lung clamp placed through the utility incision is used to retract the upper lobe superiorly. Once the fissure is exposed, a long curved sponge stick is used to elevate the right upper lobe, and an endoscopic GIA stapler with 4.8 mm staples is passed through the utility incision to complete both minor and major fissures. The lobe is then placed in a large surgical tissue pouch and removed via the utility incision.

Certain basic surgical concepts—dissection of hilar structures, passage of a monofilament suture around the structure, and transection with a stapler—are similar for all lobectomies. However, the order in which structures are transected and the ports through which staplers are passed differ.

Right lower lobe. The lower lobe is retracted superiorly, the inferior pulmonary ligament is transected, and the level 9 lymph nodes are removed. Once the entire inferior pulmonary vein has been dissected, a stapler is placed via the utility incision to transect the vessel. The lower lobe bronchus is exposed from its inferior aspect to its bifurcation with the middle lobe bronchus. The bronchus is left intact until the pulmonary artery to the right lower lobe is exposed medially and superiorly from the overlying fissure. Once the pulmonary artery has been adequately exposed, the bronchus is transected with a 4.8 mm universal stapler placed through the utility incision. The pulmonary artery is then transected via the utility incision, followed by the fissure.

Right middle lobe. With the middle lobe retracted laterally, the pleura overlying the middle lobe vein is incised. Once dissection of the vein is complete, the vessel is transected with an endovascular stapler placed via the posterior port, and the middle lobe bronchus is exposed. The bronchus is encircled with a monofilament suture, and an endoscopic GIA stapler with 3.5 mm staples is placed via the posterior port to transect the bronchus. An empty sponge stick is then used to place traction on the middle lobe bronchus, exposing the one or two branches of the middle lobe artery, which are then transected via the posterior port. On occasion, the angle is such that the middle lobe artery must be transected via the utility incision. The minor fissure is then completed by passing staplers via the utility incision.

Left-side resections *Left upper lobe.* The left upper lobe is retracted laterally, and the superior pulmonary vein is dissected free and transected via the posterior port. The first apical branch of the pulmonary artery is dissected free and transected with an endoscopic GIA vascular stapler introduced via the posterior port. The anterior aspect of the fissure is opened with one or two applications of an

endoscopic GIA stapler introduced via the access incision. The bifurcation of the left upper and left lower lobe bronchi is identified, and the left upper lobe bronchus is transected with an endoscopic GIA stapler with 4.8 mm staples introduced via the posterior port. An empty sponge stick is then used to retract the stump of the bronchus laterally, which facilitates exposure of several branches of the pulmonary artery, including the lingular artery. These branches are transected individually via the posterior port. The fissure is then completed by passing an endoscopic GIA stapler with 4.8 mm staples via the posterior port.

Left lower lobe. The lower lobe is retracted superiorly, the inferior pulmonary ligament is transected, and level 9 lymph nodes are removed. Once the inferior pulmonary vein has been dissected free, an endoscopic GIA vascular stapler is placed via the utility incision to transect the vessel. The lower lobe bronchus is exposed from its inferior aspect to its bifurcation with the upper lobe bronchus. The bronchus is left intact until the pulmonary artery to the lower lobe is exposed medially and superiorly from the overlying fissure. After the pulmonary artery has been adequately exposed, the bronchus is transected with an endoscopic GIA stapler with 4.8 mm staples placed via the utility incision. The pulmonary artery is then transected via the utility incision, and the fissure is completed via the posterior port. In cases with a very thick incomplete fissure, the fissure between the lingula and lower lobe should be opened before dissection of the pulmonary artery to facilitate subsequent arterial exposure.

Lobectomy (Mass Ligation)

The mass ligation method, or so-called SIS (simultaneous individual stapling) lobectomy, has also been used for VATS lobectomy.⁵⁹ Four incisions are made: an incision for the camera port at the seventh intercostal space, a 2 cm incision in the midaxillary line at the sixth intercostal space for the insertion of staplers, and two 3 cm incisions at the fourth intercostal space in the anterior and posterior axillary lines for the insertion of additional instruments. In the initial report of this technique, the bronchus and the pulmonary vessels were ligated separately, but the vessels were stapled en masse.⁶⁰ Subsequently, the technique was refined so that the bronchus and the vessels were stapled simultaneously by applying the stapler twice, the first time loosely to obtain closure of the bronchus and the second time more tightly to obtain hemostatic closure of the vessels.

Although the early results of SIS lobectomy were satisfactory,⁶¹ concerns arose about the long-term risks of bronchovascular or arteriovenous fistula formation resulting from mass ligation of the hilar structures. Consequently, this approach has not gained wide acceptance and is rarely used at present.

Pneumonectomy

The approach to VATS pneumonectomy is similar to the sequential anatomic ligation approach to VATS lobectomy. The thoracoscope is inserted at the seventh intercostal space in the midaxillary line, and a utility thoracotomy is performed at the fourth intercostal space in the same line. Two port sites are then created at the sixth intercostal space in the anterior and posterior axillary lines. The hilar vessels are sequentially isolated, ligated, and divided with endoscopic or standard staplers. The inferior pulmonary vein is done first, followed by the superior pulmonary vein and the pulmonary artery. The bronchus is stapled and divided last.^{62,63}

TROUBLESHOOTING

If ambiguous anatomy or excessive bleeding is encountered at any point during the procedure or if oncologic principles are violated, conversion to a thoracotomy is mandatory to ensure patient safety. A sponge on a stick, an open thoracotomy tray, and a polypropylene suture should always be readily available for emergency control of hemorrhage.

To prevent too-distal or too-proximal dissection (which can lead to bleeding and violation of oncologic principles), the surgeon should alternate frequently between panoramic and close-up views. In addition, to ensure that the mainstem bronchus has not been inadvertently dissected, the remaining lobes may be reinflated before bronchial transection.

Robot-Assisted VATS Lobectomy

Current minimally invasive surgical technology has several notable weaknesses. First, the camera platform is unstable, which means that the operating surgeon must rely on an assistant with a variable amount of experience and knowledge of the technical aspects of the procedure to provide the needed visualization. Second, the straight instruments used are limited with respect to range of movement and degrees of freedom when placed through small incisions—a limitation that can be particularly significant with thoracic procedures in which incision size is further limited by the size of the intercostal space. Third, the cameras provide only two-dimensional imaging. Finally, as a result of all of the preceding factors, the ergonomics of these minimally invasive procedures for the operating surgeon and the assistants are often very poor.⁶⁴ These weaknesses provided the impetus for the application of robotic techniques to minimally invasive surgery.

The first generation of surgical robots focused primarily on the issue of the unstable camera platform. In 1994, the Automated Endoscopic System for Optimal Positioning (AESOP) (Computer Motion, Santa Barbara, California), a voice-activated robotic camera holder, was approved by the Food and Drug Administration for clinical use in abdominal surgery. Subsequently, the EndoAssist (Armstrong Healthcare Limited, High Wycombe, United Kingdom), which allows the operating surgeon to control camera movement through natural head movement, was also approved by the FDA.

The newest generation of surgical robots was designed to address issues beyond the camera platform by employing telerobotic technology to enable the operating surgeon to control the surgical robot and its instruments by using a remote computer console. At present, two FDA-approved systems are commercially available: the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, California) and the ZEUS Surgical System (Computer Motion, Santa Barbara, California). Both were originally designed for closed-chest cardiac surgery,^{65,66} and most of the published literature to date has been concerned with this application. Nevertheless, the published experience with surgical telerobotics in minimally invasive surgery continues to expand, ranging from laparoscopic cholecystectomy to laparoscopic Nissen fundoplication to laparoscopic radical prostatectomy.⁶⁷⁻⁶⁹

At MSKCC, we employ the da Vinci Surgical System, which consists of three main parts. The first part is the basic robot. The robot has three arms—two instrument arms with a camera arm between them—all attached to a central column. Each instrument arm attaches to an 8 mm trocar, and the whole unit is placed into the patient; surgical instruments are then introduced through the trocar for intracorporeal use. The camera arm attaches to a 12 mm trocar that is already positioned inside the patient. The second part of the system is the surgeon's console, an ergonomically comfortable worksta-

tion that contains the computer, the three-dimensional imaging center, and the master controls that govern the robot's function. The third part is the equipment tower, which holds the light source, the camera, and additional necessary components (e.g., the electrocautery, the ultrasonic scalpel, and the insufflator).

For our purposes, the da Vinci robot has three signal advantages. First, it offers a true three-dimensional imaging system with binocular vision. The scope is 12 mm in diameter, with a separate 5 mm scope for each eye. The left and right images remain separated from the telescopes to the surgeon's eyes, so that the right eye sees the right image and the left eye sees the left image. Second, the instrument and camera arms are all controlled by the surgeon through the master controls and their interface with the computer; no voice or visual activation is necessary. Third, all of the surgical instruments, with the exception of the SonoSurg (Olympus America, Melville, New York), have seven degrees of freedom and two degrees of axial rotation, which means that they can be articulated in a manner that replicates the action of a human wrist.

OPERATIVE TECHNIQUE

To date, there have been only two published reports of the use of robotic technology during VATS lobectomy. One is a case report of a VATS left lower lobectomy done with robotic assistance,⁷⁰ and the other is a series of five patients, two of whom were converted to thoracotomy for technical reasons.⁷¹ It is clear from the lack of a substantial literature that a standardized approach has not yet been established. At MSKCC, however, we have developed a technique of robot-assisted VATS lobectomy that employs the da Vinci Surgical System as an adjunct to our standard VATS lobectomy technique. This robot-assisted approach has proved to be safe and feasible in more than 30 consecutive patients.

Step 1: Initial Exploration of Chest and Positioning of Robot

The patient is placed in a maximally flexed lateral decubitus position after single-lung ventilation is established. Initial thoracic exploration is conducted by means of conventional thoracoscopy to verify resectability and to establish the three standard VATS lobectomy access incisions. As noted [*see VATS Lobectomy and Pneumonectomy, Operative Technique, above*], the location of the main utility incision varies slightly, depending on the lobe of interest. Employing standard VATS lobectomy incisions has the benefit of allowing conversion to a conventional VATS procedure if the need arises (e.g., as a result of minor bleeding, inadequate exposure, or mechanical or technical problems with the robot). Once the incisions have been made, the conventional VATS instruments are removed, and the robot is brought into position from the posterior aspect of the patient, with the center column at an angle of approximately 45° with respect to the patient's longitudinal axis. This positioning allows the field of dissection to include the hilar structures and most of the chest.

A 12 mm trocar is placed through the anterior inferior access incision, and the camera arm is attached to the trocar. The three-dimensional 30° scope is introduced through the trocar and secured to the camera arm. The remainder of the positioning is accomplished under direct vision, both from outside the patient and from within the thorax. The trocars attached to the two instrument arms are introduced into the two remaining access incisions. Care must be taken to ensure that the instrument arms have full range of motion and do not collide with each other or with any portion of the patient.

Once the camera and the instrument arms are in place, surgical instruments are inserted through the attached trocars under direct

thoracoscopic vision. Our practice is to start the procedure with a Cadiere forceps in the left instrument arm (placed in the main utility incision) and a blunt permanent spatula hooked to an electrocautery in the right instrument arm. When all instruments have been positioned optimally, the operating surgeon scrubs out and moves to the control console.

Step 2: Robot-Assisted VATS Dissection

Two assistants are required: the first stands at the anterior aspect of the patient and assists through the main utility incision by providing additional retraction of the lung and suction when necessary, and the second is positioned at the posterior inferior access incision.

At MSKCC, we typically begin the procedure with MLND. All major nodal stations are explored with a combination of electrocauterization and blunt dissection, and all nodal tissue is removed and sent for frozen-section analysis to rule out occult stage III disease in patients with non-small cell lung cancer. Currently, we use the SonoSurg in an effort to prevent postoperative chyle leakage, though we have not yet encountered this complication.

If there are no contraindications to lobectomy, individual isolation of the hilar structures proceeds with dissection around the hilar vessels and bronchi performed with a combination of cauterization and sharp and blunt dissection, much as would be done through a thoracotomy. The tissues overlying each structure, particularly the regional lymph nodes, are precisely dissected away. When either a vessel or the bronchus is sufficiently mobilized, two blunt-tipped Cadiere forceps are used to reach around the structure, place a tie, and create sufficient space for placement of an endovascular stapler.

Step 3: Lobectomy

Right upper lobe The main utility incision is created in the midaxillary line at the level of the superior pulmonary vein. The right upper lobe is retracted inferiorly and posteriorly for MLND from the right paratracheal space, then anteriorly for the subcarinal space. Next, the right upper lobe is retracted laterally, and the mediastinal pleura overlying the superior pulmonary vein is incised with the Cadiere forceps in the left instrument arm and the permanent spatula attached to the cautery in the right instrument arm. The full extent of the vein is defined by identifying the takeoff of the middle lobe vein inferiorly and the junction between the superior vein and the truncus arteriosus superiorly. Any regional nodes present are resected. The spatula is replaced with a second Cadiere forceps, and the vein is encircled with a tie to allow gentle retraction. The left instrument arm is removed from the posterior inferior access incision just far enough to permit introduction of a 2.5 mm endoscopic GIA vascular stapler that is passed behind the vessel. The tie is removed, the stapler is closed, and the vessel is stapled and divided. The left instrument arm is replaced, and dissection continues by dividing the mediastinal pleura superiorly and posteriorly over the truncus arteriosus toward the bronchus with a combination of cauterization and blunt dissection. Any additional regional nodes encountered are resected.

The truncus branches are isolated with the Cadiere forceps and divided in the same manner as the vein. Attention is turned to the right upper lobe bronchus, and the peribronchial tissue is bluntly swept distally. The bronchus is mobilized with the Cadiere forceps, and an endoscopic GIA stapler with 4.8 mm staples is introduced again via the posterior access incision and closed around the bronchus. The remaining lung is minimally ventilated to ensure that the middle and the lower lobe are uncompromised; if this is the case,

the upper lobe bronchus is stapled and divided. The upper lobe is then retracted laterally and inferiorly. Additional hilar nodal tissue is resected, and the origins of the posterior ascending (or recurrent) artery, middle lobe artery, and superior segment pulmonary artery branches are defined. The recurrent artery branch is divided with an endoscopic GIA vascular stapler with 2.5 mm staples.

Once each of the hilar structures of the upper lobe has been divided, only the fissure remains. At this point, the robotic portion of the procedure is terminated. The instruments and the instrument arms are removed under direct vision, followed by the camera, the camera arm, and, finally, the robot. Conventional thoracoscopy is reestablished, and the fissure between the upper lobe and the remaining middle and lower lobes is completed with multiple firings of the 4.8 mm endoscopic GIA stapler. The specimen is placed in a large laparotomy sac and brought out through the anterior superior access incision. Hemostasis is confirmed, intercostal nerve blocks are created with 0.5% bupivacaine, and a single chest tube is placed under direct vision. The remaining lung is inflated, and the wounds are closed in the standard fashion.

Right middle lobe The main access incision is created in the midaxillary line one interspace below the level of the superior pulmonary vein, and MLND of the right paratracheal and subcarinal spaces is performed. With the middle lobe retracted laterally, the mediastinal pleura overlying the middle lobe pulmonary vein is incised with the Cadiere forceps in the left instrument arm and the permanent spatula attached to the cautery in the right arm. The mediastinal pleura is further incised down to the level of the inferior pulmonary vein. The spatula is replaced with a second Cadiere forceps; the vein is encircled with a tie and divided with the 2.5 mm endoscopic GIA vascular stapler inserted via the posterior access incision.

Next, the anterior portion of the major fissure is completed with the spatula and the cautery, and all regional lymph nodes encountered are excised. The middle lobe bronchus is identified and mobilized, with the peribronchial tissue swept distally. Division of the bronchus with a 3.5 mm endoscopic GIA stapler placed via the posterior incision facilitates subsequent dissection and ligation of the middle lobe branches of the pulmonary artery. This is best accomplished by resecting the tissue overlying the ongoing pulmonary artery proximally up to the takeoff of the middle lobe arterial supply. The middle lobe pulmonary artery is encircled and divided with the 2.5 mm endoscopic GIA vascular stapler through the posterior incision. The minor fissure is completed with multiple firings of the 4.8 mm endoscopic GIA stapler through the anterior superior utility incision. The lobe is placed in a large tissue pouch and brought out through the anterior utility incision. The robot is removed, and the procedure is completed in the same manner as a right upper lobectomy.

Right lower lobe As in a right middle lobectomy, the anterior utility incision is placed in the midaxillary line one interspace inferior to the level of the superior pulmonary vein, and MLND of the subcarinal space is performed. The lower lobe is retracted toward the apex of the chest, the inferior pulmonary ligament is divided with the electrocautery, and additional mediastinal lymph nodes from levels 8 and 9 are resected. The pleura overlying the inferior pulmonary vein is incised superiorly both anterior and posterior to the vessel. The Cadiere forceps are used to isolate this vein, and a 2.5 mm endoscopic GIA vascular stapler placed through the utility incision is used to divide the vessel. Retraction of the lung is maintained superiorly and posteriorly while the

major fissure is completed anteriorly with the spatula and the attached cautery.

The plane between the lower lobe bronchus and the basilar segmental pulmonary artery is developed bluntly. This step facilitates dissection of the pulmonary artery branches, especially if the major fissure is incomplete. In this instance, the bronchus may be divided before the artery with the 4.8 mm endoscopic GIA stapler inserted via the utility incision. The remainder of the pulmonary artery may be approached either inferiorly or via the fissure and may be similarly ligated with the 2.5 mm endoscopic GIA vascular stapler. The basilar and superior segmental branches may be divided separately if doing so is technically more feasible. The posterior aspect of the major fissure is completed with the stapler, and the lobe is removed. The robot is extracted, and the procedure is completed in the same manner as a right upper lobectomy.

Left upper lobe The main utility incision is created in the midaxillary line at the level of the superior pulmonary vein. The left upper lobe is retracted inferiorly and posteriorly to allow MLND from the aortopulmonary window. The lung is then retracted laterally, and the mediastinal pleura overlying the superior pulmonary vein is incised. As on the right side, the Cadiere forceps is in the left instrument arm and the permanent spatula attached to the cautery in the right. The mediastinal pleura is further incised down to the level of the inferior pulmonary vein. The full extent of the vein is defined by identifying the upper lobe bronchus inferiorly and the junction between the superior vein and the anterior pulmonary artery branches superiorly. Any regional nodes present are resected. The spatula is replaced with a second Cadiere forceps, and the vein is encircled with a tie. The left instrument arm is removed from the posterior inferior access incision to permit introduction of a 2.5 mm endoscopic GIA vascular stapler, which is passed behind the vessel. The tie is removed, the stapler is closed, and the vessel is stapled and divided.

The left instrument arm is replaced, and dissection is continued to mobilize the anterior pulmonary artery branches, which are encircled and divided with a 2.5 mm endoscopic GIA vascular stapler introduced through the posterior access incision. Ligating these arterial branches greatly facilitates division of the upper lobe bronchus. The upper lobe bronchus is then mobilized by means of blunt dissection and cauterization, with care taken not to include the entire left mainstem bronchus. A 4.8 mm endoscopic GIA stapler is used to staple and divide the bronchus. Once this is accomplished, the upper lobe is retracted laterally, which allows quick and easy identification, mobilization, and division of the apicoposterior and lingular pulmonary artery branches with multiple firings of the 2.5 mm endoscopic GIA vascular stapler. Conventional thoracoscopy is then reestablished, and the fissure between the upper and lower lobes is completed with multiple firings of the 4.8 mm endoscopic GIA stapler. The lobe is placed in a large laparotomy sac and brought out through the anterior utility incision, and the procedure is completed in the same manner as a right upper lobectomy.

Left lower lobe The anterior utility incision is placed in the midaxillary line one interspace below the level of the superior pulmonary vein. The left upper lobe is retracted inferiorly and posteriorly to allow MLND from the aortopulmonary window. Once this is done, the lower lobe is retracted toward the apex of the chest, the inferior pulmonary ligament is divided with the electrocautery, and additional mediastinal lymph nodes from levels 8 and 9 are resected. The pleura overlying the inferior pulmonary vein is incised superiorly both anterior and posterior to the vessel. The Cadiere forceps are used to isolate the inferior vein, and a 2.5 mm

endoscopic GIA vascular stapler is placed through the utility incision to divide the vessel. Retraction of the lung is maintained superiorly and posteriorly while the major fissure is completed anteriorly with the spatula and the attached cautery.

The plane between the lower lobe bronchus and the basilar segmental pulmonary artery is developed bluntly. This step facilitates dissection of the pulmonary artery branches, especially if the major fissure is incomplete. In this instance, the bronchus may be divided before the artery with the 4.8 mm endoscopic GIA stapler placed via the utility incision. The remainder of the pulmonary artery may be approached either inferiorly or via the fissure and may be similarly ligated with the 2.5 mm endoscopic GIA vascular stapler. The basilar and superior segmental branches may be divided separately if doing so is technically more feasible. The posterior aspect of the major fissure is completed with the stapler, and the lobe is removed. A subcarinal lymph node dissection is performed using blunt and cautery dissection with the Cadiere forceps and the spatula. The robot is removed, and the procedure is completed in the same manner as a right upper lobectomy.

TROUBLESHOOTING

If concerns arise at any time during robot-assisted VATS lobectomy about exposure, accurate identification of anatomic structures, the oncologic adequacy of the procedure, or safety, the surgeon must carefully consider whether it would be best to convert to a standard VATS lobectomy or even to a thoracotomy. If such conversion is indicated at any point in the procedure, the robot can be quickly and easily moved away from the patient. The instruments are removed under direct vision, followed by the camera. The instrument arms and the camera arm are backed away from the patient, and the robot can then be taken away.

There are several unique caveats that apply to robot-assisted VATS procedures. First, before even attempting such a procedure, the operating surgeon, the assistants, and all other operating personnel must be fully trained on the particular robotic surgical system being used. In the early stages of a center's experience with a system, it is advisable to have a company representative present to help manage any complex technical issues that may arise. Second, care must be taken both during initial positioning and throughout the procedure to ensure that the arms of the robot do not collide with one another or, more important, with the patient. Third, there must be constant communication between all team members and constant vigilance during the procedure. Untimely or unintended manipulation of any component of the robotic system during dissection around delicate hilar structures can be potentially disastrous and should be completely avoidable.

VATS Mediastinal Lymph Node Dissection

OPERATIVE TECHNIQUE

For biopsy of the aortopulmonary window nodes or anterior mediastinal masses, VATS MLND is often performed as an alternative to a Chamberlain procedure and is thought by some surgeons to provide better exposure and a superior cosmetic result.⁷² The thoracoscope is inserted at the fifth or sixth intercostal space in the posterior axillary line. Instruments for retracting the lung inferiorly are introduced via a port at the seventh intercostal space in the midaxillary line. Instruments for dissecting nodes are introduced through ports placed at the fourth intercostal space in the anterior axillary line and in the auscultatory triangle. The lymph nodes are dissected free with graspers (e.g., curved sponge sticks or polyp forceps), scissors, the electrocautery, and endoscopic hemostatic clips. A similar

approach can be used for biopsy of other mediastinal nodes, including the paratracheal and periesophageal nodes. Dissection of level 4 and level 2 nodes on the right is facilitated by transection of the azygos vein. This method has become an accepted approach to the surgical staging of esophageal cancer.^{73,74} It is more difficult to do a complete en bloc subcarinal lymph node dissection on the left than on the right with this method, though nodal sampling of this region by means of VATS is certainly feasible, especially when an access incision is used.

TROUBLESHOOTING

Care should be taken not to injure the phrenic nerve as it courses along the superior vena cava on the right and across the anterior aspect of the aortopulmonary window on the left. The vagus nerve should be visualized, and the origin of the recurrent laryngeal nerve avoided during dissection. The recurrent laryngeal nerve is easily injured on the left side, where it passes around the ligamentum arteriosum before traveling under the aortic arch; however, it can also be injured on the right side if MLND is carried too high superiorly along the origin of the innominate artery.

It is unwise to perform a VATS MLND after induction chemotherapy or chemoradiotherapy because the lymph nodes will often be densely adherent to surrounding structures. This is especially true on the right side, where the superior mediastinal lymph nodes are usually densely adherent to the superior vena cava, the azygos vein, and the right main pulmonary artery. A thoracotomy, with extensive exposure and sharp dissection, is usually required for a safe and complete MLND.

All lymphatic branches should be ligated during node biopsy or dissection to prevent leakage of chyle. There are often large lymphatic branches in the distal right paratracheal area. In addition, the thoracic duct can be injured if periesophageal or posterior mediastinal lymph nodes are being removed.

VATS Esophagectomy

OPERATIVE TECHNIQUE

To date, surgeons' experience with thoracoscopic esophageal resection has been limited. VATS esophagectomy can take either a transhiatal or a transthoracic approach.

Transhiatal Approach

The technique originally described for VATS transhiatal esophagectomy⁷⁵ is a modification of the open technique advocated by Orringer⁷⁶ [see 4:4 *Open Esophageal Procedures*] and allows the esophagectomy to be performed entirely under direct vision with the help of a specially designed operating mediastinoscope. This instrument has a partially concave olive tip that distracts the mediastinal tissues away from the mediastinoscope and cradles the esophagus in a stable position during the dissection. The mediastinoscope incorporates an optical system, an irrigation canal, and an operating channel for insertion of scissors, suction devices, and monopolar and bipolar cautery forceps.

The mediastinoscope is introduced through the neck incision used to expose the cervical esophagus, after the stomach and the distal esophagus have been mobilized via laparotomy. The thoracic esophagus is circumferentially freed from the surrounding mediastinal structures, beginning at the thoracic inlet and moving inferiorly to the hiatus, primarily by means of blunt dissection with the suction device. Vessels are cauterized or clipped. Dissection is performed first along the posterior wall of the esophagus, then along both lateral walls, and finally on the anterior surface of the esoph-

agus. At the level of the primary tumor, periesophageal soft tissues are resected en bloc to ensure complete removal of the cancer.

When the esophagus has been fully mobilized down to the diaphragmatic hiatus, a plastic tube is passed into the hiatus, where it is grasped by the mediastinoscope. Both the mediastinoscope and the plastic tube are then withdrawn to the cervical incision. The cervical esophagus is transected at the sternal notch with the GIA stapler, and the plastic tube is sutured to the distal end of the divided esophagus. The tube is then gently pulled back down to the diaphragmatic hiatus; in the process, the thoracic esophagus is folded onto itself. The mediastinoscope is reintroduced and used to follow the esophagus as it is removed from the mediastinum. Any undivided vessels or lymphatics are easily visualized and are either ligated or cauterized. After the esophagus is extracted, the stomach is passed up to the neck via the posterior mediastinum, and the esophagogastric anastomosis is performed in the standard manner for a transhiatal esophagectomy [see *Figure 12*].

Transthoracic Approach

Transthoracic thoracoscopic techniques for esophagectomy have been described by several authors.⁷⁷⁻⁷⁹ One group has refined a clinical VATS technique that is based on results from animal studies.⁸⁰ The most widely accepted method of performing a thoracoscopic and laparoscopic esophagectomy, however, is the one developed by Luketich and associates, who have performed more than 200 cases to date and have published a report of 77 patients that demonstrated the feasibility of their approach.⁸¹

A double-lumen endotracheal tube is inserted, the patient is placed in the left lateral decubitus position, and four thoracoports are placed. A 0 suture is placed in the central tendon of the diaphragm and brought out through an inferior anterior 1 mm skin nick to provide downward traction on the diaphragm and adequate exposure of the esophagus. The mediastinal pleura is opened widely, and the anterior edge is retracted with two stay sutures. The azygos vein is divided with an endoscopic stapler, and the inferior half of the thoracic esophagus is mobilized away from the aorta and the pericardium. The subcarinal lymph nodes are removed en bloc. The upper third of the thoracic esophagus is mobilized away from the trachea, and the right paratracheal lymph nodes are removed, with care taken not to injure the recurrent laryngeal nerve. A Penrose drain is placed around the esophagus and placed through the thoracic inlet for later retrieval via the neck incision. Once the esophagus has been fully mobilized, the pleural traction sutures are removed, a chest tube is inserted through the camera port site, and the other port incisions are closed.

The patient is then moved to the supine position. The stomach is mobilized laparoscopically. Port placement is similar to that for laparoscopic Nissen fundoplication. The patient is placed in a steep reverse Trendelenburg position. The gastrohepatic ligament is divided to expose the right crus of the diaphragm. The short gastric vessels are divided with ultrasonic shears; the right gastroepiploic artery is preserved. The stomach is retracted superiorly to facilitate nodal dissection of the celiac and gastric vessels. The left gastric artery and the left gastric (coronary) vein are then divided with an endovascular stapler. A pyloroplasty is performed, with ultrasonic shears used for the incision and an endoscopic suturing device for the repair. The gastric tube is then created with a universal 4.8 stapler, with care taken to preserve the right gastric vessels. Once the gastric tube is complete, it is attached to the specimen with several applications of the suturing device in preparation for transport to the neck. A laparoscopic jejunostomy is then performed. The right and left crural areas are opened last to facilitate passage on the conduit without loss of pneumoperitoneum.

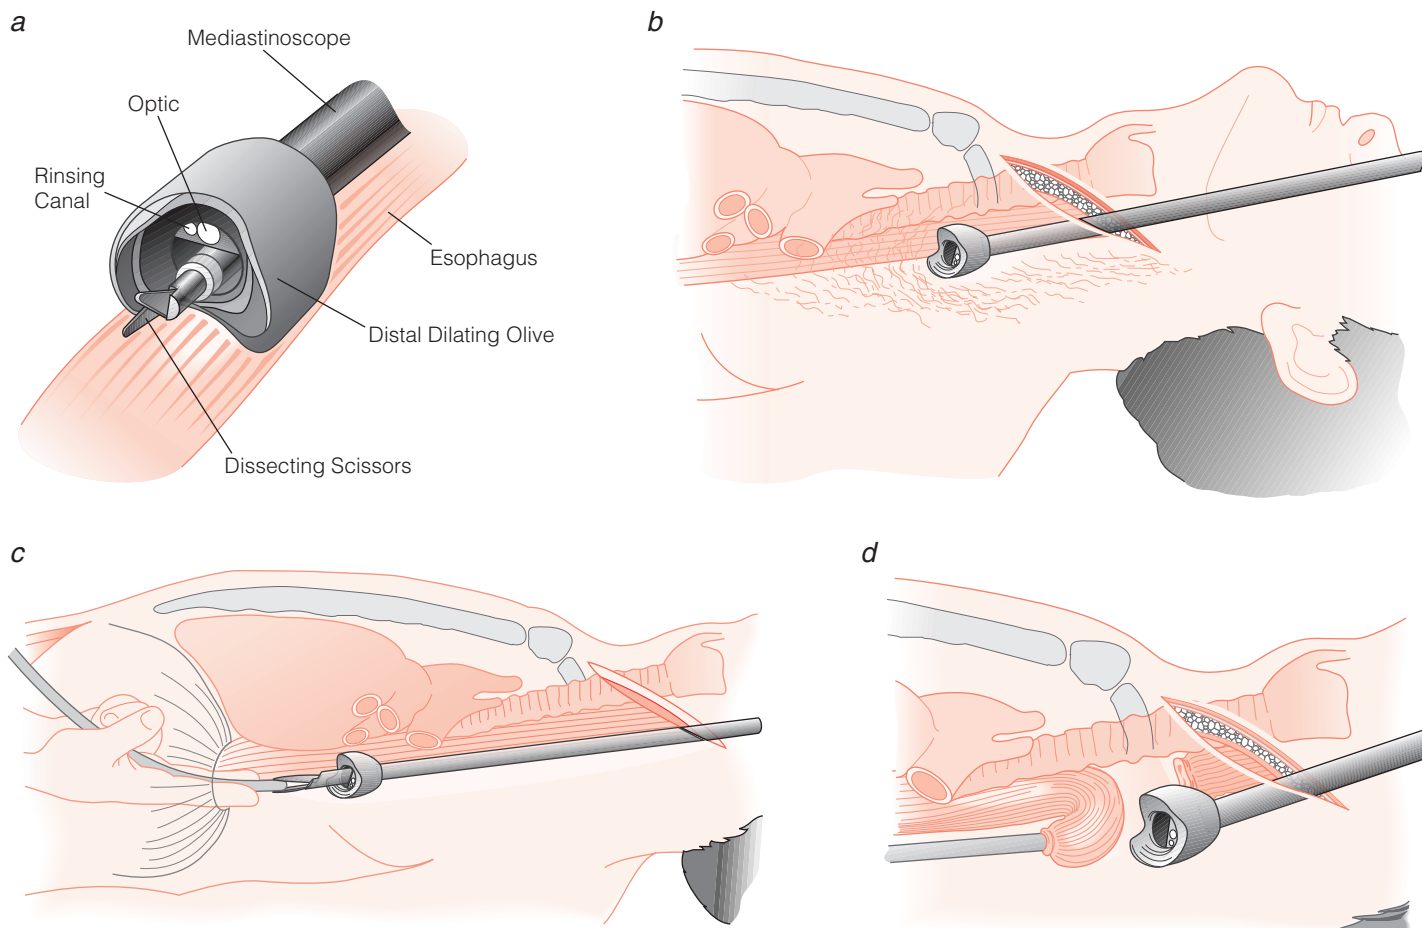

Figure 12 VATS esophagectomy. In the transhiatal approach, a specially designed operating mediastinoscope with an olive-shaped tip (a) is used. This tip mechanically distracts the mediastinal tissues away from the mediastinoscope and keeps the esophagus in a stable position during dissection. The scope is shown cradling the esophagus with the dissecting scissors inserted. During periesophageal dissection, the distal dilating olive of the mediastinoscope is placed behind the esophagus (b). The olive creates and maintains space by careful probing of the periesophageal areolar tissue. When the esophagus has been fully mobilized down to the diaphragmatic hiatus, a plastic tube is passed into the hiatus, where it is grasped by the mediastinoscope. Both the mediastinoscope and the plastic tube are pulled up from the hiatus (c). After esophageal resection with an endoscopic GIA stapler, the esophagus is folded over by using endoscopic control (d). Structures still attached to the esophagus are placed in traction, coagulated, and divided.

A 5 cm collar incision is made to the left of the midline, and the cervical esophagus is exposed. The Penrose drain that was left in the thoracic inlet is then delivered into the wound to facilitate mobilization of the desired portion of the esophagus. The esophagus is divided in the neck, and the specimen and the conduit are delivered through the posterior mediastinum under laparoscopic visualization to ensure proper alignment of the conduit. The cervical anastomosis may be either handsewn or stapled.⁸²

TROUBLESHOOTING

The technical problems associated with VATS esophagectomy are similar to those associated with open thoracic esophagectomy, including thoracic duct injury, recurrent nerve palsy, bleeding from the intercostal vessels, and anastomotic leakage [see 4:4 *Open Esophageal Procedures*]. These problems are best prevented by obtaining good visualization of the superior and posterior mediastinum, which can be achieved by using a 30° angled thoracoscope. The most common reason for conversion to thoracotomy is the presence of a locally advanced tumor that necessitates exten-

sive dissection for safe mobilization away from adjacent mediastinal structures.

To date, comparison of the results of VATS esophagectomy with those of open esophagectomy has not shown VATS to yield a significant decrease in major complications, especially postoperative respiratory insufficiency and cardiac arrhythmias.^{83,84} As a result, most centers still prefer the standard open transhiatal or transthoracic approaches to esophagectomy.

VATS may also be used in the management of postoperative chylothorax.⁸⁵ The thoracic duct can be ligated thoracoscopically, though it is sometimes difficult to identify and ligate the primary site of a postoperative lymphatic leak without reopening the thoracotomy.

VATS Pericardial Window

OPERATIVE TECHNIQUE

Some surgeons create a pericardial window by means of VATS as an alternative to taking the subxiphoid approach or the left anterior

thoracotomy approach.^{86,87} A double-lumen endotracheal tube is inserted with the patient under general anesthesia, and the patient is rotated into the right lateral decubitus position. Three access sites are used, with the thoracoscope inserted at the seventh intercostal space in the posterior axillary line and the instruments introduced through two ports, one at the tip of the scapula and the other at the sixth intercostal space in the axillary line [see Figure 13a]. The pericardium is retracted with a grasper forceps, and scissors are used to resect 8 to 10 cm² areas of pericardium both anterior and posterior to the phrenic nerve. If indicated, talc pleurodesis can be performed to control an associated pleural effusion. One or two chest tubes are then inserted through the port-site incisions.

TROUBLESHOOTING

When a pericardial effusion causes cardiac tamponade, a sub-xiphoid approach is preferable to VATS for creating a pericardial window because it is safer to perform in a hemodynamically unstable patient. A VATS pericardial window is also inadvisable in patients with constrictive physiology or with intrapericardial adhesions discovered at the time of operation. Conversion to an open procedure with formal pericardiectomy is advisable under these circumstances.

VATS Procedures for Mediastinal Masses

A 1998 multicenter trial aimed at defining the role of VATS in the management of mediastinal tumors suggested that VATS can be used safely to diagnose and resect most middle and posterior mediastinal masses, especially in view of the typically benign nature of these tumors.⁸⁸

VATS thymectomy has been employed to treat myasthenia gravis and thymoma.⁸⁹ To date, only anecdotal experience has

been reported, and no studies examining long-term outcome have been published. Although a VATS approach to myasthenia gravis may appear attractive at first, it is not the least invasive approach to the thymus. Transcervical thymectomy is a minimally invasive approach to the thymus that does not require a chest incision, does not violate the pleural space, and allows most patients to be discharged home the next day.⁹⁰ There is still a degree of controversy as to whether complete thymic resection, including all ectopic thymic tissue, is necessary to obtain clinical remission in patients with myasthenia gravis.⁹¹ For patients with a thymic mass, we prefer a transsternal approach. It is imperative to maintain oncologic surgical principles; accordingly, en bloc resection is emphasized, so that pleural seeding is avoided and the risk of incomplete resection minimized. For patients with myasthenia gravis who do not have a thymoma, however, we believe that there is a need for prospective studies comparing VATS with other surgical approaches to thymectomy.

OPERATIVE TECHNIQUE

VATS has been used to resect masses in all of the mediastinal compartments. VATS resection is an ideal approach to posterior neurogenic tumors that do not extend into the neural foramen or the spinal canal.^{92,93} With the patient in the lateral decubitus position, the operating table is rotated anteriorly so that the lung falls away from the paravertebral region. The port sites are placed anteriorly: the thoracoscope is inserted at the fifth intercostal space in the midaxillary line, a lung retractor is inserted at the sixth intercostal space in the anterior axillary line, and dissecting instruments are inserted at the second and fourth intercostal spaces in the anterior axillary line [see Figure 13b]. The mass is manipulated with a grasper to expose the posteriorly located pedicle, which is

Figure 13 (a) VATS pericardial window. Three access sites are used. The thoracoscope is inserted in the posterior axillary line at the seventh intercostal space, the endoscopic scissors are inserted through one port at the tip of the scapula, and the grasper forceps is inserted through another port in the anterior axillary line at the sixth intercostal space. (b, c) VATS procedures for mediastinal masses. For posterior masses, the port sites are placed anteriorly (b), and the thoracoscope is inserted at the fifth intercostal space in the midaxillary line. A lung retractor is inserted at the sixth intercostal space in the anterior axillary line, and dissecting instruments are inserted at the second and fourth intercostal spaces in the anterior axillary line. For anterior mediastinal masses and thymectomy, the port sites are placed in more posterior locations (c). The thoracoscope is introduced at the fifth intercostal space in the midaxillary or the posterior axillary line, and instruments are inserted through one port at the second intercostal space in the midaxillary line and another at the fifth or sixth intercostal space in the anterior axillary line.

then dissected, ligated, and divided with the scissors, clip appliers, and the electrocautery.^{94,95}

For removal of anterior mediastinal masses, the port sites are placed in more posterior locations. The thoracoscope is introduced at the fifth intercostal space in the midaxillary or posterior axillary line, and instruments are inserted through two ports, one at the second intercostal space at the midaxillary line and the other at the fifth or sixth intercostal space in the anterior axillary line [see *Figure 13c*]. The mass is retracted with a grasper and dissected free with a combination of sharp and blunt dissection, clip appliers, and the electrocautery.^{96,97}

A similar technique is used to resect middle mediastinal masses, most of which are pericardial or bronchogenic cysts.^{98,99} The access sites should be chosen according to the location of the mass on the preoperative CT scan. Generally, however, the triangulated site placement used for pulmonary wedge resections provides more suitable exposure than the site placement used for anterior or posterior mediastinal masses.

TROUBLESHOOTING

The placement of the thoracoports and the positioning of the operating team for the resection of posterior mediastinal tumors or for thoracic diskectomy differ significantly from the usual practice in most other VATS procedures. In place of the standard arrangement of trocars in an inverted triangle, the viewing port is placed in the posterior axillary line and the operating ports in the anterior axillary line. The thoracic surgeon and the neurosurgeon both stand on the anterior side of the patient, each viewing a monitor on the opposite side. In addition, a 30° scope is essential for visualizing the intervertebral disk space.^{93,95}

Removal of dumbbell neurogenic tumors can be accomplished thoracoscopically if immediately preceded by posterior surgical removal of the spinal component of the tumor via laminectomy and intervertebral foraminotomy. Preoperative MRI scanning is crucial for defining the extent of the tumor within the spinal canal.⁹⁴ Resection of posterior mediastinal tumors is sometimes associated with significant bleeding from intercostal or spinal arteries. If such bleeding occurs, there should be no hesitation in converting to a thoracotomy.

Ideally, anterior mediastinal cysts should be resected in toto to prevent recurrence. However, if the cysts are firmly adherent to vital mediastinal structures, partial excision with cauterization of the endothelial lining may be safer.

VATS Management of Thoracic Trauma

The major contraindication to thoracoscopy in thoracic trauma is hemodynamic instability. For major life-threatening injuries involving the great vessels and the mediastinum, thoracotomy is required to obtain expeditious control of injured structures [see *7:5 Injuries to the Chest*]. However, hemodynamically stable patients with certain thoracic problems (e.g., diaphragmatic injury, slow continued intrathoracic bleeding, persistent air leakage, and emphyema) may be diagnosed and often treated by means of VATS.^{100,101}

In the assessment of a trauma patient with a potential diaphragmatic injury, it is important not to ignore the high incidence of associated intra-abdominal injury. If intra-abdominal injury has been ruled out and there is concern about the presence of a diaphragmatic tear, thoracoscopic assessment of the diaphragm is justified. Such assessment allows a more thorough evaluation of the entire diaphragm than the laparoscopic approach, which is limited by the liver on the right side. In the largest series published to date, 60 of 171 patients who underwent thoracoscopy for pen-

etrating chest injuries had diaphragmatic injuries that necessitated repair.¹⁰² For hemodynamically stable patients with suspected diaphragmatic injuries, the VATS approach appears reasonable.

When a patient has an ongoing intrathoracic problem (e.g., persistent bleeding or a large air leak 24 to 48 hours after a traumatic injury), VATS should be considered before a thoracotomy is done because most problems encountered at this time (e.g., chest wall bleeding and laceration of the lung parenchyma) can be managed endoscopically, without the need for a thoracotomy.

TROUBLESHOOTING

The main pitfall in thoracoscopic evaluation of the diaphragm is failure to assess the abdomen appropriately and consequent failure to recognize an occult intra-abdominal injury. When laparoscopy is performed in a patient with a diaphragmatic injury, insufflation of CO₂ may cause a tension pneumothorax to develop on the side of the diaphragmatic injury. Accordingly, whenever diaphragmatic injury is a possibility, the chest should be included in the operative field to allow chest tube insertion if required. Because thoracoscopy does not require CO₂ insufflation, it is safer in such situations.

VATS Sympathectomy and Splanchnicectomy

Thoracic sympathectomy is known to be the most effective treatment for upper limb hyperhidrosis, and VATS is now an accepted approach to this operation.

The main indication for splanchnicectomy is intractable abdominal pain from unresectable malignancies (e.g., pancreatic or gastric carcinoma) and chronic pancreatitis. The effects of celiac ganglion blocks are transient, and surgical manipulation of this area is usually very difficult because of the primary disease process, previous operations, or both. In the past, thoracotomy was generally considered too invasive an approach to splanchnic denervation in these patients. Currently, however, because of the less invasive nature of thoracoscopy and the quicker recovery time associated with it, thoracoscopic splanchnicectomy is an attractive therapeutic option.¹⁰³

OPERATIVE TECHNIQUE

Sympathectomy

VATS sympathectomy is performed with the patient under general anesthesia and a double-lumen tube in place. Several techniques have been described. Initially, the common practice was to use three port sites: one for the thoracoscope at the third intercostal space in the midaxillary line, one at the third intercostal space in the anterior axillary line, and one at the tip of the scapula. Currently, the procedure is most often performed with two incisions: one at the fifth interspace at the border of the pectoralis and one at the fourth interspace in the anterior axillary line. The pleura is incised and divided from T2 to T5, and the sympathetic chain is dissected free with scissors and excised. For complete control of upper limb hyperhidrosis, VATS must be done bilaterally.^{104,105}

A 1998 study reviewed the long-term results in 630 patients who had undergone thoracoscopic sympathectomy for hyperhidrosis (median follow-up, 15 years).¹⁰⁶ Of these patients, 68% were fully satisfied, and 26% were only partially satisfied but nevertheless would agree again to the operation. Hyperhidrosis was cured permanently in 93%. Compensatory sweating and gustatory sweating occurred in 67% and 47% of cases, respectively. Overall, patients were well satisfied with the results and considered the compensatory sweating less of a problem than the original hyperhidrosis.

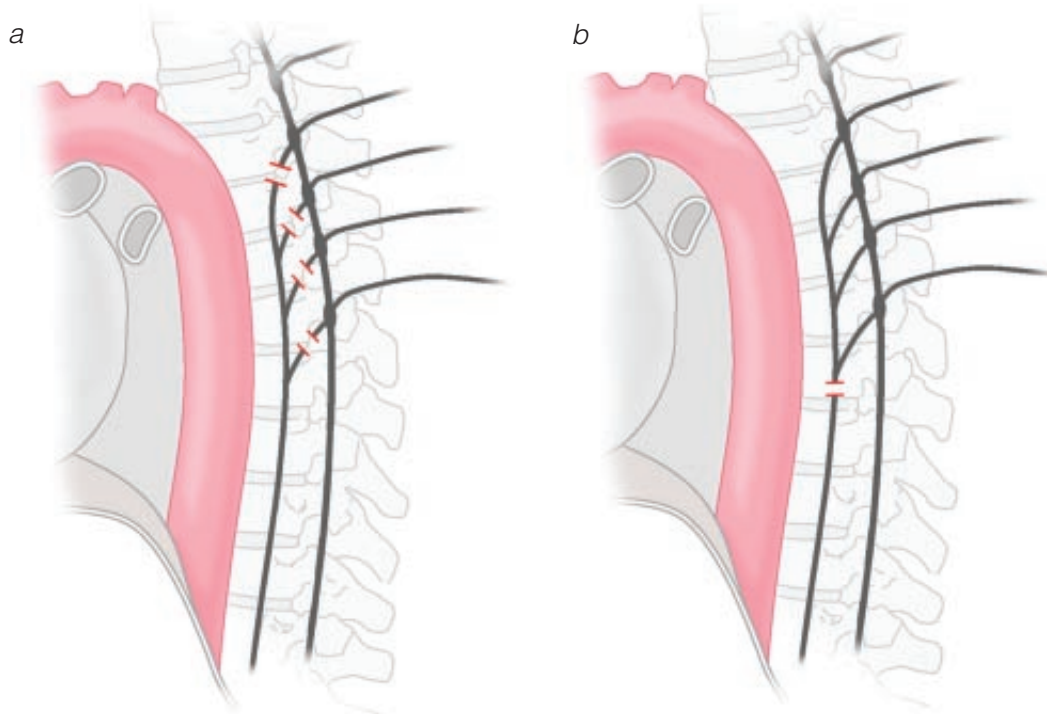

Figure 14 VATS splanchnicectomy. Splanchnicectomy may be accomplished by either (a) dividing the roots of the splanchnic nerves or (b) dividing the splanchnic nerve itself.

Splanchnicectomy

The technical aspects of VATS splanchnicectomy are quite simple: a sound knowledge of the splanchnic anatomy and a basic set of thoracoscopic instruments are all that is needed. Single-lung ventilation is required. Three thoracoports are placed. A silk stitch is placed in the central tendon of the diaphragm and pulled through the most anterior and inferior port to allow better visualization of the splanchnic nerves. The camera is also placed through this port. An endoscopic grasper and an endoscopic scissors with an electrocautery attachment are used to remove the nerve segment from T5 to T9. The greater and lesser splanchnic nerves are resected [see *Figure 14*]. The least splanchnic nerve is rarely visualized.

TROUBLESHOOTING

Care should be taken to identify the first and second ribs. Division of the sympathetic trunk at the level of the first rib causes Horner syndrome and does not reduce palmar hyperhidrosis.

Division of the rami communicantes rather than the main sympathetic trunk reduces the incidence of undesirable side effects, especially compensatory hyperhidrosis of the trunk, but its overall success rate in controlling upper limb hyperhidrosis is lower. Abolition of only the T2 and T3 ganglia may control palmar hyperhidrosis without being as likely to result in unacceptable compensatory truncal sweating. Some have advocated limited T3 sympathectomy for primary hyperhidrosis to prevent compensatory sweating.¹⁰⁷ Target areas for axillary sweating also include T4 and T5. In addition, an accessory sympathetic nerve fiber that runs lateral to the sympathetic chain (known as the nerve of Kuntz) should be sought and, if identified, divided. Compensatory hyperhidrosis of the inner thighs is a not uncommon complication.

Neuralgia is frequent after VATS sympathectomy. Some authors advocate a 2-day postoperative course of dexamethasone to reduce the incidence of this problem.¹⁰⁸

Miscellaneous VATS Procedures

Several other procedures have been performed by VATS, including ligation of the thoracic duct¹⁰⁹ and resection of the adrenal gland.¹¹⁰ For adrenal resection, three incisions are placed at the ninth or 10th intercostal space, extending from the anterior axillary line to the posterior axillary line. A fan retractor is inserted through a radial incision in the diaphragm and used to retract the perirenal fat. The adrenal gland is dissected free and removed, and the associated vessels are clipped or cauterized.¹¹⁰

Cost Considerations

It is hard to estimate the cost-effectiveness of VATS procedures because the instrumentation, the types of procedures performed, and the surgical expertise with these operations are all still evolving. Initially, VATS procedures proved expensive for several reasons (e.g., the cost of purchasing video and endoscopic equipment, the cost of disposable instrumentation, and the need for long operating times as surgeons and nursing staff gained experience with the procedures). Soon after VATS was introduced, a study from the Mayo Clinic compared the cost of performing VATS pulmonary wedge resections with that of the same operation done by thoracotomy.¹¹¹ The VATS approach was associated with substantially shorter hospital stays but also with increased OR costs; hence, the use of VATS did not result in any significant overall savings. Since that study, however, as some VATS procedures (e.g., pulmonary wedge resection) have become standard operations and more reusable instrumentation has become available, the cost of VATS has undoubtedly decreased. Whether other, more complex VATS procedures (e.g., thoracoscopic esophagectomy) are cost-effective remains to be determined.

Statement of AATS/STS Joint Committee on Thoracoscopy and Video Assisted Thoracic Surgery¹¹⁵

The Councils of the American Association for Thoracic Surgery and the Society of Thoracic Surgeons have formed a Joint Committee on Thoracoscopy and Video Assisted Thoracic Surgery. The purpose of this Committee is to facilitate the education of thoracic surgeons in this new technology and to provide guidelines for appropriate training in and performance of thoracoscopy and video assisted, minimally invasive thoracic surgery.

The following guidelines are recommended by the Joint Committee:

1. In order to ensure optimal quality patient care, thoracoscopy and video assisted thoracic surgery (TVATS) should be performed only by thoracic surgeons who are qualified, through documented training and experience, to perform open thoracic surgical procedures and manage their potential complications. The surgeon must have the judgment, training, and capability to proceed immediately to a standard open thoracic procedure if necessary.

The preoperative and postoperative care of patients treated by TVATS should be the responsibility of the operating surgeon.

2. It is recommended that TVATS techniques be learned through appropriate instruction:
 - a. As part of a formal approved thoracic surgical residency or fellowship program which includes structured and documented experience in these procedures.
 - b. For the practicing thoracic surgeon, completion of a course that follows the guidelines approved by the Joint Committee, with hands-on laboratory experience, plus observation of these techniques performed by thoracic surgeons experienced in such procedures.
3. The granting of privileges to perform TVATS remains the responsibility of the credentialing body of individual hospitals.

For the AATS/STS Joint Committee on Thoracoscopy and Video Assisted Thoracic Surgery: Martin F. McKneally, M.D., and Ralph J. Lewis, M.D., co-chairmen; Richard P. Anderson, M.D., Richard G. Fosburg, M.D., William A. Gay, Jr., M.D., Robert H. Jones, M.D., and Mark B. Orringer, M.D.

Training and Certification in VATS and Robotic Surgery

Thoracoscopy is most frequently performed by thoracic surgeons.² In some centers, however (particularly in Europe), pulmonologists became highly experienced in the application of traditional thoracoscopic techniques to the diagnosis of pleural disease. The experience of Boutin epitomizes the involvement of physicians who do not have specific surgical training.^{4,8} The development of small-caliber endoscopes that could be used with local anesthesia outside the OR made it easy for nonsurgeons to perform thoracoscopy.

After the 1950s, thoracoscopy was largely forgotten by surgeons and pulmonologists in the United States until the advent of VATS. The dramatic initial popularity of this technique generated considerable debate about whether nonsurgeons should perform VATS in the same way as they perform other invasive endoscopic procedures.¹¹²⁻¹¹⁴ During this period, laparoscopic cholecystectomy became widely practiced, often by persons who lacked adequate training, and reports of serious complications emerged.

Within this context, the Society of Thoracic Surgeons (STS) and the American Association for Thoracic Surgery (AATS) formed a joint committee to establish standards and guidelines for training and certification in VATS [see *Sidebar* Statement of AATS/STS Joint Committee on Thoracoscopy and Video Assisted Thoracic Surgery].¹¹⁵ As a result of the educational efforts of this committee, many surgeons were trained within a short time, and VATS was quickly incorporated into thoracic surgical practice and residency training.

The important considerations with respect to the training and practice of VATS have been well articulated.^{114,115} VATS is not minor surgery: it is a minimally invasive, complex intrathoracic procedure that should be performed only by persons who are familiar with intrathoracic anatomy and pathology and are fully competent to manage complications and make intraoperative decisions in such a way as to ensure safe outcomes for thoracic surgical patients. The complications encountered during thoracoscopic operations are potentially immediately life-threatening, whereas those encountered during other endoscopic procedures usually are not. For that reason, VATS procedures should not be performed by anyone—surgeon or nonsurgeon—who lacks the training and experience to perform immediate thoracotomy and repair of intrathoracic injuries.

VATS is now an integral part of the practice of thoracic surgery.¹¹⁶ The direct involvement of the major thoracic societies in the dispersion of this technology has discouraged the casual and unsafe application of VATS and has promoted an ongoing critical appraisal of VATS procedures.

The use of robotic assistance in a particular VATS procedure imposes two special requirements on the individual practitioner. First, the robot must be FDA approved for use in that procedure. The list of approved procedures continues to grow and currently includes the majority of general thoracic operations. Second, the practitioner must complete system training for the specific surgical robotic system being used. For the da Vinci Surgical System, Intuitive Surgical runs a 2-day certification course that includes thorough system training, as well as practical instruction with animal and cadaver models. At present, however, although each institution has its own individual requirements for robotic use, there is no standardized method for demonstrating competence.

8 PLEURAL EFFUSION

Rafael S. Andrade, M.D., and Michael Maddaus, M.D., F.A.C.S.

Approach to the Patient with a Pleural Effusion

Pleural effusion is a common problem in surgical practice. It results from perturbations of normal pleural fluid transport, which are produced by three main mechanisms—abnormalities in Starling’s equilibrium, increased capillary and mesothelial permeability, and interference with lymphatic drainage. These mechanisms are associated with a variety of different causes [see Table 1].^{1,2} Often, more than one mechanism is involved. An inflammatory effusion, for instance, is marked by increases in capillary and mesothelial permeability, which lead to elevated intrapleural oncotic pressure.

Pleural effusion is classified as either transudative or exudative, depending on the chemical composition of the fluid. A transudate is an ultrafiltrate of serum and has a low total protein content (≤ 3 g/dl); an exudate is the result of increased permeability and has a high total protein content. Increased pleural permeability results from complex inflammatory mediator interactions between the mesothelium (whose cells play an active role in inflammation, phagocytosis, leukocyte migration, tissue repair, antigen presentation, coagulation, and fibrinolysis^{3,4}) and the capillary endothelium. The distinction between transudative and exudative pleural effusion is clinically significant in that the two types of effusion have different causes [see Table 2].^{1,4}

Clinical Evaluation

A complete history, physical examination, and clinical acuity are the initial tools used for diagnosing pleural effusion. Important facts from a patient’s history (e.g., respiratory symptoms, pain, extrathoracic symptoms, duration of symptoms, previous medical conditions, and risk factors for cardiopulmonary diseases or can-

cer) can raise the index of suspicion for an effusion and provide guidance regarding possible causes. Careful physical examination of the chest can detect an effusion, and many physical signs may provide clues to the cause. Physical signs that are particularly useful for diagnostic purposes include jugular venous distention and tachycardia (suggestive of congestive heart failure); lymphadenopathy, digital clubbing, and localized bone tenderness (suggestive of lung cancer); and ascites (suggestive of ovarian tumors or cirrhosis).

Pleural effusion can occur in a wide variety of clinical situations, however, and it often evades clinical detection by history and physical examination. Consequently, imaging tests are indispensable in the workup of a patient with a possible pleural effusion. Pleural fluid analysis, pleural biopsy, and thoracoscopy may also be required for evaluation.

Investigative Studies

IMAGING

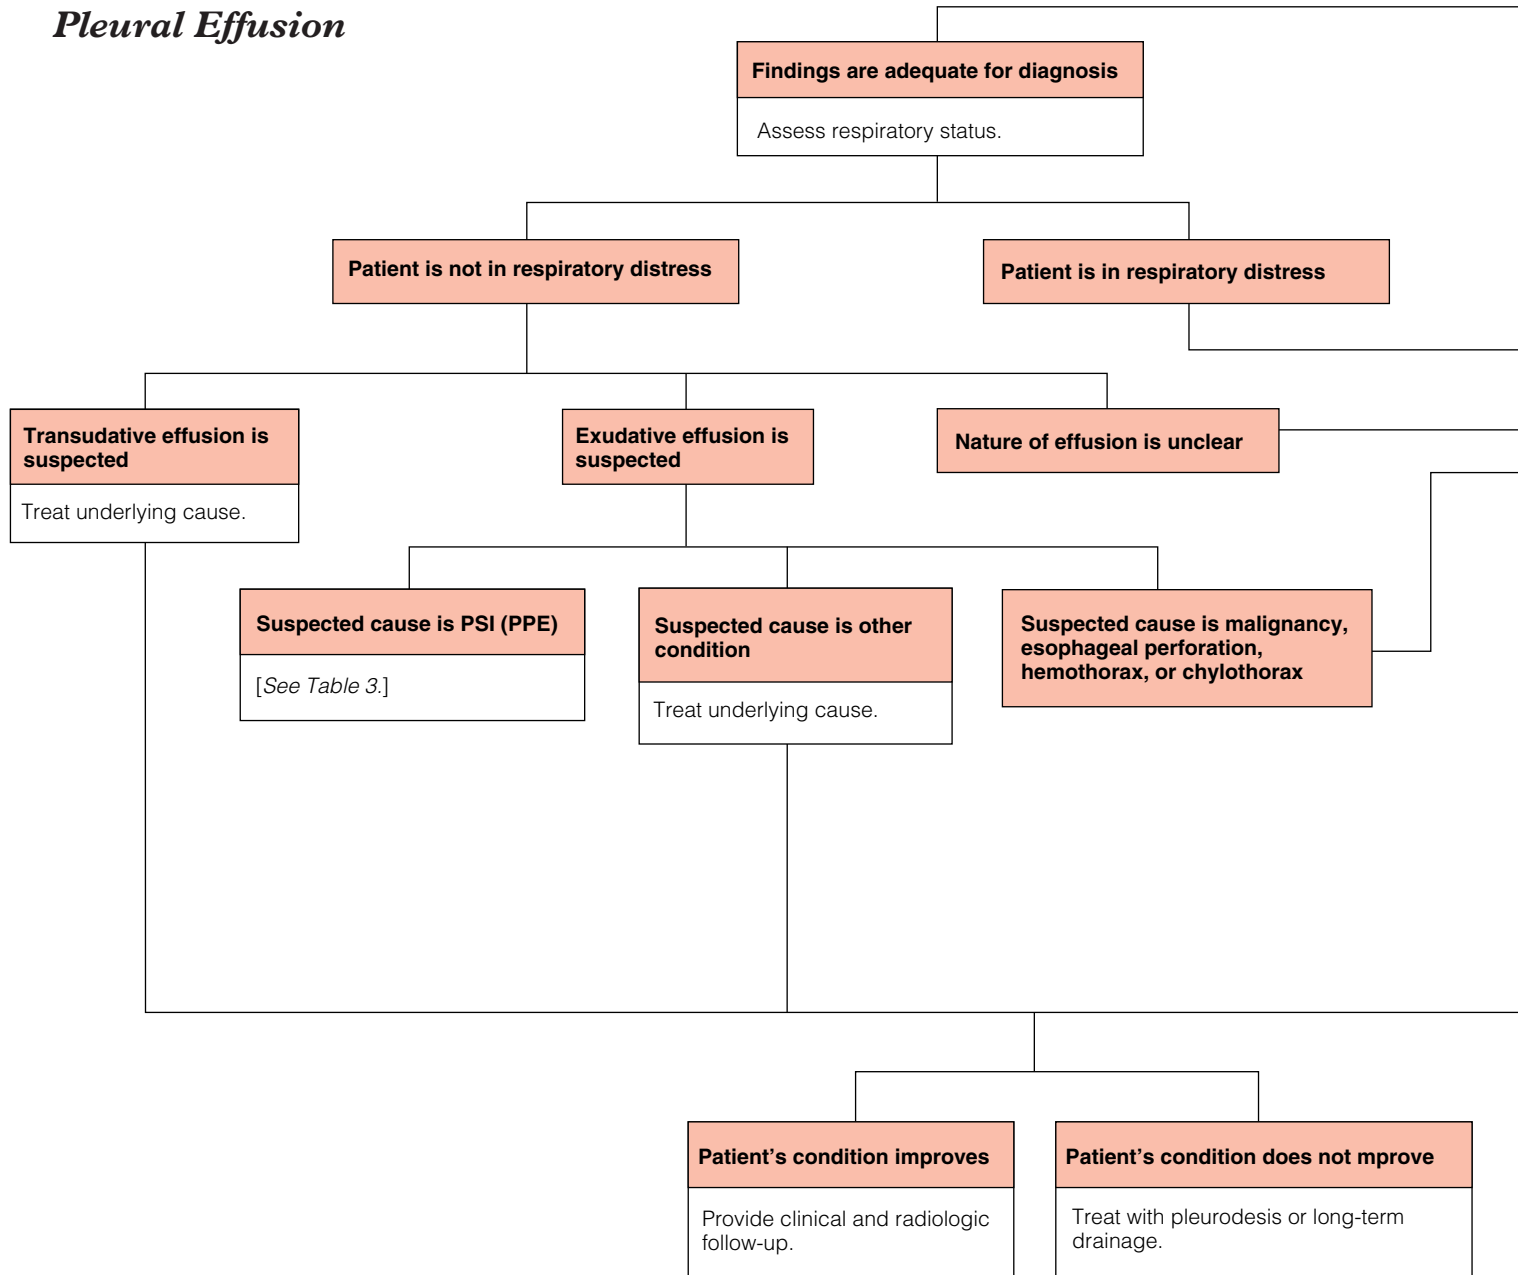

Chest Radiography

To be detectable on a standard upright posteroanterior chest radiograph, an effusion must have a volume greater than 150 ml. If the volume is 150 to 500 ml, the lateral costophrenic angle will be blunted; if the volume is greater than 500 ml, a meniscus will be created.^{5,6} A lateral decubitus chest radiograph can detect an effusion as small as 5 ml. As a general rule, a layering effusion that is at least 1 cm thick is accessible to thoracentesis.^{6,7} A loculated effusion may appear as a so-called pseudotumor on a chest radiograph and typically will not layer freely on a lateral decubitus radiograph. Subtle changes on an upright chest radiograph (e.g., accentuation of a fissure, elevation of a hemidiaphragm [see 4:3 *Paralyzed Diaphragm*], or increased separation between the lung and subdiaphragmatic gas [see Figure 1]) may also signal an effu-

Table 1 Pathophysiologic Mechanisms of Pleural Effusion

Mechanism	Specific Alteration	Cause
Abnormality in Starling’s equilibrium	Increased capillary and lymphatic hydrostatic pressure	Increased venous pressure (e.g., biventricular heart failure, renal failure)
	Decreased capillary oncotic pressure	Hypoproteinemia (e.g., nephrotic syndrome)
	Decreased intrapleural hydrostatic pressure	Ex vacuo effusion (e.g., atelectasis)
	Increased intrapleural oncotic pressure	Inflammation (e.g., infection, cancer, autoimmune disease)
Increase in capillary and mesothelial permeability	Increased filtration	Inflammation (e.g., infection, cancer, autoimmune disease)
Interference with lymphatic drainage	Obstruction	Cancer, structural abnormalities

Approach to the Patient with a Pleural Effusion

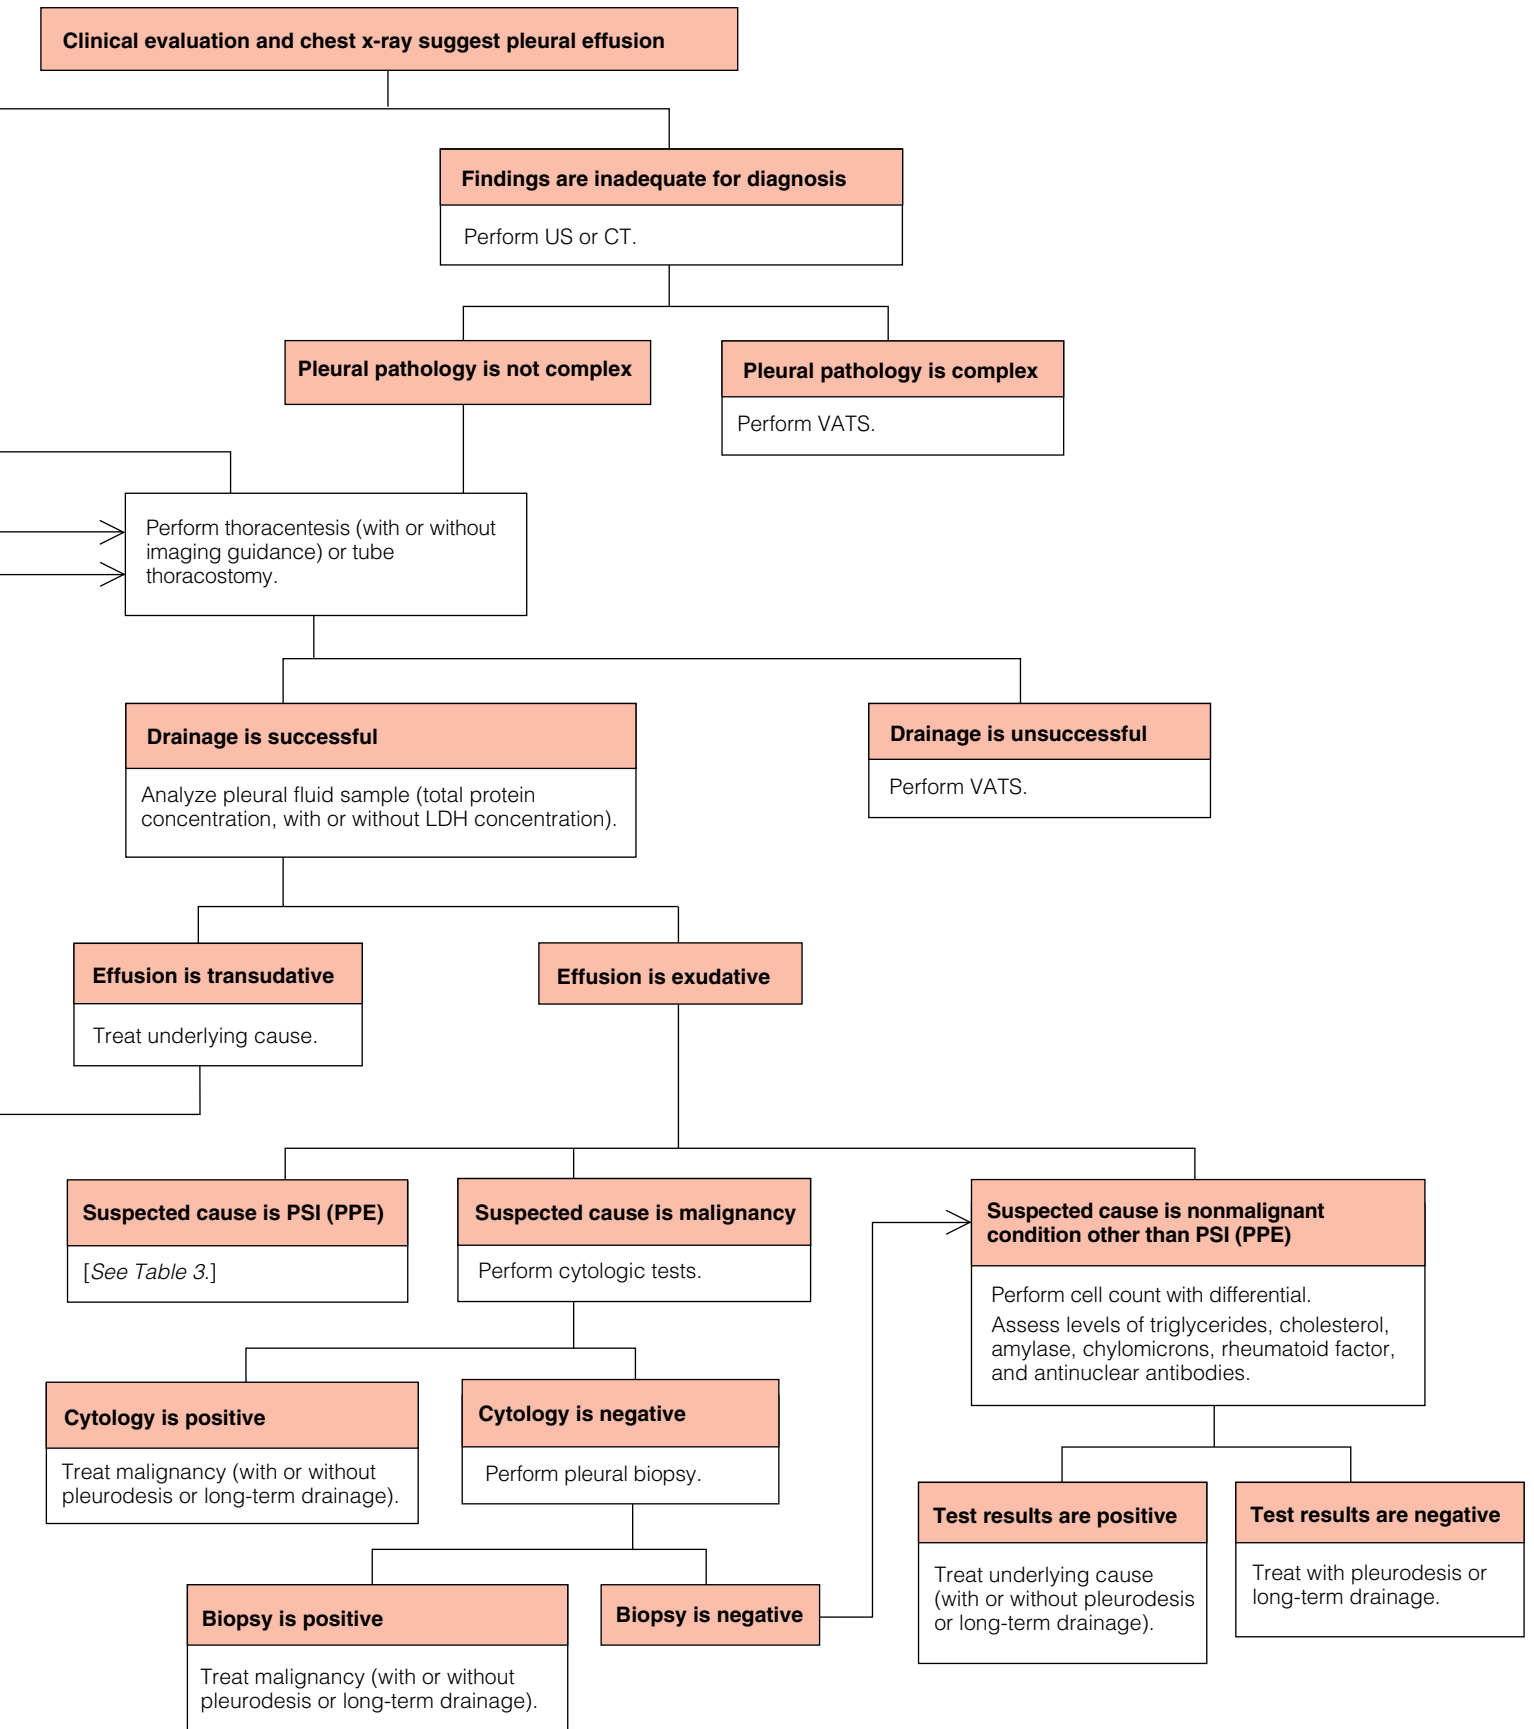

Table 2 Causes of Transudative and Exudative Pleural Effusion

Type of Effusion	Cause
Transudative	Congestive heart failure
	Cirrhosis
	Nephrotic syndrome
	Acute atelectasis

Postmyocardial infarction (Dressler syndrome)	
Chronic atelectasis	
Radiation therapy	
Asbestos exposure	
Meigs syndrome	
Ovarian hyperstimulation	
Transudative or exudative	Pulmonary embolus

sion. Additional findings on a standard chest radiograph (e.g., laterality, the size of the cardiac silhouette, the position of the mediastinum, pulmonary parenchymal changes, pleural calcifications, and osseous abnormalities) may point to a specific cause.

Supine chest radiographs are less sensitive than other chest radiographs. With these images, suspicion of an effusion is triggered by increased homogeneous density of the lower hemithorax, loss of normal diaphragmatic silhouette, blunting of the lateral costophrenic angle, or apical capping [see Figure 2].⁸

Ultrasonography

Chest ultrasonograms are more reliable for detecting and localizing small (5 to 100 ml) or loculated pleural effusions than chest radiographs are.^{5,9,10} Ultrasonography is particularly helpful for guiding thoracentesis for small-volume effusions and for assessing pleural effusions in critically ill patients.^{6,11}

Computed Tomography of the Chest

Computed tomography of the chest is a very sensitive tool for evaluating pleural effusion. Free-flowing fluid causes a sickle-shaped opacity in the most dependent portion of the thorax, and even small effusions are readily detected [see Figure 3]. CT may also reveal clues to the cause of the effusion, such as a fluid-fluid level (suggestive of acute hemorrhage), pleural thickening and enhancement (suggestive of pleural space infection [see Figure 4]), calcified pleural plaques (suggestive of asbestosis), and diffuse irregular nodularity and pleural thickening (suggestive of pleural metastases or mesothelioma). CT is especially useful for characterizing loculated effusions, for differentiating pleural thickening or pleural masses from pleural effusion, for distinguishing be-

tween effusion and lung abscess, and for guiding and monitoring closed drainage of effusions.^{6,10,12,13}

Magnetic Resonance Imaging

Magnetic resonance imaging of the chest provides no useful information beyond what can be obtained with CT scanning. MRI is neither efficient nor cost-effective in standard evaluation of pleural effusion.^{12,14}

THORACENTESIS

If the cause of a pleural effusion cannot be explained by the clinical circumstances (e.g., congestive heart failure or a recent surgical procedure), diagnostic thoracentesis [see Sidebar Techniques

of Bedside Thoracentesis and Tube Thoracostomy] is indicated. Thoracentesis may also have therapeutic value, in that drainage of fluid may relieve dyspnea. Absolute contraindications to thoracentesis include lack of cooperation on the patient's part, clinical instability with hemodynamic or respiratory compromise, severe coagulopathy, and high-pressure ventilation. Relative contraindications to thoracentesis include a nonlayering effusion, loculations, and previous thoracic trauma, chest tube placement, or surgery.

A large effusion can be drained without any special imaging guidance other than an upright lateral chest radiograph. Thoracentesis for a small or loculated effusion is best done with ultrasound guidance; success rates are as high as 97%.¹⁵

Figure 1 Posteroanterior chest radiograph of a patient with bilateral pleural effusion reveals costophrenic blunting and increased separation between the left lung and subdiaphragmatic gas.

Figure 2 Supine chest radiograph of a patient with bilateral pleural effusion shows increased homogeneous density of the lower hemithoraces.

Figure 3 Chest CT shows a free-flowing, sickle-shaped right-side effusion.

The incidence of complications associated with thoracentesis varies, depending on the experience of the operator and on the use of imaging guidance. Pneumothorax occurs in 3% to 20% of patients, of whom approximately 20% require tube thoracostomy [see *Sidebar* Techniques of Bedside Thoracentesis and Tube Thoracostomy]. Patients commonly experience pain and cough with lung reexpansion during drainage. Reexpansion pulmonary edema is an uncommon complication that can occur with rapid drainage of a large-volume effusion. It is common practice to drain no more than 1 to 1.5 L at a time, even though no evidence supports this practice. Experimental data suggest that active aspiration of fluid can cause high negative intrapleural pressures, potentially precipitating edema formation; gravity drainage may be

preferable to minimize the chance of edema. Additional potential complications include so-called dry tap, vasovagal reaction, hemorrhage hypovolemia, and pleural space infection (PSI).^{10,16-18}

PLEURAL FLUID ANALYSIS

Assessment of a pleural fluid sample is guided, to some extent, by the clinical context in which the pleural effusion occurs. When the cause of the effusion is unknown, evaluation of a pleural fluid sample typically includes measurement of total protein and lactic dehydrogenase (LDH) concentrations, a cell count with differential, cause-specific testing, and microbiologic and cytologic analysis.

Biochemical Analysis of Pleural Fluid

A total protein concentration higher than 3 g/dl is generally used as the main criterion for distinguishing a transudate from an exudate; however, the use of this criterion may result in misclassification of as many as 15% of effusions. According to Light's criteria,¹⁹ which have a sensitivity of 99% and a specificity of 98% for identifying exudates, an effusion is an exudate if any of the following three findings is present:

1. A pleural fluid-to-serum protein ratio higher than 0.5
2. A pleural fluid-to-serum LDH ratio higher than 0.6
3. A pleural fluid LDH concentration higher than two thirds of the upper limit of the serum reference range

A 1997 meta-analysis of the diagnostic value of tests used to distinguish transudates from exudates did not find any test or combination of tests to be clearly superior.²⁰ The choice of a test for this purpose is therefore a matter of individual preference. If only one test is to be performed, measurement of the total protein concentration is the most practical choice, in view of its accuracy and availability.

Figure 4 Chest CT of a patient with right-side empyema shows a loculated effusion. The pleura is enhanced with I.V. contrast.

Techniques of Bedside Thoracentesis and Tube Thoracostomy

Bedside Thoracentesis

Bedside thoracentesis should be performed on a bed or an examination table (as a safeguard if hypotension develops). The patient should be upright and seated (provided that he or she is awake and cooperative), with the arms leaning comfortably on a bedside table and the back facing the surgeon.

The proper intercostal space for catheter insertion is determined through physical examination and radiologic evaluation of the effusion; generally, the ninth or 10th intercostal space in the midscapular line is a good choice. The area is prepared and anesthetized with 1% lidocaine, 3 to 5 mg/kg, with care taken not to injure the intercostal bundle. To confirm that the catheter is in the correct location, we recommend drawing a small amount of pleural fluid at the time of local anesthetic infiltration. Several thoracentesis kits with one-way valves are available. To minimize the risk of reexpansion pulmonary edema, fluid should be allowed to drain by gravity, and drainage should not exceed 1.5 L. Frequently, a dry cough and pleuritic pain develop as drainage approaches its end. To minimize anxiety, the patient should be warned about this possibility in advance. After the completion of thoracentesis, a chest radiograph should be obtained.

Bedside Tube Thoracostomy

Bedside tube thoracostomy should be performed with the patient supine. The side on which the thoracostomy will be created should be elevated, and the patient's ipsilateral arm should be abducted. Supplemental oxygen should be supplied. Monitoring must include, at the least, continuous oxygen saturation plethysmography and intermittent measurement of blood pressure and heart rate. Tube thoracostomy is potentially very painful; accordingly, in a nonemergency situation, every effort should be made to minimize pain and anxiety. We usually administer intravenous ketorolac about 30 to 60 minutes before the procedure.

During preparation for chest tube placement, narcotics and sedatives should be administered intravenously; additional doses should then be administered at the beginning of and during the procedure.

The ideal location for chest tube placement is determined by clinical and radiographic examination. The area is prepared and draped widely, and a local anesthetic is used at a near-maximum dosage, with care taken to anesthetize skin, subcutaneous tissue, muscle, and periosteum. A 1.5 cm skin incision is made, a soft tissue tunnel is created with blunt instrument and finger dissection, the upper edge of the rib is identified clearly, and additional local anesthetic is applied to the periosteum and the intercostal muscles. The subcutaneous tunnel should generally be directed posteriorly so that the chest tube will sit along the posterior chest wall and will not be trapped in a fissure. The intercostal muscle is pierced bluntly, and digital examination of the pleural space is performed to confirm that an intrapleural location has been reached and to search for abnormalities such as adhesions or tumor implants. The chest tube is then directed to the desired location with the aid of a clamp. As with thoracentesis, fluid should be allowed to drain by gravity, but drainage should not exceed 1.5 L. If the effusion exceeds 1.5 L, the chest tube should be clamped and the remaining fluid allowed to drain intermittently in 200 ml aliquots every 2 hours. Immediately after completion of the procedure, a chest radiograph should be obtained to verify lung expansion and confirm the position of the chest tube. When chest tube output falls below 200 ml/day and reexpansion of the lung is verified, pleurodesis should be performed. We recommend that patient-controlled analgesia be employed while the chest tube remains in place.

The size of the chest tube is determined by the suspected cause and by the radiologic characteristics of the effusion. For a free-flowing transudative effusion, a small (20 to 24 French) chest tube or even a pigtail catheter usually suffices; for a thick exudative effusion or a hemothorax, a tube as large as 40 French may be required.

Assessment of pleural fluid pH and glucose levels may be used adjunctively for risk stratification in patients with PSI, but the clinical utility of these measurements is not well established (see below).²¹

There are numerous pleural fluid components whose concentrations can be measured to help determine the specific cause of a pleural effusion, such as triglycerides, chylomicrons, and cholesterol (to help diagnose chylothorax); amylase (to help diagnose esophageal perforation or pancreatitis); rheumatoid factor (to help diagnose rheumatoid effusion); antinuclear antibodies (to help diagnose lupus pleuritis); carcinoembryonic antigen (to help diagnose malignancy); and adenosine deaminase (to help diagnose tuberculous pleurisy).^{3,22-25}

Cell Counts

Analysis of the number and type of white blood cells (WBCs) present in pleural fluid is often diagnostically useful. Pleural effusions can be categorized according to the type of WBC that is predominant. Generally, pleural fluid neutrophilia points to acute inflammation (e.g., from PSI or pulmonary infarction) as the underlying cause; however, the presence of a neutrophilic effusion does not exclude malignancy. Pleural fluid lymphocytosis, in which lymphocytes account for more than 50% of WBCs, most frequently is indicative of malignancy (occurring in 50% of malignant effusions), tuberculosis (occurring in 15% to 20% of tuberculous effusions), or chylothorax.²⁶ Pleural fluid eosinophilia, in which eosinophils account for more than 10% of WBCs, can be caused by a wide variety of benign and malignant conditions—even, in some cases, by the mere presence of air or blood in the pleural space. Approximately one third of eosinophilic effusions

are idiopathic. As a rule, the presence of mesothelial cells is of little diagnostic value; the exception to this rule is that if such cells account for more than 5% of WBCs, a tuberculous effusion is unlikely.^{23,27}

Microbiologic Tests

If a PSI is suspected, Gram staining and standard bacterial cultures are indicated. If tuberculous pleurisy is a possibility, acid-fast stains and mycobacterial cultures should be performed. Fungal, viral, and parasitic PSIs are uncommon; accordingly, special stains and cultures for these conditions are indicated only if dictated by a specific clinical setting.²⁸

Cytologic Tests

Cytologic testing of pleural fluid is routinely performed whenever the cause of an effusion is unclear. The diagnostic yield for malignancy varies depending on the stage of the disease, but it generally is in the range of 50% to 60% (higher in patients with bulky pleural tumors). Repeat cytologic testing may increase the yield to more than 70%,^{10,29} and testing of three or more samples may increase the yield to 90%.³⁰

PLEURAL BIOPSY

In approximately 25% of patients with exudative effusion, the cause remains unknown after clinical evaluation, imaging, and pleural fluid analysis. The next step in the evaluation of such patients is pleural biopsy.

Percutaneous pleural biopsy is an infrequently used tool that has a diagnostic yield of 57% for carcinoma. Its low yield for malignant effusion can be explained by the uneven distribution of

pleural metastases. For tuberculous pleurisy, however, the diagnostic yield of percutaneous pleural biopsy is 75%, and the yield rises to 90% when this procedure is combined with pleural fluid culture. In about 10% to 20% of patients with exudative pleural effusion, laboratory analysis of pleural fluid and percutaneous biopsy fail to produce a specific diagnosis.¹⁸ The contraindications and complications associated with percutaneous pleural biopsy are similar to those associated with thoracentesis.³¹

Video-assisted thoracoscopic surgery (VATS) is also employed for pleural biopsy; its diagnostic yield in this setting is 92% for malignancy and nearly 100% for tuberculous pleurisy. VATS is a therapeutic procedure as well, allowing the surgeon to perform pleurodesis, decortication, or pleurectomy if necessary. VATS pleural biopsy is typically performed with the patient under general anesthesia, but if the patient is highly debilitated, it can be done with regional and local anesthesia.³² Procedure-specific complications include hypoxemia, hemorrhage, prolonged air leakage, subcutaneous emphysema, and empyema, each of which occurs at a rate of about 2%. The mortality associated with diagnostic thoracoscopy ranges from 0.01% to 0.09%.^{29,31} When VATS is performed to remove a suspected malignant lesion, a protective plastic device is required to minimize the possibility of tumor seeding. Incisional tumor seeding after a VATS biopsy is rare but can occur at any time after the procedure (reported range, 2 weeks to 29 months).³³

If mesothelioma is suspected, open lung biopsy (through a 5 to 7 cm incision) is the preferred diagnostic procedure. Ideally, the biopsy incision should be placed at the location of a potential thoracotomy incision so that future excision of the biopsy scar can be accomplished in a manner that minimizes the risk of local tumor recurrence.³⁴

Management

PLEURAL EFFUSION IN THE INTENSIVE CARE UNIT

Pleural effusion develops in as many as 60% of intensive care unit patients who are evaluated with ultrasonography.¹¹ When pleural effusion occurs in the ICU, drainage should be liberally employed to optimize the patient's hemodynamic and respiratory status and to detect PSI early. Thoracentesis can be done in critically ill ventilator-dependent patients with the help of bedside ultrasonography. Chest tube thoracostomy does not require ultrasonographic guidance and may be a safer choice for patients on high-pressure ventilation.

MALIGNANT PLEURAL EFFUSION

Pleural effusion is associated with malignancy in 30% to 65% of patients, and approximately 75% of patients with malignant effusion have lung or breast cancer.³⁵ The principal aim of therapy is to relieve dyspnea and to limit the number of procedures and hospital days that patients with a limited life expectancy must endure.

Drainage can be achieved by means of thoracentesis, chest tube placement, or VATS. Thoracentesis is a valuable option for initial patient evaluation, particularly in the office setting. Because malignant pleural effusion recurs rapidly unless patients undergo effective systemic or local treatment, repeat thoracentesis is generally not recommended for anything other than urgent relief of symptoms. Chest tubes are placed primarily with the intention of performing bedside pleurodesis.

Figure 5 Shown is a Pleurx catheter after placement and subcutaneous tunneling. The vacuum container is not connected.

Small-bore subcutaneously tunneled catheters may be employed for long-term management of malignant pleural effusions. Two options are available: the Pleurx catheter (Denver Biomedical, Golden, Colorado) [see Figure 5] and the Tenckhoff peritoneal dialysis catheter. Regardless of which option is chosen, the procedure is essentially the same: the catheter is inserted with the patient under local or general anesthesia, the patient is discharged on the same day or on the day after insertion, and the pleural fluid is drained either according to a schedule or on an as-needed basis. Small-bore tunneled catheters are comfortable, but patients may object to having a permanent catheter or to undergoing home-based procedures. In 20% to 58% of patients with a permanent catheter, pleurodesis develops within 4 to 6 weeks. Catheter removal, if desired, is easily done in the office setting. Technical failures and infection may occur in as many as 20% of patients with permanent catheters, but such problems are easily managed.³⁶⁻³⁹

Pleuroperitoneal shunting has been advocated as an alternative for long-term management of malignant pleural effusions. Experience with this mode of drainage is limited, however, and the potential for technical complications is high.^{40,41}

Recurrence of malignant pleural effusion is best prevented by using sclerosants to induce pleurodesis. The sclerosant may be instilled either via a bedside tube thoracostomy or thoracoscopically; a median hospitalization of 6.5 days is required.³⁶ Of the various sclerosants available, talc is the most efficacious, with an overall success rate of 80% to 96%.^{42,43} The ideal talc dose has not been determined; the usual dose is 4 or 5 g. Talc pleurodesis with a 5 g dose has generally proved efficient and safe. For obvious reasons, simultaneous bilateral talc instillation should be avoided.⁴² A phase III intergroup study (CALGB 9334) that compared bedside talc slurry pleurodesis with thoracoscopic talc insufflation pleurodesis found no difference in outcome at 30 days; however, subgroup analysis revealed that thoracoscopic talc insufflation pleurodesis was superior in patients with primary lung cancer or breast cancer.⁴⁴ Thoracoscopically guided talc pleurodesis can be performed with an operative mortality of less than 1%.^{45,46}

Pain and fever are frequent side effects of talc pleurodesis, but the main concern is the possible development of acute lung injury (ALI) and respiratory failure. Respiratory failure occurs in approximately 1% to 4% of patients. The cause of respiratory failure sec-

Table 3 Categorization of PPE by Risk of Poor Outcome

Pleural Space Anatomy	Pleural Fluid Bacteriology	Category	Risk of Poor Outcome	Drainage
Minimal free-flowing effusion (< 10 mm on lateral decubitus x-ray)	Culture and Gram stain results unknown	1	Very low	No
Small to moderate free-flowing effusion (> 10 mm but < 50% hemithorax)	Negative culture and Gram stain	2	Low	No
Large free-flowing effusion (> 50% hemithorax), loculated effusion, or effusion with thickened parietal pleura (as seen on contrast-enhanced CT)	Positive culture or Gram stain	3	Moderate	Yes
	Pus	4	High	Yes

ondary to talc pleurodesis is not clear and is probably related to multiple factors (e.g., talc dose, talc absorption, underlying lung disease, reexpansion pulmonary edema, systemic inflammatory response, tumor burden, and lymphatic obstruction). There is no definitive evidence that the talc dose is correlated with the incidence of ALI; respiratory failure has been reported even with a 2 g talc dose.^{42,47-51}

Treatment of malignant pleural effusion must be individualized. The key factors governing the choice of treatment approach are (1) the patient's performance status, (2) the prognosis, (3) the pleural tumor bulk, and (4) the ability of the lung to reexpand. Patients who have poor performance status (e.g., those with advanced tumors or significant comorbid conditions) or a very poor short-term prognosis should undergo the least invasive treatment—namely, drainage only. Patients who have better functional status and are expected to survive longer should undergo thoroscopically guided talc pleurodesis. Intrathoracic tumor bulk is important in that a bulky pleural lesion will interfere with pleurodesis. The lung's ability to reexpand after drainage of a malignant effusion is significant because if the lung is atelectatic as a result of airway obstruction or trapped as a result of pleural seeding, no agent will be able to induce pleurodesis, and the best treatment will be long-term drainage.

PLEURAL SPACE INFECTION

PSI can be caused by a variety of factors, including pneumonia, trauma, and intrathoracic procedures. It has a wide clinical spectrum, ranging from a small parapneumonic effusion (PPE) to a pus-filled pleural space (empyema) with respiratory compromise and sepsis. (The terms PSI and PPE are often used interchangeably.) PSI can be classified either according to its pathophysiologic stage (exudative, fibrinopurulent, or organizing) or according to its anatomic appearance (nonloculated versus loculated or noncomplicated versus complicated). The term empyema is commonly reserved for the most advanced stage of PSI.⁵²

The pathophysiology of PSI or PPE can be divided into three stages. The exudative stage is characterized by the development of an exudative effusion secondary to increased pleural permeability; the pleural space is often sterile initially, but if it is left untreated, bacterial infection is likely to ensue. The fibrinopurulent stage is marked by the progressive deposition of fibrin and the increasing presence of WBCs; gradual angioblastic and fibroblastic proliferation leads to extensive fibrin deposits, and the effusion becomes loculated (complicated). The organizing stage starts as early as 1 week after infection, with increasing collagen deposition and lung entrapment. After 3 or 4 weeks, the organized collagen has formed a peel, and the pleural fluid is grossly purulent. Eventually, dense fibrosis, contraction, and lung entrapment develop.^{53,54}

In most patients, PSI is caused by bacteria. The most common pathogens are *Staphylococcus aureus*, *Streptococcus pneumoniae*, enteric gram-negative bacilli, and anaerobes. Approximately 30% to 40% of cultures are polymicrobial. In a subgroup of patients, there is sterile pus in the pleural space, as a consequence either of previous antimicrobial therapy or of bacterial autolysis. The pathogens identified vary according to the cause of PSI. For instance, *S. aureus* and *S. pneumoniae* predominate in PPE; *S. aureus*, in postthoracotomy PSI; mixed oropharyngeal organisms, in PSI resulting from esophageal perforation²⁸; and acid-fast bacteria, in tuberculous empyema.⁵⁵

Parapneumonic Effusion

PPE occurs in as many as 57% of patients hospitalized with pneumonia, and pneumonia accounts for 42% to 73% of cases of PSI. In most cases, early PPE is effectively treated by timely antibiotic therapy aimed at the underlying pneumonia.^{21,28}

In 2000, a panel convened by the Health and Science Policy Committee of the American College of Chest Physicians (ACCP) reviewed the available literature with the aim of developing an evidence-based clinical practice guideline for the treatment of PPE.²¹ The panel formulated a clear and relatively simple classification system that used pleural anatomy and bacteriology to stratify patients according to the risk of a poor outcome [see Table 3]. It then made therapeutic recommendations on the basis of this classification. Some authors have used pleural fluid chemistry test results (e.g., pH and glucose concentration) as additional criteria for categorizing PPE; for example, a pleural fluid pH lower than 7.20 or a glucose level lower than 60 mg/dl has been considered suggestive of moderate risk. To date, however, the clinical utility and decision thresholds of pH and glucose values have not been well defined. Accordingly, we prefer to omit pleural fluid chemistry from these guidelines.

The ACCP Health and Science Policy Committee evaluated six primary management approaches: no drainage, therapeutic thoracentesis, tube thoracostomy, fibrinolytic therapy, VATS, and open surgery. Overall, pooled outcomes favored patients treated with fibrinolytics, VATS, and open surgery. However, the success of an approach is related to the patient's risk category. The recommendations for drainage in relation to risk category are general guidelines, based on level C and D evidence (with level C referring to historically controlled series and case series and level D to expert opinion). With these recommendations (and their limitations) in mind, treatment should be tailored to the specific situation of each patient.

Category 1 and 2 PPE PPE in categories 1 (very low risk) and 2 (low risk) can be treated with antibiotic therapy directed at

the underlying pneumonia. Some patients with category 2 PPE may require drainage for relief of dyspnea through either thoracentesis or tube thoracostomy.

Category 3 and 4 PPE Drainage options for categories 3 (moderate risk) and 4 (high risk) PPE include tube thoracostomy alone, tube thoracostomy with intrapleural fibrinolytic therapy, VATS drainage, and open surgical drainage. These various approaches are not mutually exclusive: in some cases, patient outcomes may be optimized by combining them.⁵⁶

Tube thoracostomy alone may be appropriate for category 3 patients with free-flowing effusion. With loculated effusion, however, the key to successful therapy is breaking down the fibrin septations. Evidence from three small randomized, controlled trials suggested that intrapleural fibrinolytic therapy has an advantage over tube thoracostomy alone for patients with category 3 or 4 PPE; a large trial is being conducted to address this specific issue.⁵³ To date, only one randomized study, including 20 patients with category 3 or 4 PPE, has compared VATS with fibrinolytic therapy. The primary treatment success rate was significantly higher in the VATS treatment group, the duration of chest tube drainage was less, and the total hospital stay was shorter.⁵⁷ VATS allows not only adequate drainage and visualization of the pleural space but also decortication of the lung if required; however, if decortication cannot be thoroughly accomplished by means of VATS and satisfactory lung expansion cannot be achieved, a thoracotomy should be performed.⁵⁸

The principles of PPE treatment can be applied to PSI from any cause, but in view of the paucity of reliable data, caution should be exercised.

Posttraumatic PSI

PSI occurs in about 1% to 5% of patients who have sustained blunt or penetrating thoracic injury. The incidence of PSI in the setting of trauma increases with the number of chest tubes placed and with the duration of chest tube drainage. The effect of an undrained hemothorax on the risk of PSI has not been completely defined, and prophylactic antibiotics have not been shown to reduce the incidence of PSI.⁵²

As noted (see above), the general guidelines for the treatment of PPE apply to the treatment of posttraumatic PSI.

Iatrogenic PSI

Iatrogenic PSI develops when a preexisting pleural effusion is inoculated with bacteria during an invasive procedure (e.g., thoracentesis or tube thoracostomy). The presence of fluid in the pleural space appears to be a prerequisite for infection.⁵²

A bronchopleural fistula (BPF) is by definition a PSI and therefore has a similarly broad spectrum of clinical presentation. The overall incidence of BPF after lobar resection is approximately 1%; it is somewhat higher after resections for inflammatory diseases than after resections for cancer. The incidence of BPF after pneumonectomy varies, depending on the side on which the pneumonectomy was done, the indications for surgery, the extent of preoperative irradiation, and the comorbid conditions present. In a report encompassing 464 pneumonectomies for cancer, the incidence of BPF was 8.6% after right pneumonectomy and 2.3% after left pneumonectomy. The overall incidence of postpneumonectomy empyema (generally but not always secondary to a BPF) is 1% to 3%.^{59,60}

PSI that is not associated with a BPF is treated in accordance with the treatment guidelines for PPE, but if a BPF is present, operative management is required.

Tuberculous PSI

Pleural effusion is common in patients with clinically evident pulmonary tuberculosis. Most cases of tuberculous effusion are secondary to hypersensitivity and resolve spontaneously. Tuberculous empyema is relatively rare; it is typically the result of active pleural infection by acid-fast bacteria.⁵⁵

Tuberculous PSI is also treated in accordance with the general treatment guidelines for bacterial PSI. Chronic tuberculous PSI may present specific problems, such as drug resistance and impaired ability (or even inability) to reexpand the lung. Surgical procedures performed to manage chronic tuberculous empyema include VATS, standard open decortication, thoracoplasty, parietal wall collapse, open drainage, myoplasty, and omentopexy.⁵⁵

CHYLOTHORAX AND PSEUDOCYLOTHORAX

Chylothorax is the presence of chyle in the pleural space as a consequence of blockage of or damage to the thoracic duct or one of its tributaries. The rate at which chyle flows through the thoracic duct can be higher than 100 ml/hr, and thus, large amounts of chyle can leak into the pleural space.⁶¹ The principal causes of chylothorax are surgical trauma and malignancy (70% to 80% are caused by non-Hodgkin lymphoma).^{46,61,62} Congenital chylothorax is more often due to malformation of the thoracic duct than to birth trauma.²⁴

The diagnosis of chylothorax is made by measuring triglyceride levels in pleural fluid. Levels higher than 110 mg/dl are highly suggestive of chylothorax; levels between 50 and 100 mg/dl are equivocal; and levels lower than 50 mg/dl rule out chylothorax.²⁴ A pleura-to-serum triglyceride ratio higher than 1 can be a useful indicator⁶³; the presence of chylomicrons is synonymous with chylothorax.²⁵

Treatment of chylothorax depends on its cause and severity. Postoperative chylothorax may be treated initially with conservative measures (e.g., with a nihil per os [NPO] regimen, total parenteral nutrition, and administration of octreotide). However, drainage totaling more than 500 ml/day is considered to predict failure of conservative management. Thoracic duct ligation is the surgical treatment of choice and can often be performed thoracoscopically. To help identify the leak intraoperatively, it may be helpful to administer 100 to 200 ml of heavy cream or olive oil orally 2 to 3 hours before the operation.^{64,65} Early surgical intervention is important because the ongoing loss of lymph has significant effects on fluid homeostasis, nutrition, and immunocompetence (secondary to lymphocyte loss). In the early postligation period, medical management should be continued to allow any small leaks to seal. An alternative to surgical ligation that has evoked some interest is transabdominal percutaneous embolization of the thoracic duct. This technique requires significant expertise.⁶⁶

Lymphoma-related chylothorax is caused principally by obstruction and usually develops on the left side [see Figure 6]. In a stiff and infiltrated duct, minor triggers (e.g., a Valsalva maneuver) can lead to duct rupture. Although patients with chylothorax often have extensive disease, supradiaphragmatic disease is not always present. Lymphoma-related chylothorax is best managed with thoracentesis and with therapy directed at the underlying cause. If first-line therapy fails, thoracoscopic talc pleurodesis is recommended; a small series reported 100% resolution of lymphoma-related chylothorax with thoracoscopic talc pleurodesis. If the chylothorax does not respond to any of these approaches, it may respond to thoracic duct ligation or pleuroperitoneal shunting. Chylothorax in the presence of lymphoma-related chylous ascites is a difficult problem that is

Figure 6 Chest CT shows left-side chylothorax secondary to lymphoma. Subtle mediastinal lymphadenopathy obstructing the thoracic duct (arrow) is apparent.

generally refractory to most forms of therapy (though pleurodesis is occasionally successful).^{46,61,62,67,68}

Pseudochylothorax is a rare disorder associated with the formation of persistent exudates that last for months or years. The most common cause is tuberculosis; the second most common cause is rheumatoid arthritis. Biochemical analysis of pleural fluid from patients with pseudochylothorax reveals very high cholesterol levels (> 200 mg/dl) and the presence of cholesterol crystals. Treatment is generally conservative.^{24,25}

IDIOPATHIC PERSISTENT PLEURAL EFFUSION

In a small percentage of patients, the cause of pleural effusion remains unknown despite extensive diagnostic evaluation. Tuberculosis and other granulomatous diseases, malignancy, and pulmonary embolism account for most cases of idiopathic effusion; those causes are identified later in the course of the disease or at autopsy. Other causes include constrictive pericarditis, subphrenic abscess, connective tissue diseases, drug-induced pleuritis, peritoneal dialysis, and cirrhosis.²³ In the management of persistent benign or idiopathic effusion, talc pleurodesis has a high success rate and minimal long-term implications.^{69,70}

Discussion

Pleural Anatomy

The pleura is a continuous membrane that covers the parietal and visceral surfaces of the thorax. In adults, it has an estimated surface area of 2,000 cm².⁷¹ Light microscopy shows the pleura to have five layers: (1) a mesothelial cell layer; (2) a mesothelial connective tissue layer with basal lamina; (3) a superficial elastic layer; (4) a loose connective tissue layer with adipose tissue, blood vessels, nerves, and lymphatic vessels; and (5) a deep fibroelastic layer. The parietal pleura establishes a pleurolymphatic communication on the diaphragm to allow clearance of large (> 1,000 nm) particles and cells from the normal pleural space. The structure of this pleurolymphatic communication consists of stomata 2 to 12 μm in diameter, which overlie bulblike lymphatic channels (lacunae) separated by a layer of loose connective tissue (the membrana cribriformis).

Electron microscopy reveals microvilli on the mesothelial cell surface of the pleura. The main function of these microvilli is to enmesh glycoproteins rich in hyaluronic acid for purposes of lubrication. The structure of the intercellular junction in the mesothelial cells of the pleura is similar to that in the endothelial cells

of the venules, which suggests that the pleural mesothelial cell layer may be as leaky as the venular endothelium.^{3,4,72}

Pleural Fluid Physiology

The amount of pleural fluid in an adult is 1 to 10 ml and forms a 10 μm-thick layer.^{1,3,71,72} Fluid exchange across the pleural surface depends on three mechanisms: (1) passive filtration following Starling's equilibrium, (2) active solute transport, and (3) lymphatic clearance. In the normal pleura, Starling's equilibrium favors the flow of fluid in a parietal-to-visceral direction.⁷¹ The rate at which fluid traverses the pleura ranges from 20 to 160 ml/day in adults; maximal lymphatic clearance is believed to be approximately 700 ml/day.^{2,71,73-76}

The chemical composition of normal pleural fluid is similar to that of interstitial fluid. The protein concentration is typically 1 to 2 g/dl. The concentration of high-molecular-weight proteins (e.g., LDH) is approximately half that seen in serum. Cell counts in normal pleural fluid range from 1,400 to 4,500 cells/mm³; macrophages account for the majority of the cells.^{3,72}

9 PERICARDIAL PROCEDURES

Shari L Meyerson, M.D., and Thomas A. D'Amico, M.D., F.A.C.S.

Surgical procedures are performed on the pericardium either for diagnostic purposes or for relief of the hemodynamic consequences of pericardial disease. The pericardial processes for which intervention is required can be divided into two broad categories: pericardial effusion and constrictive pericarditis. The decisions that must be made regarding the selection of patients, the timing of surgery, and the choice of technique or approach often pose substantial challenges to the surgeon. Accordingly, a thorough knowledge of the anatomy, physiology, and pathophysiology of the pericardium is essential for successful management of pericardial disease processes.

Anatomic and Physiologic Considerations

ANATOMY

Like the pleura, the pericardium consists of two layers. The inner layer, the visceral pericardium (or epicardium), is a monolayer of mesothelial cells that is adherent to the heart. The outer layer, the parietal pericardium, is a tough fibrous structure composed of dense bundles of collagen fibers with occasional elastic fibers. The fibrous structure of this layer renders the pericardial sac relatively noncompliant, and this noncompliance plays a significant role in pericardial function and pathophysiology.

The pericardium surrounds the heart and the great vessels [see *Figure 1*]. Its parietal and visceral surfaces meet superiorly at the ascending aorta and the superior vena cava. From that point, it continues down the right border of the heart and over the anterior surface of the pulmonary veins to the inferior vena cava. After crossing the inferior vena cava, the inferior pericardium is densely adherent to the diaphragm. Just past the apex of the heart, it turns superiorly again and runs over the pulmonary veins back to the aorta.

Anteriorly, there are normally no connections between the visceral and parietal layers of the pericardium. Posteriorly, the pattern of pericardial reflections around the pulmonary veins and the venae cavae creates two sinuses. The oblique pericardial sinus is the space in the center of the pulmonary veins, directly behind the left atrium. The transverse pericardial sinus is bordered anteriorly by the aorta and the main pulmonary artery and posteriorly by the dome of the left atrium and the superior vena cava.

PHYSIOLOGY

The pericardium is normally filled with 15 to 50 ml of serous fluid, which serves as lubrication to facilitate the motion of the heart within this structure. By virtue of its relative noncompliance, the pericardium exerts an influence on cardiac hemodynamics. This influence can easily be seen in the normal inspiratory varia-

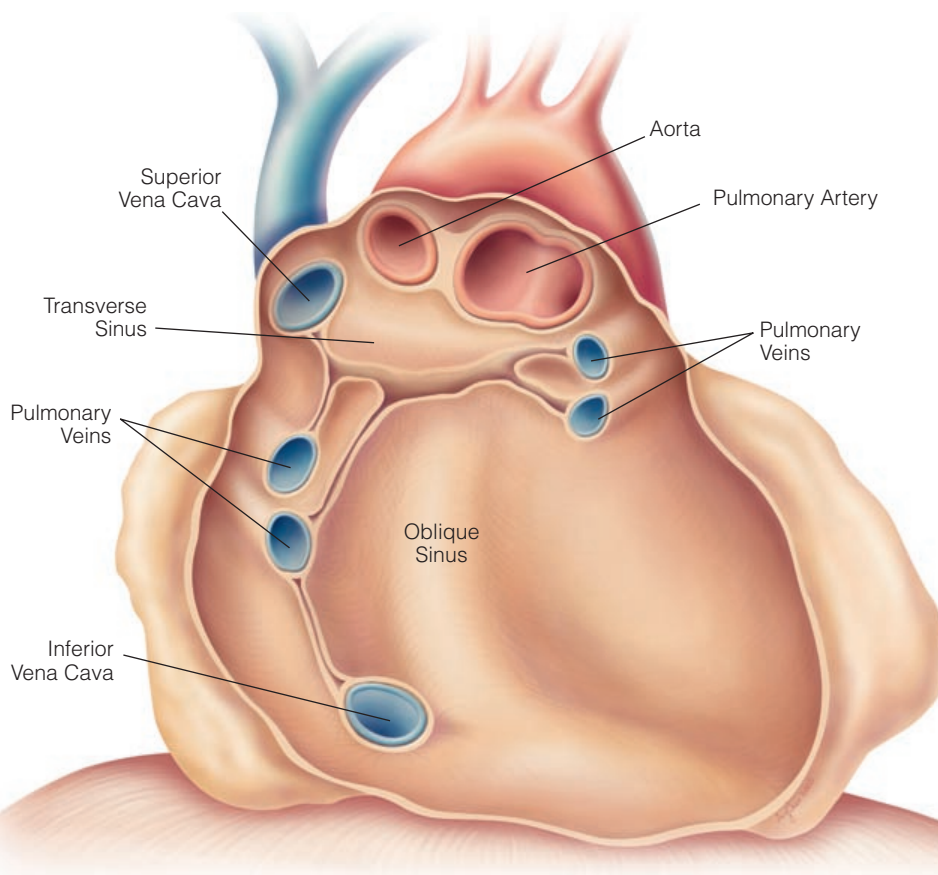

Figure 1 Shown is a view of the pericardium with the heart removed.

Table 1 Causes of Constrictive Pericarditis

Common causes	Unknown
	Infection
	Tuberculosis
	Viral infection (coxsackievirus B)
	Bacterial infection
	Fungal infection (histoplasmosis, coccidioidomycosis)
	Parasitic infection (amebiasis, echinococcosis)
	Cardiac surgery or pacemaker insertion
	Penetrating, nonpenetrating, or iatrogenic trauma
	Radiation therapy
	Connective tissue disorders (rheumatoid arthritis, systemic lupus erythematosus, scleroderma)
	Renal failure
	Neoplasm
	Metastatic disease (breast, lung, lymphatic system, skin)
Primary mesothelioma	
Drugs (procainamide, methysergide, hydralazine)	
Uncommon causes	Myocardial infarction
	Asbestosis
	Amyloidosis
	Sarcoidosis
	Dermatomyositis
	Actinomycosis
	Lassa fever
	Whipple disease
	Mulibrey nanism

tion in systemic arterial pressure. Under normal circumstances, intrapericardial pressure is slightly less than 0 mm Hg, becoming more negative during inspiration and less negative during expiration. Negative intrathoracic pressure during inspiration augments right ventricular filling. Because the pericardium does not allow significant acute right ventricular dilation, the ventricular cavity enlarges by shifting the septum toward the left ventricle. In addition, the noncompliance of the pericardium prevents the free wall of the left ventricle from distending to recapture its normal cavity volume. Thus, the volume ejected from the left ventricle is slightly decreased, resulting in lower systemic arterial pressure. Normally, this effect is exceedingly small. However, it becomes more pronounced when the pericardium is filled with fluid: ventricular distention is restricted even further, and paradoxical pulse becomes clinically apparent.

Although the pericardium is resistant to rapid distention, it is capable of distending over time. If filled slowly, it can expand to contain significant amounts of fluid (sometimes more than 1 L) before hemodynamic consequences develop. In the setting of an acute pericardial effusion (e.g., from trauma), however, devastating hemodynamic consequences may occur with only 100 to 200 ml of blood in the pericardium. When the elastic capacity of the pericardium is exceeded, even small increases in volume cause large increases in intrapericardial pressure.

Constrictive pericarditis is defined as a chronic fibrous thickening of the pericardium that causes cardiac compression sufficient to prevent normal diastolic filling. It can best be thought of as the chronic sequela of acute pericarditis or of any situation resulting in pericardial irritation and adhesion formation. Almost any cause of acute pericarditis can result in pericardial constriction [see Table 1]. In many patients, there is no clear antecedent event, and the cause of the constrictive pericarditis cannot be determined with certainty. Pathologic examination typically demonstrates end-stage fibrosis, and these cases are presumed to be viral in origin. Historically, mycobacterial tuberculosis has been the most common infectious

cause of constrictive pericarditis, and it is still the dominant infectious cause in many developing countries today.^{1,2} In the United States, tuberculosis is the cause of constrictive pericarditis in approximately 6% of patients who undergo pericardiectomy.³ Constrictive pericarditis also occurs after instrumentation of the pericardium and is seen occasionally (in 0.2% to 0.3% of cases) after cardiac surgery.^{4,5} It also may develop after iatrogenic cardiac perforation in the course of catheterization or pacemaker placement and after blunt or penetrating trauma—essentially, after any process resulting in an incompletely drained hemopericardium.^{6,7}

The pericardium may harbor metastatic disease or locally advanced disease (e.g., mesothelioma), which may lead to pericardial constriction.^{8,9} Connective tissue disorders (e.g., rheumatoid arthritis and lupus) can cause recurrent acute pericarditis and pericardial effusions, eventually resulting in constrictive pericarditis. A similar situation may arise in patients receiving radiation therapy and patients with renal failure.

The stiffening and thickening of the pericardium have three major physiologic effects. First, the thicker pericardium isolates the heart from changes in intrathoracic pressure. Normally, the pulmonary veins (which are intrathoracic structures) and the cardiac chambers experience the same changes in intrathoracic pressure. In the presence of pericardial constriction, however, the negative intrathoracic pressure generated during inspiration cannot be transmitted to the heart. This isolation of the heart results in decreased flow through the pulmonary veins during inspiration and reduced left-side filling.

Second, the ventricles become interdependent. Because total pericardial volume does not change, the inspiratory decrease in left ventricular filling seen with constriction must be accompanied by an increase in right ventricular filling, with a resultant septal shift toward the left ventricle. During expiration, the opposite occurs: left ventricular filling increases and right ventricular filling decreases, and there is a septal shift toward the right ventricle.

Third, the encasement of the heart impairs the diastolic filling of all cardiac chambers. Elevated atrial pressure causes rapid initial filling of the ventricle (with as much as 75% of the ventricle filled during the first 25% of diastole), but by the middle of diastole, filling abruptly decreases as a result of the rigid pericardium. Because of this limit to diastolic filling, increasing the heart rate becomes the most effective method of increasing cardiac output.¹⁰

Pericardial Drainage Procedures for Pericardial Effusion

A number of different processes can result in the accumulation of fluid in the pericardial space [see Table 2]. Regardless of the origin of the fluid accumulation, once the pericardium has reached the limits of its elasticity, the only way in which it can increase its volume is by reducing the volume occupied by the heart within it. Increases in pericardial pressure result in progressive cardiac compression and reductions in intracardiac volumes and myocardial

Table 2 Common Causes of Pericardial Effusion

Malignancy	Myocardial infarction
Trauma	Iatrogenesis (intracardiac procedures)
Uremia	Aortic dissection
Infection (viral, bacterial, fungal, tubercular)	Radiation
Autoimmune processes	Idiopathic origin
Cardiac surgery (postoperative complication)	

diastolic compliance. This effect is most pronounced in the chambers with the lowest normal intracavitary pressures—namely, the right atrium and the right ventricle.¹¹ Changes in systemic cardiac output occur as a result of right heart compression, which leads to diminished right ventricular stroke volume, reduced pulmonary blood flow, and decreased left ventricular filling. In the early stages of pericardial effusion, various compensatory changes act to preserve cardiac output. Such changes include an increased ejection fraction, tachycardia, increased intravascular volume via renal conservation of salt and water, increased peripheral vascular resistance, and time-dependent pericardial stretch.^{12,13}

PREOPERATIVE EVALUATION

The presenting symptoms of pericardial effusion may be nonspecific and related to the underlying disorder (e.g., fever, chest pressure, and fatigue). Fluid accumulation that is substantial enough to have hemodynamic consequences is defined as cardiac tamponade. Patients with early tamponade may have dyspnea, tachycardia, mild hypotension, decreased urine output, and paradoxical pulse. As tamponade progresses, patients may manifest signs of end-organ hypoperfusion (e.g., mental status changes, renal insufficiency, and shock). The classic physical findings known as Beck's triad (i.e., jugular venous distention, systemic hypotension, and distant heart sounds) are more common with acute tamponade (such as results from trauma) than with slow-developing tamponade (such as results from medical processes). In patients with slow-developing tamponade, systemic fluid retention is observed, often manifested by peripheral edema or ascites.

Most commonly, pericardial effusion is diagnosed when a patient exhibits new symptoms in the context of an underlying disorder associated with pericardial effusion (e.g., renal failure or malignancy). Chest x-rays may reveal a globular heart or an increasing cardiac silhouette on serial films. Currently, echocardiography is the most commonly employed and most useful modality for the diagnosis of pericardial effusion: it reliably determines the presence, location, and relative volume of fluid accumulations. In many cases, echocardiography can identify early tamponade, often before symptoms develop. A variety of echocardiographic findings have been associated with pericardial effusion, of which the most useful are right atrial collapse and right ventricular collapse. Right atrial collapse during late diastole tends to occur early in the development of tamponade because of the normally low right atrial filling pressures. Right ventricular free wall collapse during early diastole suggests progression of tamponade. Other useful signs are loss of the normal inspiratory collapse of the inferior vena cava and an increase in right ventricular diameter with a reciprocal decrease in left ventricular diameter during inspiration.

In patients who are undergoing invasive hemodynamic monitoring (e.g., those who have just undergone cardiac surgery), hemodynamic findings suggestive of tamponade include elevation of right atrial pressure and equalization of right atrial pressure and pulmonary capillary wedge pressure. It is important to remember, however, that localized tamponade can occur (especially in the postoperative period) without these changes. A common cause is localized clot in the oblique pericardial sinus behind the left atrium, which causes reduced left atrial compliance.

OPERATIVE PLANNING

Choice of Procedure

There are three procedures that are commonly performed for surgical diagnosis and treatment of pericardial effusion: peri-

Figure 2 Computed tomography demonstrates right pleural and pericardial effusions, for which a right thoracoscopic approach is ideal.

cardiocentesis, subxiphoid pericardiostomy (pericardial window), and thoracoscopic pericardiostomy (via either the right or the left pleural space). The choice of a surgical approach to the pericardial space depends on the clinical condition of the patient, as well as on the underlying diagnosis (if known). Patients with tamponade may decompensate rapidly during the vasodilatation and positive pressure ventilation associated with general anesthesia. Accordingly, careful consideration must be given to the type of anesthesia employed for pericardial drainage procedures.

Pericardiocentesis is routinely done with local anesthesia only, and it may be the best choice in an acutely unstable patient with tamponade. If this option is chosen, however, the choice must be made with the understanding that pericardiocentesis, because of its high recurrence rate and its limited diagnostic capacity, is unlikely to constitute definitive therapy. Subxiphoid pericardiostomy is generally done with initial local anesthesia followed by induction of general anesthesia, and most patients with tamponade can undergo this procedure. The subxiphoid approach provides the hemodynamic benefits of pericardiocentesis, offers the enhanced diagnostic capability of pericardial biopsy, and has a low recurrence rate. Consequently, it is the procedure of choice for patients with tamponade who are stable enough to be transported to the operating suite. Thoracoscopic pericardiostomy has the advantage of enabling simultaneous treatment of pleural processes, which are commonly present in these patients [see Figure 2]. Ipsilateral pleural and pericardial spaces can be fully explored, pleural effusions can be drained, loculations can be divided, and biopsy specimens can be obtained as needed. The thoracoscopic approach can be especially useful in the case of a known loculated effusion that is limited to one area of the pericardium, in that a pericardial window can be created via either pleural space. This approach also allows resection of a larger segment of pericardium, which may improve the diagnostic yield and reduce the likelihood of recurrent effusion. The major limitation of thoracoscopic pericardiostomy is the need for lung isolation and lateral positioning, which should not be attempted in patients with evidence of tamponade. By weighing the relative risks and benefits of these three procedures, the surgeon can choose the optimal approach for each patient.

PERICARDIOCENTESIS

Operative Technique

Pericardiocentesis is performed either at the bedside in an urgent situation or, preferably, under echocardiographic guidance in a catheterization laboratory. The basic technique is simple.

Step 1: placement of needle A local anesthetic is infiltrated along the left side of the xiphoid. An 18-gauge spinal needle attached to a three-way stopcock and syringe is then advanced into the pericardial space and directed cephalad toward the left shoulder at a 45° angle until fluid is aspirated [see *Figure 3*]; if air is aspirated, the needle is withdrawn and redirected more medially. Once fluid is aspirated freely, it is inspected. If the fluid is bloody, 5 ml is withdrawn and placed on a sponge. If the fluid on the sponge clots, it is fresh blood, probably from a cardiac injury occurring during the procedure or from intracardiac positioning of the needle; blood that has been in the pericardium for even a short time becomes defibrinated and will not clot.¹⁴

Troubleshooting. The inherent danger of cardiac injury during pericardiocentesis should be obvious. The risk is highest with small or loculated effusions and patients with coagulation abnormalities. The possibility of cardiac aspiration or injury can be minimized, though not eliminated, by means of various safety measures. The simplest of these measures is to attach an ECG lead to the needle and employ continuous ECG monitoring. If the needle contacts the epicardium, ST segment elevation will be observed, in which case the needle is withdrawn until the ST elevation disappears. Another useful safety measure is to employ echocardiographic guidance to help direct aspiration of a loculated area. Simultaneous cardiac catheterization has also been used to locate the right coronary artery and the atrioventricular groove.

Step 2: placement of drainage catheter and aspiration of fluid Once the needle is within the pericardial space, a guide wire is placed through it, and a small-bore drainage catheter is advanced into the effusion by means of a modified Seldinger technique. Fluid is aspirated and sent for laboratory evaluation (including cell count, chemistry, culture, and cytology). The catheter is then connected to a closed drainage system for 24 to 72 hours; this may help reduce recurrence.

Complications

The most common complications of pericardiocentesis are pneumothorax, cardiac injury, misdiagnosis, and recurrence of pericardial effusion. In every patient undergoing pericardiocentesis, pneumothorax must be ruled out by means of chest x-ray at the completion of the procedure or, if respiratory or hemodynamic changes develop intraoperatively, during the procedure. Cardiac injuries range from minor needle lacerations to the epicardium, which are self-limited in patients with normal coagulation parameters, to potentially fatal injuries that lead to acute cardiac tamponade. Incorrect diagnoses based on pericardiocentesis are not uncommon. Although a diagnosis can be confirmed by positive results from fluid culture or cytology, negative results from cytology do not rule out malignant effusion. Cytologic analysis of pericardial fluid is diagnostic in only 55% to 85% of patients.¹⁵ Further diagnostic maneuvers often must be undertaken, usually involving subxiphoid or thoracoscopic approaches with pericardial biopsy. Recurrence of pericardial effusion after pericardiocentesis is extremely common. In a review that included 139 patients with malignant pericardial effusions who were treated with pericardiocentesis,

successful fluid removal with symptomatic relief was achieved in 97.1% of cases.¹⁶ Of the 139 patients, 2.9% experienced complications (e.g., pneumothorax and ventricular laceration), and one (0.7%) died. In all, 45 of the patients received no further therapy, and in 25 (55%) of the 45, recurrent effusions developed that necessitated reintervention.

Several techniques for preventing recurrent pericardial effusion have been tried. Instillation of a sclerosing agent (e.g., tetracycline, thiotepea, or bleomycin) into the pericardium to promote fusion of the two layers of the pericardium has been shown to increase the success rate of pericardiocentesis by as much as 85%.¹⁷⁻¹⁹ Placement of an indwelling catheter (see above) also has been shown to improve the success rate.^{16,20} Several authors have described creating a pericardial window percutaneously by means of balloon dilation of the tract created by pericardiocentesis, which theoretically allows fluid to drain into the pleural space or the subcutaneous tissues, where it can be absorbed.^{21,22} However, it is unclear how long a window created in this fashion will remain patent. Although pericardiocentesis provides initial symptomatic relief in most patients, the observation that 15% to 45% of patients require a further procedure for diagnosis and as many as 55% require reintervention for recurrence has led some authorities to question its benefit.

SUBXIPHOID PERICARDIOSTOMY (PERICARDIAL WINDOW)

Operative Technique

Subxiphoid pericardiostomy may be performed either to diagnose pericardial effusion or to manage tamponade. For diagnosis, the procedure is usually done with general anesthesia. In an unstable patient with significant tamponade, who would be at risk for hemodynamic collapse with general anesthesia, the procedure may be performed with the patient under local anesthesia and mild sedation and breathing spontaneously. If there is any question of tamponade, the patient is prepared and draped while awake, and anesthesia is induced only when the surgeon is ready to begin. In all patients, the entire chest should be prepared, in case a full sternotomy is required. Ideally, the patient is sedated and the airway

Figure 3 Pericardiocentesis. The needle is angled toward the left shoulder at an angle of 45°.

Figure 4 Subxiphoid pericardiostomy. (a) A small vertical incision is made from the xiphisternal junction down to a point just below the tip of the xiphoid, the upper extent of the linea alba is divided, and the xiphoid is removed. (b) The pericardium is opened, and the edge of the opening is grasped and elevated. A pericardial specimen several square centimeters in size is then resected to create the pericardial window.

controlled while spontaneous respiration is maintained to minimize hemodynamic effects. If necessary, a local anesthetic may be infiltrated and the incision made before induction of anesthesia.

Step 1: initial incision and exposure of pericardium A small vertical incision is made from the xiphisternal junction downward to a point slightly below the tip of the xiphoid process [see *Figure 4a*]. The upper extent of the linea alba is divided, with care taken not to enter the peritoneum. Peritoneal openings are easily repaired but can make the procedure technically more difficult, in that abdominal contents tend to impede visualization, especially in spontaneously breathing patients. The soft tissue attachments to the xiphoid are divided, the veins running along either side of the xiphoid are controlled, and the xiphoid process is removed.

The tissue plane behind the lower sternum is developed by means of blunt dissection. This maneuver exposes the retrosternal space to allow visualization of the pericardium. To enhance exposure, the sternum is retracted upward by an assistant. The anterior pericardial surface is then exposed by sweeping away the remaining mediastinal fat. If necessary, the confluence of the pericardium and the diaphragm may be retracted caudally to improve exposure.

Step 2: opening of pericardium The location of the pericardial incision can be confirmed by palpating cardiac motion through the exposed pericardium. The pericardium is then opened with a scalpel; shallow strokes should be employed to reduce the chances of injuring underlying myocardium that may be adherent

to the pericardium. Upon entry into the pericardium, there is an initial outrush of fluid. A sanguineous effusion can be difficult to differentiate from cardiac injury; therefore, the patient's hemodynamics should be carefully monitored during this time. When the pressure placed on the heart by an effusion is released, blood pressure will usually rise and heart rate fall; however, if the heart has been accidentally injured, the opposite will occur. Once hemodynamic stability is achieved, administration of a diuretic (e.g., furosemide) should be considered to reduce the risk of pulmonary edema developing as a result of systemic fluid retention.

Step 3: creation of pericardial window Pericardial fluid is collected for microbiologic and cytologic analysis and for any additional testing suggested by the clinical scenario. The pericardial space is gently explored with the fingers, and all remaining fluid is evacuated. The edge of the pericardial opening is grasped with a clamp and elevated [see *Figure 4b*]. A pericardial specimen several square centimeters in size—or as large as can safely be managed—is resected and sent for pathologic and microbiologic analysis.

Step 4: drainage and closure A separate stab incision for drain placement is made below and to one side of the lowermost aspect of the skin incision. Bringing the drainage tube out through a separate incision helps prevent incisional complications (e.g., infection and hernia). A 24 to 28 French chest tube (either straight or right-angle) is tunneled through the fascia at the entry site so that it lies beneath the divided linea alba in the preperitoneal

space. The tube is then directed through the pericardial window and into the pericardial space and secured at skin level. The fascia at the linea alba is closed with interrupted sutures to provide secure closure and prevent late hernia; the skin and subcutaneous tissue are closed in the standard fashion. The chest tube is connected to a drainage system with a water seal. Pericardial drainage is maintained for several days postoperatively until the output falls below 100 ml/day. This period allows time for apposition and adhesion formation between the visceral pericardium and the parietal pericardium.

Although some fluid may initially drain into the subcutaneous tissues and be absorbed, the name pericardial window is something of a misnomer. The surgically created window in the pericardium is unlikely to remain patent over the long term, and in fact, obliteration of the pericardial space has been shown to be the mechanism responsible for the success of this procedure.^{23,24}

Complications

Complications from subxiphoid pericardiostomy are rare; bleeding, infection, incisional hernia, anesthetic complications, and cardiac injury have been reported. In a study that included 155 patients who underwent subxiphoid pericardiostomy over a 5-year period, not a single death was attributable to the operative procedure itself.²³ The 30-day mortality was high but was related to the underlying disease process: 33% in patients with malignant effusions and 5% in those with benign effusions. Recurrent pericardial effusion necessitating additional procedures occurred in four patients (2.5%). In a study that compared 94 patients who underwent subxiphoid pericardiostomy with 23 patients who underwent pericardiocentesis, the rate of recurrent effusion that necessitated reintervention was 1.1% after subxiphoid window but 30.4% after pericardiocentesis.²⁵ In this series, the rate of major complications after the pericardial window procedure was 1.1% (one patient with bleeding that necessitated reexploration), compared with a major complication rate of 17% after pericardiocentesis (including a mortality of 4%).

Several studies have shown that the most important predictor of long-term outcome is the underlying disease process. In one, the median survival time was 800 days for patients with benign disease, 105 days for patients with known cancer but negative results from pericardial cytology and pathology, and only 56 days for patients with malignant effusions.²³ It appears, however, that cancer patients with hematologic malignancies and pericardial effusion survive significantly longer than patients with other malignancies. In another study, the mean survival time after drainage of pericardial effusion was 20 months for patients with hematologic malignancies, compared with 5 months for patients with any other malignancies.²⁶ The investigators suggested that this finding may be related to the relative responsiveness of hematologic cancers to systemic chemotherapy. Patients with HIV disease have been shown to have universally dismal outcomes after they present with pericardial effusion. In this population, surgical pericardial drainage generally is not diagnostically revealing and is of little therapeutic value. Several authors have questioned whether pericardial drainage should even be offered to these patients.²⁷

THORACOSCOPIC PERICARDIOSTOMY

Operative Technique

Thoracoscopic pericardiostomy is a safe and effective approach to the diagnosis and management of pericardial effusion, especially in patients with a unilateral pleural disease process that can be simultaneously addressed in the course of the procedure. Tho-

racoscopic pericardial drainage necessitates single-lung ventilation and thus is unsuitable for unstable patients, especially those with tamponade. Such ventilation can be accomplished by means of either a dual-lumen endotracheal tube or a bronchial blocker placed through a standard endotracheal tube.

Once the tube is in place, the patient is turned to the appropriate lateral decubitus position. The side of approach is chosen on the basis of the location of a loculated effusion or the site of any coexisting pathologic condition (e.g., a pleural effusion or pulmonary nodule). If the disease process or processes present do not dictate a particular side of approach, the right side is frequently preferred. It is often easier to operate on the right side because there is more working room within the pleural space; however, operating on the left side usually allows the surgeon to create a larger pericardial window. If tamponade is present in a patient for whom the thoracoscopic approach is desired, pericardiocentesis may be performed before induction of general anesthesia.²⁸

Step 1: placement of ports and entry into pleural space

An initial camera port is placed in the posterior axillary line at the eighth intercostal space [see Figure 5]. The pleural space is entered and explored, and any effusion present is drained. Pleural fluid is sent separately for culture and cytologic analysis. To prevent inadvertent entry into the pericardium, which is often distended, a second incision is created anteriorly at the fifth intercostal space under camera visualization.

Step 2: opening of pericardium On the left side, the phrenic nerve, which runs midway between the hilum and the anterior chest wall, is carefully identified, and an initial pericardial incision is made approximately 1 cm anterior to this nerve. Care must be taken to place this first incision in an area that is free of cardiac adhesions. When grasped, the pericardium should tent outward slightly. Often, cardiac motion is visible through the pericardium.

Step 3: creation of pericardial window A pericardial window several square centimeters in area is removed. A similar window may be created posterior to the phrenic nerve—again, with care taken to stay at least 1 cm away from the nerve. The pericardial space is inspected, and any loculations are opened. The procedure is similar when performed on the right side, except that the phrenic nerve on the right runs much closer to the hilum; accordingly, instead of two pericardial windows (anterior and posterior to the nerve), only a single, larger pericardial window is created (anterior to the nerve).

In patients who can tolerate general anesthesia, a pericardial window can be created thoracoscopically with excellent diagnostic yield and relief of symptoms.²⁹ The thoracoscopic approach allows directed access and can be useful in treating effusions that recur after subxiphoid pericardiostomy.³⁰

Pericardiectomy for Constrictive Pericarditis

PREOPERATIVE EVALUATION

Constrictive pericarditis appears to be about three times as common in males as in females, and it may occur at any point in life from childhood to the ninth decade.³¹ The symptoms of constrictive pericarditis usually develop progressively over a period of years but may develop within weeks to months after a defined inciting event (e.g., mediastinal irradiation or cardiac surgery). Signs and symptoms are related to pulmonary venous congestion

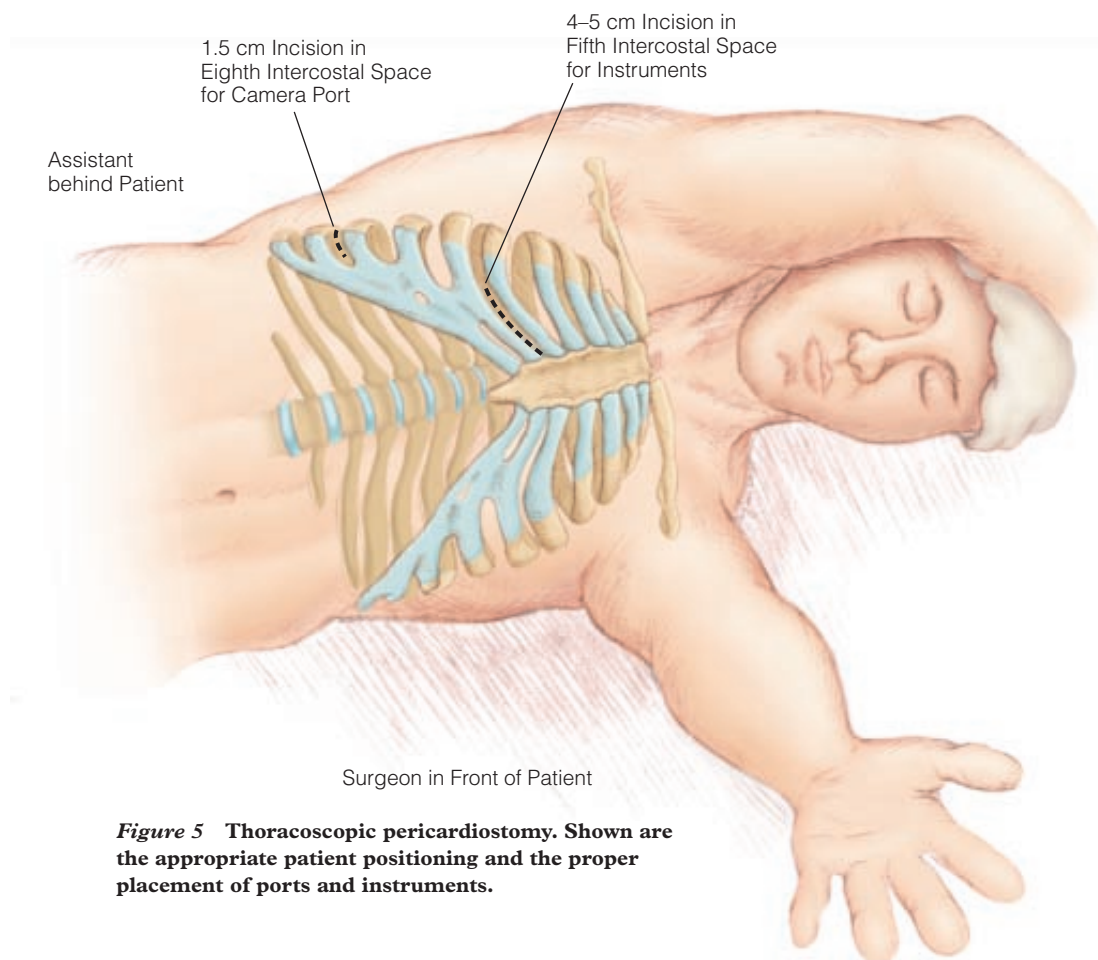

Figure 5 Thoracoscopic pericardiectomy. Shown are the appropriate patient positioning and the proper placement of ports and instruments.

(e.g., exertional dyspnea) and systemic venous congestion (e.g., elevated jugular venous pressure, hepatomegaly, ascites, and peripheral edema).

The physiologic effects of the thickened pericardium form the basis for the diagnosis of constrictive pericarditis and, more important, for the differentiation of constrictive pericarditis from restrictive cardiomyopathy, which often presents a similar picture. Echocardiography can be employed to rule out other causes of right-side failure. Specific findings that suggest pericardial constriction include septal bounce (a respiratory phase-related septal shift) and decreased transmitral flow velocity during inspiration. Computed tomography and magnetic resonance imaging may demonstrate thickened, often calcified, pericardium; however, the degree of pericardial thickening does not necessarily correlate with the presence of hemodynamic effects.

Cardiac catheterization may demonstrate increases in and equalization of end-diastolic pressure in all four cardiac chambers, a dip-and-plateau pattern (the square-root sign) in the ventricular pressure curves as a result of rapid early filling and limited late filling, and rapid x and y descents in the atrial pressure curves. The most useful information obtainable through cardiac catheterization has to do with the respiratory variation of ventricular pressure. In a patient with a normal heart or a patient with restrictive cardiomyopathy, inspiration causes a decrease in both right ventricular pressure and left ventricular pressure as a consequence of decreased intrathoracic pressure. In a patient with constrictive pericarditis, because of the interdependence of the ventricles, inspiration causes a decrease in left ventricular pressure but an increase in right ventricular pressure.³²

OPERATIVE PLANNING

Choice of Approach

Pericardiectomy may be performed via either a median sternotomy or a left anterolateral thoracotomy, with equivalent results. Median sternotomy provides better access to the right atrium and the great vessels, as well as easier access for cannulation if cardiopulmonary bypass is required; left anterolateral thoracotomy allows more complete release of the left ventricle. With either approach, the patient should undergo full monitoring, including radial artery catheterization and central venous catheterization, with consideration given to placement of a pulmonary arterial catheter if there is significant hemodynamic compromise. Because significant blood loss can occur when densely adherent pericardium is resected, large-bore intravenous access should be available as well.

OPERATIVE TECHNIQUE

Median Sternotomy

Step 1: initial incision and exposure The patient is placed in the supine position, and the skin incision is carried down to the level of the sternum. If there is no history of previous pericardial procedures and it is possible to develop the plane behind the sternum bluntly at the superior and inferior aspects, a standard sternotomy saw can be used for the median sternotomy. If, however, there are likely to be adhesions between the sternum and the pericardium or the heart (as in the case of constrictive pericarditis after coronary artery bypass grafting), a careful reoperative sternotomy

should be performed with an oscillating saw. Access to the femoral vessels should be available within the sterile field; placement of a femoral arterial line will facilitate percutaneous cannulation in the event that the heart is injured during sternal reentry.

After the sternum is opened, all adhesions are dissected away from the sternum, with care taken to stay as close to the posterior surface of the sternum as possible. Both pleural spaces are opened, and the left and right phrenic nerves are identified.

Step 2: dissection and resection of pericardium The phrenic nerves define the limits of pericardial resection bilaterally. Small loculated spaces are often present within the pericardium, especially near the great vessels and the diaphragm, and provide good starting places for pericardiectomy. Once an initial flap is raised, it is used to provide retraction to facilitate further dissection. Careful attention must be paid to the coronary artery anatomy: coronary arteries and bypass grafts are vulnerable to injury. If the pericardium is densely adherent in the region of a coronary artery, small islands of pericardium may be left on the heart. Areas of calcification can be addressed with the use of bone-cutting instruments; however, if an island of calcification appears to extend into the myocardium, it should not be removed.

Epicardium can also be involved in the disease process and should be resected or scored until no further restriction to ventricular filling remains. The heart should be dissected free of the left

pulmonary veins all the way over to the right pulmonary veins (including the origins of the venae cavae). The pericardium is resected from the left phrenic nerve to the right phrenic nerve [see Figure 6].

Cardiopulmonary bypass can make dissection easier, but in view of the greater risk of bleeding and the increased transfusion requirements, it is best avoided if possible. Cardiopulmonary bypass does facilitate repair of cardiac injuries during sternal reentry or dissection, and it should be used if cardiac procedures are to be performed concomitantly.

Step 3: drainage and closure After completion of the pericardiectomy, mediastinal and pleural drains are placed, and the sternum is closed in the usual fashion.

Left Anterolateral Thoracotomy

Step 1: initial incision and exposure The patient is placed in the supine position, with a roll under the left side of the torso to elevate the left side 45°. It is often difficult to establish cardiopulmonary bypass through the chest via this approach; therefore, the femoral vessels should be available within the sterile field so that femorofemoral bypass can be instituted if necessary. A curvilinear submammary incision is created, and the chest is entered at the fifth interspace. For improved exposure, the internal thoracic vessels may be divided and the intercostal muscles divided posteriorly. The left phrenic nerve is carefully identified.

Step 2: dissection and resection of pericardium As with the median sternotomy approach, loculated spaces are often present near the great vessels and the diaphragm, and these vessels provide good starting places for dissection. The entire pericardium is dissected free over the left ventricle, and an island of pericardium is left attached to the phrenic nerve along its length [see Figure 7]. The pericardium is resected from the pulmonary veins to a point just posterior to the phrenic nerve. Resection resumes anterior to the nerve and continues across the anterior aspect of the heart as far as possible, ideally to the right atrioventricular groove. The same precautions should be taken around the coronary vessels as are taken with the median sternotomy approach.

Step 3: drainage and closure After completion of the pericardiectomy, mediastinal and pleural drains are placed, and the thoracotomy is closed in the usual fashion.

OUTCOME EVALUATION

There is no proven difference between the two approaches to pericardiectomy with respect to outcome. Accordingly, the choice between them is based on whether one option affords better access to the areas believed to be most involved (e.g., a median sternotomy is more effective for releasing the right side of the heart) and whether the surgeon is more comfortable with one approach or the other.

The underlying cause of constrictive pericarditis is a significant predictor of long-term survival. In a study of 163 patients who underwent pericardiectomy, 7-year survival rates were highest in patients with idiopathic constrictive pericarditis (88%), somewhat lower in patients with postoperative constriction (66%), and lowest in patients with radiation-induced constriction (27%).³³ Predictors of decreased survival included previous radiation therapy, renal dysfunction, pulmonary hypertension, and abnormal left ventricular systolic function. Perioperative mortality was 6% overall but 21% in patients who had received radiation therapy and 8% in postsurgical patients. The slightly higher mortality recorded in

Figure 6 Pericardiectomy: median sternotomy approach. The pericardium is resected from the left phrenic nerve to the right phrenic nerve.

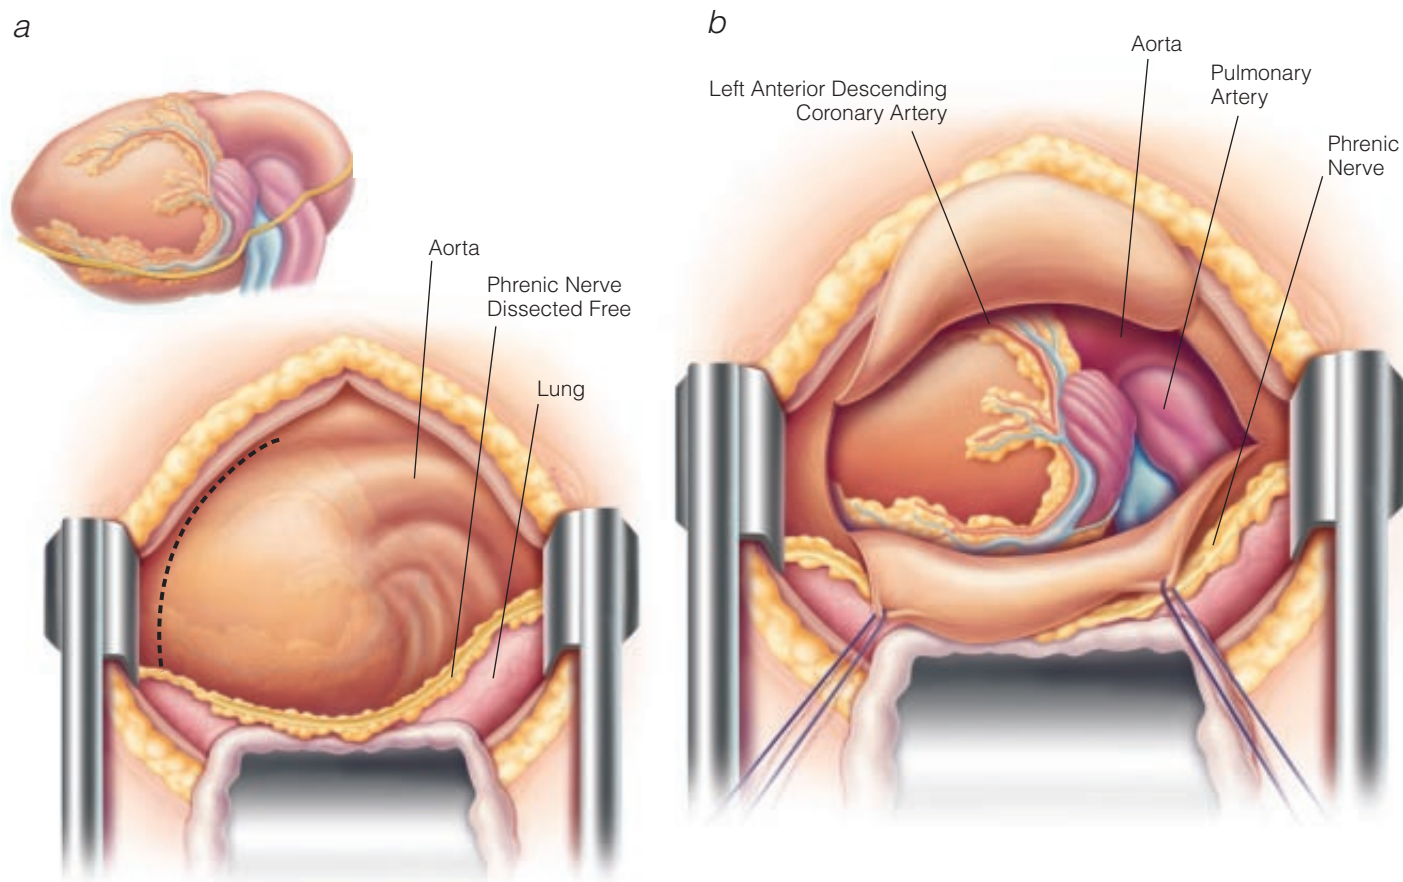

Figure 7 Pericardiectomy: left anterolateral thoracotomy approach. (a) The left phrenic nerve is identified. (b) The entire pericardium is dissected free over the left ventricle, with an island of pericardium left attached to the phrenic nerve along its length. Care must be taken to avoid injuring coronary vessels.

postoperative patients may reflect underlying cardiac dysfunction, as well as the vulnerability of previous bypass grafts to injury. The poor outcomes after pericardiectomy for radiation-induced constriction indicate that constriction is not the sole factor responsible for cardiac failure in this situation. Although cardiac failure has been attributed to myocardial atrophy caused by prolonged constriction, the excellent outcomes reported after pericardiectomy for idiopathic constrictive pericarditis suggest that constriction is rarely the only cause of cardiac failure.

Another study reported similar findings, with radiation-induced constriction leading to significantly decreased 10-year survival after pericardiectomy.³¹ The authors also noted that patients who underwent pericardiectomy for radiation-induced constriction had demonstrably worse late functional status. Fifteen of 17 long-term survivors with a history of previous radiation therapy showed New York Heart Association class III or IV symptoms, whereas only 31 of 112 patients without a history of radiation therapy had major symptoms of heart failure.

10 PULMONARY RESECTION

Ara Vaporciyan, M.D., F.A.C.S.

Anatomic resections of the lung (including pneumonectomy and lobectomy) are the standard operative techniques employed to treat both neoplastic and nonneoplastic diseases of the lung. Any surgeon who intends to operate on the pulmonary system must be keenly aware of the anatomy of the pulmonary vasculature, the bronchi, and the relation between the two. There is no substitute for this degree of familiarity. Detailed discussions are available in existing anatomy textbooks. In what follows, I describe several of the more common techniques employed for anatomic resections of the lung.

Preoperative Evaluation

Detailed discussion of the physiologic evaluation of the patient and of the indications for lobectomy or pneumonectomy is beyond the scope of this chapter. In general, the patient must have sufficient pulmonary reserve to tolerate the planned resection. In addition, it is essential to carry out a thorough evaluation of all other systems, especially the cardiac system. In patients who have received preoperative chemotherapy, the hematologic and renal systems should receive particular attention.

Operative Planning

ANESTHESIA

Although pulmonary resections can be performed with bilateral lung ventilation, careful hilar dissection is greatly facilitated by using unilateral lung ventilation. The advent of double-lumen endotracheal tubes and bronchial blockers has made it possible to isolate the ipsilateral lung and has made it easier for surgeons to carry out complex hilar dissections with the required precision. In patients with centrally located tumors, care must be taken with tube placement: inadvertent trauma to an endobronchial tumor during placement of a double-lumen tube can lead to significant bleeding and compromise of the airway. Bronchoscopic confirmation of tube position is recommended after the patient has been positioned.

Requirements for monitoring and intravenous access are determined by the patient's preoperative status and by the complexity of the resection. In most cases, the standard practice is to place a radial arterial catheter, two large-bore peripheral intravenous catheters, and a Foley catheter, with more invasive monitoring employed if mandated by the patient's clinical condition. Thoracic epidural catheters are also commonly employed for postoperative pain control. If carefully placed by an experienced anesthesiologist, these catheters can remain in place for as long as 7 days or until the chest tubes are removed.

PATIENT POSITIONING

Patients are routinely placed in the lateral decubitus position, with the table flexed just cephalad to the superior iliac crest. This positioning allows sufficient access for most incisions. If an anterior thoracotomy or a sternotomy is planned, the patient may be

placed in the supine position, with a pillow placed in such a way as to elevate the area of the thorax that will be operated on.

When the patient is in the lateral decubitus position, several measures should be adopted to guard against injury. Adequate padding should be employed to prevent the development of pressure points on the contralateral lower extremity. A low axillary roll should be used to prevent injury to the contralateral brachial plexus and shoulder girdle. Finally, adequate padding should be placed beneath the head to keep the cervical spine in a neutral position.

GENERAL TECHNICAL CONSIDERATIONS

Incisions

Posterior lateral thoracotomy remains the standard incision for anatomic pulmonary resections; however, safe and complete resections can also be performed through a variety of smaller incisions, including posterior muscle-sparing, anterior muscle-sparing, and axillary thoracotomies. In most cases, the thorax is entered at the fifth intercostal space, an approach that affords excellent exposure of the hilar structures. The anterior muscle-sparing thoracotomy is generally placed at the fourth intercostal space because of the more caudal positioning of the anterior aspects of the ribs. Although a sternotomy may be employed to gain access to the upper lobes, it does not provide good exposure of the lower lobes and the bronchi.

Thoracoscopic lobectomy [see 4:7 *Video-Assisted Thoracic Surgery*] is being performed with increasing frequency, especially for early-stage lesions. This procedure employs two or three 1 cm ports and a utility thoracotomy (frequently in the axillary position) for instrumentation and removal of the specimen. Rib spreading is not necessary, because visualization is achieved via the thoracoscope. The various thoracoscopic lobar resections are generally similar with regard to isolation and division of the hilar vessels and bronchi. Complete nodal dissections are also performed thoracoscopically. The main advantages of this approach seem to be reduced postoperative pain and earlier return to normal activity, but to date, no randomized trials have shown these advantages to be significant. Because of the technical challenges posed by thoracoscopic pulmonary resections, surgeons should have a complete mastery of the hilar anatomy before attempting these procedures.

Special Intraoperative Issues

Upon entry into the thoracic cavity, all benign-appearing filmy adhesions should be mobilized. Any malignant-appearing, broad-based, or dense adhesions should be noted, and a decision whether to perform an extrapleural dissection or a chest wall resection should be made on the basis of the depth of involvement and the preoperative imaging studies. If there is reason to believe that the chest wall or the parietal pleura may be involved, a more aggressive approach may be required to achieve a complete resection. These techniques are beyond the scope of this chapter.

Once the lung is freed of all adhesions, the inferior pulmonary ligament is divided and the lung rendered completely atelectatic. The entire lung and the parietal pleura are inspected and palpat-

ed. In patients with malignant disease, biopsies of any suspicious nodules are performed. The presence or absence of pleural fluid should be noted; if fluid is present, it should be aspirated and sent for immediate cytologic analysis.

Frequently, the fissures are incomplete as a consequence of congenital absence, inflammatory disease, or a neoplasm. If the adhesions within the fissure are filmy, they may be divided sharply or with the electrocautery while the lung is being ventilated. If the adhesions are more densely adherent, the fissures may have to be completed with staplers. During resection for malignancy, any evidence of tumor extension across a fissure or of hilar nodal involvement should be noted. A decision is then made regarding the extent of the required resection. If there is only minor extension, wedge resection of a portion of the additional lobe is indicated. If, however, the involvement is significant, segmentectomy, bilobectomy, or pneumonectomy may be indicated. Often, I develop the fissures during ventilation until a dense or incomplete region is encountered, at which point I complete the remainder of the fissure with staples. For this approach to work, the vascular and bronchial anatomy must already have been completely delineated. If the vascular structures cannot be identified in the fissure because the fissure is fused, the pulmonary artery branches will have to be approached from the anterior and posterior hilum.

Traditionally, during a lobectomy, the arterial branches are divided first, followed by the venous branches. However, if conditions exist that limit exposure (e.g., a centrally placed tumor or significant inflammation and scarring), the surgeon should start with the structures that provide the most accessible targets. Veins may be ligated first. Proponents of this approach believe that it may limit the escape of circulating tumor cells (an event that rarely, if ever, occurs); opponents claim that initial vein ligation may lead to venous congestion and retention of blood that is subsequently lost with the specimen, though peribronchial venous channels will frequently prevent this result. The bronchus may also be ligated first. However, there are two points that should be kept in mind if this is done. First, the distal limb of the bronchus (the specimen side) should be oversewn to prevent drainage of mucus into the chest. Second, after division of the bronchus, the lobe is much more mobile; therefore, to prevent avulsion of the pulmonary artery branches, care should be taken not to employ excessive torsion or traction.

The techniques used for dissection, ligation, and division of pulmonary arteries and their branches differ from those used for other vessels. Pulmonary vessels are low-pressure, high-flow, thin-walled, fragile structures. Accordingly, for rapid and safe dissection, a perivascular plane, known as the plane of Leriche, should be sought. This plane may be absent in the presence of long-standing granulomatous or tuberculous disease, after major chemotherapy, after thoracic radiotherapy, and in cases of reoperation. In these situations, proximal control of the main pulmonary artery and the two pulmonary veins may be necessary before the more peripheral arterial dissection can be started. Before any pulmonary vessel is divided, it should be controlled either with two separate suture ligatures proximal to the line of division or with vascular staples; stapling devices are especially useful for larger vessels.

Exposure of the bronchus should not involve stripping the bronchial surface of its adventitia. Aggressive dissection may compromise the vascular supply and lead to impaired healing and bronchial dehiscence. Overlying nodal tissues should be cleared, and major bronchial arteries should be clipped just proximal to the point of division. Bronchial closure has been greatly facilitated by the use of automatic staplers. Because the bronchus is frequently the last structure to be divided before removal of the specimen, I

often apply staples only to the proximal side of the bronchus and divide the bronchus distal to the staple line. Once the stapler is applied, every effort should be made to minimize its movement during firing, so as to prevent injury to the remaining proximal bronchial segment. With the stapler applied but not yet fired, the remaining lung should be ventilated to determine whether there is any impairment of ventilation secondary to placement of the stapler too close to a proximal lobar bronchus. Only when the absence of ventilatory impairment has been confirmed should the stapler be fired. When bronchial length is limited, one may perform suture closure of the bronchial stump rather than attempt to force a stapler around the bronchus. Whenever there is a high risk of bronchial stump dehiscence (e.g., after chemotherapy, radiotherapy, or chemoradiotherapy; in patients for whom adjuvant therapy is planned; or after right pneumonectomy), a vascularized rotational tissue flap (e.g., from the pericardium, the pericardial fat pad, or intercostal muscle) should be used to reinforce the bronchial closure.

Closure and Drainage

Once the bronchial closure is complete, the next step is to test its adequacy. The bronchial stump is submerged under normal saline, and the lung is inflated to a tracheal pressure of 45 cm H₂O. Any area of hilar dissection and divided fissures should be evaluated in a similar fashion. Significant parenchymal air leaks should be repaired with interrupted fine sutures (e.g., 4-0 polypropylene). If the air leak is from a diffuse raw surface, especially after upper lobectomy, construction of a pleural tent should be considered. Any air leak from the bronchial stump should be assessed very carefully. A simple repair with fine absorbable sutures may suffice, or the entire closure may have to be redone. Strong consideration should be given to reinforcing the stump with vascularized tissue (see above).

The chest is usually drained with two chest tubes that are positioned anteriorly and posteriorly and exit through separate stab incisions in the chest wall. If an epidural or a paravertebral catheter is being employed for postoperative pain management, the chest tubes should exit through an intercostal space that is no more than two spaces below the intercostal space used for entry into the chest. Failure to follow this recommendation is likely to result in pain originating from the chest tube site that will not be adequately addressed postoperatively and will lead to a significant increase in discomfort.

After a pneumonectomy, the chest tubes can be omitted. If this option is chosen, a needle should be used to aspirate 1,000 to 1,200 ml of air from the hemithorax operated on after closure of the skin. If a chest tube is used, a balanced drainage system is employed without suction. At most institutions, suction is employed postoperatively for all other resections (i.e., lobectomy, segmentectomy, and wedge resection); however, careful use of water seal in selected patients (i.e., those with small air leaks whose lungs do not collapse while on water seal) may allow earlier withdrawal of the tube.

Operative Technique

RIGHT LUNG

Right Upper Lobectomy

Dissection begins within the interlobar fissure, and the pulmonary artery is exposed at the junction of the major and minor fissures [see *Figure 1*]. In many cases, the artery is partially

obscured by a level 11 interlobar lymph node, which should be removed. Also present is the posterior segmental branch of the superior pulmonary vein, which traverses the fissure in a posterior-to-anterior direction. The pulmonary artery lies medial and inferior to this venous branch.

Once the pulmonary artery is identified, the branches within the fissure are exposed, including the posterior ascending artery to the right upper lobe, the right middle-lobe artery, the superior segmental artery to the right lower lobe, and the basilar branches to the right lower lobe. If the exposure is adequate, the posterior ascending branch can be ligated and divided. If additional length is required, the fissure between the superior segment of the lower lobe and the posterior segment of the upper lobe can be completed. This is accomplished by opening the pleura in the posterior hilum along the lateral edge of the bronchus intermedius. A level 11 lymph node will be encountered between the right upper-lobe bronchus and the bronchus intermedius. Removal of this interlobar node (sometimes referred to as the sump node) will expose the posterior ascending branch. Either the branch can be directly ligated and divided via this exposure, or the fissure can be completed with gastrointestinal anastomosis (GIA) staplers, with the vessel ligated and divided after completion of the fissure.

The lung is then rotated posteriorly, and the pleura is incised posterior to the course of the phrenic nerve, which usually passes close to the base of the superior pulmonary vein. The phrenic nerve is carefully and gently mobilized anteriorly. The superior pulmonary vein is dissected, and the apical, anterior, and posterior branches are encircled [see Figure 2]. Care is taken to preserve the middle-lobe branches. The branches draining the upper lobe are then ligated and divided or controlled with a vascular stapler. Division of the veins before division of the arterial supply will not cause the lobe to become engorged. Instead, through collateral venous drainage to the middle lobe or via bronchial venous channels, blood will be shunted away from the upper lobe.

The interlobar (or truncus posterior) branch of the right pulmonary artery will be visible as it courses posterior to the superior pulmonary vein branches. Dissection continues along the lateral surface of the interlobar artery. Once the branches to the middle-lobe artery are identified, the dissection should reach the region previously dissected within the fissure. The fissure between the middle lobe and the upper lobe can now be completed through serial application of GIA staplers.

The right upper lobe is then rotated more inferiorly to provide a better view of the superior aspect of the hilum. This step allows complete exposure of the truncus anterior branch. Frequently, the truncus anterior branch originates from the main right pulmonary artery medial to the course of the superior vena cava; some elements of the pericardium may also encircle the artery at this location. Once the vessel is exposed, it is either suture-ligated and divided or transected with an endovascular stapler.

The upper lobe is retracted superiorly and posteriorly, and the interlobar artery is gently retracted anteriorly. The bronchus to the right upper lobe is circumferentially exposed, and all nodal tissue surrounding the right upper-lobe bronchus is swept distally so that it can be included with the specimen. Every effort is made to avoid devascularizing the bronchus. Once an adequate length of the right upper-lobe bronchus is exposed, the lung is rotated anteriorly to allow visualization of the course of the bronchus intermedius [see Figure 3]. The bronchus is ligated with a transverse anastomosis (TA)-30 stapler loaded with 4.8 mm staples. Care is taken to achieve close apposition of the anterior wall to the posterior membranous wall of the bronchus. With the stapler applied but not

fired, the right lung is ventilated to confirm that the bronchus intermedius has not been compromised. The stapler is fired, the bronchus is divided, and the specimen is removed.

To prevent middle-lobe syndrome resulting from torsion of the narrow hilum of the middle lobe after an upper lobectomy, the middle lobe should be secured to the lower lobe. Once the lungs are reexpanded, a small portion of the lower lobe and a comparable portion of the middle lobe are grasped along the major fissure. A single application (or, at most, two applications) of a TA stapler should suffice to secure the lobes to each other at this site and thus prevent middle-lobe torsion.

Right Middle Lobectomy

The initial steps in a right middle lobectomy are similar to those in a right upper lobectomy. The pulmonary artery and its branches are identified within the fissure. The middle-lobe artery is identified [see Figure 1]. Not infrequently, there are two middle-lobe arteries. When this is the case, the most proximal branch is commonly located across from the posterior ascending branch to the right upper lobe. Once the anatomy has been confirmed, the arterial branches to the middle lobe can be individually ligated and divided. If additional exposure is needed before ligation, the fis-

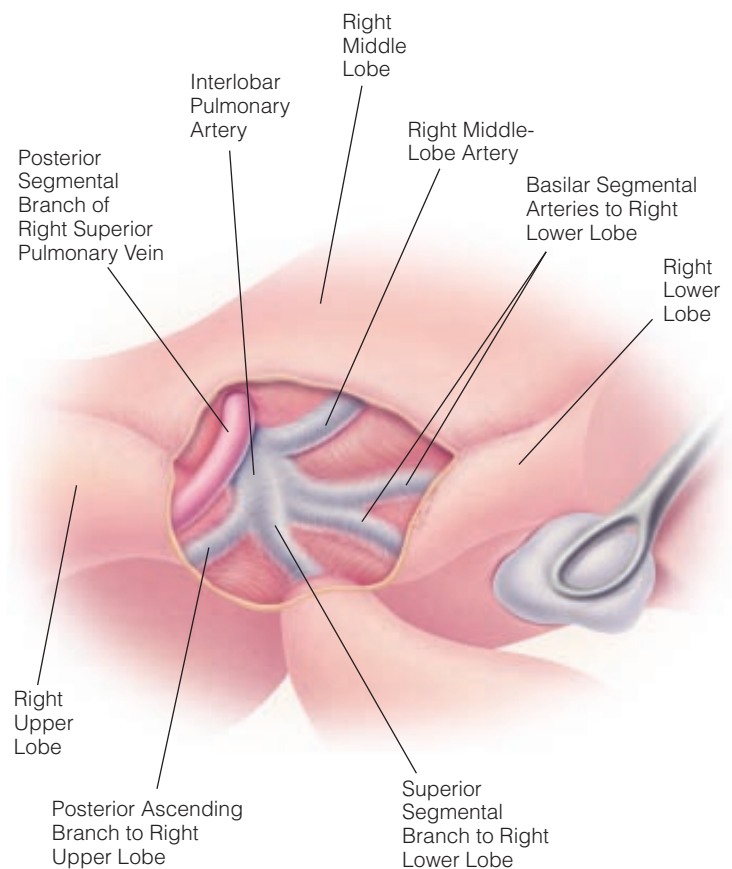

Figure 1 Right upper lobectomy. Shown is the surgeon's view of the right interlobar fissure. The fissures have been completed, and the segmental arteries to the upper, middle, and lower lobes have been identified. The posterior ascending branch to the upper lobe most commonly varies with respect to size and origin. This vessel may be absent or diminutive and may arise from the superior segmental branch to the lower lobe. The posterior segmental vein draining into the superior pulmonary vein (not seen) is clearly visualized in the right upper lobe, lateral to the pulmonary artery branches.

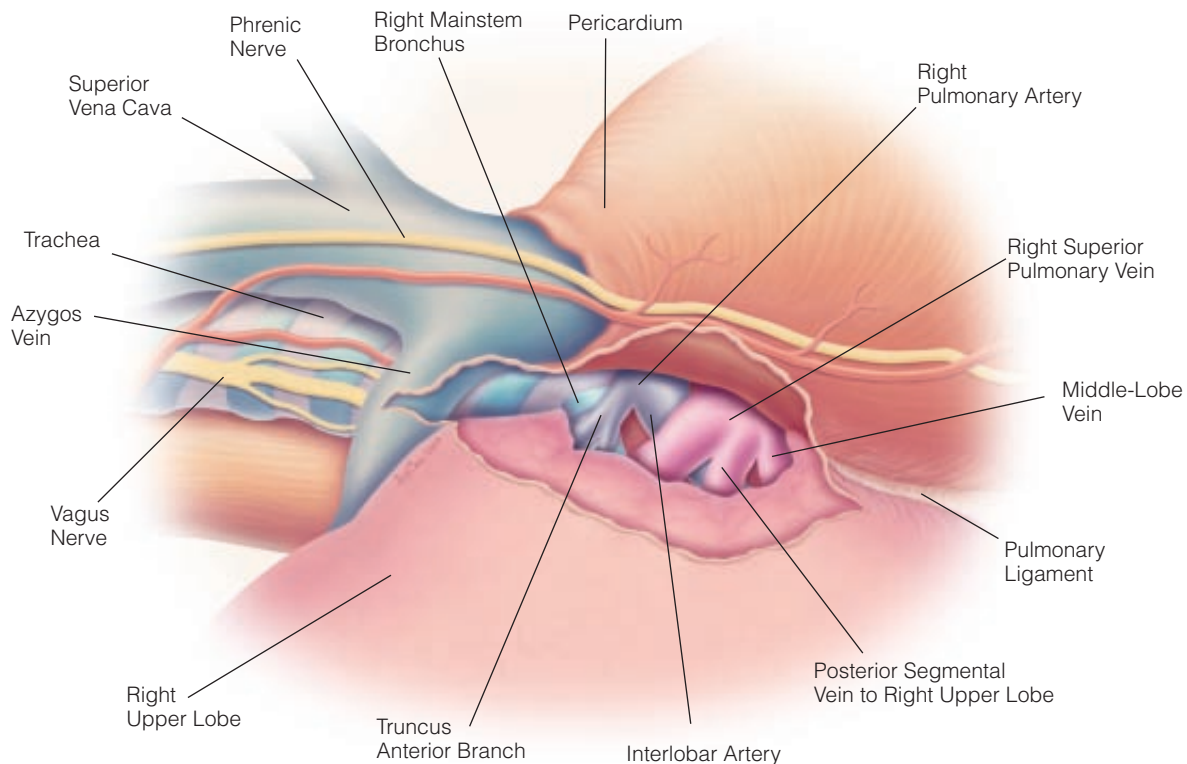

Figure 2 Right upper lobectomy. Shown is the surgeon's view of the anterior right hilum. The apical venous branches of the superior pulmonary vein obscure the interlobar pulmonary artery and, to a lesser degree, the truncus anterior branch. Division of these venous branches during upper lobectomy improves exposure of the truncus anterior. The splitting of the main pulmonary artery into its two main branches may occur more proximally, and care should be taken to identify both branches before either one is divided. Another significant possible variation is a branch of the middle-lobe vein that arises from the intrapericardial portion of the superior pulmonary vein.

asures can be completed to yield added exposure of a proximal middle-lobe artery.

Once the arteries are divided (or if additional exposure is required), the lung is rotated posteriorly to expose the superior pulmonary vein [see Figure 2]. The branches to the middle lobe are carefully identified, doubly ligated, and divided. The posterior segmental branch of the superior pulmonary vein should now be easily identifiable, originating just cephalad to the middle-lobe vein and coursing posteriorly (lateral to the interlobar artery) to drain the posterior segment of the right upper lobe. As noted (see above), this venous branch is easily identified during dissection of the interlobar artery within the fissure. To complete the fissure between the upper and middle lobes, dissection continues along the caudal and lateral surface of the posterior segmental venous branch until the previously performed dissection of the interlobar artery within the fissure is reached. The fissure is then completed through serial application of GIA staplers. When the fissure is complete, the surgeon has a clear view of the posterior segmental branch of the superior pulmonary vein and the interlobar branch of the pulmonary artery coursing posterior and medial to the veins. If the proximal arterial branch to the middle lobe could not be safely ligated from the fissure before, it should be easily accessible now.

The middle lobe is then rotated superiorly and posteriorly to expose the right middle-lobe bronchus [see Figure 4], which usually arises anterior and inferior to the right middle-lobe branches of the pulmonary artery. The basilar artery branches to the right lower lobe are gently mobilized posteriorly to expose the bronchus intermedius and the origin of the right middle-lobe bronchus.

Figure 3 Right upper lobectomy. Shown is the surgeon's view of the posterior right hilum. The carina, the right mainstem bronchus, the right upper lobe, and the bronchus intermedius are easily seen. The interlobar sump node has been removed and the fissure completed, and the posterior ascending branch of the pulmonary artery is visible. Care should be taken not to injure this vessel during division of the fissure. It can be ligated via this approach if it cannot be adequately exposed from the fissure. Both the truncus anterior and the posterior ascending branch of the pulmonary artery lie directly anterior to the right upper-lobe bronchus, and care should be taken not to injure these vessels during bronchial encirclement. The bronchial arteries course along the medial and lateral edges of the bronchus intermedius.

Peribronchial lymph nodes located in this region should be dissected and removed, with care taken not to injure the bronchial arterial branches. Once the bronchus is free, it is either divided and ligated with an automatic stapler or transected and oversewn as previously described (see above).

Right Lower Lobectomy

Once again, the pulmonary artery is exposed within the oblique fissure. The pulmonary branches to the superior segment and the basilar segments of the right lower lobe are identified [see Figure 1]. All branches within the fissure are identified, including the middle-lobe artery and the posterior ascending branch to the right upper lobe. The superior segmental artery is encircled and doubly ligated, with care taken not to injure the posterior ascending branch if it arises from or close to the origin of the superior segmental branch. The basilar segmental branches are then encircled and doubly ligated, with the same care taken not to injure the middle-lobe branch. Both vessels are then divided.

The fissure between the superior segment of the lower lobe and the posterior segment of the upper lobe is frequently incomplete. If necessary, it is completed as previously described [see Right Upper Lobectomy, above]. The pleura is incised along the bronchus intermedius, and the lymph node (sump node) just distal to the takeoff of the right upper-lobe bronchus is removed, so that the previously dissected pulmonary artery is exposed. Serial application of GIA staplers is employed to complete the fissure.

The fissure between the middle and lower lobes may also have to be completed (though in many cases, it is congenitally com-

Figure 4 Right middle lobectomy. Shown is the surgeon's view of the right middle-lobe bronchus. Gentle retraction of the basilar segmental artery to the lower lobe posteriorly allows clear visualization of the origin of the middle-lobe bronchus.

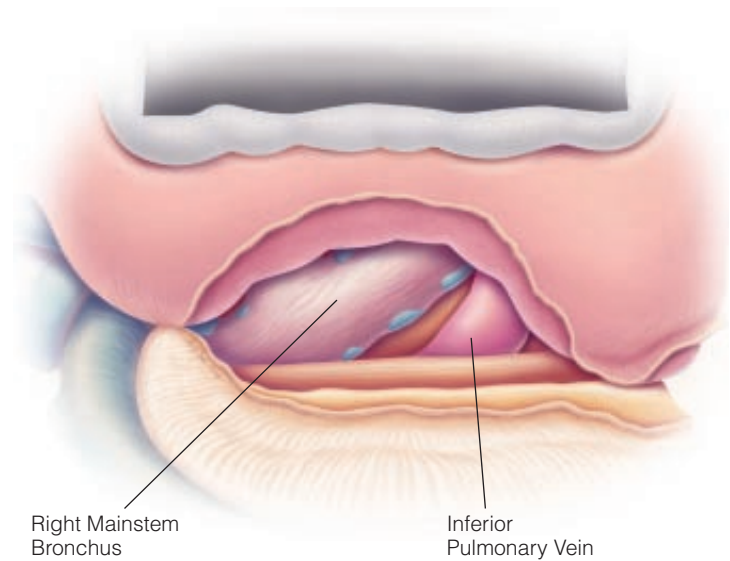

Figure 5 Right lower lobectomy. Shown is the surgeon's view of the right inferior pulmonary vein. For encirclement of this vein, dissection may also have to be performed on its anterior surface. The branch to the superior segment can be seen overlying the origin of the superior segmental bronchus.

plete). The pleura is incised within the anterior hilum to allow identification of the superior and inferior pulmonary veins. The basilar segmental bronchi and the middle-lobe bronchus should be exposed. Removal of lymphoid tissue allows easy application of a GIA stapler to complete the fissure.

The inferior pulmonary vein is then encircled as it exits the pericardium [see Figure 5]. This step is facilitated by dissecting the superior edge of the inferior pulmonary vein with the lung rotated first anteriorly and then posteriorly. Once encircled, the pulmonary vein can easily be ligated and divided with a vascular stapler.

Division of the lower-lobe bronchus is best accomplished through the fissure; this approach facilitates identification of the middle-lobe bronchus and helps prevent inadvertent damage to or compromise of the origin of this structure. Level 11 and 12 lymph nodes are cleared distally along the bronchi to expose the origin of the superior segmental bronchus [see Figure 6]. In some patients, there is adequate length to permit oblique placement of a stapler for control of all the lower-lobe segmental bronchi without compromise of the middle-lobe bronchus. If this step is not possible, separate ligation and division of the superior segmental bronchus and of all the basilar bronchi as a unit should be performed.

The lung is rotated anteriorly, and the bronchus intermedius is dissected distally until the origin of the superior segmental bronchus is identified from this side. The branch of the inferior pulmonary vein draining the superior segment will be encountered and should be mobilized distally to allow adequate exposure of the superior segmental bronchus origin. This bronchus can now be encircled, ligated, and divided with a stapler or divided and oversewn.

Next, the basilar segmental bronchi are encircled at a point where closure will not affect airflow to the middle-lobe bronchus. Appropriate placement is confirmed by asking the anesthesiologist to ventilate the right lung while the stapler or clamp is applied to the base of the basilar bronchi. If placement is adequate, the basilar segmental bronchi are ligated and divided.

Right Pneumonectomy

With the pleura incised circumferentially around the hilum, the lung is rotated inferiorly and posteriorly [see Figure 2]. The main

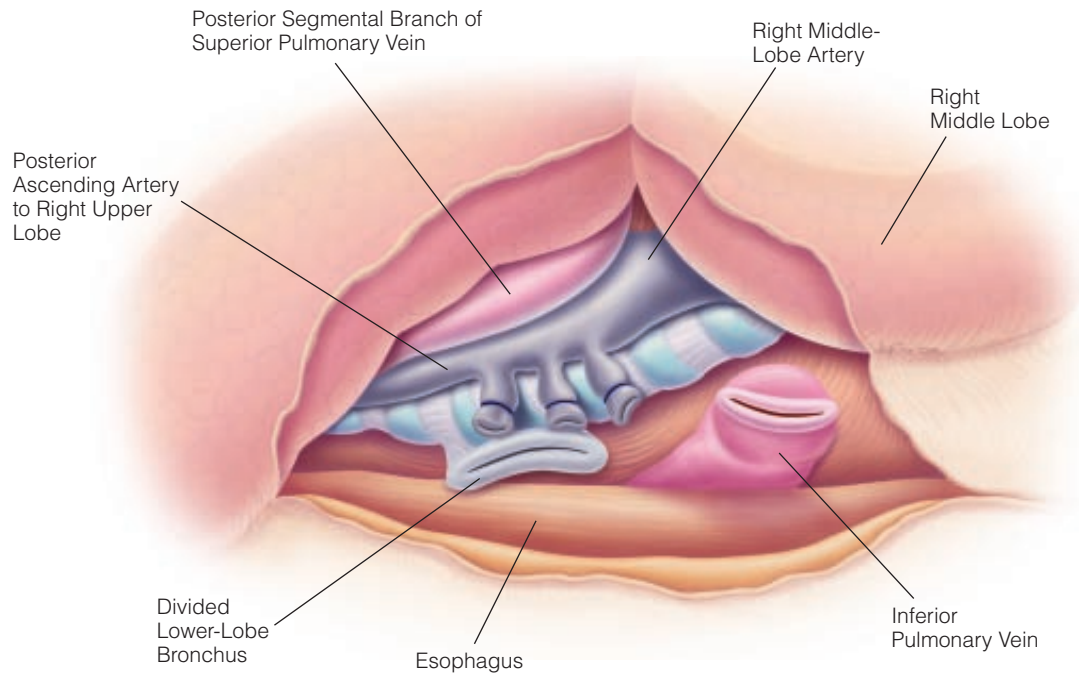

Figure 6 Right lower lobectomy. Shown is the surgeon's view of the right fissure after division of the lower-lobe vessels. The decision whether to divide the bronchi separately or to transect them with a single oblique application of the stapler depends on the proximity of the middle-lobe bronchus to the superior segmental and basilar bronchi.

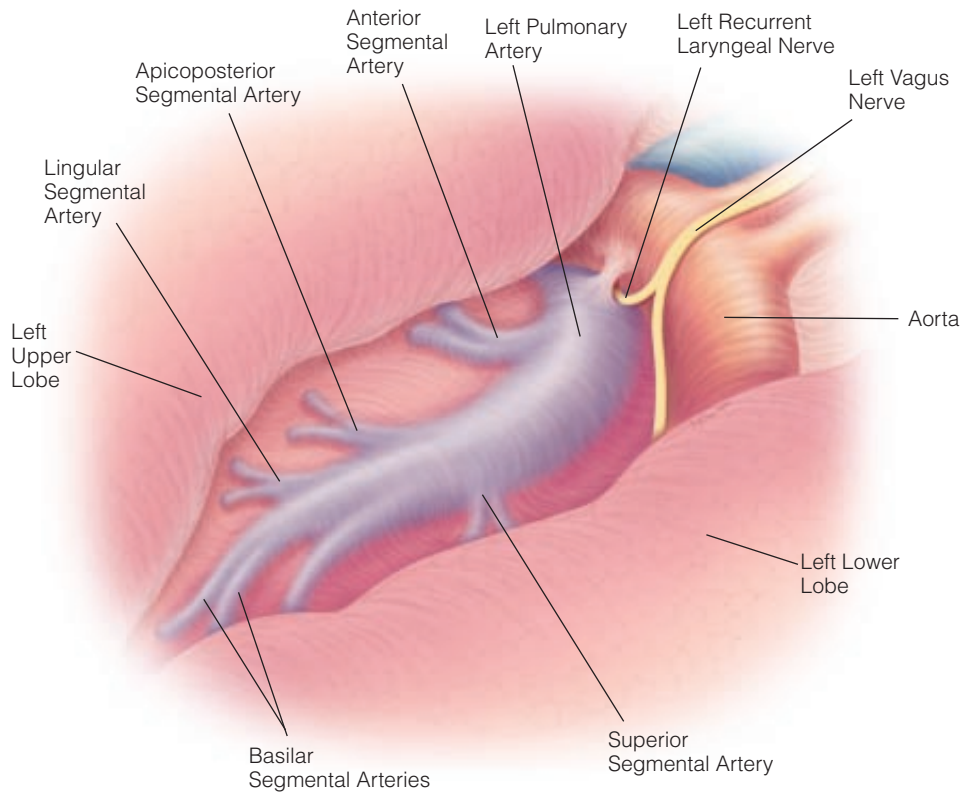

Figure 7 Left upper lobectomy. Shown is the surgeon's view of the left interlobar fissure. The recurrent laryngeal nerve can be seen coursing lateral to the ligamentum arteriosum. The arterial branches supplying the left upper lobe between the apicoposterior segmental branch and the lingular branch can vary substantially in number and size. Another frequently encountered variation is a distal lingular branch that arises from a basilar segmental branch.

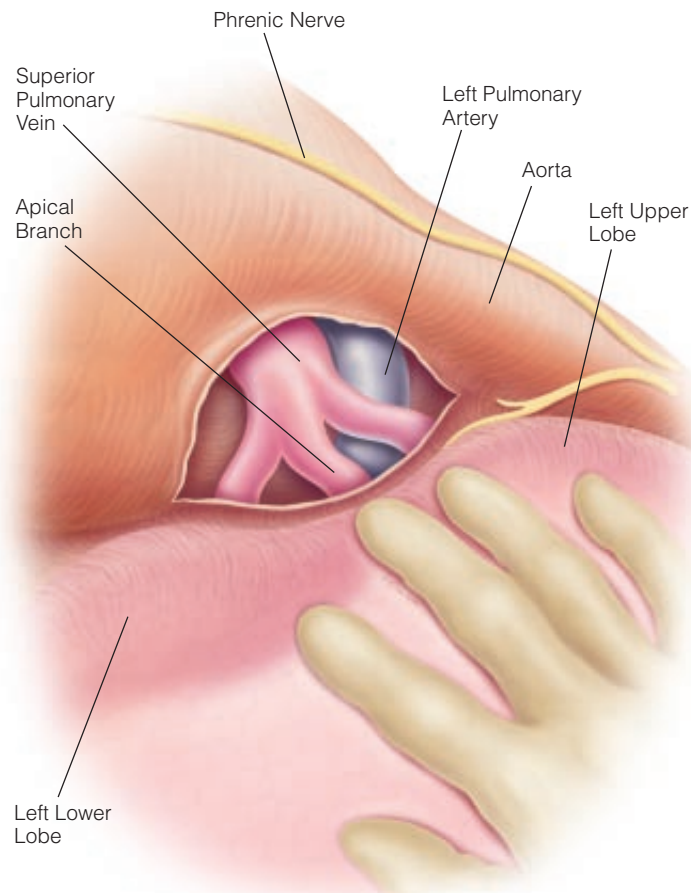

Figure 8 Left upper lobectomy. Shown is the surgeon's view of the anterior left hilum. The apical branches of the superior pulmonary vein course anterior to the apicoposterior branches of the pulmonary artery. If additional vessel length is needed because of the presence of a central tumor, the pericardium may be entered and the vein divided at that location.

trunk of the right pulmonary artery is exposed as it exits the pericardium posterior to the vena cava. Care is taken not to dissect distally on the vessel and not to encircle only the truncus anterior branch by mistake. Ligation and division of the right pulmonary artery can be accomplished in several different ways; either dividing the vessel between clamps and oversewing it with 3-0 nonabsorbable suture material or using vascular staplers is acceptable.

Next, attention is directed toward the superior pulmonary vein. The vessel is mobilized on its superior and inferior aspects with blunt and sharp dissection, encircled with blunt dissection, and ligated and divided with either clamps or a vascular stapler. With the lung retracted superiorly, the inferior pulmonary vein is dissected as in a right lower lobectomy [see Figure 5]. Once isolated, this vein is also ligated and divided as previously described (see above).

With the lung retracted anteriorly, attention is directed toward the right mainstem bronchus [see Figure 3]. The subcarinal lymph nodes are mobilized, and the bronchial artery on the posterior medial aspect of the right mainstem bronchus is controlled. The remaining peribronchial tissues are then mobilized distally with blunt and sharp dissection. To avoid leaving a long bronchial stump, exposure of the bronchus to within 1 cm of the carina is advisable.

The bronchus can be closed with a TA stapler loaded with 4.8 mm staples. The staples should be oriented so as to allow good approximation of the anterior and posterior membranous walls. If

suture closure is selected instead, the bronchus is divided with the clamp placed on the distal bronchus to prevent spillage. The open end of the bronchus is then closed with nonabsorbable simple sutures, with the cartilaginous wall approximated to the membranous wall. To guard against necrosis of the bronchus, care should be taken not to tie the sutures too tightly. Coverage of the pneumonectomy stump with viable tissue is preferred, especially if the patient has received or will receive chemotherapy, radiation therapy, or both. The ideal choice for this purpose is either a rotated intercostal muscle flap or a pericardial fat pad rotational flap. The flap is secured with carefully placed 4-0 polypropylene sutures.

In the preceding description, the artery is divided first, followed by the individual veins and finally by the bronchus; however, the steps of this operation can be carried out in any order. The position of the tumor may make the approach I describe difficult. For example, an anteriorly placed tumor may hinder exposure of the anterior hilum. In this situation, the bronchus can be divided first, and the pulmonary artery can be approached from the posterior hilum. As another example, if the tumor is very proximal, the pericardium can be entered via a U-shaped incision along the anterior, caudal, and posterior hilum. The pulmonary veins can then be divided en masse as they originate from the left atrium, and the pulmonary artery can be divided as it courses posterior to the ascending aorta.

LEFT LUNG

Left Upper Lobectomy

After the thorax is entered, the lung is rendered atelectatic and the thorax is explored. The inferior pulmonary ligament is divided. The interlobar fissure is developed with a combination of sharp and electrocautery dissection. The posterior aspect of the fissure, between the apicoposterior segment of the left upper lobe and the superior segment of the left lower lobe, is completed (with a linear stapler if necessary) to expose the proximal portion of the pulmonary artery.

With the lung retracted inferiorly, dissection continues proximally along the pulmonary artery. The pleura is incised under the arch of the aorta to expose the left main pulmonary artery. A variable number of small vessels and vagal branches to the lung are encountered that must be ligated and divided. Care is taken not to injure the recurrent laryngeal nerve as it branches from the vagus and travels under the arch just distal to the ligamentum arteriosum.

The left upper lobe is then retracted anteriorly and superiorly to expose the pulmonary arteries supplying the lobe [see Figure 7]. There is an anterior segmental branch that frequently arises directly opposite the superior segmental branch to the lower lobe, as well as a more distally situated lingular branch. These vessels should be identified, individually ligated, and divided. Not infrequently, multiple posterior apical branches are encountered; in fact, as many as seven vessels supplying the left upper lobe may be identified.

Next, the whole lung is retracted caudally and inferiorly to expose the aortic arch. A large arterial branch supplying the apicoposterior aspect of the upper lobe is usually encountered. Although the superior and posterior aspects of this artery are easily dissected, the anterior aspect is frequently obscured by an apical branch of the superior pulmonary vein; division of this venous branch may improve exposure and facilitate control of the artery. Once the artery is encircled, it is ligated and divided. To prevent avulsion of this vessel from the main pulmonary artery, care must be taken not to exert excessive traction on the lung.

With the lung now retracted posteriorly, the mediastinal pleura is opened parallel to and posterior to the course of the phrenic

Upper-Lobe Bronchus
Left Pulmonary Artery

the lingula and the lower lobe is completed with serial application of GIA staplers [see Figure 9]. The left upper lobe bronchus is encircled and either clamped or controlled with a TA stapler. To prevent inadvertent injury, the pulmonary artery branches to the lower lobe should be gently retracted posteriorly during stapler placement. With the stapler applied (or the clamp in place), the anesthesiologist ventilates the left lung to verify that air is flowing freely to the entire left lower lobe. Once unobstructed airflow is confirmed, the stapler is fired and the bronchus divided.

Left Lower Lobectomy

As in a left upper lobectomy, dissection begins within the interlobar fissure. The pulmonary artery is identified, and the branches to the upper and lower lobes are dissected [see Figure 7]. The superior segmental artery is encircled first and is ligated and divided; not uncommonly, there are actually two separate superior segmental arteries. The basilar segmental arteries are then encircled distal to the origin of the lingular artery. These vessels are also ligated and divided, with care taken not to encroach on the blood flow to the lingula.

The lung is rotated superiorly to expose the inferior pulmonary vein. As in a right lower lobectomy, the vein is encircled by dissecting first on its anterior surface with the lung rotated posteriorly, then on its posterior surface with the lung rotated anteriorly [see Figure 10]. Once the vein is encircled, it is ligated and divided.

Attention is then redirected toward the interlobar fissure, and the left lower lobe bronchus is identified [see Figure 11]. The origin of the bronchus is cleared by sweeping nodal tissue distally with blunt and sharp dissection. The upper-lobe branches of the pulmonary artery are gently retracted superiorly to allow placement of a TA stapler on the bronchus. With the stapler applied, the anesthesiologist ventilates the left lung to confirm the adequacy of airflow to the upper lobe. The stapler is fired, and the bronchus is divided distal to the staple line.

Left Pneumonectomy

The initial steps of a left pneumonectomy are similar to those of a left upper lobectomy. The lung is retracted caudally, and the pleu-

Figure 9 Left upper lobectomy. Shown is the surgeon's view of the left fissure after division of the upper-lobe arteries. Care should be taken not to injure the pulmonary artery inadvertently when applying a stapler.

nerve [see Figure 8]. The superior pulmonary vein can then be identified easily. If the apical branch was not previously ligated, the surgeon should make every effort not to damage the pulmonary artery branches that lie posterior to this portion of the vein. The majority of the superior pulmonary vein lies anterior to the left upper lobe bronchus. Once this vein is encircled, it is ligated and divided.

Attention is then redirected toward the fissure, and the peribronchial nodal tissue surrounding the left upper lobe bronchus is swept distally with blunt and sharp dissection. The fissure between

Upper-Lobe Bronchus
Left Pulmonary Artery

Figure 10 Left lower lobectomy. Shown is the surgeon's view of the left inferior pulmonary vein. The left side, unlike the right side, affords only limited access to the subcarinal space. However, the length of the inferior pulmonary vein outside the pericardium is greater on the left side than on the right.

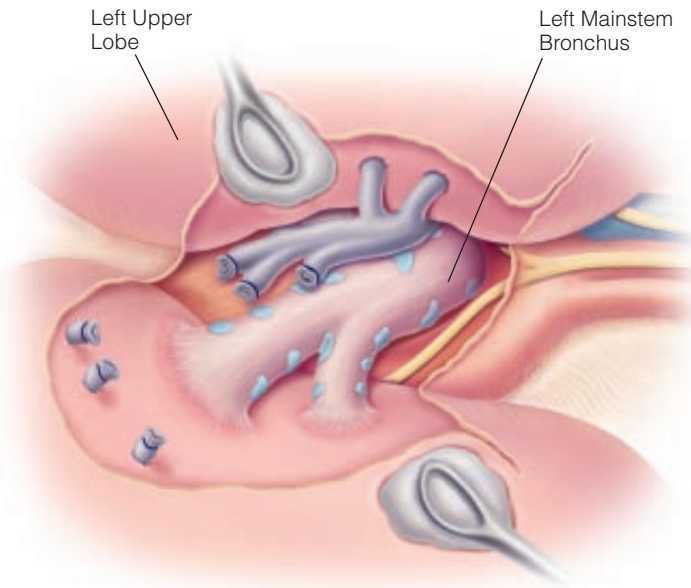

Figure 11 Left lower lobectomy. Shown is the surgeon's view of the left fissure after division of the lower-lobe vessels. In this procedure, a single oblique transection of the entire left lower-lobe bronchus can be employed without any concern that a proximal bronchus will be compromised; this step would not be feasible in a right lower lobectomy, in that the right middle-lobe bronchus arises from the bronchus intermedius.

ra is incised along the course of the aortic arch [see Figure 7]. The superior and posterior surfaces of the pulmonary artery are dissected as it enters the thorax under the aortic arch. Once the perivascular space is entered, the entire vessel can usually be encircled with blunt dissection. If the superior pulmonary vein's apical branch limits access to the anterior surface of the pulmonary artery, the branch may be ligated and divided first to improve exposure of the artery; alternatively, the superior pulmonary vein itself may be ligated and

divided first to facilitate arterial exposure (see below).

Once the pulmonary artery is encircled, the vessel can be ligated and divided. My preferred method is to use an endovascular GIA stapler, the advantages of which include its rapidity of use, its consistently reproducible results, and its ability to control the vessel along a broad surface. Mass ligation is not advisable, because the risk of dislocation of the tie is too great. When the length of exposed artery is too short or a stapler cannot be placed safely, the surgeon may apply vascular clamps to the proximal and distal portions of the vessel instead. Once the vessel is divided, the proximal end may be oversewn with a continuous polypropylene suture.

If additional vessel length is required because of the presence of a proximal tumor, the ligamentum arteriosum may be divided. The recurrent laryngeal nerve should be identified and preserved. In dividing the left pulmonary artery proximal to the ligamentum arteriosum, care should be taken not to narrow the main pulmonary artery and thereby reduce right-side blood flow. For maximal safety, systemic blood pressures and oxygenation should be evaluated for 1 to 2 minutes after application of the clamp or stapler but before ligation.

With the lung retracted posteriorly, the pleura is incised posterior to the course of the phrenic nerve, and the superior pulmonary vein is identified [see Figure 8]. The vein is encircled with blunt dissection, then ligated and divided. As noted (see above), the apical branch usually travels across the apical branch of the pulmonary artery, and care should be taken not to injure this vessel during dissection.

The lung is then retracted superiorly to expose the inferior pulmonary vein. Dissection is performed on the anterior and posterior aspects of the inferior pulmonary vein, and blunt dissection is used to achieve complete encirclement of the vein [see Figure 10], which is ligated and divided.

Next, the lung is retracted anteriorly and superiorly. Complete dissection of the subcarinal lymph nodes is performed, facilitated by division of one or two pulmonary branches of the left vagus nerve and both bronchial arteries. Gentle traction is applied in

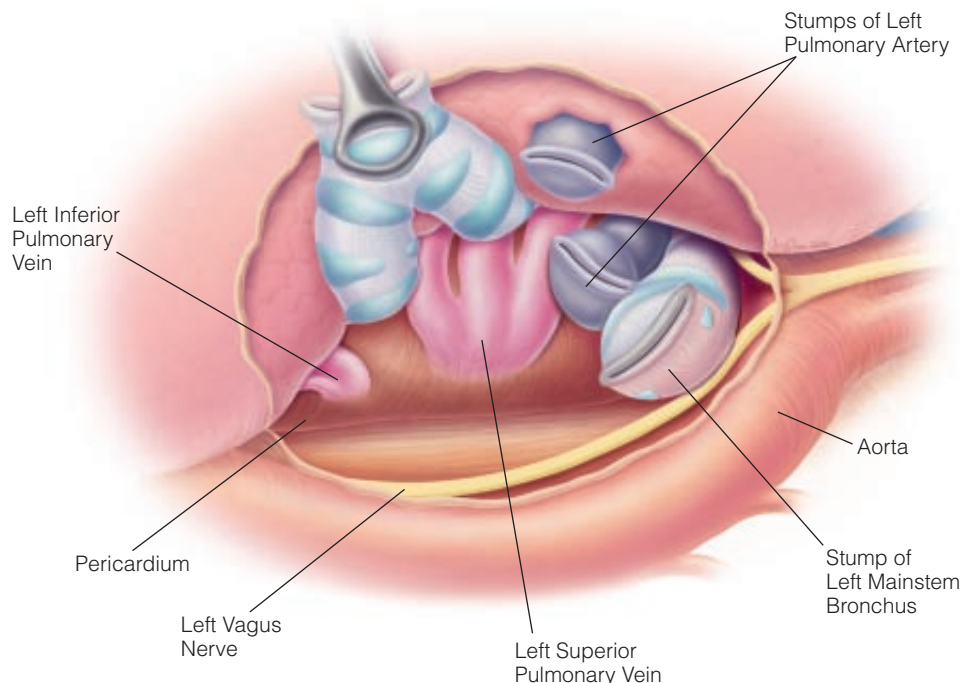

Figure 12 Left pneumonectomy. Shown is the surgeon's view of the posterior left hilum. The carina is located deep under the aortic arch. A left-side double-lumen tube or bronchial blocker may have to be withdrawn to afford better exposure of the proximal left mainstem bronchus. The orientation of the superior pulmonary vein and the pulmonary artery (anterior and superior to the bronchus, respectively) should be noted.

conjunction with blunt dissection to allow encirclement of the proximal left mainstem bronchus [see *Figure 12*]. An effort should be made to encircle the bronchus within 1 cm of the carina. A TA stapler is then passed around the left mainstem bronchus and applied at this point. If excessive traction is required to achieve this placement, the bronchial stump can be left slightly longer: 1 to 1.5 cm, as measured from the carina. The stapler is fired, and

the bronchus is divided distal to the staple line.

Frequently, the position of the bronchial stump under the aortic arch and deep within the mediastinum renders coverage of the stump unnecessary. If the surgeon is concerned about possible stump dehiscence (e.g., in a patient who has undergone high-dose preoperative radiotherapy), coverage with a flap from the pericardial fat pad or intercostal muscle is appropriate.

11 COUGH AND HEMOPTYSIS

Subroto Paul, M.D., and Raphael Bueno, M.D., F.A.C.S.

An acute or chronic cough is one of the most common chief presenting complaints. In the United States, it accounts for approximately 30 to 50 million physician visits each year, and more than \$1 billion is spent annually on its workup and treatment.¹ A cough can result from a wide variety of conditions, ranging from fairly non-life-threatening causes (e.g., bronchitis) to life-threatening ones (e.g., lung cancer). Hemoptysis is also a common presenting complaint, with a similarly broad spectrum of possible causes. It may range in severity from mild blood streaking in sputum to massive hemorrhage that, if left untreated, can lead to shock and rapid death from blood loss and asphyxiation. Even mild hemoptysis is distressing to many patients and physicians and calls for prompt attention and diagnosis. In cases of massive hemoptysis, expedient evaluation and management are essential, often involving airway control with intubation and hemodynamic resuscitation.

Because both cough and hemoptysis may be signs of urgent or life-threatening disease, patients who present with either or both of these symptoms should undergo a thorough, methodical workup consisting of a detailed history, a careful physical examination, and appropriate diagnostic studies (usually computed tomography of the chest and bronchoscopy).

Cough

A cough is a forceful expiration that is mediated through the activation of a complex reflex arc. The cough reflex is triggered by the stimulation of various cough receptors, which are found not only in the epithelium of the respiratory tract but also in the lower esophagus, the stomach, and the diaphragm.^{2,3} These receptors can be activated by mechanical, chemical, or thermal stimuli; once activated, they send signals to the medulla via the vagus nerve, the glossopharyngeal nerve, the trigeminal nerve, or the phrenic nerve. A center in the medulla then activates the muscles of expiration by means of efferent signals transmitted via the vagus and phrenic nerves.^{2,3}

Mechanical stimuli that can trigger the cough reflex include inhaled particulate matter and intrinsic and extrinsic tracheo-bronchial compression. Intrinsic compression may be caused by airway tumors, foreign bodies, granulomatous airway disease, or bronchial smooth muscle that is constricted as a result of disease or exposure to noxious materials. Extrinsic compression may be caused by aortic aneurysmal disease, a pulmonary parenchymal neoplasm (e.g., lung cancer or a tumor that has metastasized to the lung), edema from pulmonary parenchymal infection (e.g., pneumonia or abscess), or pulmonary parenchymal fibrosis resulting from any of a variety of interstitial lung diseases (e.g., idiopathic pulmonary fibrosis or sarcoidosis). Chemical stimuli that can trigger coughing include inhaled irritant gases and aspirated gastric acid or bile. A common thermal stimulus is hot or cold inhaled air (or other gas).⁴⁻⁷

CLINICAL EVALUATION

An acute or self-limited cough is defined as one that resolves within 3 weeks. Usually, an acute cough is the result of minor infection or inhalation of irritant gases or particulate matter; sometimes, however, it is associated with a more serious condition. Generally, a cough requires diagnostic attention when it persists for 3 weeks or longer, at which time it is deemed chronic. Numerous conditions are capable of causing a chronic cough [see Table 1], and the differential diagnosis of this complaint is broad.

Careful diagnostic evaluation is required to identify potentially life-threatening causes of chronic coughing [see Figure 1]. Such evaluation relies heavily on the history. Medications, tobacco use, and occupational exposure must all be considered in the effort to narrow the differential diagnosis. Associated symptoms offer important clues; for example, in a patient with water brash and a chronic cough, reflux is more likely to be the cause of the cough than it would be in a patient with copious nasal secretions.^{5,7,8} The quality of the sputum is a particularly significant variable: purulent sputum may lead one to suspect infection, whereas bloody sputum may lead one to suspect malignancy, especially in a smoker. Substantial experience and acute clinical judgment are required to distinguish the relatively few patients with serious diseases from the millions of patients who present with a benign cough each year.

MANAGEMENT OF SPECIFIC CAUSES

Common causes of a chronic cough include acute and chronic bronchitis, bronchiectasis, asthma, postnasal drip, and gastroesophageal reflux.^{4,5,9-15} Other, less common causes include drugs (e.g., angiotensin-converting enzyme [ACE] inhibitors), interstitial lung disease, congestive heart failure (CHF), bronchogenic carcinoma, tracheobronchial foreign bodies, and endobronchial tumors (benign or malignant).^{7,16-18}

Table 1 Differential Diagnosis of Cough

Most common causes	Acute and chronic bronchitis Bronchiectasis Asthma Postnasal drip Gastroesophageal reflux
Less common causes	Drugs Angiotensin-converting enzyme inhibitors Interstitial lung disease Eosinophilic bronchitis Congestive heart failure Bronchogenic carcinoma Tracheobronchial foreign body Psychogenic

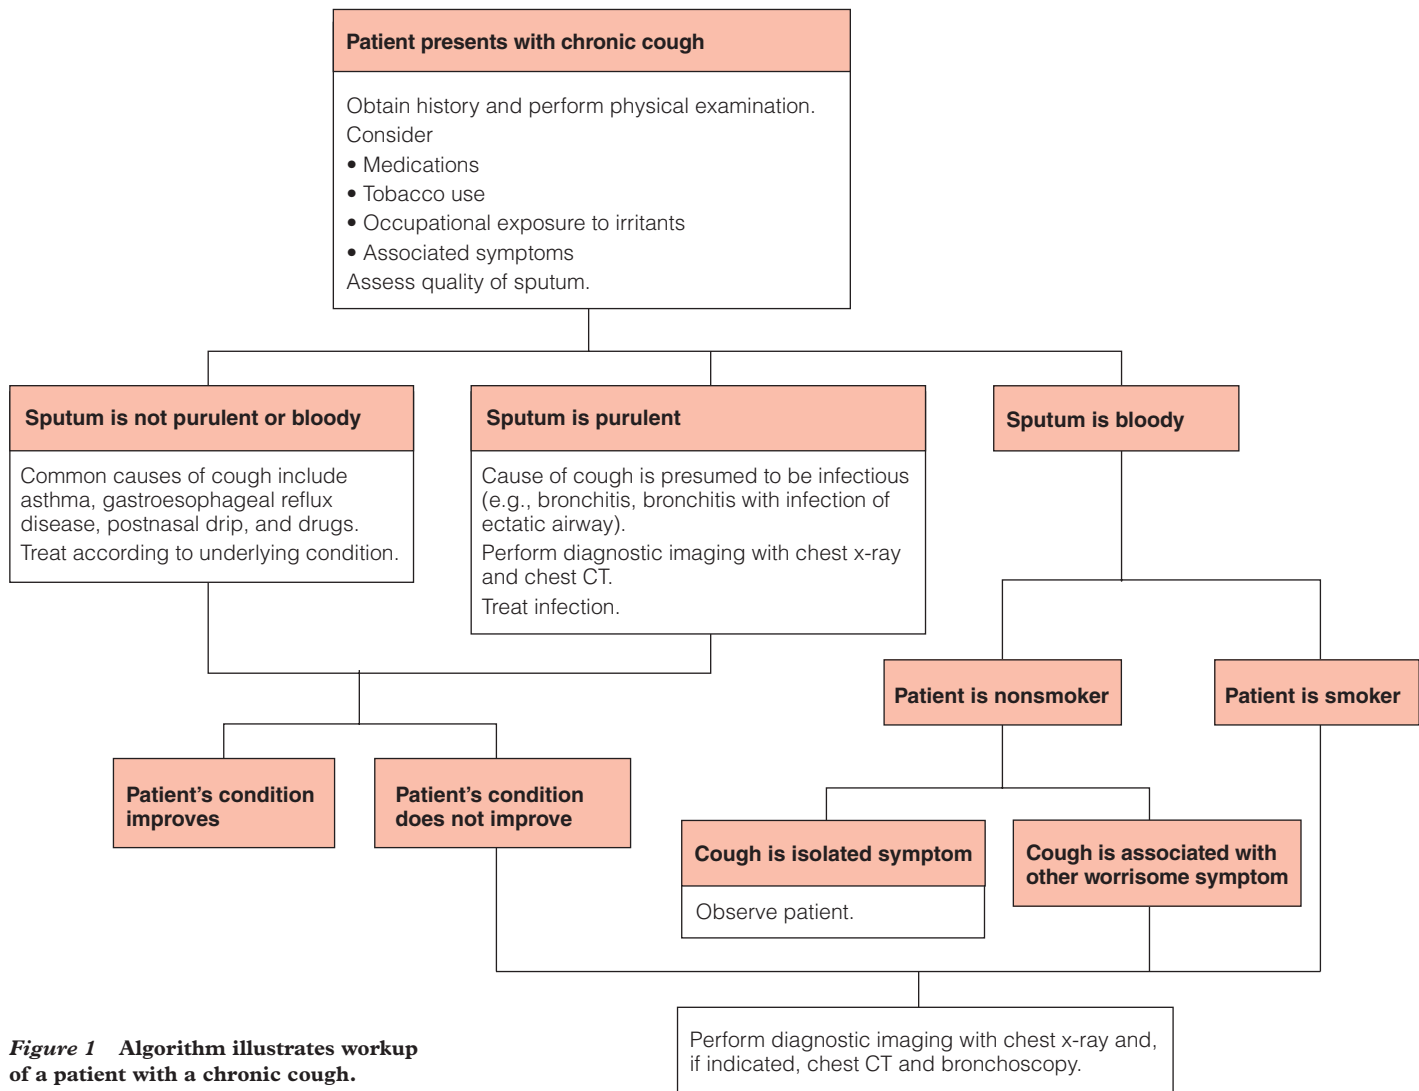

Figure 1 Algorithm illustrates workup of a patient with a chronic cough.

Tracheobronchial irritation can trigger the cough reflex. Acute irritation from inhaled substances (e.g., toxic fumes or cigarette smoke) can lead to bronchospasm and thence to coughing. In addition, patients with asthma or reactive airway disease may present with a cough. Asthma, in fact, is one of the most common causes of cough. Although asthma is typically associated with shortness of breath and expiratory wheezing, some variants of asthma have cough as the sole presenting symptom (so-called cough-variant or cough-type asthma).^{5,15,19} Most persons with cough resulting from tracheobronchial irritation have a family history of atopy or asthma. Diagnosis rests on a history of symptom exacerbation with irritants or upper respiratory infections on the associated findings of end-expiratory wheeze; it is confirmed by spirometry.

Tracheobronchial infection can also lead to a chronic cough. Acute bronchitis from viral or bacterial infection (either primary infection or superinfection) is typically signaled by thick, purulent secretions. It is usually self-limited, though in some cases, it may have to be treated with a short course of antibiotics.²⁰ Chronic bronchitis is defined by the presence of a cough with sputum production that persists for at least 3 months and sometimes for years. The sputum is clear or white, and there is no evidence of systemic infection. Chronic bronchitis almost always occurs in current smokers (or recent quitters), who almost invariably have

chronically inflamed airways.^{5,6} In a smoker, a chronic cough is not a particularly worrisome symptom; however, if the character of the cough or the quality of the sputum changes, further workup is indicated to look for a possible superimposed infection or neoplasm.²¹ With both acute and chronic bronchitis, the diagnosis can usually be made on the basis of the history and the physical findings (especially the sputum quality).

Persistent airway inflammation from any cause (e.g., chronic bronchitis, asthma, granulomatous airway disease, or cystic fibrosis) can lead to bronchiectasis, a state characterized by chronic airway dilatation with cystic changes in the lower bronchial tree. The anatomic abnormalities in the dilated, cystic bronchi cause pooling of mucus and secretions and impair clearance of secretions.^{7,10,17} Cough, either dry or productive, is the major presenting symptom of bronchiectasis. This condition is often accompanied by infection of the ectatic airway, which leads to purulent secretion and systemic signs of illness that necessitate prompt antibiotic therapy. In patients with cystic fibrosis, for example, daily postural drainage of the bronchiectatic airways is required, and frequent hospitalization for intensive antibiotic therapy and chest physiotherapy is necessary. The diagnosis of bronchiectasis is made on the basis of the history and diagnostic imaging (including chest x-ray and, currently, chest CT).

Postnasal drip is one of the most common causes of cough. It

usually results from allergic rhinitis, sinusitis, or nasopharyngitis. Nasal secretions irritate the larynx and trachea, leading to the activation of the cough reflex arc.^{7,12,14} Generally, the diagnosis is made on the basis of the history and the symptom complex. Often, however, the symptoms are vague, and the diagnosis is confirmed only when the patient responds to empirical therapy directed at the presumed underlying cause. Steroid nasal sprays and antihistamines are useful for ameliorating symptoms. In recalcitrant cases, an otolaryngologic examination may be required to exclude sinus disorders.

Gastroesophageal reflux is increasingly being recognized as a cause of cough and asthma. Several mechanisms have been postulated for reflux-induced cough, including (1) mechanical aspiration of gastric contents that leads to stimulation of cough receptors in the distal airways and (2) stimulation of cough receptors in the distal esophagus and the proximal stomach from refluxed acid or bile. The data currently available tend to support the second mechanism for reflux-induced cough and bronchospasm.^{9,11,13} Regardless of the mechanism responsible, the diagnosis is difficult to make if the typical symptoms of reflux and heartburn are absent. As awareness of reflux-induced asthma and cough grows, more patients are being evaluated with barium studies and esophageal pH monitoring, which often provide the correct diagnosis when clinical evaluation cannot.⁹

Specific medications may also give rise to a cough. In particular, cough is a well-recognized complication of ACE inhibitor therapy.^{3,4,7,8} Cough may also result from nonselective beta-blocker therapy or may develop as a consequence of idiosyncratic reactions to a variety of drugs and herbal remedies.

The presence of bronchogenic cancer is always a concern in a smoker with a chronic cough.^{3,5,8,21,22} Any irritation of the airway, whether intrinsic (by airway tumors) or extrinsic (by parenchymal tumors), with or without associated inflammation, can lead to coughing through mechanical or chemical stimulation of cough receptors. In the general population as a whole, a chronic cough is rarely the sole presenting symptom of developing lung cancer. In smokers, the presence of a chronic cough, in and of itself, is not particularly worrisome, but any change in the character of the cough, especially a change in sputum quality, is grounds for concern. Any degree of hemoptysis in a former smoker should be taken seriously, especially if it is not associated with an infection; prompt evaluation with a chest x-ray and, if indicated, chest CT and bronchoscopy is indicated.²³⁻²⁵

A chronic cough may also be a consequence of CHF (from any cause), though this is not a common occurrence. Mild CHF with symptoms of orthopnea at night may be associated with coughing. The diagnosis is made on the basis of a history of orthopnea and associated cardiac risk factors or valvular disease, followed by cardiac echocardiography.

Occasionally, the presence of a small unrecognized tracheobronchial foreign body can lead to chronic irritation of the bronchial epithelium and thence to a persistent cough; this presentation is more common in children than in adults.¹⁶ The diagnosis is usually made by performing bronchoscopy in a patient who is believed to be harboring a foreign body on the basis of chest imaging.

Eosinophilic bronchitis is a rare cause of chronic cough that may be suspected in patients with no other clearly explainable diagnosis.^{26,27} Patients typically have a history of atopy, and the diagnosis is made on the basis of clinical suspicion and the results of bronchial epithelial biopsy. Steroids are the mainstay of treatment.

In rare instances, a chronic cough may be the consequence of a fistula that connects some part of the airway or the lung to an adja-

cent structure (e.g., the esophagus, the mediastinum, or the pleura). Such a fistula can result from cancer, surgery, trauma, aspiration or swallowing of foreign objects (e.g., fish bones), radiation therapy, chemotherapy, or infection. In this setting, the cough is caused by secretions that enter the airway via the fistula.

In the occasional patient, a chronic cough may be of psychogenic origin.

Finally, a chronic cough can be caused by an endobronchial tumor (benign, malignant, or low-grade malignant). This is a quite rare circumstance that occasionally develops in patients who have no risk factors for lung cancer. Not uncommonly, a patient with a carcinoid tumor of the airway will have been treated with inhalers and steroids for years because of the presumptive diagnosis of asthma.

Hemoptysis

As noted (see above), hemoptysis may be a harbinger of life-threatening illness and should therefore be taken seriously in all circumstances. As a rule, the blood seen in the sputum derives from either the pulmonary arteries or the bronchial arteries^{23,25,28}; only rarely does it come from the pulmonary veins. Although the bronchial arteries provide less blood flow than the pulmonary arteries do, they supply the bulk of the blood received by the airways and, accordingly, are the source of the blood in most cases of hemoptysis. Hemoptysis can be caused by either tracheobronchial disease or pulmonary parenchymal disease [see Table 2].^{23,25,28} One should also consider the possibility that hemoptysis may be the result of an aneurysm of the aorta (or one of its main branches) that has ruptured into the lung.

CLINICAL EVALUATION

The differential diagnosis of hemoptysis, like that of cough, is quite broad. The history and the physical examination play important diagnostic roles. The presence of associated signs of other diseases (e.g., interstitial lung diseases) often helps narrow the differential diagnosis.^{23,25,28}

INVESTIGATIVE STUDIES

Any patient with significant hemoptysis should be admitted to a hospital and evaluated promptly. Routine chest x-rays are insensitive. Chest CT with contrast can often identify the cause of hemoptysis for both tracheobronchial or parenchymal lesions^{29,30}; CT scanners capable of three-dimensional helical reconstruction are especially useful in this regard. MRI has also been employed to evaluate hemoptysis, but it has no clear advantages over chest CT in this setting. Given that infection is commonly associated with hemoptysis, one should probably consider administering antibiotics to most patients. Antitussives may be helpful in patients whose hemoptysis is exacerbated by excessive coughing. Coagulopathy should be considered and, if present, corrected aggressively. Bronchoscopy is the key to the diagnosis, in that it is frequently able to define the pathology of the preceding hemoptysis (especially if the underlying condition is of tracheobronchial origin). It is particularly effective if performed within 48 hours of presentation.^{23,25,28,31} Although either flexible bronchoscopy or rigid bronchoscopy may be used, flexible bronchoscopy is preferred because it is less traumatic to the airways and generally does not require general anesthesia.

Patients with massive hemoptysis should be promptly transported to the operating room (if there is time) and selectively intubated with a rigid bronchoscope or special endotracheal tubes. Balloon catheters may be placed for selective occlusion of the air-

Table 2 Differential Diagnosis of Hemoptysis

Miscellaneous conditions	Mitral valve disease Coagulopathy

way or airways from which the hemoptysis originates, permitting ventilation to continue through the unaffected airways. A rapid evaluation must then be carried out to identify and manage the source of the bleeding. To this end, it may be necessary to perform urgent angiographic embolization of a bronchial artery, to place a stent in a pulmonary artery, or to resect a portion of the lung. Unfortunately, the majority of patients with massive hemoptysis do not survive, dying of hemorrhagic shock and suffocation. Thus, the goal of the treating physician should be to identify and treat these patients before they experience their final hemoptysis.

MANAGEMENT OF SPECIFIC CAUSES

Tracheobronchial disease is the most common cause of hemoptysis. Acute or chronic bronchitis leads to airway inflammation and sputum production, often associated with hemoptysis from the bronchial artery branches found within the mucosa; the bleeding is usually minor.^{23,25,28} Bronchiectasis leads to bronchial artery dilatation, along with cystic dilatation of the bronchial tree^{10,23,25,28}; the bleeding is often massive in this setting.

Numerous types of tracheobronchial neoplasms, including various benign and malignant primary epithelial and soft tissue tumors, have been associated with hemoptysis.³²⁻³⁹ The majority of primary airway tumors are malignant, with squamous cell carcinoma and adenoid cystic carcinoma being the primary malignancies most frequently seen in the trachea.³²⁻³⁸ The majority of malignant airway tumors, however, are metastases rather than primary malignancies. Invasion of the tracheobronchial tree by adjacent lung, thyroid, esophageal, or laryngeal tumors is not common, but it has been described.^{33,34,39,40} Colon cancers, breast cancers, melanomas, and renal cancers have been reported to metastasize to the trachea, albeit very rarely.^{39,41} There are also low-grade tumors

(e.g., carcinoid and mucoepidermal carcinoma) that present in the bronchial tree and may be associated with hemoptysis.

Tracheobronchial trauma, whether acquired or iatrogenic, is another cause of bloody sputum. Penetrating trauma to the bronchial tree or the pulmonary parenchyma, for example, can lead to significant hemoptysis, especially if a major branch of the bronchial artery is involved.^{23,25,28,42} Particularly massive hemoptysis may occur if a tracheoinnominate fistula develops after tracheostomy.⁴³⁻⁴⁵ There are two types of tracheoinnominate fistula: one develops at the tracheal stoma site as a consequence of erosion of the artery by the tracheostomy tube, and the other develops as a consequence of a more distal tracheal injury by a high-pressure cuff, which in turn injures the artery. Major bleeding can occur with either type. Prompt diagnosis with bronchoscopy is required in any patient with a tracheostomy who presents with hemoptysis; an initial "sentinel" bleed can be followed by life-threatening hemorrhage.^{24,25,46,47} Treatment usually involves stabilization with rigid bronchoscopy and immediate sternotomy to control the artery and resect the fistula.

Other forms of iatrogenic injury may occur in patients with tracheobronchial stents, which often irritate the mucosa and cause bleeding. In most cases, such bleeding is mild, but on occasion, the stents (particularly the metallic expandable ones) erode through the bronchial wall and penetrate into a major blood vessel (usually the pulmonary artery or the aorta). Hemoptysis may also occur in patients who have undergone bronchial biopsies and those in whom pulmonary arterial catheters have been placed.^{48,49} The same effect may be observed in patients who have harbored foreign bodies in the tracheobronchial tree for extended periods.²⁴

Pulmonary parenchymal disease can lead to hemoptysis as well, though less often than tracheobronchial disease does. Parenchymal infection, especially from tuberculosis and aspergillosis, is a common cause of hemoptysis.^{23,25,28,50} Aspergillosis, in particular, has a propensity for vascular invasion and thus can result in massive hemoptysis.⁵⁰ The various interstitial lung diseases (e.g., collagen vascular disorders, Goodpasture syndrome, and Wegener granulomatosis) often have hemoptysis as their primary presenting symptom.⁵¹⁻⁵³ Pulmonary embolism can lead to hemoptysis if it involves a significant portion of pulmonary parenchyma.^{23,25,28,54} Mitral valve disease with resulting left atrial hypertension can also result in hemoptysis. Any form of coagulopathy resulting from a low platelet count or a deficiency in clotting factors, therapeutic or not, can lead to hemoptysis; such conditions must be corrected in patients who experience massive or persistent episodes. Another rare cause of bloody sputum is congenital pulmonary arteriovenous malformation, which typically is diagnosed only after chest imaging.^{55,56}

12 DIAPHRAGMATIC PROCEDURES

Ayesha S. Bryant, M.S.P.H., and Robert James Cerfolio, M.D., F.A.C.S., F.C.C.P

Although the diaphragm is sometimes thought of as little more than a partition between the thoracic organs and the abdominal organs, it is in fact a dynamic anatomic structure that plays a pivotal role in the physiology of respiratory mechanics. For example, paralysis of just one hemidiaphragm can lead to the loss of 50% of a patient's vital capacity.¹ Like any other anatomic structure, the diaphragm may be affected by either benign or malignant conditions. Overall, benign diseases of the diaphragm (e.g., paralysis) are far more common than malignant ones. With either type of condition, however, the development of a safe surgical treatment strategy depends on a solid knowledge of diaphragmatic anatomy and physiology. Accordingly, we begin with a brief review of the embryology and anatomy of the diaphragm. We then describe the main procedures performed to treat the more common congenital diseases (e.g., congenital diaphragmatic hernia [CDH]) and acquired pathologic conditions (e.g., paralysis and tumor) that affect this structure.

Anatomic Considerations

DEVELOPMENTAL ANATOMY

The diaphragm is a modified half-dome of musculofibrous tissue that lies between the chest and the abdomen and serves to separate these two compartments. It is formed from four embryologic components: (1) the septum transversum, (2) two pleuroperitoneal folds, (3) cervical myotomes, and (4) the dorsal mesentery. Development of the diaphragm begins during week 3 of gestation and is complete by week 8. Failure of the pleuroperitoneal folds to develop, with subsequent muscle migration, results in congenital defects.

CLASSICAL ANATOMY

The diaphragmatic musculature originates from the lower six ribs on each side, from the posterior xiphoid process, and from the external and internal arcuate ligaments. A number of different structures traverse the diaphragm, including three distinct apertures (foramina) that allow the passage of the vena cava, the esophagus, and the aorta [see Figure 1]. The aortic aperture is the lowest and most posterior of the diaphragmatic foramina, lying at the level of the 12th thoracic vertebra. Besides the aorta, the thoracic duct and, sometimes, the azygos and hemiazygos veins also pass through this aperture. The esophageal aperture is the middle foramen; it is surrounded by diaphragmatic muscle and lies at the level of the 10th thoracic vertebra. The vena caval aperture is the highest of the three foramina, lying level with the disk space between T8 and T9.

VASCULAR SUPPLY

The diaphragm is supplied by the right and left phrenic arteries, the intercostal arteries, and the musculophrenic branches of the internal thoracic arteries. Some blood is supplied by small branches of the pericardiophrenic arteries that run with the phrenic nerve, mainly where the nerves penetrate the diaphragm. Venous

drainage occurs via the inferior vena cava and the azygos vein on the right and via the suprarenal and renal veins and the hemiazygos vein on the left.

INNERVATION

The diaphragm receives its muscular neurologic impulse from the phrenic nerve, which arises primarily from the fourth cervical ramus but also has contributions from the third and fifth rami. The phrenic nerve originates around the level of the scalenus anterior and runs inferiorly through the neck and thorax before reaching its terminal point, the diaphragm. Because the phrenic nerve follows such a long course before reaching its final destination, a number of processes can disrupt the transmission of neurologic impulses through the nerve at various points and thereby cause diaphragmatic paralysis [see 4:3 *Paralyzed Diaphragm*].

Procedures for Congenital Diaphragmatic Hernia

REPAIR OF BOCHDALEK HERNIA

Bochdalek hernia, named after the Czech anatomist Vincent Alexander Bochdalek, is the most common form of CDH and is also the most common surgical emergency in neonates.¹ The usual presenting symptoms are severe respiratory distress and a scaphoid

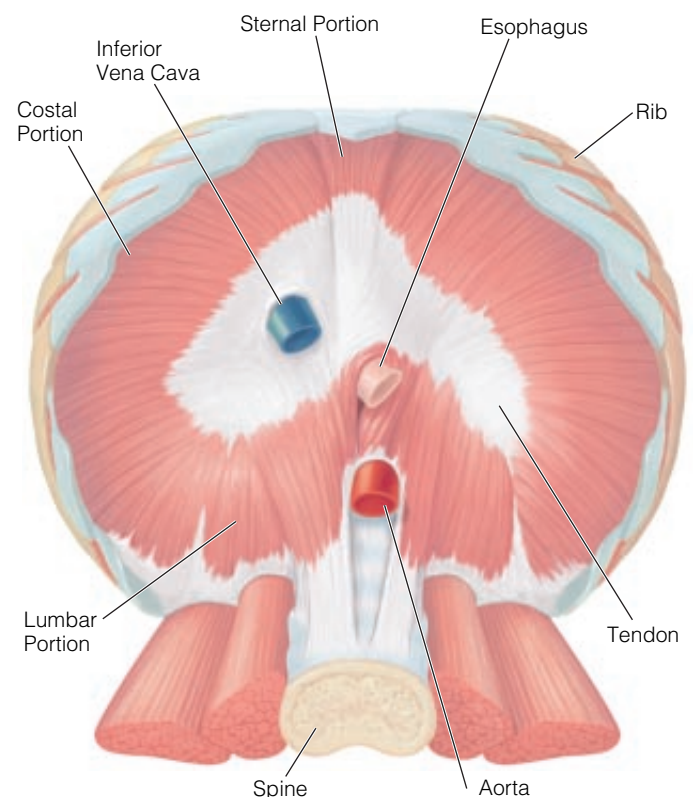

Figure 1 Shown is an inferior view of the diaphragm.

abdomen. The primary pathologic condition is the presence of posterolateral defects of the diaphragm, which result either in maldevelopment of the pleuroperitoneal folds or in improper or absent migration of the diaphragmatic musculature.

Bochdalek hernias occur in approximately one of every 2,500 live births and are twice as common in male neonates as in female neonates. Mortality ranges from 45% to 50%. The bulk of the morbidity and mortality of CDH is attributable to the resultant hypoplasia of the lung on the affected side and to various associated abnormalities (e.g., malrotation of the gut, neural tube defects, and cardiovascular anomalies).

Preoperative Evaluation

Prenatal ultrasound examination accurately diagnoses CDH in 40% to 90% of cases.² In most instances, the examination is performed to rule out polyhydramnios. It is noteworthy that polyhydramnios is present in as many as 80% of pregnant women whose fetuses have CDH.³ In neonates with CDH, besides the upper gastrointestinal tract, parts of the colon, the spleen, the kidneys, and the pancreas may herniate, and the abnormal position of these organs can be identified by means of ultrasonography. Malrotation and malfixation of the small bowel should be ruled out. Once the diagnosis is confirmed, additional radiographic, echocardiographic, and ultrasonographic studies should be performed to rule out associated anomalies.

Operative Technique

As a rule, neonates with Bochdalek hernias are taken to the operating room immediately after birth. Some studies, however, have shown that delayed surgical repair yields improved survival rates.⁴

For left-side hernias, a transabdominal subcostal approach is generally preferred, whereas for right-side hernias, a transthoracic approach may be more useful. The herniated organs are returned to the peritoneal cavity. The lung is inspected, but no attempt to expand the hypoplastic lung should be made. If any extralobar pulmonary sequestration is present (as is occasionally the case), it should be excised. Most of the defects may be closed primarily with interrupted nonabsorbable sutures; particularly large defects may be closed with a prosthetic patch. The left pleural space is drained with a chest tube, which should be placed on water seal.

Alternative technique Some surgeons have attempted surgical correction of severe Bochdalek hernias in the prenatal period. The safety and feasibility of this therapeutic approach continue to be debated. Prenatal correction of these hernias poses a risk to both the mother and the fetus, with possibly fatal results for both.⁵

REPAIR OF MORGAGNI HERNIA

Morgagni hernias, named after the Italian anatomist and pathologist Giovanni Battista Morgagni, are related to maldevelopment of the embryologic septum transversum and to failed fusion of the sternal and costal fibrotendinous elements of the diaphragm.⁶ These hernias are generally asymptomatic⁷ and are usually detected as incidental findings on radiographs. Accordingly, the average age at diagnosis is typically greater for Morgagni hernia than for Bochdalek hernia: in one report, the mean age at which the former was diagnosed was 45 years.⁸ Morgagni hernias are most commonly seen on the right side. The hernia sac usually contains omentum, but it may also contain part of the transverse colon or, less commonly, parts of the stomach, the liver, or the small bowel; almost any upper abdominal structure may herniate in this setting.

Preoperative Evaluation

On chest radiography, a Morgagni hernia appears as a mass at the right cardiophrenic angle [see *Figure 2*]. Computed tomography of the chest and abdomen, liver scintigraphy, and multiplanar magnetic resonance imaging are occasionally helpful in the diagnostic process.

Operative Technique

Morgagni hernias can be repaired via a subcostal, a paramedian, or a midline incision. We prefer to use an upper midline abdominal incision. Once the peritoneal cavity is entered, the hernia sac is identified just posterior to the xiphoid and the posterior sternal border, then opened. The herniated abdominal viscera are restored to their normal abdominal anatomic positions, and the sac is ligated. The entire hernia sac is defined, resected, and closed. The diaphragmatic defect may be repaired in several different ways, depending on its size and position. Because there is weak tissue in the area of the defect, we generally use a prosthetic patch for the repair. Either polypropylene mesh (e.g., Marlex; C. R. Bard, Inc., Murray Hill, New Jersey) or polytetrafluoroethylene (PTFE) mesh (e.g., Gore-Tex; W. L. Gore and Associates, Newark, Delaware) may be used for this purpose. We prefer PTFE because it may cause fewer adhesions to the underlying abdominal structure, which may be an important consideration if further abdominal surgery subsequently proves necessary. The prosthetic patch is sewn to the midline abdominal fascia, with wide bites taken to prevent an abdominal incisional hernia. The rest of the patch is sewn to the thickened investing fascia that made up the edges of the hernia sac. As noted, the frequently marginal quality of this tissue is the reason why a patch repair is almost always required.

Repair of a Morgagni hernia via a thoracic incision follows the same basic principles. The hernia sac is entered, the visceral contents are mobilized and reduced into the abdomen, the sac is resected, and the diaphragm is repaired. Again, the closure should be completed without tension. If the defect cannot be closed with horizontal mattress sutures, a prosthetic patch should be used.

Complications

The potential complications of surgical treatment of Morgagni hernia depend to an extent on the type of procedure undertaken to repair the defect. Laparoscopy may result in failure to reduce the contents of the hernia sac, which necessitates conversion to an open procedure. Laparotomy has been associated with postoperative pleural effusion,⁹ wound infection,¹⁰ deep vein thrombosis,¹¹ and pulmonary embolism.¹² Thoracotomy has been associated with pneumonia, sepsis, and bowel obstruction in the postoperative period.¹³

Outcome Evaluation

Most patients do not have any significant postoperative limitations after repair of a Morgagni hernia, nor are such hernias likely to recur. In one study, 16 patients who underwent transthoracic repair of a Morgagni hernia were followed for 5.7 years; no recurrences or symptoms related to the operation were reported.¹⁴

Procedures for Diaphragmatic Paralysis

The diaphragm is the most important of the respiratory muscles: diaphragmatic contraction decreases intrapleural pressure during inspiration, expands the rib cage, and thereby facilitates the movement of gases into the lungs. Accordingly, paralysis of the diaphragm can have a major adverse effect on respiratory function [see *4:3 Paralyzed Diaphragm*]. Diaphragmatic paralysis may involve

Figure 2 Repair of Morgagni hernia. The differential diagnosis of a cardiophrenic-angle mass includes pericardial fat, a lipoma, a pericardial cyst, a Morgagni hernia, and a thymoma. Shown are (a) chest x-rays and (b) chest CT scans from a 33-year-old man with an incidental finding of a Morgagni hernia.

either the whole diaphragm (bilateral paralysis) or only one leaflet or hemidiaphragm (unilateral paralysis). The possible causes of diaphragmatic paralysis are numerous [see Table 1]; the most common causes are phrenic nerve trauma related to a surgical procedure (e.g., stretching, crushing, or transection) and invasion by a malignant neoplasm.

DIAPHRAGMATIC PPLICATION FOR UNILATERAL PARALYSIS

Preoperative Evaluation

With unilateral diaphragmatic paralysis, the paralyzed hemidiaphragm paradoxically moves upward on inspiration and downward on expiration, passively following changes in intrapleural and intra-abdominal pressure. Patients with a paralyzed hemidiaphragm who are otherwise healthy usually have no symptoms at rest but experience dyspnea during exertion and show a decrease in exercise performance. Physical examination may reveal dullness to percussion and an absence of breath sounds over the lower chest on the involved side.

In most cases, the diagnosis of hemidiaphragmatic paralysis is suspected on the basis of incidental findings on a chest x-ray. Typically, the roentgenogram reveals an elevated hemidiaphragm, diminished lung volume, and basilar atelectasis. Fluoroscopy may also be performed. The diagnosis is confirmed by performing a fluoroscopic sniff test, in which paradoxical elevation of the paralyzed diaphragm is observed with sniffing.¹⁵ The sniff test is the gold standard for the diagnosis of this condition. In certain patients, a chest CT scan may be indicated for evaluating the potential cause of the paralysis. If an obvious cause is not apparent from the history or a previous evaluation, CT scanning of the chest should be performed to ensure there is no pathologic process that is compressing or invading the phrenic nerve. Similarly, MRI of the neck or the spine may be indicated in certain patients to look for conditions that might be causing the diaphragmatic paralysis.

Two other tests that are also (albeit less commonly) used for the diagnosis of unilateral diaphragmatic paralysis are electromyography and transdiaphragmatic pressure assessment. In the first, the phrenic nerve is electrically stimulated in the neck in an effort to

Table 1 Common Causes of Diaphragmatic Paralysis

distinguish between neuropathic and myopathic causes of paralysis. In the second, transdiaphragmatic pressures are measured by placing a thin-walled balloon transnasally at the lower end of the esophagus in such a way as to reflect changes in pleural pressure; a second balloon manometer is then placed in the stomach in such a way as to reflect changes in intra-abdominal pressure. The difference between the two pressures is the transdiaphragmatic pressure. Measurement of transdiaphragmatic pressure can help differentiate diaphragmatic paralysis from other causes of respiratory failure.

Yet another test involves measurement of maximal inspiratory pressures. Patients with diaphragmatic dysfunction and paralysis show a decrease in their maximal inspiratory pressures. These patients cannot generate high negative inspiratory pressures, and thus, their maximal inspiratory pressures will be less negative than -60 cm H₂O.

Operative Planning

Surgical treatment of hemidiaphragmatic paralysis is reserved for symptomatic patients who, after a follow-up period of at least 6 months, have persistent shortness of breath with exertion that is sufficiently pronounced to interfere with lifestyle. For a patient to be considered for operation, the sniff test should show significant paradoxical motion.

The basic principle of the surgical procedure is to “reef” (i.e., reduce the surface area of) the redundant floppy diaphragm by plicating it. This measure lowers the resting position of the hemidiaphragm and thus affords the lung the opportunity to expand fully. The effective result is an increase in the functional vital capacity of the ipsilateral lung. A 2002 study found that plication of the diaphragm led to long-term improvements in pulmonary function test results, as well as reduced dyspnea.¹⁶

Operative Technique

Diaphragmatic plication may be performed with either sutures or staples; we prefer sutures for this procedure. The chest is entered through a thoracotomy in the seventh or eighth intercostal space. Horizontal mattress sutures buttressed with Teflon pledgets are then placed in a lateral-to-medial direction [see Figure 3]. We typically use monofilament nonabsorbable sutures that pass easily through the muscle and can be tightened without dragging through tissue. To distribute the tension, multiple sutures must be placed; this is especially important on the right side, where the diaphragm must be pulled down against the upward force exerted by the presence of the right hemiliver. When the sutures are tied, the hemidiaphragm should be almost back to its normal anatomic location. Care must be taken to ensure that the repair is not under undue tension: excessive tension is likely to result in early dehiscence. Occasionally, a prosthetic patch may be used to buttress the repair further, but in the majority of cases, this measure should be unnecessary. If the choice is made to use staples rather than sutures, care must be taken to ensure that the underlying abdominal contents are not caught in the staple line.

DIAPHRAGMATIC PACING FOR BILATERAL PARALYSIS

Preoperative Evaluation

In patients with bilateral diaphragmatic paralysis, the respiratory accessory muscles assume all the work of breathing by contracting more intensely. Both hemidiaphragms move upward on inspiration, concomitant with inward (rather than the normal outward) movement of the abdominal wall.¹⁷ Patients typically present with severe respiratory failure or with dyspnea (sometimes misinterpreted as a sign of heart failure) that worsens in the supine position, and they generally exhibit tachypnea and rapid, shallow

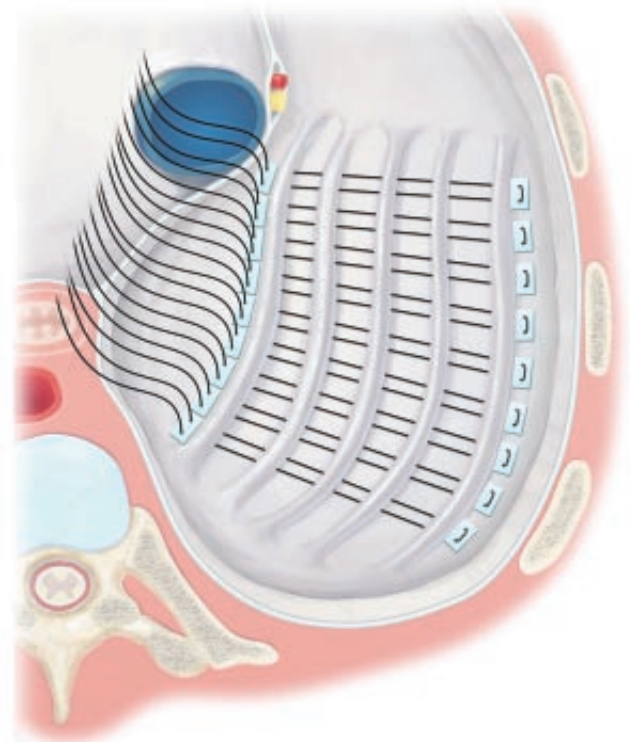

Figure 3 Diaphragmatic plication. Shown is suture plication of the right hemidiaphragm. Placement of sutures buttressed with pledgets extends anteriorly to the level of the vena cava.

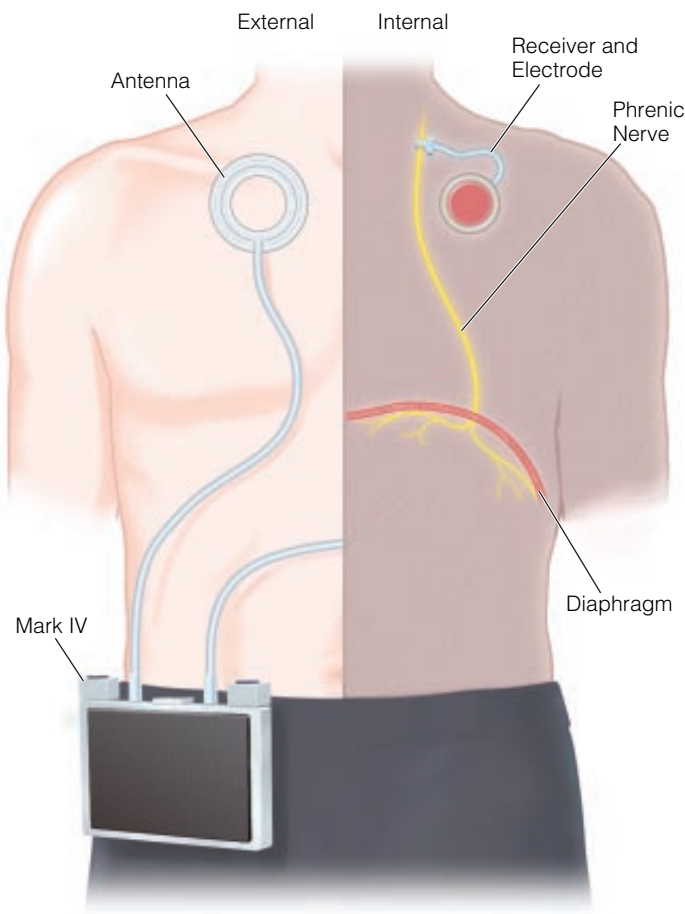

Figure 4 Diaphragmatic pacing. Shown are internal and external pacer connections.

breathing when in the recumbent position. Increased expenditure of effort in the struggle to breathe may fatigue the accessory muscles and lead to ventilatory failure. Patients also report anxiety, insomnia, morning headache, excessive daytime somnolence, confusion, fatigue, poor sleep habits, and signs of cor pulmonale.¹⁸

During physical examination, auscultation of the chest reveals limitation of diaphragmatic excursion and bilateral lower-chest dullness with absent breath sounds. The finding that establishes the diagnosis is a paradoxical inward movement of the abdomen with inspiration. As with unilateral diaphragmatic paralysis, however, it is more common for the diagnosis to be suspected on the basis of a chest roentgenogram that shows bilateral diaphragmatic elevation, then confirmed by means of the sniff test.

Operative Planning

Treatment depends on the cause and severity of the diaphragmatic paralysis. Most patients are treated with ventilatory support, but some are treated with bilateral plication or with pacing. Plication for bilateral paralysis is performed in the same way as plication for unilateral paralysis [see Diaphragmatic Plication for Unilateral Paralysis, *above*], except that both hemidiaphragms are lowered. Diaphragmatic pacing is not useful in the treatment of unilateral diaphragmatic paralysis, because of the difficulty of synchronizing the contractions of the normal hemidiaphragm with those of the paralyzed hemidiaphragm. However, it is sometimes an appropriate choice for the treatment of bilateral paralysis, especially in patients who have a central condition that is causing their apnea. Because the phrenic nerve stimulates the C3, C4, and C5

anterior horn cells in the nerve roots, diaphragmatic pacing is feasible only when the lesion is above the C2-C3 level. Accordingly, it is sometimes employed in patients with high spinal cord injuries.

To date, only one pacing device has been approved by the Food and Drug Administration: the Mark IV Breathing Pacemaker System (Avery Biomedical Devices, Commack, New York). This device possesses an internal component and an external component [see Figure 4]. The internal component is surgically placed adjacent to the skeletonized phrenic nerve and is connected to a small, wafer-shaped receiving unit placed under the skin. A battery-powered external transmitting box connected to an antenna is taped over the surface of the skin, just above the subcutaneous receiver. This transmitting box permits adjustment of pulse duration, pulse train duration, respiratory rate, pulse frequency, and current amplitude. In most patients, the only parameters that the clinician adjusts are current amplitude and respiratory rate.

Implantation of a diaphragmatic pacer requires significant experience on the part of the surgeon—not so much because of any particular technical demands imposed by the implantation itself but because of the procedures for diaphragm training that must be carried out in the postoperative period.

Choice of surgical approach Surgical implantation of a diaphragmatic pacer can be done via either a cervical approach or a thoracic approach. The primary advantage of the cervical approach is that it avoids the morbidity associated with bilateral thoracotomies, which may not be well tolerated in patients who have marginal pulmonary function or a history of severe pulmonary contusions. However, there are other ways of avoiding this morbidity, such as using video-assisted thoracoscopic surgery (VATS) or performing small muscle-sparing, rib-sparing, nerve-sparing thoracotomies.¹⁹ One disadvantage of the cervical approach is that in a small percentage of patients, the current amplitude necessary to stimulate the phrenic nerve results in transmission of the current through the soft tissues. The transmitted current stimulates the functioning portions of the brachial plexus, causing rhythmic jerking motions of the upper extremities. Another disadvantage is that there are a number of accessory nerve branches arising distal to the neck.

One advantage of the thoracic approach is that inadvertent stimulation of portions of the brachial plexus (as sometimes occurs with the cervical approach) may be avoided. Another advantage is that there is some neuroanatomic evidence that a small branch of the phrenic nerve joins the main nerve trunk only after it enters the chest cavity; thus, the thoracic approach may stimulate a larger portion of the phrenic nerve than the cervical approach would. The disadvantage of the thoracic approach is the preconceived notion that entry into the chest is associated with a higher morbidity than entry into the neck.

Operative Technique

Cervical placement In the neck, the phrenic nerve runs between the scalenus anterior and the scalenus medius. A transverse skin incision is made in the midportion of the neck, just lateral to the sternocleidomastoid muscle, and the borders of the two scalene muscles are dissected. The scalene muscles are then divided, and the phrenic nerve is identified lying in a layer of fascia just anterior to the anterior surface of the scalenus medius. Identification of this nerve is often facilitated by the use of a handheld nerve stimulator. Intraoperative fluoroscopy allows observation of diaphragmatic contraction in response to phrenic nerve stimulation, which confirms that pacing is successful.

Once the phrenic nerve is identified, it is carefully dissected free of its investing fascia, and the Y-shaped electrode is placed under

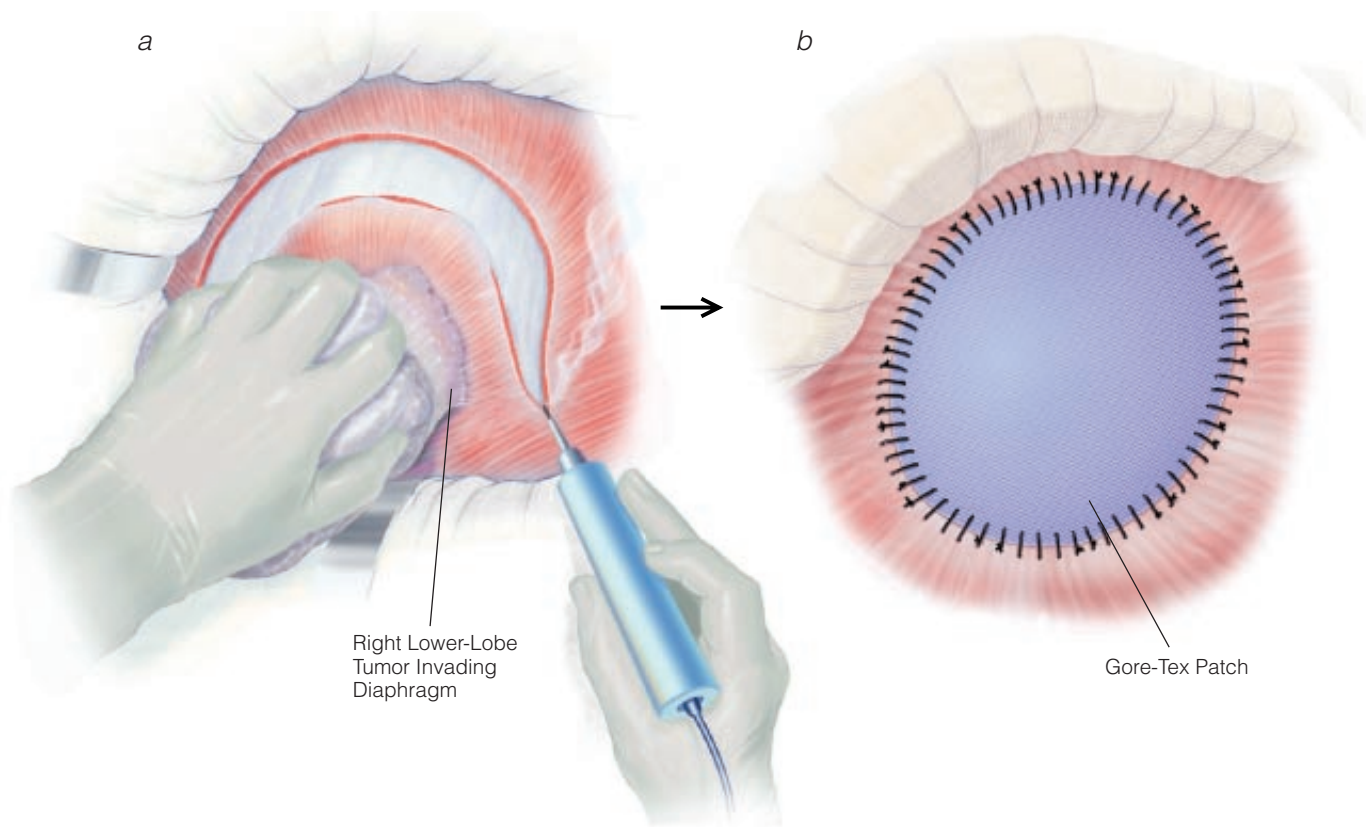

Figure 5 Resection of diaphragmatic tumor. The patient has a right lower-lobe bronchogenic malignancy with erosion into the right hemidiaphragm. (a) The tumor is resected en bloc with the diaphragmatic fibers; the electrocautery is used to achieve clear surgical margins and hemostasis. (b) The defect in the right hemidiaphragm is closed with a mesh patch.

it and secured with sutures. Care must be taken to ensure that the nerve is not injured during this step. The connecting wire from the electrode is then tunneled subcutaneously to a subcutaneous pocket that is created just below the ipsilateral clavicle. The connections are made and sealed, and the small incisions are closed.

Thoracic placement In the thoracic approach, the chest is entered through a high thoracotomy (usually over the fourth interspace), and the proximal phrenic nerve is identified. On the right side, the nerve lies along the mediastinum, situated just anterior to the vena cava and coursing along the pericardial surface. On the left side, it lies on the pericardium for most of its length. The proximal nerve is freed of its fibrous investments, and the electrode is placed under it and secured with sutures. The electrode is connected to the receiver, which is placed in a subcutaneous pocket.

As noted (see above), there are alternative approaches to pacer implantation that avoid the cervical approach but also do not involve standard thoracotomies. For example, there is limited (but growing) experience with thoracoscopic placement of phrenic nerve pacing leads.²⁰ In addition, laparoscopic implantation of intramuscular pacing electrodes onto the inferior aspect of the diaphragm has been reported.²¹

Taking into account all the advantages and disadvantages of each approach to pacer implantation, we generally prefer the thoracic approach, either via VATS or via a thoracotomy.^{20,22} The evolution of less invasive surgical techniques may allow the thoracic approach to be employed in patients who are unable to tolerate thoracotomy.

Complications

Besides the usual complications associated with any thoracic procedure (i.e., infection, bleeding, atrial fibrillation, and pneumonia),

there are several specific complications associated with diaphragmatic pacing. The most common of these are dislodgment of the pacer electrode, transmission of pacer impulses to the brachial plexus with resultant rhythmic jerking of the upper extremity (seen with cervical placement of the electrode), and hardware malfunction.

Outcome Evaluation

Retrospective analysis of the collective experience at a single center between 1981 and 1987 suggested that long-term pacing did not lead to progressive diaphragmatic dysfunction.²³ Six of the 12 patients in this cohort continued to undergo diaphragmatic pacing on a full-time basis for a median period of more than 14 years. Pacing was well tolerated in this group; the reasons for discontinuance included intercurrent medical illness and lack of social support. Concerns have been raised that prolonged diaphragmatic pacing might damage the phrenic nerve. In the series cited, however, the ability to pace the phrenic nerve was not lost in any of the patients, and the mean threshold currents for pacing did not change significantly over time.

Resection of Diaphragmatic Tumors

Primary tumors of the diaphragm are extremely rare. Benign tumors (e.g., lipomas and cystic masses) are more common than malignant tumors, which mostly are sarcomas of fibrous or muscular origin. Thoracic and abdominal tumors (e.g., bronchogenic carcinomas, pleural malignancies, and chest wall malignancies [see 4:2 Chest Wall Mass]) may involve the diaphragm secondarily through direct extension. Malignant pleural mesothelioma represents a different scenario and is not discussed here. Schwannomas, chondromas, pheochromocytomas, and endometriomas have all been re-

ported. Bilateral occurrence, calcification, sharp margins, and flattened contours are indicative of a malignant process, such as pleural metastases, mesothelioma, or a primary diaphragmatic tumor.

The most common indication for diaphragmatic resection is mesothelioma. This remains true even though mesothelioma is relatively uncommon in comparison with bronchogenic malignancy and even though few patients with mesothelioma are actually candidates for resection. Again, resection of a mesothelioma is not addressed here. The ensuing operative description focuses on diaphragmatic resection to treat either a lung cancer invading the diaphragm or a primary diaphragmatic tumor [see *Figure 5*].

OPERATIVE TECHNIQUE

Once the decision is made to resect a tumor involving the diaphragm, the key considerations are (1) the surgical approach to be taken and (2) the placement of the incision in the diaphragm. We prefer a skin incision that is lower and slightly more anterior than a normal posterolateral thoracotomy; such an incision allows easy entry over the top of the seventh rib. After entry into the chest, the lung, the pericardium, and the pleural surface are carefully visualized and palpated to search for any signs of metastatic disease.

Next, the incision in the diaphragm is planned. Ideally, the incision should be made anterior or lateral to the tumor so that a hand can be placed easily into the peritoneal cavity [see *Figure 5a*]. Intra-abdominal palpation confirms that the tumor has not extended into underlying structures. This information is almost always gleaned from the preoperative CT scan, but if any uncertainty remains after the scan, diagnostic laparoscopy may be performed before the thoracotomy to look for possible tumor extension.

The tumor is then resected with 2 to 4 cm margins. The large arteries that course through the diaphragmatic fibers are ligated. It is our practice also to place a few silk sutures (stay stitches) in

the edges of the defect; this prevents the edges from retracting, helps keep the defect as small as possible, and keeps abdominal contents from interfering with the resection. In addition, we place clips on the edges for guidance purposes, in case adjuvant radiotherapy is delivered after the operation. If adequate margins are obtained, which is usually relatively easy in a diaphragmatic resection, postoperative radiotherapy should be unnecessary. If, however, the tumor abuts vital structures (e.g., the suprahepatic vena cava), postoperative radiotherapy may have a useful role to play.

Once the entire tumor has been resected and clear margins have been confirmed by frozen-section examination, the diaphragm is reconstructed. Primary repair is rarely indicated, because in most cases, the defect is too large and the tension on the repair would be too great. Moreover, the tissue in the anterior aspect of the diaphragm is thin and is likely to tear under tension. Accordingly, repair with a prosthetic patch is the usual choice. Infection of such a patch is exceedingly rare, and with the exception of the cost, there is little downside to the use of prosthetic material in this setting. As in the repair of a CDH, we prefer PTFE mesh [see *Figure 5b*] to polypropylene mesh because it is less likely to adhere to underlying abdominal structures.

The mesh patch is sewn to the edges of the defect (preferably with nonabsorbable suture material, such as 0 polypropylene), starting at the most anterior and inferior portion of the opening and continuing toward the surgeon [see *Figure 5*]. The inferior half of the repair is done with a continuous suture. The repair is completed with two or three sutures, which are tied circumferentially. To prevent paradoxical motion, the diaphragm must not be too redundant or floppy. It should remain in the normal anatomic position so that the remaining lung can expand completely. In general, however, it is best to keep the repair taut so as to optimize pulmonary mechanics after the procedure.

13 MEDIASTINAL PROCEDURES

Joseph B. Shrager, M.D., F.A.C.S., and Vivek Patel, M.B.B.S.

Procedures for Lesions of the Anterior Mediastinum

More than half of all mediastinal masses arise from the anterior compartment. Most primary malignancies of the mediastinum also develop in the anterior mediastinum. Because of the narrowness of the space that makes up the thoracic inlet, as well as the presence of the trachea and esophagus traversing this region, anterior mediastinal masses become symptomatic earlier than their counterparts in other anatomic spaces of the mediastinum. Whereas adults with masses of the middle or posterior mediastinum usually report no significant symptoms, more than 50% of patients with anterior mediastinal masses present with chest pain, fever, cough, dyspnea, dysphagia, or vascular obstruction. Thymic neoplasms and lymphoma, the two most common masses in the anterior mediastinum, may have systemic manifestations (e.g., weakness associated with myasthenia gravis [MG] or symptoms associated with International Working Formulation [IWF] group B lymphoma).

In what follows, we focus on surgical approaches to diagnosis and treatment of the more common neoplasms of the anterior mediastinum, including thymic tumors, lymphomas, and germ cell tumors. Embryologic anomalies and neoplasms arising from normal structures in this region broaden the differential diagnosis [see Table 1]. Finally, we address thymectomy for MG, a procedure that is frequently performed even in the absence of neoplastic disease.

PREOPERATIVE EVALUATION

In a patient with an anterior mediastinal mass, it is frequently possible to make a strong provisional diagnosis of the tumor type on the basis of clinical evaluation and diagnostic imaging.¹ As noted (see above), the presence of systemic manifestations may be helpful. Physical examination must include examination of peripheral lymph node groups and testes. Computed tomography yields valuable information about the anatomic location of the tumor, its characteristics (i.e., fatty, solid, or cystic), and its degree of invasiveness (if any) [see Figure 1]. Occasionally, magnetic resonance imaging provides useful additional information about the obliteration of normal tissue planes.

Lymphoma is the most likely diagnosis in persons younger than 40 years, and the presence of IWF group B symptoms further raises the level of suspicion. The presence of palpable remote adenopathy or an elevated serum lactic dehydrogenase (LDH) level is also suggestive.² When peripheral nodes are palpable, the diagnosis may be most easily obtained by excising one of them. Patients with suspected lymphoma who have an isolated anterior mediastinal mass should undergo core-needle biopsy or a Chamberlain procedure (anterior mediastinotomy), depending on the pathologists' level of comfort with classifying lymphoma on the basis of small specimens at one's institution. Resection of lymphoma is not indicated; it may be avoided by performing a diagnostic biopsy whenever lymphoma is suspected.

Unlike lymphomas, thymic neoplasms are uncommon before the fourth decade of life. Thymoma [see Figure 1a] may be associated with any of several paraneoplastic syndromes. MG occurs in conjunction with a pathologic condition of the thymus—either

thymoma or thymic hyperplasia—in 80% to 90% of cases. Thymoma may also be associated with pure red cell aplasia, agammaglobulinemia, systemic lupus erythematosus, and various autoimmune disorders. The presence of any of these associated syndromes essentially clinches the diagnosis of thymoma. Autoantibodies to the acetylcholine receptor (anti-AChR antibodies) should be measured: their presence is diagnostic of MG, and they are found in nearly 60% of patients who have thymoma without neurologic symptoms.³ Once the diagnosis of thymoma has been made, the goal is to proceed to direct resection without preliminary biopsy; these tumors have a predilection for local recurrence once the capsule has been violated.

nign, are diagnosed in the second or third decade of life. Benign teratomas are usually well encapsulated, with frequent recapitulation of one or more tissue elements seen on radiography.⁴ The appearance of the lesions on CT is often diagnostic [see Figure 1b]. Surgical extirpation is the mainstay of treatment for these mature germ cell tumors, and biopsy is not indicated. Malignant germ cell tumors, on the other hand, are treated with primary chemotherapy, radiotherapy, or both; when suspected, they should undergo biopsy rather than proceed directly to resection. Characteristic serum tumor markers, including β -human chorionic gonadotropin (β -hCG) and alpha-fetoprotein (AFP), are elaborated by most malignant germ cell neoplasms but are not found in benign germ cell tumors.⁵ Elevation of the AFP level beyond 500 ng/ml is considered diagnostic of a nonseminomatous component in a malignant germ cell tumor and is usually associated with a concomitant increase in serum β -hCG levels.⁶ In the absence of any marked elevation in the AFP or β -hCG level, percutaneous needle biopsy usually suffices to establish the diagnosis.

OPERATIVE PLANNING

Biopsy versus Resection

Clearly, the decision whether to perform a biopsy of an anterior

or mediastinal mass is not a simple one. Routine biopsy should be avoided, not only because of the cost and the unnecessary morbidity but also because of the risk that biopsy may spread thymoma. The choice to proceed with biopsy should be made according to which tumor type is believed to be most likely on the basis of the diagnostic workup.

Well-encapsulated lesions that are believed not to represent lymphoma are resected, without a preceding biopsy, for both diagnosis and treatment. Neoplasms that commonly fall into this category include noninvasive thymomas, mature teratomas, mesenchymal tumors, and, occasionally, benign cysts. Patients with MG should be offered thymectomy, whether they have a thymic mass or not.

When lymphoma is suspected, biopsy is required. The technique employed should be minimally invasive while still permitting the acquisition of a sufficient tissue sample. CT-guided core needle biopsy may be attempted, but frequently, this technique does not provide enough tissue for the analyses required to classify the tumor.^{7,8}

For anterior mediastinal masses that appear to be locally invasive or frankly unresectable, biopsy is also preferable to immediate resection. Such lesions may represent aggressive thymomas that may benefit from neoadjuvant treatment, malignant germ cell tumors, or other rare disease processes. Once the decision has been made to proceed with biopsy rather than resection, selection of a biopsy approach is based on anatomic considerations and patient factors.

BIOPSY OF ANTERIOR MEDIASTINAL MASS

Chamberlain Approach

Anterior parasternal mediastinotomy (the Chamberlain procedure) is favored by most surgeons for biopsy of lesions in the anterior mediastinum and the aortopulmonary window. It is usually done under general anesthesia, though local anesthesia may be used instead, and it does not require single-lung ventilation. This operation affords good exposure and allows generous biopsy specimens to be taken, and it can be performed as an outpatient procedure.

Operative technique *Step 1: initial incision.* A 5 cm transverse incision is made over the second costal cartilage on the side to be operated on (the second cartilage is identified by its continuity with the sternal angle). The pectoralis major is separated in a direction parallel to the direction of its fibers, and the cartilage is resected in a subperichondrial plane [see Figure 2]. Leaving perichondrium behind facilitates postoperative regrowth of the cartilage.

Step 2: dissection and exposure. The posterior perichondrium is incised, and the parietal pleura is bluntly dissected laterally with a peanut sponge; this affords entry into the mediastinal fat and direct access to the tumor mass. Almost invariably, the internal mammary vessels can be mobilized medially and preserved, but if necessary, they may be ligated to improve exposure.

Step 3: biopsy. A generous wedge-shaped portion of the mass is excised with a scalpel. Frozen-section examination is then performed to confirm that diagnostic tissue has been obtained. It is important to remember to request that flow cytometry be performed on the specimen.

Step 4: closure. The posterior perichondrium is reapproximated, followed by the pectoralis major, the subcutaneous fat, and the skin.

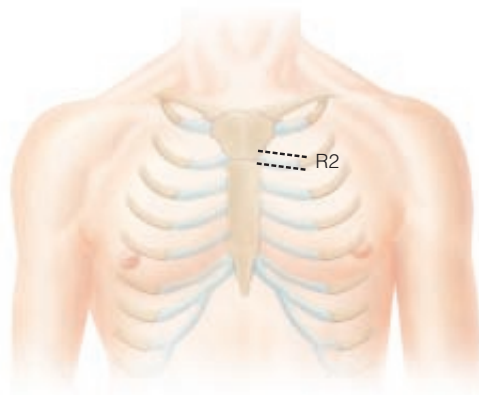

Figure 2 Biopsy of anterior mediastinal mass: Chamberlain approach. Depicted are incision and subperichondrial resection of the second costal cartilage.

Troubleshooting If the pleura was entered, a red rubber catheter is used to evacuate the pleural space as the lung is inflated with a large positive pressure breath, and the catheter is withdrawn through the layers of closure. A small postoperative pneumothorax is almost always attributable to residual air rather than to an ongoing air leak.

Sometimes, the tumors are fairly vascular and bleed moderately after biopsy is performed. This bleeding can always be controlled with electrocauterization. We often leave an absorbable hemostatic agent in place as well.

Transcervical Approach

As an alternative to the Chamberlain procedure, a mass of the anterior mediastinum may be approached for biopsy through a cervical incision, exactly as in a transcervical thymectomy [see Resection of Anterior Mediastinal Mass, Transcervical Approach, below]. The use of a Cooper thymectomy retractor (Pilling Company, Fort Washington, Pennsylvania), which elevates the sternum, affords excellent exposure of the anterior mediastinum and sometimes allows direct examination to ascertain the invasiveness of an otherwise uncertain mass. In most cases, general anesthesia is required, but transcervical biopsy can be performed as an outpatient procedure. We have used this technique at our institution and have achieved results comparable to those of anterior mediastinotomy.⁹ Proper performance of this procedure does, however, require a level of experience with the technique that is not widely available.

Video-Assisted Thoracic Surgery

Video-assisted thoracic surgery (VATS) has been applied to diagnostic biopsy [see 4:7 *Video-Assisted Thoracic Surgery*], but VATS biopsy procedures are not widely employed in the anterior mediastinum. The necessity of single-lung ventilation adds a level of complexity to the procedure beyond what is required for the Chamberlain procedure or the transcervical approach. Furthermore, intercostal incisions are frequently more painful than transcervical incisions or anterior mediastinotomies. VATS does have certain advantages that may be of value in individual cases, such as the capacity to provide simultaneous access to other compartments of the mediastinum and the ability to evaluate the pleural

space for evidence of tumor dissemination. Robot-assisted thoracoscopic procedures for anterior mediastinal masses have also been described,¹⁰ but their availability does not eliminate the major objection to transpleural approaches to mediastinal masses—namely, the possibility of spreading a disease that had been contained within the mediastinum into the pleural space.

RESECTION OF ANTERIOR MEDIASTINAL MASS

Operative Planning

The most frequent indications for resection (as opposed to biopsy) of an anterior mediastinal mass are (1) thymoma and (2) thymectomy for MG. The principles underlying thymoma resection can be applied to resection of other, rarer anterior mediastinal masses. The first successful resection of a thymic mass for MG was described in 1939.¹¹ Since the introduction of transcervical thymectomy (TCT), there has been ongoing debate regarding the optimal method for thymectomy in patients with nonthymomatous MG. There is little debate, however, regarding the optimal approach to resection of anterior mediastinal malignancies.

For all primary invasive masses of the anterior mediastinum—including invasive thymomas, malignant germ cell tumors (after systemic treatment), thymic carcinomas, and other, less common malignancies—the most important prognostic factor is complete resection. Accordingly, the operative approach must be selected with an eye to providing optimal exposure. There is little doubt that a full median sternotomy is ideal in this regard. However, a less than full sternotomy is a reasonable choice for small (< 3 cm) noninvasive thymomas or other noninvasive mediastinal tumors (e.g., mature teratomas), particularly when the diagnosis of thymoma is in doubt before operation. In such situations, we usually begin with TCT,¹² but we do not hesitate to convert to a sternotomy if unexpected invasion is identified. Some surgeons have employed a partial upper sternotomy in these settings; however, this approach limits exposure, and we do not believe that it actually reduces morbidity in comparison with a full sternotomy.

En bloc resection of malignancies is mandatory, and resection of adjacent serosal membranes (including pleura or pericardium) is required if there is any suggestion of attachment during the operation. Resection of adjacent lung parenchyma is not uncommon.

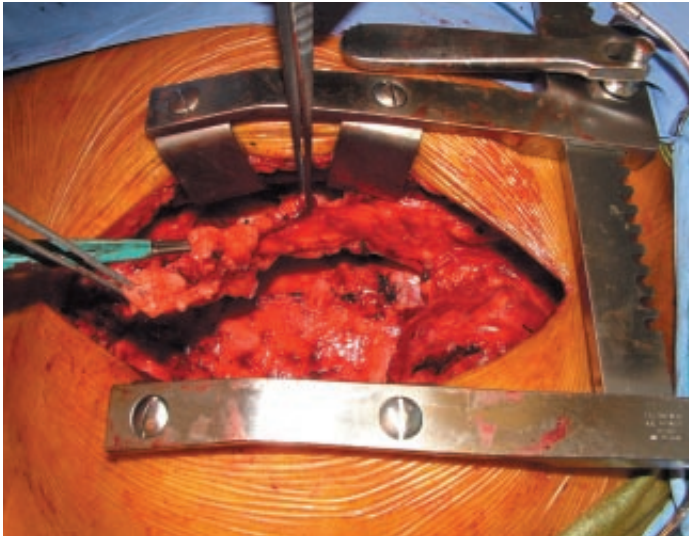

Figure 3 Resection of anterior mediastinal mass: median sternotomy approach. Intraoperative photo shows dissection of the right inferior thymic pole and associated mediastinal fat.

mon, and resection of the great vessels has been performed with both technical success and good long-term survival. All great vessels resected must be reconstructed, with the exception of the innominate vein, which may be ligated with little deleterious effect. Every effort should be made to preserve the phrenic nerves: damage to even one of these nerves can be disastrous in an already weakened myasthenia patient. In a patient with a malignancy, however, one phrenic nerve may be sacrificed if tumor invasion necessitates this step, provided that the patient's preoperative respiratory status is acceptable and curative resection is likely.

In cases of thymectomy for advanced MG, every effort must be made to optimize the patient's condition preoperatively. To this end, a multidisciplinary approach that includes a neurologist and, possibly, a pulmonologist is necessary. If the disease does not stabilize with medication (e.g., pyridostigmine, steroids, or intravenous γ -globulin), preoperative plasmapheresis may be required. The question of which MG patients should be offered thymectomy is, at best, difficult to answer. Most studies have found the impact of thymectomy to be greater if it is performed early. Accordingly, our practice is to offer TCT sooner in the course of the disease rather than later; however, we will perform the procedure at any stage, from ocular-only disease to severe, generalized weakness. Because TCT is associated with minimal morbidity, requires only a small incision, and can generally be done as an outpatient procedure, it is a very attractive option for patients with milder disease. At the same time, it is also more easily tolerated by patients with severe disease than a median sternotomy is.

An approach to thymectomy for MG that is favored by a few surgeons is so-called maximal transsternal-transcervical thymic resection, which combines a median sternotomy with an additional neck incision to provide wide access to all areas where thymic tissue has been identified. The rationale for such extensive exposure is the observation that thymic tissue may reside in several extrathymic locations. Proponents of the maximal approach argue that if thymectomy for MG is to provide optimal benefit, it should include removal of all of this extraglandular thymic tissue. This approach has never been compared with TCT in a randomized trial, but in our view, most of the available data suggest that remission rates after maximal transsternal-transcervical thymic resection

are not remarkably different from those after TCT, which is much less invasive. Because we do not personally perform the maximally invasive procedure, we do not describe it in this chapter.

Median Sternotomy Approach

As noted (see above), the standard approach to masses of the anterior mediastinum is via a median sternotomy. Resection of a thymoma of the anterior mediastinum is performed as follows.

Operative technique *Step 1: initial incision and exposure.* The patient is placed in the supine position and intubated with a single-lumen tube. If direct extension to the lung is considered a possibility, a double-lumen tube is placed. The skin incision typically extends from 2 cm below the jugular notch to the xiphisternal junction; however, depending on the extent of the expected pathologic condition, the incision may be shortened further and the full sternum divided by reaching beneath skin flaps. Finger dissection is performed beneath the sternum to rule out tumor invasion into the posterior sternal table. If the posterior sternal table is clear, the sternum is divided, hemostasis is achieved, and the edges are separated with a sternal retractor.

Step 2: determination of resectability. The anterior mediastinum is inspected, the mass is visually identified, and an initial assessment of resectability is undertaken.

Figure 4 Resection of anterior mediastinal mass: median sternotomy approach. View from feet shows the thymus and tumor mobilized off the innominate vein. The entire right thymus (both the upper and the lower pole) has been fully mobilized.

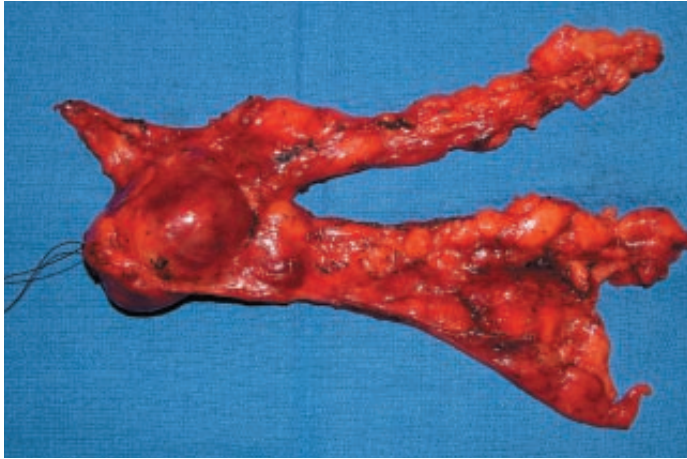

Figure 5 Resection of anterior mediastinal mass: median sternotomy approach. Shown is the resected thymoma specimen.

Step 3: mobilization of inferior poles of thymus. Dissection of the thymus begins at the caudad aspect, with the inferior poles mobilized first from the underlying pericardium through electrocautery dissection. It is difficult to determine by visual means precisely where thymic tissue merges into simple mediastinal fat; accordingly, to ensure complete resection of the thymus, all fatty tissue between the phrenic nerves and down to the level of the diaphragm is removed with the specimen. The mediastinal pleura, to which this fatty and thymic tissue tends to be adherent, is also taken with the specimen [see Figure 3].

Step 4: continuation of dissection cephalad. As dissection proceeds cephalad, the phrenic nerves are identified and followed along their entire path up to the point where they course beneath the innominate vein. Sharp dissection often must be carried very close to the nerves to secure an adequate tumor margin. It is advisable to clip small vessels near the nerve before dividing them, so as to prevent irritating bleeding, which can be difficult to control without compromising the nerve.

Figure 6 Resection of anterior mediastinal mass: median sternotomy approach. Hemiclamshell incision provides exposure to masses located at the thoracic apex.

The arteries supplying the thymus, arising laterally via branches from the internal mammary vessels, are ligated and divided as they are encountered. Care must be taken to stay away from the phrenic nerves while controlling the arterial blood supply.

Step 5: mobilization of superior poles of thymus. Dissection is then continued in the neck, where the two cervical extensions are isolated by means of gentle traction and blunt dissection and followed until they trail off into the thyrothymic ligament. This ligament is clamped, divided, and ligated superiorly at a point where only a small blood vessel is present and no visible glandular tissue remains.

Step 6: dissection of thymus from innominate vein. The cervical poles are followed down over the innominate vein. Sharp dissection is continued onto the surface of the vein, and the two to five veins draining the gland into the innominate vein are ligated and divided [see Figure 4].

Step 7: removal of specimen. Once the body of the thymus has been freed from the innominate vein, the H-shaped gland and the associated mass are removed [see Figure 5]. If the clean plane between the mass and the underlying pericardium—a plane normally composed of fine, filmy adhesions—is at all compromised, one should not hesitate to resect a portion of the pericardium en bloc with the specimen, with care taken to maintain a gross margin of at least 2 cm at all times.

Step 8: closure. Two pleural drains that traverse the mediastinum and reach the apex of each hemithorax are placed, and the sternum and the soft tissues are reapproximated in layers.

Troubleshooting If invasion of great vessels is considered a possibility before the start of the operation, the groin should be prepared and draped into the field to provide access for cardiopulmonary bypass if needed. Giant anterior mediastinal masses may necessitate extension of a partial median sternotomy incision into an ipsilateral intercostal space (usually the fourth space). Such extension may be achieved by making an ipsilateral incision in the neck along the anterior border of the sternocleidomastoid muscle and making a submammary skin incision continuous with the incision over the sternum (a hemiclamshell incision) [see Figure 6].

Transcervical Approach

Although the transcervical approach to thymic resection was the first one used in the early 1900s, it fell into disuse during the middle of the 20th century, when the median sternotomy approach became feasible. During the past 20 years, however, there has been a resurgence of interest in TCT. Today, TCT is used primarily for thymectomy in the setting of MG, though, as noted (see above), a transcervical approach can be useful for biopsy or resection of other anterior mediastinal processes as well. Proponents of TCT have published data establishing that complete remission rates from MG after so-called extended TCT using the sternum-lifting Cooper retractor¹³ are virtually equivalent to remission rates after the more invasive approaches.^{14,15} Because TCT is an outpatient procedure, hospital stay and operative recovery are certainly dramatically shorter than after thymectomy by sternotomy.

TCT should be employed very cautiously in cases in which a neoplasm is suspected or proved on the basis of preoperative studies or is identified during the course of intraoperative exploration. Because thymoma is often an indolent tumor, with recurrence developing many years after resection, long-term follow-up stud-

ies are required before TCT can be firmly recommended for treatment of even small thymomas. On the other hand, it is likely that surgeons who have extensive experience with TCT can safely resect small (< 3 cm) thymomas via this approach without risking tumor spillage or incomplete resection.

Operative technique *Step 1: initial incision and exposure.*

The patient is placed on the operating table in the supine position, with the head supported by a foam doughnut and an inflatable bag placed horizontally beneath the scapulae. The bag is inflated until the cervical spine is maximally extended. It is important that the top of the patient's head be all the way up to the edge of the table, so that the surgeon can easily reach all areas of the mediastinum from a seated position at the head.

A 5 to 6 cm curvilinear incision is made about 2 cm superior to the jugular notch and extending about 1 cm above each clavicular head [see Figure 7]. Electrocautery dissection is continued through the platysma, and subplatysmal flaps are elevated. The strap muscles are separated in the midline, and the interclavicular ligament is divided. Separating a small portion of the attachment of each sternocleidomastoid muscle from the corresponding clavicular head allows the sternum to be elevated somewhat higher, thereby improving exposure.

Step 2: mobilization of superior poles of thymus. The superior poles of the thymus are located (usually on the left side first) by means of gentle blunt dissection beneath the strap muscles. After one pole is identified, it is divided between ties at its superior extent. Its medial edge is then followed down to where it meets the medial edge of the opposite superior pole, and this opposite pole can then be similarly traced upward into the neck, ligated, and divided. A very important part of the procedure is the placement of 0 silk ligatures around an area containing strong tissue within each superior pole. These ligatures are left long and clamped. The surgeon or an assistant places traction on them during the remaining course of the dissection to manipulate and progressively mobilize the gland [see Figure 8].

Step 3: continuation of dissection downward into superior mediastinum. As traction is being placed on the upper poles, sharp and blunt dissection, staying outside the well-defined capsule of the gland, is extended downward into the superior mediastinum to the level of the innominate vein. The procedure becomes much more difficult if the capsule is violated.

Step 4: elevation of sternum. Finger dissection is performed in the substernal plane, and the arm of a Cooper thymectomy retractor is placed into the retromanubrial space to elevate the sternum. The retracting arm is placed under upward tension as the inflatable bag beneath the shoulders is deflated. This step leaves most patients actually hanging from the retractor, thereby opening up a sizable space that allows good visualization and ready passage of dissecting instruments into the anterior mediastinum. Army-Navy retractors are placed in each of the two upper corners of the incision, and their distal ends are tied to the siderails of the table with Penrose drains to provide countertraction and to hold the skin incision open.

Step 5: dissection of venous tributaries to innominate vein. With the superior poles gently pulled upward by an assistant (and at times looped over the Cooper retractor), the inferior surface of the gland is dissected until the innominate vein is encountered. The venous tributaries draining the thymus into the innominate vein are isolated sharply, ligated with fine silk sutures, and divided.

Figure 7 Resection of anterior mediastinal mass: transcervical approach. Shown is the location of the skin incision for TCT in relation to the sternal notch and the heads of the clavicles.

Step 6: dissection of posterior aspect of thymus. Once the thymus is freed from the innominate vein, dissection of the posterior aspect of the gland must be continued directly on the surface of the pericardium. This posterior dissection is carried as far down as possible, primarily in a blunt fashion. Most of the time, the surgeon holds one ring clamp containing a sponge dissector in each hand, while an assistant holds the upper poles. Occasionally, the surgeon holds the sutures attached to the upper poles in one hand while employing the sponge dissector in the other hand.

Step 7: removal of specimen. When the posterior dissection has been extended as far as possible toward the diaphragm, further mobilization of the thymus is typically accomplished by working the glandular tissue laterally, first off the pleura on one side, then off the sternum anteriorly, and finally off pleura on the opposite side. In this way, the entire gland is ultimately removed between the phrenic nerves and down to the diaphragm. During this final mobilization, the surgeon periodically asks to have ventilation held temporarily so that the pleura can fall back and thus permit improved visualization. Small feeding vessels from the mammary are doubly clipped and divided as they are encountered.

Often, the final stages of blunt dissection may be facilitated by placing a ring clamp on the body of the gland to allow slightly more vigorous retraction than can be achieved by using the upper poles alone. If any suspicious residual tissue is seen in the mediastinum at this point, it can be removed piecemeal; however, this is an unusual occurrence.

Step 8: closure. After inspection of the surgical field for hemostasis, the strap muscles and the platysma are closed over a red rubber catheter, to which suction may be applied. The catheter is subsequently removed, and the skin is closed.

Troubleshooting In the course of preoperative evaluation before TCT, it is important to be sure that the patient is able to extend the neck to a reasonable degree. TCT is simplest in young persons who are capable of good extension; it can be difficult or impossible in persons with cervical spine disease that hinders extension.

During the procedure itself, it is important that the branches of the innominate vein be tied rather than clipped; the space anterior to the vein becomes the avenue through which dissecting instruments are passed into and out of the mediastinum, and these instruments often rub against the vein fairly vigorously.

When working laterally, one must take care not to injure the phrenic nerves, and one certainly should not use the electrocautery while working at the lateral extremes of the dissection. If the pleural space is entered while one is working laterally, a red rubber catheter [see Operative Technique, Step 8, *above*] is advanced well into that pleural space, and suction in the form of several large positive pressure breaths is applied before the catheter is removed.

If a thymoma is encountered during TCT, continuation via this approach may be considered. In our view, most noninvasive thymic lesions less than 3 cm in diameter can be safely and completely resected via the transcervical approach. In addition, it generally is not difficult to resect a portion of the anterior pericardium as well if a tumor or the thymus is adherent to it. However, because the evidence currently available does not conclusively establish that TCT is equivalent to resection via sternotomy for thymoma, some surgeons prefer to convert to a sternotomy if a suspicious mass is discovered during transcervical exploration. Certainly, if any difficulty is encountered that might lead to an incomplete thymectomy or incomplete removal of a thymoma, the incision should be extended.

Approximately 90% of patients are able to go home on the same day as their procedure. The most common cause for hospital admission is a pneumothorax that must be monitored or drained.

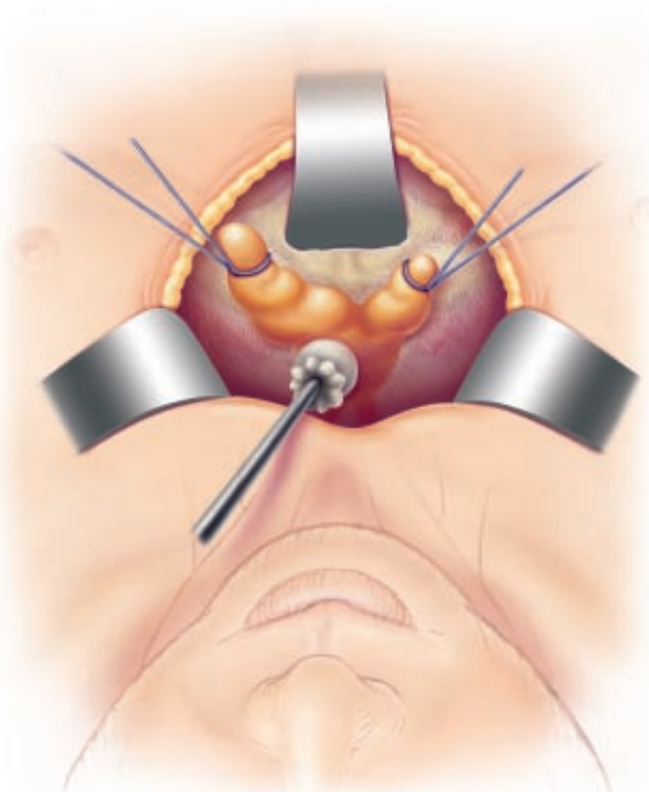

Figure 8 Resection of anterior mediastinal mass: transcervical approach. A Cooper thymectomy retractor is placed beneath the sternum, and retraction on the upper poles of the thymus is maintained with silk sutures.

Occasionally, a seroma develops at the site of the incision, but it almost always resolves either spontaneously or after a single percutaneous drainage procedure in the office.

Procedures for Lesions of the Middle Mediastinum

The majority of masses found in the middle mediastinum in adults are malignant, representing either lymphoma or lymph node metastases from primary lung carcinoma. Accordingly, the procedures performed in this anatomic area primarily involve biopsy for staging or diagnosis rather than curative or palliative resection. On infrequent occasions, however, benign or primary malignant lesions of the middle mediastinum occur for which resection is appropriate. In what follows, we briefly discuss resection of such lesions; for the most part, the principles are the same as those underlying resection of masses in the posterior mediastinum [see Procedures for Lesions of the Posterior Mediastinum, *below*].

Of particular surgical interest in the middle mediastinum are benign cysts, which may arise from the pleura, the pericardium, the airways, or the esophagus. Bronchogenic cysts, which typically develop in proximity to the carina, are probably the middle mediastinal cysts most commonly encountered in clinical practice, with pericardial cysts running a close second. On rare occasions, ectopic remnants from cervical structures (e.g., the parathyroid and thyroid glands) are encountered in this compartment.¹⁶

PREOPERATIVE EVALUATION

CT generally provides an accurate preoperative diagnosis of a benign middle mediastinal cyst, as well as information regarding abutment of adjacent structures, the consistency of the mass, and potential invasiveness. MRI may be helpful if there is concern that a cyst might actually represent an aberrant vascular structure or an aneurysm, if the simple nature of the cyst is in doubt, or if clearer delineation of suspected invasion of surrounding structures is required. Radionuclide scans (e.g., with technetium-99m or radioactive iodine) may be useful if the differential diagnosis includes a parathyroid or thyroid mass. Cystic structures adjacent to the airways and the esophagus are evaluated by means of bronchoscopy, esophagoscopy, barium esophagography, or some combination of these imaging modalities to rule out communication with the lumina.

OPERATIVE PLANNING

Middle mediastinal cysts that are symptomatic should be treated surgically. However, simple cysts of the middle mediastinum that are asymptomatic and meet all radiographic criteria for benignity may be followed. This conservative approach is often more appropriate for asymptomatic middle mediastinal cysts than for asymptomatic posterior mediastinal cysts, in that complete cyst resection (at least, for bronchogenic cysts) tends to be more complex in the middle mediastinum than in the posterior mediastinum, given the closer proximity to vital structures and the deeper placement within soft tissue. Complete resection of pericardial cysts, on the other hand, typically is easily accomplished by means of VATS; therefore, such cysts are probably best resected when discovered, even if they are asymptomatic. Although VATS resection of subcarinal bronchogenic cysts is feasible and has been described in published reports,¹⁷ it is our experience that in many instances, this approach leaves behind more than a small portion of the cyst wall.

Thus, for a symptomatic subcarinal bronchogenic cyst (a not uncommon occurrence), one is left to choose between (1) thora-

cotomy for complete resection and (2) some other approach for incomplete resection. Because this area is easily accessible by means of mediastinoscopy, and because we believe that mediastinoscopy both is simpler and causes less morbidity than VATS, we prefer partial resection via mediastinoscopy as the initial approach to these lesions.¹⁸ If cysts treated in this manner recur with associated symptoms, one can always perform thoracotomy for complete resection at that time, and little will have been lost in the meantime.

MEDIASTINOSCOPIC PARTIAL RESECTION OF SUBCARINAL BRONCHOGENIC CYST

Operative Technique

Step 1: mediastinoscopy and pretracheal dissection A standard cervical mediastinoscopy is performed, with dissection in the pretracheal plane down to the level of the carina.

Step 2: freeing of cyst from surrounding tissues With the cyst wall kept intact, as much of the wall as can safely be exposed is visualized by bluntly dissecting it away from the under-surface of the carina and the mainstem bronchi. Next, the mass is dissected away from the soft tissues anterior and posterior to it; obviously, this must be done with caution, given that the right main pulmonary artery and the esophagus are located nearby (anteriorly and posteriorly, respectively).

Step 3: aspiration of cyst contents and excision of exposed cyst wall The contents of the cyst are aspirated for cytologic and microbiologic examination, and the exposed portion of cyst wall is excised. Typically, approximately 50% of the cyst wall can be removed in this fashion. Some of the remaining cyst wall may be cauterized; this too must be done with caution, given the proximity of the adjacent vital structures.

Procedures for Lesions of the Posterior Mediastinum

The majority of posterior mediastinal masses occurring in adults are benign. These lesions may be usefully classified according to their radiologic appearance—that is, as either cystic or solid. Cystic masses in this region typically are bronchogenic cysts or esophageal duplication cysts, whereas solid masses most frequently are benign neurogenic tumors (e.g., schwannomas, neurofibromas, or ganglioneuromas). Esophageal leiomyomas (benign intramuscular tumors within the esophageal wall) are often grouped with these posterior mediastinal lesions and are managed in a similar fashion. In many cases, posterior mediastinal masses come to light as asymptomatic radiographic abnormalities; however, they may also be associated with signs of infection (in the case of infected cysts), dysphagia, chest pain, or respiratory complaints. At present, because of the growing availability of less morbid, minimally invasive approaches to posterior mediastinal masses, most authors recommend resection even when the lesion is asymptomatic. Although this recommendation remains somewhat controversial, we agree with it.

OPERATIVE PLANNING

VATS versus Thoracotomy

Resection of posterior mediastinal masses may be accomplished by means of either VATS or thoracotomy. The procedure is essentially the same with either approach, and the goal is complete resection. With some exceptions, VATS [see 4:7 *Video-Assisted Thoracic Surgery*] is considered preferable to thoracotomy in this setting;

Table 2 Indications for Planned Thoracotomy Approach to Middle or Posterior Mediastinal Mass

Suggestion of malignancy on preoperative radiography
Presence of inflammation or infection, blurring tissue planes
Large mass (> 5–6 cm)
Esophageal duplication cyst believed to communicate with esophageal lumen on the basis of preoperative CT, barium esophagography, or esophagoscopy
Esophageal lesions without evidence of overlying normal esophageal mucosa on preoperative esophagoscopy or endoscopic ultrasonography
Previous ipsilateral thoracotomy with adhesions
Tumor located at apex of the chest, which may necessitate thoracosternotomy

generally, VATS results in less postoperative pain and quicker functional recovery.^{19,20} Some surgeons argue that a VATS approach may be more likely to leave a patient with microscopic residual disease. In our experience and that of others, however, recurrences of these lesions are very rare after VATS excision.^{21,22} Given the low recurrence rate and the fact that these masses are almost always benign, we believe that the risk-benefit ratio is better with VATS in most cases.

There are, however, several circumstances in which thoracotomy is indicated from the outset [see Table 2]. A suggestion of malignancy (in particular, invasion of surrounding structures) on preoperative radiography mandates exploration and resection by thoracotomy; in this situation, the potential consequences of positive margins justify the more aggressive approach. The presence of active infection within a cyst is a relative indication for thoracotomy, in that it can cause disruption of normal tissue planes and thereby render VATS dissection more hazardous. Masses larger than approximately 6 cm also call for an open approach: such lesions are typically more difficult to mobilize safely from underlying structures than smaller lesions are, they are more likely to be malignant, and their removal between the ribs is likely to necessitate rib spreading, which may negate some of the benefit of true VATS.

When a cyst is arising from or abutting the esophagus, the possibility of a communication between the cyst and the esophageal

Figure 9 Resection of neurogenic tumor of posterior mediastinum. Intraoperative photo shows a solid neurogenic tumor of the costovertebral sulcus.

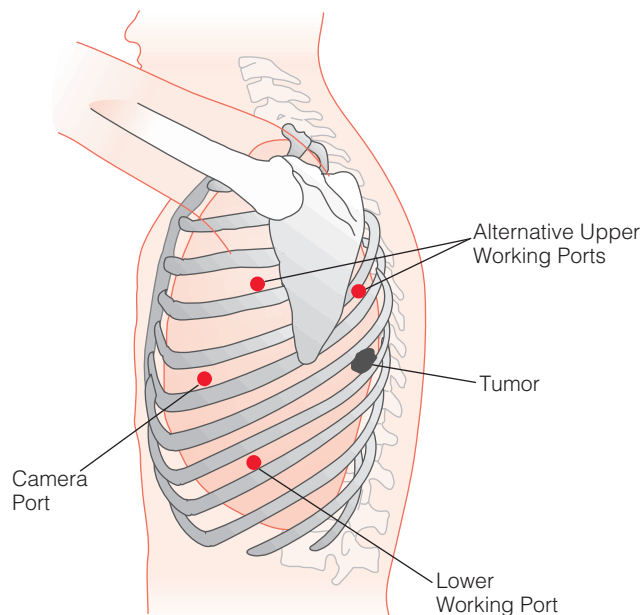

Figure 10 Resection of neurogenic tumor of posterior mediastinum. Shown is typical port placement for VATS resection of a posterior mediastinal mass.

lumen should be investigated preoperatively. Such a communication may be suggested on CT scans by the presence of an air-fluid level. To rule out this phenomenon, we perform barium esophagography during the preoperative workup, followed by intraoperative esophagoscopy at the commencement of the operation. If a communication is identified or cannot be ruled out, thoracotomy is performed. After excision of an esophageal duplication cyst with a communication, reapproximation of the esophageal mucosa is a paramount consideration; in our view, this is best done through an open approach.

In cases of suspected leiomyoma of the esophagus, preoperative investigation should be done to confirm the presence of intact overlying mucosa, which is virtually pathognomonic of this disease. Esophagoscopy is done to assess the mucosa; if the mucosa is intact, the possibility of malignancy is essentially ruled out. Simultaneously, endoscopic ultrasonography may be performed to establish the depth to which the esophageal wall is involved. With a preoperative diagnosis of probable leiomyoma, VATS is the approach of choice in our practice.

So-called dumbbell neurogenic tumors (tumors that invade the neural foramen) are special cases. Any solid mass in the costovertebral sulcus should be evaluated by means of MRI to determine whether it is invading the neural foramen if the absence of invasion was not clearly established by CT. Although invasion of the neural foramen by tumor is not in itself an indication for thoracotomy, it does necessitate a combined anterior-posterior approach with neurosurgical involvement for the intraspinal portion of the procedure. Several versions of such an approach have been described.²³⁻²⁵ We prefer to perform the posterior neurosurgical resection of the intraspinal component (laminectomy and intervertebral foraminotomy) first, then to reposition the patient and carry out the remainder of the procedure (via VATS or thoracotomy).²⁶

Although VATS is often an excellent approach to posterior mediastinal lesions, it must be emphasized that one should never hesitate to convert a VATS procedure to a thoracotomy if required. Accordingly, informed consent to undergo thoracotomy should be

sought before operation from all patients being treated for posterior mediastinal lesions, even when VATS is the intended approach.

VATS RESECTION OF NEUROGENIC TUMOR OF POSTERIOR MEDIASTINUM

Operative Technique

Resection of a solid neurogenic tumor of the posterior mediastinum that does not invade the neural foramen [see Figure 9] proceeds as follows.

Step 1: intubation and endoscopy The patient is intubated with a double-lumen endotracheal tube to allow single-lung ventilation. Preoperative bronchoscopy (for cystic lesions) or esophagoscopy (for lesions abutting the esophagus) is performed as indicated (see above).

Step 2: patient positioning and placement of ports The patient is placed in the lateral thoracotomy position and stabilized with bean bags so that the operating table can safely be tilted as much as 45° to either side. With this degree of tilt, the lung tends to fall away from the field of vision; thus, there usually is no need to place an additional port for a lung retractor.

The port for the scope is placed through an incision in the midaxillary line at the level of the mass; if it is placed much more anteriorly than the midaxillary line, the surgeon's view of posterior lesions may be obscured by the lung. The two working ports are placed through separate incisions in the posterior axillary line, made as far cephalad and caudad as possible. Sometimes, placement of an alternative upper working port posterior to the scapula is advantageous [see Figure 10]. The main working instruments are an endoscopic scissors-cautery, a ring clamp, an endoscopic peanut dissector, a Maryland dissector, a long right-angle clamp, and an endoscopic clip applicator.

Figure 11 Resection of neurogenic tumor of posterior mediastinum. Shown is circumferential incision of the pleura around a neurogenic mass.

Figure 12 Resection of neurogenic tumor of posterior mediastinum. The final remaining intercostal stalk is divided.

Step 3: incision of pleura The parietal pleura is incised around the mass, with a margin of approximately 2 cm circumferentially. The pleura is tented up with the aid of the right-angle clamp or the Maryland dissector to separate it from the underlying structures [see Figure 11]. This separation allows the use of the electrocautery, which provides hemostasis while protecting the underlying esophagus, vagus and intercostal nerves, and azygos vein. This dissection and all subsequent work are facilitated by placing gentle traction on the mass with a sponge stick or, for smaller masses, by grasping the entire mass within a ring clamp.

Step 4: dissection of soft tissue attachments Once the pleura has been incised circumferentially, the soft tissue attachments are further dissected bluntly with the endoscopic peanut dissector. Attachments that are relatively thick or vascular are best controlled by double-clipping and division. If the tumor originates from an intercostal nerve, gentle dissection is done beneath the tumor to identify the intercostal bundle that is the source of the lesion.

Step 5: division of source intercostal bundle The source intercostal bundle lateral to the tumor is mobilized, doubly clipped, and divided. Once this has been accomplished, blunt dissection is performed until the nerve root emerging from the neural foramen and the associated intercostal vessels are the last remaining attachments. If the tumor originates from the sympathetic chain, the chain is clipped above and below the tumor, and the intercostal bundle is spared if possible.

Step 6: removal of specimen The remaining stalk is doubly clipped and divided [see Figure 12], and the mass is removed in an endoscopic bagging device.

Step 7: drainage A 24 French chest tube is positioned posteriorly at the apex.

Troubleshooting

Care must be taken to ensure that only very gentle traction is exerted on a mass adjacent to the neural foramen. Overzealous traction can cause tearing of the nerve root proximal to the extraspinal extent of the dura, and this tearing can lead to a cere-

brospinal fluid leak, which most often becomes evident only postoperatively (in the form of persistent clear chest tube output). The diagnosis of CSF leakage can be confirmed by measuring the β_2 -transferrin level in the fluid. If CSF leakage is confirmed, reoperation with a neurosurgeon is mandatory; the leak is repaired and buttressed with vascularized tissue.

After resection of a tumor at the costovertebral sulcus, regular neurologic examinations of the lower extremities are indicated. Tamponade with hemostatic agents should never be employed for bleeding at the neural foramen: doing so can result in an intraspinal hematoma with subsequent cord compression. Careful use of the electrocautery at the bony margins of the foramen or watchful waiting is preferable. If hemostasis cannot be achieved with these measures, a neurosurgical consultation should be obtained. In the event of oozing from the vicinity of a foramen that is not easily controlled, there should be no hesitation in converting a VATS procedure to an open procedure.

In a minority of patients, clipping and division of an intercostal nerve results in intercostal neuralgia after the procedure; the possibility that this may occur must be discussed with the patient preoperatively. Many patients who undergo division of a lower thoracic intercostal nerve that supplies an upper abdominal dermatome notice postoperative bulging of the ipsilateral abdomen in the area supplied by that nerve.

RESECTION OF BENIGN CYST OF POSTERIOR MEDIASTINUM

Resection of a benign cystic mass of the posterior mediastinum closely resembles resection of a neurogenic tumor [see Resection of Neurogenic Tumor of Posterior Mediastinum, *above*]; the differences are relatively minor [see Troubleshooting, *below*].

Troubleshooting

In the initial stages of dissection of a benign cyst of the posterior mediastinum, care should be taken not to rupture the cyst; initial mobilization from surrounding structures is easier when the cyst wall is under tension [see Figure 13]. If the area of the cyst wall that directly abuts the mediastinum is found to be too adherent to underlying structures to be removed safely, we intentionally rupture the cyst, then remove as much of the cyst wall as possible. As much as 35% of the cyst wall may be left in place. In such cases,

Figure 13 Resection of benign cyst of posterior mediastinum. Intraoperative photo shows a fluid-filled posterior mediastinal cyst. The tenseness of the cyst wall facilitates initial dissection.

Figure 14 Resection of esophageal leiomyoma. (a) Shown is an esophageal leiomyoma beneath the azygos vein. (b) The mediastinal pleura overlying the leiomyoma is incised. (c) The azygos vein is divided with an endoscopic stapler. (d) The muscle fibers overlying the mass are divided. (e) Gentle traction is applied to facilitate blunt dissection. (f) Shown is a completely resected horseshoe-shaped esophageal leiomyoma.

we ablate the residual intact cyst wall with the electrocautery to destroy any potential secretory tissue. If more than approximately 35% of the cyst must be left in place, conversion to thoracotomy should be considered.

RESECTION OF ESOPHAGEAL LEIOMYOMA

Operative Technique

In addition to the steps described for resection of a neurogenic mass, there are several special maneuvers that facilitate resection of esophageal intramural masses, such as leiomyomata [see Figure 14a] and duplication cysts.

1. The pleura is incised longitudinally with the electrocautery after it is tented up away from the esophagus, the vagus nerve, and the azygos vein with a right-angle clamp or a Maryland dissector [see Figure 14b].
2. In some cases, exposure is facilitated by dividing the azygos vein with an endoscopic stapler [see Figure 14c].
3. The longitudinal esophageal muscle fibers that overlie the mass are separated bluntly or with the electrocautery. These fibers are often markedly attenuated as a result of the expansion of the mass [see Figure 14d].
4. Blunt dissection with an endoscopic peanut dissector allows careful, progressive mobilization of the mass, first from the muscle layer and then from the underlying mucosa. Gentle traction on the mass facilitates exposure at this point in the pro-

cedure [see Figure 14e]. Having an assistant place the endoscope within the esophageal lumen to distend and illuminate the mucosa also may be helpful at this stage. Once the mass has been completely resected, it is sent for pathologic examination [see Figure 14f].

5. The esophagus is distended by insufflating air from above while the distal esophagus is occluded with a sponge stick. The air-filled esophagus is then submerged in saline, and the area of the resection is examined for air leakage.

Troubleshooting

Some surgeons routinely close the muscular defect in the esophagus after resection so as to reduce the risk that an esophageal diverticulum will develop. Such closure may be accomplished by means of thoracoscopic suturing. Often, though, the muscle layer is attenuated to the point where useful reapproximation is nearly impossible. For this reason, as well as because we believe that a diverticulum is unlikely to develop in the absence of a distal functional obstruction, we do not routinely close the muscular defect.

Frequently, duplication cysts are more adherent to the underlying esophageal mucosa than leiomyomata are, and transillumination of the esophageal wall helps define the plane at which blunt dissection should be performed. Where the cyst wall becomes difficult to separate from the mucosa, a small amount of the wall may be left in place if, in the surgeon's judgment, attempting to remove all of it might lead to a breach in the mucosa.

14 SOLITARY PULMONARY NODULE

Shamus R. Carr, M.D., and Taine T.V. Pechet, M.D., F.A.C.S.

Assessment of a Solitary Pulmonary Nodule

The solitary pulmonary nodule (SPN) is a common finding that is observed in more than 150,000 persons each year in the United States.¹ An SPN is defined as a single radiographically visible pulmonary lesion that is less than 3 cm in diameter, is completely surrounded by pulmonary parenchyma, and is not associated with atelectasis or adenopathy.²

Any pulmonary lesion larger than 3 cm is considered a mass and as such has a greater likelihood of being malignant.^{3,4} SPNs are detected on routine chest radiography at a rate of 1 in 500 x-rays, but with the growing use of computed tomographic scanning, they are now being diagnosed with increasing frequency.

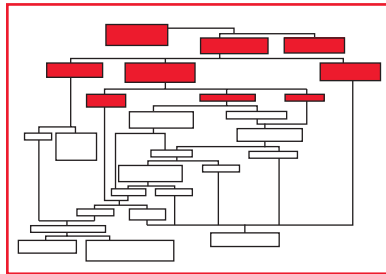

The differential diagnosis of an SPN is broad and includes vascular diseases, infections, inflammatory conditions, congenital abnormalities, benign tumors, and malignancies [see Table 1]. Although most SPNs are benign, as many as one third represent primary malignancies, and nearly one quarter may be solitary metastases.^{1,5,6} Various approaches have been developed to aid in the characterization and identification of SPNs. Certain clinical characteristics—such as greater age, history of tobacco use, and previous history of cancer—have been shown to increase the likelihood that the SPN is malignant.⁷ Some authors have attempted to use Bayes's theorem, logistic regression models, or neural network analysis to predict the likelihood of malignancy.⁷⁻⁹ Such methods are highly sensitive and specific, but they are cumbersome and of limited practical use in actual clinical evaluation of a patient with an SPN.

Clinical Evaluation

Once an SPN has been discovered, the essential task is to determine whether the lesion is benign or malignant. Evaluation and workup should be governed by the dictum “malignant until proven otherwise.” The basis for this initial assumption of malignancy is the observation that the average overall 5-year survival rate is quite poor—10% to 15%—once a diagnosis of lung cancer is made.¹⁰ Appropriate evaluation involves careful assessment of the patient's history and risk factors for malignancy in conjunction with the results of radiographic studies [see Investigative Studies, below] to develop an individualized care plan.

FACTORS INFLUENCING PROBABILITY OF MALIGNANCY

Of the various factors that influence the probability that cancer will be found in an SPN before radiographic evaluation, those most strongly associated with lung cancer are age, smoking history, and occupational history. Pulmonary function test results indi-

cative of severe obstructive ventilatory impairment are also associated with an increased likelihood of malignancy.¹¹ In addition, the presence of endemic granulomatous disease has been shown to increase the probability that an SPN is harboring cancer.⁷

Other factors that influence the probability of malignancy in an SPN are based on the findings from CT scanning [see Investigative Studies, Imaging, Computed Tomography, below]. The size, contour, internal characteristics, and growth rate of the nodule are all potentially significant indicators of malignant disease [see Table 2].

Age

Lung cancer is rare before the age of 40 years, but its incidence steadily increases from that point until the age of 80.⁵ Above the age of 70, the likelihood that an SPN is malignant increases.⁸ After the age of 80, the incidence of malignancy in an SPN seems to level off or even decrease.

Tobacco Exposure

The link between cigarette smoking and lung cancer has been well established since the 1950s, and the incidence of lung cancer in smokers is directly correlated with the number of pack-years of smoking.¹² The Surgeon General's Report from 2004 states that “the evidence is sufficient to infer a causal relationship between smoking and lung cancer.”¹³

Occupational History

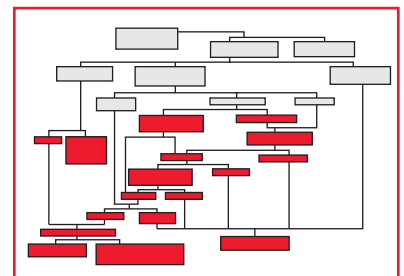

Patients with a history of workplace exposure to a radioactive substance (e.g., uranium or plutonium) are at increased risk for lung cancer, but this association is not as well documented as the association of lung cancer with tobacco use. Miners of heavy metals (e.g., nickel, cadmium, and silica) are also at increased risk. There is some evidence to suggest that patients with idiopathic pulmonary fibrosis and pneumoconiosis are at increased risk for bronchoalveolar cell carcinoma.¹⁴ Radon exposure is the second leading cause of lung cancer, and cigarette smoking further increases the risks associated with radon exposure.¹⁵ Asbestos exposure in combination with cigarette smoking also places patients at significantly increased risk for lung cancer.

Investigative Studies

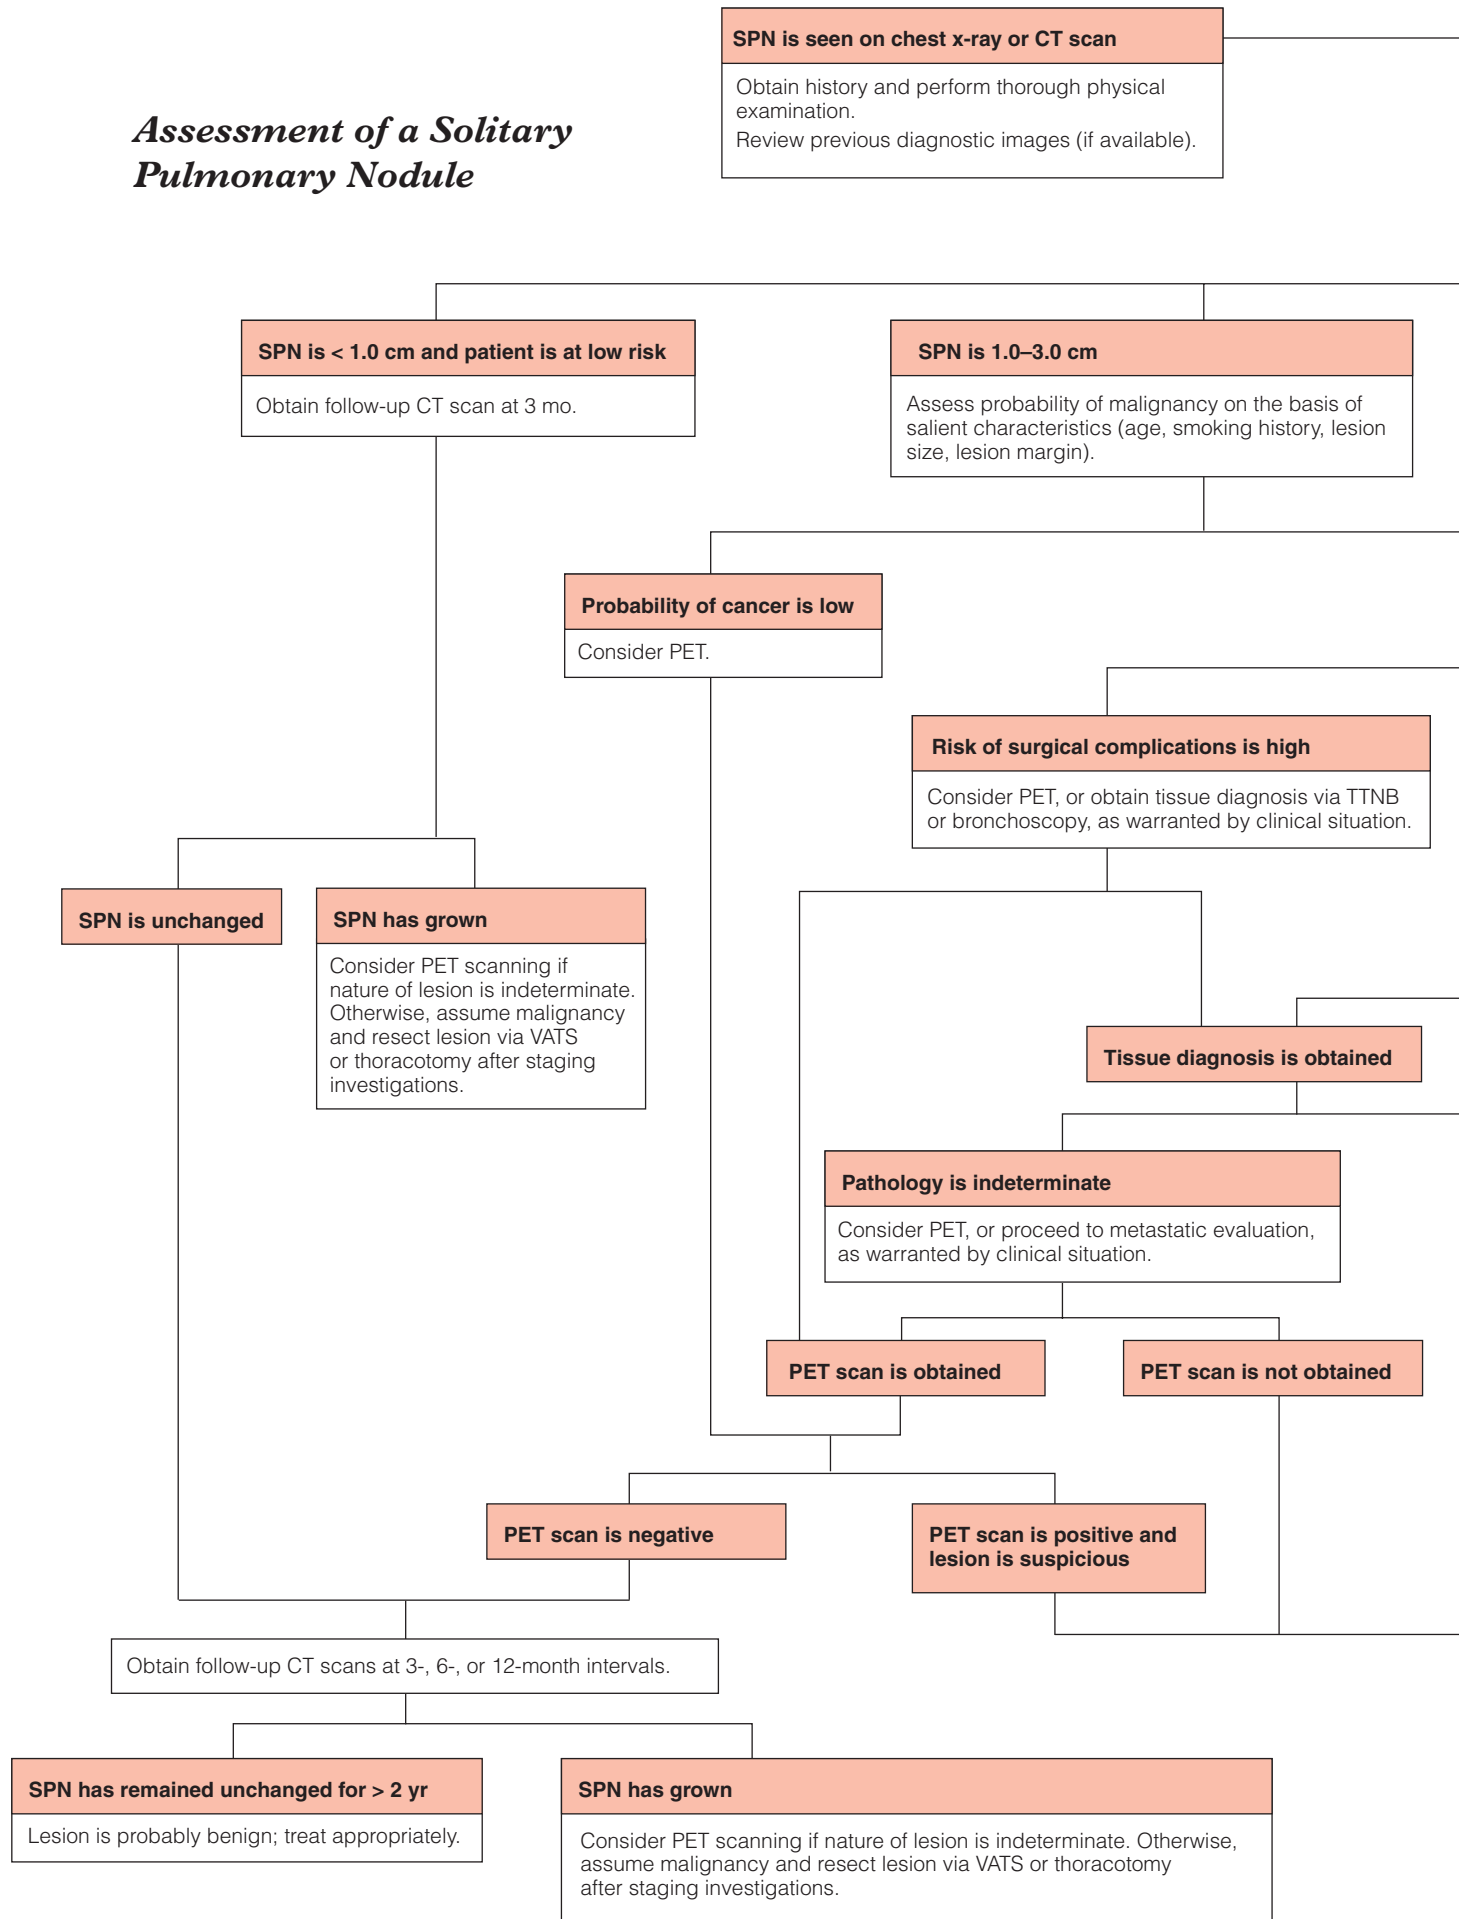

IMAGING

Chest Radiography

Whereas the prevalence of lung cancer is low in comparison to that of breast or prostate cancer, the mortality for lung cancer exceeds that for breast, prostate, and colon cancer combined. As noted [see Clinical Evaluation, above],

Assessment of a Solitary Pulmonary Nodule

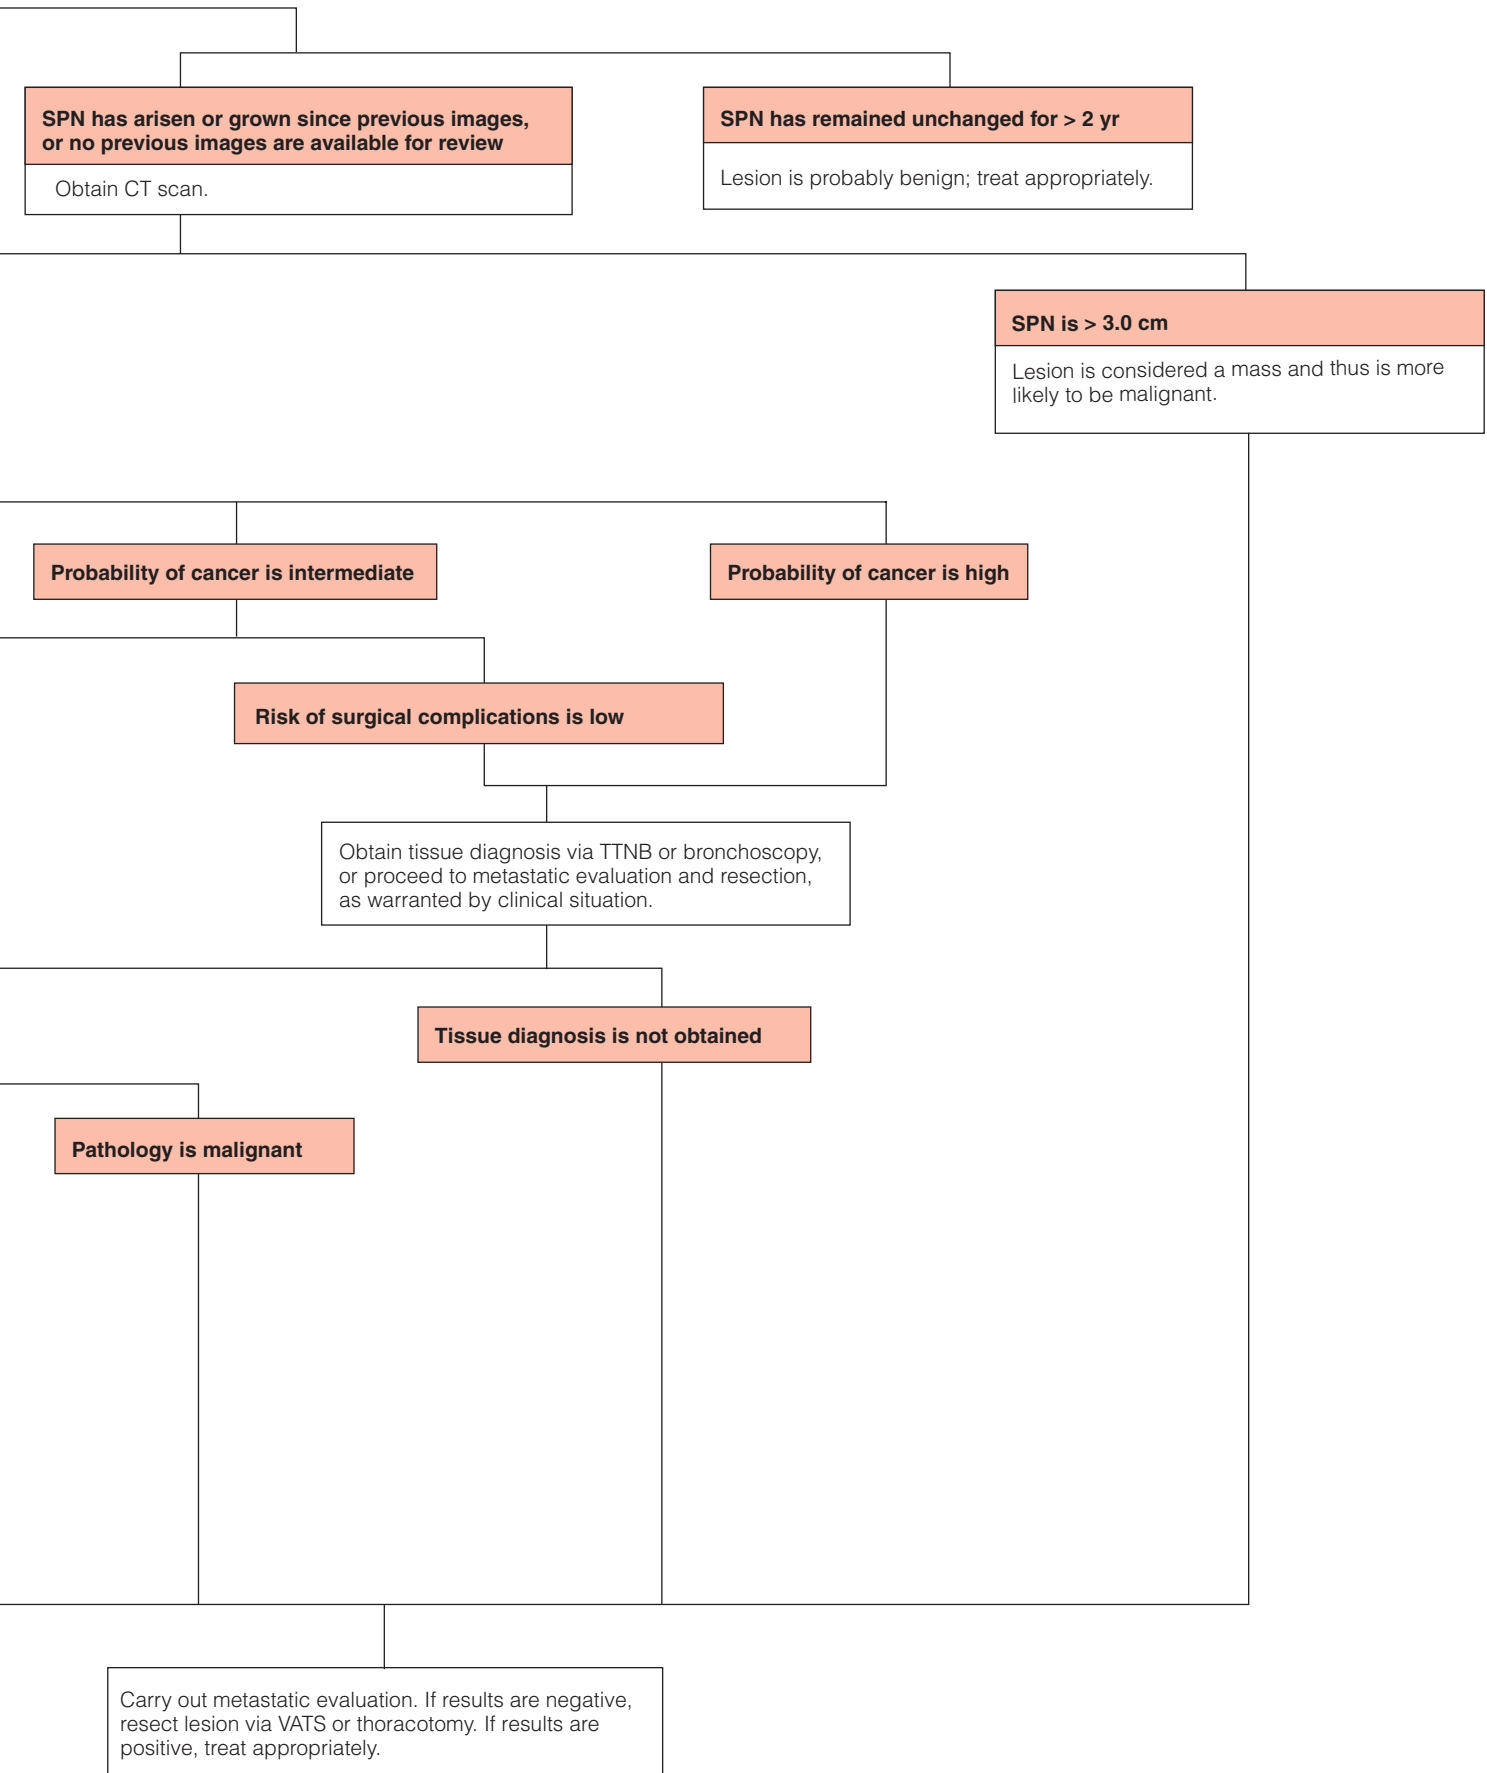

Table 1 Differential Diagnosis of Solitary Pulmonary Nodule

Benign	Vascular disease	Arteriovenous malformations Pulmonary artery aneurysm
	Infection	Tuberculosis <i>Mycobacterium avium</i> complex infection Aspergilloma Histoplasmosis Echinococcosis Blastomycosis Cryptococcosis Coccidioidomycosis Ascariasis Dirofilariasis
	Inflammatory condition	Rheumatoid nodule Sarcoidosis Wegener granulomatosis
	Congenital abnormality	Foregut duplication cyst
	Other	Rounded atelectasis Pulmonary amyloidosis
	Benign tumor	Hamartoma Lipoma Fibroma
Malignant	Primary lung cancer	Non-small cell lung cancer Squamous cell carcinoma Adenocarcinoma Large cell cancer Bronchoalveolar carcinoma Small cell lung cancer Carcinoid Lymphoma
	Metastatic cancer	Colon cancer Testicular cancer Melanoma Sarcoma Breast cancer

the overall 5-year survival rate for lung cancer patients is dismal, in part because lung cancer is typically identified at a more advanced stage than other cancers are. Several trials performed before the advent of CT scanning attempted to employ chest radiography for early screening of lung cancer, but they were unable to demonstrate that such screening yielded any better survival than no screening at all.¹⁶⁻¹⁸ One explanation for these disappointing results may be that fewer than 10% of lung cancers are stage I at presentation.¹⁶

Although chest radiography is ineffective as a screening tool for early-stage lung cancer, it remains a valuable investigative tool in the evaluation of SPNs. If an SPN's appearance on chest x-rays has not changed for more than 2 years, the SPN will be benign in more than 90% of cases. In such cases, only yearly follow-up is typically required; additional diagnostic tests are usually unnecessary.^{19,20} Therefore, an effort should always be made to obtain old chest radiographs if they are known to exist.

Computed Tomography

The advent of CT scanning has led to an increase in the number of SPNs detected²¹—but of course, it has also led to an increase in the number of SPNs found that prove to be benign.

Advocates of CT scanning for assessment of SPNs base their argument on two central points. First, as many as 83% of CT-detected stage I malignancies are not visible on chest x-ray.²² Second, non-small cell lung cancer (NSCLC) is the malignancy most commonly identified, and the survival rate for stage I NSCLC is relatively high. In patients whose SPN proves to be NSCLC, the 5-year survival rate is 67% for stage IA disease. This figure falls rapidly as the disease stage rises: the 5-year survival rate is 55% for stage IIA NSCLC and only 10% for stage IIIA NSCLC with mediastinal nodal metastasis.²³

Numerous studies have evaluated the use of screening CT both in the general population and in at-risk groups consisting of older patients with a smoking history.^{22,24,25} The greatest drawback to screening CT is the high false positive rate: nodules are identified on 23% to 66% of all CT scans, depending on the thickness of the slices,^{22,26} and nearly 98% of these nodules are eventually determined to be benign. Sequential CT scanning is often required to determine whether an SPN is benign or malignant. In 10% to 15% of patients, however, this determination cannot be made even when two CT scans are compared. Such patients may be assessed with other imaging modalities (e.g., positron emission tomography [PET]) or may be referred for transthoracic needle biopsy (TTNB) or other invasive diagnostic tests.

There is currently some controversy regarding the optimal timing of follow-up CT scanning after initial identification of an SPN. In the literature, the recommended interval between initial CT scanning and repeat CT scanning has ranged from 1 month to 1 year.^{22,25,26} These varying recommendations are based on what is considered the doubling time for an SPN. In a study from 2000 that included 13 patients with a known diagnosis and lesions less than 10 mm in diameter at initial evaluation, volumetric growth rates were measured to establish the doubling times of the nodules.¹⁰ The doubling times ranged from 51 days to more than 1 year. For malignant lesions, the average doubling time was less than 177 days, whereas for benign lesions, it was more than 396 days.

In addition to delineating the size and contours of an SPN, CT scans provide information on its internal characteristics. Certain lesion characteristics noted on CT, though not absolutely definitive, point more toward a benign condition, whereas others point more toward malignancy. For example, although cavitation may occur in either benign or malignant lesions, SPNs with walls thicker than 16 mm are much more likely to be malignant, whereas those with walls thinner than 4 mm are much more likely to be benign.²⁷ As another example, the presence of intranodular fat is a reliable indicator of a hamartoma (a benign lesion) and is seen in as many as 50% of hamartomas.²⁸ In addition, calcification is most commonly associated with hamartomas and other benign nodules. Unfortunately, between one third and two thirds of benign lesions visualized are not calcified, and as many as 6% of malignant lesions are calcified.²⁹⁻³¹ Finally, increased enhancement (measured in Hounsfield units [HU]) after injection with intravenous contrast is strongly suggestive of malignancy. Lesions that enhance by less than 15 HU are most likely benign (positive predictive value, 99%), whereas lesions that enhance by more than 20 HU are typically malignant (sensitivity, 98%; specificity, 73%).³² Lesions that enhance by 15 to 20 HU should be considered indeterminate.

Because most SPNs are benign and because the risk of misdiagnosing a malignant lesion is so great, it is important to make use of all of the data obtained from CT scanning in the effort to make cost-effective, logical decisions regarding further evaluation or treatment. Careful evaluation of the size, contours, and internal

characteristics of an SPN on successive CT scans—in conjunction with thoughtful consideration of the patient’s age, smoking history, and occupational exposure—provides the framework for appropriate treatment. Because the doubling time is considerably shorter for malignant lesions than for benign lesions, a repeat CT scan should be performed 3 months after the initial study. If the lesion is visibly larger on the repeat scan, it is probably malignant, and further diagnostic evaluation should be carried out with an eye toward resection. If, however, the lesion is still present and has not grown, a follow-up CT scan between 3 months and 12 months is warranted; the precise timing remains controversial and should be determined on the basis of individual patient and SPN characteristics. New volumetric modeling methods have been developed that may be capable of detecting conformational changes over much shorter intervals, but at present, they are not frequently used.³³

Positron Emission Tomography

PET is an imaging modality that employs radiolabeled isotopes of fluorine, carbon, or oxygen; the most commonly used isotope is ¹⁸F-fluorodeoxyglucose (FDG). The rationale for FDG-PET scanning in the evaluation of SPNs is based on the higher metabolic rate of most malignancies and the preferential trapping of FDG in malignant cells.³⁴ However, increased FDG activity can also occur in benign SPNs,^{35,36} especially those arising from active granulomatous diseases^{37,38} or inflammatory processes.³⁹ These benign diseases can produce false positive PET scans and thereby reduce the sensitivity of the test. Conversely, some malignancies—bronchoalveolar carcinoma and carcinoid tumors, in particular—have low metabolic activity and commonly produce false negative PET scans.⁴⁰⁻⁴⁴ Thus, a negative PET scan is not a particularly helpful result, and it is necessary to follow the lesion with serial CT scans.

Efforts have been made to increase the sensitivity and specificity of PET scanning in the diagnosis of SPNs. One such effort involves the use of the standardized uptake value (SUV), which is a numerical indication of the activity concentration in a lesion, normalized for the injected dose.⁴⁵ In many studies, an SPN is considered malignant when its SUV is higher than 2.5. Because of the method used to calculate the SUV, however, small tumors (<

1.0 cm) may have an SUV lower than 2.5 and still be malignant. The reason is that their small volume causes their true activity concentration to be underestimated, with the result that their SUV drops below the threshold value for malignancy. In one prospective study of patients with SPNs, the overall sensitivity of FDG-PET scanning was 79%, and the overall specificity was 65%.⁴⁶ When the SPN was smaller than 1.0 cm, however, all of the scans were negative, even though 40% of the nodules were malignant.

In cases where the SPN is larger than 1.0 cm and no previous radiographs or CT scans are available for comparison, PET scanning can provide information that may facilitate the decision whether to follow the lesion closely or to proceed with biopsy. PET scanning has a definite place in the evaluation of SPNs, but it is not appropriate for every patient. A study that examined the cost-effectiveness of PET in the evaluation of SPNs concluded that it was cost-effective for patients who had an intermediate pretest probability of a malignant SPN and who were at high risk for surgical complications.⁴⁷ In all other groups, PET was not cost-effective, and CT led to similar outcomes (in terms of quality-adjusted life years) and to lower costs.

BIOPSY

If an SPN demonstrates characteristics suggestive of malignancy, a tissue diagnosis should be obtained. There are several alternative biopsy techniques that may be performed in place of resection, including TTNB and bronchoscopy. Traditionally, open lung biopsy was performed for an SPN, but this approach has the drawback of the morbidity associated with a thoracotomy. For peripheral lesions, video-assisted thoroscopic surgery (VATS) has now supplanted thoracotomy as the procedure of choice. For central lesions that cannot be diagnosed by means of less invasive techniques, more invasive approaches will still be required.

Transthoracic Needle Biopsy

Lesions that are between 1.0 and 3.0 cm in diameter should be considered for TTNB. The diagnostic yield of this procedure for SPNs is excellent, reaching 95% in some studies. The reported sensitivity ranges from 80% to 95%, and the specificity ranges from 50% to 88%.⁴⁸⁻⁵⁰ A study of 222 patients who underwent TTNB for an SPN reported a positive predictive value of 98.6% and a negative predictive value of 96.6%⁵¹; however, several other studies reported false negative rates ranging from 3% to 29%.^{48,52} The complication rate associated with TTNB is relatively high—potentially as high as 30% and rarely lower than 10%, in even the most experienced hands.^{49,53} Most commonly, a pneumothorax results; however, chest tube placement is required only if the patient becomes symptomatic, a situation that occurs in approximately 50% of cases. In the absence of symptoms, observation with serial chest x-rays is generally appropriate. If no increase in the size of the SPN is observed, the patient can be discharged with the expectation that the pneumothorax will resolve.

For lesions smaller than 1.0 cm, the risk-to-benefit ratio of TTNB rises to the point where other techniques are typically preferred. The utility of TTNB depends primarily on the characteristics of the SPN—in particular, its location. Nodules that are central or close to the diaphragm or the pericardium are less well suited to this technique than those at other sites are.

Bronchoscopy

Bronchoscopy has a well-established role in the evaluation of central SPNs, which are amenable to direct visualization and biopsy. Most SPNs, however, are not central. Various adjunctive measures, including transbronchial needle biopsy and cytology brush-

Table 2 Factors Affecting Malignant Probability of Solitary Pulmonary Nodule⁸

Factor	Likelihood Ratio for Malignancy
Spiculated margins on CT scan	5.54
Age > 70 yr	4.16
Lesion size 2.1–3.0 cm	3.67
Doubling time < 465 days	3.40
History of smoking	2.27
Age 50–69 yr	1.90
Lesion size 1.1–2.0 cm	0.74
Lesion size < 1 cm	0.52
Smooth margins on CT scan	0.30
No history of smoking	0.19
Doubling time > 465 days	0.01

ings, are employed to improve the yield of bronchoscopy. Newer techniques, including the use of endobronchial ultrasonography, are currently under active investigation.

For SPNs between 2.0 and 3.0 cm in diameter, the diagnostic yield of bronchoscopy ranges from 20% to 80%, depending on the size of the lesion, the incidence of malignancy in the study population, and the proximity of the lesion to the bronchial tree.^{54,55} For SPNs smaller than 1.5 cm, the yield drops to 10%.⁵⁶ Even though bronchoscopy has a low complication rate (about 5%), its low diagnostic yield for malignancy limits its utility in the evaluation of SPNs.

Excisional Biopsy

The decision whether to proceed to excisional lung biopsy (open or thoracoscopic) must be carefully considered. The risk-to-benefit ratio of excisional biopsy is determined by clinical characteristics affecting perioperative morbidity and mortality, as well as by the risk of malignancy.

Resection is the definitive diagnostic technique. The morbidity associated with VATS is less than that associated with thoracotomy; accordingly, when VATS lung biopsy is technically feasible, it is preferable to open lung biopsy. The overall morbidity is lower than 1% for VATS wedge resection, compared with 3% to 7% for the equivalent open procedure.⁵⁷ Patients who have undergone VATS lung biopsy experience less pain, have shorter hospital stays, and recover sooner than those who have undergone open biopsy.^{57,58}

A technical consideration that must be taken into account when VATS is planned is possible conversion to a thoracotomy. The conversion rate for VATS to thoracotomy has been reported to be as high as 33%, but there is evidence to suggest that this rate can be significantly reduced with careful patient selection and increasing experience in minimally invasive techniques.^{59,60}

Peripheral SPNs more than 1.0 cm in diameter are the lesions best suited to VATS excision. As SPNs become smaller and more central, they become harder to identify, and the rate of conversion to thoracotomy rises. A wide variety of techniques have been employed to improve the identification of SPNs for VATS, ranging from radioisotope use through guide-wire localization. None of these techniques have achieved wide acceptance, and most surgeons rely on simple finger palpation through one of the port sites.

Differential Diagnosis

MALIGNANT LESIONS

Non–Small Cell Lung Cancer

As noted, NSCLC is the malignancy most frequently identified in an SPN. Most lung cancer patients are asymptomatic, and those who are symptomatic usually have advanced disease, including mediastinal lymph node involvement. Arterial invasion has also been shown to have an adverse effect on survival in patients with early-stage NSCLC.⁶¹ The most common sites of metastases are the lungs, the brain, the bones, and the adrenal glands. Accordingly, it is essential to perform a metastatic workup that focuses on these areas to identify metastatic disease before proceeding with resection.

Bronchoalveolar carcinoma is a subtype of NSCLC that is well differentiated and has a prolonged doubling time. Because of its slow growth rate, it may be missed by PET scanning.⁴² Bronchoalveolar carcinoma may present as an SPN, as airspace disease, or as multiple nodules.

Small Cell Lung Cancer

Small cell carcinoma accounts for approximately 20% of lung cancers. Typically, it presents as a central mass in association with significant nodal disease, often accompanied by distant metastases.⁶² Small cell carcinoma typically has a very short doubling time. Paraneoplastic syndromes are more common with small cell lung cancer than with NSCLC.

Pulmonary Carcinoid

Pulmonary carcinoid tumors are uncommon neuroendocrine neoplasms that account for 1% to 2% of lung cancers.⁶³ They are classified as either typical or atypical, depending on their histology.⁶⁴ Either type of carcinoid may present as an SPN, usually in the fifth or sixth decade of life. Typical carcinoid tumors have a very long doubling time—up to 80 months—and thus may be mistaken for benign lesions.⁶⁵ Atypical carcinoid tumors have a much shorter doubling time and are more likely to show an increase in size on serial CT scans. Typical carcinoid tumors have an extremely low incidence of recurrence and are not usually associated with nodal metastasis.

Metastatic Malignancies

Metastases to the lung frequently appear as smooth, round, well-demarcated lesions. They often are multiple and rarely are associated with mediastinal adenopathy. Most pulmonary metastases derive from the lungs, the colon, the testicles, the breasts, melanomas, or sarcomas. Treatment tends to be palliative, based on the diagnosis of the primary tumor, but it may be curative in cases of metastatic sarcoma or testicular carcinoma. In patients with these cancers, limited wedge resection of a metastasis to the lung has been shown to confer a survival advantage; this measure may also be beneficial for patients with metastatic colon or head and neck cancer and, occasionally, for those with metastatic melanoma.⁶⁶

BENIGN LESIONS

Pulmonary Hamartoma

Pulmonary hamartomas are the most common benign pulmonary tumors and the third most common cause of SPNs overall. Most (90%) arise in the periphery of the lung, but endobronchial hamartomas are seen as well. Because they are most common in the periphery, hamartomas are usually asymptomatic. When a potential hamartoma appears as an SPN on a chest x-ray, CT scanning is warranted for further evaluation.

Certain typical CT findings suggest that the SPN is likely to be a hamartoma. One such finding is a particular pattern of calcification. Calcification is more common in benign lesions than in malignant tumors. There are four patterns of calcification that are considered benign: central, diffuse, laminated, and “popcornlike.” The first three patterns are most commonly associated with an infectious condition (e.g., histoplasmosis or tuberculosis). The popcornlike pattern, however, indicates that the lesion is probably a hamartoma. Unfortunately, calcification is present in only about 50% of benign lesions, and only about 50% of hamartomas are calcified.²⁹ It is important to remember that pulmonary carcinoid tumors and metastases to the lung (especially those from osteosarcomas, chondrosarcomas, or synovial cell sarcomas) may also have calcifications.

Another reliable marker of a hamartoma is the finding of fat within the lesion on a CT scan; however, fewer than 50% of hamartomas demonstrate this characteristic.

Inflammatory Nodules

Sarcoidosis is known as the great mimicker, but it rarely presents as an SPN.⁶⁷ Most commonly, it presents as hilar and mediastinal lymphadenopathy and diffuse parenchymal involvement. When it does present as an SPN, it is almost invariably a solid lesion, hardly ever a cavitary one. The incidence of sarcoidosis is highest in African-American women between 20 and 40 years of age. If sarcoidosis is suspected during the evaluation of an SPN, an elevated angiotensin-converting enzyme level supports the diagnosis, but a normal level does not exclude it. If a biopsy is performed, the presence of noncaseating granulomas on pathologic evaluation establishes the diagnosis.

Pulmonary rheumatoid nodules are present in fewer than 1% of patients with rheumatoid arthritis.⁶⁸ They are usually associated with rheumatoid nodules in other parts of the body but may precede any systemic manifestations of the disease. Pulmonary rheumatoid nodules, though generally asymptomatic in themselves, arise from underlying rheumatoid activity. When the underlying disease is active, the nodules may grow, simulating malignancy. An elevated serum rheumatoid factor level is typical and helps confirm the diagnosis.

Wegener granulomatosis is a necrotizing vasculitis that affects both the upper and the lower respiratory tract, as well as the kidneys. It presents with an SPN in approximately 20% of patients.⁶⁹ If vasculitis is suspected during evaluation of an SPN, laboratory studies should include testing for cytoplasmic antineutrophil cytoplasmic antibodies (c-ANCA); a positive result on this test is highly suggestive of Wegener granulomatosis. Treatment includes the cytotoxic drug cyclophosphamide, either alone or in combination with corticosteroids.

Infectious Nodules

An SPN can also represent an infectious granuloma caused by tuberculosis, atypical mycobacterial diseases, histoplasmosis, coccidioidomycosis, or aspergillosis. Such granulomas normally have a cavitary appearance on CT scans. Occasionally, an upright chest x-ray taken with the patient in the lateral decubitus position shows shifting of the position of the cavity's contents or a crescent of air around the mass (the Monod sign).⁷⁰ This radiographic finding is characteristic of a mycetoma, usually aspergilloma. Depending on the circumstances—in particular, on whether there has been significant hemoptysis and whether pulmonary function is reasonably well preserved—many of these lesions are best treated by means of resection. Others are best diagnosed by noninvasive techniques and treated with antibiotics.

Pulmonary dirofilariasis is a rare but well-attested cause of SPNs that is the consequence of infestation of human lungs by the canine heartworm *Dirofilaria immitis*. This organism is transmitted to humans in larval form by mosquitoes that have ingested blood from affected dogs.⁷¹ Because humans are not suitable hosts for this organism, the larvae die and embolize to the lungs, where they initiate a granulomatous response. Typically, these lesions are pleura based, and the diagnosis is made at the time of resection.⁷² Once the diagnosis is made, no further therapy is required.

Echinococcosis is a hydatid disease caused by the tapeworm *Echinococcus granulosus*. It is endemic to certain areas of the world where sheep and cattle are raised. Normally, it is ingested incidentally; the parasite penetrates the bowel wall and travels to the lungs in 10% to 30% of cases.^{73,74} A complete blood count usually demonstrates peripheral eosinophilia. If echinococcosis is suspected, a hemagglutination test, which has a sensitivity of 66% to 100% and a specificity of 98% to 99% for *Echinococcus*, should be performed. TTNB should not be performed, because there is a risk that cyst

rupture could result in an anaphylactic reaction to the highly antigenic contents. Patients may be treated with anthelmintic agents, but the incidence of persistent or recurrent disease is high. Accordingly, surgical resection should be considered.

OTHER CONSIDERATIONS

Pulmonary amyloidosis may present in either a diffuse or a nodular form. The prognosis is most favorable when it presents as an asymptomatic SPN. Typically, the nodule is well defined and between 2 and 4 cm in diameter. Unless the patient exhibits systemic manifestations of amyloidosis, the diagnosis can be confirmed only by biopsy of the nodule.³⁵

Rounded atelectasis usually presents as a pleura-based nodular density that occurs secondary to pleural scarring and thickening. An effort should be made to look for associated pleural plaques resulting from asbestos exposure. The CT scan usually demonstrates an SPN with a “comet tail.” Biopsy is not required unless mesothelioma is strongly suspected or the SPN is seen to have grown on successive CT scans.⁷⁵

Management

Currently, there are no evidence-based guidelines that fully delineate a recommended approach to the workup and management of SPNs.⁷⁶ The following is a summary of our preferred approach.

The ultimate aim in the evaluation of an SPN is to classify the lesion as either benign or malignant. The first step toward that end is to compare current chest x-rays or CT scans with any previous images that are available. An SPN whose size has been stable for 2 years on diagnostic images will be benign 90% to 95% of the time. If no previous images are available for comparison, the patient should undergo a complete evaluation as if the nodule were an early-stage NSCLC. This evaluation must be individualized according to the characteristics of the patient and the lesion. On the basis of the patient's age and smoking history, the size of the SPN, and the characteristics of the lesion's borders, an SPN for which no previous diagnostic images are available can be initially classified as having a low, intermediate, or high probability of cancer [see Table 3].^{7,77,78} This classification governs the subsequent workup. Whereas a patient with a high-probability SPN needs a complete workup, with the goal being resection, the same workup would not be cost-effective for a patient with a low-probability SPN. It is important not to subject a patient with a high-probability SPN to studies that will not change clinical management or outcome: doing so will delay diagnosis and treatment unnecessarily.

At this point in the evaluation, if the nature of the SPN is still

Table 3 Initial Assessment of Probability of Cancer in Solitary Pulmonary Nodule

Characteristics of Patient or Lesion	Probability of Cancer		
	Low	Intermediate	High
Patient age	< 40 yr	40–60 yr	> 60 yr
Patient smoking history	Never smoked	< 20 pack-years	≥ 20 pack-years
Lesion size	< 1.0 cm	1.1–2.2 cm	≥ 2.3 cm
Lesion margin	Smooth	Scalloped	Spiculated

indeterminate and the lesion is larger than 1.0 cm, there may be a role for PET scanning. If PET scanning yields negative results, the SPN is probably benign, and follow-up with CT scanning is appropriate. If PET scanning yields positive results and the patient is a high surgical risk, TTNB may be performed to establish a diagnosis. If, however, the patient is a reasonable surgical risk, proceeding directly to VATS resection (and, potentially, to lobectomy) offers the best chance of a cure.

For patients with SPNs smaller than 1.0 cm, the optimal approach may be to perform serial CT scanning at 3-month inter-

vals for a minimum of 2 years. The rationale for this approach is based on the difficulty of identifying these lesions with VATS, the low likelihood of establishing a diagnosis with TTNB, and the possibility that the lesion may be benign. If the lesion has grown visibly between scans, it is probably malignant, and proceeding with resection for diagnosis and treatment is appropriate. The likelihood that nodal metastases will develop in a closely followed SPN smaller than 1.0 cm is low.⁶⁰ If the SPN proves to be malignant, scanning at 3-month intervals is unlikely to alter the eventual outcome.

16 DECORTICATION AND PLEURECTOMY

Eric S. Lambright, M.D.

In normal circumstances, the pleural space is a potential cavity between the lung and the chest wall—more specifically, between the visceral pleura and the parietal pleura. In the average healthy patient, this space is less than 1 mm thick. There are a number of pathologic processes that can alter the transport of cells and fluid within this space and thus give rise to clinically significant sequelae. One such process is fibrothorax, which is defined as the presence of abnormal fibrous tissue within the pleural space, resulting in entrapment of the underlying pulmonary parenchyma (a state variously referred to as trapped lung, restrictive pleurisy, or encased lung). Decortication is the surgical procedure by which this restrictive fibrous layer is peeled away from the lung; the literal meaning of the term is the stripping away of a rind (from the Latin word *cortex* “bark, rind, shell”). The technical goals of the operation are to reexpand the lung and resolve the pathologic process affecting the pleural space so that pulmonary function and chest wall mechanics will improve and the patient’s symptoms will be relieved.

Successful management of a patient with fibrothorax depends on close adherence to basic surgical tenets: appropriate selection of patients for surgical treatment, preoperative optimization of the patient’s physiologic status, exacting attention to the technical aspects of the procedure, and timely intervention to address perioperative complications. If insufficient attention is paid to any of these important tenets, decortication may fail to achieve any significant improvement in the patient’s symptoms or physiologic status, potentially leaving him or her in an even more debilitated state.

Preoperative Evaluation

PATHOPHYSIOLOGY OF FIBROTHORAX

Although any insult to the pleura can result in an inflammatory response with fibrin deposition,¹ hemothorax and infection (bacterial and mycobacterial) remain the most common causes of fibrothorax [see Table 1]. Typically, empyemas evolve over a 4- to 6-week period as the infection progresses throughout the pleural space. The first (exudative) phase is characterized by a thin, fibrin-containing fluid exudate. The second (fibropurulent) phase is characterized by a heavy fibrin deposit over the pleural surface with the development of loculations and fibrous debris in the thoracic cavity. The third (organizational) phase, which begins at about 3 to 5 weeks, is characterized by the formation of a thick fibrous peel that imprisons the lung and prevents expansion. When fully developed, this peel has three distinct layers: (1) an outer layer consisting of loosely organized vascular tissue, (2) a middle layer consisting of fibrous connective tissue that is relatively avascular and acellular, and (3) an inner layer consisting of necrotic tissue and fibrinoid masses.² Generally, if a hemothorax is small, it will be reabsorbed, provided that the lymphatic system is intact. However, if the hemothorax is relatively large, if there is continued bleeding, or if bacteria are present, there is a high likelihood that a fibrous peel will eventually form.³

HISTORY AND PHYSICAL EXAMINATION

The physiologic consequences of a fibrothorax culminate in pulmonary restriction, manifested by decreased lung volumes, reduced diffusion capacity, and lower expiratory flow rates. Movement of the chest is impaired.⁴ The initial clinical presentation of a fibrothorax depends on its cause and severity, as well as on the presence or absence of underlying parenchymal disease. Typically, dyspnea on exertion is the most common presenting symptom, though cough, fever, pleuritic chest discomfort, malaise, night sweats, weight loss, or chest pressure may also be present. In obtaining the clinical history, it is important to determine whether the condition is chronic and whether there are any other underlying disease processes that may be complicating the pulmonary disease process. Physical examination yields relatively nonspecific findings; typically, decreased breath sounds and decreased chest wall excursion are noted.

DIAGNOSTIC IMAGING AND PHYSIOLOGIC TESTING

Radiographic evaluation is the mainstay of diagnosis [see Figures 1, 2, and 3]. Computed tomography (CT) of the chest is the imaging modality of choice for delineating abnormalities of the pleural space and defining the character of the pleural disease process. CT scanning can assess the extent and thickness of pleural involvement and characterize associated parenchymal disease. It readily identifies parenchymal abnormalities such as fibrosis, bronchiectasis, and malignancy. Such factors play a role in surgical decision making. In particular, malignancy must be included in the differential diagnosis of fibrothorax and ruled out; the management options for malignant disease are quite different from those for benign disease.

Physiologic testing with spirometry and evaluation of diffusing capacity helps define the degree of pulmonary dysfunction and facilitates risk stratification. The results of pulmonary function testing may be quite abnormal preoperatively and are often worse than would have been expected from the radiographic evaluation. Marked abnormalities in physiologic testing should not be considered absolute contraindications to surgical intervention, because some degree of improvement may be anticipated. The improvement in dyspnea, pulmonary reexpansion, and parenchymal function that can realistically be expected after decortication may be

Chronic pneumothorax

Figure 1 (a) Shown is a chest x-ray from a patient with a 2-month history of dyspnea and cough associated with intermittent fever and night sweats. Treatments included three courses of antibiotics and bronchodilator therapy. (b) A chest CT scan from the same patient shows a large pleural collection containing air and demonstrates pleural thickening (arrow). The findings are consistent with empyema. Thoracentesis was performed, demonstrating white, creamy purulence but failing to achieve reexpansion of the lung. Decortication was performed.

estimated on the basis of the preoperative diagnostic imaging and physiologic testing. Ultimately, the surgeon's judgment plays the key role in deciding for or against surgical intervention.

EXCLUSION OF MALIGNANCY

In the evaluation of a patient with a fibrothorax, it is essential to keep in mind the possibility of a malignant pleural process. If malignancy is a concern, this possibility should be excluded before a decision is made to proceed with decortication. Decortication of a malignant fibrous peel is difficult, and the outcome is not particularly satisfying from the standpoint of lung expansion; accordingly, for a pleural malignancy, a lesser, palliative intervention is generally more appropriate than decortication. Metastatic involve-

ment of the pleura (usually by adenocarcinoma) is far more common than malignant pleural mesothelioma, which is a primary malignancy of the pleural space. Cytologic evaluation of the pleural fluid will establish the diagnosis of metastatic pleural involvement in most cases; however, it tends to be less effective in establishing the diagnosis of malignant mesothelioma. If the presentation of a chronic pleural process is atypical and the etiology is poorly defined, a degree of suspicion for malignancy must be maintained. Appropriate initial pleural biopsies can be useful for ruling out underlying malignancy before decortication. Currently, pleural biopsy is usually performed by means of video thoracoscopy, but closed pleural biopsy is still done occasionally (though it is fast becoming a lost art). If a malignancy is identified, therapeutic alter-

Figure 2 (a) Shown is a preoperative chest CT scan from a patient with a 6-week history of malaise and weight loss who ultimately presented with hypotension and respiratory insufficiency necessitating mechanical ventilatory support. (b) A chest CT scan obtained from the same patient after decortication shows complete reexpansion of the lung.

Figure 3 Shown is a chest CT scan from a patient with a pulmonary abscess (arrow) complicated by pleural space infection. The pleural space was drained via a chest tube thoracostomy. The lung did not completely reexpand. Sepsis was controlled with antibiotics. Decortication was not considered, because of the extensiveness of the underlying pulmonary parenchymal process.

natives such as pleurodesis or use of the Pleurx pleural catheter (Denver Biomedical, Golden, Colorado) may be indicated.

Operative Planning

INDICATIONS FOR SURGICAL INTERVENTION

Fibrothorax is a potentially preventable complication. As noted (see above), it is a manifestation of a chronic disease process; thus, the earlier a therapeutic intervention is initiated, the better the chances that fibrothorax can be prevented. In patients with a traumatic hemothorax, early and complete drainage often serves to prevent fibrothorax.⁵ Observational studies have consistently demonstrated that early evacuation of a clotted hemothorax reduces morbidity and mortality and prevents empyema.^{6,7} When parapneumonic effusions are thin, simple aspiration or chest tube drainage may suffice. Often, the fibropurulent stage characterized by loculated empyema or clotted hemothorax can be successfully managed by means of thoracoscopic intervention with debridement of the intrathoracic debris and irrigation; this approach allows the parenchyma to reexpand before a restrictive peel can be formed.⁸

The primary indication for decortication in a patient with fibrothorax is symptomatic pulmonary restriction resulting from the development of a fibrinous peel. The timing of the operation is an important consideration. In many cases, pleuropulmonary processes are self-limiting, and the symptoms resolve over time. As a rule, decortication should be considered (1) if pleural thickening has been present for a substantial period (> 4 to 6 weeks), (2) if respiratory symptoms remain disabling, and (3) if there is radiographic evidence of reversible entrapment of the lung. Decortication is often necessary when lesser interventions have not achieved control of a pleural space infection or have not enabled the lung to reexpand. For tuberculous empyema, drug therapy remains the treatment of choice. Decortication may also be performed to treat pleural effusions that persist despite long-term medical therapy.

A condition that poses a major challenge to the thoracic surgeon is pleural space infection with underlying parenchymal dis-

ease or airway stenosis.^{9,10} In this setting, decortication is destined to fail: the lung parenchyma will not reexpand to fill the pleural space completely, and any surgical intervention carried out on the diseased lung will only aggravate the underlying disease process. Pleuropneumonectomy may be the only option, though it should be considered a last resort, to be used only if there is significant parenchymal destruction. Decortication may be precluded by invasive uncontrolled pulmonary infection, contralateral pulmonary disease, or a chronically debilitated state that results in a significant or even prohibitive level of operative risk. Medical optimization may be required as an initial step. Often, however, the underlying pleural infection process remains unresolved despite optimal medical management, and surgical intervention becomes necessary in a patient who remains medically fragile. Optimally, the patient's nutritional status should be normalized (with forced feedings, if necessary), and sepsis, if present, should be controlled with appropriate antibiotic therapy.

TECHNICAL CONSIDERATIONS

Essentially, pleural cavity infection and fibrosis are problems of residual intrapleural space. The lung cannot expand sufficiently to fill the hemithorax, and as a consequence, the residual space becomes or remains infected. These problems often prove difficult for the thoracic surgeon to address; good surgical judgment is crucial for ensuring optimal outcomes. In planning for decortication, there are a number of technical issues that must be considered, including the timing of intervention (taking into account whether the disease process is chronic or subacute), the quality of the underlying pulmonary parenchyma, the expected ability of the lung to reexpand, the possible need to address residual space issues, and the physiologic status of the patient. The goal of the procedure is to remove the peel from the visceral pleura so as to allow the lung to reexpand and, equally important, to ensure that any potential residual space is obliterated.¹¹

There are few absolute contraindications to pulmonary decortication, other than a patient who is unfit to undergo surgery or the presence of underlying parenchymal or bronchial disease that would prevent lung reexpansion. There are, however, some situations in which a lesser intervention (e.g., chest tube thoracostomy, rib resection, or open window thoracostomy) might yield a better outcome than decortication would from the patient's perspective. In general, decortication is not required for a small, well-defined residual cavity; it is usually reserved for a diffuse pleural process. Whether the disease process is chronic or subacute will also influence the surgeon's choice of approach. For example, in the earlier stages of pleural space infection, when the peel is less organized, a thoracoscopic approach that includes cleansing of the pleural space, removal of the pleural debris, and breaking up of loculations may prove adequate. With a chronic process, however, an attempt at thoracoscopic decortication may do more harm than good.

Operative Technique

The first step in open decortication (which at times includes parietal pleurectomy in addition to decortication) is bronchoscopic evaluation aimed at identifying any endobronchial obstructions that might prevent satisfactory lung expansion. Such evaluation sometimes yields unexpected findings, such as malignancy, bronchial stenosis, or a broncholith.

The chest is entered at the appropriate predetermined interspace (usually the fifth or sixth) via a standard posterolateral thoracotomy [see Figure 4]; alternatively, a vertical axillary thoracotomy may be employed. With either approach, the latissimus dorsi

Figure 4 Decortication. The chest is entered through a posterolateral thoracotomy at the fifth or sixth interspace.

and the serratus anterior should be spared because either or both might subsequently be required for a transposition muscle flap. Because the chest is often rigid and contracted as a result of the underlying inflammatory process, it may be helpful to resect a rib in a subperiosteal fashion. This measure facilitates exposure and helps define the extrapleural plane for the initiation of parietal pleurectomy.

When the disease process is chronic (i.e., has lasted longer than 6 weeks), the parietal pleura and the visceral pleura are often fused. In this situation, one would proceed with pleurectomy. When adhesions are present between the pleural layers but the visceral pleura has not fused with the parietal pleura [see Figure 5], the adhesions may be lysed with a combination of sharp dissection and electrocauterization.

The key to a technically successful decortication is to define the correct plane between the pleural peel and the visceral pleura. If the pleural resection is inadequate, lung expansion will be compromised. If the pleurectomy is too deep, parenchymal injury will result, bleeding and air leakage will occur, and postoperative recovery will be prolonged. Gentle manual ventilation of the lung

operated on, coupled with continuous positive airway pressure (CPAP), should provide appropriate countertraction from the underlying lung parenchyma.

An incision is made in the pleural peel, and the appropriate decortication plane is identified [see Figure 6a]. The pleural peel is then grasped with hemostats, and blunt and sharp dissection is carried out over a broad area to separate the peel from the visceral pleura [see Figure 6b]; a sponge-ball or peanut dissector may be useful for this purpose. Care must be taken to keep from injuring the underlying pulmonary parenchyma, which is fragile; inadvertent injury may result in prolonged and unnecessary air leaks. Some degree of patience is required, in that this operation often becomes tedious. For an optimal surgical outcome, all portions of the lung encased by the peel should be addressed. To this end, it is often necessary to follow the peel into the fissure, down onto the diaphragm, and into the posterior and anterior sulci. At times, a second entry point into the chest through another interspace may be required to achieve an optimal technical result. Should better exposure be deemed necessary, one should not hesitate to proceed with this counterincision.

Figure 5 Decortication. Any adhesions between the visceral pleura and the parietal pleura are lysed with a combination of sharp dissection and electrocauterization.

Figure 6 Decortication. (a) With the lung expanded, the pleural peel is sharply incised, and the appropriate decortication plane is identified. (b) The peel is separated from the visceral pleura with blunt and sharp dissection.

Once resected, the peel is sent for pathologic and microbiologic evaluation. The lung is tested to confirm that it is capable of complete reexpansion. Any large parenchymal air leaks that are noted may be oversewn, but this step often is not necessary. The various pulmonary parenchymal sealants now commercially available may reasonably be considered for control of parenchymal air-leaks. Chest tubes are placed—typically, one along the diaphragm, a second anteriorly, and a third posteriorly, toward the apex. Provided that the lung is satisfactorily reexpanded, air leaks will seal promptly. Hemostasis must be ensured: a residual hemothorax in a patient with a pleural space infection will serve as a nidus for ongoing infection.

The role of parietal pleurectomy in this setting remains unclear. Opinions differ, but objective data are sparse. Parietal pleurectomy does result in some improvement of the mechanics of the thoracic cage¹²; however, it also increases the risk of bleeding, prolongs the procedure, and places vital intrathoracic structures (e.g., the phrenic and vagus nerves, the esophagus, the brachial plexus, and certain blood vessels) at risk for injury. In addition, it is often possible that the pleural process will resolve without parietal pleurectomy once the underlying issues are addressed. The technically optimal strategy may be to adopt a compromise approach—that is, to perform a partial parietal pleurectomy and to take extra care when dissecting near the vital mediastinal structures.

Postoperative management of the chest tube is dictated by culture results, intraoperative findings, and the patient's clinical sta-

tus. Concerns related to residual space may be managed by means of open tube thoracostomy, open window thoracostomy, or placement of a muscle flap. On rare occasions, thoracoplasty with multiple rib resection may be considered to obliterate any infection in the residual space by bringing the chest wall down to fill the space.

Outcome Evaluation

The morbidity and mortality to be expected after decortication depend on the severity of the underlying illness and on the occurrence of perioperative complications. In a review from 1985, mortality was less than 8%.¹³ Complications tend to be either infection related (e.g., perioperative sepsis syndrome) or technique related (e.g., bronchopleural fistula, hemorrhage, and persistent air leakage); some of them may necessitate additional surgical intervention. As with all operations in the chest, close attention to detail and meticulous surgical technique are critical for minimizing the incidence of postoperative complications.

The degree of functional improvement attained after decortication depends primarily on the presence and extent of disease in the underlying lung parenchyma.¹⁴⁻¹⁶ If the parenchyma of the lung is normal, complete reexpansion of the lung and obliteration of the pleural space should be achievable. Lung volumes usually improve measurably after decortication, but they generally do not return to normal.^{14,17} Changes within the chest (i.e., mediastinal shift and elevation of the diaphragm, with a resultant decrease in

Table 2 Causes of Failed Decortication

Underlying parenchymal disease	Active tuberculosis or invasive pulmonary infection Bronchial stenosis Chronic lung collapse
Technical considerations	Residual space Inadequate lung expansion Air leakage Postoperative hemothorax

the size of the thorax) may account for this finding. It is unclear to what extent the expected functional improvement is influenced by whether the pleural process is acute or chronic. Some authors have observed an association between shorter durations of pleural disease before treatment and improved outcomes^{18,19}; others have not observed such an association.¹⁴ Failure to achieve improvement after decortication appears to be most strongly related to errors of surgical judgment (in particular, poor patient selection) and to insufficiently meticulous surgical technique (leading to perioperative complications).

Although to date, no studies have dealt specifically with failure after decortication, it is likely that technical difficulties are the most common cause of such failure, with the main problem being inadequate obliteration of the pleural space [see Table 2].

Inability to define the plane of dissection between the peel and the visceral pleura is an especially troublesome technical challenge that can adversely affect results. If visceral pleurectomy is performed, air leakage and postoperative hemorrhage may compromise pulmonary function. Care must be taken throughout the operation to protect the phrenic nerve from injury; fortunately, this usually is not an issue, because the mediastinal pleura is rarely involved in the inflammatory process. Incomplete parietal pleurectomy or inability to free the diaphragm may also compromise results.

If patients are appropriately selected, complete reexpansion of the lung after decortication can usually be achieved. Occasionally, however, an issue related to residual pleural space may arise after an otherwise technically satisfactory decortication. If this space is not obliterated, failure is inevitable. Options for addressing the residual space problem include thoracoplasty and tissue transposition. Either the latissimus dorsi or the abdominal omentum will provide sufficient bulk for obliteration of the residual space.^{20,21} The omentum is preferable when the space is in the inferior hemithorax, whereas the latissimus dorsi is preferable when the space is in the superior hemithorax. At the time of the initial incision, the surgeon should keep in mind the possibility that tissue transposition may eventually prove necessary and should therefore opt for a muscle-sparing thoracotomy if possible.

At present, the use of thoracoscopy to address fibrothorax definitively cannot be recommended.

1 ACUTE ABDOMINAL PAIN

David I. Soybel, M.D., F.A.C.S.

The term acute abdominal pain generally refers to previously undiagnosed pain that arises suddenly and is of less than 7 days' (usually less than 48 hours') duration.¹ It may be caused by a great variety of intraperitoneal disorders, many of which call for surgical treatment, as well as by a range of extraperitoneal disorders,² which typically do not call for surgical treatment [see Clinical Evaluation, Tentative Differential Diagnosis, below]. Abdominal pain that persists for 6 hours or longer is usually caused by disorders of surgical significance.³ The primary goals in the management of patients with acute abdominal pain are (1) to establish a differential diagnosis and a plan for confirming the diagnosis through appropriate imaging studies, (2) to determine whether operative intervention is necessary, and (3) to prepare the patient for operation in a manner that minimizes perioperative morbidity and mortality.

In many cases, these goals are easily accomplished. On occasion, however, the evaluation of patients with acute abdominal pain can be one of the most difficult challenges in clinical surgery. It is essential to keep in mind that most (at least two thirds) of the patients who present with acute abdominal pain have disorders for which surgical intervention is not required.^{2,4,5} In addition, most clinicians depend on recognition of specific patterns and sequences of symptoms and signs to determine the need for further testing and to make decisions regarding the timing of operation; however, at least one third of patients with acute abdominal pain exhibit atypical features that render pattern recognition unreliable.^{2,5} Finally, it is not clear that individual clinicians always or even usually agree on presenting symptoms and physical signs. In one study of abdominal pain in children, agreement between individual observers was reached 50% of the time for the physical sign of rebound tenderness; however, for five other signs (abdominal distention, abdominal tenderness to percussion, abdominal tenderness to palpation, abdominal guarding, and bowel sounds), interobserver agreement was not reached in more than one third of patients. These findings highlight the difficulties inherent in evaluation and management of acute abdominal pain. In addition, they emphasize the importance of integrating care among different providers to minimize loss of information and maximize continuity of care.

Clinical Evaluation

HISTORY

A careful and methodical clinical history should be obtained. Key features of the history include the dimensions of pain (i.e., mode of onset, duration, frequency, character, location, chronology, radiation, and intensity), as well as the presence or absence of any aggravating or alleviating factors and associated symptoms. Often, such a history is more valuable than any single laboratory or x-ray finding and determines the course of subsequent evaluation and management.

Unfortunately, when the ability of clinicians to take an organized and accurate history has been studied, the results have been disap-

pointing.⁶ For this reason, the use of standardized history and physical forms, with or without the aid of diagnostic computer programs, has been recommended.⁷⁻¹⁰ A large-scale study that included 16,737 patients with acute abdominal pain demonstrated that integration of computer-aided diagnosis into management yielded a 20% improvement in diagnostic accuracy.⁷ The study also documented statistically significant reductions in inappropriate admissions, negative laparotomies, serious management errors (e.g., failure to operate on patients who require surgery), and length of hospital stay, as well as statistically significant increases in the number of patients who were immediately discharged home without adverse effects and the promptness with which those requiring surgery underwent operation. Although many factors may have contributed to the observed benefits of computer-aided decision-making, it is clear that the use of structured and standardized means of collecting clinical and laboratory data was crucial. An example of such a structured data sheet is the pain chart developed by the World Organization of Gastroenterology (OMGE) [see Figure 1]. Because this pain chart is not exhaustive and does not cover all potential situations, individual surgeons may want to add to it; however, they would be well advised not to omit any of the symptoms and signs on the OMGE data sheet from their routine examination of patients with acute abdominal pain.¹¹

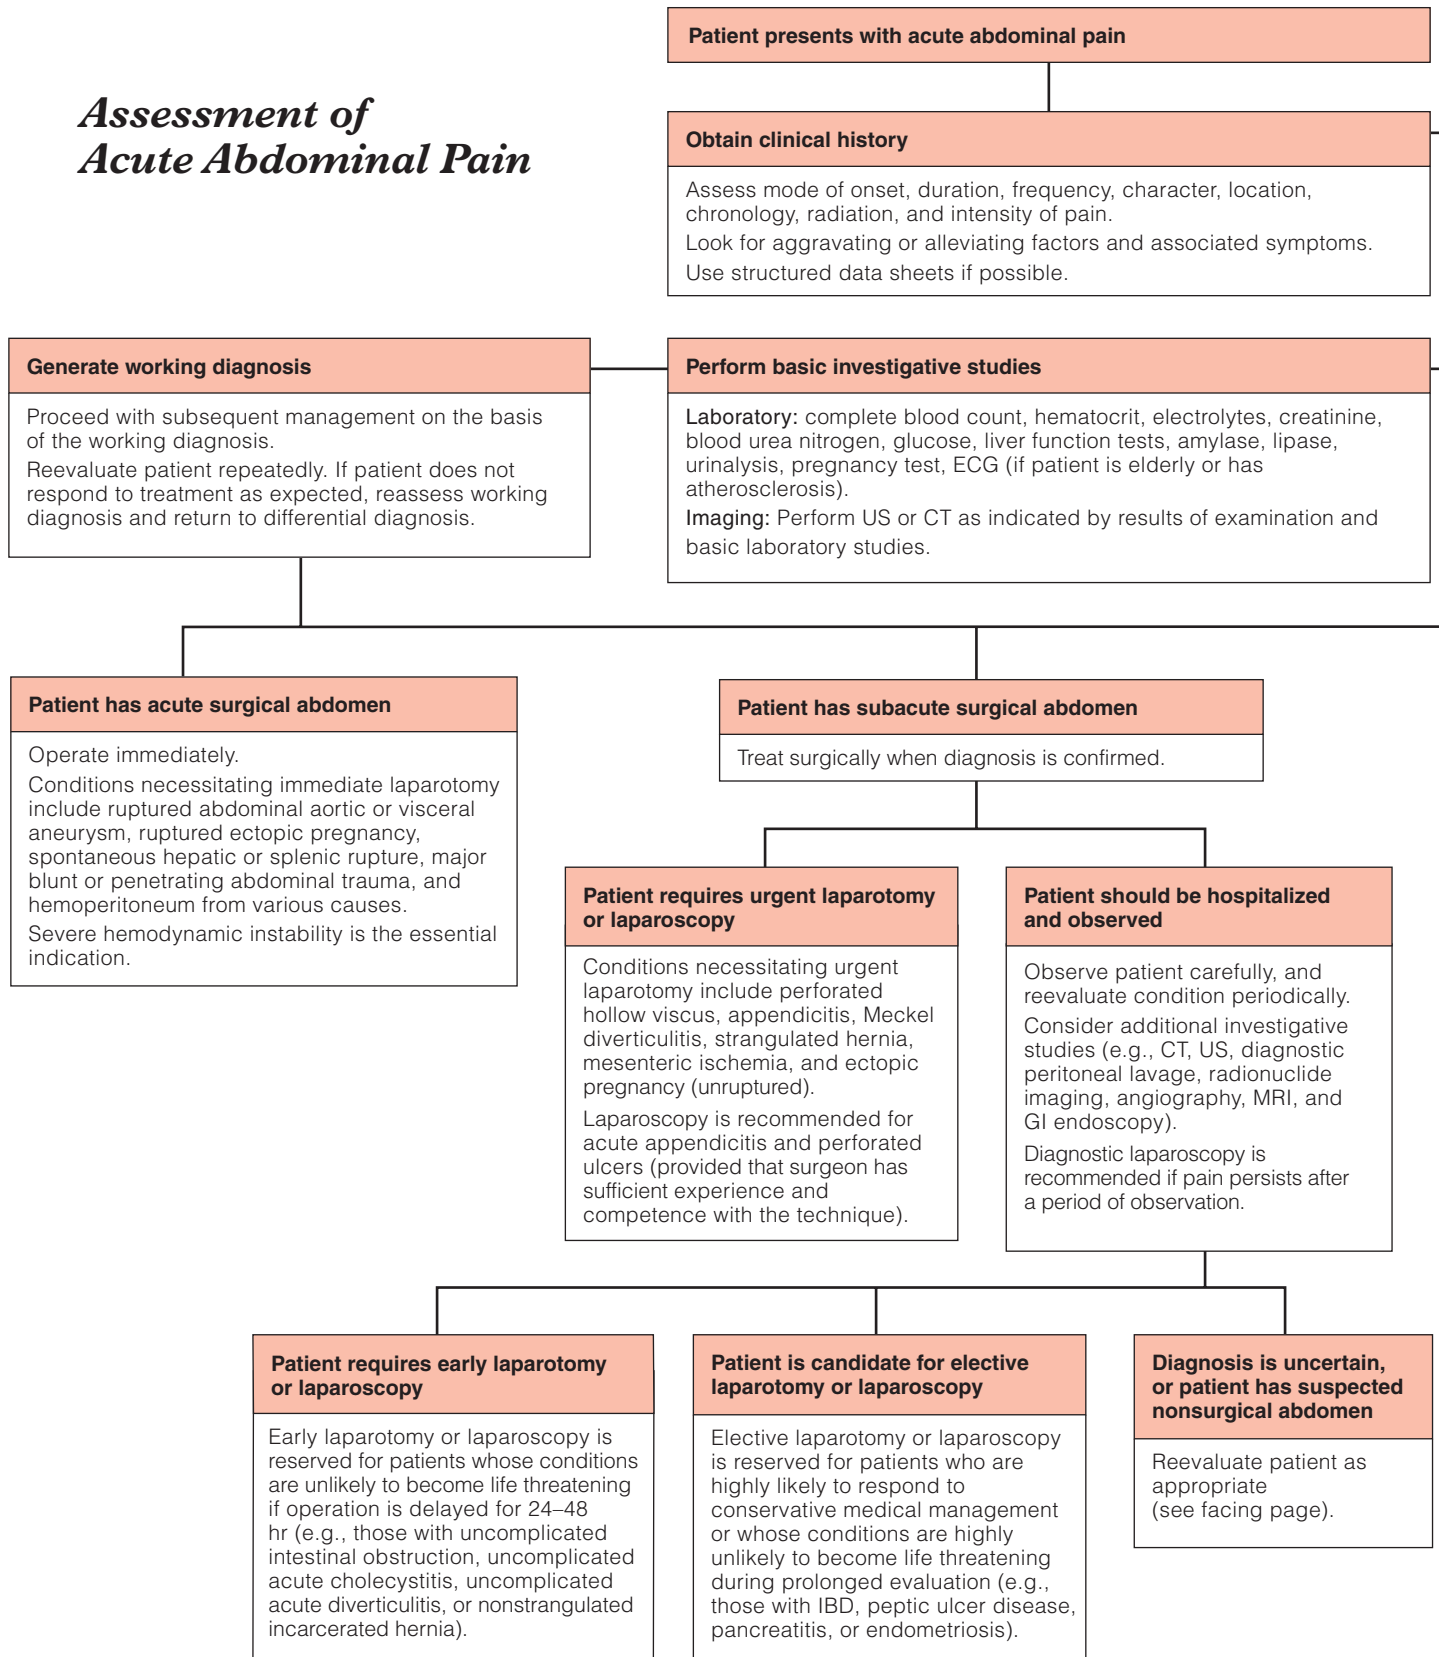

The patient's own words often provide important clues to the correct diagnosis. The examiner should refrain from suggesting specific symptoms, except as a last resort. Any questions that must be asked should be open-ended—for example, "What happens when you eat?" rather than "Does eating make the pain worse?" Leading questions should be avoided. When a leading question must be asked, it should be posed first as a negative question (i.e., one that calls for an answer in the negative) because a negative answer to a question is more likely to be honest and accurate. For example, if peritoneal inflammation is suspected, the question asked should be "Does coughing make the pain better?" rather than "Does coughing make the pain worse?"

The mode of onset of abdominal pain may help the examiner determine the severity of the underlying disease. Pain that has a sudden onset suggests an intra-abdominal catastrophe, such as a ruptured abdominal aortic aneurysm (AAA), a perforated viscus, or a ruptured ectopic pregnancy; a near loss of consciousness or stamina associated with sudden-onset pain should heighten the level of concern for such a catastrophe. Rapidly progressive pain that becomes intensely focused in a well-defined area within a period of a few minutes to an hour or two suggests a condition such as acute cholecystitis or pancreatitis. Pain that has a gradual onset over several hours, usually beginning as slight or vague discomfort and slowly progressing to steady and more localized pain, suggests a subacute process and is characteristic of processes that lead to peritoneal inflammation. Numerous disorders may be associated with this mode of onset, including acute appendicitis, diverticulitis, pelvic inflammatory disease (PID), and intestinal obstruction.

Pain can be either intermittent or continuous. Intermittent or cramping pain (colic) is pain that occurs for a short period (a few minutes), followed by longer periods (a few minutes to one-half

Assessment of Acute Abdominal Pain

Generate tentative differential diagnosis

Remember that the majority of patients will turn out to have nonsurgical diagnoses.
 Take into account effects of age and gender on diagnostic possibilities.

Perform physical examination

Evaluate general appearance and ability to answer questions; estimate degree of obvious pain; note position in bed; identify area of maximal pain; look for extra-abdominal causes of pain and signs of systemic illness.
 Perform systematic abdominal examination: (1) inspection, (2) auscultation, (3) percussion, (4) palpation.
 Perform rectal, genital, and pelvic examinations.

Patient has abdominal pain of uncertain origin

Observe patient to determine whether operation is indicated.

Patient should be hospitalized and observed

Provide narcotic analgesia as appropriate.
 Observe patient carefully, and reevaluate condition periodically.
 Consider additional investigative studies. CT and US may be especially useful.

Patient can be evaluated in outpatient setting

Patient has suspected surgical abdomen

Reevaluate patient as appropriate (see facing page).

Diagnosis is uncertain, or patient has suspected nonsurgical abdomen

Reevaluate patient as appropriate (see above, right, and facing page).

Patient has nonsurgical condition or chronic relapsing condition that does not necessitate operative intervention

Nonsurgical conditions causing acute abdominal pain include both extraperitoneal [see Table 2] and intraperitoneal disorders.

Patient should be hospitalized and observed

Provide narcotic analgesia as appropriate.
 Observe patient carefully, and reevaluate condition periodically.
 Consider additional investigative studies.

Diagnosis is uncertain or patient has suspected surgical abdomen

Reevaluate patient as appropriate (see above, left, and facing page).

Diagnosis is nonsurgical

Refer patient for medical management.

Figure 1 Shown on facing page is a data sheet modified from the abdominal pain chart developed by the OMGE.¹⁰

hour) of complete remission during which there is no pain at all. Intermittent pain is characteristic of obstruction of a hollow viscus and results from vigorous peristalsis in the wall of the viscus proximal to the site of obstruction. This pain is perceived as deep in the abdomen and is poorly localized. The patient is restless, may writhe about incessantly in an effort to find a comfortable position, and often presses on the abdominal wall in an attempt to alleviate the pain. Whereas the intermittent pain associated with intestinal obstruction (typically described as gripping and mounting) is usually severe but bearable, the pain associated with obstruction of small conduits (e.g., the biliary tract, the ureters, and the uterine tubes) often becomes unbearable. Obstruction of the gallbladder or the bile ducts gives rise to a type of pain often referred to as biliary colic; however, this term is a misnomer, in that biliary pain is usually constant because of the lack of a strong muscular coat in the biliary tree and the absence of regular peristalsis.

Continuous or constant pain is pain that is present for hours or days without any period of complete relief; it is more common than intermittent pain. Continuous pain is usually indicative of a process that will lead, or has already led, to peritoneal inflammation or ischemia. It may be of steady intensity throughout, or it may be associated with intermittent pain. For example, the typical colicky pain associated with simple intestinal obstruction changes when strangulation occurs, becoming continuous pain that persists between episodes or waves of cramping pain.

Certain types of pain are generally held to be typical of certain pathologic states. For example, the pain of a perforated ulcer is often described as burning, that of a dissecting aneurysm as tearing, and that of bowel obstruction as gripping. One may imagine that the first type of pain is explained by the efflux of acid, the second by the sudden expansion of the retroperitoneum, and the third by the churning of hyperperistalsis. Colorful as these images may be, in most cases, the pain begins in a nondescript way. It is only by carefully following the patient's description of the evolution and time course of the pain that such images may be formed with confidence.

For several reasons—atypical pain patterns, dual innervation by visceral and somatic afferents, normal variations in organ position, and widely diverse underlying pathologic states—the location of abdominal pain is only a rough guide to diagnosis. It is nevertheless true that in most disorders, the pain tends to occur in characteristic locations, such as the right upper quadrant (cholecystitis), the right lower quadrant (appendicitis), the epigastrium (pancreatitis), or the left lower quadrant (sigmoid diverticulitis) [see Figure 2]. It is important to determine the location of the pain at onset because this may differ from the location at the time of presentation (so-called shifting pain). In fact, the chronological sequence of events in the patient's history is often more important for diagnosis than the location of the pain alone. For example, the classic pain of appendicitis begins in the periumbilical region and settles in the right lower quadrant. A similar shift in location can occur when escaping gastroduodenal contents from a perforated ulcer pool in the right lower quadrant.

It is also important to take into account radiation or referral of the pain, which tends to occur in characteristic patterns [see Figure 3]. For example, biliary pain is referred to the right subscapular area, and the boring pain of pancreatitis typically radiates straight through to the back. Obstruction of the small intestine and the proximal colon is referred to the umbilicus, and obstruction distal to the splenic flexure is often referred to the suprapubic area. Spasm in the ureter often radiates to the suprapubic area and into the groin. The more severe the pain is, the more likely it is to be associated with referral to other areas.

The intensity or severity of the pain is related to the magnitude of the underlying insult. It is important to distinguish between the in-

tensity of the pain and the patient's reaction to it because there appear to be significant individual differences with respect to tolerance of and reaction to pain. Pain that is intense enough to awaken the patient from sleep usually indicates a significant underlying organic cause. Past episodes of pain and factors that aggravate or relieve the pain often provide useful diagnostic clues. For example, pain caused by peritonitis tends to be exacerbated by motion, deep breathing, coughing, or sneezing, and patients with peritonitis tend to lie quietly in bed and avoid any movement. The typical pain of acute pancreatitis is exacerbated by lying down and relieved by sitting up. Pain that is relieved by eating or taking antacids suggests duodenal ulcer disease, whereas diffuse abdominal pain that appears 30 minutes to 1 hour after meals suggests intestinal angina.

Associated gastrointestinal symptoms (e.g., nausea, vomiting, anorexia, diarrhea, and constipation) often accompany abdominal pain; however, these symptoms are nonspecific and therefore may not be of great value in the differential diagnosis. Vomiting in particular is common: when sufficiently stimulated by pain impulses traveling via secondary visceral afferent fibers, the medullary vomiting centers activate efferent fibers and cause reflex vomiting. Once again, the chronology of events is important, in that pain often precedes vomiting in patients with conditions necessitating operation, whereas the opposite is usually the case in patients with medical (i.e., non-surgical) conditions.^{5,12} This is particularly true for adult patients with acute appendicitis, in whom pain almost always precedes vomiting by several hours. In children, vomiting is commonly observed closer to the onset of the pain, though it is rarely the initial symptom.

Similarly, constipation may result from a reflex paralytic ileus when sufficiently stimulated visceral afferent fibers activate efferent sympathetic fibers (splanchnic nerves) to reduce intestinal peristalsis. Diarrhea is characteristic of gastroenteritis but may also accompany incomplete intestinal or colonic obstruction. More significant is a history of obstipation, because if it can be definitely established that a patient with acute abdominal pain has not passed gas or stool for 24 to 48 hours, it is certain that some degree of intestinal obstruction is present. Other associated symptoms that should be noted include jaundice, melena, hematochezia, hematemesis, and hematuria. These symptoms are much more specific than the ones just discussed and can be extremely valuable in the differential diagnosis. Most conditions that cause acute abdominal pain of surgical significance are associated with some degree of fever if they are allowed to continue long enough. Fever suggests an inflammatory process; however, it is usually low grade and often absent altogether, particularly in elderly and immunocompromised patients. The combination of a high fever with chills and rigors indicates bacteremia, and concomitant changes in mental status (e.g., agitation, disorientation, and lethargy) suggest impending septic shock.

A history of trauma (even if the patient considers the traumatic event trivial) should be actively sought in all cases of unexplained acute abdominal pain; such a history may not be readily volunteered (as is often the case with trauma resulting from domestic violence). The history may be particularly relevant in a patient taking anticoagulants and presenting with acute onset of abdominal pain accompanied by tenderness but no clear signs of inflammation. Hematoma within the rectus muscle sheath can easily be mistaken for appendicitis or other lower abdominal illnesses; hematoma elsewhere can produce symptoms of obstruction or acute bleeding into the peritoneum and the retroperitoneum. In female patients, it is essential to obtain a detailed gynecologic history that includes the timing of symptoms within the menstrual cycle, the date of the last menses, previous and current use of contraception, any abnormal vaginal bleeding or discharge, an obstetric history, and any risk fac-

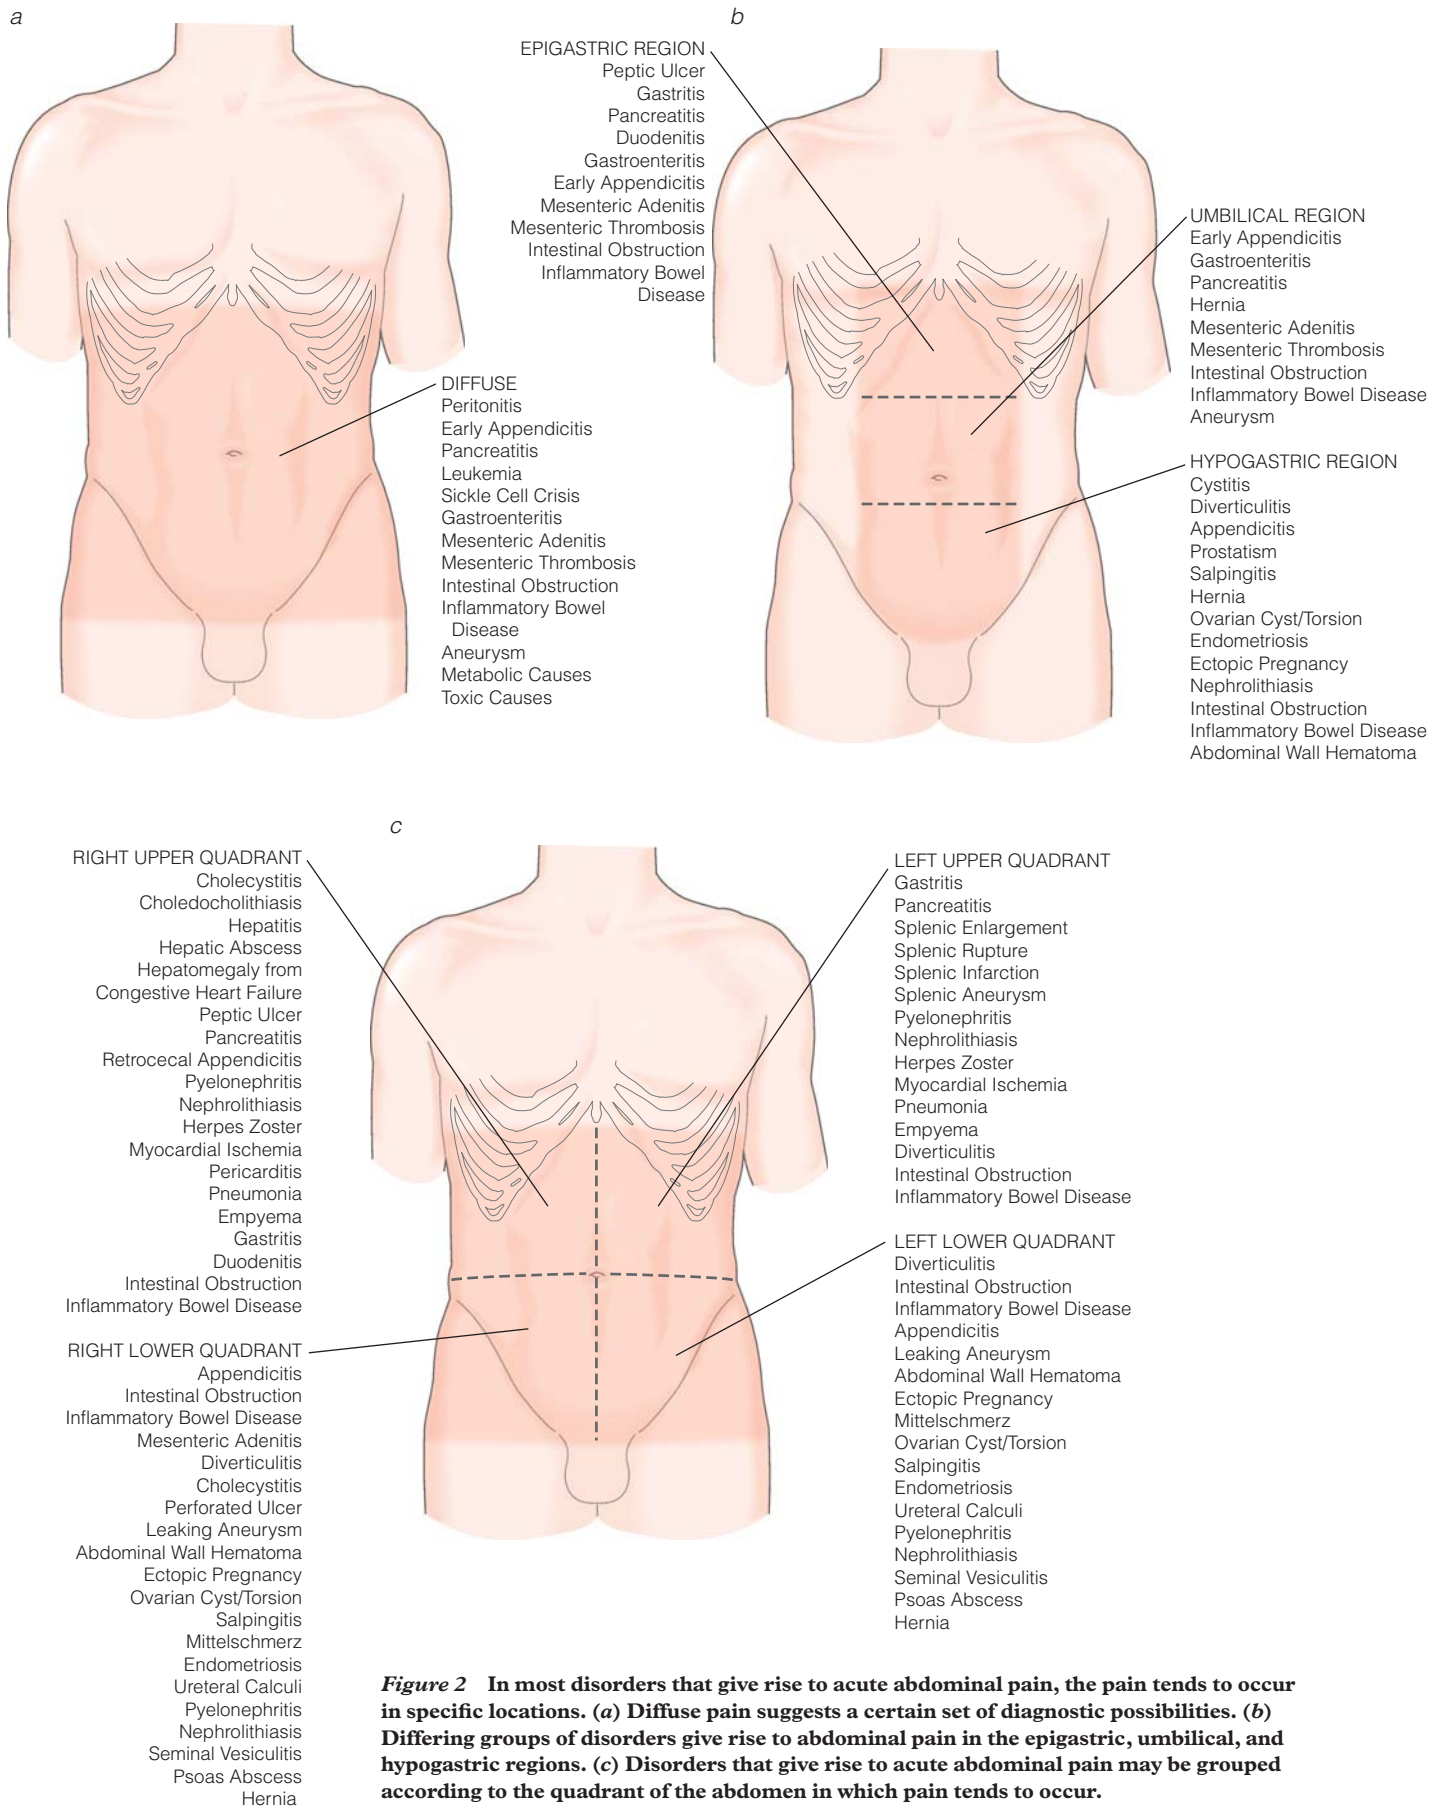

Figure 2 In most disorders that give rise to acute abdominal pain, the pain tends to occur in specific locations. (a) Diffuse pain suggests a certain set of diagnostic possibilities. (b) Differing groups of disorders give rise to abdominal pain in the epigastric, umbilical, and hypogastric regions. (c) Disorders that give rise to acute abdominal pain may be grouped according to the quadrant of the abdomen in which pain tends to occur.

Figure 3 Pain of abdominal origin tends to be referred in characteristic patterns.⁸⁰ The more severe the pain is, the more likely it is to be referred. Shown are anterior (left) and posterior (right) areas of referred pain.

tors for ectopic pregnancy (e.g., PID, use of an intrauterine device, or previous ectopic or tubal surgery).

A complete history of previous medical conditions must be obtained because associated diseases of the cardiac, pulmonary, and renal systems may give rise to acute abdominal symptoms and may also significantly affect the morbidity and mortality associated with surgical intervention. Weight changes, past illnesses, recent travel, environmental exposure to toxins or infectious agents, and medications used should also be investigated. A history of previous abdominal operations should be obtained but should not be relied on too heavily in the absence of operative reports. A careful family history is important for detection of hereditary disorders that may cause acute abdominal pain. A detailed social history should also be obtained that includes any history of tobacco, alcohol, or illicit drug use, as well as a sexual history.

TENTATIVE DIFFERENTIAL DIAGNOSIS

Once the history has been obtained, the examiner should generate a tentative differential diagnosis and carry out the physical examination in search of specific signs or findings that either rule out or confirm the diagnostic possibilities. Given the diversity of conditions that can cause acute abdominal pain [see Tables 1 and 2], there is no substitute for general awareness of the most common causes of acute abdominal pain and the influence of age, gender, and geography on the likelihood of any of these potential causes. Although acute abdominal pain is the most common surgical emergency and most non-trauma-related surgical admissions (and 1% of all hospital admissions) are accounted for by patients complaining of abdominal pain, little information is available regarding the clinical spectrum of disease in these patients.¹³ Nevertheless, detailed epidemiologic information can be an invaluable asset in the diagnosis and treatment of acute abdominal pain. Now that patients from different parts of the world are increasingly being seen in

North American emergency rooms, it is important to consider endemic diseases, including tuberculosis,^{14,15} parasitic diseases,¹⁶⁻¹⁸ bezoars from unusual dietary habits,^{19,20} and unusual malignancies.^{21,22}

The value of detailed epidemiologic knowledge notwithstanding, it is worthwhile to keep in mind the truism that common things are common. Regarding which things are common, the most extensive information currently available comes from the ongoing survey begun in 1977 by the Research Committee of the OMGE. As of the last progress report on this survey, which was published in 1988,²³ more than 200 physicians at 26 centers in 17 countries had accumulated data on 10,320 patients with acute abdominal pain [see Table 3]. The most common diagnosis in these patients was nonspecific abdominal pain (NSAP)—that is, the retrospective diagnosis of exclusion in which no cause for the pain can be identified.^{24,25} Nonspecific abdominal pain accounted for 34% of all patients seen; the four most common diagnoses accounted for more than 75%. The most common surgical diagnosis in the OMGE survey was acute appendicitis, followed by acute cholecystitis, small bowel obstruction, and gynecologic disorders. Relatively few patients had perforated peptic ulcer, a finding that confirms the current downward trend in the incidence of this condition. Cancer was found to be a significant cause of acute abdominal pain. There was little variation in the geographic distribution of surgical causes of acute abdominal pain (i.e., conditions necessitating operation) among developed countries. In patients who required operation, the most common causes were acute appendicitis (42.6%), acute cholecystitis (14.7%), small bowel obstruction (6.2%), perforated peptic ulcer (3.7%), and acute pancreatitis (4.5%).²³ The OMGE survey's finding that NSAP was the most common diagnosis in patients with acute abdominal pain has been confirmed by several studies^{12,13,25}; the finding that acute appendicitis, cholecystitis, and intestinal obstruction were the three most common diagnoses in patients with acute abdominal pain who require operation has also been amply confirmed [see Table 3].^{1,12,13}

The data described so far provide a comprehensive picture of the most likely diagnoses for patients with acute abdominal pain in many centers around the world; however, this picture does not take

Table 1 Intraperitoneal Causes of Acute Abdominal Pain⁸¹

Inflammatory		
Peritoneal	Pancreatic abscess	Torsion or degeneration of fibroid
Chemical and nonbacterial peritonitis	Hepatic abscess	Ectopic pregnancy
Perforated peptic ulcer/biliary tree, pancreatitis, ruptured ovarian cyst, mittelschmerz	Splenic abscess	
Bacterial peritonitis	Mesenteric	Hemoperitoneum
Primary peritonitis	Lymphadenitis (bacterial, viral)	Ruptured hepatic neoplasm
Pneumococcal, streptococcal, tuberculous	Epiplonic appendagitis	Spontaneous splenic rupture
Spontaneous bacterial peritonitis	Pelvic	Ruptured mesentery
Perforated hollow viscus	Pelvic inflammatory disease (salpingitis)	Ruptured uterus
Esophagus, stomach, duodenum, small intestine, bile duct, gallbladder, colon, urinary bladder	Tube-ovarian abscess	Ruptured graafian follicle
Hollow visceral	Endometritis	Ruptured ectopic pregnancy
Appendicitis	Mechanical (obstruction, acute distention)	Ruptured aortic or visceral aneurysm
Cholecystitis	Hollow visceral	
Peptic ulcer	Intestinal obstruction	Ischemic
Gastroenteritis	Adhesions, hernias, neoplasms, volvulus	Mesenteric thrombosis
Gastritis	Intussusception, gallstone ileus, foreign bodies	Hepatic infarction (toxemia, purpura)
Duodenitis	Bezoars, parasites	Splenic infarction
Inflammatory bowel disease	Biliary obstruction	Omental ischemia
Meckel diverticulitis	Calculi, neoplasms, choledochal cyst, hemobilia	Strangulated hernia
Colitis (bacterial, amebic)	Solid visceral	Neoplastic
Diverticulitis	Acute splenomegaly	Primary or metastatic intraperitoneal neoplasms
Solid visceral	Acute hepatomegaly (congestive heart failure, Budd-Chiari syndrome)	
Pancreatitis	Mesenteric	Traumatic
Hepatitis	Omental torsion	Blunt trauma
	Pelvic	Penetrating trauma
	Ovarian cyst	Iatrogenic trauma
		Domestic violence
		Miscellaneous
		Endometriosis

into account the effect of age on the relative likelihood of the various potential diagnoses. It is well known that the disease spectrum of acute abdominal pain is different in different age groups, especially in the very old^{4,26,27} and the very young.²⁸⁻³⁰ In the OMGE survey, well over 90% of cases of acute abdominal pain in children were diagnosed as acute appendicitis (32%) or NSAP (62%).²⁸ Similar age-related differences in the spectrum of disease have been confirmed by other studies,¹⁶ as have various gender-related differences.

This variation in the disease spectrum is readily apparent when the 10,320 patients from the OMGE survey are segregated by age [see Table 4]. In patients 50 years of age or older,²⁷ cholecystitis was more common than either NSAP or acute appendicitis; small bowel obstruction, diverticular disease, and pancreatitis were all approximately five times more common than in patients younger than 50 years. Hernias were also a much more common problem in older patients. In the entire group of patients, only one of every 10 instances of intestinal obstruction was attributable to a hernia, whereas in patients 50 years of age or older, one of every three instances was caused by an undiagnosed hernia. Cancer was 40 times more likely to be the cause of acute abdominal pain in patients 50 years of age or older; vascular diseases (including myocardial infarction, mesenteric ischemia, and ruptured AAA) were 25 times more common in patients 50 years of age or older and 100 times more common in patients older than 70 years. What is more, outcome was clearly related to age: mortality was significantly higher in patients older than 70 years (5%) than in those younger than 50 years (< 1%). Whereas the peak incidence of acute abdominal pain occurred in patients in their teens and 20s,²⁸ the great majority of deaths occurred in patients older than 70 years.²⁷

PHYSICAL EXAMINATION

In the physical examination of a patient, as in the taking of the history, there is no substitute for organization and patience; the amount of information that can be obtained is directly

proportional to the gentleness and thoroughness of the examiner. The physical examination begins with a brief but thorough evaluation of the patient's general appearance and ability to answer questions. The degree of obvious pain should be estimated. The patient's position in bed should be noted. A patient who lies motionless with flexed hips and knees is more likely to have generalized peritonitis. A restless patient who writhes about in bed is more likely to have colicky pain.

The area of maximal pain should be identified before the physical examination is begun. The examiner can easily do this by simply asking the patient to cough and then to point with two fingers to the area where pain seems to be focused. This allows the examiner to avoid the area in the early stages of the examination and to confirm it at a later stage without causing the patient unnecessary discomfort in the meantime.

The physical examination should be directed, in the sense that it should address critical findings that would confirm or exclude the likeliest disorders in the differential diagnosis. In this context, however, it should be complete. Some processes that can cause abdominal pain occur within the chest (e.g., pneumonia, ischemic heart disease or arrhythmia, esophageal muscular disorders); thus, auscultation of the lungs and the heart is integral to the examination. Pelvic examination should be performed in women, and examina-

tion of the rectum and the groin should be performed in all patients. It should not be assumed that advanced imaging technology (e.g., CT, MRI, or ultrasonography [US]) will provide the diagnosis most quickly or with the highest level of confidence. The sensitivity and specificity (not to mention the cost-effectiveness) of any laboratory or imaging study are grounded in the intelligent gathering and categorization of signs and symptoms.^{31,32}

Before attention is directed to the patient's abdomen, signs of systemic illness should be sought. Systemic signs of shock (e.g., diaphoresis, pallor, hypothermia, tachypnea, tachycardia with orthostasis, and frank hypotension) usually accompany a rapidly progressive or advanced intra-abdominal condition and, in the absence of extra-abdominal causes, are indications for immediate laparotomy. The absence of any alteration in vital signs, however, does not necessarily exclude a serious intra-abdominal process.

Examination of the abdomen begins with the patient resting in a comfortable supine position. A right-handed examiner should stand on the patient's right side, and the patient's abdomen should be level with the elbow at rest. In some cases, to make sure that the examination is unhurried and the patient's anxiety is allayed, the examiner may find it useful to sit at the bedside. The examination should include inspection, auscultation, percussion, and palpation of all areas of the abdomen, the flanks, and the groin (including all hernia orifices) in addition to rectal and genital examinations (and, in female patients, a full gynecologic examination). A systematic ap-

proach is crucial: an examiner who methodically follows a set pattern of abdominal examination every time will be rewarded more frequently than one who improvises haphazardly with each patient.

The first step in the abdominal examination is careful inspection of the anterior and posterior abdominal walls, the flanks, the perineum, and the genitalia for previous surgical scars (possible adhesions), hernias (incarceration or strangulation), distention (intestinal obstruction), obvious masses (distended gallbladder, abscesses, or tumors), ecchymosis or abrasions (trauma), striae (pregnancy or ascites), an everted umbilicus (increased intra-abdominal pressure), visible pulsations (aneurysm), visible peristalsis (obstruction), limitation of movement of the abdominal wall with ventilatory movements (peritonitis), or engorged veins (portal hypertension).

The next recommended step in the abdominal examination is auscultation. Although it is important to note the presence (or absence) of bowel sounds and their quality, auscultation is probably the least rewarding aspect of the physical examination. Severe intra-abdominal conditions, even intra-abdominal catastrophes, may occur in patients with normal bowel sounds, and patients with silent abdomens may have no significant intra-abdominal pathology at all. In general, however, the absence of bowel sounds indicates a paralytic ileus; hyperactive or hypoactive bowel sounds often are variations of normal activity; and high-pitched bowel sounds with splashes, tinkles (echoing as in a large cavern), or rushes (prolonged, loud gurgles) indicate mechanical bowel obstruction.

Table 2 Extraperitoneal Causes of Acute Abdominal Pain

Genitourinary	Endocrine	Hematologic
Pyelonephritis	Diabetic ketoacidosis	Sickle cell crisis
Perinephric abscess	Hyperparathyroidism (hypercalcemia)	Acute leukemia
Renal infarct	Acute adrenal insufficiency (Addisonian crisis)	Acute hemolytic states
Nephrolithiasis	Hyperthyroidism or hypothyroidism	Coagulopathies
Ureteral obstruction (lithiasis, tumor)		Pernicious anemia
Acute cystitis	Musculoskeletal	Other dyscrasias
Prostatitis	Rectus sheath hematoma	
Seminal vesiculitis	Arthritis/diskitis of thoracolumbar spine	Vascular
Epididymitis		Vasculitis
Orchitis	Neurogenic	Periarteritis
Testicular torsion	Herpes zoster	
Dysmenorrhea	Tabes dorsalis	Toxins
Threatened abortion	Nerve root compression	Bacterial toxins (tetanus, staphylococcus)
	Spinal cord tumors	Insect venom (black widow spider)
Pulmonary	Osteomyelitis of the spine	Animal venom
Pneumonia	Abdominal epilepsy	Heavy metals (lead, arsenic, mercury)
Empyema	Abdominal migraine	Poisonous mushrooms
Pulmonary embolus	Multiple sclerosis	Drugs
Pulmonary infarction		Withdrawal from narcotics
Pneumothorax	Inflammatory	
	Schönlein-Henoch purpura	Retroperitoneal
Cardiac	Systemic lupus erythematosus	Retroperitoneal hemorrhage (spontaneous adrenal hemorrhage)
Myocardial ischemia	Polyarteritis nodosa	Psoas abscess
Myocardial infarction	Dermatomyositis	
Acute rheumatic fever	Scleroderma	Psychogenic
Acute pericarditis		Hypochondriasis
	Infectious	Somatization disorders
Metabolic	Bacterial	
Acute intermittent porphyria	Parasitic (malaria)	Factitious
Familial Mediterranean fever	Viral (measles, mumps, infectious mononucleosis)	Munchausen syndrome
Hypolipoproteinemia	Rickettsial (Rocky Mountain spotted fever)	Malingering
Hemochromatosis		
Hereditary angioneurotic edema		

Table 3 Frequency of Specific Diagnoses in Patients with Acute Abdominal Pain

Diagnosis	Frequency in Individual Studies (% of Patients)					
	OMGE ²³ (N = 10,320)	Wilson ⁸² (N = 1,196)	Irvin ¹³ (N = 1,190)	Brewer ¹² (N = 1,000)	de Dombal ¹ (N = 552)	Hawthorn ⁸³ (N = 496)
Nonspecific abdominal pain	34.0	45.6	34.9	41.3	50.5	36.0
Acute appendicitis	28.1	15.6	16.8	4.3	26.3	14.9

The third step is percussion to search for any areas of dullness, fluid collections, sections of gas-filled bowel, or pockets of free air under the abdominal wall. Tympany may be present in patients with bowel obstruction or hollow viscus perforation. Percussion can be useful as a way of estimating organ size and of determining the presence of ascites (signaled by a fluid wave or shifting dullness). Gentle percussion over the four quadrants of the abdomen can also be used to elicit a sign of peritoneal irritation, and patients tolerate this maneuver reasonably well. Pain associated with mild levels of percussion is a good indicator of peritonitis if the maneuver is performed in the same way each time. In general, however, maneuvers associated with palpation are best for determining whether peritonitis is present.

The last step, palpation, is the most informative aspect of the physical examination. Palpation of the abdomen must be done very gently to avoid causing additional pain early in the examination. It should begin as far as possible from the area of maximal pain and then should gradually advance toward this area, which should be the last to be palpated. The examiner should place the entire hand on the patient's abdomen with the fingers together and extended, applying pressure with the pulps (not the tips) of the fingers by flexing the wrists and the metacarpophalangeal joints. It is essential to determine whether true involuntary muscle guarding (muscle spasm) is present. This determination is made by means of gentle palpation over the abdominal wall while the patient takes a long, deep breath. If guarding is voluntary, the underlying muscle immediately relaxes under the gentle pressure of the palpating hand. If, however, the patient has true involuntary guarding, the muscle remains in spasm

(i.e., taut and rigid) throughout the respiratory cycle (so-called boardlike abdomen). True involuntary guarding is indicative of localized or generalized peritonitis. It must be remembered that mus-

Table 4 Frequency of Specific Diagnoses in Younger and Older Patients with Acute Abdominal Pain in the OMGE Study^{23,27}

Diagnosis	Frequency (% of Patients)	
	Age < 50 Yr (N = 6,317)	Age ≥ 50 Yr (N = 2,406)
Nonspecific abdominal pain	39.5	15.7
Appendicitis	32.0	15.2
Cholecystitis	6.3	20.9
Obstruction	2.5	12.3
Pancreatitis	1.6	7.3
Diverticular disease	< 0.1	5.5
Cancer	< 0.1	4.1
Hernia	< 0.1	3.1
Vascular disease	< 0.1	2.3

Table 5 Common Abdominal Signs and Findings Noted on Physical Examination⁶

Sign or Finding	Description	Associated Clinical Condition(s)
Aaron sign	Referred pain or feeling of distress in epigastrium or precordial region on continued firm pressure over the McBurney point	Acute appendicitis
Ballance sign	Presence of dull percussion note in both flanks, constant on left side but shifting with change of position on right side	Ruptured spleen
Bassler sign	Sharp pain elicited by pinching appendix between thumb of examiner and iliacus muscle	Chronic appendicitis
Beevor sign	Upward movement of umbilicus	Paralysis of lower portions of rectus abdominis muscles
Blumberg sign	Transient abdominal wall rebound tenderness	Peritoneal inflammation
Carnett sign	Disappearance of abdominal tenderness when anterior abdominal muscles are contracted	Abdominal pain of intra-abdominal origin
Chandelier sign	Intense lower abdominal and pelvic pain on manipulation of cervix	Pelvic inflammatory disease
Charcot sign	Intermittent right upper quadrant abdominal pain, jaundice, and fever	Cholelithiasis
Chaussier sign	Severe epigastric pain in gravid female	Prodrome of eclampsia
Claybrook sign	Transmission of breath and heart sounds through abdominal wall	Ruptured abdominal viscus
Courvoisier sign	Palpable, nontender gallbladder in presence of clinical jaundice	Periapillary neoplasm
Cruveilhier sign	Varicose veins radiating from umbilicus (<i>caput medusae</i>)	Portal hypertension
Cullen sign	Periumbilical darkening of skin from blood	Hemoperitoneum (especially in ruptured ectopic pregnancy)
Cutaneous hyperesthesia	Increased abdominal wall sensation to light touch	Parietal peritoneal inflammation secondary to inflammatory intra-abdominal pathology
Dance sign	Slight retraction in area of right iliac fossa	Intussusception
Danforth sign	Shoulder pain on inspiration	Hemoperitoneum (especially in ruptured ectopic pregnancy)
Direct abdominal wall tenderness	—	Localized inflammation of abdominal wall, peritoneum, or an intra-abdominal viscus
Fothergill sign	Abdominal wall mass that does not cross midline and remains palpable when rectus muscle is tense	Rectus muscle hematoma

(continued)

cle rigidity is relative: for example, muscle guarding may be less pronounced or absent in debilitated and elderly patients who have poor abdominal musculature. In addition, the evaluation of muscle guarding is dependent on the patient's cooperation.

Palpation is also useful for determining the extent and severity of the patient's tenderness. Diffuse tenderness indicates generalized peritoneal inflammation. Mild diffuse tenderness without guarding usually indicates gastroenteritis or some other inflammatory intestinal process without peritoneal inflammation. Localized tenderness suggests an early stage of disease with limited peritoneal inflammation. Rebound tenderness is elicited by applying gentle but deep pressure to the region of interest and then letting go abruptly. As a means of distraction, the examiner may use the stethoscope to apply the pressure. The main difficulties associated with palpation are that the deep pressure may increase anxiety and that the surprise of the sudden withdrawal may elicit pain where peritoneal irritation is not the cause.

Careful palpation can elicit several specific signs [see Table 5], such as the Rovsing sign (pain in the right lower quadrant when the left lower quadrant is palpated deeply), which is associated with acute appendicitis, and the Murphy sign (arrest of inspiration when the right upper quadrant is deeply palpated), which is associated with acute cholecystitis. These signs are indicative of localized peritoneal inflammation. Similarly, specific maneuvers can elicit signs of localized peritoneal irritation. The psoas sign is elicited by placing

the patient in the left lateral decubitus position and extending the right leg. In settings where appendicitis is suspected, pain on extension of the right leg indicates that the psoas is irritated and thus that the inflamed appendix is in a retrocecal position. The obturator sign is elicited by raising the flexed right leg and rotating the thigh internally. In settings where appendicitis is suspected, pain on rotation of the right thigh indicates that the obturator is irritated and thus that the inflamed appendix is in a pelvic position. The Kehr sign is elicited when the patient is placed in the Trendelenburg position. Pain in the shoulder indicates irritation of the diaphragm by a noxious fluid (e.g., gastric contents from a perforated ulcer, pus from a ruptured appendix, or free blood from a fallopian tube pregnancy). Another useful maneuver is the Carnett test, in which the patient elevates his or her head off the bed, thus tensing the abdominal muscles. When the pain is caused by abdominal wall conditions (e.g., rectal sheath hematoma), tenderness to palpation persists, but when the pain is caused by intraperitoneal conditions, tenderness to palpation decreases or disappears (the Carnett sign).

Rectal, genital, and (in women) pelvic examinations are essential to the evaluation of all patients with acute abdominal pain. The rectal examination should include evaluation of sphincter tone, tenderness (localized versus diffuse), and prostate size and tenderness, as well as a search for the presence of hemorrhoids, masses, fecal impaction, foreign bodies, and gross or occult blood. The genital examination should search for adenopathy, masses, discoloration,

Table 5 (continued)

Sign or Finding	Description	Associated Clinical Condition(s)
Grey Turner sign	Local areas of discoloration around umbilicus and flanks	Acute hemorrhagic pancreatitis
Iliopsoas sign	Elevation and extension of leg against pressure of examiner's hand causes pain	Appendicitis (retrocecal) or an inflammatory mass in contact with psoas
Kehr sign	Left shoulder pain when patient is supine or in the Trendelenburg position (pain may occur spontaneously or after application of pressure to left subcostal region)	Hemoperitoneum (especially ruptured spleen)
Kustner sign	Palpable mass anterior to uterus	Dermoid cyst of ovary
Mannkopf sign	Acceleration of pulse when a painful point is pressed on by examiner	Absent in factitious abdominal pain
McClintock sign	Heart rate > 100 beats/min 1 hr post partum	Postpartum hemorrhage
Murphy sign	Palpation of right upper abdominal quadrant during deep inspiration results in right upper quadrant abdominal pain	Acute cholecystitis
Obturator sign	Flexion of right thigh at right angles to trunk and external rotation of same leg in supine position result in hypogastric pain	Appendicitis (pelvic appendix); pelvic abscess; an inflammatory mass in contact with muscle
Puddle sign	Alteration in intensity of transmitted sound in intra-abdominal cavity secondary to percussion when patient is positioned on all fours and stethoscope is gradually moved toward flank opposite percussion	Free peritoneal fluid
Ransohoff sign	Yellow pigmentation in umbilical region	Ruptured common bile duct
Rovsing sign	Pain referred to the McBurney point on application of pressure to descending colon	Acute appendicitis
Subcutaneous crepitation	Palpable crepitus in abdominal wall	Subcutaneous emphysema or gas gangrene
Summer sign	Increased abdominal muscle tone on exceedingly gentle palpation of right or left iliac fossa	Early appendicitis; nephrolithiasis; ureterolithiasis; ovarian torsion
Ten Horn sign	Pain caused by gentle traction on right spermatic cord	Acute appendicitis
Toma sign	Right-sided tympany and left-sided dullness in supine position as a result of peritoneal inflammation and subsequent mesenteric contraction of intestine to right side of abdominal cavity	Inflammatory ascites

edema, and crepitus. The pelvic examination in women should check for vaginal discharge or bleeding, cervical discharge or bleeding, cervical mobility and tenderness, uterine tenderness, uterine size, and adnexal tenderness or masses. Although a carefully performed pelvic examination can be invaluable in differentiating non-surgical conditions (e.g., pelvic inflammatory disease and tubo-ovarian abscess) from conditions necessitating prompt operation (e.g., acute appendicitis), the possibility that a surgical condition is present should not be prematurely dismissed solely on the basis of a finding of tenderness on pelvic or rectal examination.

Investigative Studies

Laboratory tests and imaging studies rarely, if ever, establish a definitive diagnosis by themselves; however, if used in the correct clinical setting, they can confirm or exclude specific diagnoses suggested by the history and the physical examination.

LABORATORY TESTS

In all patients except those in extremis, a complete blood count, blood chemistries, and a urinalysis are routinely obtained before a decision to operate. The hematocrit is important in that it allows the surgeon to detect significant changes in plasma volume (e.g., dehydration caused by vomiting, diarrhea, or fluid loss into the peri-

toneum or the intestinal lumen), preexisting anemia, or bleeding. An elevated white blood cell (WBC) count is indicative of an inflammatory process and is a particularly helpful finding if associated with a marked left shift; however, the presence or absence of leukocytosis should never be the single deciding factor as to whether the patient should undergo an operation. A low WBC count may be a feature of viral infections, gastroenteritis, or NSAP. Other tests, such as C-reactive protein assay, may be useful for increasing confidence in the diagnosis of an acute inflammatory condition. An important consideration in the use of any such test is that derangements develop over time, becoming more likely as the illness progresses; thus, serial examinations might be more useful than a single test result obtained at an arbitrary point. Indeed, for the diagnosis of acute appendicitis, serial observations of the leukocyte count and the C-reactive protein level have been shown to possess greater predictive value than single observations.³³

Serum electrolyte, blood urea nitrogen (BUN), and creatinine concentrations are useful in determining the nature and extent of fluid losses. Blood glucose and other blood chemistries may also be helpful. Liver function tests (serum bilirubin, alkaline phosphatase, and transaminase levels) are mandatory when abdominal pain is suspected of being hepatobiliary in origin. Similarly, amylase and lipase determinations are mandatory when pancreatitis is suspected, though it must be remembered that amylase levels may be low or normal in patients with pancreatitis and may be markedly elevated in patients with other conditions (e.g., intestinal obstruction, mesenteric thrombosis, and perforated ulcer).

Urinalysis may reveal red blood cells (RBCs) (suggestive of renal

or ureteral calculi), WBCs (suggestive of urinary tract infection or inflammatory processes adjacent to the ureters, such as retrocecal appendicitis), increased specific gravity (suggestive of dehydration), glucose, ketones (suggestive of diabetes), or bilirubin (suggestive of hepatitis). A pregnancy test should be considered in any woman of childbearing age who is experiencing acute abdominal pain.

Electrocardiography is mandatory in elderly patients and in patients with a history of cardiomyopathy, dysrhythmia, or ischemic heart disease. Abdominal pain may be a manifestation of myocardial disease, and the physiologic stress of acute abdominal pain can increase myocardial oxygen demands and induce ischemia in patients with coronary artery disease.

IMAGING

Until relatively recently, initial radiologic evaluation of the patient with acute abdominal pain included plain films of the abdomen in the supine and standing positions and chest radiographs.³⁴ Currently, CT scanning (when available) is generally considered more likely to be helpful in most situations.^{35,36} Still, there remain some situations in which plain films may be a more useful and safe form of investigation—as, for example, when a strangulating obstruction is thought to be the most likely diagnosis and plain films are used for rapid confirmation. If the diagnosis of strangulating obstruction is in doubt, however, CT scanning—particularly with the newer generations of scanning instruments—is useful for making a definitive diagnosis and for identifying clinically unsuspected strangulation.³⁷⁻³⁹

When performed in the correct clinical setting, imaging studies may confirm diagnoses such as pneumonia (signaled by pulmonary infiltrates); intestinal obstruction (air-fluid levels and dilated loops of bowel); intestinal perforation (pneumoperitoneum); biliary, renal, or ureteral calculi (abnormal calcifications); appendicitis (fecalith); incarcerated hernia (bowel protruding beyond the confines of the peritoneal cavity); mesenteric infarction (air in the portal vein); chronic pancreatitis (pancreatic calcifications); acute pancreatitis (the so-called colon cutoff sign); visceral aneurysms (calcified rim); retroperitoneal hematoma or abscess (obliteration of the psoas shadow); and ischemic colitis (so-called thumbprinting on the colonic wall).

Although in most settings, CT is the preferred modality for primary evaluation of acute abdominal pain, there are certain settings in which US should be considered. When gallstones are considered a likely diagnosis, US is more apt to be diagnostic than CT is, given that about 85% of gallstones are not detectable by x-rays. In disorders of the female genitourinary tract, US is also quite sensitive and specific for diagnoses such as ovarian cyst, fallopian tube pregnancy, and intrauterine pregnancy. Although there are reassuring reports that the risks of radiation from CT scanning can be managed in children and pregnant women with abdominal pain,^{40,41} there remain theoretical concerns regarding the teratogenicity of the radiation dose.⁴² Accordingly, it would seem prudent to consider US the preferred initial imaging test for such patients. In these circumstances, CT is employed only if the diagnosis remains unresolved and if the potential delay in diagnosis (from not obtaining a CT scan) is likely to cause harm.

Working or Presumed Diagnosis

The tentative differential diagnosis developed on the basis of the clinical history is refined on the basis of the physical examination and the investigative studies per-

formed, and a working or presumed diagnosis is generated. Once a working diagnosis has been established, subsequent management depends on the accepted treatment for the particular condition believed to be present. In general, the course of management follows four basic pathways [see Management: Surgical versus Nonsurgical Treatment, below], depending on whether the patient (1) has an acute surgical condition that necessitates immediate laparotomy, (2) is believed to have an underlying surgical condition that does not necessitate immediate laparotomy but does call for urgent or early operation, (3) has an uncertain diagnosis that does not necessitate immediate or urgent laparotomy and that may prove to be nonsurgical, or (4) is believed to have an underlying nonsurgical condition.

It must be emphasized that the patient must be constantly reevaluated (preferably by the same examiner) even after the working diagnosis has been established. If the patient does not respond to treatment as expected, the working diagnosis must be reconsidered, and the possibility that another condition exists must be immediately entertained and investigated by returning to the differential diagnosis.

Management: Surgical versus Nonsurgical Treatment

ACUTE SURGICAL ABDOMEN

A thorough but expeditious approach to patients with acute abdominal pain is essential because in some patients, action must be taken immediately and there is not enough time for an exhaustive evaluation. As outlined (see above), such an approach should include a brief initial assessment, a complete clinical history, a thorough physical examination, and targeted laboratory and imaging studies. These steps can usually be completed in less than 1 hour and should be insisted on in the evaluation of most patients. In most cases, it is wise to resist the temptation to rush to the operating room with an incompletely evaluated, unprepared, and unstable patient. Sometimes, the anxiety of the patient or the impatience of the health care providers requesting the surgeon's consultation creates an unwarranted feeling of urgency. Often, however, the anxiety or impatience is on the part of the surgeon and, if indulged, may be a cause of subsequent regret.

There are very few abdominal crises that mandate immediate operation, and even with these conditions, it is still necessary to spend a few minutes on assessing the seriousness of the problem and establishing a probable diagnosis. Among the most common of the abdominal catastrophes that necessitate immediate operation are ruptured AAAs or visceral aneurysms, ruptured ectopic pregnancies, and spontaneous hepatic or splenic ruptures. The relative rarity of such conditions notwithstanding, it must always be remembered that patients with acute abdominal pain may have a progressive underlying intra-abdominal disorder causing the acute pain and that unnecessary delays in diagnosis and treatment can adversely affect outcome, often with catastrophic consequences.

SUBACUTE SURGICAL ABDOMEN

When immediate operation is not called for, the physician must decide whether urgent laparotomy or nonurgent but early op-

eration is necessary. Urgent laparotomy implies operation within 4 hours of the patient's arrival; thus, there is usually sufficient time for adequate resuscitation, with proper rehydration and restoration of vital organ function, before the procedure. Indications for urgent laparotomy may be encountered during the physical examination, may be revealed by the basic laboratory and radiologic studies, or may not become apparent until other investigative studies are performed. Involuntary guarding or rigidity during the physical examination, particularly if spreading, is a strong indication for urgent laparotomy. Other indications include increasing severe localized tenderness, progressive tense distention, physical signs of sepsis (e.g., high fever, tachycardia, hypotension, and mental-status changes), and physical signs of ischemia (e.g., fever and tachycardia). Basic laboratory and radiologic indications for urgent laparotomy include pneumoperitoneum, massive or progressive intestinal distention, signs of sepsis (e.g., marked or rising leukocytosis, increasing glucose intolerance, and acidosis), and signs of continued hemorrhage (e.g., a falling hematocrit). Additional findings that constitute indications for urgent laparotomy include free extravasation of radiologic contrast material, mesenteric occlusion on angiography, endoscopically uncontrollable bleeding, and positive results from peritoneal lavage (i.e., the presence of blood, pus, bile, urine, or GI contents). Acute appendicitis, perforated hollow viscera, and strangulated hernias are examples of common conditions that necessitate urgent laparotomy.

If early operation is contemplated, it may still be prudent to obtain additional studies to obtain information related to the site of the lesion or to associated anatomic pitfalls. In deciding whether to order such studies, it is important to consider not only whether the additional information obtained will increase confidence in the diagnosis but also whether the extra time, expense, and discomfort involved will be justified by the quality and usefulness of the information.⁴³ During a short, defined period of resuscitation, it may be possible to employ CT scanning to identify the location of the inflamed appendix in difficult (i.e., retrocecal or pelvic) locations. Knowing the location of the appendix and its morphology can be helpful in directing the incision in an open operation or determining the most expeditious exposure in a laparoscopic procedure. CT scanning may also be used to identify an atypical site of a visceral perforation (e.g., the proximal stomach, the distal or posterior wall of the duodenum, or the transverse colon), thereby guiding placement of the incision and obviating needless dissection of tissue planes. In the setting of distal bowel obstruction, an expeditious Gastrografin (Bracco Diagnostics, Princeton, New Jersey) enema or CT scan may alert the surgeon to the possibility of an otherwise undetectable malignancy (e.g., cecal carcinoma causing distal bowel obstruction). In cases where ischemic bowel is suspected, the site of vascular blockage can be localized by using a CT-angiogram imaging protocol. In each of these examples, the information gained may permit the surgeon to plan the operation, to optimize time spent under anesthesia, and to minimize postoperative discomfort after laparotomy.

The use of preoperative imaging has become increasingly important as an operative planning tool, particularly when laparoscopic approaches are contemplated for management of acute abdominal emergencies. In the 1990s and the first few years of the 21st century, a number of trials were performed to determine whether laparoscopy or open operation should be the approach of choice when the primary clinical diagnosis is acute appendicitis. This topic has been reviewed extensively in the literature⁴⁴⁻⁴⁶ and in a 2004 update of a Cochrane meta-analysis.⁴⁷ In some environments, the answer to this question remains unclear.^{48,49} In many settings, however, the current consensus is that uncomplicated appendicitis can be

treated laparoscopically, with a clear expectation of less postoperative pain, a shorter hospital stay, and an earlier return to work and regular activities. These advantages, though significant, do not indicate that a laparoscopic approach is to be preferred in all or most clinical settings or that it is necessarily more cost-effective than an open approach.⁴⁷ Laparoscopic appendectomy requires a high level of organization with respect to operating room resources, and this level of organization may be difficult to achieve in institutions where the procedure is not performed regularly (particularly in the middle of the night). In addition, it is not clear whether patients with appendicitis that is complicated by a well-established abscess or bowel obstruction benefit from laparoscopic approaches.

Anatomic considerations also enter into the decision whether to perform the procedure laparoscopically. For instance, it can be very difficult to separate a perforated retrocecal appendix from adherent colon in a safe manner. In many cases, it is prudent not to persist in attempting to extract the appendix without a standard open incision, excellent exposure, and controlled technique. The importance of anatomic considerations underscores the usefulness of preoperative CT in identifying pathologic anatomy, associated abnormalities, and potential pitfalls for either open or laparoscopic approaches.

The advantages of laparoscopy in the management of other abdominal emergencies are less clear-cut. It is important that the surgeon determine not only whether the particular clinical scenario is amenable to a laparoscopic approach but also whether the experience of the entire team and that of the institution as a whole are sufficient for what may be an advanced procedure performed in an acute situation. With this caveat in mind, various investigators have demonstrated that laparoscopy can be employed safely and with good clinical results in selected patients with perforated peptic ulcers.⁵⁰⁻⁵⁴ Two prospective, randomized, controlled trials comparing open repair of perforated peptic ulcers with laparoscopic repair found that the latter was safe and reliable and was associated with shorter operating times, less postoperative pain, fewer chest complications, shorter postoperative hospital stays, and earlier return to normal daily activities than the former.^{52,54}

ACUTE ABDOMINAL PAIN REQUIRING OBSERVATION

It is widely recognized that of all patients admitted for acute abdominal pain, only a minority require immediate or urgent operation.^{2,12} It is therefore both

cost-effective and prudent to adopt a system of evaluation that allows for thought and investigation before definitive treatment in all patients with acute abdominal pain except those identified early on as needing immediate or urgent laparotomy. The traditional wisdom has been that spending time on observation opens the door for complications (e.g., perforating appendicitis, intestinal perforation associated with bowel obstruction, or strangulation of an incarcerated hernia). However, clinical trials evaluating active in-hospital observation of patients with acute abdominal pain of uncertain origin have demonstrated that such observation is safe, is not accompanied by an increased incidence of complications, and results in fewer negative laparotomies.⁵⁵ Many institutions now employ CT scanning liberally in patients with uncertain diagnoses; this practice should greatly minimize the incidence of diagnostic failures or delays in patients with acute conditions necessitating surgical intervention.³²

The initial resuscitation and assessment are followed by appropriate imaging studies and serial observation. Specific monitoring mea-

tures are chosen (e.g., examination of the abdomen, measurement of urine output, a WBC count, and repeat CT scans), and end points of therapy should be identified. Active observation allows the surgeon to identify most of the patients whose acute abdominal pain is caused by NSAP or by various specific nonsurgical conditions. It must be emphasized that active observation involves more than simply admitting the patient to the hospital and passively watching for obvious problems: it implies an active process of thoughtful, discriminating, and meticulous reevaluation (preferably by the same examiner) at intervals ranging from minutes to a few hours, complemented by appropriately timed additional investigative studies.

A major point of contention in the management of patients with acute abdominal pain is the use of narcotic analgesics during the observation period. The main argument for withholding pain medication is that it may obscure the evolution of specific findings that would lead to the decision to operate. The main argument for giving narcotic analgesics is that in a controlled setting where patients are being observed by experienced clinicians, outcomes are not compromised and patients are more comfortable.⁵⁶ It has also been suggested that providing early pain relief may allow the more critical clinical signs to be more clearly identified⁵⁷ and that severe pain persisting despite adequate doses of narcotics suggests a serious condition for which operative intervention is likely to be necessary.

In my view, the decision whether to provide or withhold narcotic analgesia must be individualized.⁵⁸ The current consensus is that for most patients undergoing evaluation and observation for acute abdominal pain, it is safe to provide medication in doses that would “take the edge off” the pain without rendering the patient unable to cooperate during the observation period. It may be especially desirable to provide medication in a manner that allows the patient to be comfortable while lying in the CT scanner. In these cases, the goal of pain relief is to make it easier to obtain accurate information that will facilitate and expedite the diagnosis and the development of a treatment plan. Given the high diagnostic yield and accuracy of the new generation of CT scanners, it is generally safe to provide pain medication while obtaining the diagnosis.

On occasion, however, reflex administration of pain medication solely with the aim of relieving pain may be undesirable or even harmful. For example, in situations where advanced imaging is unavailable, physical examination may be so crucial to decision making that any risk of obscuring important physical findings is deemed unacceptable, and therefore, pain medication should be withheld. In addition, narcotic analgesia should be used cautiously in patients with acute intestinal obstruction when strangulation is a concern.⁵⁹ These patients present with abdominal pain that is out of proportion to the physical findings, a syndrome whose differential diagnosis includes acute intestinal ischemia, pancreatitis, ruptured aortic aneurysm, ureteral colic, and various medical causes (e.g., sickle cell crisis and porphyria). A period of resuscitation and evaluation, in conjunction with advanced imaging studies (e.g., CT) may then yield a tentative diagnosis of intestinal obstruction caused by adhesions (e.g., if the patient has a history of abdominal surgery and no evidence of herniation or obturation) without evidence of bowel ischemia. In this setting, the decision whether to admit the patient for observation rather than immediate operation depends on the extent to which the surgeon is confident that the obstruction is not a “closed loop.”⁵⁹ However, within a relatively short period (perhaps 4 to 24 hours), the surgeon must determine whether any indications for operation will arise, and the main parameters for observation include the WBC count, the urine output, and the development of peritoneal findings. In such cases, it may well be prudent to withhold pain medication until there is a high level of confidence that the timing of surgery will not be delayed.

A final point is that over the course of a 24- to 48-hour observation period, the patient’s condition may neither deteriorate nor improve, and supplemental investigation may be considered. Diagnostic laparoscopy has been recommended in cases where surgical disease is suspected but its probability is not high enough to warrant open laparotomy.^{60,61} It is particularly valuable in young women of childbearing age, in whom gynecologic disorders frequently mimic acute appendicitis.⁶²⁻⁶⁴ A 1998 report showed that diagnostic laparoscopy had the same diagnostic yield as open laparotomy in 55 patients with acute abdomen; 34 (62%) of these patients were safely managed with laparoscopy alone, with no increase in morbidity and with a shorter average hospital stay.⁶³ Diagnostic laparoscopy has also been shown to be useful for assessing acute abdominal pain in acutely ill patients in the intensive care unit.^{60,65}

In patients with AIDS,^{66,67} there are a number of unusual diagnoses that may be related to or coincident with an episode of abdominal pain. The differential diagnosis includes lymphoma, Kaposi sarcoma, tuberculosis and variants thereof, and opportunistic bacterial, fungal, and viral (especially cytomegaloviral) infections. Laparoscopy has been used for the purposes of diagnosis, biopsy, and treatment in patients with an established AIDS diagnosis who manifest acute abdominal pain syndrome.^{66,67} The complication rate and mortality associated with surgery are related to the underlying illness, and outcomes have improved steadily over the years.⁶⁸ It is important to note that patients who are infected with HIV but have no clinical manifestations of AIDS are evaluated and managed in the same fashion as patients without HIV infection when they present with acute abdominal pain. The differential diagnosis and the outcomes are essentially no different, unless there are reasons to think that the new onset of pain in an HIV-infected patient is a manifestation of AIDS.^{58,68}

Subacute or Chronic Relapsing Abdominal Pain: Role of Outpatient Evaluation and Management

For every patient who requires hospitalization for acute abdominal pain, there are at least two or three others who have self-limiting conditions for which neither operation nor hospitalization is necessary. Much or all of the evaluation of such patients, as well as any treatment that may be needed, can now be completed in the outpatient department. To treat acute abdominal pain cost-effectively and efficiently, the surgeon must be able not only to identify patients who need immediate or urgent laparotomy or laparoscopy but also to reliably identify those whose condition does not present a serious risk and who therefore can be managed without hospitalization. The reliability and intelligence of the patient, the proximity and availability of medical facilities, and the availability of responsible adults to observe and assist the patient at home are factors that should be carefully considered before the decision is made to evaluate or treat individuals with acute abdominal pain as outpatients.

SUSPECTED NONSURGICAL ABDOMEN

There are numerous disorders that cause acute abdominal pain but do not call for surgical intervention. These nonsurgical conditions are often extremely

difficult to differentiate from surgical conditions that present with almost indistinguishable characteristics.² For example, the acute abdominal pain of lead poisoning or acute porphyria is difficult to differentiate from the intermittent pain of intestinal obstruction, in that

marked hyperperistalsis is the hallmark of both. As another example, the pain of acute hypolipoproteinemia may be accompanied by pancreatitis, which, if not recognized, can lead to unnecessary laparotomy. Similarly, acute and prostrating abdominal pain accompanied by rigidity of the abdominal wall and a low hematocrit may lead to unnecessary urgent laparotomy in patients with sickle cell anemia crises. To further complicate the clinical picture, cholelithiasis is also often found in patients with sickle cell anemia.

In addition to numerous extraperitoneal disorders [see Table 2], nonsurgical causes of acute abdominal pain include a wide variety of intraperitoneal disorders, such as acute gastroenteritis (from enteric bacterial, viral, parasitic, or fungal infection), acute gastritis, acute duodenitis, hepatitis, mesenteric adenitis, salpingitis, Fitz-Hugh–Curtis syndrome, mittelschmerz, ovarian cyst, endometritis, endometriosis, threatened abortion, spontaneous bacterial peritonitis, and tuberculous peritonitis. As noted (see above), acute abdominal pain in immunosuppressed patients or patients with AIDS is now encountered with increasing frequency and can be caused by a number of unusual conditions (e.g., cytomegalovirus enterocolitis, opportunistic infections, lymphoma, and Kaposi sarcoma), as well as by the more usual ones.

Although such disorders typically are not treated by operative means, operation is sometimes required when the diagnosis is uncertain or when a surgical illness cannot be excluded with confidence. In such cases, laparoscopy can be very helpful, permitting relatively complete and systematic exploration without involving the potential morbidity or the longer postoperative recovery and rehabilitation period associated with open exploration.⁶⁹⁻⁷² From the surgeon's point of view, an optimal outcome for laparoscopic exploration in these settings is one in which a diagnosis is established by means of visualization, with or without biopsy, and in which symptoms improve as a consequence of a therapy directed by the laparoscopic findings. Overall, candidate lesions—including appendiceal pathology (e.g., chronic appendicitis or carcinoid tumor), adhesions, hernias, endometriosis, mesenteric lymphadenopathy—are identified in about 50% of cases, with pelvic adhesions the most common finding. From the patient's point of view, however, establishing a precise diagnosis may not be particularly critical, and symptomatic improvement, by itself, may suffice to render the outcome successful. Indeed, a number of reports have emphasized that laparoscopy often leads to improvement in symptoms even if no lesion is identified or treated.^{69,70} This point may be illustrated by considering pelvic adhesions.

Given the frequency with which laparoscopic exploration identi-

fies pelvic adhesions, adhesiolysis might be expected to alleviate abdominal pain in many cases. However, it is unclear whether adhesiolysis is therapeutically beneficial when there is no firm evidence that the adhesions are contributing to the pain syndrome. In one prospective, randomized trial,⁷³ 100 patients with laparoscopically identified adhesions were randomly allocated to either a group that underwent adhesiolysis or one that did not. Both groups reported substantial pain relief and a significantly improved quality of life, but there were no differences in outcome between them, which suggested that the benefit of laparoscopy could not be attributed to adhesiolysis. Longer-term studies also failed to support the hypothesis that pelvic adhesions are responsible for chronic pelvic pain.⁷⁴ However, in a study conducted concurrently with the aforementioned randomized trial, 224 consecutive patients underwent laparoscopically assisted adhesiolysis, and 74% of the 224 obtained short-term relief.⁷⁵ Factors that contributed to a successful outcome were gender, age, and adhesions severe enough to have led to inadvertent enterotomy and a consequent need for open exploration. It may, therefore, be possible to identify specific subgroups that would benefit from the addition of adhesiolysis to exploratory laparoscopy.

A similar issue arises with respect to pathologic conditions of the appendix—namely, whether appendectomy should be performed when no other source of the abdominal pain can be identified. Early enthusiasm for appendectomy in patients with chronic right lower quadrant pain was sparked by observations of acute or chronic inflammation in specimens that seemed visibly normal.^{76,77} In subsequent reports, however, this enthusiasm was tempered by the recognition that these pathologic findings were not very prevalent and that appendectomy did not always reduce the pain.^{78,79} No randomized trial of appendectomy for chronic abdominal pain has been performed in a clearly defined patient group, as has been done for adhesiolysis.⁷³

At present, the surgeon can only use his or her best judgment as to the likelihood that a given episode of abdominal pain may originate from a set of visible adhesions or a visually normal appendix. It should be remembered that unnecessary or potentially meddling interventions are always best avoided; however, it should also be remembered that failure to alleviate chronic relapsing abdominal pain will lead to a program of chronic pain management, including long-term management with potentially addictive and enervating agents. Thus, if adhesiolysis or appendectomy can be performed with the expectation of low morbidity and without conversion to laparotomy, it seems reasonable to perform these procedures during laparoscopy if no other source of pain can be identified.

2 ABDOMINAL MASS

Wilbur B. Bowne, M.D., and Michael E. Zenilman, M.D., F.A.C.S.

Evaluation of an Abdominal Mass

Abdominal masses are commonly addressed by surgeons, as well as by members of many clinical subspecialties. In terms of clinical importance, abdominal masses cover a broad spectrum: some have few or no apparent consequences, others significantly impair quality of life, and still others represent severe conditions that are associated with poor outcomes and high mortalities. For each patient, therefore, it is essential to formulate a management approach that is tailored to the particular clinical situation. Effective decision-making in this regard involves establishing the correct diagnosis, introducing an effective treatment plan, eliminating risks and complicating factors, initiating preventive measures, and determining the prognosis.

The history of the abdominal mass in the medical literature is ancient, dating back to the Egyptians. The varied differential diagnosis of such masses was discussed in the Papyrus Ebers (ca. 1500 B.C.).¹ Egyptian medical scholars kept detailed notes chronicling conditions encountered and describing methods of abdominal examination that were based on studies of basic anatomy and embalming practices. Centuries later, in his *Book of Prognostics*, the Greek physician Hippocrates (ca. 400 B.C.) discussed the prognostic significance of various types of abdominal masses:

The state of the hypochondrium is best when it is free from pain, soft, and of equal size on the right side and the left. But if inflamed, or painful, or distended; or when the right and left sides are of disproportionate sizes; all of these appearances are to be dreaded. A swelling in the hypochondrium, that is hard and painful, is very bad.... Such swellings at the commencement of disease prognosticate speedy death. Such swellings as are soft, free from pain, and yield to the finger, occasion more protracted crises, and are less dangerous than others.²

Along with the basic methods of clinical evaluation known since antiquity, the modern surgeon has an armamentarium of sophisticated diagnostic studies that aid in the detection, diagnosis, and appropriate treatment of abdominal masses.

In this chapter, we begin with essential definitions and anatomic considerations and then outline our fundamental approach to evaluating patients with an abdominal mass, which integrates the clinical history, the physical examination, and various investigative studies. In particular, we address current developments in investigative techniques, including radiographic and molecular imaging studies that facilitate anatomic evaluation, diagnosis, and determination of the biologic significance of the abdominal mass; we also address minimally invasive diagnostic interventions. Throughout, we emphasize an algorithmic, evidence-based approach to detection and evaluation of abdominal masses. Specific perioperative and operative strategies for addressing particular diagnoses are outlined in other chapters.

Clinical Evaluation

In general, the term abdominal mass refers to a palpable mass that lies anterior to the paraspinous muscles in a region bordered by the costal margins, the iliac crests, and the pubic symphysis. One method of description divides the abdomen into nine areas: epigastric, umbilical, suprapubic, right hypochondriac, left hypochondriac, right lumbar, left lumbar, right inguinal, and left inguinal.³ Our preferred method

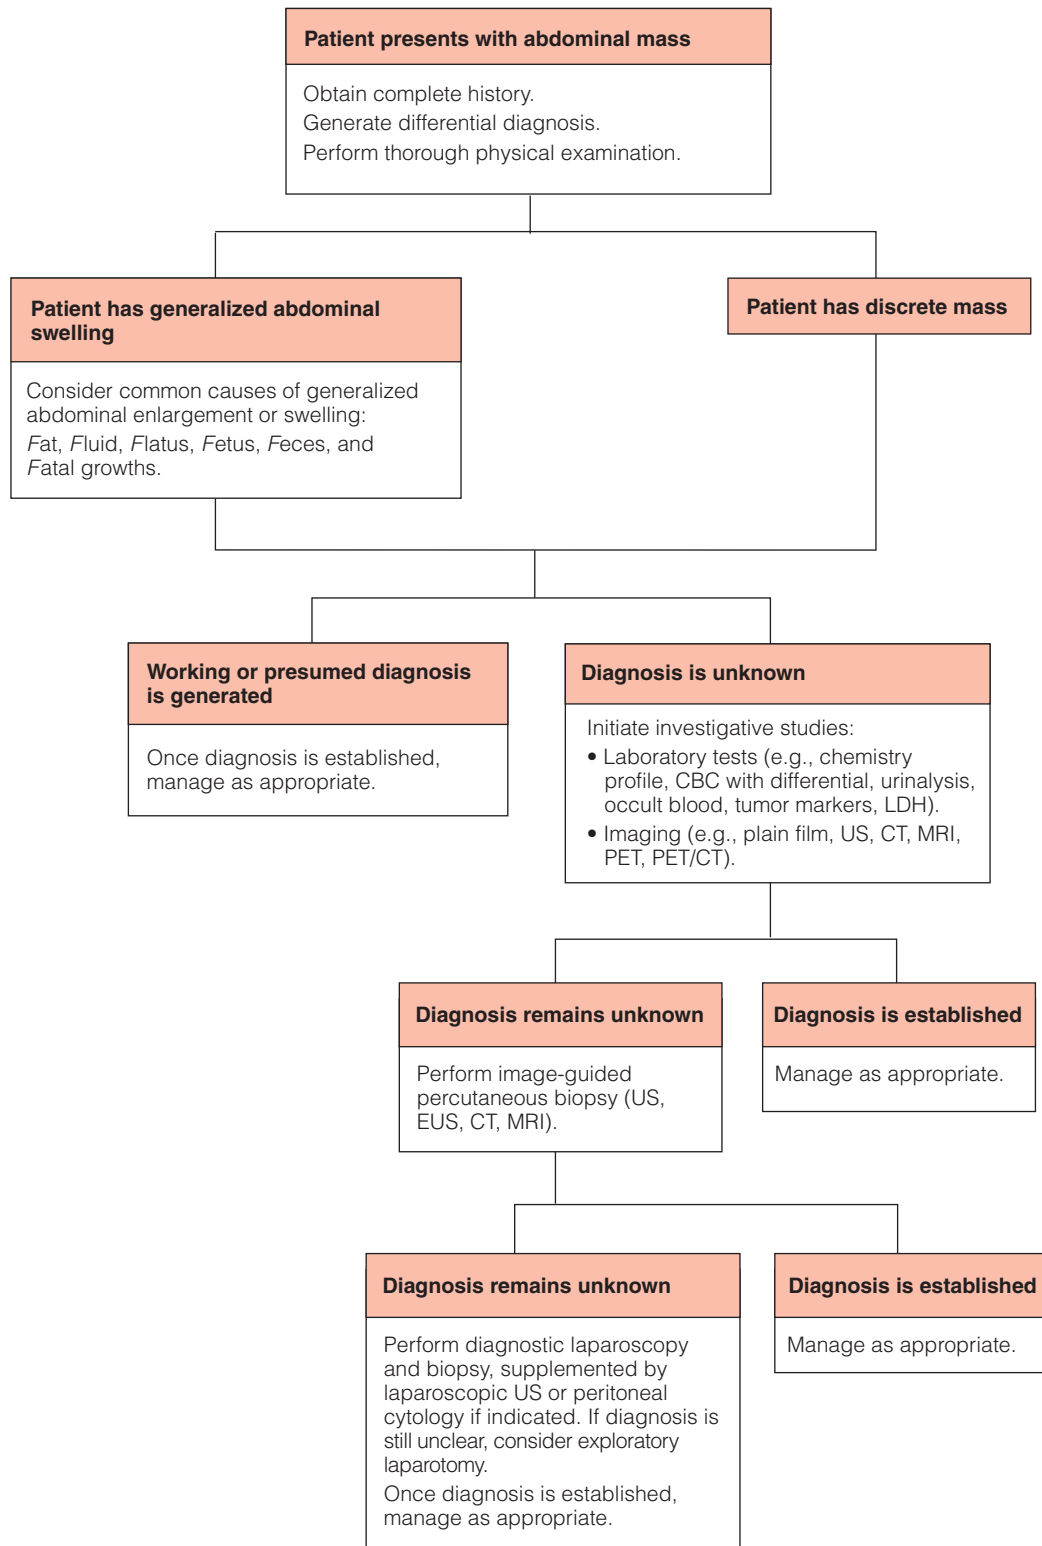

divides the abdominal cavity into four quadrants—right upper, right lower, left upper, and left lower—and makes specific reference to the epigastrium and the hypogastrium as necessary. This method of description also includes masses discovered within the retroperitoneum and the abdominal wall. For practical purposes, the abdominal wall begins from the diaphragm superiorly and continues inferiorly to the pelvic cavity through the pelvic inlet. The anterior, posterior, and lateral boundaries of the abdominal wall should be familiar to surgeons. Further anatomic detail is available in other sources.^{4,5}

A sound understanding of the normal anatomy in each abdominal quadrant is essential for the evaluation of the abdominal mass. Particular abnormalities tend to be associated with particular regions or quadrants of the abdomen, and these associations should be considered first in the differential diagnosis. Commonly, an abnormal enlargement or mass in the abdomen comes to the clinician's attention in one of three ways: it is detected and reported by the patient, it is discovered by the clinician on physical examination, or it is noticed as an unrelated incidental finding on a radiographic study. Subsequent clinical decision making is then influenced by whether the lesion is intra-abdominal, pelvic, retroperitoneal, or situated within the abdominal wall. In certain cases, a prompt diagnosis can be made after the physical examination, with no further investigation required; obesity, ascites, pregnancy, hernias, infection or abscess, cysts, and lipomas are examples of conditions that can generally be diagnosed at this point.

Of the various factors that go into making the diagnosis and implementing therapy, clinical experience is undoubtedly paramount. Nevertheless, even the most experienced physicians are subject to some degree of clinical inaccuracy. A randomized study from 1981 found that even when experienced clinicians were certain about the presence of a mass, there was still an appreciable (22%) chance that further investigation would not reveal any abnormality.⁶ The evaluation of abdominal masses continues to pose many clinical challenges for the surgeon. There is no magical

Evaluation of an Abdominal Mass

formula for mastering the necessary diagnostic skills; the closest thing to such a formula is an approach that combines knowledge and application of fundamental anatomic principles with continuous development and appropriate utilization of new diagnostic modalities. For accurate assessment of the origin and character of the abdominal mass, it is essential to possess a thorough understanding of the normal anatomy, the anatomic variations that may be observed, and the distortions that may be caused by the various potential disease processes. As has been said of many professions besides surgery, “You must know the territory.” Ultimately, whether a correct diagnosis calls for further intervention or for referral to colleagues with complementary technical expertise depends on the experience of the practitioner.

Fundamental to the successful diagnosis of any abdominal mass are a detailed medical and surgical history and a meticulous physical examination (see below).

HISTORY

Establishing a solid surgeon-patient relationship is vital for building patient trust and confidence, particularly during a period of great uncertainty and vulnerability in the patient’s life. Accordingly, our philosophy in dealing with an abdominal mass is to evaluate the patient first and then consider radiographic and laboratory studies if the initial assessment does not yield a diagnosis. A careful and methodical clinical history should be taken that includes all factors pertaining to the lesion. Information about the lesion’s mode of onset, duration, character, chronology, and location should be obtained, as well as confirmation of the presence or absence of associated symptoms.

Interviewing strategies for collecting clinical data may vary from surgeon to surgeon.⁷ For example, some prefer to conduct a clinical history while sitting rather than standing because this posture tends to suggest the absence of undue haste and the presence of appropriate concern and empathy. A focused, comprehensive interview usually provides all the information necessary for making the correct diagnosis. Our practice is to start by asking nondirective questions—for example, “When did you first notice the mass on your left side?” or “How long did you experience this pain in your abdomen?” It is important to allow patients to describe the history in their own words. It is also important to avoid questions with a built-in degree of bias—for example, “Didn’t you know the mass was on your left side?” or “The pain must have been there for some time?” Such questions can lead to biased answers that may misrepresent the chronology or the true natural history of the disease. In most cases, we then proceed to ask questions designed to elicit more specific information (e.g., previous operations, previous medical conditions or therapies, family medical history, or recent travel). It is sometimes necessary to fill in the details by asking direct questions about particular points not already mentioned by the patient. For example, an inquiry regarding gastrointestinal symptoms associated with the abdominal mass may be either nonspecific (e.g., concerned with nausea, vomiting, diarrhea, or constipation) or specific (e.g., concerned with jaundice, melena, hematochezia, hematemesis, hematuria, or changes in stool caliber). Non-GI symptoms (including urologic, gynecologic or obstetric, vascular, and endocrinologic symptoms) should not be overlooked. A history of surgery, trauma, or neoadjuvant or adjuvant cancer therapy may be diagnostically important.⁸ For instance, the presence of an abdominal mass representing recurrent cancer raises important clinical questions concerning the advisability of additional therapy or palliative measures, which may carry significant morbidity and mortality.⁹⁻¹²

DIFFERENTIAL DIAGNOSIS

For practical purposes, the differential diagnosis for an abdominal mass is divided into categories corresponding to the anatomic divisions of the abdomen (i.e., the four quadrants, the epigastrium, and the hypogastrium) [see *Figure 1*]. The challenge for the modern surgeon is how to narrow down the diagnostic possibilities while avoiding needlessly extensive and expensive evaluations. To accomplish this goal with efficiency, the surgeon must draw both on his or her own reservoir of fundamental knowledge and on the available patient data (e.g., age, gender, associated symptoms, and comorbidities).

After obtaining a thorough clinical history, the surgeon should be able to generate a differential diagnosis. The physical examination may then help confirm or rule out diagnostic possibilities. For example, the presence or absence of pain or tenderness may distinguish an inflammatory or nonneoplastic process from a neoplastic one (e.g., cholecystitis from Courvoisier gallbladder or, perhaps, diverticulitis from carcinoma of the colon). Likewise, the acuteness of the condition may help eliminate diagnostic possibilities, as when an incarcerated abdominal wall hernia is distinguished from a lipomatous mass. So too may the nature of the process, as when a pulsatile mass such as an aneurysm is distinguished from a nonpulsatile one such as a hematoma or a cyst.

Masses of the abdominal wall commonly are subcutaneous lipomas, and care should be taken to differentiate them from neoplastic lesions such as desmoid tumors,¹³ dermatofibrosarcoma protuberans (DFSP),¹⁴ and other related¹⁵ or nonrelated tumors.^{16,17} When an abdominal mass is associated with uncommon or unexpected findings, the surgeon must be alert to the possibility of an uncommon or unexpected disease process.^{18,19} It remains true, however, that knowledge of the most common disease processes associated with region-specific abdominal masses, combined with familiarity with the characteristic signs and symptoms, is the foundation of the clinical assessment of such masses.

PHYSICAL EXAMINATION

The physical examination plays an essential role in the evaluation and workup of an abdominal mass. Current investigative studies are also important in this setting, but all too often, clinicians become overly reliant on various imaging modalities, sometimes overlooking the importance of a careful and thorough examination. Such overreliance can increase the chances of missing subtle physical findings—such as an enlarged lymph node, subcutaneous irregularity, or referred pain—that could have a significant effect on the management of the abdominal mass. Our practice in examining patients with an abdominal mass is to follow an organized, systematic approach consisting of inspection, auscultation, percussion, and palpation, in that order. More detailed discussions of these specific maneuvers are available elsewhere.²⁰

The physical examination has three main objectives. First, the examiner must evaluate the patient’s condition as it directly or indirectly relates to the mass (e.g., by noting associated systemic illness, pain, malaise, or cachexia). Second, the examiner must assess the acuteness of the patient’s condition (e.g., by determining whether a left upper quadrant mass is likely to be a ruptured spleen or simply a long-standing mass in the abdominal wall), which will dictate whether the next step is immediate treatment or further evaluation. Third, the examiner must carefully examine each abdominal quadrant, assessing both normal and abnormal anatomic relations as possible sources of the presumed mass.

How to distinguish a normal abdominal mass or swelling from an abnormal one remains a common challenge for the surgeon.

Figure 1 Schema represents differential diagnosis of an abdominal mass by quadrant or region. Fundamental knowledge of normal anatomy and clinical presentations is the basis for distinguishing the various disease processes. Abdominal wall hernia is considered a possibility in every region or quadrant.

Physical findings on examination are sometimes variable and can be affected by factors such as obesity, body habitus, associated medical conditions, and the patient's ability to cooperate. For example, the normal aorta is often palpable within the epigastrium and may be slightly tender; in elderly, asthenic patients, the normal aorta may be mistaken for an aneurysm. Likewise, the cecum and the descending colon, both of which are usually palpable in thin patients (especially when they contain feces), sometimes masquerade as a cancerous mass; subsequent disimpaction causes such "masses" to resolve. Obesity may preclude evaluation of a potential abdominal mass: it can be difficult to identify discrete palpable masses amid the often remarkable adiposity present within the abdominal wall and the surrounding structures. Ascites may also obscure abdominal masses, making examination more problematic. Transient gaseous distention or intestinal bloating occasionally presents a similar problem, but it usually resolves spontaneously, except in cases of intestinal obstruction. Either gastric dilatation or intestinal obstruction may lead to abdominal distention that is severe enough to necessitate nasogastric decompression. Not uncommonly, in women of childbearing age, a lower abdominal mass may represent a gravid uterus. In such cases, a gynecologic examination must be conducted and a pregnancy test performed before further studies are ordered. The multiplicity of potential benign causes notwithstanding, the possibility of a neoplasm (single or multiple) clearly remains a matter of considerable concern in the evaluation of any patient with abdominal distention. A convenient method of recalling the main causes of generalized enlargement or distention of the abdomen is to use the so-called "six Fs" mnemonic device: *Fat, Fluid, Flatus, Fetus, Feces, and Fatal growths.*²¹⁻²³

Palpable or discrete masses should always be localized with respect to the previously described landmarks (see above), and they should, if possible, be described in terms of size, shape, consistency, contour, presence or absence of tenderness, pulsatility, and fixation. Knowledge of the location of the mass in the abdomen shortens the list of structures or organs to be considered and may give insight into the nature and extent of the pathologic process. Frequently, however, the mass's location can only be vaguely outlined, particularly when fluid is present, when the abdomen is tender or tense, or when the patient is obese. Gastric neoplasms, pancreatic neoplasms, colonic neoplasms, sarcomas, pancreatic cysts, and distended gallbladders may be palpable, typically at advanced stages of disease. Recognition of such masses can be facilitated by repeating the abdominal examination after analgesics have been administered or after the patient has been anesthetized in preparation for a procedure.

Working or Presumed Diagnosis

Once a thorough clinical history has been obtained and a careful physical examination conducted, it is usually possible to generate a working diagnosis. Once the working diagnosis has been established, subsequent management is considered in light of its appropriateness for the presumed condition. Sometimes, however, the diagnosis remains unknown even after a comprehensive clinical history and physical examination; in such cases, further studies are required. A wide range of laboratory and imag-

ing studies are now available for establishing the diagnosis. If these studies do not resolve the diagnostic uncertainty, additional procedures, including image-guided percutaneous biopsy, diagnostic laparoscopy, and exploratory laparotomy, may be employed as necessary.

Investigative Studies

Surgeons are in a unique position to care for patients presenting with an abdominal mass and should guide the collaborative management effort and the choice of appropriate investigative studies. It is therefore essential that surgeons be familiar with every available method for efficient and cost-effective diagnosis of an abdominal mass. For any given situation, the selection of investigative studies should be based on the preferences of the patient, the knowledge and judgment of the surgeon, and the capabilities of the institution. In this way, surgeons who practice outside large, specialized referral centers will still be able to provide integral leadership for most disease management efforts arising from the diagnosis of an abdominal mass.

LABORATORY STUDIES

The diagnostic workup of an abdominal mass usually includes laboratory evaluation. If the cause of the mass remains unknown, preliminary laboratory analysis should include a chemistry profile (electrolyte, blood urea nitrogen [BUN], and creatinine concentrations, as well as liver function tests), a complete blood count (CBC) with differential, and urinalysis. An abnormal laboratory value sometimes plays an important role in establishing the identity or pathogenesis of an abdominal mass. For example, an elevated alkaline phosphatase or liver transaminase level may suggest metastasis to the liver. Likewise, an elevated serum amylase concentration may be suggestive of a pancreatic pseudocyst rather than a cystic neoplasm or an adenocarcinoma; however, an elevated total serum bilirubin level (i.e., > 10 mg/dl) may be more suggestive of a malignant process secondary to adenocarcinoma of the pancreatic head or cholangiocarcinoma. Routine testing for occult blood in the stool should not be overlooked. Tumor markers (e.g., carcinoembryonic antigen [CEA], the cancer antigens CA 19-9 and CA 125, and α -fetoprotein [AFP]) may also help differentiate between benign disease processes and malignant ones, distinguish high-level disease from low-level disease, and, in some cases, establish a disease diagnosis (e.g., elevated AFP levels in patients with hepatocellular carcinoma). Similarly, an elevated serum lactate dehydrogenase (LDH) level may prove invaluable in the staging and prognosis of certain diseases (e.g., melanoma) connected with an abdominal mass.²⁴ Furthermore, the ability to distinguish between functional abdominal masses and nonfunctional ones (e.g., adrenal tumors) also has important implications for evaluation and management.

In some cases, when the type of mass remains unknown, needless and expensive laboratory analysis can and should be avoided if it appears that other studies may prove more beneficial.

IMAGING

Diagnostic radiology is a dynamic specialty that has undergone rapid change in conjunction with the ongoing evolution of imaging technology. Not only has the number of imaging modalities increased, but each modality continues to be

improved and refined for use in evaluating abdominal masses. In particular, advances in cross-sectional imaging techniques, such as ultrasonography (US), computed tomography, magnetic resonance imaging, and positron emission tomography (PET), have made it possible to assess these lesions more precisely. Consequently, whenever the surgeon is confronted with the scenario of a clinically suspected or palpable abdominal mass, accurate diagnostic imaging is of paramount importance. The appropriate use of different imaging modalities in the evaluation of the palpable abdominal mass is well described by the American College of Radiology guidelines,^{25,26} which are updated every 6 years.

The use of noninvasive US and CT as first-line procedures for the evaluation of palpable masses has received considerable clinical attention.^{6,27-30} Investigators have found both US and CT to be excellent for affirming or excluding a clinically suspected abdominal mass, with sensitivity and specificity values exceeding 95%. This finding is particularly noteworthy because in only 16% to 38% of patients referred for a suspected abdominal mass will the diagnosis be corroborated by an imaging study.³¹ Both US and CT are also capable of visualizing the organ from which the mass arises: US successfully determines the organ of origin approximately 88% to 91% of the time, and CT does so approximately 93% of the time. Prediction of the pathologic diagnosis of an abdominal mass, however, remains a challenge for both modalities. US correctly predicts the pathologic diagnosis in 77% to 81% of cases, whereas CT suggests the diagnosis in 88% of cases. Further advancements in cross-sectional imaging (e.g., multidetector CT [MDCT] with three-dimensional reconstruction and magnetic resonance angiography [MRA]) and the addition of molecular and functional imaging modalities (e.g., PET) will undoubtedly improve the predictive abilities of CT and US. At any rate, the current state of imaging technology affords clinicians the ability to distinguish benign from malignant processes, to assess tumor biology, and to detect lesions that impose a minimal disease burden. As a consequence, clinicians are more likely to detect clinically occult disease or discover it incidentally.

Employing an integrative assessment approach (which includes clinical history, physical examination, and investigative studies) should lead to more targeted, efficient, and cost-effective strategies for evaluating abdominal masses. For example, the surgeon can correlate the clinical location of the abdominal mass with pertinent findings from the history and laboratory studies to determine which imaging modality is the most expeditious and cost-effective for a given circumstance. Each imaging modality has unique strengths and weaknesses.

Plain Abdominal Radiographs

By definition, a plain film is a radiograph made without the use of an artificially introduced contrast substance.³² Commonly employed for initial surveillance of the abdomen, the plain film still has an important place within the investigative armamentarium. Otherwise known as a KUB (kidney-ureter-bladder) study, this low-cost technique may reveal nonspecific or indirect evidence of an abdominal mass, such as variations in the size and density of an organ or displacement of normal structures or fat planes. Furthermore, the radiolucency of air within the bowel may also prove helpful for recognizing worrisome displacement of viscera as a result of a large abdominal mass. Occasionally, a simple plain radiograph can assist the surgeon in making a specific diagnosis, such as calcified aortic aneurysm, acute gastric distention, fecal impaction, porcelain gallbladder, and certain malignancies [see Figure 2].

Figure 2 Plain abdominal radiograph shows a 10 cm functional left adrenocortical carcinoma. Calcifications creating a rim enhancement are easily identified. The diagnosis was confirmed by means of laboratory analysis and abdominal CT.

Conventional Gastrointestinal Imaging

As a consequence of the technical advances in cross-sectional imaging and endoscopy, conventional GI contrast studies are now largely relegated to more adjunctive roles in the evaluation of abdominal masses. In the upper and middle portions of the abdomen, we occasionally use upper GI studies, small bowel follow-through (SBFT), or enteroclysis to evaluate inflammatory masses (e.g., lesions arising from Crohn disease), masses that are inaccessible to endoscopy, or unusual masses with uncertain diagnoses. For such lesions, we employ single- or double-contrast barium protocols to ensure that significant pathology is not missed; however, these studies are notoriously insensitive and do not provide an opportunity for tissue diagnosis. In the lower portion of the abdomen, barium studies still play a significant role in the evaluation of masses whose history includes GI symptoms (e.g., anemia and weight loss) suggestive of a colonic neoplasm, as well as for evaluating inflammatory masses arising from diverticular disease. In certain cases, we employ a single-contrast barium enema for masses that are causing near-complete obstruction; this study is also helpful for assessing the remaining large bowel for synchronous disease. For small lesions (masses < 1 cm), we typically favor a double-contrast barium enema.

Currently, in the evaluation of an abdominal mass, barium studies are used mainly to complement colonoscopy and CT.

Novel approaches (e.g., CT virtual colonoscopy), in conjunction with advances in cross-sectional imaging, may eventually render conventional GI imaging unnecessary.

Ultrasonography

Compared with other modalities, US has several advantages in the evaluation of suspected abdominal masses, including widespread availability, speed of use, the absence of ionizing radiation, low cost, and the ability to document the size, consistency (solid or cystic), and origin of a mass with real-time images.^{27,33} When directed at solving a specific clinical problem, US generally provides more diagnostic information. Moreover, the necessary equipment can easily be transported to the patient's bedside or another clinical setting; thus, no patient preparation is required, and only minimal patient cooperation is needed.

We consider US indispensable in the assessment of abdominal masses. At the same time, we acknowledge that one disadvantage of US is the extent to which the quality of the results depends on the technical proficiency and diligence of the operator or technician (though this disadvantage can actually become an advantage when personnel are well trained and experienced). In the hands of an inexperienced operator, US may yield inconclusive or untrustworthy results that contribute to delayed diagnosis or even misdiagnosis. In an effort to help minimize this problem, we encourage the surgeons at our institution (who are trained in US) to perform their own studies in the clinic and the operating room. This approach further expedites recognition of disease [see Figure 3], positively influences management, and facilitates operative decision making regarding abdominal masses [see Figure 4].

Another disadvantage of US is its inability to visualize the entire abdominal cavity as a consequence of the acoustic barriers presented by gas-containing structures (e.g., the bowel) and the absorptive interfaces (acoustic shadowing) provided by soft tissue and bone. For optimal visualization of abdominal masses, US should be performed through "acoustic windows" that allow adequate transmission of sound. Accordingly, US is most effective as a tool for evaluating masses in those regions of the abdomen where an acoustic window exists (e.g., the right and left upper quadrants and the

Figure 3 Sagittal ultrasonogram of the pancreas demonstrates a large mass in the pancreatic head of a 71-year-old patient referred for "gallstones" after experiencing a 10 lb weight loss. The mass lies anterior to the inferior vena cava.

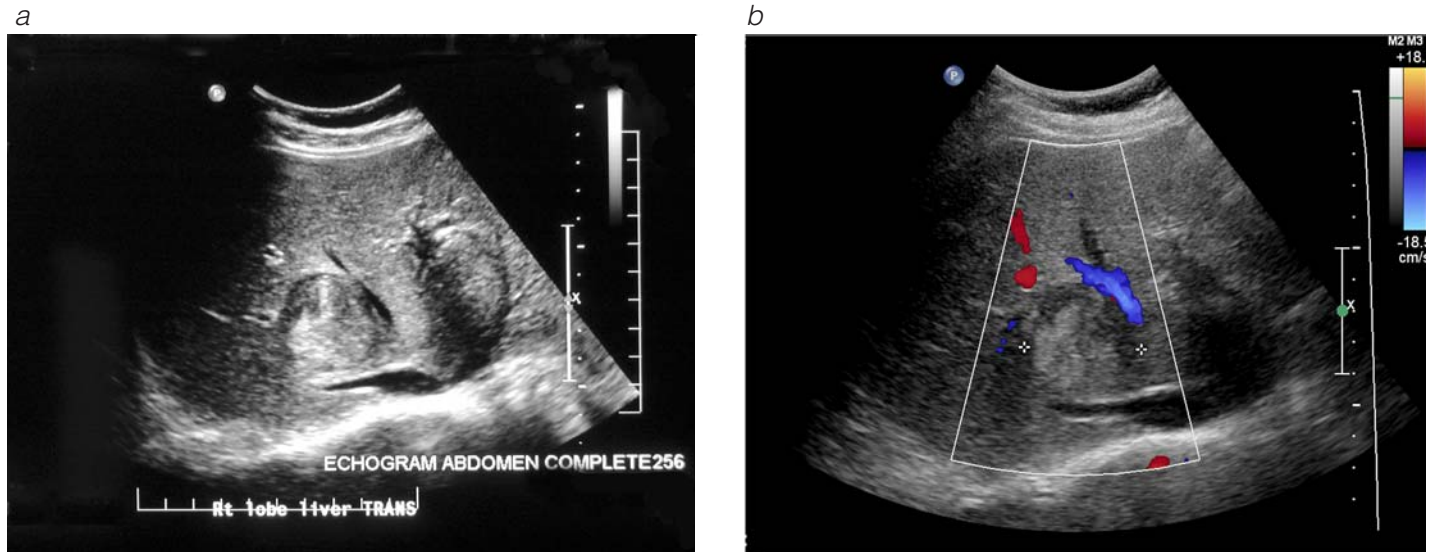

Figure 4 (a) Transverse ultrasonogram of the liver of a 72-year-old cirrhotic patient with a hepatitis C infection shows a 4.0 × 3.5 cm hepatoma, nestled between the right and middle hepatic veins and closely apposed to the inferior vena cava. (b) Color Doppler ultrasonogram from the same patient displays blood flow in the middle hepatic vein and the surrounding liver parenchyma. Blood flow toward the transducer is usually displayed in shades of red, whereas blood flow away from the transducer is displayed in shades of blue. Color Doppler ultrasonography allows evaluation of the patency and flow characteristics of the hepatic circulation as it relates to the mass.

pelvis). Fortunately, the shortcomings of US can be compensated for by employing other cross-sectional imaging modalities.

Computed Tomography

At present, helical (spiral) CT is the most efficient and cost-effective imaging modality for the evaluation of abdominal masses.^{6,27,34,35} Unlike US, CT provides cross-sectional images with excellent spatial resolution and exquisite density discrimination that are unaffected by bowel gas, bone, or excessive abdominal fat. CT routinely visualizes the abdominal wall, the viscera, the mesentery, and the retroperitoneum, clearly defining important tissue planes

Figure 5 CT scan of a 65-year-old man with a large retroperitoneal leiomyosarcoma clearly demonstrates close association of this mass with the right hemiliver, as well as displacement of the inferior vena cava.

and delineating the relations between the abdominal mass and adjacent structures [see Figure 5]. Such data are essential for guiding diagnostic procedures, determining whether operative management is indicated, and selecting the optimal operative approach. Although modalities such as MRI, PET, and endoscopic ultrasonography (EUS) have advantages over CT in one area or another, CT continues to be superior overall for assessing abdominal masses and remains our preferred imaging method for this purpose.

The use of contrast during the acquisition of CT scans is vital. Opacification of the bowel enables the examiner to distinguish the abdominal mass from surrounding viscera or other adjacent structures. Contrast-enhanced scans also allow delineation of the relevant vascular anatomy; in fact, CT angiography has now relegated conventional angiography to a minimal role in the evaluation of certain abdominal masses.^{36,37} Triple-phase or multiphase scanning that includes noncontrast images is now recommended. Such scans achieve optimal definition and characterization of liver and pancreatic masses. This achievement is of significant clinical value: state-of-the-art CT imaging of malignant pancreatic masses, as well as of other malignancies, has the potential to improve outcome not only by correctly detecting the mass but also by accurately assessing the extent of disease, thereby helping determine which patients may benefit from surgical management or neoadjuvant therapy [see Figure 6].

The advent of MDCT technology offers the possibility of even better imaging of abdominal masses than standard contrast CT provides. MDCT scanners can image specific organs or masses with 1 mm slices in less than 20 seconds, and the resultant data can be displayed not only as an axial image but also in a three-dimensional representation that includes detailed vascular mapping.³⁵ Studies suggest that MDCT may be the most useful modality for preoperative assessment of the resectability of pancreatic and other abdominal masses.³⁶ MDCT has a sensitivity of 90% and a specificity of 99%, respectively, and it is not observer dependent.

Currently, although MRI (see below) offers unique tissue contrast and inherent multiplanar capabilities for imaging abdominal

Figure 6 CT angiography performed to evaluate vascular invasion in a 58-year-old patient with a pancreatic mass demonstrates nearly complete encasement of the superior mesenteric vein. The superior mesenteric artery is not involved with the mass.

masses, CT has several advantages—high resolution, short scan times, and fast patient throughput—that make it a more widely preferred imaging modality for this purpose.

Magnetic Resonance Imaging

Since its introduction in the mid-1980s, MRI has become one of radiology's great success stories (though, because it still is not as widely available as US or CT, its cost-effectiveness has yet to be determined). Few would dispute the enormous impact MRI has had on our ability to diagnose pathologic conditions of the brain, the spine, and the musculoskeletal system. Whereas MRI has clear advantages over CT in these areas of the body, this is not the case in the abdomen. Nevertheless, there are situations in which MRI

is a better choice than CT for evaluating an abdominal mass. An example is a case in which the use of iodinated contrast material is contraindicated. The extracellular gadolinium chelates used in MRI are very safe and can be given to patients with mild to moderate azotemia without causing renal impairment. MRI has unique characteristics that can be effectively employed to distinguish normal from pathologic tissue in a patient with an abdominal mass.³⁸

Detailed information about the principles and practices of abdominal MRI is beyond the scope of this chapter and is readily available elsewhere.³⁹ A brief technical summary may, however, be worthwhile. The abdomen and its contents are subjected to a momentary radiofrequency pulse, then allowed to return to a state of equilibrium. During the return to equilibrium, the nuclei within each specific tissue will emit specific radiofrequency signals. The strength and type of the emitted signal determine the image intensity. The way in which the different tissues are visually rendered depends on (1) the longitudinal relaxation time (T_1) and the transverse relaxation time (T_2) of the nuclei in the tissues and (2) the method of image weighting employed. By convention, tissues with short T_1 values (such as solid structures) appear bright on T_1 -weighted images, whereas structures with long T_2 values (e.g., fluid-containing tissues) appear bright on T_2 -weighted images. The tissue contrast and multiplanar capabilities of MRI allow surgeons and radiologists to distinguish not only obvious but also subtle differences between abdominal masses and normal anatomy. For example, T_1 -weighted images may be valuable for detecting abdominal masses that contain fluid (e.g., cystic masses or masses containing necrotic tissue), whereas T_2 -weighted images may be useful for characterizing these masses as either benign or malignant [see *Figure 7*]. Similarly, magnetic resonance cholangiopancreatography (MRCP) uses T_2 -weighted images to distinguish masses with different signal intensities in the pancreas, the liver, and the biliary tract.⁴⁰

Positron Emission Tomography

In 1930, Warburg reported that cancer cells show higher rates of glycolysis than normal cells do.⁴¹ This discovery has stood the

Figure 7 (a) Gadolinium-enhanced, T_1 -weighted MRI shows a large mass that appears dark and well-circumscribed in comparison with the normal-appearing enhanced liver and spleen. This abnormal mass clearly contains some fluid. The fluid-filled stomach also appears dark. (b) T_2 -weighted MRI of the same patient details subtle inhomogeneities characteristic of a malignant mass (less organized appearance with an enhanced necrotic component). Subsequent biopsy showed this mass to be a poorly differentiated adenocarcinoma from recurrent colon cancer.

Figure 8 ^{18}F FDG PET scan demonstrates a large metabolically active non-Hodgkin lymphoma giving rise to an abdominal mass.

test of time and now serves as the theoretical rationale for the use of ^{18}F -fluorodeoxyglucose (^{18}F FDG) PET imaging to assess abdominal masses caused by cancer. Briefly, ^{18}F FDG is a glucose analogue that crosses the cell membrane by sharing the glucose transporter molecules used by glucose. Like glucose, it undergoes phosphorylation by the enzyme hexokinase. The resulting molecule, ^{18}F FDG-6-phosphate, is polar and is unable to cross cell membranes or serve as a substrate for metabolism. The net effect is that ^{18}F FDG both accumulates in and is retained by cancer cells.

The molecular information obtained from PET, as measured by standard uptake values (SUV), allows identification of hypermetabolic (^{18}F FDG-avid) abdominal masses (typically arising from lymphomas, melanomas, or certain GI malignancies [see Figure 8]).⁴² PET may also prove to be an important surrogate modality for distinguishing malignant abdominal masses from benign ones.⁴³ When PET is used alone, it has the disadvantage of being unable to provide sufficient anatomic information to guide biopsy or further therapy. When PET is used with CT in PET/CT fusion imaging, however, the functional advantages of PET and the structural advantages of CT combine to enhance the detection rate for abdominal masses.⁴² If a mass is anatomically evident but metabolically inactive, it will be detected by CT. If it shows increased glycolysis but few or no CT abnormalities, it will be detected by PET. The apparent advantages of PET/CT notwithstanding, prospective, randomized validation is necessary before the widespread application of this approach to the evaluation of abdominal masses can be justified. At present, the use of PET/CT is mostly restricted to large tertiary referral centers.

BIOPSY

In many cases, the pathologist is the surgeon's greatest teacher. Despite the surgeon's most strenuous efforts, the biology of the disease or lesion will inevitably dictate the outcome. Nowhere is this statement more true than in the evaluation of the abdominal mass, and its truth becomes increasingly evident as ongoing refinements in molecular diagnosis permit ever more sophisticated discrimination among different tumor types and their respective behaviors.⁴⁴ Aside from the treatment of lymphoma, in which the surgeon is frequently called on to provide technical assistance in obtaining tissue for diagnosis, the decision whether to perform a biopsy (as well as when and how to do so) rests on the surgeon's understanding of the probable disease. For example, surgeons who treat pancreatic cancer usually proceed to surgery without biopsy if the evidence for malignancy is strong. In other cases, biopsy is performed to confirm what is already suspected on the basis of clinical and radiographic findings. Moreover, establishing the type of tumor or mass present has important implications for the use of neoadjuvant or adjuvant therapy, as well as for the planning of the surgical approach. We view the biopsy of an abdominal mass as the first stage of surgery. This procedure, though seemingly innocuous, has the potential to contaminate tissue planes and must therefore be performed carefully. Accordingly, in order to make the appropriate choice when confronted with an abdominal mass, the surgeon must possess a thorough understanding of the various methods of obtaining an accurate and safe biopsy. Factors related to the size and location of the abdominal mass, as well as factors related to institutional preference and experience, may influence the choice of biopsy technique.

Image-Guided Percutaneous Biopsy

The value of image-guided percutaneous biopsy in the evaluation of the abdominal mass is well established.^{45,46} In practice, the procedure begins with identification of the mass by means of a cross-sectional imaging modality such as US, CT, or MRI. Often, three-dimensional imaging reconstructions are generated to detail the relations of the abdominal mass to the surrounding anatomy. Once the mass is identified, decisions are made regarding the safest approach and the most appropriate technique. The biopsy needle is then inserted percutaneously under the guidance of US, CT, or MRI. The choice among the different modalities depends on several factors, including the size and location of the mass, the surgeon's judgment regarding which method is best in the circumstances, and the availability of the various modalities at a particular institution. The most important consideration, however, is the personal preference and experience of the radiologist performing the biopsy. We favor either US or CT, both of which yield good results.

In general, we prefer US-guided biopsy for large, superficial, and cystic masses. This technique is also appropriate for lesions lying at moderate depths in thin to average-size persons. In some cases, US can be employed to guide biopsy of small, deep, and solid abdominal masses; however, US-guided biopsy of these deep-seated masses (as well as of masses in obese patients) often proves difficult because of inadequate visualization resulting from sound attenuation in the soft tissues. Similarly, lesions located within or behind bone or gas-filled bowel cannot be easily visualized (a consequence of the nearly complete reflection of sound from bone or air interfaces).

Figure 9 In a percutaneous biopsy of a large abdominal mass, CT guidance is a reliable means of determining the direction and depth of the needle.

US possesses several strengths as a guidance modality for percutaneous biopsy. It is readily available, inexpensive, and portable, and it provides guidance in multiple transverse, longitudinal, or oblique planes. Moreover, it offers real-time visualization of the needle tip as it passes through tissue planes into the target area,⁴⁷ thereby allowing the surgeon to place the needle precisely and to avoid important intervening structures. In addition, color flow Doppler imaging can help prevent complications of needle placement by identifying the blood vessels involved with the mass, as well as any vessels lying within the needle path. Because of its real-time capabilities, US guidance has the potential to allow quicker, more accurate, and less expensive biopsies than CT guidance does.⁴⁸ In theory, any mass that is well visualized with US should be amenable to US-guided biopsy. In practice, however, this modality remains best suited for superficial to moderately deep abdominal masses and for patients with a thin to average body habitus.

The utility of US notwithstanding, CT remains indispensable at our institution as a guidance method for percutaneous biopsy of most regions in the body. It is particularly useful when an abdominal mass is in a location that is inaccessible to US as a result of bowel gas or body habitus. In the abdomen, CT provides excellent spatial resolution of all structures between the skin and the mass, regardless of body habitus or lesion depth, and it provides an accurate image of the needle tip. We favor CT guidance for abdominal masses that are located deep in the abdomen or in the retroperitoneum. The only limitation of CT in this setting is that it does not offer continuous visualization of the needle during insertion and biopsy. In most cases, however, CT guidance can reliably establish the direction and depth of the needle [see Figure 9].

Numerous different needles, covering a broad spectrum of calibers, lengths, and tip designs, are commercially available for use in percutaneous image-guided fine-needle aspiration (FNA) biopsy. For convenience, these needles can be grouped into two main size categories: small caliber (20 to 25 gauge) and large caliber (14 to 19 gauge). Small-caliber needles are used primarily for cytologic analysis but may also be employed to obtain small pieces of tissue for histologic analysis. The flexible shaft of small-caliber needles allows them to be passed with minimal risk of tissue or organ

laceration or of damage from tearing. Such needles are often used to confirm tumor recurrence or metastasis in patients with a pathologically confirmed primary malignancy. Large-caliber needles are typically used to obtain greater amounts of material for histologic or cytologic analysis.⁴⁹ In practice, the choice of a biopsy needle is often influenced by whether the suspected pathology is benign or malignant. For example, large-caliber needles may be necessary to obtain a sufficiently large histologic specimen when certain types of malignancies (e.g., lymphoma) are suspected. When an inflammatory mass is suspected and material is needed for culture, however, a small-caliber needle may be preferred.

Additional considerations for image-guided biopsy include the accuracy, safety, and potential complications of the proposed technique. These considerations are essential for an evidence-based approach to diagnosis of an abdominal mass.

The reported accuracy of US-guided biopsy ranges from 66% to 97%. The location, size, and histologic origin of the abdominal mass appear to influence the diagnostic accuracy of the procedure.⁴⁷ In a series that included 126 consecutive small (< 3 cm) solid masses distributed among various anatomic locations and histologic types, US-guided biopsies showed an overall accuracy of 91%.⁴⁷ Biopsy results improved as the size of the mass increased: accuracy rose from 79% in masses 1 cm or less in diameter to 98% in masses 2 to 3 cm in diameter. The accuracy of US-guided biopsy in the liver, where most of the biopsies were performed, exceeded 96%. Another study found US-guided biopsy to be 91% accurate for abdominal masses less than 2.5 cm in diameter.⁵⁰ Two organ-specific reviews concluded that US-guided biopsy of hepatic masses had an accuracy of 94%⁵¹ and that US-guided biopsy of pancreatic masses had an accuracy of 95%.⁵²

The reported accuracy of CT-guided biopsy ranges from 80% to 100%. As with US-guided biopsy, the size, location, and histologic origin of the mass influence the results.⁵³⁻⁵⁵ In a study of 200 consecutive CT-guided needle biopsies, the overall accuracy for all sites biopsied was 95%. The reported organ-specific accuracy was as follows: kidneys, 100%; liver, 99%; retroperitoneum, 87.5%; and pancreas, 82%.⁵⁶ In a prospective study of 1,000 consecutive CT-guided biopsies, the reported sensitivity was 91.8% and the specificity 98.9%.⁵⁵ At our institution, as well as others, CT-guided biopsy is now considered a reliable tool for the diagnosis and classification of malignant abdominal lymphomas.⁵⁷

The safety of image-guided percutaneous biopsy is well documented. Several large multi-institutional reviews reported major complication rates ranging from 0.05% to 0.18% and mortalities ranging from 0.008% to 0.031%.⁵⁸⁻⁶⁰ A large prospective study of 3,393 biopsies (1,825 US-guided; 1,568 CT-guided) documented an overall mortality of 0.06%, a major complication rate of 0.34% (0.3% with US; 0.5% with CT), and a minor complication rate of 2.9% (2.4% with US; 3.3% with CT).⁴⁷ Procedure-related morbidity and mortality appear to be largely unaffected by whether a small-caliber or a large-caliber biopsy needle is used. A review of 11,700 patients who underwent percutaneous abdominal biopsy with 20- to 23-gauge needles found an overall complication rate of only 0.05% and an overall mortality of only 0.008%.⁵⁸ A single-institution review of 8,000 US-guided needle biopsies performed with both small- and large-caliber needles reported equivalent results: a major complication rate of 0.187% and a mortality of 0.038%.⁶¹ Of the rare major complications that occur, hemorrhage is the most frequently reported; pneumothorax, pancreatitis, bile leakage, peritonitis, and needle track seeding may also develop.

Needle-track seeding remains an important theoretical consideration when an abdominal mass appears likely to be malignant. According to some investigators, percutaneous needle biopsy has

the potential to seed between 10^3 to 10^4 tumor cells into the needle track.^{62,63} Nevertheless, tumor dissemination after percutaneous biopsy remains exceedingly rare: with fewer than 100 cases reported in the world literature, it has an estimated frequency of 0.005%,⁶⁴⁻⁶⁶ mostly occurring after biopsy of pancreatic, hepatic, or retroperitoneal masses. Poorly planned biopsies of malignant abdominal masses have the potential to exert adverse effects on subsequent surgery and to compromise local tumor control; fortunately, such negative consequences remain rare.

EUS-Guided Imaging and Biopsy

EUS provides unique imaging information because it involves the close apposition of a high-frequency ultrasound transducer, called an echoendoscope (whereby image resolution is directly related to frequency), to the structures being studied. As a result, it can delineate abdominal masses and associated structures with greater anatomic detail than standard transcutaneous ultrasonography can. In general, EUS-guided biopsy is well suited for abdominal masses that are too small for visualization by means of other cross-sectional imaging modalities or that are inaccessible to percutaneous biopsy.⁶⁷ The most frequently used EUS device is the radial echoendoscope, which creates a 360° tomographic image perpendicular to the scope. The circumferential view obtained with this instrument facilitates orientation and therefore is more efficient for diagnostic imaging. Alternatively, the linear-array echoendoscope, which generates an image parallel to the shaft of the scope, may be used. This instrument produces high-quality gray-scale images, as well as color and duplex images. EUS-guided biopsy with a linear scanning system offers clear and consistent visualization of the biopsy needle along its entire path in real time, with excellent delineation of intervening tissues and without any interference from intestinal gas.

EUS has proved to be superior to other cross-sectional imaging modalities for detection and staging of pancreatic, gastric, and esophageal masses.⁶⁸⁻⁷¹ For instance, in a patient with a pancreatic mass, EUS not only identifies the size of the mass and the peripancreatic lymph nodes but also delineates the relations of these structures to major blood vessels. EUS has also proved to be helpful in selecting patients for various neoadjuvant protocols. Furthermore, the availability of high-frequency catheter-based intraductal ultrasonography (IDUS) now enables surgeons to visualize masses within the biliary tree and obtain biopsy specimens from them.⁷²

Advantages notwithstanding, EUS technology has several important limitations. As with all forms of ultrasonography, a substantial period is required before the operator achieves proficiency. EUS is highly operator dependent; when it is done by an inexperienced operator, the potential exists for serious misinterpretations. For example, if an operator obtains only one view of a mass in the head of the pancreas, the mass may appear to be invading vascular structures when it is not actually doing so. In the evaluation of pancreatic masses around vessels, the operator should always obtain multiple views. It cannot be overemphasized that EUS and EUS-guided biopsy require personnel with sufficient experience and skill in both ultrasonography and endoscopy.

EUS is frequently employed for diagnosis and staging of upper GI malignancies. In a large single-institution study of 267 pancreatic masses that were sampled by means of EUS-guided biopsy and subsequently resected, the overall diagnostic accuracy was 95.6%, the sensitivity was 94.6%, and the specificity was 100%.⁷³ In studies of gastric and esophageal masses, diagnostic accuracy was related to the location of the biopsy,⁷⁴ the histology of the dis-

ease,⁷⁵ and the number of samples obtained. In one series that included more than 200 patients with esophageal or gastric masses, a diagnosis was made in 70% of patients after the first biopsy, 95% of patients after the fourth biopsy, and 98.9% of patients after the seventh biopsy.⁷⁶ Several other studies have confirmed the high sensitivity and specificity of EUS-guided biopsy (especially for the diagnosis of extraluminal abdominal masses) and verified the safety of the procedure (reported complication rates range from 0.3% to 2%).^{68-71,77} It is worth noting that in the resection of a potentially curable abdominal mass, concern about needle-track contamination is obviated when the path of the needle is removed as part of the surgical specimen (as in pancreaticoduodenectomy for a pancreatic head mass or gastrectomy for a stomach mass).

We consider EUS-guided biopsy for the diagnosis of masses that are not readily accessible to percutaneous biopsy, on the grounds that it can obviate more invasive procedures (e.g., laparoscopy and laparotomy). In a 10-year study of the impact of EUS on patient management, 86% of patients required no further imaging, and 25% were able to avoid unnecessary laparotomy.⁷⁷ Overall, EUS changed clinical management significantly in as many as one third of the 537 patients studied.⁷⁷ Nevertheless, despite the high diagnostic yield achieved with EUS-guided biopsy, results that are negative for tumor should not always be interpreted as proving that no tumor is present; laparoscopic or open biopsy may still be indicated.

DIAGNOSTIC LAPAROSCOPY

The available evidence now clearly supports the role of laparoscopy in the diagnosis and management of abdominal masses. We and others advocate the liberal use of laparoscopy as a primary staging tool for upper and lower GI malignancies, believing it to be a safe, cost-effective tool that offers a clear benefit in more than 20% of patients with these diseases.^{78,79} Preventing unnecessary laparotomy in selected patients by performing diagnostic laparoscopy is associated with shorter hospital stays and earlier initiation of locoregional or systemic therapy. Moreover, laparoscopic ultrasonography⁸⁰ and peritoneal cytology⁸¹ are known to provide added value in the staging of disease. Furthermore, diagnostic laparoscopy can safely provide tissue samples from suspected lymphomatous masses for full diagnostic analysis.⁸² With the growth of dedicated minimally invasive fellowships and the improved quality and availability of laparoscopic training for general surgery residents and related subspecialties, the skill sets required for diagnostic laparoscopy are coming to be more widely mastered, and the concerns once commonly expressed regarding intra-abdominal adhesions and effective biopsy techniques for abdominal masses now appear to be less problematic.

Indications for Exploratory Laparotomy

Advances in diagnostic imaging, endoscopy, and minimally invasive surgery have nearly eliminated the need for open exploration for the sole purpose of establishing a diagnosis in patients with an abdominal mass. In selected cases, however, exploratory laparotomy may still help in the assessment of abdominal masses that were initially misinterpreted on preoperative evaluation. In general, exploratory laparotomy should be reserved for those rare instances in which other modalities have failed to yield crucial information needed for evaluation and diagnosis of an abdominal mass.

Approach to the Jaundiced Patient

The term jaundice refers to the yellowish discoloration of skin, sclerae, and mucous membranes that results from excessive deposition of bilirubin in tissues. It usually is unmistakable but on occasion may manifest itself subtly. It is generally held that jaundice develops when serum bilirubin levels rise above 34.2 $\mu\text{mol/L}$ (2 mg/dl)¹; however, the appearance of jaundice also depends on whether it is conjugated or unconjugated bilirubin that is elevated and on how long the episode of jaundice lasts.

In what follows, we outline a problem-based approach to the jaundiced patient that involves assessing the incremental information provided by successive clinical and laboratory investigations, as well as the information obtained by means of modern imaging modalities. We also propose a classification of jaundice that stresses the therapeutic options most pertinent to surgeons. We have not attempted a detailed review of bilirubin metabolism and the various pediatric disorders that cause jaundice; such issues are beyond the scope of this chapter. Finally, we emphasize that modern decision making in the approach to the jaundiced patient includes not only careful evaluation of anatomic issues but also close attention to patient morbidity and quality-of-life concerns, as well as a focus on working up the patient in a cost-effective fashion. For optimal treatment, in our view, an integrated approach that involves the surgeon, the gastroenterologist, and the radiologist is essential.

Clinical Evaluation and Investigative Studies

HISTORY AND PHYSICAL EXAMINATION

When a patient presents with a skin discoloration suggestive of jaundice, the first step is to confirm that icterus is indeed present. To this end, the mucous membranes of the mouth, the palms, the soles, and the sclerae should be examined in natural light. Because such areas are protected from the sun, photodegradation of bile is minimized; thus, the yellowish discoloration of elastic tissues may be more easily detected. Occasionally, deposition of a yellowish pigment on skin may mimic jaundice but may in fact be related to the consumption of large quantities of food containing lycopene or carotene or drugs such as rifampin or quinacrine. In these cases, the skin is usually the only site of coloration, and careful inspection of sclerae and mucous membranes generally reveals no icteric pigmentation. In certain cultures, long-term application of tea bags to the eyes may lead to a brownish discoloration of the sclerae that can mimic jaundice.²

DIRECT VERSUS INDIRECT HYPERBILIRUBINEMIA

Once the presence of jaundice has been confirmed, further clinical assessment determines whether the hyperbilirubinemia is predominantly direct or indirect. This distinction is based on the division of bilirubin into conjugated and unconjugated fractions,

which are also known, respectively, as direct and indirect fractions on the basis of their behavior in the van den Bergh (dialysis) reaction.³ If the patient has normal-colored urine and stools, unconjugated bilirubin [see Sidebar Unconjugated (Indirect) Bilirubin] is predominant [see Table 1]. If the patient has dark urine, pale stools, or any other signs or symptoms of a cholestatic syndrome (see below), the serum bilirubin fractionation usually indicates that conjugated bilirubin is predominant. Rarely, the clinical picture may be secondary to a massive increase in both direct and indirect bilirubin production after the latter has overcome the ability of the hepatocytes to secrete conjugated bilirubin.

It is nearly always possible to distinguish between direct and indirect hyperbilirubinemia on clinical grounds alone.⁴ Our emphasis here is on direct hyperbilirubinemia, which is the type that is more relevant to general surgeons.

Cholestatic Syndrome

The term cholestasis refers to decreased delivery of bilirubin into the intestine (and subsequent accumulation in the hepato-

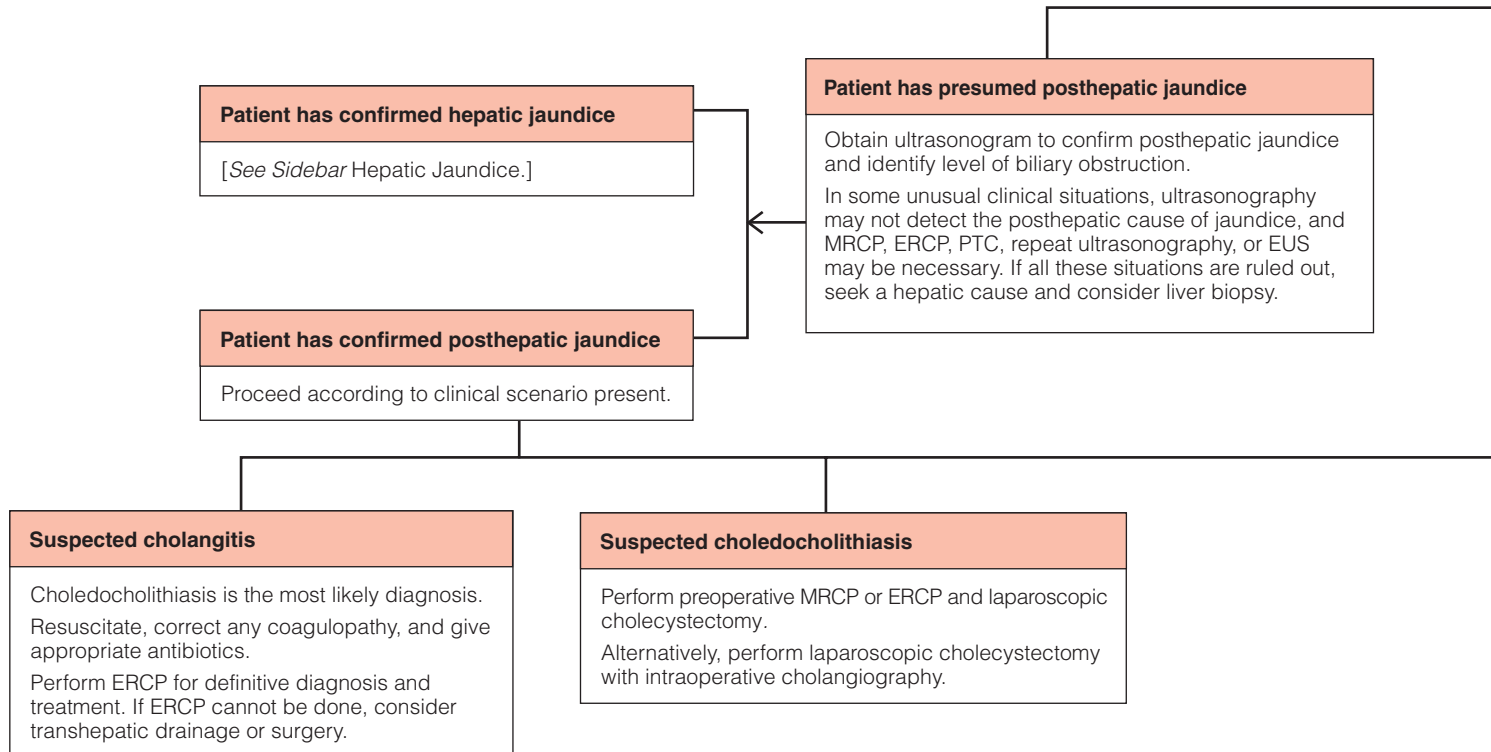

Unconjugated (Indirect) Bilirubin

The breakdown of heme leads to the production of unconjugated bilirubin, which is water insoluble, is tightly bound to albumin, and does not pass into the urine. Excessive production of unconjugated bilirubin typically follows an episode of hemolysis. In the absence of concomitant liver disease or biliary obstruction, the liver can usually handle the extra bilirubin, and only a modest rise in serum levels is observed. There is a substantial increase in bile pigment excretion, leading to large quantities of stercobilinogen in the stool. A patient with hemolysis may therefore be slightly jaundiced with normal-colored urine and stools. Blood tests reveal that 60% to 85% of bilirubin is indirect.¹²⁴

Possible causes of indirect hyperbilirubinemia include a variety of disorders that result in significant hemolysis or ineffective erythropoiesis. The diagnosis of indirect hyperbilirubinemia attributable to hemolysis is confirmed by an elevated serum lactate dehydrogenase (LDH) level, a decreased serum haptoglobin level, and evidence of hemolysis on microscopic examination of the blood smear.

Disorders associated with defects in hepatic bilirubin uptake or conjugation can also produce unconjugated hyperbilirubinemia. The most common of these, Gilbert syndrome, is a benign condition affecting up to 7% of the general population.^{125,126} It is not a single disease but a heterogeneous group of disorders, all of which are characterized by a homozygosity for a defect in the promoter controlling the transcription of the UDP glucuronyl transferase I gene.¹²⁷ The consequent impairment of bilirubin glucuronidation presents as a mild unconjugated hyperbilirubinemia. The elevated bilirubin level is usually detected on routine blood testing, and affected patients may report that their skin turns yellow when they are fatigued or at stressful times (e.g., after missing meals, after vomiting, or in the presence of an infection). Other causes of an unconjugated hyperbilirubinemia are beyond the scope of this chapter.

Approach to the Jaundiced Patient

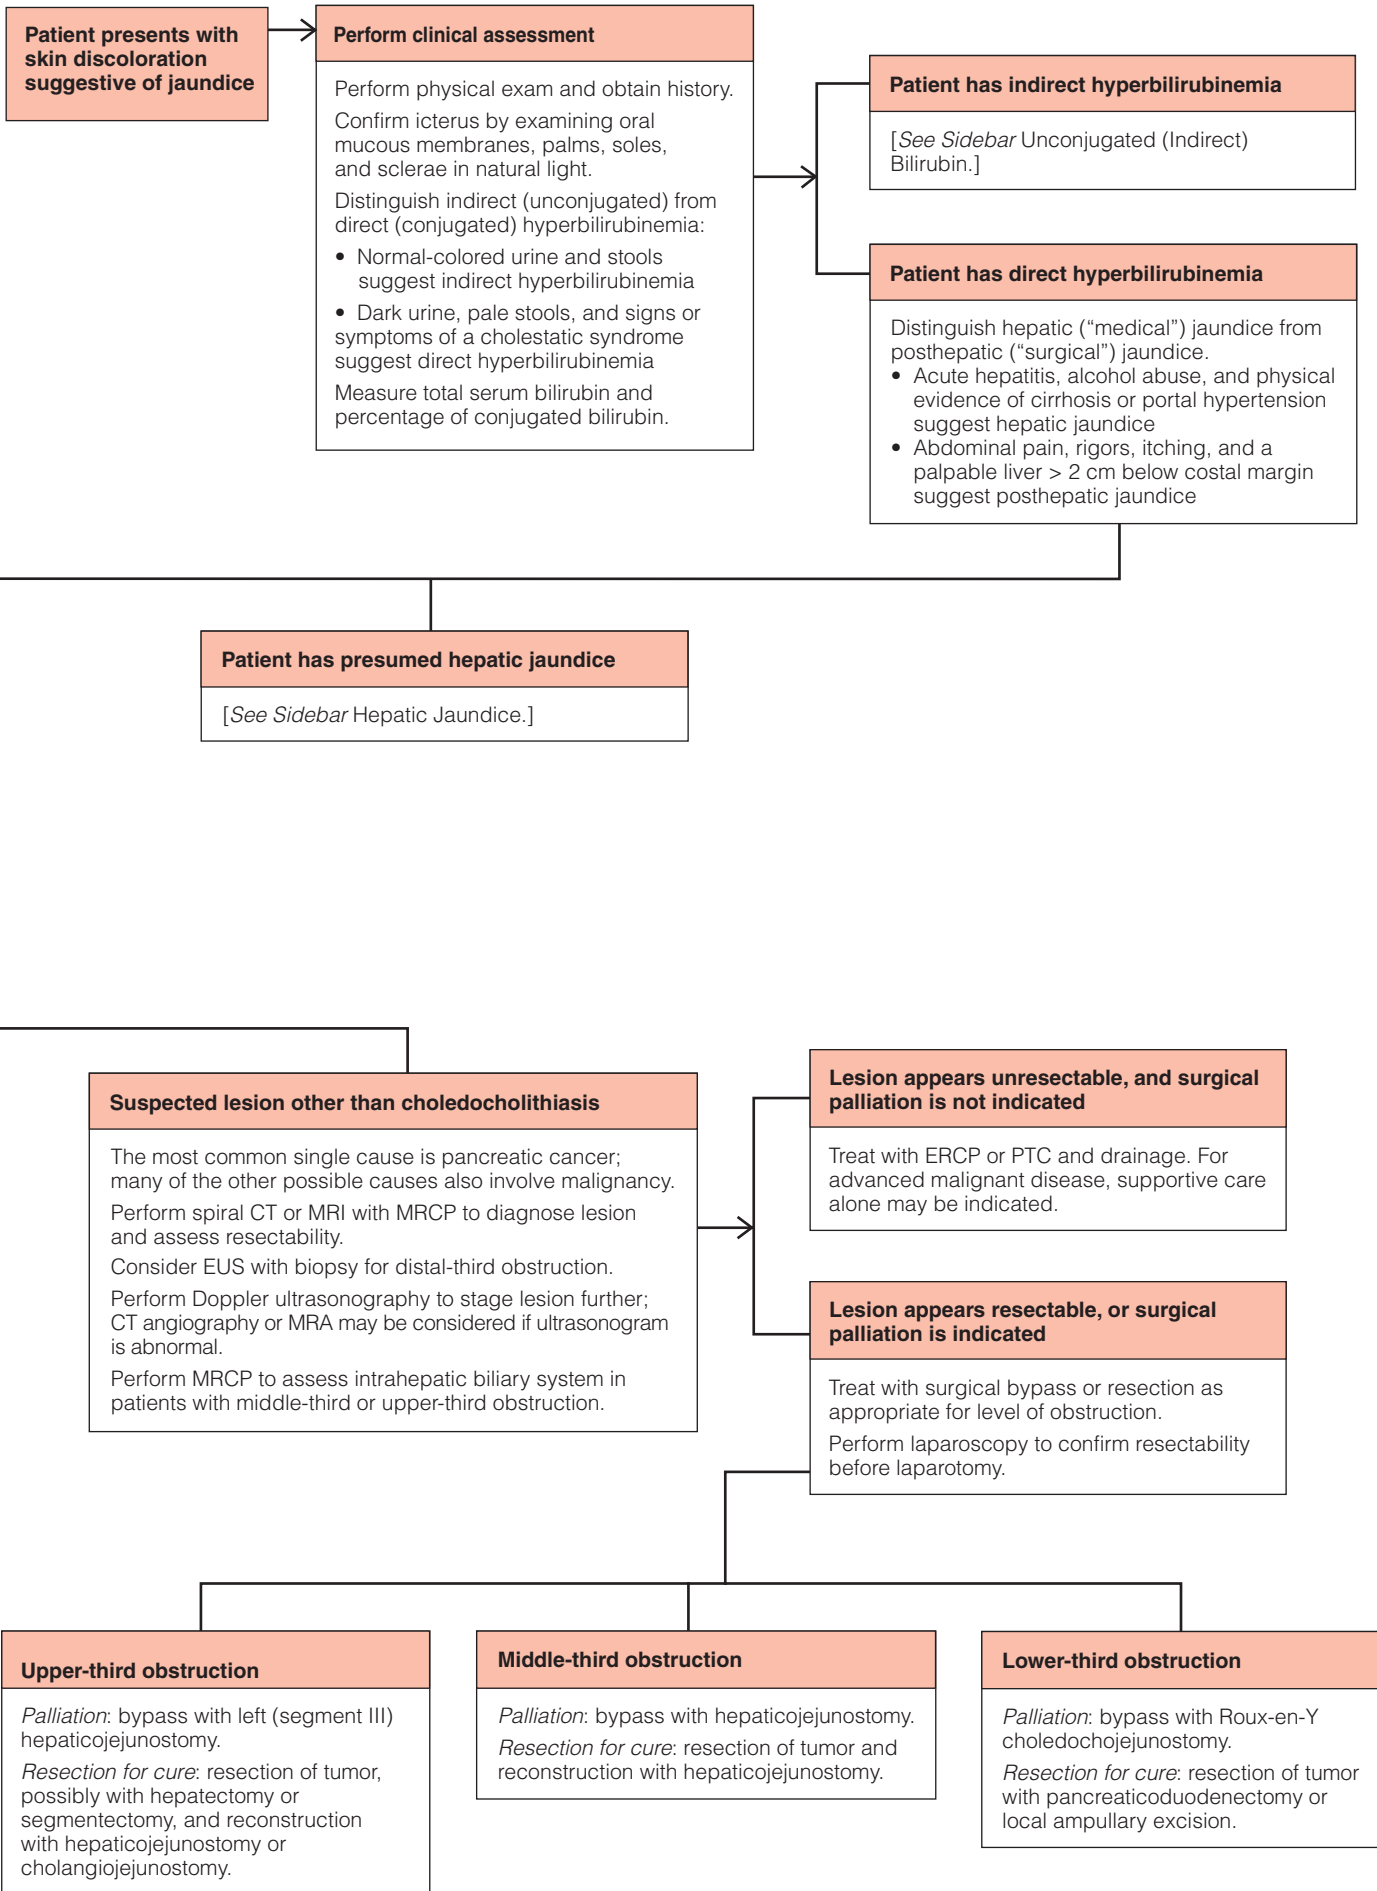

Table 1 Causes of Unconjugated Hyperbilirubinemia

Increased RBC breakdown	
Acute hemolysis	
Chronic hemolytic disorders

Gilbert syndrome	
Decreased hepatic bilirubin conjugation	
Gilbert syndrome	
Crigler-Najjar syndrome types I and II	
Familial unconjugated hyperbilirubinemia	

cytes and in blood), irrespective of the underlying cause. When cholestasis is mild, it may not be associated with clinical jaundice. As it worsens, a conjugated hyperbilirubinemia develops that presents as jaundice. The conjugated hyperbilirubinemia may derive either from a defect in hepatocellular function (hepatic jaundice, also referred to as nonobstructive or medical jaundice) or from a blockage somewhere in the biliary tree (posthepatic jaundice, also referred to as obstructive or surgical jaundice). In this chapter, we refer to hepatic and posthepatic causes of jaundice, reserving the term cholestasis for the specific clinical syndrome that is attributable to a chronic lack of delivery of bile into the intestine. This syndrome is characterized by signs and symptoms that are related either to the conjugated hyperbilirubinemia or to chronic malabsorption of fat-soluble vitamins (i.e., vitamins A, D, E, and K): jaundice, dark urine, pale stools, pruritus, bruising, steatorrhea, night blindness, osteomalacia, and neuromuscular weakness.⁵

HEPATIC VERSUS POSTHEPATIC JAUNDICE

Once the presence of direct hyperbilirubinemia is confirmed, the next step is to determine whether the jaundice is hepatic or posthepatic. A number of authors have studied the reliability of clinical assessment for making this determination.⁶⁻¹⁷ The sensitivities of history, physical examination, and blood tests alone range from 70% to 95%,⁶⁻¹¹ whereas the specificities are approximately 75%.^{10,11} The overall accuracy of clinical assessment of hepatic and posthepatic causes of jaundice ranges from 87% to 97%.^{8,12} Clinically, hepatic jaundice is most often signaled by acute hepatitis, a history of alcohol abuse, or physical findings reflecting cirrhosis or portal hypertension¹³; posthepatic jaundice is most often signaled by abdominal pain, rigors, itching, or a palpable liver more than 2 cm below the costal margin.¹⁴

By using discriminant analysis in a pediatric patient population, two investigators were able to isolate three biochemical tests that differentiated between biliary atresia and intrahepatic cholestasis with an accuracy of 95%: total serum bilirubin concentration, alkaline phosphatase level, and γ -glutamyltranspeptidase level.¹⁵ Serum transaminase levels added no independent information of significance to the model. Another multivariate analysis model demonstrated that patients with posthepatic jaundice were younger, had a longer history of jaundice, were more likely to present with fever, and had greater elevations of serum protein concentrations and shorter coagulation times than patients with hepatic jaundice.¹⁶

This model, however, despite its 96% sensitivity (greater than that of any single radiologic diagnostic modality), could not accurately predict the level of a biliary obstruction. Other investigators have reported similar findings,^{8,12,13} and most agree that strategies that omit ultrasonography are clearly inferior.¹⁷

In summary, a clinical approach supported by simple biochemical evaluation displays good predictive ability to distinguish hepatic from posthepatic jaundice; however, a clinical approach alone does not accurately identify the level of biliary obstruction in a patient with posthepatic jaundice.

The remainder of this chapter focuses primarily on management of posthepatic jaundice; hepatic jaundice is less often seen and dealt with by general surgeons [see Table 2 and Sidebar Hepatic Jaundice].

IMAGING

Once the history has been obtained and bedside and laboratory assessments have been completed, the next step is imaging, the goals of which are (1) to confirm the presence of an extrahepatic obstruction (i.e., to verify that the jaundice is indeed posthepatic rather than hepatic), (2) to determine the level of the obstruction, (3) to identify the specific cause of the obstruction, and (4) to provide complementary information relating to the underlying diagnosis (e.g., staging information in cases of malignancy).

Of the many imaging methods available today, the gold standard for defining the level of a biliary obstruction before operation in a jaundiced patient remains direct cholangiography, which can be performed either via endoscopic retrograde cholangiopancreatography (ERCP) [see 5:18 *Gastrointestinal Endoscopy*] or via percutaneous transhepatic cholangiography (PTC).²⁰ Unlike other imaging modalities, direct cholangiography poses significant risks to the patient: there is a 4% to 7% incidence of pancreatitis or cholangitis after ERCP,^{18,19} and there is a 4% incidence of bile leakage, cholangitis, or bleeding after PTC.²⁰ There are also several risks that are particular to the manipulation of an obstructed biliary system (see below). For these reasons, the role of ERCP and PTC is increasingly a therapeutic one: therefore, it is important to

Table 2 Causes of Hepatic Jaundice¹³³

Hepatitis
Viral

Systemic infections
Total parenteral nutrition
Postoperative intrahepatic cholestasis
Cholestasis of pregnancy
Benign recurrent intrahepatic cholestasis
Infantile cholestatic syndromes
Inherited metabolic defects
No identifiable cause (idiopathic hepatic jaundice)

Hepatic Jaundice

Hepatic jaundice may be either acute or chronic and may be caused by a variety of conditions [see Table 2].

Acute hepatic jaundice may arise de novo or in the setting of ongoing liver disease. Historical clues may suggest a particular cause, such as medications or viral hepatitis. Physical examination usually reveals little. In the presence of preexisting chronic liver disease, bedside stigmata (e.g., ascites, spider nevi, caput medusae, palmar erythema, gynecomastia, or Dupuytren contracture) may be present. Although specific therapies exist for certain clinical problems (e.g., acetylcysteine for acetaminophen ingestion and penicillin plus silibinin for *Amanita phalloides* poisoning), treatment in most cases remains supportive. Patients in whom encephalopathy develops within 2 to 8 weeks of the onset of jaundice are usually classified as having fulminant hepatic failure [see 8:9 *Hepatic Failure*]. Evidence of encephalopathy, renal failure, or a severe coagulopathy is predictive of poor outcome in this setting.¹²⁸ The most common causes of fulminant hepatic failure are viral hepatitis and drug toxicity. The mortality from fulminant hepatic failure remains high even though liver transplantation has favorably affected the prognosis.¹²⁹

In cases of chronic hepatic jaundice, the patient may have chronic hepatitis or cholestasis, with or without cirrhosis. The cause usually is determined on the basis of the history in conjunction with the results of serology, biochemistry, viral DNA analysis, and, occasionally, histology. Causes include viral infection, drug-induced chronic hepatitis, autoimmune liver disease, genetic disorders (e.g., Wilson disease and α_1 -antitrypsin deficiency), chronic cholestatic disorders, alcoholic liver disease, and steatohepatitis.¹³⁰ Physical examination reveals the stigmata of chronic liver disease and occasionally suggests a specific cause (e.g., Kayser-Fleischer rings on slit-lamp examination in Wilson disease). Treatment, once again, is usually supportive, depending on the clinical presentation; whether more specific therapy is needed and what form it takes depend on the cause of liver disease. Although physiologic tests have been developed to quantify hepatic reserve, the most widely used and best-validated prognostic index remains the

Child-Pugh classification (see below), which correlates with individual survival and has been shown to predict operative risk.¹³¹ Liver transplantation is the treatment of choice in most cases of end-stage liver disease.

The Child-Pugh Classification¹³¹
 Numerical Score (points)

Variable	1	2	3
Encephalopathy	Nil (0)	Slight to moderate (1, 2)	Moderate to severe (3–5)
Ascites	Nil	Slight	Moderate to severe
Bilirubin, mg/dl (μmol/L*)	< 2 (< 34)	2–3 (34–51)	> 3 (> 51)
Albumin, g/dl (g/L*)	> 3.5 (> 35)	2.8–3.5 (28–35)	< 2.8 (< 28)
Prothrombin index	> 70%	40%–70%	< 40%

Modified Child's risk grade (depending on total score): 5 or 6 points, grade A; 7 to 9 points, grade B; 10 to 15 points, grade C.
 *Système International d'Unités, or SI units.

The Model for End-Stage Liver Disease (MELD) score is now used to prioritize the allocation of organs for liver transplantation by the United Network for Organ Sharing.¹³² This score is based on the serum bilirubin and creatinine concentrations, the international normalized ratio (INR), and the presence of hepatocellular carcinoma; it does not make use of some of the more subjective components of the Child-Pugh score (e.g., ascites and encephalopathy).

gather as much imaging information as possible on the likely cause of the jaundice before performing either investigation.²¹ We have found the following approach to be an efficacious, cost-effective,²² and safe way of obtaining such information in a patient with presumed posthepatic jaundice.

The presence of ductal dilatation of the intrahepatic or extrahepatic biliary system confirms that a posthepatic cause is responsible for the jaundice. Ultrasonography detects ductal dilatation with an accuracy of 95%, though results are to some extent operator-dependent.²³ If ultrasonography does not reveal bile duct dilatation, it is unlikely that an obstructing lesion is present. In some cases, even though ductal dilatation is absent, other ultrasonographic findings may still point to a specific hepatic cause of jaundice (e.g., cirrhosis or infiltration of the liver by tumor).

There are a few specific instances in which ultrasonography may fail to detect a posthepatic cause of jaundice. For instance, very early in the course of an obstructive process, not enough time may have elapsed for biliary dilatation to occur. In this setting, a hepato-iminodiacetic acid (HIDA) scan has often helped identify bile duct blockage.²⁴ The yield from this test is highest when the serum bilirubin level is lower than 100 μmol/L.¹ Occasionally, the intrahepatic biliary tree is unable to dilate; possible causes of such inability include extensive hepatic fibrosis, cirrhosis, sclerosing cholangitis, and liver transplantation. If one of these diagnoses is suspected, ERCP, magnetic resonance cholangiopancreatography (MRCP), or PTC will eventually be required to confirm the diagnosis of biliary obstruction. Occasionally, the biliary tree dilatation may be intermittent; possible causes of this condition include

choledocholithiasis and some biliary tumors. In a patient with gallstones, transient liver test abnormalities by themselves may suggest an intermediate to high likelihood of common bile duct (CBD) stones, even if there is no biliary ductal dilatation.^{25,26} If one of these diagnoses is suspected, ultrasonography may be repeated after a short period of observation (when clinically applicable); biliary ductal dilatation then generally becomes apparent. If all of these unusual clinical situations have been ruled out, a hepatic cause for the jaundice should be sought [see Table 2] and a liver biopsy considered.^{27,28}

Besides being able to identify the presence of extrahepatic ductal obstruction with a high degree of reliability, ultrasonography can accurately determine the level of the obstruction in 90% of cases.²⁹ For example, a dilated gallbladder suggests that the obstruction is probably located in the middle third or the distal third of the CBD.

Some centers prefer CT to ultrasonography as the initial imaging modality,³⁰ but we, like a number of other authors,³¹ find ultrasonography to be the most expedient, least invasive, and most economical imaging method for differentiating between hepatic and posthepatic causes of jaundice, as well as for suggesting the level of obstruction.³² Traditional imaging techniques, such as oral or intravenous cholangiography, have a negligible role to play in this setting because of their very poor accuracy and safety, especially in jaundiced patients.

MRCP [see Figure 1] and endoscopic ultrasonography (EUS) have been used to visualize the biliary and pancreatic trees in various populations of patients with obstructive jaundice.^{33–37}

Compared with direct cholangiography, both appear to be excellent at diagnosing biliary obstruction and establishing its location and nature.^{38,39} MRCP exhibits more modest detection rates when diagnosing small CBD stones.^{40,41} Spiral (helical) CT scanning is also useful in diagnosing biliary obstruction and determining its cause, though concomitant oral or I.V. cholangiography is required to detect choledocholithiasis.⁴²⁻⁴⁴

In addition to their ability to detect choledocholithiasis, spiral CT, EUS, and MRCP in combination with abdominal magnetic resonance imaging (e.g., of the pancreas) are very useful in diagnosing and staging biliopancreatic tumors.⁴⁵⁻⁴⁷ Cytology specimens are readily obtained via fine-needle aspiration (FNA) during CT or EUS.⁴⁶

It is our current practice to employ these modalities as second-line tests after the initial abdominal ultrasonographic examination. To obtain a diagnosis, we favor EUS for periampullary pathologic conditions and MRI with MRCP for more proximal diseases of the biliary tree.

In making the choice among the various available second-line tests, local expertise and cost-effectiveness become important considerations. Unfortunately, the reports on cost-effectiveness published to date have suffered either from limited assumptions (when the methodology involved decision modeling) or from the lack of an effectiveness-type design (when the methodology involved allocation of patients).

Workup and Management of Posthepatic Jaundice

Once ultrasonography has confirmed that ductal obstruction is present, there are three possible clinical scenarios: suspected cholangitis, suspected choledocholithiasis without cholangitis, and a suspected lesion other than choledocholithiasis. The direction of the subsequent workup depends on which of the three appears most likely.

SUSPECTED CHOLANGITIS

If a jaundiced patient exhibits a clinical picture compatible with acute suppurative cholangitis (Charcot's triad or Reynaud's pentad), the most likely diagnosis is choledocholithiasis. After appropriate resuscitation, correction of any coagulopathies present, and administration of antibiotics, ERCP is indicated for diagnosis and treatment.⁴⁸ If ERCP is unavailable or is not feasible (e.g., because of previous Roux-en-Y reconstruction), transhepatic drainage or surgery may be necessary. It is important to emphasize here that the mainstay of treatment of severe cholangitis is not just the administration of appropriate antibiotics but rather the establishment of adequate biliary drainage.

SUSPECTED CHOLEDOCHOLITHIASIS WITHOUT CHOLANGITIS

Choledocholithiasis is the most common cause of biliary obstruction.^{13,14} It should be strongly suspected if the jaundice is episodic or painful or if ultrasonography has demonstrated the presence of gallstones or bile duct stones. Patients with suspected choledocholithiasis should be referred for laparoscopic cholecystectomy with either preoperative ERCP, intraoperative cholangiography, or intraoperative ultrasonography [see 5:21 *Cholecystectomy and Common Bile Duct Exploration*].⁴⁹ We favor preoperative ERCP in this setting of jaundice because its diagnostic yield is high,⁵⁰ it allows confirmation of the diagnosis preoperatively (thus obviating intraoperative surprises), and it is capable of clearing the

Figure 1 ERCP (a) and corresponding MRCP (b) demonstrate presence of a stone in the distal CBD.

CBD of stones in 95% of cases. Decision analyses appear to confirm the utility of this strategy when laparoscopic CBD exploration is not an option.⁵¹⁻⁵⁵ Many authors, however, favor a fully laparoscopic approach, in which choledocholithiasis is detected in the

OR by means of intraoperative cholangiography^{56,57} or ultrasonography⁵⁸⁻⁶⁰ and laparoscopic biliary clearance is performed when choledocholithiasis is confirmed. Given that both the ERCP approach and the fully laparoscopic approach have advantages and limitations, the optimal approach in a particular setting should be dictated by local expertise.

SUSPECTED LESION OTHER THAN CHOLEDOCHOLITHIASIS

If no gallstones are identified, if the clinical presentation is less acute (e.g., constant abdominal or back pain), or if there are associated constitutional symptoms (e.g., weight loss, fatigue, and long-standing anorexia), the presence of a lesion other than choledocholithiasis should be suspected. In such cases, another imaging modality besides the ultrasonography already performed must be considered before the decision is made to proceed to cholangiography or operation.

Possible causes of posthepatic obstruction (other than choledocholithiasis) may be classified into three categories, depending on the location of the obstructing lesion (as suggested by the pattern of gallbladder and biliary tree dilatation on the ultrasonogram): the upper third of the biliary tree, the middle third, or the lower (distal) third [see Table 3]. Once it has been determined that choledocholithiasis is unlikely, the most common cause of such obstruction is pancreatic cancer [see 5:9 *Tumors of the Pancreas, Biliary Tract, and Liver*].^{13,14} In adults, many of the other possible causes also involve malignant processes. Consequently, the next step in the workup of the patient is typically the assessment of resectability and operability [see 5:22 *Procedures for Benign and Malignant Biliary Tract Disease*].

Diagnosis and Assessment of Resectability

Assessment of the resectability of a tumor usually hinges on whether the superior mesenteric vein, the portal vein, the superior mesenteric artery, and the porta hepatis are free of tumor and on whether there is evidence of significant local adenopathy or extrapancreatic extension of tumor. Unfortunately, the majority of lesions will be clearly unresectable, either because of tumor extension or because of the presence of hepatic or peritoneal metastases.

Many imaging modalities are currently used to determine resectability, and several of these have been established as effective alternatives to direct cholangiography because they involve little if any morbidity. Their accuracy varies according to the underlying pathology and the expertise of the user. They have been studied mostly with respect to the staging and diagnosis of pancreatic, periampullary, and biliary hilar cancers.

For determining resectability and staging lesions before operation, we rely mainly on spiral CT. The advent and widespread availability of multidetector CT have made this modality the dominant second-line imaging method in cases of suspected pancreatic masses. For optimal evaluation of the pancreas, a fine-cut dual-phase (arterial phase and portal venous phase) scan should be obtained. Oral administration of water allows better evaluation of the duodenum and the ampulla.^{61,62} At present, spiral CT is considered to be superior for the diagnosis and staging of lesions such as pancreatic cancer.^{45,63,64} It exhibits a high negative predictive value and has a false positive rate of less than 10%; its sensitivity is optimal for pancreatic lesions larger than 1.5 cm in diameter. Ascites, liver metastases, lymph nodes larger than 2 cm in diameter, and invasion into adjacent organs are all signs of advanced disease.⁶⁵ On the basis of these criteria, spiral CT can predict that a

lesion will not be resectable with an accuracy approaching 95%; however, as many as 33% of tumors that appear to be resectable on CT are found to be unresectable at operation.⁶⁴

MRI-based staging, along with MRCP, can further dictate the subsequent choice of therapy.⁶⁵⁻⁶⁸ MRI may be particularly useful for following up patients in whom clip artifacts interfere with a CT image.⁶⁵ It also appears to be successful in detecting cholangiocarcinoma spreading along the proximal biliary tree.⁶⁹ Given the renewed interest in biliary contrast media and the availability of software optimized for multidetector scanners, CT cholangiography may soon rival MRCP for evaluation of the biliary tree in cases of suspected malignancy.⁷⁰

Only in a few very rare instances is traditional angiography used to assess resectability or stage a hepatobiliary or pancreatic neoplasm. Increasingly, it is being replaced by CT angiography or duplex Doppler ultrasonography, which can confirm the presence of flow in the hepatic arterial or portal venous systems and occasionally can demonstrate invasion of these vessels by tumor.⁷¹ Magnetic resonance angiography (MRA) has also been used with excellent results. As yet, none of these noninvasive modalities has been shown to be clearly superior to any of the others.⁷²

Table 3 Causes of Posthepatic Jaundice

Upper-third obstruction
Polycystic liver disease
Caroli disease
Hepatocellular carcinoma
Oriental cholangiohepatitis
Hepatic arterial thrombosis (e.g., after liver transplantation or chemotherapy)
Hemobilia (e.g., after biliary manipulation)
Iatrogenic bile duct injury (e.g., after laparoscopic cholecystectomy)
Cholangiocarcinoma (Klatskin tumor)
Sclerosing cholangitis
Papillomas of the bile duct
Middle-third obstruction
Cholangiocarcinoma
Sclerosing cholangitis
Papillomas of the bile duct
Gallbladder cancer
Choledochal cyst
Intrabiliary parasites
Mirizzi syndrome
Extrinsic nodal compression (e.g., from breast cancer or lymphoma)
Iatrogenic bile duct injury (e.g., after open cholecystectomy)
Cystic fibrosis
Benign idiopathic bile duct stricture
Lower-third obstruction
Cholangiocarcinoma
Sclerosing cholangitis
Papillomas of the bile duct
Pancreatic tumors
Ampullary tumors
Chronic pancreatitis
Sphincter of Oddi dysfunction
Papillary stenosis
Duodenal diverticula
Penetrating duodenal ulcer
Retroduodenal adenopathy (e.g., lymphoma, carcinoid)

Figure 2 (a) ERCP demonstrates missing liver segments. (b) Transhepatic cholangiography of segment 6 reveals the excluded liver ductal system. (c) MRCP shows the excluded liver segments, as well as the biliary system, which still communicates with the common hepatic duct.

EUS is a highly sensitive method of imaging the pancreas and the duodenum.^{46,73,74} In two large studies, it was found to be superior to CT and standard ultrasonography in staging pancreatic and ampullary cancers.^{75,76} Subsequent studies indicated that whereas EUS is superior to CT for detection and staging, it provides similar information regarding nodal status and overall assessment of resectability.^{61,77} From a cost-minimization point of view, the optimal strategy is to begin with a dual-phase CT scan and to follow up with EUS only in cases in which further information or a tissue diagnosis is required.^{78,79} In another large series, EUS was reported to be more accurate than CT in the comparative staging of pancreatic and ampullary cancers. It has also been found useful for identifying small (< 2 cm) pancreatic tumors, which may be suspected in a patient who has an obstruction of the distal third of the bile duct and whose CT scan is normal.⁷⁴ Furthermore, EUS is currently the dominant technique for staging ampullary tumors.⁸⁰

In patients with a suspected pancreatic tumor, direct FNA of the lesion at the time of EUS has become the gold-standard method for obtaining a tissue diagnosis. In the case of potentially resectable lesions, however, this measure adds very little to the decision-making process. The limited data currently available suggest that assays of tumor markers in serum and pancreatic fluid are useful, particularly for cystic lesions of the pancreas.⁸¹

At this point in the evaluation, patients can be referred either for cholangiography (ERCP or MRCP) to clarify a still-unclear diagnosis or for biliary decompression (see below). MRI of the pancreas with MRCP continues to improve rapidly. It is a noninvasive modality that evaluates the pancreas, vasculature, and the pancreatobiliary ductal system in a single examination, with the additional benefit of avoiding ionizing radiation and iodinated contrast agents.⁸² MRCP remains our test of choice for evaluation of middle- and upper-third lesions in cases in which decompression is not required.

In the event that none of these modalities point to a diagnosis, the use of ¹⁸F-fluorodeoxyglucose (FDG) positron emission tomography (PET) may be considered to help differentiate benign pancreatic conditions from malignant ones.^{83,84} Besides facilitating diagnosis, FDG-PET provides information regarding occult metastases and can be useful in detecting recurrent disease. Experi-

ence with FDG-PET is growing rapidly as this imaging modality becomes more readily accessible.

When a biliary stricture is detected at cholangiography, brush cytology or biopsy is mandatory. Biliary cytology, however, has been disappointing, particularly at ERCP: diagnostic accuracy ranges from 40% to 85%,^{85,86} mostly because the negative predictive value is poor. Accuracy improves with multiple sampling and when a biliary rather than a pancreatic malignancy is detected. In addition, biopsy tends to be more accurate than brush cytology.⁸⁵

Nonoperative Management: Drainage and Cholangiography

In the majority of patients with malignant obstructions, treatment is palliative rather than curative. It is therefore especially important to recognize and minimize the iatrogenic risks related to the manipulation of an obstructed biliary system; this is why staging and cholangiography are currently being performed with EUS and MRCP.

Cholangiography and decompression of obstructed biliary system As a rule, we favor ERCP, though PTC may be preferable for obstructions near the hepatic duct bifurcation. Whichever imaging modality is used, the following four principles apply.

1. In the absence of preexisting or concomitant hepatocellular dysfunction, drainage of one half of the liver is generally sufficient for resolution of jaundice.⁸⁷
2. Because of its external diameter, a transhepatic drain, once inserted, does not necessarily permit equal drainage of all segments of the liver, particularly if there are a number of intrahepatic ductal stenoses. Accordingly, some patients with conditions such as sclerosing cholangitis or a growing tumor may experience persistent sepsis from an infected excluded liver segment even when the prosthesis is patent [see Figure 2]. An excluded segment may even be responsible for severe persistent pruritus.

- Any attempt at opacifying an obstructed biliary tree introduces a significant risk of subsequent cholangitis, even when appropriate antibiotic prophylaxis is provided. Accordingly, when one elects to perform direct cholangiography, there should be a plan for biliary drainage either at the time of ERCP or PTC or soon thereafter.
- Even though jaundice is believed to be associated with multiple adverse systemic effects (e.g., renal failure, sepsis, and impaired wound healing),^{88,89} routine preoperative drainage of an obstructed biliary system does not benefit patients who will soon undergo resection.^{90,91} There is a growing body of evidence suggesting that in patients with either pancreatic^{92,93} or hepatic⁹⁴ malignancies, routine preoperative direct cholangiography with decompression is associated with a higher incidence of postoperative complications when tumor resection is ultimately carried out.

When direct cholangiography is ordered, it should be thought of as more than just a diagnostic test: it is the ideal setting for cytology, biopsy, or even drainage of the obstructed bile duct via a sphincterotomy, a nasobiliary tube, or a catheter or stent. Accordingly, it is essential that the surgeon, the gastroenterologist, and the radiologist discuss the possible need for drainage well before it is required. Early, open communication among all the members of the treating team is a hallmark of the modern management of biliary obstruction.

Palliation in patients with advanced malignant disease

When a patient has advanced malignant disease, drainage of the biliary system for palliation is not routinely indicated, because the risk of complications related to the procedure may outweigh the potential benefit. Indeed, the best treatment for a patient with asymptomatic obstructive jaundice and liver metastases may be supportive care alone.⁹⁵ Biliary decompression is indicated if cholangitis or severe pruritus interferes with quality of life.

We, like others,²² consider a stent placed with ERCP to be the palliative modality of choice for advanced disease, though upper-third lesions may be managed most easily through the initial placement of an internal/external catheter at the time of PTC. Metal expandable stents remain patent longer than large conventional plastic stents,^{96,97} but the high price of the metal stents has kept them from being widely used, and their overall cost-effectiveness has yet to be clearly demonstrated. Whether plastic biliary stents should be replaced prophylactically or only after obstruction has occurred remains controversial; however, results from a randomized, controlled trial (RCT) favor the former approach.⁹⁸ In another RCT, the use of prophylactic ciprofloxacin did not prolong stent patency but did reduce the incidence of cholangitis and improve quality of life scores.⁹⁹

RCTs suggest that surgical biliary bypass should be reserved for patients who are expected to survive for 6 months or longer because bypass is associated with more prolonged palliation at the cost of greater initial morbidity.¹⁰⁰

The role of prophylactic gastric drainage at the time of operative biliary drainage remains controversial,^{101,102} though two RCTs demonstrated a reduced incidence of subsequent clinical gastric outlet obstruction when this measure was employed. Jaundiced patients with unresectable lesions who also present with duodenal or jejunal obstruction should be referred for gastrojejunostomy at the time of biliary bypass surgery. There is evidence to suggest that when a pancreatic malignancy is present, intraoperative celiac ganglion injection should be performed for either prophylactic or therapeutic pain control.¹⁰³

Operative Management at Specific Sites: Bypass and Resection

Surgical treatment of tumors causing biliary obstruction is determined primarily by the level of the biliary obstruction. Current evidence indicates that modern surgical approaches are resulting in lower postoperative morbidity and, possibly, improved 5-year survival¹⁰⁴; however, the prognosis is still uniformly poor, except for patients with ampullary tumors. In fact, the surgical procedure rarely proves curative, even after meticulous preoperative patient selection.

At one time, there was considerable enthusiasm for routine use of staging laparoscopy; at present, however, selective use is recommended.¹⁰⁵ The benefits of staging laparoscopy include more accurate assessment of resectability and prevention of the prolonged hospital stay and convalescence associated with an unnecessary laparotomy. Laparoscopy is used mostly to detect peritoneal carcinomatosis, liver metastases, malignant ascites, and gross hilar adenopathy.^{106,107} The main limitation of laparoscopy in this setting appears to be that it does not accurately detect the spread of tumors to lymph nodes or the vascular system.¹⁰⁸ In several studies, a combined approach that included both laparoscopy and laparoscopic ultrasonography was associated with shorter hospital stays and lower costs.^{105,107-109}

Figure 3 ERCP demonstrates extrinsic compression of the common hepatic duct by a stone in Hartmann's pouch. A biliary stent has been inserted for drainage.

In what follows, only the general principles of resection or bypass at each level of obstruction are discussed; operative technical details are addressed elsewhere [see 5:22 *Procedures for Benign and Malignant Biliary Tract Disease*]. Our preferred method of biliary anastomosis, for either reconstruction or bypass, involves the fashioning of a Roux-en-Y loop, followed by a mucosa-to-mucosa anastomosis. In all cases, a cholecystectomy is performed to facilitate access to the biliary tree.

Upper-third obstruction

Palliation. Because the left hepatic duct has a long extrahepatic segment that makes it more accessible, the preferred bypass technique for an obstructing upper-third lesion is a left (or segment 3) hepaticojejunostomy. This operation has superseded the Longmire procedure because it does not involve formal resection of liver parenchyma. Laparoscopic bypass techniques that make use of segment 3 have been developed, but their performance has yet to be formally assessed, and they cannot yet be incorporated into a management algorithm.^{110,111}

Resection for cure. The hilar plate is taken down to lengthen the hepatic duct segment available for subsequent anastomosis. Often, a formal hepatectomy or segmentectomy is required to ensure an adequate proximal margin of resection. If the resection must be carried out proximal to the hepatic duct bifurcation, several cholangiojejunostomies will have to be done to anastomose individual hepatic biliary branches. Frozen-section examination of the proximal and distal resection margins is important because of the propensity of tumors such as cholangiocarcinoma to spread in a submucosal or perineural plane.

The results of aggressive hilar tumor resections that included as much liver tissue as was necessary to obtain a negative margin appear to justify this approach.¹¹² In cases of left hepatic involvement, resection of the caudate lobe (segments 1 and 9) is indicated as well.^{113,114}

Middle-third obstruction

Palliation. Surgical bypass of middle-third lesions is technically simpler because a hepaticojejunostomy can often be performed distal to the hepatic duct bifurcation, which means that exposure of the hilar plate or the intrahepatic ducts is unnecessary.

Resection for cure. Discrete tumors in this part of the bile duct, though uncommon, are usually quite amenable to resection along with the lymphatic chains in the porta hepatis. Resection of an early gallbladder cancer may, on occasion, necessitate the concomitant resection of segment 5, though the value of resecting this segment prophylactically has not been conclusively demonstrated.¹¹⁵ Sometimes, jaundice from a suspected middle-third lesion is in fact caused by a case of Mirizzi syndrome [see Figure 3]. In such cases, a gallstone is responsible for extrinsic obstruction of the CBD, either by causing inflammation of the gallbladder wall or via direct impingement. Proper treatment of this syndrome may involve hepaticojejunostomy in addition to cholecystectomy if a cholecystocholedochal fistula is present.¹¹⁶

Figure 4 Jaundice has occurred after laparoscopic cholecystectomy as a result of bile leakage from a distal biliary tributary. A stent has been inserted to decrease bile duct luminal pressure and foster spontaneous resolution.

Lower-third obstruction

Palliation. The preferred bypass technique for lower-third lesions is a Roux-en-Y choledochojejunostomy. Cholecystojejunostomy carries a higher risk of complications and subsequent development of jaundice¹¹⁷; this remains true even

when it is performed laparoscopically. Occasionally, it may be done as a temporizing measure before a more definitive procedure in the context of an upcoming transfer to a specialized center.

Resection for cure. Occasionally, an impacted CBD stone at the duodenal ampulla mimics a tumor and is not clearly identified preoperatively. Because of the growing use of EUS and MRCP, such a situation is increasingly uncommon. Resection of a lower-third lesion usually involves a pancreaticoduodenectomy [see 5:24 *Procedures for Benign and Malignant Pancreatic Disease*], though transduodenal ampullary resection may be an acceptable alternative for a small adenoma of the ampulla [see 5:24 *Procedures for Benign and Malignant Gastric and Duodenal Disease*]; local duodenal resection without removal of the head of the pancreas has also

been described.¹¹⁸ For optimal results, pancreaticoduodenectomy is best performed in specialized centers.¹¹⁹

It has been suggested that postoperative adjuvant therapy may improve the prognosis after resection of a pancreatic adenocarcinoma,¹⁰⁴ but this debate falls outside the scope of our discussion.

Postoperative Jaundice

A clinical scenario of particular pertinence to surgeons that we have not yet addressed is the development of jaundice in the postoperative setting.

Jaundice develops in approximately 1% of all surgical patients after operation.¹²⁰ When jaundice occurs after a hepatobiliary procedure, it may be attributable to specific biliary causes, such as retained CBD stones, postoperative biliary leakage (through reabsorption of bile leaking into the peritoneum) [see Figure 4], injury to the CBD, and the subsequent development of biliary strictures. In most instances, however, the jaundice derives from a combination of disease processes, and only rarely is invasive testing or active treatment required.¹²¹

A diagnostic approach similar to the one outlined earlier (see above) is applicable to postoperative jaundice; however, another useful approach is to consider the possible causes in the light of the time interval between the operation and the subsequent development of jaundice.

- Jaundice may develop within 48 hours of the operation; this is most often the result of the breakdown of red blood cells, occurring in the context of multiple blood transfusions (particularly with stored blood), the resorption of a large hematoma, or a transfusion reaction. Hemolysis may also develop in a patient with a known underlying hemolytic anemia and may be precipitated by the administration of specific drugs (e.g., sulfa drugs in a patient who has glucose-6-phosphate dehydrogenase deficiency).¹²² Cardiopulmonary bypass or the insertion of a prosthetic valve may be associated with the development of early postoperative jaundice as well. Gilbert syndrome [see Sidebar Hepatic Jaundice] may first manifest itself early in the postoperative period. Occasionally, a mild conjugated hyperbilirubinemia may be related to Dubin-Johnson syndrome, which is an inherited disorder of bilirubin metabolism. This condition is usually self-limited and is characterized by the presence of a melaninlike pigment in the liver.
- Intraoperative hypotension or hypoxemia or the early develop-

ment of heart failure can lead to conjugated hyperbilirubinemia within 5 to 10 days after operation. The hyperbilirubinemia may be associated with other end-organ damage (e.g., acute tubular necrosis). In fact, any impairment of renal function causes a decrease in bilirubin excretion and can be responsible for a mild hyperbilirubinemia.

- Jaundice may develop 7 to 10 days after operation in association with a medication-induced hepatitis attributable to an anesthetic agent. This syndrome has an estimated incidence of 1/10,000 after an initial exposure.¹²² More commonly, the jaundice is related to the administration of antibiotics or other medications used in the perioperative setting.¹²²
- After the first week, jaundice associated with intrahepatic cholestasis is often a manifestation of a septic response and usually presents in the setting of overt infection, particularly in patients with multiple organ dysfunction syndrome. Gram-negative sepsis from an intra-abdominal source is typical; if it persists, the outcome is likely to be poor. Jaundice may occur in as many as 30% of patients receiving total parenteral nutrition (TPN). It may be attributable to steatosis, particularly with formulas containing large amounts of carbohydrates. In addition, decreased export of bilirubin from the hepatocytes may lead to cholestasis, the severity of which appears to be related to the duration of TPN administration. Acalculous cholecystitis or even ductal obstruction may develop as a result of sludge in the gallbladder and the CBD. An elevated postoperative bilirubin level at any time may also result from unsuspected hepatic or posthepatic causes (e.g., occult cirrhosis, choledocholithiasis, or cholecystitis). A rare cause of postoperative jaundice is the development of thyrotoxicosis. Another entity to consider (as a diagnosis of exclusion) is so-called benign postoperative cholestasis, a primarily cholestatic, self-limited process with no clearly demonstrable cause that typically arises within 2 to 10 days after operation. Benign postoperative cholestasis may be attributable to a combination of mechanisms, including an increased pigment load, impaired liver function resulting from hypoxemia and hypotension, and decreased renal bilirubin excretion caused by varying degrees of tubular necrosis.¹²³ The predominantly conjugated hyperbilirubinemia may reach 40 mg/dl and remain elevated for as long as 3 weeks.¹²²
- In the late postoperative period, the development of non-A, non-B, non-C viral hepatitis after transfusion of blood products will usually occur within 5 to 12 weeks of operation.

4 INTESTINAL OBSTRUCTION

W. Scott Helton, M.D., F.A.C.S., and Piero M. Fisichella, M.D.

Assessment of Intestinal Obstruction

Intestinal obstruction is a common medical problem and accounts for a large percentage of surgical admissions for acute abdominal pain [see 5:1 *Acute Abdominal Pain*].¹ It develops when air and secretions are prevented from passing aborally as a result of either intrinsic or extrinsic compression (i.e., mechanical obstruction) or gastrointestinal paralysis (i.e., nonmechanical obstruction in the form of ileus or pseudo-obstruction). Small intestinal ileus is the most common form of intestinal obstruction; it occurs after most abdominal operations and is a common response to acute extra-abdominal medical conditions and intra-abdominal inflammatory conditions [see Table 1].² Mechanical small bowel obstruction is somewhat less common; such obstruction is secondary to intra-abdominal adhesions, hernias, or cancer in about 90% of cases [see Table 2]. Mechanical colonic obstruction accounts for only 10% to 15% of all cases of mechanical obstruction and most often develops in response to obstructing carcinoma, diverticulitis, or volvulus [see Table 3]. Acute colonic pseudo-obstruction occurs most frequently in the postoperative period or in response to another acute medical illness.

There are several different methods of classifying mechanical obstruction: acute versus chronic, partial versus complete, simple versus closed-loop, and gangrenous versus nongangrenous. The importance of these classifications is that the natural history of the condition, its response to treatment, and the associated morbidity and mortality all vary according to which type of obstruction is present.

When chyme and gas can traverse the point of obstruction, obstruction is partial; when this is not the case, obstruction is complete. When the bowel is occluded at a single point along the intestinal tract, leading to intestinal dilatation, hypersecretion, and bacterial overgrowth proximal to the obstruction and decompression distal to the obstruction, simple obstruction is present. When a segment of bowel is occluded at two points along its course by a single constrictive lesion that occludes both the proximal and the distal end of the intestinal loop as well as traps the bowel's mesentery, closed-loop obstruction is present. When the blood supply to a closed-loop segment of bowel becomes compromised, leading to ischemia and eventually to bowel wall necrosis and perforation, strangulation is present. The most common causes of simple obstruction are intra-abdominal adhesions, tumors, and strictures; the most common causes of closed-loop obstruction are hernias, adhesions, and volvulus.

One of the most difficult tasks in general surgery is deciding when to operate on a patient with intestinal obstruction. The purpose of the following discussion is to outline a safe, efficient, and cost-effective stepwise approach to making this often difficult decision and to optimizing the management of patients with this problem. Absolutes are few and far between: treatment must always be highly individualized. Consequently, the following recommendations are intended only as guidelines, not as surgical dicta.

Clinical Evaluation

HISTORY AND CLINICAL SETTING

When a patient complains of acute obstipation, abdominal pain and distention, nausea, and vomiting, the probability that either mechanical bowel obstruction or ileus is present is very high.³ Mechanical obstruction can often be distinguished from ileus or pseudo-obstruction on the basis of the location, character, and severity of abdominal pain. Pain from mechanical obstruction is usually located in the middle of the abdomen, whereas pain from ileus and pseudo-obstruction is diffuse. Pain from ileus is usually mild, and pain from obstruction is typically more severe. In general, pain increases in severity and depth over time as obstruction progresses; however, in mechanical obstruction, pain severity may decrease over time as a result of bowel fatigue and atony. The periodicity of pain can help localize the level of obstruction: pain from proximal intestinal obstruction has a short periodicity (3 to 4 minutes), and distal small bowel or colonic pain has longer intervals (15 to 20 minutes) between episodes of nausea, cramping, and vomiting.

Abdominal distention, nausea, and vomiting usually develop after pain has already been felt for some time. The patient should be asked what degree of abdominal distention is present and whether there has been a sudden or rapid change. Distention developing over many weeks suggests a chronic process or progressive partial obstruction. Massive abdominal distention coupled with minimal crampy pain, nausea, and vomiting suggests long-standing intermittent mechanical obstruction or some form of chronic intestinal pseudo-obstruction. The combination of a gradual change in bowel habits, progressive abdominal distention, early satiety, mild crampy pain after meals, and weight loss also suggests chronic partial mechanical bowel obstruction. If the patient has undergone evaluation for similar symptoms before, any previous abdominal radiographs or contrast studies should be reviewed. The patient should be asked when flatus was last passed: failure to pass flatus may signal a transition from partial to complete bowel obstruction. Patients with an intestinal stoma (ileostomy or colostomy) who present with signs and symptoms of obstruction often report abdominal distention and pain after a sudden change in stomal output of stool, liquid, or air.

The patient should also be asked about (1) previous episodes of bowel obstruction, (2) previous abdominal or pelvic operations, (3) a history of abdominal cancer, and (4) a history of intra-abdominal inflammation (e.g., inflammatory bowel disease, cholecystitis, pancreatitis, pelvic inflammatory disease, or abdominal trauma). Any of these factors increases the chance that the obstruction is secondary to an adhesion or recurrent cancer. Obstructive symptoms that come and go suddenly over several days in a patient older than 65 years should increase the index of suspicion for gallstone ileus.⁴

Table 1 Causes of Ileus

Intra-abdominal causes

- Intraperitoneal problems
 - Peritonitis or abscess
 - Inflammatory condition
 - Mechanical: operation, foreign body
 - Chemical: gastric juice, bile, blood
 - Autoimmune: serositis, vasculitis
 - Intestinal ischemia: arterial or venous, sickle-cell disease
- Retroperitoneal problems
 - Pancreatitis
 - Retroperitoneal hematoma
 - Spine fracture
 - Aortic operation
 - Renal colic
 - Pyelonephritis
 - Metastasis

Extra-abdominal causes

- Thoracic problems
 - Myocardial infarction
 - Pneumonia
 - Congestive heart failure
 - Rib fractures
- Metabolic abnormalities
 - Electrolyte imbalance (e.g., hypokalemia)
 - Sepsis
 - Lead poisoning
 - Porphyria
 - Hypothyroidism
 - Hypoparathyroidism
 - Uremia
- Medicines
 - Opiates
 - Anticholinergics
 - Alpha agonists
 - Antihistamines
 - Catecholamines
- Spinal cord injury or operations
- Head, thoracic, or retroperitoneal trauma
- Chemotherapy, radiation therapy

gic side effects. Patients who are receiving chemotherapy or have undergone abdominal radiation therapy are prone to ileus. Severe infection, fluid and electrolyte imbalances, narcotic and anticholinergic medications, and intra-abdominal inflammation of any origin may be implicated. Acute massive abdominal distention in a hospitalized patient usually results from acute gastric distention, small bowel ileus, or acute colonic pseudo-obstruction. Excessive anticoagulation can lead to retroperitoneal, intra-abdominal, or intramural hematoma that can cause mechanical obstruction or ileus. Finally, there are specific problems that tend to arise in the postoperative period; these are discussed more fully elsewhere [see Urgent Operation, Early Postoperative Technical Complications, and No Operation, Early Postoperative Obstruction, below].

PHYSICAL EXAMINATION AND RESUSCITATION

The initial steps in the physical examination are (1) developing a gestalt of the patient's illness and (2) assessing the patient's vital signs, hydration status, and

cardiopulmonary system. A nasogastric tube, a Foley catheter, and an I.V. line are placed immediately while the physical examination is in progress. The volume and character of the gastric aspirate and urine are noted. A clear, gastric effluent is suggestive of gastric outlet obstruction. A bilious, nonfeculent aspirate is a typical sign of medial to proximal small bowel obstruction or colonic obstruction

If the patient has experienced episodes of obstruction before, one should ask about the etiology and the response to treatment. If the patient has ever undergone an abdominal operation, one should try to obtain and read the operative report, which can provide a great deal of helpful information (e.g., description of adhesions, assessment of their severity, and evaluation of intra-abdominal pathology and anatomy). If abdominal cancer was present, one should find out what operation was performed and attempt to determine the likelihood of intra-abdominal recurrence.

The clinical setting often provides clues to the cause and type of bowel obstruction. In hospitalized patients, there is likely to be an associated medical condition or metabolic derangement that led to obstruction. A thorough review of the patient's medical history and hospital course should be undertaken to identify precipitating events that could have led to intestinal obstipation. One should ask the patient about any previous abdominal irradiation and should note and take into account all medications the patient is taking, especially anticoagulants and agents with anticholinergic

Table 2 Causes of Small Bowel Obstruction in Adults

Extrinsic causes

- Adhesions*
- Hernias (external, internal [paraduodenal], incisional)*
- Metastatic cancer*
- Volvulus
- Intra-abdominal abscess
- Intra-abdominal hematoma
- Pancreatic pseudocyst
- Intra-abdominal drains
- Tight fascial opening at stoma

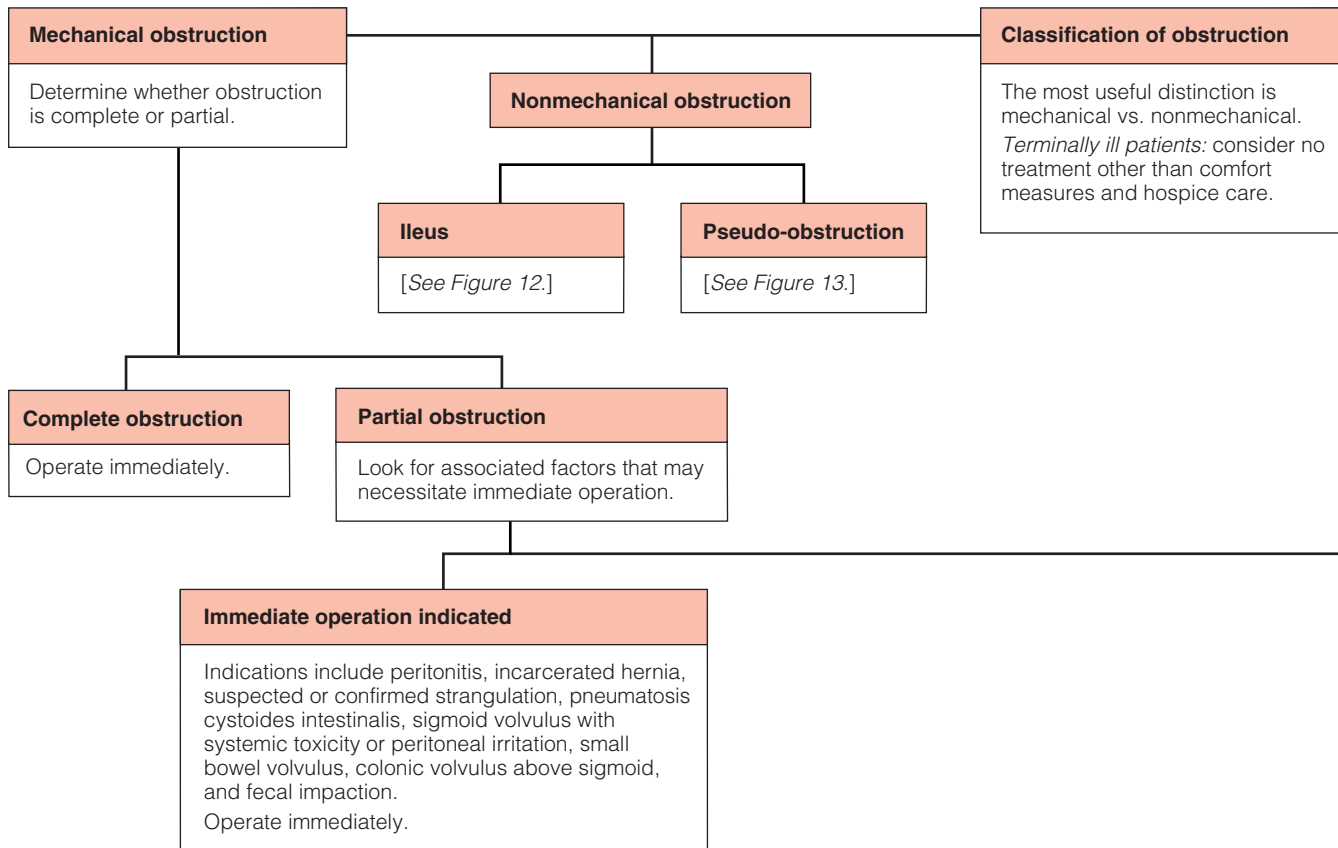

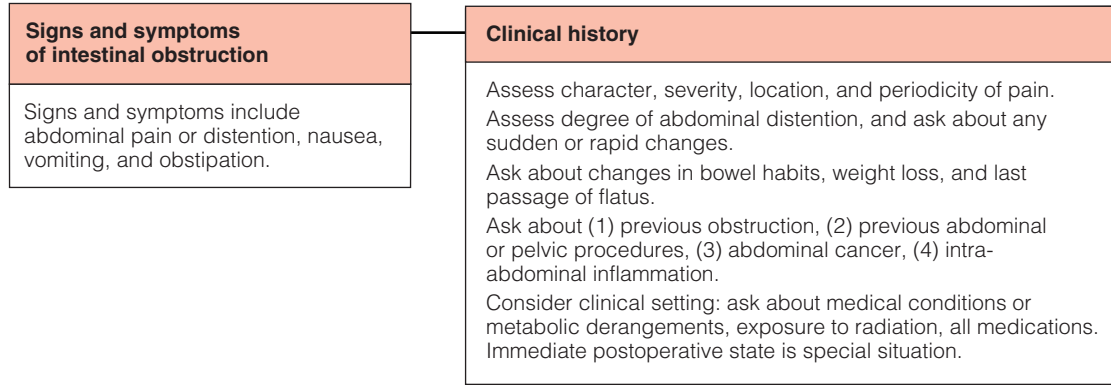

Intraluminal causes

- Tumors*
- Gallstones
- Foreign body
- Worms
- Bezoars

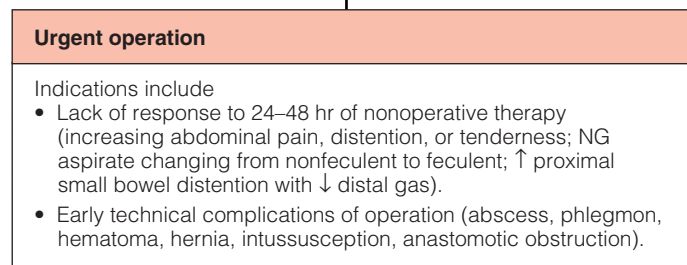

Intramural abnormalities

- Tumors
- Strictures
- Hematoma
- Intussusception
- Regional enteritis
- Radiation enteritis

*Approximately 85% of all small bowel obstructions are secondary to adhesions, hernias, or tumors.

Assessment of Intestinal Obstruction

Physical exam and resuscitate as necessary

Develop gestalt of patient's illness, and assess patient's vital signs, hydration, and cardiopulmonary system.
Place NG tube, Foley catheter, and I.V. line immediately.
Assess volume and character of NG aspirate, and measure urine output.
Replace lost fluid with isotonic saline or lactated Ringer solution.
Look for signs of abscess, pneumonia, or myocardial infarction, and be alert for dyspnea, labored breathing, or jaundice.
Perform systematic abdominal examination: observation → auscultation → palpation and percussion. Look for abdominal masses, tenderness, incisions, and hernias; assess bowel sounds; examine rectum for masses, fecal impaction, and occult blood.

Investigative studies

Obtain chest x-rays and abdominal films.
If uncertainty about presence or nature of colonic obstruction remains, perform sigmoidoscopy and barium enema examination.
Measure serum electrolytes and creatinine, determine hematocrit, and order coagulation profile. If ileus is suspected, measure serum magnesium and calcium and order urinalysis.
Perform CT (with oral or I.V. contrast agents), fast MRI, or abdominal ultrasonography.

Immediate operation not indicated

Manage initially with nonoperative measures.
Reassess patient every 4 hr.
For partial obstruction, administer oral diatrizoate meglumine.
Look for changes in pain, abdominal findings, and volume and character of NG aspirate.
Repeat abdominal x-rays, and look for changes in gas distribution, pneumatosis cystoides intestinalis, and free intraperitoneal air.
Classify patient's condition as improved, unchanged, or worse.
Decide whether operative treatment is necessary and, if so, whether it should be done on urgent or elective basis.
Arrival of contrast agent in right colon within 24 hr is highly predictive of successful resolution of adhesive obstruction without operation.

No operation

Conditions that typically resolve with nonoperative therapy include adhesive obstruction (unless it does not improve in 12 hr), early postoperative obstruction (unless it does not improve in 2 wk), and various inflammatory conditions (IBD, radiation enteritis, diverticulitis, acute Crohn disease).

Elective operation

Indications include nontoxic, nontender sigmoid volvulus with sigmoidoscopically managed obstruction; recurrent adhesive or stricture-related small bowel obstruction; partial colonic obstruction unresponsive to 24 hr of nonoperative therapy; development and resolution of small bowel obstruction in patient who has never undergone abdominal operation.

Table 3 Causes of Colonic Obstruction

Common causes
Cancer (primary, anastomotic, metastatic)
Volvulus
Diverticulitis
Pseudo-obstruction
Hernia
Anastomotic stricture
Unusual causes
Intussusception
Fecal impaction
Strictures (from one of the following)
Inflammatory bowel disease
Endometriosis
Radiation therapy
Ischemia
Foreign body
Extrinsic compression by a mass
Pancreatic pseudocyst
Hematoma
Metastasis
Primary tumors

with a competent ileocecal valve. A feculent aspirate is a typical sign of distal small bowel obstruction. Volume replacement, if necessary, is initiated with isotonic saline solution or lactated Ringer solution. Urine output must be adequate (at least 0.5 ml/kg/hr) before the patient can be taken to the OR; supplemental potassium chloride (40 mEq/L) is administered once this is achieved.

Fever may be present, suggesting that the obstruction may be a manifestation of an intra-abdominal abscess. Signs of pneumonia or myocardial infarction should be sought: these conditions, like intestinal obstruction, can have upper abdominal pain, distention, nausea, and vomiting as presenting symptoms. Dyspnea and labored breathing may occur secondary to severe abdominal distention or pain, in which case immediate relief should be provided by placing the patient in the lateral decubitus position and offering narcotics as soon as the initial physical examination is performed. Jaundice raises the possibility of gallstone ileus or metastatic cancer.

Examination of the abdomen proceeds in an orderly manner from observation to auscultation to palpation and percussion. The patient is placed in the supine position with the legs flexed at the hip to decrease tension on the rectus muscles. The degree of abdominal distention observed varies, depending on the level of obstruction: proximal obstructions may cause little or no distention. Abdominal scars should be noted. Abdominal asymmetry or a protruding mass suggests an underlying malignancy, an abscess, or closed-loop obstruction. The abdominal wall should be observed for evidence of peristaltic waves, which are indicative of acute small bowel obstruction.

Auscultation should be performed for at least 3 to 4 minutes to determine the presence and quality of bowel sounds. High-pitched bowel tones, tingles, and rushes are suggestive of an obstructive process, especially when temporally associated with waves of crampy pain, nausea, or vomiting. The absence of bowel tones is typical of intestinal paralysis but may also indicate intestinal fatigue from long-standing obstruction, closed-loop obstruction, or pseudo-obstruction.

Approximately 70% of patients with bowel obstruction have symmetrical tenderness, whereas fewer than 50% have rebound tenderness, guarding, or rigidity.³ The traditional teaching is that localized tenderness and guarding indicate underlying strangulated bowel; however, prospective studies have demonstrated that these physical findings are neither specific nor sensitive for detecting underlying strangulation⁵ or even obstruction.³ Nevertheless, most surgeons still believe that guarding, rebound tenderness, and localized tenderness reflect underlying strangulation and therefore are indications for operation. Patients with ileus tend to have generalized abdominal tenderness that cannot be distinguished from the tenderness of mechanical obstruction. Gentle percussion is performed over all quadrants of the abdomen to search for areas of dullness (suggestive of an underlying mass), tympany (suggestive of underlying distended bowel), and peritoneal irritation.

A thorough search is made for inguinal, femoral, umbilical, and incisional hernias. The rectum is examined for masses, fecal impaction, and occult blood. If the patient has an ileostomy or a colostomy, the stoma is examined digitally to make sure that there is no obstruction at the level of the fascia.

Investigative Studies

IMAGING

One should obtain a chest x-ray in all patients with bowel obstruction to exclude a pneumonic process and to look for subdiaphragmatic air. In most cases, supine, upright, or lateral decubitus films of the abdomen can distinguish the type of obstruction present (mechanical or nonmechanical, partial or complete) and establish the location of the obstruction (stomach, small bowel, or colon). A useful technique for evaluating abdominal radiographs is to look systematically for intestinal gas along the normal route of the GI tract, beginning at the stomach, continuing through the small bowel, and, finally, following the course of the colon to the rectum. The following questions should be kept in mind as this is done.

- Are there abnormally dilated loops of bowel, signs of small bowel dilatation, or air-fluid levels?
- Are air-fluid levels and bowel loops in the same place on supine and upright films?
- Is there gas throughout the entire length of the colon (suggestive of ileus or partial mechanical obstruction)?
- Is there a paucity of distal colonic gas or an abrupt cutoff of colonic gas with proximal colonic distention and air-fluid levels (suggestive of complete or near-complete colonic obstruction)?
- Is there evidence of strangulation (e.g., thickened small bowel loops, mucosal thumb printing, pneumatosis cystoides intestinalis, or free peritoneal air)?
- Is there massive distention of the colon, especially of the cecum or sigmoid (suggestive of either volvulus or pseudo-obstruction)?
- Are there any biliary or renal calculi, and is there any air in the biliary tree (suggestive of gallstone ileus⁶ or a renal stone that could be causing ileus)?

It is important to be able to distinguish between small and large bowel gas. Gas in a distended small bowel outlines the valvulae conniventes, which traverse the entire diameter of the bowel lumen [see Figure 1]. Gas in a distended colon, on the other hand, outlines the colonic haustral markings, which cross only part of the bowel lumen and typically interdigitate [see Figures 2 and 3]. Distended

Figure 1 Supine radiograph from a patient with complete small bowel obstruction shows distended small bowel loops in the central abdomen with prominent valvulae conniventes (small white arrow). Bowel wall between the loops is thickened and edematous (large white arrow). No air is seen in the colon or the rectum. Note the presence of an isolated small bowel loop in the right lower quadrant (black arrow), which is seen fixed in the same location on upright films, as shown in Figure 4.

small bowel loops usually occupy the central abdomen [see Figure 1], whereas distended large bowel loops are typically seen around the periphery [see Figure 2]. In patients with ileus, distention usually extends uniformly throughout the stomach, the small bowel, and the colon [see Figure 3], and air-fluid levels may be found in the colon and the small intestine.

Patients with gastric outlet obstruction or gastric atony typically have a giant gastric bubble if no nasogastric tube has been placed, with little or no air in the small bowel or the colon. Patients with mechanical small bowel obstruction usually have multiple air-fluid levels, with distended bowel loops of varying sizes arranged in an inverted U configuration [see Figure 4]. A dilated loop of small bowel appearing in the same location on supine and upright films suggests obstruction of a fixed segment of bowel by an adhesion or an internal hernia [see Figures 1 and 4]. Small bowel obstruction is often accompanied by a paucity of gas in the colon. The complete absence of colonic gas is strongly suggestive of complete small bowel obstruction; however, the presence of colonic gas does not exclude complete small bowel obstruction, in that there may have been unevacuated gas distal

Figure 2 Radiograph from a patient with acute colonic pseudo-obstruction shows a dilated colon with haustral markings (white arrow) and edematous small bowel loops (black arrow). Air extends down to the distal sigmoid. This picture is also consistent with rectal obstruction, which could have been excluded by rigid sigmoidoscopy.

Figure 3 Radiograph from a patient with postoperative ileus shows massive gastric distention (A), distended small bowel loops (B), air throughout the colon, mild dilatation of the sigmoid colon (C) with air mixed with stool, and a haustral fold in the apex of the sigmoid colon (D).

Figure 4 Upright radiograph from the same patient as the supine radiograph in Figure 1 shows multiple air-fluid levels of varying size arranged in inverted Us. In the right lower pelvis, a loop of small bowel is seen in exactly the same location as on the supine abdominal film (black arrow), a finding suggestive of adhesive obstruction.

to a point of complete obstruction before the radiograph was taken. On the other hand, if repeat radiographs demonstrate decreased or absent colonic or rectal gas in a patient with small bowel obstruction who previously had more colonic or rectal gas, it is probable that partial obstruction has become complete, and immediate operation is almost always indicated. High-grade obstruction of the colon with an incompetent ileocecal valve may manifest itself as distended small bowel loops with air-fluid levels, thereby mimicking small bowel obstruction. Hence, it is sometimes necessary to perform a barium enema to exclude colonic obstruction.

Massive gaseous distention of the colon is usually secondary to distal colonic or rectal obstruction, volvulus, or pseudo-obstruction [see Figures 2, 5, 6, and 7]. There are well-defined radiographic criteria that are highly sensitive and specific for sigmoid volvulus.⁶ If there is any uncertainty regarding the presence, type, or level of colonic obstruction, immediate sigmoidoscopy followed by barium enema is diagnostic.

LABORATORY TESTS

Serum electrolyte concentrations, the hematocrit, the serum

creatinine concentration, and the coagulation profile (prothrombin time [or international normalized ratio—INR] and platelet count) are helpful in determining the severity of volume depletion and guiding resuscitative efforts. If ileus is suspected, serum magnesium and calcium levels should be measured, and urinalysis should be done to check for hematuria.

Determination of Need for Operation and Classification of Obstruction

The combination of a thorough history, a carefully performed physical examination, and correctly interpreted abdominal radiographs usually allows one to identify the type of bowel obstruction present and to decide whether a patient requires immediate, urgent, or delayed operation [see Table 4] or can safely be treated initially with nonoperative measures. To this end, it is particularly important and useful to stratify patients into those with mechanical obstruction and those with nonmechanical obstruction. In patients with mechanical bowel obstruction, an effort should be made to determine whether the obstruction is complete or partial. Except for a few clinical situations, patients with complete bowel obstruction require immediate operation; conversely, patients with partial bowel obstruction rarely do. Finally, an effort should be made to establish the level and cause of obstruction because these factors often help guide therapy and affect the probability of success in response to specific therapeutic intervention. Patients with nonmechanical obstruction, which derives from ileus or pseudo-obstruction [see Ileus and Pseudo-obstruction, below], do not require immediate operation.

ADJUNCTIVE TESTS FOR EQUIVOCAL SITUATIONS

Sigmoidoscopy

When one is uncertain whether the obstruction is mechanical or not on the basis of the information in hand, additional diagnostic measures are immediately indicated. When large amounts of colonic air extend down to the rectum, flexible or rigid sigmoidoscopy will readily exclude a rectal or distal sigmoid obstruction. Care must be exercised to avoid insufflating large amounts of air during endoscopy: excessive insufflation can cause overdistention of the colon above the level of the possible obstruction, which can be counterproductive and harmful. If sigmoidoscopy yields normal findings but partial colonic obstruction seems to be the correct diagnosis, a water-soluble contrast enema should be administered.⁷ Barium studies may be harmful in patients with acute obstruction when they are performed before the nature of the obstruction (complete or partial) is determined. Abdominal ultrasonography, though not as definitive as a contrast examination, is also able to diagnose suspected colonic obstruction in 85% of patients.⁸

Ultrasonography, Computed Tomography, and Fast Magnetic Resonance Imaging

Abdominal radiographs can be entirely normal in patients with complete, closed-loop, or strangulation obstruction.⁹ Therefore, if the patient's clinical profile and the results of physical examination are consistent with intestinal obstruction despite normal abdominal radiographs, abdominal ultrasonography, CT scanning, or fast MRI should be performed immediately.⁹⁻¹⁸ All three modalities are

highly sensitive and specific for intestinal obstruction when performed properly and interpreted by experienced clinicians. Two prospective clinical trials found ultrasonography to be as sensitive as and more specific than abdominal radiography in diagnosing intestinal obstruction.^{19,20} Ultrasonography, CT, and fast MRI are all capable of detecting the cause of the obstruction, as well as the presence of closed-loop or strangulation obstruction.^{8,10,15-18,21-24}

Sonographic criteria have been established for small bowel and colonic obstruction^{8,21,22}: (1) simultaneous observation of distended and collapsed bowel segments, (2) free peritoneal fluid, (3) inspissated intestinal contents, (4) paradoxical pendulating peristalsis, (5) highly reflective fluid within the bowel lumen, (6) bowel wall edema between serosa and mucosa, and (7) a fixed mass of aperistaltic, fluid-filled, dilated intestinal loops. One group of authors has recommended that when abdominal radiographs are inconclusive or normal in patients with suspected colonic obstruction, ultrasonography, rather than CT or barium enema, should be the next diagnostic step.⁸ Ultrasonography is well suited to critically ill patients: because it can be performed at the bedside, the risk associated with transport to the radiology suite is avoided. Given that ultrasonography is relatively inexpensive, is easy and quick to perform, and often can provide a great deal of information about the location, nature, and severity of the obstruction, it should be employed early on in the evaluation of all patients with intestinal obstruction.¹⁹

Several authors have recommended that patients with suspected small bowel obstruction and equivocal plain abdominal films undergo CT scanning before a small bowel contrast series is ordered.¹¹⁻¹⁴ CT scanning has several advantages over a small bowel contrast examination in this setting: (1) it can ascertain the level of obstruction, (2) it can assess the severity of the obstruction and determine its cause, and (3) it can detect closed-loop obstruction and early strangulation [see Figures 8, 9, 10, and 11]. CT can also detect inflammatory or neoplastic processes both outside and inside the peritoneal cavity and can visualize small amounts of intraperitoneal air or pneumatosis cystoides intestinalis not seen on conventional films [see Figure 10]. Prospective studies have demonstrated that the accuracy of CT in diagnosing bowel obstruction is higher than 95% and that its sensitivity and specificity are each higher than 94%.^{23,24} CT scanning distinguishes colonic mechanical obstruction from pseudo-obstruction more accurately than conventional films do and thus is the preferred modality in many cases.²⁵

There is evidence to indicate that fast MRI with T₂-weighted images is more sensitive, specific, and accurate than contrast-enhanced helical CT scanning in establishing the location and cause of bowel obstruction.¹⁷ The advantages of fast MRI over helical CT scanning are (1) that the image acquisition time is short (1 to 2 seconds per slice), which means that the image can be acquired in the space of a single held breath, and (2) that no contrast agents are required. In addition, because of its multiplanar capability, MRI is also more effective at demonstrating the transition point of the obstruction. When helical CT scanning is nondiagnostic in a patient with suspected bowel obstruction and fast MRI is not available, a small bowel follow-through examination with dilute barium is often useful.¹⁴

Figure 5 (a) Radiograph from a patient with massive sigmoid volvulus shows a distended ahastral sigmoid loop (white arrow), inferior convergence of the walls of the sigmoid loop to the left of the midline, and approximation of the medial walls of the sigmoid loop as a summation line (black arrow). (b) Barium enema of the colon shows a tapered obstruction at the rectosigmoid junction with a typical bird's-beak deformity (black arrow).

Figure 6 (a) Radiograph from a patient with cecal volvulus shows a dilated cecum with no air distally in the colorectum. Convergence of the medial walls of the loop (black arrow) points to the right, a typical finding in cecal volvulus. (b) Barium examination demonstrates a bird's-beak deformity tapering at the point of volvulus (large white arrow). Note walls of dilated cecum (small white arrows).

Figure 7 Shown is a radiograph from a patient with complete colonic obstruction from an obstructing carcinoma in the descending left colon with proximal air-fluid levels. The absence of air distally in the rectum or the sigmoid is suggestive of complete obstruction. The ileocecal valve is competent, and thus, there is no small bowel air.

Contrast Studies

Enteroclysis (direct injection of BaSO₄ into the small bowel) is generally considered the most sensitive method of distinguishing between ileus and partial mechanical small bowel obstruction: it has a diagnostic sensitivity of 87% for adhesive obstruction.^{26,27} Many surgeons are concerned that injection of barium might cause partial obstruction to progress to complete obstruction; however, there is no evidence that this ever occurs, and one therefore should not refrain from using barium to diagnose partial small bowel obstruction.²⁸⁻³¹ If complete obstruction is identified, the patient should undergo immediate operation. If partial obstruction is identified in either the small or the large bowel, the patient is treated accordingly. If (1) mechanical obstruction is not identified and (2) a point of obstruction, as evidenced by the finding of both dilated and decompressed intestinal loops, cannot be identified through abdominal ultrasonography, CT scanning, or fast MRI, then the diagnosis is almost certainly ileus, in which case one's attention is directed toward identifying and correcting the underlying precipitating cause [see *Table 1 and Mechanical Obstruction, No Operation, Adhesive Partial Small Bowel Obstruction, below*].

Mechanical Obstruction

TERMINAL ILLNESS

Patients with a terminal illness (e.g., AIDS or advanced carcinomatosis) to whom surgical treatment offers little hope of improved quality or duration of life may choose not to undergo operative intervention for acute bowel obstruction. These patients should be offered comfort measures, including continuous morphine infusion, rehydration, and administration of antisecretory

Table 4 Guidelines for Operative and Nonoperative Therapy

Situations necessitating emergent operation

- Incarcerated, strangulated hernias
- Peritonitis
- Pneumatosis cystoides intestinalis
- Pneumoperitoneum
- Suspected or proven intestinal strangulation
- Closed-loop obstruction
- Nonsigmoid colonic volvulus
- Sigmoid volvulus associated with toxicity or peritoneal signs
- Complete bowel obstruction

Situations necessitating urgent operation

- Progressive bowel obstruction at any time after nonoperative measures are started
- Failure to improve with conservative therapy within 24–48 hr
- Early postoperative technical complications

Situations in which delayed operation is usually safe

- Immediate postoperative obstruction
- Sigmoid volvulus successfully decompressed by sigmoidoscopy
- Acute exacerbation of Crohn disease, diverticulitis, or radiation enteritis
- Chronic, recurrent partial obstruction
- Paraduodenal hernia
- Gastric outlet obstruction
- Postoperative adhesions
- Resolved partial colonic obstruction

die of malignant bowel obstruction in a hospital should be offered hospice care or home visiting nurse services with continuous octreotide infusion, I.V. rehydration, and gastrostomy decompression.^{37,38} Three prospective, randomized clinical trials demonstrated that octreotide significantly attenuated the severity of nausea and vomiting and the degree of subjective discomfort in patients with inoperable obstruction and permitted the discontinuance of nasogastric tube decompression.^{33,34,39} One of these studies also demonstrated that octreotide significantly reduced the degree of fatigue and anorexia experienced.³⁹ When long-term gastric decompression is required for palliation in a terminally ill patient, percutaneous endoscopic gastrostomy or jejunostomy should be considered [see 5:18 *Gastrointestinal Endoscopy*].⁴⁰ Attention must always be paid to quality-of-life issues and to the patient's potential interest in pursuing nonoperative forms of palliation. For many terminally ill or incurable patients with bowel obstruction, the most humane and sensible treatment comprises nothing more than instituting palliative measures such as those described.

IMMEDIATE OPERATION

All patients with complete bowel obstruction, whether of the small intestine or the large, should undergo immediate operation unless extraordinary circumstances (e.g., diffuse carcinomatosis, terminal illness, or sigmoid volvulus that responds to sigmoidoscopic decompression) are present. If one attempts to manage complete intestinal obstruction nonoperatively, one risks delaying definitive treatment of patients with intestinal ischemia and subjecting them to significantly increased morbidity and mortality should perforation or severe infection develop.^{5,41}

Immediate operation is also indicated when bowel obstruction is associated with peritonitis; incarcerated strangulated hernias;

agents.³²⁻³⁴ In some of these patients, endoscopic deployment of plastic stents may relieve high-grade partial obstruction, thus rendering laparotomy unnecessary.^{35,36} Patients who do not wish to

Figure 8 CT scan from a patient with partial small bowel obstruction shows distended, fluid-filled loops of small bowel with air-fluid levels, hyperemia, and bowel wall thickening (large white arrow). Note the discrepancy in caliber between dilated small bowel and decompressed small bowel (dashed white arrow) and the stranding (small black arrow) in the small bowel mesentery. Air in a decompressed descending colon (large black arrow) is indicative of partial obstruction.

Figure 9 CT scan from a patient with adhesive partial small bowel obstruction shows massively dilated small intestine (black arrow) proximal to a thick adhesive band (large white arrow) and decompressed small bowel distal to the adhesion (dashed white arrow). The patient was operated on because of the low probability that this obstruction would resolve with conservative management.

Figure 10 CT scan from a patient with partial small bowel obstruction from cancer shows distended small bowel (dashed white arrows) proximal to a mass (small white arrow). There is air in the cecum (black arrow), the transverse colon, and the descending colon (large white arrow). The small bowel is maximally dilated, with hyperemic, edematous bowel wall (B) just proximal to an obstructing recurrent colon carcinoma. Even though plain radiographs showed partial small bowel obstruction, this CT scan led to early operation because continued nonoperative management would not resolve the problem.

suspected or confirmed strangulation; pneumatosis cystoides intestinalis; sigmoid volvulus accompanied by systemic toxicity or peritoneal irritation; colonic volvulus above the sigmoid colon; or fecal impaction. These conditions will not resolve without operation and are associated with increased morbidity, mortality, and cost if diagnosis and treatment are delayed. The only time one would not operate immediately on any patient with one of these diagnoses is when the patient requires cardiopulmonary stabilization, additional resuscitation, or both. Whenever there is any doubt as to the presence of any of these conditions, additional diagnostic tests (e.g., ultrasonography, CT, fast MRI, or contrast studies) are indicated to confirm or exclude them.

Strangulation and Closed-Loop Obstruction

Morbidity and mortality from intestinal obstruction vary significantly and depend primarily on the presence of strangulation and subsequent infection. Strangulation obstruction occurs in approximately 10% of all patients with small intestinal obstruction. It carries a mortality of 10% to 37%, whereas simple obstruction carries a mortality of less than 5%.^{5,28,42,43} Early recognition and immediate operative treatment of strangulation obstruction are the only current means of decreasing this mortality. Strangulation obstruction occurs most frequently in patients with incarcerated hernias, closed-loop obstruction, volvulus, or complete bowel obstruction; hence, identification of any of these specific causes of obstruction is an important and clear indication for immediate operation. Radiographic evidence of pneumatosis cystoides intestinalis or free intraperitoneal air in a patient with a clinical picture of bowel obstruction is indicative of strangulation, perforation, or both and constitutes an indication for operation. High-quality abdominal CT with I.V. contrast can detect advanced strangulation and identify early, reversible strangulation [see Figure 11].^{13,15,16}

Abdominal ultrasonography can also identify edematous, hemorrhagic loops of intestine. Accordingly, whenever one is concerned about possible strangulation or closed-loop obstruction but is not yet committed to taking the patient immediately to the OR, an ultrasonogram or a CT scan should be obtained. In fact, given that ultrasonography, CT, and fast MRI are the only well-established means of diagnosing strangulation obstruction short of exploratory laparotomy or laparoscopy, an argument can be made that one of these modalities should be performed in all patients who have been admitted to the hospital with bowel obstruction and are initially being treated nonoperatively.

Many surgeons base the decision whether to operate on patients with bowel obstruction on the presence or absence of the so-called classic signs of strangulation obstruction—continuous abdominal pain, fever, tachycardia, peritoneal signs, and leukocytosis—and on their clinical experience. Unfortunately, these classically taught signs, even in conjunction with abdominal x-rays and clinical judgment, are incapable of reliably detecting closed-loop or gangrenous bowel obstruction.^{5,28,41,44} In fact, one prospective clinical trial concluded that the five classic signs of strangulation obstruction and experienced clinical judgment were not sensitive for, specific for, or predictive of strangulation⁵: in more than 50% of the patients who had intestinal strangulation, the condition was not recognized preoperatively. Such findings suggest that early nonoperative recognition of intestinal strangulation is not feasible without ultrasonography, CT, or fast MRI.

Incarcerated or Strangulated Hernias

A hernia that is incarcerated, tender, erythematous, warm, or edematous is an indication for immediate operation. Primary or incisional hernias may not be palpable in obese patients, in which case ultrasonography, CT scanning, or fast MRI should be performed.

Figure 11 Early closed-loop small bowel obstruction CT scan from a patient with early closed-loop obstruction of the small intestine shows markedly edematous, hyperemic small bowel, a finding indicative of early strangulation (white arrow). The patient had minimal symptoms, and there was air in the transverse colon and the descending colon (a finding indicative of partial small bowel obstruction); however, the finding of gangrenous, nonperforated small bowel on this CT scan led to early operation.

Nonsigmoid Volvulus and Sigmoid Volvulus with Systemic Toxicity or Peritoneal Signs

All intestinal volvuli are closed-loop obstructions and thus carry a high risk of intestinal strangulation, infarction, and perforation. Patients typically present with acute, colicky abdominal pain, massive distention, nausea, and vomiting. Sigmoid volvulus is the most common form of colonic volvulus, followed by cecal volvulus. Abdominal radiographs are fairly diagnostic for colonic volvulus [see Figures 5 and 6]. In contrast, small bowel volvulus may not be visualized on plain radiographs, because the closed loop fills completely with fluid and no air-fluid level can be seen. Small bowel volvulus is readily detected by ultrasonography or CT scanning; one or both of these procedures should be performed in patients presenting with signs and symptoms of bowel obstruction and normal abdominal radiographs. Small bowel volvulus is an indication for immediate operation.

If one observes signs of systemic toxicity, a bloody rectal discharge, fever, leukocytosis, or peritoneal irritation in a patient with sigmoid volvulus, the patient should undergo immediate operation; if all of these signs are absent, the patient should undergo sigmoidoscopy. When there are no signs of peritonitis or generalized toxicity, sigmoidoscopic decompression is safe and effective in more than 95% of patients with sigmoid volvulus.⁴⁵ If mucosal gangrene or a bloody effluent is noted at the time of sigmoidoscopy, immediate operative intervention is necessary even in the absence of any clinical signs or symptoms of strangulation. After sigmoidoscopy, the patient can undergo elective bowel preparation and a single-stage sigmoid resection before being discharged from the hospital. If, however, clinical toxicity, a bloody rectal discharge, fever, or peritoneal irritation arises at any time after sigmoidoscopic decompression while the patient is being prepared for an elective procedure, immediate operation is indicated.

Patients with volvulus proximal to the sigmoid colon should undergo immediate operation regardless of whether peritoneal irritation is present. The incidence of strangulation infarction is high in such patients, and nonoperative therapy often fails. If the diagnosis of nonsigmoid colonic volvulus is in doubt, a barium enema is indicated to exclude colonic pseudo-obstruction.

Fecal Impaction

Complete colonic obstruction secondary to fecal impaction in the rectum can sometimes be successfully relieved through disimpaction at the bedside; however, this can be difficult and extremely uncomfortable for the patient. The most expeditious and successful method of relieving the obstruction is to disimpact the patient while he or she is under general or spinal anesthesia. In one study, the pulsed-irrigated enhanced-evacuation (PIEE) procedure, which can be performed at the bedside, successfully resolved fecal impaction in approximately 75% of geriatric patients.⁴⁶ In another study, administration of a polyethylene glycol 3350 solution over 3 days successfully resolved intestinal obstruction from fecal impaction in 75% of pediatric patients.⁴⁷

URGENT OPERATION

Lack of Response to Nonoperative Therapy within 24 to 48 Hours

It is usually safe to manage partial bowel obstruction initially by nonoperative means: a nihil per os (NPO) regimen, nasogas-

tric decompression, analgesics, and octreotide. Such therapy is successful in most cases, especially if the cause of obstruction is postoperative adhesions, but there is always the risk that complete bowel obstruction or strangulation already exists but is undetected. Furthermore, there is the risk that while the patient is being observed, partial obstruction will progress to complete obstruction or strangulation and perforation will develop. It is therefore crucial to be alert to changes in the patient's condition.

Repeated examination of the abdomen by the same clinician is the most sensitive way of detecting progressive obstruction. Examinations should be performed no less frequently than every 3 hours. If abdominal pain, tenderness, or distention increases or the gastric aspirate changes from nonfeculent to feculent, abdominal exploration is usually indicated. Abdominal radiographs should be repeated every 6 hours after nasogastric decompression and reviewed by the surgeon who is following the patient. If proximal small bowel distention increases or distal intestinal gas decreases, nonoperative therapy is less likely to be successful; in these circumstances, early operative intervention should be seriously considered. Conversely, if the patient's condition appears stable or improved and x-rays indicate that the obstruction either has resolved somewhat or at least is no worse, it is generally safe to continue nonoperative care for another 12 to 24 hours. If the clinical picture is stable after 24 hours of observation, one must decide whether to operate or to continue nonoperative therapy. Clinical judgment and experience, coupled with thorough and accurate assessment of the patient's underlying diagnosis and clinical condition, have traditionally been the most reliable guides for making this decision. Currently, however, it appears that the decision whether to operate can be made more cost-effectively and reliably on the basis of abdominal imaging studies [see No Operation, Adhesive Partial Small Bowel Obstruction, below].

Early Postoperative Technical Complications

When normal bowel function initially returns after an abdominal operation but then is replaced by a clinical picture suggestive of early postoperative mechanical obstruction, the explanation may be a technical complication of the operation (e.g., phlegmon, abscess, intussusception, a narrow anastomosis, an internal hernia, or obstruction at the level of a stoma). An early, aggressive diagnostic workup should be performed to identify or exclude these problems because they are unlikely to respond to nasogastric decompression or other forms of conservative management. It is critical to know exactly what was done within the abdomen in the course of the operation. To this end, one should try to speak directly with the operating surgeon rather than attempt to deduce the needed information from the operative report.

If the patient had peritonitis or a colonic anastomosis at the initial operation, one should order a CT scan to look for an intra-abdominal abscess. An abscess or a phlegmon at the site of an anastomosis is usually secondary to anastomotic leakage and is an indication for reoperation. CT scanning can also identify intra-abdominal hematomas, which should be evacuated through early reoperation. In patients recovering from a proctectomy, herniation of the small bowel through a defect in the pelvic floor is a common cause of intestinal obstruction. Oral contrast studies can help identify patients with an internal hernia, intussusception, or anastomotic obstruction and should be performed after the CT scan. A retrograde barium examination should be performed in patients thought to have a problem related to a stoma or an intestinal anastomosis. When none of the above factors appears to

be the cause of the postoperative obstruction, it is reasonable for the surgeon to assume that the obstruction is secondary to postoperative adhesions, which are best treated conservatively (see below).

NO OPERATION

In selected patients, nonoperative management of partial small bowel obstruction is highly successful and carries an acceptably low mortality. Such patients include those whose partial obstruction is secondary to intra-abdominal adhesions, occurs in the immediate postoperative period, or derives from an inflammatory condition (e.g., inflammatory bowel disease, radiation enteritis, or diverticulitis).

Adhesive Partial Small Bowel Obstruction

Adhesions are the major cause of bowel obstruction. Obstruction resulting from adhesions can occur as early as 1 month or as late as 20 years after operation.⁴⁸ Adhesive partial small bowel obstruction is treated initially with nasogastric decompression, I.V. rehydration, and analgesia. Parenteral nutrition should be begun if one believes that oral or enteral nutrition will not be adequate within 5 days. Nonoperative therapy leads to resolution of adhesive partial obstruction in as many as 90% of patients^{49,50}; however, such resolution is followed by recurrence of obstruction in approximately 50% of cases.^{51,52} When operative adhesiolysis is performed, the mortality is less than 5% for patients with simple obstruction but may be as high as 30% for patients with strangulation or necrotic bowel necessitating intestinal resection.⁴⁸ In view of this substantial difference in mortality, it is extremely important to be able to confidently distinguish obstruction that is likely to resolve with nonoperative treatment from obstruction that is not. Patients with adhesive partial obstruction that can be accurately predicted to resolve with medical therapy can and should be treated nonoperatively.

Some studies suggest that the nature of the previous abdominal operation or the type of adhesions present may influence the probability that the obstruction will not respond to medical therapy.⁵³⁻⁵⁷ Operations associated with a lower likelihood of response to medical therapy include those performed through a midline incision; those involving the aorta, the colon, the rectum, the appendix, or the pelvic adnexa; and those done to relieve previous carcinomatous obstruction. Matted adhesions, which are more common in patients who have undergone midline incisions or colorectal procedures, are less amenable to conservative management than a simple obstructive band is.⁵³ In the context of this kind of operative history, strong consideration should be given to surgical intervention if the obstruction does not resolve within 24 hours—unless comorbid medical conditions tip the risk-benefit balance in the direction of nonoperative therapy.

There is an ongoing debate regarding how long patients with partial adhesive obstruction should be treated conservatively. After 48 hours of nonoperative management, the risk of complications increases substantially, and the probability that the obstruction will resolve diminishes.⁴³ Generally, if the obstruction is going to resolve with nonoperative therapy, there will be a fairly prompt response within the first 8 to 12 hours. Therefore, if a patient's condition has deteriorated or has not significantly improved by 12 hours after nasogastric decompression and resuscitation, exploratory laparotomy is advisable. During this obser-

vation period, the patient must be constantly reevaluated, ideally by the same examiner. Analgesics can be safely administered, and repeat abdominal examinations should be performed at 3-hour intervals when the influence of narcotics has waned. Repeat abdominal x-rays should be obtained no later than 6 hours after nasogastric decompression, and the pattern of gas distribution should be compared with that seen on the admission films. A decrease in intestinal gas distal to a point of obstruction coupled with an increase in proximal dilatation suggests that the obstruction is worsening; conversely, a decrease in intestinal distention coupled with the appearance of more gas distally in the colon suggests that the obstruction is being reduced. The degree of abdominal distention, the passage of flatus, and the nature of the nasogastric aspirate should be evaluated periodically. If abdominal distention does not decrease or the gastric aspirate changes from bilious to feculent, the patient should be operated on.

Experimental and clinical studies suggest that patients undergoing nonoperative treatment of bowel obstruction may benefit from the administration of somatostatin analogues as a result of the potent effects these substances exert on intestinal sodium, chloride, and water absorption.⁵⁷ In one study, animals with either complete or closed-loop partial small bowel obstruction were given either long-acting somatostatin or saline; the treatment group had significantly less intestinal distention, less infarction, and longer survival than the control group.^{57,58} In a prospective, randomized clinical trial evaluating the use of somatostatin in patients who had complete small bowel obstruction without clinical or radiologic evidence of strangulation, the treatment group was less likely to need operation, had less proximal intestinal distention, and exhibited decreased mucosal necrosis proximal to the point of obstruction.⁵⁹ In other trials, long-acting somatostatin analogues and other nonsecretagogues significantly decreased the amount of gastric contents aspirated and alleviated the symptoms of intestinal obstruction in terminally ill patients with nonoperable malignant disease.^{32,33,37-40}

It should be possible to determine with a high degree of accuracy and safety which patients will require operation for adhesive small bowel obstruction within 24 to 48 hours of admission to the hospital. As a rule, patients with closed-loop or complete bowel obstruction, who require immediate or urgent operation, can be readily identified by means of abdominal CT or MRI.^{12-14,17,18} For the remaining patients, who have some degree of partial obstruction, the success or failure of conservative management can be predicted with high accuracy by recording the arrival of contrast material (either a water-soluble agent or a mixed barium preparation) in the right colon within a defined time.^{14,30,60-63} One prospective study documented the arrival of diatrizoate meglumine–diatrizoate sodium in the colon within 24 hours and found this measure to have a sensitivity of 98%, a specificity of 100%, an accuracy of 99%, a positive predictive value of 100%, and a negative predictive value of 96% as a predictor of successful nonoperative treatment.⁶⁴ Other studies achieved comparable results with shorter arrival times (e.g., 4 or 8 hours).^{14,61,65}

Several prospective, randomized clinical trials have addressed the issue of whether administration of contrast material can itself be therapeutic with respect to resolving adhesive small bowel obstruction. Two such studies examined small bowel follow-through with barium, either alone or mixed with diatrizoate meglumine.^{30,31} Both found that the intervals between admission and operation were shorter for patients randomized to the contrast arm than for those in the control group but that contrast examination did not lead to more expeditious resolution of obstruction. Both studies also demonstrated that barium could be adminis-

tered to patients with small bowel obstruction safely and without complications.

Four prospective, randomized trials have investigated the effects of administering water-soluble hyperosmolar contrast agents to patients with small bowel obstruction.^{60,62,63,66} In one study, administration of 100 ml of diatrizoate meglumine (1,900 mOsm/L) through the nasogastric tube promoted resolution of adhesive partial obstruction and shortened hospital stay but had no effect on whether laparotomy was required.⁶⁰ No contrast-related complications were observed. In the second study, administration of a different water-soluble hyperosmolar contrast agent, ioxitalamate meglumine (1,500 mOsm/L), had no therapeutic effect on patients with partial small bowel obstruction.⁶⁶ Again, no contrast-related complications were observed. In the third study, administration of 100 ml of diatrizoate meglumine through the nasogastric tube significantly accelerated the resolution of adhesive partial small bowel obstruction and shortened hospital stay.⁶² Patients in whom contrast reached the colon within 24 hours were able to tolerate immediate oral feeding. In addition, the time needed to decide on operative adhesiolysis was shorter in patients receiving the contrast agent. In the fourth study, patients whose partial adhesive small bowel obstruction did not resolve after 48 hours either received 100 ml of diatrizoate meglumine or underwent operative adhesiolysis.⁶³ If administration of the contrast agent revealed complete bowel obstruction, operative treatment was immediately initiated. If it revealed partial obstruction, conservative treatment was continued; in 100% of these patients, the obstruction then resolved without operation. No contrast-mediated complications, no bowel strangulation, and no deaths were reported. The significant treatment effect reported in three of the four randomized clinical trials, along with the absence of any deleterious contrast-related complications in all four, constitutes sufficient evidence to support the administration of 100 ml of diatrizoate meglumine to patients with adhesive partial small bowel obstruction.

By accelerating the resolution of partial small bowel obstruction and ileus, administration of water-soluble contrast agents can shorten the expected hospital stay and thereby reduce the cost of care. Thus, it is reasonable that the first step in managing suspected partial small bowel obstruction from adhesions or postoperative ileus should be to administer water-soluble contrast material intragastrically. When bowel function does not return within 24 hours and the obstruction is demonstrated to be partial, continued observation is safe and resolution without operation is still highly probable. Eventually, however, there will be a point beyond which continued observation is no longer cost-effective in comparison with operative adhesiolysis (especially laparoscopic adhesiolysis). Additional prospective trials are necessary to determine precisely how long the waiting period before operative treatment should be.

Laparoscopic adhesiolysis Several clinical reports have demonstrated that laparoscopic adhesiolysis for acute small bowel obstruction is both feasible and safe.⁶⁷⁻⁷² Laparoscopic or laparoscopic-assisted lysis of adhesions relieves bowel obstruction in more than 50% of patients and is associated with lower morbidity, earlier return of bowel function, quicker resumption of normal diet, and a shorter hospital stay than open operative lysis.^{67-71,73} To minimize the risk for bowel injury at the beginning of the operation, the first trocar is inserted under direct vision by means of an open technique, and the incision is placed well away from any previous scars.^{74,75}

At present, there are no prospective, randomized, controlled clinical trials comparing laparoscopic with open adhesiolysis. Perhaps

the best study published to date on this issue is a retrospective, matched-pair analysis that used an intention-to-treat analysis.⁷¹ In this study, 52% of the patients in the laparoscopic group underwent conversion to open lysis of adhesions either for completion of adhesiolysis or for management of complications. No perforations or recurrent obstructions were missed. Perforations were more common overall in the laparoscopic group than in the open group, though this difference was largely eliminated when patients from the laparoscopic group who underwent conversion to open lysis were not considered. Patients with two or more previous laparotomies had a higher incidence of intraoperative complications than those with fewer laparotomies. Accordingly, the authors recommended against laparoscopic adhesiolysis in patients with two or more previous laparotomies. The high conversion rate in this study notwithstanding, the laparoscopic group as a whole (including conversions) experienced an overall reduction in postoperative complications.

Another potential advantage of laparoscopic adhesiolysis is that it results in fewer intra-abdominal adhesions than open laparotomy^{76,77} and thus may reduce the risk of recurrent bowel obstruction. However, one study found that despite a reduction in median length of stay, patients treated laparoscopically were at increased risk for early unplanned reoperation as a consequence of either incomplete relief of obstruction or complications.⁷⁰ In fact, bowel perforation in the course of laparoscopic adhesiolysis often is not detected during the procedure and presents in a delayed fashion.⁷⁵ Many such injuries are attributable either to insertion of the initial trocar or to delayed perforation of a thermal injury. When laparoscopic adhesiolysis fails to identify and relieve an obvious point of obstruction or when adhesiolysis is inadequate or unsafe, conversion to an open approach is indicated.

Early Postoperative Obstruction

Early postoperative mechanical small bowel obstruction is not uncommon: it occurs in approximately 10% of patients undergoing abdominal procedures.⁷⁸ Postoperative bowel obstruction is often difficult to diagnose because it gives rise to many of the same signs and symptoms as postoperative ileus: obstipation, distention, nausea, vomiting, abdominal pain, and altered bowel sounds. In most cases, there are roentgenographic signs indicative of small bowel obstruction rather than ileus; however, in some cases, abdominal x-rays fail to diagnose the obstruction.⁷⁹ Traditionally, when plain radiographs are equivocal, an upper GI barium study with follow-through views is the next test performed to distinguish ileus from partial or complete small bowel obstruction⁸⁰; however, such studies may yield the wrong diagnosis in as many as 30% of cases.^{26,79,81} A number of authorities believe that abdominal ultrasonography is excellent at distinguishing postoperative ileus from mechanical obstruction and recommend that it be done before any contrast study.²²

Early postoperative obstruction is caused by adhesions in about 90% of patients.^{79,82} When there are no signs of toxicity and no acute abdominal signs, such obstruction can usually be managed safely with nasogastric decompression.^{78,79,81,82} As many as 87% of patients respond to nasogastric suction within 2 weeks. About 70% of the patients who respond to nonoperative treatment do so within 1 week, and an additional 25% respond during the following 7 days. If postoperative obstruction does not resolve in the first 2 weeks, it is unlikely to do so with continued nonoperative therapy, and reoperation is probably indicated^{79,82}; about 25% of patients whose postoperative obstruction was initially treated nonoperatively eventually require reoperation. An exception to this guideline arises in patients known to have severe dense adhesions (sometimes

referred to as obliterative peritonitis) in response to multiple sequential laparotomies. These patients may have a combination of mechanical obstruction and diffuse small bowel and colonic ileus. The risk of closed-loop obstruction, volvulus, or strangulation in this group of patients is low. Repeat laparotomies and attempts to lyse adhesions may lead to complications, the development of enterocutaneous fistulae, or exacerbation of the adhesions. Often, the best approach to managing these patients is observation for prolonged periods (i.e., months). Total parenteral nutrition (TPN) is indicated. The addition of octreotide to the TPN solution may be helpful and may make patients more comfortable.

Because the risk of intestinal strangulation in patients with postoperative adhesive obstruction is extremely low (< 1%),^{79,83} one can generally treat these patients nonoperatively for longer periods. In fact, the conservative approach is often the wise one: reoperation may do more harm than good (e.g., by causing enterotomies and inducing denser adhesions). The traditional indications for operation in patients with early postoperative obstruction include (1) deteriorating clinical status, (2) worsening obstructive symptoms, and (3) failure to respond to nonoperative management within 2 weeks. With the rising cost of hospitalization, it might in fact be more cost-effective to reoperate on patients who have persistent obstruction after 7 days. This speculation would have to be tested by a well-organized cost-benefit study conducted in a prospective fashion.

Some physicians have maintained that long intestinal tubes are beneficial in the management of postoperative bowel obstruction.⁵⁰ However, there is no convincing evidence that long intestinal tubes are any better for resolving bowel obstruction than conventional nasogastric tubes are. In fact, some authorities have reported that the use of such tubes increases morbidity.^{28,43,44} One prospective, randomized clinical trial that addressed this issue found no differences between the two types of tube with respect to the percentage of patients who were able to avoid operation, the incidence of complications, the time between admission and operation, or the duration of postoperative ileus.⁸⁴

Inflammatory Conditions

Partial bowel obstruction secondary to inflammatory bowel disease, radiation enteritis, or diverticulitis usually resolves with nonoperative therapy. Bowel obstruction accompanying an acute exacerbation of Crohn disease usually resolves with nasogastric suction, I.V. antibiotics, and anti-inflammatory agents. If, however, CT scanning detects intra-abdominal abscess, there is evidence of a chronic stricture, or the patient exhibits persistent obstructive symptoms, operation may be necessary. Similarly, bowel obstruction arising from acute enteritis caused by radiation exposure or chemotherapy usually resolves with supportive care. Chronic radiation-induced strictures are problematic; astute clinical judgment must be exercised to determine when operative treatment is the best option.

Patients with acute diverticulitis typically present with a history of altered bowel movements, fever, leukocytosis, localized pain, tenderness, and guarding in the left lower quadrant of the abdomen. Approximately 20% of patients with colonic diverticulitis also present with signs and symptoms of partial colonic obstruction. A CT scan should be obtained early in all patients with diverticulitis to ascertain whether there is a pericolonic abscess that could be drained percutaneously.⁸⁵ Partial colonic obstruction in these patients usually resolves with antibiotic therapy, an NPO regimen, and nasogastric decompression. If obstructive symptoms persist for more than 7 days or if obstructive symptoms from a documented stricture recur, operation is indicated.

ELECTIVE OPERATION

Nontoxic, Nontender Sigmoid Volvulus

Patients with nontoxic, nontender sigmoid volvulus whose bowel obstruction is initially treated successfully with sigmoidoscopic decompression are at risk for recurrent colonic obstruction. Accordingly, these patients should undergo elective sigmoid resection after complete bowel preparation.

Recurrent Adhesive or Stricture-Related Partial Small Bowel Obstruction

Many patients whose adhesive bowel obstruction resolves experience no further obstructive episodes. If a patient does present with recurrent obstruction from presumed adhesions, either a contrast examination of the bowel or CT scanning is indicated to determine whether there is a surgically correctable point of stenosis. A strong argument can be made that non-high-risk patients should undergo elective operation after presenting with their second episode of mechanical obstruction. Similarly, patients with recurrent obstruction from strictures of any sort should undergo elective operation, given that these lesions are unlikely to resolve.

Partial Colonic Obstruction

The most common causes of partial colonic obstruction are colon cancer, strictures, and diverticulitis. Cancer and strictures usually must be managed surgically because they generally go on to cause obstruction later. Strictures from ischemia or endometriosis usually call for elective colonic resection. Inflammatory strictures from diverticulitis may resolve; however, if obstructive symptoms persist or if barium enema examination continues to yield evidence of colonic narrowing, elective resection is warranted.

When abdominal x-rays suggest distal colonic obstruction, digital examination and rigid sigmoidoscopy are performed to exclude fecal impaction, tumors, strictures, and sigmoid volvulus. If obstruction is proximal to the sigmoidoscope, barium contrast examination is indicated. If barium examination does not demonstrate mechanical obstruction, a presumptive diagnosis of colonic pseudo-obstruction is made.

The morbidity and mortality associated with elective colorectal procedures are significantly lower than those associated with emergency colonic surgery. Furthermore, immediate operation for left-side colonic obstruction almost always necessitates the creation of a diverting colostomy. If a colostomy takedown subsequently proves necessary, the overall cost of caring for the patient will be significantly higher than it would have been had a single-stage procedure been performed. For these reasons, one should initially treat partial colonic obstruction with nasogastric suction, enemas, and I.V. rehydration in the hope that the obstruction will resolve and that the patient thus can undergo mechanical and antibiotic bowel preparation and a single-stage procedure comprising resection and primary anastomosis. Patients who do not respond to nonoperative measures within 24 hours should undergo operation within 12 hours with the aim of preventing perforation.

In patients with partially obstructing rectal or distal sigmoid tumors or strictures that can be traversed with a radiologic guide wire, balloon dilatation can be performed and a self-expanding stent deployed.^{36,86-89} Clinical improvement and resolution of obstruction occur in more than 90% of patients within 96

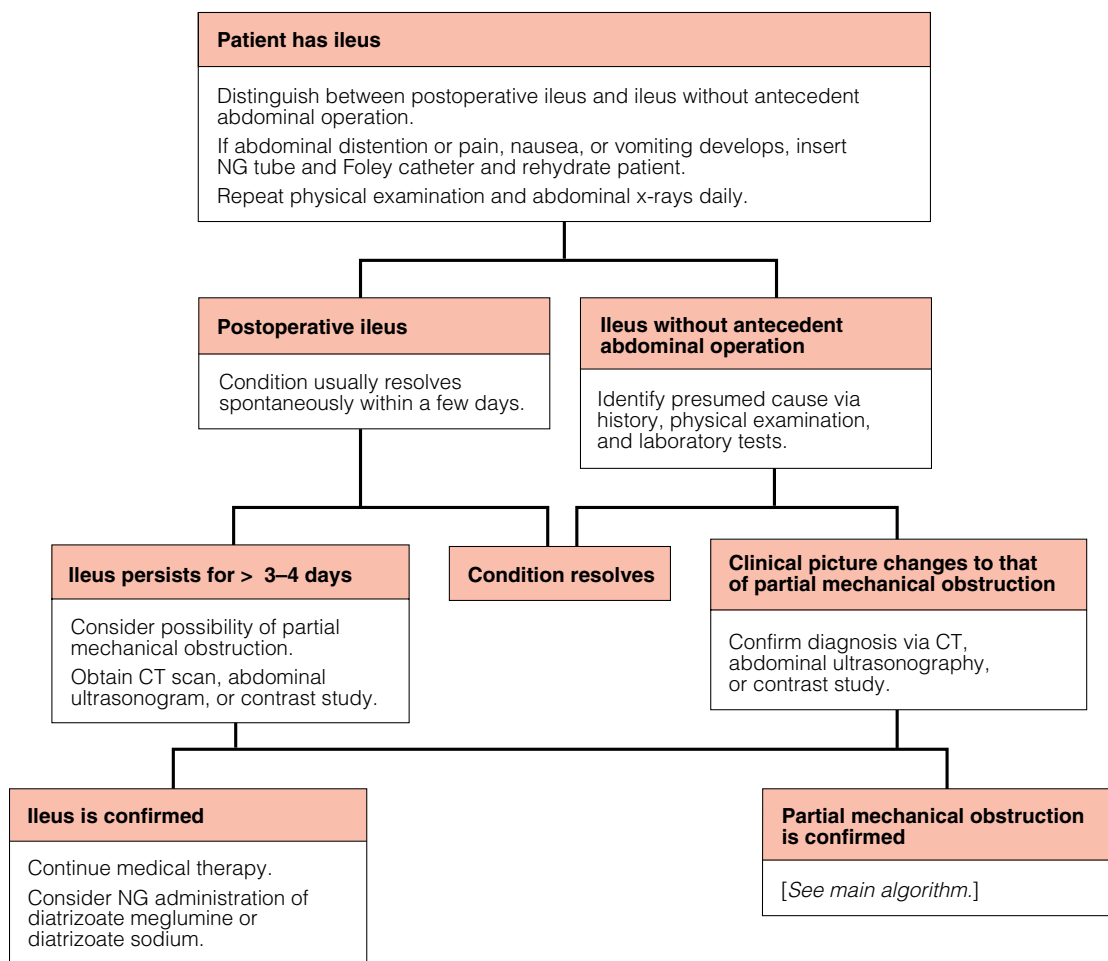

Figure 12 Shown is an algorithm outlining an approach to management of ileus.

hours.^{36,88} With restoration of the bowel lumen, patients can be prepared for elective surgery, can be spared the creation of a diverting colostomy, and can avoid the extra expense and morbidity associated with the performance of two operations.^{88,89} This approach is also highly successful as primary therapy for bowel obstruction in patients who are not surgical candidates.³⁶ In patients with large, fixed rectal masses, one should obtain CT scans of the pelvis to assess the extent of the tumor. Transrectal laser fulguration and endoluminal stenting are palliative options for restoring bowel lumen patency that may be considered for patients with nonresectable recurrent rectal cancer or radiation strictures in whom operative risk is prohibitively high.

Bowel Obstruction without Previous Abdominal Operation

When partial small bowel obstruction develops and resolves in a patient who has not previously undergone an abdominal operation, a diagnostic workup should be performed to identify the cause of the obstruction; there may be an underlying condition that is likely to cause recurrent obstruction (e.g., an internal hernia, a tumor, malrotation, or metastatic cancer). The first diagnostic test to be ordered should be a CT scan, followed by an upper GI barium study with follow-through views and a barium enema.⁹⁰ If a pathologic lesion is identified, elective operation is indicated. An argument can be made that no additional diagnostic tests should be performed in these patients and that diagnostic laparoscopy should be performed instead to enable laparoscopic surgery in case a cause of obstruction is identified that can be treated with

a minimally invasive procedure. If no cause of obstruction is found at laparoscopy, open laparotomy is performed.

Paraduodenal hernia Paraduodenal hernia, a congenital defect resulting from intestinal malrotation, is probably more common than was once thought. It accounts for approximately 50% of internal hernias. Patients with paraduodenal hernia may present with a catastrophic closed-loop obstruction; more often, however, they exhibit mild, nonspecific GI symptoms such as nausea, vomiting, esophageal reflux, and abdominal pain. Duodeno-gastric reflux and prominent bile gastritis in the absence of a previous operation or diabetic gastroparesis are indirect signs of a paraduodenal hernia. The diagnosis is established by means of either an upper GI contrast study with small bowel follow-through or CT scanning. When a paraduodenal hernia is identified, operative treatment is indicated. Such treatment is usually successful in alleviating symptoms and preventing strangulation obstruction.⁹¹

Nonmechanical Obstruction

ILEUS

Ileus, or intestinal paralysis, is most common after abdominal operations but can also occur in response

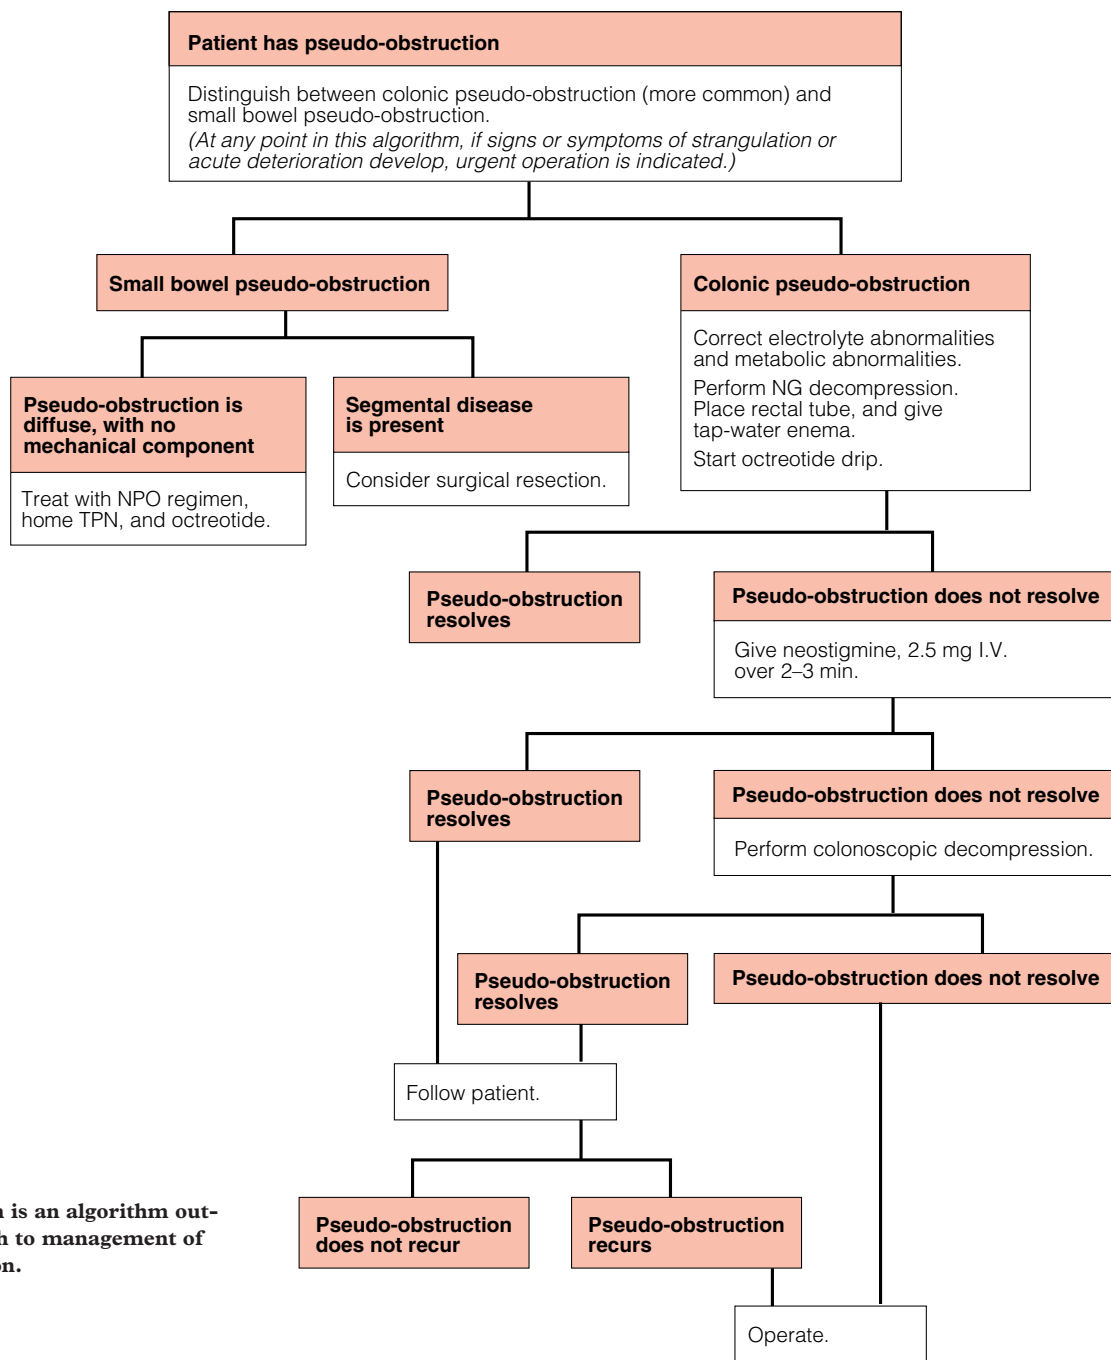

Figure 13 Shown is an algorithm outlining an approach to management of pseudo-obstruction.

to any acute medical condition or metabolic derangement [see Table 1]. The pathophysiologic mechanisms that cause ileus are incompletely understood but appear to involve disruption of normal neurohumoral responses.⁹² Ileus may be classified into two broad categories: postoperative ileus and ileus without antecedent abdominal operation. Postoperative ileus is manifested by atony of the stomach, the small intestine, and the colon and usually resolves spontaneously within a few days as normal bowel motility returns. Typically, the small bowel regains its motility within 24 hours of operation, followed 3 to 4 days later by the stomach and the colon. Initial therapy of ileus is directed at identifying and correcting the presumed cause [see Figure 12]. If the patient experiences abdominal distention, abdominal pain, nausea, or vomiting, then nasogastric decompression, placement of a Foley catheter,

and I.V. rehydration are indicated. In postoperative patients, it is best not to use strong narcotics for analgesia and instead to rely on epidural anesthesia and nonsteroidal anti-inflammatory drugs. When ileus develops in patients who have not recently undergone an operation, a thorough history, a careful physical examination, and well-chosen laboratory tests are necessary to identify the possible causes.

When ileus persists for what is, in one's best clinical judgment, an inordinate length of time for the operation performed (typically, longer than 3 to 4 days), the possibility of partial mechanical obstruction, possibly associated with an intra-abdominal abscess or another source of infection, must be considered. If an abscess is suspected, an abdominal CT scan should be obtained. Abdominal ultrasonography has been reported to distinguish postoperative

ileus from mechanical obstruction reliably.²² A small bowel contrast examination with barium identifies partial mechanical small bowel obstruction in about 75% of patients.^{26,28} CT scanning distinguishes ileus from obstruction in about 80% of patients.

Intragastric administration of a water-soluble contrast agent has shown great potential in the treatment of ileus.^{93,94} In one study, administration of 120 ml of diatrizoate meglumine or diatrizoate sodium via nasogastric tube to 40 adults with postoperative small bowel ileus led to restored intestinal motility within 6 hours in all 40, allowing them to resume oral alimentation within 24 hours.⁹³ Given these results, a prospective, randomized trial that addresses cost-management end points is warranted.

PSEUDO-OBSTRUCTION

Pseudo-obstruction [see *Figure 13*] can exist in the small bowel or the colon and can be either acute or chronic. Acute colonic pseudo-obstruction, also known as Ogilvie syndrome, is the most common form. Colonic pseudo-obstruction occurs most commonly in hospitalized patients in the postoperative period or in response to a nonsurgical acute illness (e.g., pneumonia, myocardial infarction, hypoxia, shock, intestinal ischemia, or electrolyte imbalance). The pathophysiologic mechanisms underlying idiopathic pseudo-obstruction appear to be related to an imbalance in the parasympathetic and sympathetic influences on colonic motility.

The presenting symptoms of acute colonic pseudo-obstruction are massive dilatation of the colon (with the cecum more dilated than the distal colon), crampy pain, nausea, and vomiting.⁹⁵ If peritoneal irritation or systemic toxicity is present, immediate laparotomy is indicated; if not, treatment involves nasogastric decompression, placement of a rectal tube, tap-water enemas, correction of any underlying metabolic disturbances, and avoidance of narcotic and anticholinergic medications. With conservative management, acute colonic pseudo-obstruction resolves within 4 days in more than 80% of cases.⁹⁶ Colonoscopy was previously the method of choice for decompression in this setting.⁹⁷ It has been shown, however, that I.V. administration of neostigmine, 2.5 mg over 2 to 3 minutes, leads to prompt resolution of acute colonic pseudo-obstruction within minutes in nearly all cases.^{98,99} Now that this previously difficult and potentially lethal problem can readily be treated pharmacologically, colonoscopic decompression and surgical intervention should be reserved for cases in which pharmacologic measures fail.

Chronic intestinal pseudo-obstruction is a rare acquired disorder that is caused by various diseases involving GI smooth muscle, the enteric nervous system, or the extrinsic autonomic nerve supply to the gut.¹⁰⁰ These disorders are treated with an NPO regimen, home TPN, and octreotide. Patients with chronic intestinal pseudo-obstruction should be followed closely for long periods and should undergo repeat contrast studies: a condition

occasionally develops that can cause mechanical obstruction and that may be surgically correctable.^{101,102}

Cost Considerations

Cost considerations are exerting an ever-growing influence on surgical care in general and on the decision whether to operate in particular. A large percentage of the high total cost of caring for patients with ileus or mechanical intestinal obstruction is accounted for by the cost associated with hospitalization or the need for laparotomy.

Strategies for reducing the overall cost of managing patients with bowel obstruction may take several forms: the development of diagnostic and therapeutic methods that lead to more rapid diagnosis and resolution of ileus and partial small bowel obstruction; the development of techniques for rapid identification of patients with complete or closed-loop obstruction and early reversible strangulation, which would permit earlier operative intervention and thereby reduce the incidence of complications; the development of therapeutic approaches that prevent postoperative ileus; and the development of methods for preventing intra-abdominal adhesions, which would significantly reduce the overall incidence of bowel obstruction. Two prospective, randomized clinical trials demonstrated that placement of a bioresorbable membrane composed of sodium hyaluronate and carboxymethylcellulose underneath abdominal fascial closures significantly reduced the severity and density of postoperative adhesions.^{103,104} In theory, use of such a product should reduce the incidence of adhesion-related bowel obstruction; however, longer-term studies are required to determine whether this will actually be the case.

From a management viewpoint, if a specific diagnostic test, medication, or approach (e.g., laparoscopy) costs less than a day of hospitalization does, it immediately becomes cost-effective if it reduces complications and shortens length of stay by 1 day. Intragastric administration of a water-soluble contrast agent to relieve small bowel ileus or partial adhesive obstruction is an example of an innovative, cost-effective therapeutic strategy. Diagnostic laparoscopy, abdominal ultrasonography, CT scanning, and fast MRI have all been successfully used to make earlier definitive management decisions and to prevent gangrenous obstruction. Laparoscopic adhesiolysis also leads to earlier hospital discharge. On the basis of the collective experience reported in a substantial number of studies (see above), a logical proposal for cost-effective management of patients with bowel obstruction would be to perform ultrasonography or abdominal CT scanning immediately after initial resuscitation, then to perform laparoscopic surgery on those patients in whom the contrast agent does not arrive in the right colon within 24 hours. However, prospective, randomized clinical trials are needed to evaluate the cost-effectiveness of this and other newer management strategies.

5 UPPER GASTROINTESTINAL BLEEDING

Kristi L. Harold, M.D., and Richard T. Schlinkert, M.D., F.A.C.S.

Assessment and Management of Upper Gastrointestinal Bleeding

The most common causes of upper gastrointestinal bleeding are chronic duodenal ulcers, chronic gastric ulcers, esophageal varices, gastric varices, Mallory-Weiss tears, acute hemorrhagic gastritis, and gastric neoplasms [see Management of Specific Sources of Upper GI Bleeding, *below*]. Less common causes include various other gastrointestinal conditions and certain hepatobiliary and pancreatic disorders.

Presentation and Initial Management

INITIAL ASSESSMENT AND MANAGEMENT

Upper gastrointestinal hemorrhage may present as severe bleeding with hematemesis, hematochezia, and hypotension; as gradual bleeding with melena; or as occult bleeding detected by positive tests for blood in the stool. The initial steps in the evaluation of patients with upper GI bleeding are based on the perceived rate of bleeding and the degree of hemodynamic stability. Hemodynamically stable patients who show no evidence of active bleeding or comorbidities and in whom endoscopic findings are favorable may be treated on an outpatient basis, whereas patients who show evidence of serious bleeding should be managed aggressively and hospitalized.

The airway, breathing, and circulation should be rapidly assessed, and the examiner should note whether the patient has a history of or currently exhibits hematemesis, melena, or hematochezia. Blood should be drawn for a complete blood count, blood chemistries (including tests of liver function and renal function), and measurement of the prothrombin time (PT) and the partial thromboplastin time (PTT). Blood should be sent to the blood bank for typing and crossmatching.

If the patient is stable and shows no evidence of recent or active hemorrhage, the surgeon may proceed with the workup.

If, however, the patient is stable but shows evidence of recent or active bleeding, a large-bore intravenous line should be placed before workup is begun; the presence of the line ensures immediate I.V. access should the patient subsequently become unstable.

If the patient is unstable, resuscitation should be begun immediately.

RESUSCITATION

Resuscitation of an unstable patient is begun by establishing a secure airway and ensuring adequate ventilation. Oxygen should be given as necessary, either by mask or by endotracheal tube and ventilator. A large-bore I.V. line should then be placed, through which lactated Ringer solution should be infused at a rate high enough to maintain tissue perfusion. A urinary catheter should be inserted and urine output monitored. Blood should be given as necessary, and any coagulopathies should be corrected if possible. It is all too easy to forget these basic steps in a desire to evaluate and manage massive GI hemorrhage.

If the patient remains unstable and continues to bleed despite supportive measures, he or she should be taken to the operating room for intraoperative diagnosis. The abdomen should be opened through an upper midline incision, and an anterior gastrotomy should be performed. If inspection does not reveal the source of the bleeding or if bleeding is observed beyond the pylorus, a duodenotomy is made, with care taken to preserve the pylorus if possible. Bleeding from the proximal stomach may be difficult to verify, but it should be actively sought if no other bleeding site is identified.

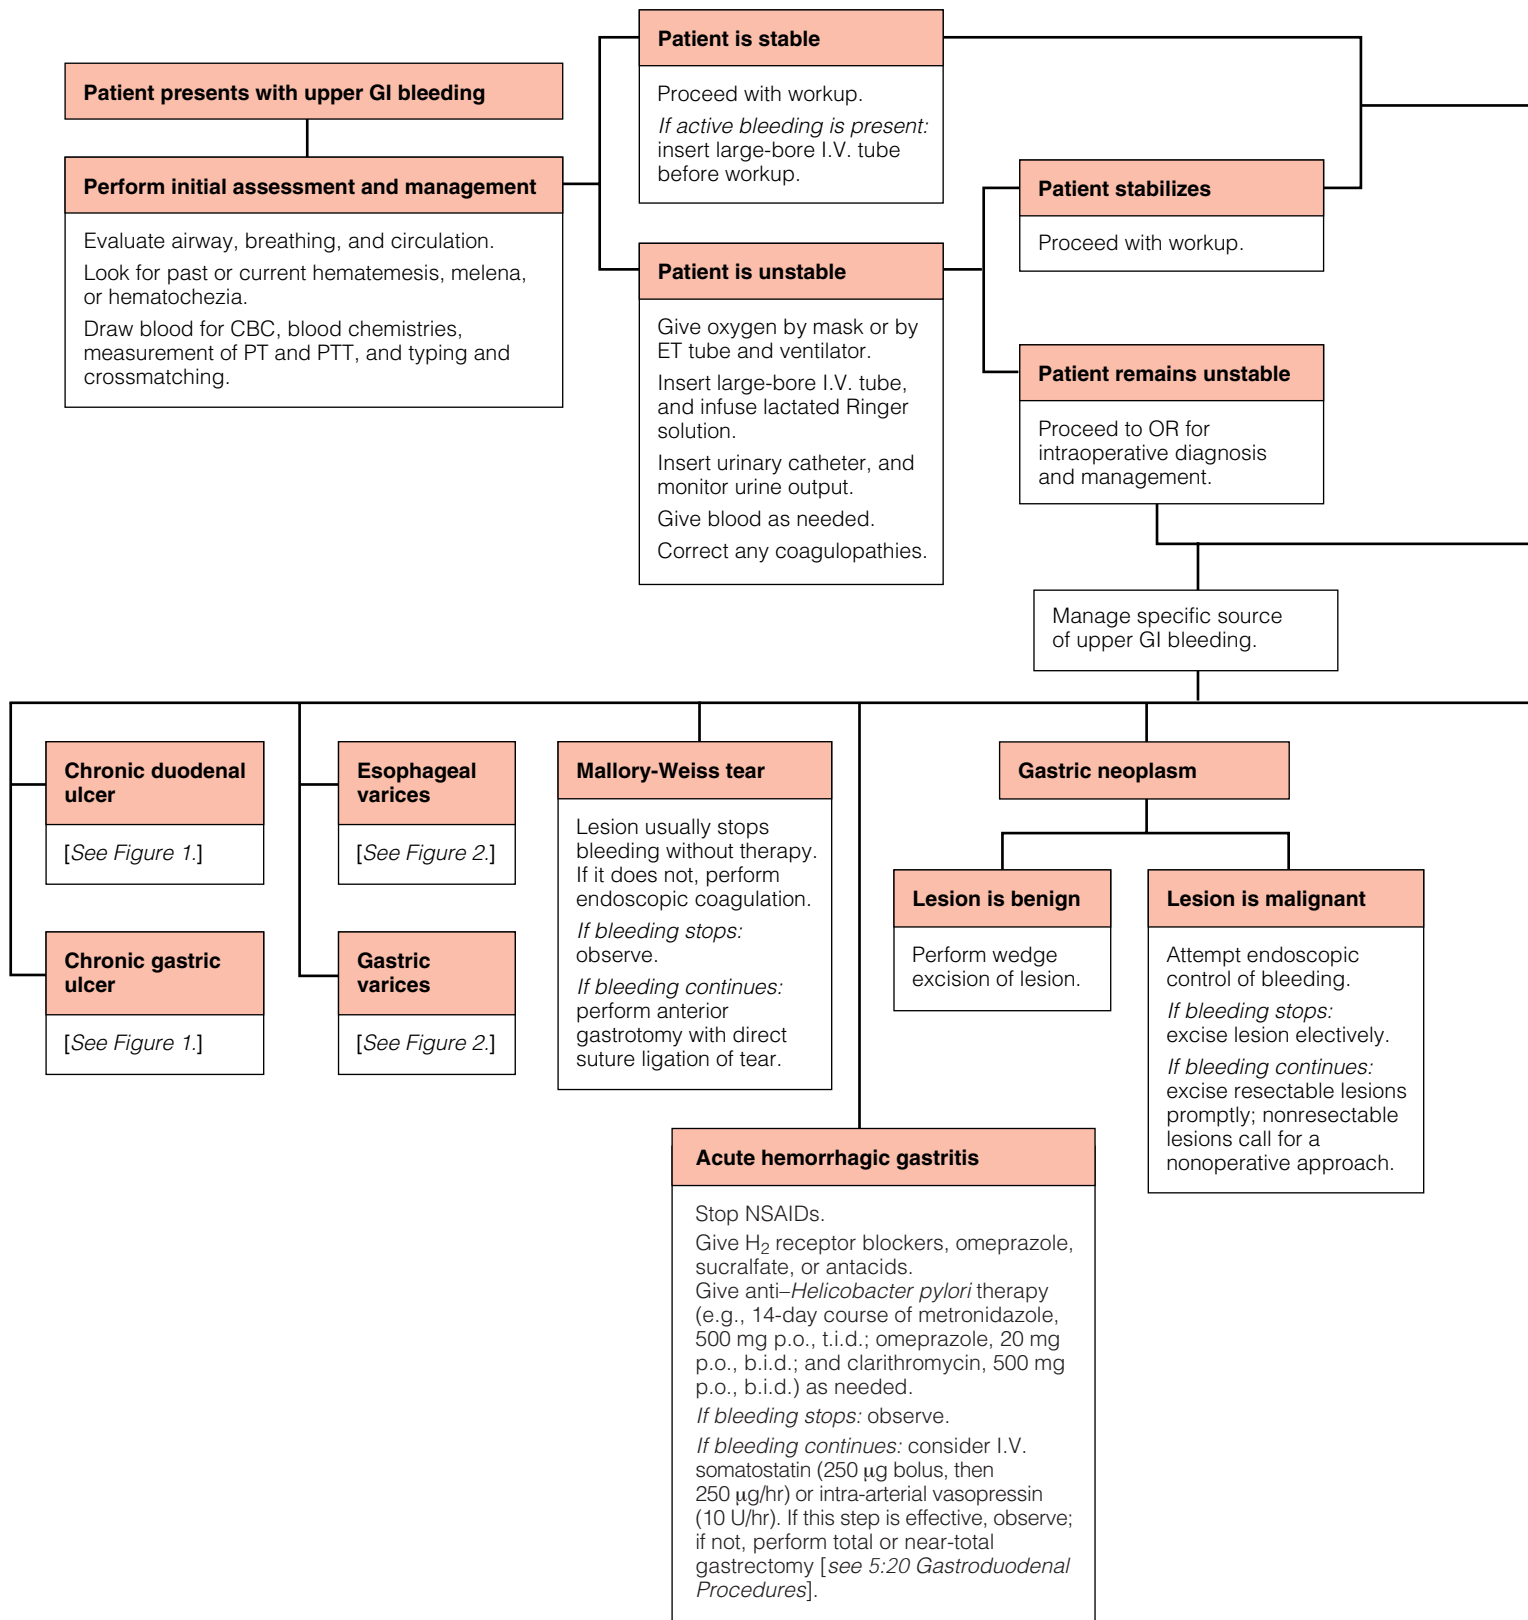

Clinical Evaluation

HISTORY

Only after the initial measures to protect the airway and stabilize the patient have been completed should an attempt be made to establish the cause of the bleeding. The history should focus on known causes of upper GI bleeding (e.g., ulcers, recent trauma or stress, liver disease, varices, alcoholism, and vomiting) and on the possible use of medications that interfere with coagulation (e.g., aspirin, nonsteroidal anti-inflammatory drugs [NSAIDs], and dipyridamole) or alter hemodynamics (e.g., beta blockers and antihypertensive agents). The cardiac history is particularly important for assessing the patient's ability to withstand varying degrees of anemia.

Assessment and Management of Upper Gastrointestinal Bleeding

Work up patient

Obtain history, focusing on known causes of upper GI bleeding and suspect medications.
 Perform physical examination.
 Perform NG aspiration.
 Perform esophagogastroduodenoscopy [see 5:18 *Gastrointestinal Endoscopy*].
 Use other tests as appropriate:

- tagged red cell scans
- arteriography
- roentgenography with BaSO₄
- video capsule endoscopy
- intraoperative endoscopic exploration

Dieulafoy lesion

Attempt endoscopic control of bleeding.
If bleeding stops: observe.
If bleeding continues: ligate or excise vessel.

Hemosuccus pancreaticus

Perform distal pancreatectomy [see 5:24 *Pancreatic Procedures*], including excision of pseudocyst and ligation of bleeding vessel.

Vascular ectases

Attempt endoscopic control of bleeding.
 Consider I.V. somatostatin (250 µg bolus, then 250 µg/hr).
If bleeding stops: observe.
If bleeding continues: resect lesion.

Jejunal ulcer

Manage underlying causes if known (e.g., medications, infections, or gastrinomas).
If bleeding stops: observe.
If bleeding continues: excise bleeding segment of jejunum.

Esophageal hiatal hernia

Hemobilia

Perform arteriographic embolization of affected portion of liver.
 Other options are hepatic artery ligation and hepatic resection.

Aortoenteric fistula

Resect aortic graft.
 Close enteric site of fistula.
 Place extra-anatomic or in situ arterial graft.

Duodenal or jejunal diverticula

Excise lesion, with or without the aid of intraoperative endoscopy.

Paraesophageal hernia

Repair surgically (either via open laparotomy or via minimally invasive approach) [see 4:4 *Open Esophageal Procedures* and 4:5 *Minimally Invasive Esophageal Procedures*].

Sliding hernia

Give PPI and, if applicable, anti-*H. pylori* therapy (e.g., 14-day course of metronidazole, 500 mg p.o., t.i.d.; omeprazole, 20 mg p.o., b.i.d.; and clarithromycin, 500 mg p.o., b.i.d.).
If bleeding stops: continue medical therapy.
If bleeding continues: perform Nissen fundoplication [see 4:4 *Open Esophageal Procedures* and 4:5 *Minimally Invasive Esophageal Procedures*].

PHYSICAL EXAMINATION

The physical examination is seldom of much help in determining the exact site of bleeding, but it may reveal jaundice, ascites, or other signs of hepatic disease; a tumor mass; or a bruit from an abdominal vascular lesion.

NASOGASTRIC ASPIRATION

The next step is nasogastric aspiration. A bloody aspirate is an indication for esophagogastroduodenoscopy (EGD), as is a clear, nonbilious aspirate if a bleeding site distal to the pylorus has not been excluded. If the aspirate is clear and bile-stained, the source of the bleeding is unlikely to be the stomach, the duodenum, the liver, the biliary tree, or the pancreas. Nonetheless, if subsequent evaluation of the lower GI tract for the source of the bleeding is unrewarding, an upper GI site that had stopped bleeding when the nasogastric tube was passed or that was distal to the ligament of Treitz should still be considered.

Investigative Tests

UPPER GI ENDOSCOPY (ESOPHAGOGASTRODUODENOSCOPY)

EGD [see 5:18 *Gastrointestinal Endoscopy*] almost always reveals the source of upper GI bleeding; its utility and accuracy have been well documented in the literature. This procedure requires considerable skill: identification of bleeding sites in a blood-filled stomach is far from easy. Hematemesis is an indication for emergency EGD, usually within 1 hour of presentation. If the rate of bleeding is high, saline lavage may be performed to clear the stomach of blood and clots. If the rate of bleeding is moderate or low, as is often the case in patients with melena, urgent EGD is indicated.

EGD is not only an excellent diagnostic tool but also a valuable therapeutic modality. Indeed, most upper GI hemorrhages may be controlled endoscopically, though the degree of success to be expected in individual cases varies according to the expertise of the endoscopist and the specific cause of the bleeding. Therapeutic endoscopic maneuvers include injection, thermal coagulation, and mechanical occlusion of bleeding sites (by means of clip application or variceal banding). The choice of therapy depends on the cause, the site, and the rate of bleeding.

OTHER TESTS

If endoscopic examination reveals no lesions in the stomach or the duodenum and bleeding has ceased, enteroclysis (direct introduction of BaSO₄ into the small bowel) and roentgenography of the duodenum and the jejunum should be done next. This is probably a more sensitive radiologic test than a standard small bowel roentgenogram. Nonetheless, the absence of a lesion on this test does not rule out the small bowel as the source of the hemorrhage; not uncommonly, the x-ray is negative when a bleeding small bowel lesion is present.

Tagged red cell scans may confirm the presence of an active bleeding site; however, scans are fairly nonspecific with respect to determining the anatomic location of the bleeding. Arteriography may demonstrate that a lesion is present, but it cannot reliably identify a bleeding site unless the bleeding is brisk (> 1 ml/min). Occasionally, arteriography reveals the cause of the bleeding even if the bleeding has stopped. Recurrent bleeding or bleeding that is suspected to be secondary to small bowel pathology may be evaluated by means of video capsule endoscopy, which is capable of localizing a variety of lesions (including arteriovenous malformations, ulcers, strictures, and malignancies) so as to direct surgical

intervention. Video capsule endoscopy should be used with caution in patients exhibiting obstructive symptoms: if the capsule becomes trapped, complete obstruction may result.

Intraoperative endoscopic exploration may also prove useful in this situation. Before the small bowel is manipulated, a pediatric colonoscope is introduced either orally or through a distal jejunal enterotomy; the latter method allows easier viewing of the entire small bowel. The mucosal detail is examined as the surgeon guides the scope through the small bowel. The bowel must be handled gently to avoid a mucosal injury, which could mimic a significant lesion.

These tests, in conjunction with EGD, should allow the surgeon to establish the cause of upper GI bleeding at least 90% of the time.

Management of Specific Sources of Upper GI Bleeding

CHRONIC DUODENAL ULCER

The development of effective medical regimens

for controlling uncomplicated duodenal ulcers has led to a drastic reduction in the number of elective surgical procedures performed for this purpose. Nevertheless, the incidence of bleeding from duodenal ulcers that is severe enough to necessitate emergency endoscopic or operative intervention has not decreased over the past decade.

Once EGD has demonstrated that a duodenal ulcer is the source of the bleeding, the first question that must be addressed is whether active bleeding is present. If it is, an attempt should be made to control the hemorrhage endoscopically [see Figure 1]. Because ongoing blood loss eventually leads to coagulopathies, the surgeon must exercise good judgment in deciding how long to pursue endoscopic treatment before concluding that such treatment has failed and that surgical treatment is necessary. In general, substantial bleeding (four to six units or more) that is not easily controlled endoscopically is an indication for immediate surgical intervention. Likewise, ongoing hemorrhage in a hemodynamically unstable patient (especially an elderly one) calls for immediate surgical therapy.

If bleeding is controlled endoscopically, then a proton pump inhibitor (PPI)—such as pantoprazole, 40 mg/day—should be given intravenously. In addition, antibiotic therapy directed against *Helicobacter pylori* (e.g., a 14-day course of metronidazole, 500 mg p.o., t.i.d.; omeprazole, 20 mg p.o., b.i.d.; and clarithromycin, 500 mg p.o., b.i.d.) should be considered if the organism is present; such therapy has been shown to decrease rebleeding rates after antacid medication has been stopped. Food need not be withheld unless the likelihood of rebleeding is high, in which case operation or repeat endoscopy would be necessary. Resumption of oral feeding does not appear to affect rebleeding rates.

If bleeding continues despite medical and endoscopic therapy, it should be managed surgically. In addition, certain patients whose bleeding was controlled endoscopically—such as those with a visible gastroduodenal artery and a clot in the base of the ulcer, those who experience rebleeding despite medical and endoscopic therapy, and those with giant ulcers—should be strongly considered for surgical therapy.

Surgical management may be accomplished either laparoscopically or via an open approach. The latter [see 5:20 *Gastroduodenal Procedures*] begins with an upper midline incision. The duodenum is mobilized and an anterior longitudinal duodenotomy performed

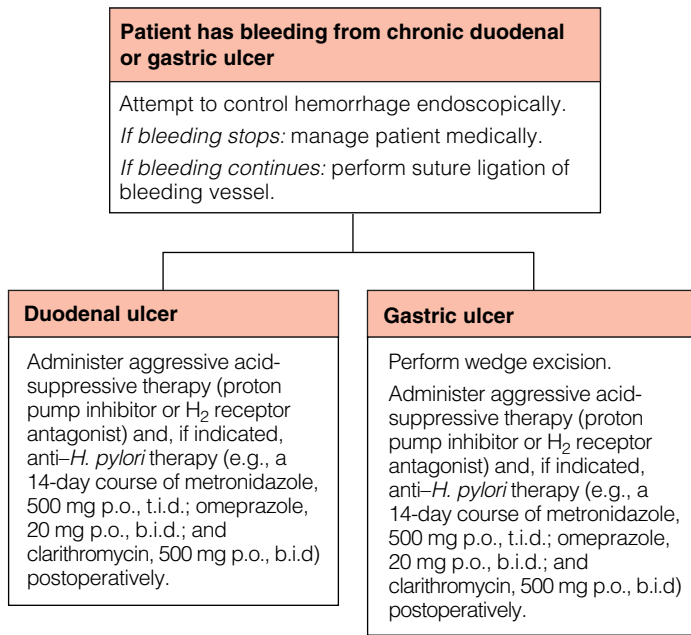

Figure 1 Shown is an algorithm for management of bleeding from chronic duodenal or gastric ulcers.

over the site of the ulcer. The bleeding vessel, which is usually on the posterior wall of the first portion of the duodenum, is ligated with nonabsorbable sutures at sites proximal and distal to the bleeding point. A third stitch is placed posterior to the bleeding vessel. Pains must be taken to avoid injury to the common bile duct during the placement of these sutures. The duodenotomy is then closed.

The role of vagotomy in the management of bleeding duodenal ulcers has been called into question. Previously, proximal gastric vagotomy was recommended for stable patients. It was considered preferable to truncal vagotomy because it is less likely to result in gastric atony, alkaline reflux gastritis, dumping, and diarrhea. In unstable patients, truncal vagotomy was typically performed in conjunction with pyloroplasty [see 5:20 *Gastroduodenal Procedures*]. Frozen section to confirm the presence of nerve tissue is helpful for ensuring that the vagotomy is complete.

The recommendation for truncal vagotomy was based on data from studies done before PPI and anti-*H. pylori* therapy came into use. Subsequent studies that evaluated rebleeding rates with current medical regimens, however, demonstrated much lower rebleeding rates. Furthermore, it seems probable that long-term PPI therapy (e.g., omeprazole, 20 mg p.o., q.d.)—the medical equivalent of vagotomy—in conjunction with eradication of *H. pylori* and avoidance of NSAIDs, should decrease rebleeding rates significantly. Therefore, one may consider an alternative treatment approach in patients who had not been receiving ulcer therapy before the bleeding began—namely, ligation of the bleeding vessel, postoperative administration of PPIs, and anti-*H. pylori* therapy. This approach avoids the complications associated with truncal vagotomy.

CHRONIC GASTRIC ULCER

Initially, bleeding from a chronic gastric ulcer is managed in much the same way as that from a chronic duodenal ulcer (i.e., endoscopically) [see Figure 1]. To prevent aggravation of the bleeding, early biopsy generally is not recommended; repeat endoscopy and biopsy are done at a later date. Emergency surgical indications for gastric ulcers are the same as those for duodenal ulcers. In

addition, if a gastric ulcer does not resolve after 6 weeks of medical therapy, surgical excision is often indicated.

In stable patients, surgical management of a nonhealing chronic gastric ulcer generally consists of a hemigastrectomy that includes the ulcer site; if the ulcer is located more proximally, it may be removed by means of wedge excision [see 5:20 *Gastroduodenal Procedures*]. Excision of the ulcer should be immediately followed by frozen section to rule out cancer. There is no need for a vagotomy in these instances. In unstable patients, hemigastrectomy should probably be avoided because of the increased morbidity and mortality that can follow it. Wedge excision should be combined with aggressive acid-suppressive therapy (PPIs or H₂ receptor antagonists), followed by anti-*H. pylori* treatment. Truncal vagotomy with pyloroplasty is rarely indicated; however, it may be considered in a patient with previous complications from ulcer disease.

ESOPHAGEAL VARICES

The value of endoscopy in the diagnosis and management of variceal bleeding cannot be overemphasized. Even in patients with known varices, the site of bleeding is frequently non-

variceal; endoscopy is therefore essential. If bleeding varices are identified, rubber banding or intravariceal sclerotherapy with a sclerosing agent (1.5% sodium tetradecyl sulfate, ethanolamine, sodium morrhuate, or absolute alcohol) is performed [see Figure 2]. If these measures do not control the hemorrhage, balloon tamponade is indicated. Patients who are to undergo this procedure should have an endotracheal tube in place. The tube we prefer to use for balloon tamponade is the four-port Minnesota tube, although the Sengstaken-Blakemore tube is also acceptable. The Minnesota tube has a gastric balloon, an esophageal balloon, and aspiration ports for the esophagus and the stomach. The gastric balloon is inflated first and placed on traction. If the bleeding is not controlled, the esophageal balloon is then inflated. The pressure in the balloons should be released in 24 to 48 hours to prevent necrosis of the esophageal or the gastric wall. Successful balloon tamponade is followed by endoscopic variceal injection or variceal banding.

I.V. somatostatin (250 µg bolus, followed by infusion of 250 µg/hr) should be administered in conjunction with the above-mentioned steps. Vasopressin (10 U/hr) may also be given; however, it causes diffuse vasoconstriction, and nitroglycerin is required to alleviate cardiac side effects. Somatostatin has proved superior to placebo in controlling variceal hemorrhage when used in conjunction with endoscopic sclerotherapy. It is as effective as vasopressin while giving rise to fewer side effects. Octreotide, a synthetic analogue of somatostatin, shares many of the properties of somatostatin but perhaps not all. Both agents decrease secretion of gastric acid and pepsin; to date, however, the decreased gastric blood flow observed with somatostatin administration has not been reported with octreotide administration. Nevertheless, some clinicians in the United States elect to use octreotide (25 to 50 µg/hr) in place of I.V. somatostatin because the former tends to be more widely available in the United States. Multiple prospective, randomized trials showed that propranolol (40 mg b.i.d., p.o.) decreased the incidence of first-time variceal bleeding as well as the incidence of recurrent variceal bleeding. Propranolol should not be used during active bleeding but should be started once bleeding stops.

After the acute variceal bleeding has been controlled, any remaining varices should be subjected to injection sclerotherapy or banding at 2-week intervals until they too are obliterated.

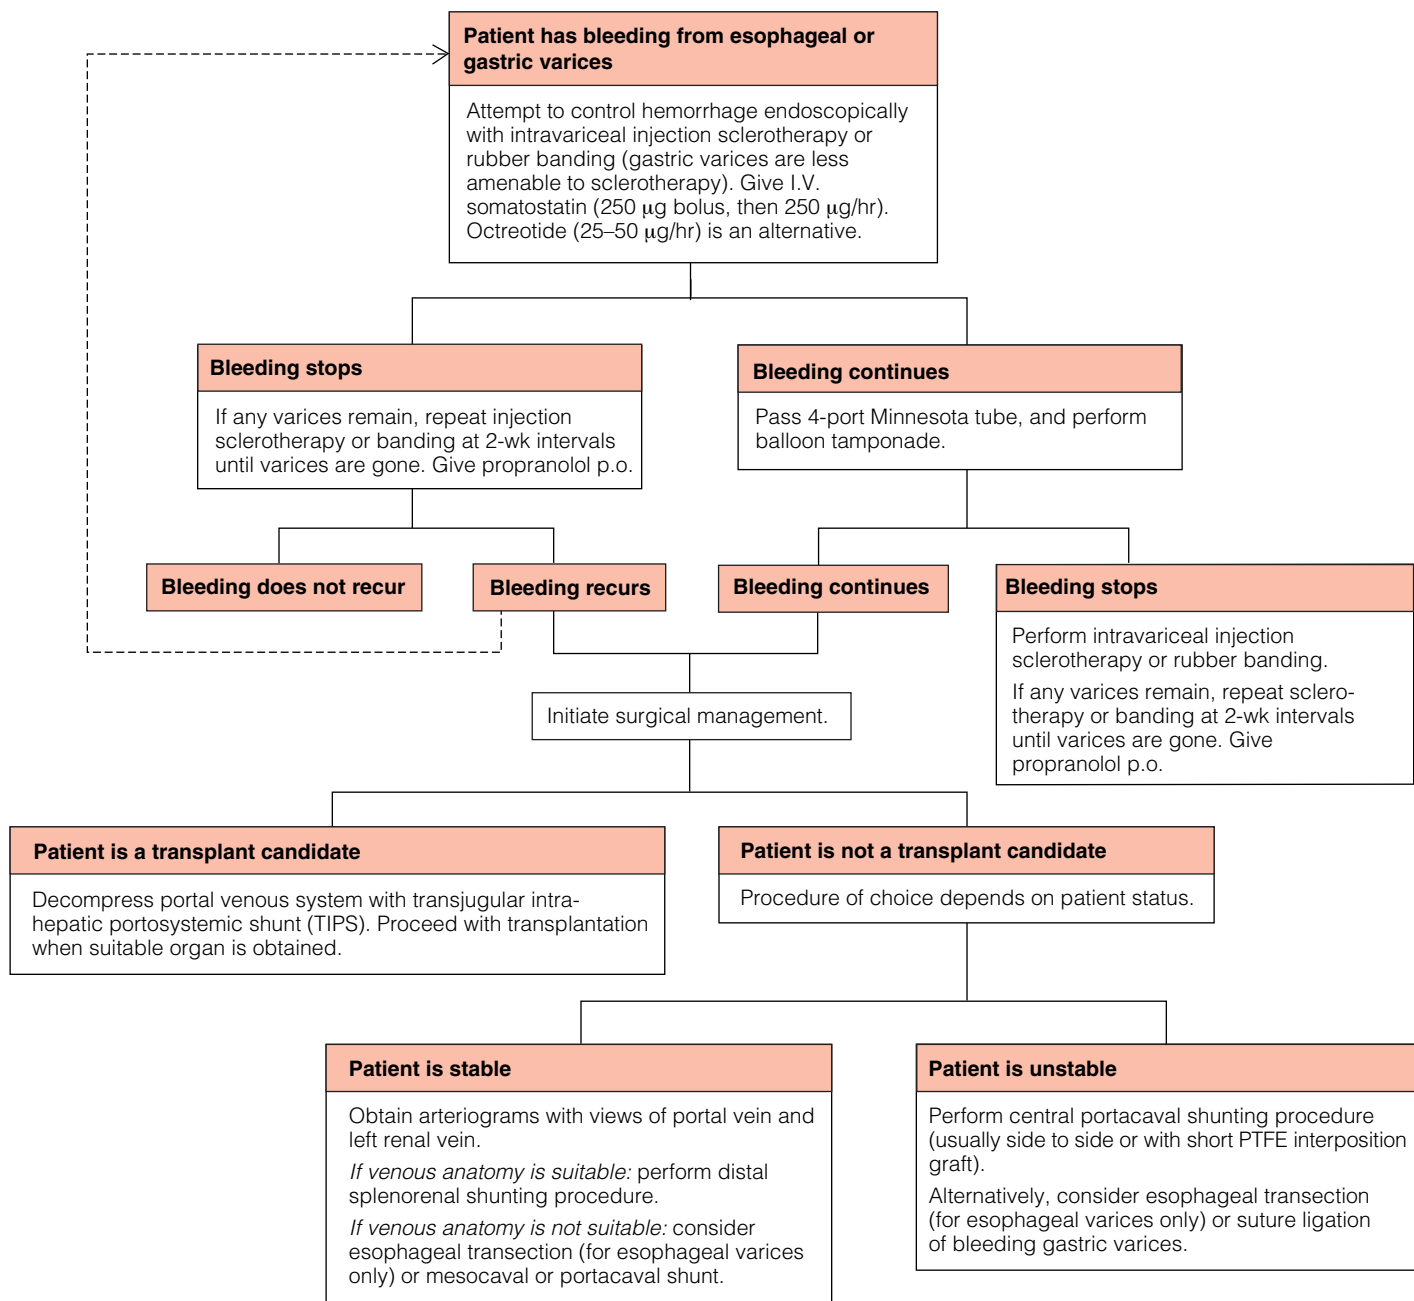

Figure 2 Shown is an algorithm for management of bleeding from esophageal or gastric varices.

The main indications for surgical intervention in patients with bleeding esophageal varices are uncontrolled hemorrhage and persistent rebleeding despite endoscopic and medical therapy. When surgical intervention is planned, it is essential to determine whether the patient is a transplant candidate. If so, operation should be avoided and bleeding managed by decompressing the portal venous system with a transjugular intrahepatic portosystemic shunt (TIPS). TIPS yields excellent short-term results with respect to stopping bleeding and providing time to locate a liver suitable for transplantation; however, it has not been shown to have the capacity to control hemorrhage by itself over the long term. Thus, its use in patients who are not transplant candidates is questionable.

If the patient is not a transplant candidate and is not actively bleeding, a distal splenorenal shunt is preferable. Arteriograms with views of the portal vein and the left renal vein are obtained. Alternatively, computed tomographic angiography with three-

dimensional reconstruction may be performed. If the venous anatomy is suitable—that is, if the diameter of the splenic vein is greater than 0.75 cm (preferably greater than 1.0 cm) and the vein is within one vertebral body of the renal vein on venography—a distal splenorenal shunting procedure should be feasible. If the venous anatomy is not suitable, then esophageal transection, a mesocaval venous graft, or a portacaval shunt is required.

In the emergency setting, we prefer a central portacaval shunt, usually in a side-to-side orientation or with a short polytetrafluoroethylene (PTFE) interposition graft. Esophageal transection is also a reasonable choice. This procedure is associated with a lower incidence of encephalopathy than a portacaval shunting procedure; however, it is associated with higher rates of rebleeding (particularly late rebleeding), and it can be difficult to perform when active bleeding is present. Suture ligation of the bleeding varices with devascularization (the Segura procedure) should also be considered.

In general, prognosis is related to the underlying liver disease. For example, patients with varices that are secondary to chronic extrahepatic portal venous or splenic venous occlusion generally have a much better prognosis than those whose portal hypertension is secondary to hepatic parenchymal causes. The severity of the cirrhosis also determines short-term and long-term survival and may influence the decision whether to perform a shunting procedure.

Varices in children are generally secondary to portal vein thrombosis. A conservative, nonoperative approach is preferred. If operation is required, either a portacaval shunt, a distal splenorenal shunt, or a devascularization procedure is performed. In children or adults with varices that are secondary to splenic vein thrombosis (sinistral portal hypertension), a splenectomy is usually curative; the procedure may be performed laparoscopically [see 5:25 *Splenectomy*].

GASTRIC VARICES

Gastric varices are managed in much the same way as esophageal varices [see Figure 2], though they are less amenable to sclerotherapy. If sclerotherapy fails to control bleeding from gastric varices, surgical intervention—in the form of distal splenorenal shunting, portosystemic shunting, or suture ligation with gastric devascularization—is indicated. If the patient is a suitable candidate, liver transplantation may be performed as an alternative to shunting.

MALLORY-WEISS TEARS

Mallory-Weiss tears are linear tears at the esophagogastric junction that are usually caused by vomiting. Any patient who presents with vomiting that initially is not bloody but later turns so should be suspected of having a Mallory-Weiss tear. As a rule, these lesions stop bleeding without therapy. If bleeding is substantial or persistent, however, endoscopic coagulation may be necessary. In rare instances, the tear will have to be oversewn at operation. This is accomplished via an anterior gastrotomy and direct suture ligation of the tear.

ACUTE HEMORRHAGIC GASTRITIS

Bleeding from gastritis is virtually always managed medically with H₂ receptor blockers, PPIs, sucralfate, or antacids (either alone or in combination), along with antibiotics if *H. pylori* is present. Somatostatin may be beneficial. Sometimes, administration of vasopressin via the left gastric artery is needed to control bleeding. In rare cases, total or near-total gastrectomy [see 5:20 *Gastrointestinal Procedures*] is required; however, the mortality associated with this operation in this setting is high. Stress ulcer prophylaxis in severely ill or traumatized patients is essential to prevent this problem. The gastric pH should be kept as close to neutral as possible. If the gastritis is relatively mild, a biopsy specimen should be obtained and tested for *H. pylori*. Treatment consists of acid reduction and anti-*H. pylori* therapy.

NEOPLASMS

Benign tumors of the upper GI tract (e.g., leiomyomas, hamartomas, and hemangiomas) bleed at times. Wedge excision of the offending lesion is the procedure of choice. Gastrointestinal stro-

mal tumors run the gamut from benign to highly aggressive. They typically present as a submucosal mass that may cause bleeding as a result of mucosal ulceration. The bleeding may be treated with wedge excision of the tumor. Such excision can often be accomplished laparoscopically [see 5:20 *Gastrointestinal Procedures*].

Bleeding from malignant neoplasms, whether early stage or late stage, generally can be controlled initially by endoscopic means; however, rebleeding rates are high. If the lesion is resectable, it should be excised promptly once the patient is stable and any coagulopathies have been corrected. If disease is advanced, however, surgical options are limited, and a nonoperative approach, though necessarily imperfect, is preferable.

ESOPHAGEAL HIATAL HERNIA

Not infrequently, the source of chronic enteric blood loss is an esophageal hiatal hernia. Major bleeding is rare in this condition but may occur as a result of linear erosions at the level of the diaphragm (Cameron lesions), gastritis within the hernia, or torsion of a paraesophageal hernia. Endoscopy is generally diagnostic, though the sources of chronic blood loss are not always obvious. Recognition that the bleeding derives from a Cameron lesion should incline the surgeon toward operative intervention [see 4:4 *Open Esophageal Procedures* and 4:5 *Minimally Invasive Esophageal Procedures*]: this lesion is usually mechanically induced and therefore tends to be less responsive to antacid therapy.

Chronic bleeding from a sliding esophageal hiatal hernia should be treated initially with a PPI; anti-*H. pylori* therapy should be added if biopsy shows this organism to be present. Operation (i.e., laparoscopic Nissen fundoplication [see 4:5 *Minimally Invasive Esophageal Procedures*]) should be considered for fit patients who have complications associated with their hiatal hernia. A paraesophageal hernia should be repaired surgically; we prefer the laparoscopic approach when feasible.

DIEULAFOY LESION

A Dieulafoy lesion (also referred to as exulceratio simplex) is the rupturing of a 1 to 3 mm bleeding vessel through the gastric mucosa (usually in the proximal stomach) without surrounding ulceration. This lesion tends to be found high on the lesser curvature, but it can also occur in other locations. Histologic studies have not revealed any intrinsic abnormalities either of the mucosa or of the vessel.

Initial treatment consists of either coagulation of the bleeding vessel with a heater probe or mechanical control with clips or rubber bands; local injection of epinephrine may help control acute hemorrhage while this is being done. In skilled hands, endoscopic therapy has a 95% success rate, and long-term control is excellent. If endoscopic therapy fails, surgical options, including ligation or excision of the vessel involved, come into play. Arteriographic embolization may be employed in patients who are too ill to tolerate surgical intervention.

HEMOBILIA

Hemobilia should be suspected in all patients who present with the classic triad of epigastric and right upper quadrant pain, GI bleeding, and jaundice; however, only about 40% of patients with hemobilia present with the entire triad. Endoscopy demonstrating blood coming from the ampulla of Vater points to a source in the biliary tree or the pancreas (hemosuccus pancreaticus).

Arteriography may provide the definitive diagnosis: a bleeding tumor, a ruptured artery from trauma, or another cause. Arteriographic embolization of the affected portion of the liver is the preferred treatment option; hepatic artery ligation (selective if possible) or hepatic resection [see 5:23 *Hepatic Resection*] may be required.

HEMOSUCCUS PANCREATICUS

Bleeding into the pancreatic duct, generally from erosion of a pancreatic pseudocyst into the splenic artery, is signaled by upper abdominal pain followed by hematochezia. If endoscopy is performed when hematochezia is present, the bleeding site may not be seen; however, if endoscopy is performed when pain is first noted, blood may be seen coming from the ampulla of Vater. The combination of significant GI bleeding, abdominal pain, a history of alcohol abuse or pancreatitis, and hyperamylasemia should suggest the diagnosis. Angiography can be diagnostic and, at times, therapeutic. Distal pancreatectomy [see 5:24 *Pancreatic Procedures*], including excision of the pseudocyst and ligation of the splenic artery, is the preferred treatment and generally leads to cure.

AORTOENTERIC FISTULA

Aortoenteric fistulas may occur spontaneously as a result of rupture of an aortic aneurysm or perforation of a duodenal lesion; more often, they arise after aortic surgery. A common initial manifestation of an aortoenteric fistula is a small herald bleed that is followed a few days later by a massive hemorrhage. Patients often present with the triad of GI hemorrhage, a pulsatile mass, and infection; however, not all of these symptoms are invariably present. A high index of suspicion facilitates diagnosis. Endoscopy may show an aortic graft eroding into the enteric lumen, but this

is an uncommon finding. CT scanning is the procedure of choice for diagnosis. The finding of air around the aorta or the aortic graft is diagnostic and is an indication for emergency exploration. The preferred surgical treatment is resection of the graft with extra-abdominal bypass. Some authorities, however, advocate resection of the graft with in situ graft replacement.

VASCULAR ECTASES

Vascular ectases (also referred to as vascular dysplasia, angiodysplasia, angiomas, telangiectasia, and arteriovenous malformations) may bleed briskly. As a rule, gastric lesions are readily identified and the bleeding controlled by endoscopic means. Lesions that continue to bleed, either acutely or chronically, despite endoscopic measures should be excised. Some patients have multiple and extensive lesions that necessitate resection of large portions of the stomach or the small intestine. Pharmacotherapy and hormone therapy have been tried; the results have been mixed.

DUODENAL AND JEJUNAL DIVERTICULA

Duodenal and jejunal diverticula are rare causes of upper GI bleeding. Accurate identification of a bleeding site within a given diverticulum is difficult, but an attempt should be made to accomplish this by means of peroral enteroscopy or video capsule endoscopy. Excision is the preferred treatment and is accomplished by means of segmental resection. Great care must be taken in the treatment of duodenal diverticula in the region of the ampulla of Vater to ensure that the pancreatic duct and the bile ducts are not injured during excision.

JEJUNAL ULCER

Ulcerations of the jejunum are also rare. They may be secondary to medications (e.g., NSAIDs), infection, a gastrinoma, or idiopathic causes. Offending medications should be stopped, infections should be treated, and gastrinomas should be excised. If these measures do not control the hemorrhage, the bleeding segment of the jejunum should be excised.

6 LOWER GASTROINTESTINAL BLEEDING

Michael J. Rosen, M.D., and Jeffrey L. Ponsky, M.D., F.A.C.S.

Approach to Lower GI Bleeding

Lower gastrointestinal bleeding is defined as abnormal hemorrhage into the lumen of the bowel from a source distal to the ligation of Treitz. In the majority of cases, lower GI bleeding derives from the colon; however, the small bowel is identified as the source of bleeding in as many as one third of cases,^{1,2} and the upper GI tract is identified as the source in as many as 11% of patients presenting with bright-red blood per rectum.³

Lower GI bleeding is more common in men than in women. The incidence rises steeply with advancing age, exhibiting a greater than 200-fold increase from the third decade of life to the ninth. This increase is largely attributable to the various colonic disorders commonly associated with aging (e.g., diverticulosis and angiodysplasia).⁴⁻⁶ The exact incidence of lower GI bleeding is not known, because there is no standardized technique for localizing it. Several investigators, however, estimate the incidence to be in the range of 20 to 27 cases per 100,000 adults.^{4,7} A 1997 survey of GI bleeding from the American College of Gastroenterology found that lower GI hemorrhage accounted for 24% of all GI bleeding events.⁸ Another study published the same year found that 0.7% of 17,941 discharges from a Veterans Affairs hospital were for patients who had had lower GI bleeding.⁹

The basic components of management are (1) initial hemodynamic stabilization, (2) localization of the bleeding site, and (3) site-specific therapeutic intervention. There are many conditions that can cause lower GI hemorrhage [see Discussion, Etiology of Lower GI Bleeding, *below*]; accordingly, successful localization depends on timely and appropriate use of a variety of diagnostic tests. Despite the abundance of diagnostic modalities available, attempts to localize the source of the hemorrhage fail in as many as 8% to 12% of patients.^{10,11} Once the bleeding site is localized, the appropriate therapeutic intervention must be carried out as expeditiously as possible.

Lower GI bleeding can be acute and life-threatening, chronic, or even occult. In what follows, we focus on severe, life-threatening hematochezia, reviewing the wide array of possible causes of lower GI bleeding and outlining the diagnostic and therapeutic modalities available for treating this difficult clinical problem.

Initial Evaluation and Resuscitation

Initial evaluation of a patient with lower GI bleeding should include a focused history and physical examination, to be carried out simultaneously with resuscitation. Of particular importance in taking the history is to ascertain

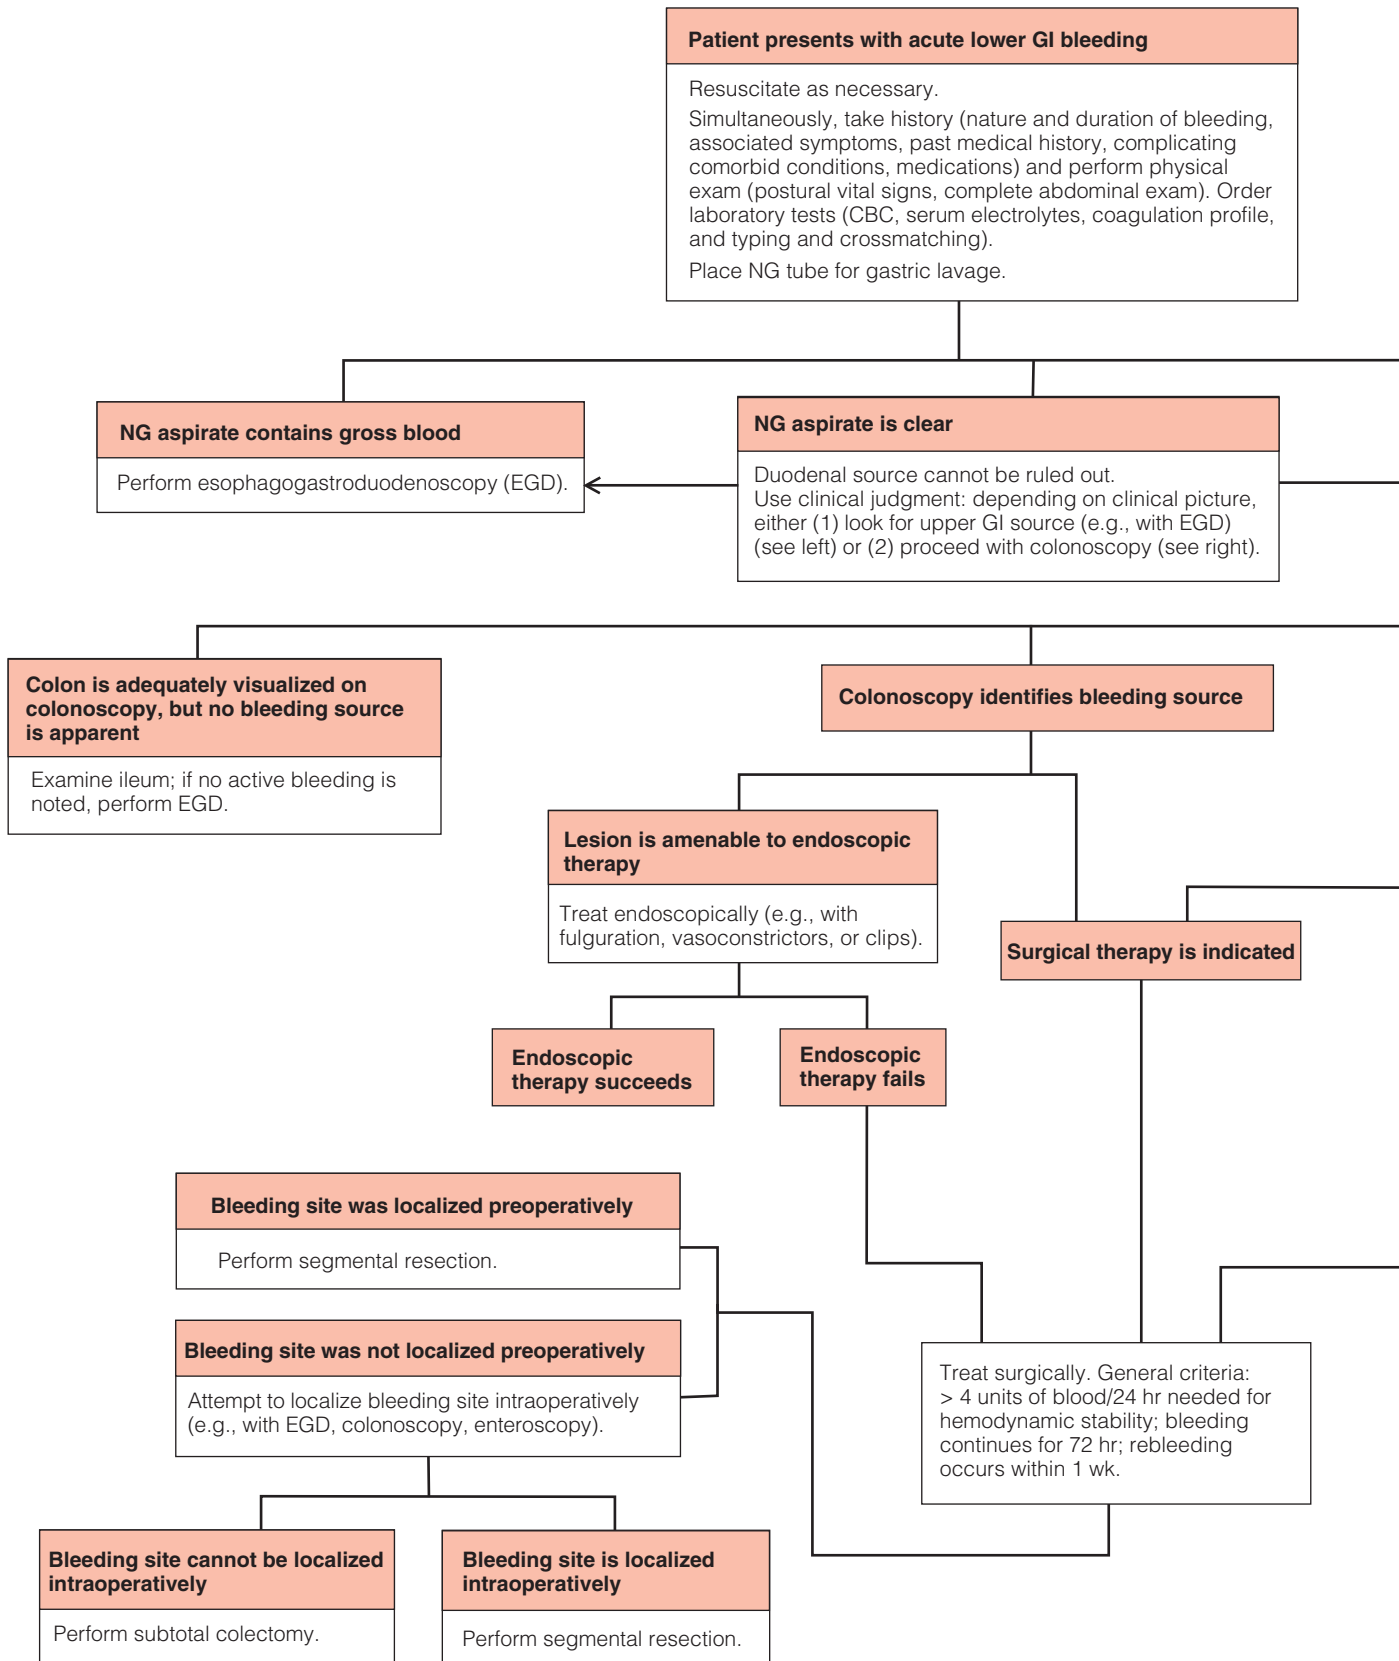

the nature and duration of the bleeding, including stool color and frequency. The patient should also be asked about any associated symptoms of potential significance (e.g., abdominal pain, changes in bowel habits, fever, urgency, tenesmus, or weight loss), as well as about relevant past medical events (e.g., previous GI bleeding episodes, injuries, surgical procedures, peptic ulcer disease, inflammatory bowel disease [IBD], and abdominal or pelvic irradiation). Any complicating comorbid conditions (e.g., heart or liver disease and clotting disorders) should be investigated. A comprehensive review of medications—in particular, nonsteroidal anti-inflammatory drugs (NSAIDs) and anticoagulants—is mandatory.¹²

The physical examination should include determination of postural vital signs so that intravascular volume status can be accurately estimated. A drop in the orthostatic blood pressure greater than 10 mm Hg or an increase in the pulse rate greater than 10 beats/min indicates that more than 800 ml of blood (> 15% of the total circulating blood volume) has been lost. Marked tachycardia and tachypnea in association with hypotension and depressed mental status indicates that more than 1,500 ml of blood (> 30% of the total circulating blood volume) has been lost. A complete abdominal examination, including digital rectal examination and anoscopy, should be performed.

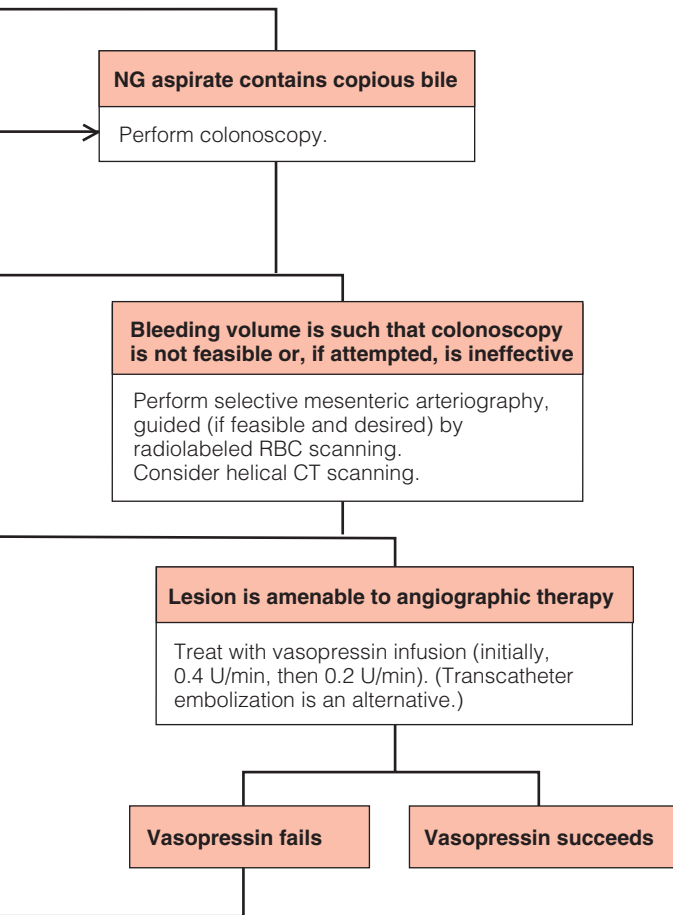

Laboratory evaluation should include a complete blood count, measurement of serum electrolyte concentrations, a coagulation profile (prothrombin time and partial thromboplastin time) [see 1:4 *Bleeding and Transfusion*], and typing and crossmatching.

A nasogastric tube should be placed for gastric lavage. If lavage yields positive results (i.e., the aspirate contains gross blood or so-called coffee grounds), esophagogastroduodenoscopy (EGD) is indicated [see 5:18 *Gastrointestinal Endoscopy*]. An aspirate that contains copious amounts of bile is strongly suggestive of a lower GI source of bleeding, and the workup proceeds accordingly [see Investigative Studies, *below*]. The choice is less clear-cut with a clear aspirate. In the absence of bile, such an aspirate cannot rule out a duodenal source for the bleeding. Accordingly, there is some degree of latitude for clinical judgment: depending on the overall clinical picture, the surgeon may choose either to perform EGD to rule out a duodenal bleeding source or to proceed with colonoscopy on the assumption that the source of the bleeding is in the lower GI tract.

Resuscitative efforts should begin immediately, with the aim of maintaining the patient in a euvolemic state. Two large-bore peripheral intravenous catheters should be inserted and isotonic I.V. fluid administered. A Foley catheter should be placed to facilitate monitoring of intravascular volume status. Whether and in what form to administer blood products is determined on an individual basis, with appropriate weight given to the presence or absence of comorbid conditions, the rate of blood loss, and the

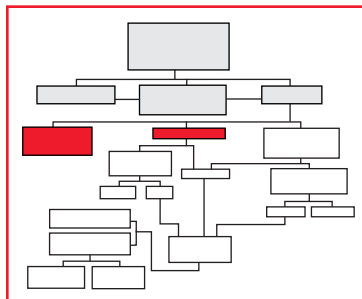

Approach to Lower GI Bleeding

degree of hemodynamic stability. Severe hemodynamic instability may necessitate monitoring in the intensive care unit.

Investigative Studies

A number of diagnostic techniques are available for determining the source of lower GI hemorrhage, the most useful of which are colonoscopy [see 5:18 *Gastrointestinal Endoscopy*], radionuclide scanning, computed tomography, and angiography (in the form of selective mesenteric arteriography). The goal of these tests is to locate the site of bleeding accurately so that definitive therapy can be properly directed. Which diagnostic test is chosen for a specific patient depends on several factors, including the hemodynamic stability of the patient, the bleeding rate, the comorbid conditions present, and the local expertise available at the physician's hospital.

COLONOSCOPY

Several large series that evaluated the diagnostic utility of colonoscopy in patients with lower GI bleeding found this modality to be moderately to highly accurate, with overall diagnostic yields ranging from 53% to 97% [see Table 1].^{3,13-17} Those studies that reported morbidity found colonoscopy to be safe as well, with an average complication rate of 0.5%. Colonoscopy has both a higher diagnostic yield and a lower complication rate than arteriography in this setting and thus would appear to be a more attractive initial test in most circumstances.^{3,18} An argument has been made—one with which we agree—that colonoscopy should be considered the procedure of choice for structural evaluation of lower GI bleeding and that arteriography should be reserved for patients with massive, ongoing bleeding in whom endoscopy is not feasible or colonoscopy fails to reveal the source of the hemorrhage.¹²

The merits of colonic purging have been extensively debated in the literature.^{3,11,14} Although no firm conclusion has been reached, we feel that adequate colonic purging can improve both the diagnostic yield and the safety of colonoscopy. Given the absence of any definitive data suggesting that colonic purging either reactivates or increases bleeding,¹² it is our practice to administer an oral purge after the patient has been adequately resuscitated.

If the entire colon has been adequately visualized and no source for the bleeding has been identified, the ileum should be intubated; fresh blood in this region suggests a possible small bowel source. If no active bleeding is observed in the ileum, upper GI endoscopy should be performed to rule out an upper GI bleeding site.

When colonoscopy and routine upper GI endoscopy fail to locate a bleeding source, push enteroscopy may be helpful. This procedure can be carried out in several ways. It can be performed purely endoscopically with a pediatric colonoscope. This approach generally requires a high level of skill on the part of the endoscopist, in that the lack of retroperitoneal attachments of the small intestine makes endoscopic navigation extremely challenging. In most cases, only the proximal 150 cm of the small intestine can be evaluated in this way. Alternatively, push enteroscopy can be performed in the operating room at the time of exploratory laparotomy. The surgeon can manually “milk” the small bowel over the scope to evaluate its distal portion. In addition, an enterotomy can be made, and the scope can be passed in both a retrograde and an antegrade fashion so that the entire small intestine can be evaluat-

ed. Depending on the indication and on the technique employed, the diagnostic yield from push enteroscopy has ranged from 13% to 78%.¹⁹ Typically, yields are highest (40% to 60%) in patients with significant GI hemorrhage.

RADIOLABELED RED BLOOD CELL SCANNING

Radionuclide scanning is highly sensitive for lower GI hemorrhage; it is capable of detecting bleeding at rates as slow as 0.1 to 0.4 ml/min.²⁰ Two imaging tracers, both labeled with technetium-99m (^{99m}Tc), are currently available for radionuclide scanning in this setting: ^{99m}Tc-labeled sulfur colloid (^{99m}Tc-SC) and ^{99m}Tc-labeled red blood cells (RBCs). ^{99m}Tc-SC requires no preparation time and can be injected immediately into the patient; however, its rapid absorption into the liver and the spleen can often hinder accurate localization of overlying bleeding sites.⁹ At our institution, we prefer to use ^{99m}Tc-labeled RBCs. This agent requires some preparation time, but it has a much longer half-life than ^{99m}Tc-SC does, it is not taken up by the liver and spleen, and it can be detected on images as long as 24 to 48 hours after injection [see Figure 1].^{21,22}

One study directly compared these two techniques and found ^{99m}Tc-labeled RBC scanning to have an accuracy of 93%, compared with an accuracy of only 12% for ^{99m}Tc-SC scanning.²³ The high sensitivity of ^{99m}Tc-labeled RBC scanning—80% to 98%—is well attested, but there is considerable disagreement in the literature with regard to its specificity in identifying the anatomic site of bleeding.²⁴⁻²⁷ For example, on one hand, a 1996 study found radiolabeled RBC scanning to be 97% accurate for localizing bleeding in 37 patients undergoing surgical resection²⁷; on the other hand, a 1990 study reported a 42% rate of incorrect resection when surgical therapy was based solely on this modality.²⁶ In 2005, one group retrospectively reviewed 127 bleeding scans in an effort to identify factors that might predict a positive scan.²⁸ The investigators found that tagged RBC scans were 48% accurate in localizing bleeding sites later confirmed by endoscopy, surgery, or pathologic evaluation. Multivariate analysis demonstrated that both the number of units of blood transfused in the 24 hours preceding the scan and the lowest recorded hematocrit differed significantly between patients with positive scans and those with negative scans. However, the clinical significance of a positive scan was unclear in this study, in that the rate of endoscopy was not significantly different between patients who had positive scans and those who did not.

To date, no prospective, randomized trials have compared radionuclide scanning with colonoscopy as the initial diagnostic procedure for patients with lower GI hemorrhage. In our view,

Table 1 Diagnostic Accuracy of Colonoscopy in Localizing Source of Lower GI Hemorrhage

Study	No. of Patients	Diagnostic Yield (%)
Richter ¹³	78	70 (90%)
Jensen ³	80	68 (85%)
Rossini ¹⁴	409	311 (76%)
Goenka ¹⁵	166	141 (85%)
Ohyama ¹⁶	345	307 (89%)
Chaudhry ¹⁷	85	82 (97%)
Total	1,163	979 (84%)

Figure 1 ^{99m}Tc-labeled RBC scan demonstrates collection of tracer at hepatic flexure.

however, given that radionuclide scanning (unlike colonoscopy and angiography) has no therapeutic intervention capabilities, its best use is in patients with non-life-threatening lower GI bleeding as a prelude and a guide to mesenteric angiography after active hemorrhage has been confirmed.

COMPUTED TOMOGRAPHY

With the ongoing improvements in high-speed abdominal CT scanning, there has been growing interest in the evaluation of GI bleeding with CT.²⁹ Helical CT scanners can provide direct or indirect evidence of the source of GI bleeding. Typical findings that can facilitate localization of bleeding sites include spontaneous hyperdensity of the peribowel fat, contrast enhancement of the bowel wall, vascular extravasation of the contrast medium, thickening of the bowel wall, polyps, tumors, and vascular dilatation.

Figure 2 Angiographic study documents extravasation of contrast into small bowel.

CT evaluation of GI bleeding has several noteworthy advantages: the scanners typically are readily available, mobilization of special teams or units is not required, the scans can be completed rapidly in the emergency department, and bowel preparation is unnecessary. In one experimental study, CT scanners were able to detect arterial bleeding at rates as low as 0.07 ml/min, which suggests that CT scanning is more sensitive than angiography for this purpose.³⁰ In addition, CT scans are noninvasive and carry little morbidity. Unfortunately, like radionuclide scanning, CT has no therapeutic capability.

A 2003 study of 19 patients with GI hemorrhage compared triphasic helical CT evaluation with colonoscopy and surgery for localization of bleeding sites.³⁰ In this series, five patients had small bowel bleeding sites, and 14 had colonic sites. Helical CT scanning correctly identified four of the five small bowel lesions and 11 of the 14 colonic lesions. These findings, though preliminary, suggest that CT is a potentially valuable evaluation method in certain cases of GI bleeding. Perhaps CT scanning can eventually replace radionuclide scanning, which is often inaccurate. One potential drawback to the use of CT in this setting is the excessive dye load if angiography is employed as well.

ANGIOGRAPHY

Selective Mesenteric Arteriography

Selective mesenteric arteriography is somewhat less sensitive than radionuclide scanning for lower GI hemorrhage: bleeding must be occurring at a rate of at least 1.0 to 1.5 ml/min to be detectable with this test.³¹ The procedure involves percutaneous placement of a transfemoral arterial catheter for evaluation of the superior mesenteric, inferior mesenteric, and celiac arteries. A positive test result is defined as extravasation of contrast into the lumen of the bowel [see Figure 2]. Once the bleeding vessel has been localized angiographically, the area must be marked so that it can be successfully identified intraoperatively; this is commonly accomplished by infusing methylene blue into the bleeding artery [see Figure 3].^{32,33}

In several large series [see Table 2], the overall diagnostic yield of arteriography ranged from 27% to 67%.^{27,34-38} The complication rate for arteriography performed for lower GI bleeding ranges from 2% to 4%.^{2,38} Reported complications include contrast allergy, renal failure, bleeding from arterial puncture, and embolism from a dislodged thrombus.¹²

Unlike radionuclide scanning, arteriography provides several therapeutic options, including vasopressin infusion and embolization of bleeding vessels. Nonetheless, given that arteriography has a lower diagnostic yield and a higher complication rate than colonoscopy does, it is reasonable to attempt colonoscopy first in patients with lower GI hemorrhage and to reserve angiography for patients in whom the volume of bleeding is such that colonoscopy would be neither safe nor accurate.

Provocative Angiography for Continued Obscure Bleeding

In a minority of patients, obscure bleeding persists despite negative findings from endoscopy, mesenteric arteriography, and radio-labeled RBC scanning. This obscure bleeding presents a considerable diagnostic challenge, which some investigators have proposed addressing by means of so-called provocative angiography.^{39,40}

Figure 3 Intraoperative examination of the bowel is aided by injection of methylene blue dye, which facilitates localization of the bleeding site and thereby helps direct surgical resection.

Provocative angiography involves the use of short-acting anticoagulant agents (unfractionated heparin, vasodilators, thrombolytics, or combinations thereof) in association with angiography. Once the bleeding point has been localized, methylene blue is injected and the patient is immediately brought to the OR for surgical treatment. To date, unfortunately, little has been published on this technique, but it does appear to be a promising approach to this difficult problem.

Management

Although, in the majority of cases, lower GI bleeding stops spontaneously, in a significant number of cases, hemorrhage continues and necessitates therapeutic intervention. Treatment options include endoscopic therapy, angiographic therapy, and surgical resection.

ENDOSCOPIC THERAPY

When colonoscopy identifies a bleeding source, endoscopic treatment may be an option [see 5:18 *Gastrointestinal Endoscopy*]. Endoscopic modalities used to treat lower GI bleeding include use of thermal contact probes,^{41,42} laser photocoagulation,⁴³ electrocauterization,⁴⁴ injection of vasoconstrictors, application of metallic clips,⁴⁵ and injection sclerotherapy.⁴⁶ The choice of a specific modality often depends on the nature of the offending lesion and on the expertise and resources available locally. A 1995 survey of members of the American College of Gastroenterology found that endoscopic therapy was used in 27% of patients presenting with lower GI bleeding.⁸

Diverticular hemorrhage can be difficult to treat endoscopically because of the high bleeding rate and the location of the bleeding point within the diverticulum. In 2000, one group of investigators reported their experience with endoscopic therapy for severe

hematochezia and diverticulosis in a prospective series of 121 patients.⁴⁷ In this series, none of the patients treated endoscopically with epinephrine injections, bipolar coagulation, or both required surgery and none experienced recurrent bleeding episodes. A 2001 study from another group, however, reported high rates of recurrent bleeding episodes in both the early and the late post-treatment periods.⁴⁸ In the absence of prospective, randomized trials, it is difficult to draw definitive conclusions about the utility of endoscopic therapy in treating diverticular hemorrhage.

Angiodysplasias resulting in GI hemorrhage typically are amenable to endoscopic treatment. That these lesions are frequently found in the right colon makes perforation a concern; this complication is reported in approximately 2% of patients.⁴⁹ Good success rates have been reported with both injection and thermal methods.⁵⁰ In one series, endoscopic fulguration was successful in 87% of patients, and no rebleeding episodes occurred over a 1- to 7-year follow-up period.⁵⁰ Bleeding from multiple telangiectatic lesions in the distal colon resulting from radiation injury can be treated with thermal contact probes, lasers, or noncontact devices such as the argon plasma coagulator.⁵¹

Postpolypectomy hemorrhage can often be successfully treated by endoscopic means. Methods used include simple resnaring of the stalk while pressure is maintained⁵²; electrocauterization, with or without epinephrine injection; endoscopic band ligation; and placement of metallic clips. For patients whose bleeding is attributable to benign anorectal causes, endoscopic therapy may include epinephrine injection, sclerosant injection, or band ligation of internal hemorrhoids.⁵³

ANGIOGRAPHIC THERAPY

Diagnostic use of angiography in patients with lower GI bleeding can often be followed by angiographic therapy. The two main angiographic treatment options are intra-arterial injection of vasopressin and transcatheter embolization.

Vasopressin acts to control bleeding by causing arteriolar vasoconstriction and bowel wall contraction.⁹ Once the bleeding site has been localized angiographically, the catheter is positioned in

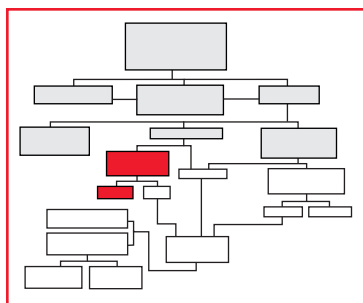

Table 2 Diagnostic Accuracy of Mesenteric Angiography in Localizing Source of Lower GI Hemorrhage

Study	No. of Patients	No. of Positive Angiograms (%)
Pennoyer ³⁴	131	37 (28%)
Ng ²⁷	49	22 (45%)
Rantis ³⁵	30	8 (27%)
Leitman ³⁶	68	27 (40%)
Casarella ³⁷	69	46 (67%)
Colacchio ³⁸	98	40 (41%)
Total	445	180 (40%)

the main trunk of the vessel. Infusion of vasopressin is initiated at a rate of 0.2 U/min and can be increased to a rate of 0.4 U/min. Within 20 to 30 minutes, another angiogram is performed to determine whether the bleeding has ceased. If the bleeding is under control, the catheter is left in place and vasopressin is continuously infused for 6 to 12 hours. If the bleeding continues to be controlled, infusion is continued for an additional 6 to 12 hours at 50% of the previous rate. Finally, vasopressin infusion is replaced by continuous saline infusion, and if bleeding does not recur, the catheter is removed.^{54,55}

The vasoconstrictive action of vasopressin can have deleterious systemic side effects, including myocardial ischemia, peripheral ischemia, hypertension, dysrhythmias, mesenteric thrombosis, intestinal infarction, and death.^{9,36} Occasionally, simultaneous I.V. administration of nitroglycerin is necessary to counteract these systemic effects. The reported success rate of vasopressin in controlling lower GI bleeding ranges from 60% to 100%, and the incidence of major complications ranges from 10% to 20%.⁵⁶⁻⁵⁸ Rebleeding rates as high as 50% have been reported.^{57,58}

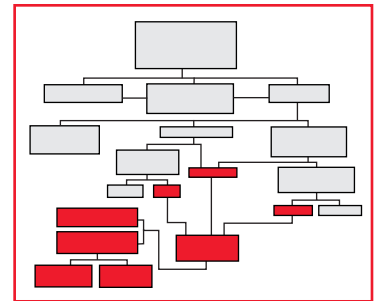

An alternative for patients with coronary vascular disease, severe peripheral vascular disease, or other comorbidities that prevent safe administration of vasopressin is transcatheter embolization. In this technique, a catheter is superselectively placed into the identified bleeding vessel and an embolizing agent (e.g., a gelatin sponge, a microcoil, polyvinyl alcohol particles, or a balloon) is injected. Several small series found this technique to be 90% to 100% successful at stopping bleeding.⁵⁹⁻⁶³ Equally impressive was the finding that the rebleeding rates in these series were 0%. The complication rates of this procedure are generally reasonable as well; however, intestinal infarction has been reported.^{36,64}

The use of small microcatheters and the ability to superselectively embolize individual vessels have reduced the potential for ischemic perforation. It is possible that as more experience is gained with these techniques, superselective embolization may replace catheter-directed vasoconstrictive therapy, thus obviating the potential deleterious systemic effects of vasopressin administration. Some researchers have suggested that with the exception of cases of diffuse bleeding lesions or cases whose demands exceed the technical limitations of superselective catheterization, emboli-

zation therapy should be the first choice for angiographic treatment of lower GI bleeding.^{65,66}

SURGICAL THERAPY

Although there are no absolute criteria for surgical treatment of lower GI bleeding, there are several factors—including hemodynamic status, associated comorbidities, transfusion requirements, and persistent bleeding—that are instrumental in making an appropriate and timely decision

whether to operate. In general, patients who require more than 4 units of blood in a 24-hour period to remain hemodynamically stable, whose bleeding has not stopped after 72 hours, or who experience rebleeding within 1 week after an initial episode should undergo surgery.⁹

If the patient's hemodynamic status permits, surgical treatment should be undertaken after accurate localization of the bleeding site. When possible, directed segmental resection is the procedure of choice: it is associated with rebleeding rates ranging from 0% to 14% and mortality rates ranging from 0% to 13%.^{10,36,67} Blind segmental colectomy should never be performed: it is associated with rebleeding rates as high as 75% and mortality rates as high as 50%.⁶⁸ If hemodynamic compromise and ongoing hemorrhage make it necessary to perform surgical exploration before the bleeding site can be localized, every effort should be made to identify the source of bleeding intraoperatively before embarking on resection. Intraoperative options for bleeding-site localization include colonoscopy (to allow for this option, patients should always be placed in the lithotomy position), EGD, and transoral passage of a pediatric colonoscope for enteroscopy with simultaneous intraperitoneal assistance for small bowel manipulation.⁹ If the bleeding site still cannot be accurately localized, subtotal colectomy is the procedure of choice. This procedure is associated with mortality rates ranging from 5% to 33%,^{69,70} which underscores the importance of accurate preoperative localization of bleeding before surgical intervention.

Discussion

Etiology of Lower GI Bleeding

As noted, lower GI bleeding has a wide array of possible causes [see Table 3].^{9,71} Of these, diverticular disease is the most common, accounting for 30% to 40% of all cases.⁷² Arteriovenous malformations (AVMs), though extensively described in the literature, are considerably less common causes, accounting for 1% to 4% of cases.^{73,74} Other significant causative conditions are IBD, benign and malignant neoplasms, ischemia, infectious colitis, anorectal disease, coagulopathy, use of NSAIDs, radiation proctitis, AIDS, and small bowel disorders.

DIVERTICULAR DISEASE

The reported prevalence of colonic diverticulosis in Western societies is 37% to 45%.⁷⁵ The vast majority of colonic diverticula are actually false diverticula (pseudodiverticula) that contain only serosa and mucosa [see 5:12 Diverticulitis]. They occur at weak points in the colonic wall where the vasa recta penetrate the mus-

cularis to supply the mucosa⁹; as the diverticulum expands, these vessels are displaced. A 1976 anatomic study of colonic specimens from patients with diverticular bleeding used angiography to demonstrate that in all cases, the vasa recta overlying the diverticulum ruptured into the lumen of the diverticulum, not into the peritoneum [see Figure 4].⁷⁶

It has been estimated that approximately 17% of patients with colonic diverticulosis experience bleeding, which may range from minor to severe and life-threatening.⁷⁷ As many as 80% to 85% of diverticular hemorrhages stop spontaneously.⁷⁸ In one series, surgery was unlikely to be necessary if fewer than 4 units of packed RBCs were transfused in a 24-hour period, whereas 60% of patients receiving more than 4 units of packed RBCs in a 24-hour period required surgical intervention.⁵ The risk of a second bleeding episode is approximately 25%.³ Semielective surgical therapy is usually offered after a second diverticular bleeding episode because once a second such episode has occurred, the risk that a

Table 3 Common Causes of Lower GI Hemorrhage

Cause of Bleeding	Frequency
Diverticulosis	17%–40%
Arteriovenous malformation	2%–30%
Colitis	9%–21%
Neoplasia (including postpolypectomy bleeding)	7%–33%
Benign anorectal disease	4%–10%
Upper GI source	0%–11%
Small bowel source	2%–9%

third will follow exceeds 50%.⁷⁹ In a series of 83 conservatively managed cases of diverticular disease, the predicted yearly recurrence rates were 9% at 1 year, 10% at 2 years, 19% at 3 years, and 25% at 4 years.⁴

COLITIS

The broad term colitis includes IBD, infectious colitis, radiation colitis, and idiopathic ulcers. IBD, in turn, includes Crohn disease [see 5:11 *Crohn Disease*] and ulcerative colitis [see 5:13 *Fulminant Ulcerative Colitis*]. Patients with IBD usually present with bloody diarrhea that is not life-threatening; however, 6% to 10% of patients with ulcerative colitis have lower GI bleeding severe enough to necessitate emergency surgical resection,^{80,81} and 0.6% to 1.3% of patients with Crohn disease have acute life-threatening lower GI bleeding.^{80,82} In one review, 50% of patients with intestinal hemorrhage from IBD experienced spontaneous cessation of bleeding.⁸⁰ Approximately 35% of patients whose bleeding stops without intervention will have another bleeding episode. Because of this high recurrence rate, semielective surgery is recommended after the first episode of severe GI bleeding secondary to IBD.

Colitis caused by various infectious agents (e.g., *Salmonella typhi*,^{83,84} *Escherichia coli* O157:H7,⁸⁵ *Clostridium difficile*,⁸⁶ and

cytomegalovirus) can result in severe lower GI bleeding, but this is a relatively rare occurrence.

Increasing use of radiation therapy to treat pelvic malignancies has led to a corresponding increase in the incidence of chronic radiation proctitis.⁸⁷ Radiation therapy damages bowel mucosa, resulting in the formation of vascular telangiectases that are prone to bleeding.⁸⁸ From 1% to 5% of cases of acute lower GI bleeding from radiation-induced proctocolitis are severe enough to necessitate hospitalization.^{4,14} In a survey of patients with prostate cancer who underwent pelvic irradiation, 5% of the patients reported hematochezia daily.⁸⁹ Initial therapy for clinically significant hematochezia related to radiation proctitis should include some form of endoscopic treatment (e.g., argon-beam coagulation). Surgery should be reserved for unstoppable hemorrhage or other major complications, such as fistulas and strictures.⁸⁷

NEOPLASIA

Significant GI bleeding from colorectal neoplasia [see 5:15 *Adenocarcinoma of the Colon and Rectum*] accounts for 7% to 33% of cases of severe lower GI hemorrhage.^{3,11,14,36,90} Such bleeding is believed to result from erosions on the luminal surface.⁹¹ One report identified ulcerated cancers as the cause in 21% of cases of hematochezia.¹⁴ Adenomatous polyps are implicated in 5% to 11% of cases of acute lower GI bleeding.^{7,8,14,92,93} Lower GI hemorrhage, either immediate or delayed, is the most common reported complication after endoscopic polypectomy, occurring in 0.2% to 6% of cases.^{3,4,94,95} Immediate postpolypectomy bleeding is believed to result from incomplete coagulation of the stalk before transection.⁵² Delayed bleeding has been reported as long as 15 days after polypectomy and is thought to be secondary to sloughing of the coagulum; it is less common than immediate bleeding, occurring in only 0.3% of cases.^{14,52}

COAGULOPATHY

Lower GI bleeding can be a presenting symptom both for patients with iatrogenic coagulopathy from heparin or warfarin therapy and for patients with a hematologic coagulopathy from thrombocytopenia [see 1:4 *Bleeding and Transfusion*]. It is unclear, however, whether severe coagulopathy leads to spontaneous hemorrhage or whether it predisposes to bleeding from an existing lesion.^{96,97} In an early series of leukemic patients with thrombocytopenia and severe GI hemorrhage, 50% of bleeding patients had platelet counts lower than 20,000/mm³ without any identifiable mucosal lesions; furthermore, when the platelet count rose above 20,000/mm³, the incidence of bleeding decreased to 0.8%.⁹⁶ The investigator concluded that severe thrombocytopenia led to spontaneous GI hemorrhage. Other investigators subsequently challenged this conclusion, arguing that spontaneous bleeding from coagulopathy is in fact rare.⁹⁸ In one report, the distribution of pathologic lesions in patients with GI bleeding who were taking heparin or warfarin was essentially equivalent to that in the general population.⁹⁸ Regardless of what the precise relation between coagulopathy and GI hemorrhage may be, a thorough investigation for an anatomic lesion is imperative in the workup of patients with lower GI bleeding even in the face of coagulopathy or thrombocytopenia.

BENIGN ANORECTAL DISEASE

Hemorrhoids, ulcer/fissure disease, and fistula in ano [see 5:17 *Benign Rectal, Anal, and Perineal Problems*] must not be overlooked as causes of GI hemorrhage: in one review comprising almost 18,000 cases of lower GI bleeding, 11% were attributable to anorectal pathology. It is crucial to remember that identification of

Figure 4 Shown is the appearance of a bleeding diverticulum on colonoscopy.

Figure 5 Shown is the appearance of an arteriovenous malformation on colonoscopy.

a benign anorectal lesion does not eliminate the possibility of a more proximal cause of hemorrhage. In general, patients with hemorrhoids identified on physical examination should still undergo thorough endoscopic evaluation of the colon to rule out other pathologic conditions.

Portal hypertension [see 5:10 *Portal Hypertension*], congestive heart failure, and splenic vein thrombosis can cause colonic or anorectal varices, which can result in massive lower GI hemorrhage.⁹⁹ The reported incidence of anorectal varices in patients with portal hypertension ranges from 78% to 89%.^{100,101} If local measures fail to control hemorrhage, some form of portosystemic shunting is indicated.

COLONIC ARTERIOVENOUS MALFORMATIONS

The term arteriovenous malformation includes vascular ectasias, angiomas, and angiodysplasias. AVMs are ectatic blood vessels seen in the mucosa and submucosa of the GI tract. They are degenerative lesions of the GI tract, occurring more frequently with advancing age.⁹ In autopsy series, the reported incidence of colonic AVMs is 1% to 2%.¹⁰² In patients older than 50 years, the incidence of colonic AVMs is estimated to range from 2% to 30%.¹⁰³⁻¹⁰⁶ In healthy asymptomatic adults, the prevalence is estimated to be approximately 0.8%.¹⁰⁷

Colonic AVMs are believed to derive from chronic colonic wall muscle contraction, which leads to chronic partial obstruction of the submucosal veins, causing the vessels to become dilated and tortuous. This process eventually renders the precapillary sphincters incompetent, resulting in direct arterial-venous communication.^{108,109} Colonic AVMs are most commonly found in the cecum.¹⁰ They have been associated with several systemic diseases, including atherosclerotic cardiovascular disease, aortic stenosis, chronic renal disease, collagen vascular disease, von Willebrand disease, chronic obstructive pulmonary disease, and cirrhosis of the liver; to date, however, no definite causal relationship to any of these conditions has been established.^{6,21,44,110}

The diagnosis of a colonic AVM is made at the time of angiography or colonoscopy. During angiography, visualization of ectatic, slow-emptying veins, vascular tufts, or early-filling veins estab-

lishes the diagnosis.¹¹¹ During endoscopy, angiodysplasias appear as red, flat lesions about 2 to 10 mm in diameter, sometimes accompanied by a feeding vessel [see *Figure 5*].^{6,41,44,72}

Typically, the bleeding caused by colonic AVMs is chronic, slow, and intermittent.⁹ Although these lesions can cause severe lower GI hemorrhage, they are a relatively uncommon cause: in most large series, they account for only about 2% of cases of acute bleeding.^{74,104} The bleeding stops spontaneously in 85% to 90% of cases,¹⁰ but it recurs in 25% to 85%.¹¹² Accordingly, definitive surgical or colonoscopic treatment should be rendered once the lesion has been identified.

COLONIC ISCHEMIA

Acute lower GI bleeding can also be a presenting symptom of colonic ischemia. In several large series, colonic ischemia accounted for 3% to 9% of cases of acute lower GI hemorrhage.^{4,7,8,14,92} Other vascular diseases reported as potential causes are polyarteritis nodosa, Wegener granulomatosis, and rheumatoid vasculitis.^{113,114} The resultant vasculitis can cause ulceration, necrosis, and ultimately hemorrhage.¹¹⁵

SMALL INTESTINAL SOURCES

Small intestinal sources account for 0.7% to 9% of cases of acute lower GI bleeding.^{3,4,116-118} About 70% to 80% of cases of small bowel hemorrhage are attributable to AVMs; other, less common causes are jejunoileal diverticula, Meckel's diverticulum,¹¹⁹ neoplasia, regional enteritis, and aortoenteric fistulas [see *Figure 6*].^{90,120,121}

Figure 6 Shown are intraoperative specimens of small bowel tumors causing lower GI hemorrhage.

Accurate localization of a bleeding site in the small intestine can be highly challenging: the length and the free intraperitoneal position of the small bowel make endoscopic examination difficult, and the nature of the overlying loops makes angiographic localization imprecise. For these reasons, the small intestine is usually left for last in the attempt to localize the source of lower GI bleeding and is examined only after sources in the colon, the upper GI tract, and the anorectum have been ruled out.⁹

AIDS

The etiology of lower GI bleeding in patients with AIDS differs from that in the general population.⁹¹ In AIDS patients, lower GI bleeding is caused predominantly by conditions related to the underlying HIV infection. Cytomegalovirus colitis is the most common cause of such bleeding in this population, occurring in 39% of cases.¹²² AIDS patients with hemorrhoids or anal fissures often experience significant bleeding as a result of HIV-induced thrombocytopenia.¹²² A 1998 study reported that in 23% of AIDS

patients hospitalized for lower GI bleeding, benign anorectal disease was the cause.¹²³ Other significant causes of lower GI hemorrhage in this population are colonic histoplasmosis, Kaposi sarcoma of the colon, and bacterial colitis.^{123,124}

NSAID USE

The association between NSAID use and upper GI hemorrhage is well known.¹²⁵ Current data suggest that NSAIDs have a toxic effect on colonic mucosa as well.¹²⁶ An epidemiologic study estimated the incidence of NSAID-associated large bowel bleeding to be 7/100,000.¹²⁷ A retrospective review found that patients who had experienced lower GI bleeding were twice as likely to have taken NSAIDs as those who had not.¹²⁸ NSAIDs have also been linked to diverticular hemorrhage: in one study, 92% of patients with diverticular bleeding were taking NSAIDs.¹⁰⁷ The exact mechanism of NSAID-induced colonic injury is unknown; nevertheless, heightened clinical awareness of this potential cause of lower GI bleeding is warranted.⁹¹

7 MORBID OBESITY

Harvey J. Sugerman, M.D.

Approach to the Morbidly Obese Patient

Many surgeons are afraid to operate on the morbidly obese patient (i.e., a patient whose weight is 100 lb greater than ideal body weight or who has a body mass index [BMI] greater than 35 kg/mg²) because they presuppose a marked increase in perioperative morbidity and mortality. Although the morbidly obese patient is certainly at greater risk, this risk can be markedly reduced by paying careful attention to detail in preoperative and postoperative care. The increased risks encountered in these patients include wound infection, dehiscence, thrombophlebitis, pulmonary embolism, anesthetic calamities, acute postoperative asphyxia in patients with obstructive sleep apnea syndrome (SAS), acute respiratory failure, right ventricular or biventricular cardiac failure, and missed acute catastrophes of the abdomen, such as an anastomotic leak. In a series of about 3,000 gastric procedures for morbid obesity itself, we have observed the following incidence of complications: wound infection that delayed hospital discharge, 5%, as well as minor infections or seromas in an additional 10%; clinically apparent phlebitis, 0.4%; clinically diagnosed fatal pulmonary embolism, 0.2%; and pneumonia, 0.5%. We have observed a 1% operative mortality. Although many of these patients had severe preoperative morbidity (respiratory insufficiency, pseudotumor cerebri, or insulin-dependent diabetes), the risks of complications approach the risks associated with major abdominal operation in nonobese patients. In what follows, the focus is on issues that the surgeon should carefully consider when operating on an extremely overweight patient.

Cardiac Dysfunction

Morbidly obese patients are at significant risk of coronary artery disease as a result of an increased incidence of systemic hypertension, hypercholesterolemia, and diabetes. Because of this increased risk for cardiac dysfunction, preoperative electrocardiography probably should be performed on all obese patients 30 years of age or older.

Most morbidly obese patients have minimal evidence of cardiac dysfunction as detected by Swan-Ganz catheterization. Markedly elevated pulmonary arterial pressure (PAP) and pulmonary arterial

wedge pressure (PAWP) values will frequently be noted in patients with the respiratory insufficiency of obesity, especially those with obesity hypoventilation syndrome (OHS) [see Respiratory Insufficiency, Obesity Hypoventilation Syndrome, *below*].¹ Intubation and ventilation in these patients will often be followed by a vigorous diuresis, and it is not unusual for a patient to lose 50 lb or more of retained fluid. In a few obese patients, acute respiratory insufficiency will be caused by a greatly expanded central blood volume and heart failure. Abnormal blood gas values in these individuals will be corrected by vigorous diuresis alone. As with most other abnormalities related to morbid obesity, weight loss will also correct cardiac dysfunction.

Respiratory Insufficiency

Morbidly obese patients may suffer from obstructive SAS or OHS. The simultaneous presence of SAS and OHS is known as the pickwickian syndrome [see Discussion, Respiratory Insufficiency of Obesity, *below*].²⁻⁴

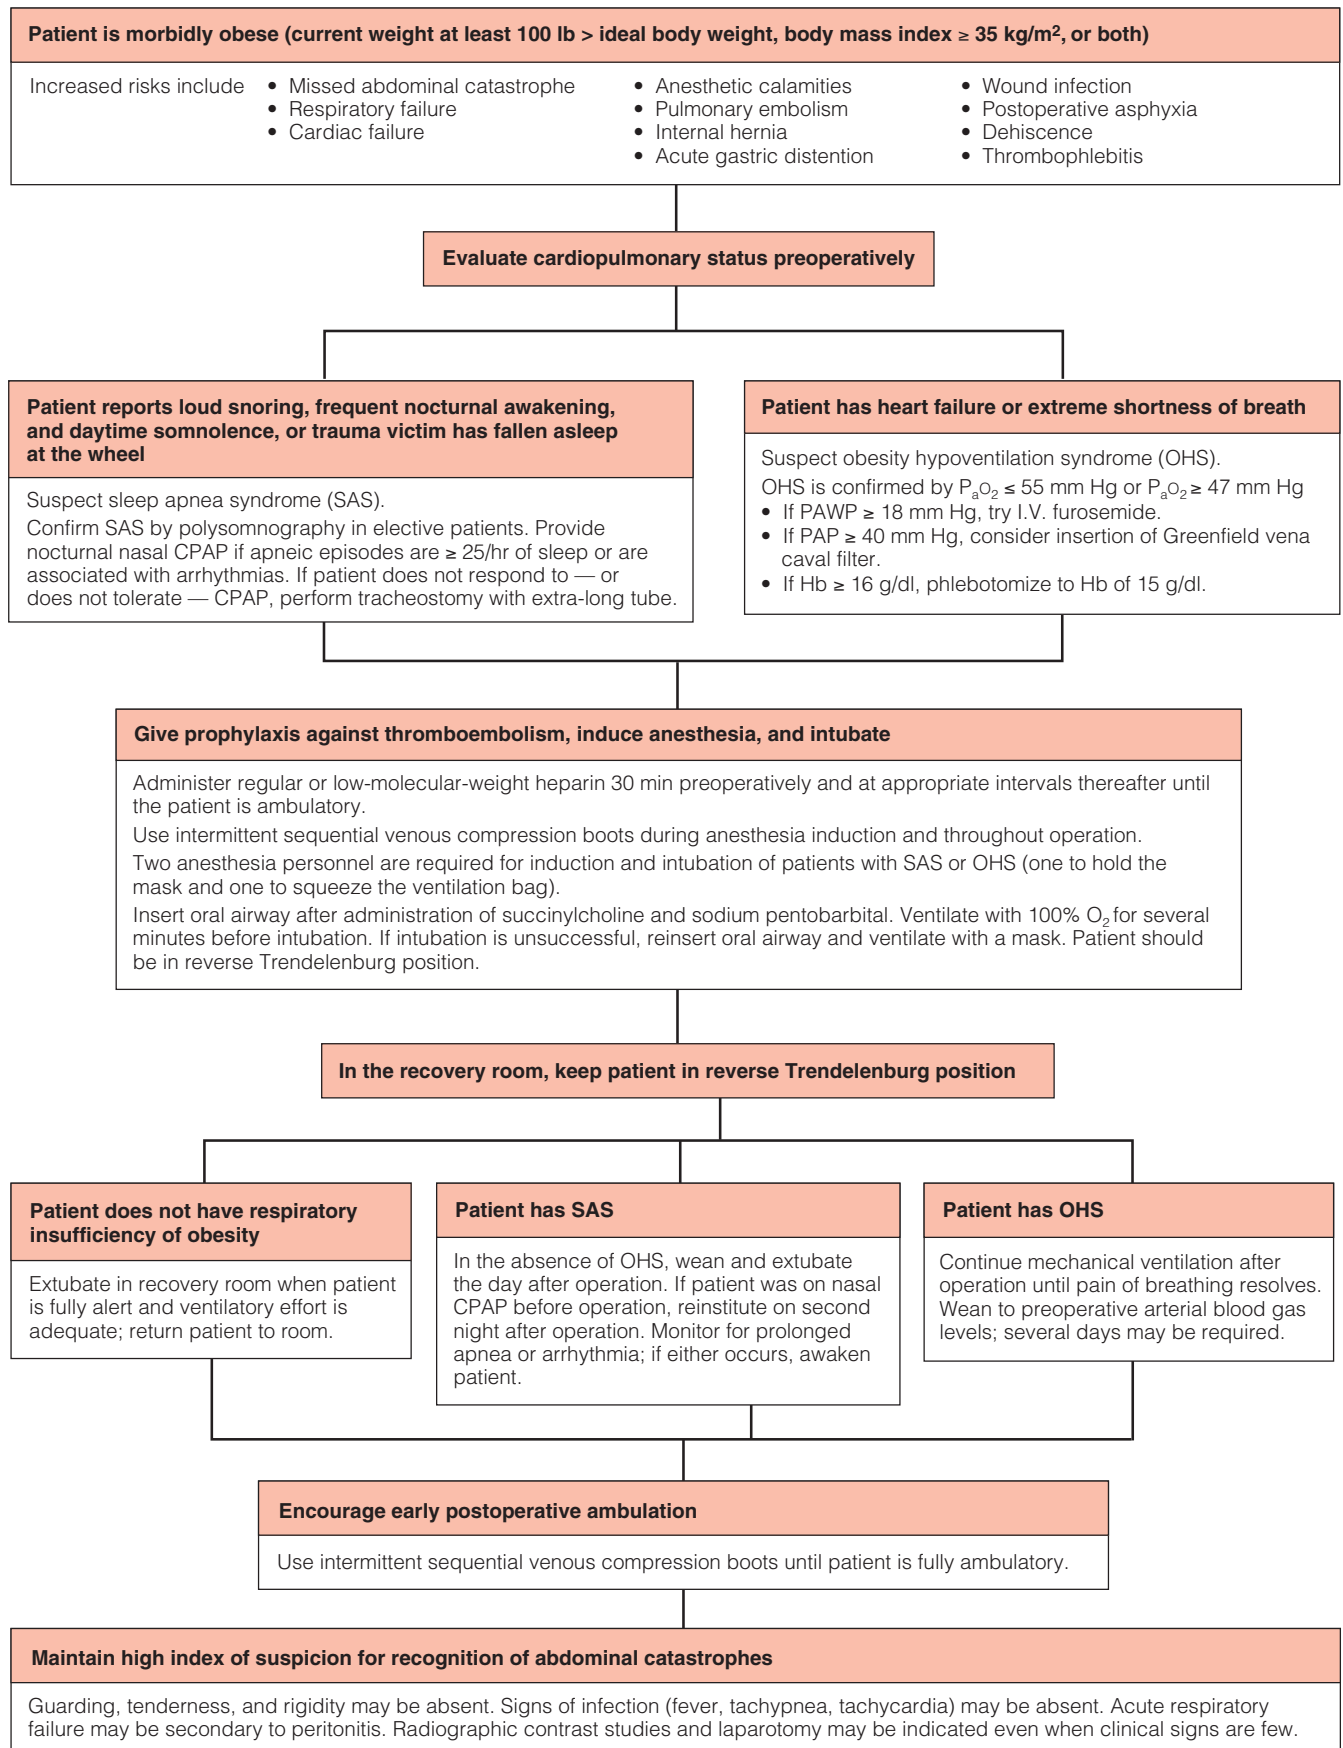

SLEEP APNEA SYNDROME

SAS is a potentially fatal complication of morbid obesity. A diagnosis of SAS should be suspected when there is a history of loud snoring, frequent nocturnal awakening with shortness of breath, and daytime somnolence. It is estimated that 2% of middle-aged women and 4% of middle-aged men in the United States workforce have SAS, and the incidence is markedly higher in the severely obese.⁵

Patients will often admit to falling asleep while driving and waking up with their car on the road's median strip or bumping its guardrail. It is extremely important that trauma surgeons be aware of the relation between obesity and somnolence should a morbidly obese patient be seen in the emergency room after an automobile accident in which he or she fell asleep at the wheel. Elective patients with suspected sleep apnea syndrome should undergo preoperative polysomnography at a sleep center to confirm the diagnosis. Medications are usually ineffective. Stimulants, such as methylphenidate hydrochloride (Ritalin), should not be used. If a patient has a respiratory disturbance index (RDI) greater than 25—indicating more than 25 apneic or hypopneic episodes per hour of sleep—or has cardiac arrhythmias in association with apnea, treatment by nocturnal nasal continuous positive airway pres-

Approach to the Morbidly Obese Patient

sure (nasal CPAP) should be provided. If the patient has severe SAS with an RDI greater than 40 and does not respond with elimination of the apneic episodes or cannot tolerate nasal CPAP, a tracheostomy should be considered. An extra-long tracheostomy tube is usually necessary because of the depth of the trachea in the morbidly obese patient.

OBESITY HYPOVENTILATION SYNDROME

OHS should be suspected in patients who present with heart failure or extreme shortness of breath. Patients who have a BMI of 50 kg/m² or greater or who have a history of pulmonary problems (e.g., smoking, chronic obstructive pulmonary disease, sarcoidosis, pulmonary fibrosis, or asthma) should undergo a baseline arterial blood gas (ABG) determination before operation. Diagnosis of OHS is confirmed when the patient's arterial oxygen tension (P_{aO_2}) is 55 mm Hg or less or the arterial carbon dioxide tension (P_{aCO_2}) is 47 mm Hg or greater. These patients often have marked elevations in mean PAP, mean PAWP, or both, as well as severe polycythemia. In patients with obesity hypoventilation syndrome, a Swan-Ganz catheter should be inserted as part of the preoperative evaluation. If PAWP is 18 mm Hg or greater, diuresis with intravenous furosemide is indicated. In many of these patients, however, an elevated PAWP reflects an increased intrathoracic pressure and is necessary to maintain adequate cardiac output; such patients do not have congestive heart failure, despite a markedly elevated filling pressure [see Discussion, *below*]. Little can be done for the pulmonary hypertension that is seen in many of these patients; raising the P_{aO_2} above 60 mm Hg usually will not lower PAP acutely.

Polycythemia can significantly increase the incidence of phlebotrombosis. If the hemoglobin (Hb) concentration is 16 g/dl or greater, phlebotomy to a concentration of 15 g/dl should be performed to reduce the postoperative risk of venous thrombosis. If PAP is 40 mm Hg or greater, consideration should be given to prophylactic insertion of a Greenfield vena caval filter because of the high risk of a fatal pulmonary embolism in these patients.⁶ Placement of this filter can be a challenge because the appropriate landmarks cannot be identified in the operating room with fluoroscopy. It is necessary before operation to tape a quarter to the patient's back over the second lumbar vertebra with the aid of fixed radiographs and then during operation to aim for the quarter with the insertion catheter, using fluoroscopy. Because these patients are usually too heavy for angiography tables, the Greenfield filter usually cannot be inserted percutaneously in the radiology department.

Embolism

The risk of deep vein thrombosis [see 6:6 *Venous Thromboembolism*] increases with a prolonged operation or a postoperative period of immobilization, and it increases even further in the morbidly obese patient. Standard or low-molecular-weight heparin should be administered subcutaneously 30 minutes before operation and at appropriate intervals thereafter (depending on the type of heparin used) for at least 2 days or until the patient is ambulatory. Because respiratory function in the

morbidly obese patient is greatly enhanced with the reverse Trendelenburg position, intermittent sequential venous compression boots should be used to counteract the increased venous stasis and the propensity for clotting. It is important that the intermittent venous compression boots be used before induction of anesthesia and throughout the operative procedure. Compression boots are usually part of a standard preoperative protocol in gastric procedures for weight control; their use should not be unintentionally neglected in preparation for other elective or emergency procedures on morbidly obese patients. Patients with severe venous stasis disease (e.g., pretibial stasis ulcers or bronze edema) are at significantly increased risk for fatal pulmonary embolism (PE).⁷ Prophylactic insertion of a Greenfield vena cava filter should be considered in both patients with severe venous stasis disease and patients with OHS and a high PAP. Bariatric surgery-induced weight loss will correct the venous stasis disease in most cases.⁷

Anesthesia in Patients with Respiratory Insufficiency

Morbidly obese patients can be intimidating to the anesthesiologist because they are at significant risk for complications from anesthesia, especially during induction. The risk is particularly great for obese patients with respiratory insufficiency. An obese patient often has a short, fat neck and a heavy chest wall, which make intubation and ventilation a challenge. If endotracheal intubation proves difficult, however, these patients can usually be well ventilated with a mask. Awake intubation can be performed, with or without fiberoptic aids, but is quite unpleasant and rarely necessary.

It is extremely important that at least two anesthesia personnel be present during induction and intubation for patients with respiratory insufficiency of obesity. An oral airway is inserted after muscle paralysis with succinylcholine and sodium pentobarbital induction. One person elevates the jaw, hyperextends the neck, and ensures a tight fit of the mask, using both hands. To ensure adequate oxygen delivery, a second person compresses the ventilation reservoir bag, using two hands because of the resistance to air flow from the poorly compliant, heavy chest wall. After ventilation with 100% oxygen for several minutes, intubation is attempted. If difficulties are encountered within 30 seconds, the steps above should be repeated until the patient has been successfully intubated. A volume ventilator is required during operation. Placing the patient in the reverse Trendelenburg position expands total lung volume and facilitates ventilation⁸; however, the reverse Trendelenburg position increases lower extremity venous pressure and therefore mandates the use of intermittent sequential venous compression boots [see Embolism, *above*]. It is helpful to monitor blood gases through a radial arterial line or digital pulse oximeter.

Postoperative Management

After operation, the obese patient should be kept in the reverse Trendelenburg position and should not be extubated until he or she is fully alert and showing evidence of adequate ventilatory effort [see 8:5 *Use of the Mechanical Ventilator*]. In the absence of respiratory insufficiency, most obese patients can be extubated in the OR or the recovery room and returned to a standard hospital room.

Patients with SAS, however, should be managed with overnight mechanical ventilation in the ICU. In the absence of concomitant OHS, they can usually be weaned and extubated the day after oper-

ation. Patients who were receiving ventilatory support with nasal CPAP before operation should have this treatment reinstated the second night after operation; monitoring for prolonged apnea should be continued in the ICU or in a stepdown unit with digital oximetry. If apnea occurs, simply waking the patient should correct the problem. Patients who required tracheostomy can also usually be weaned from the ventilator the morning after operation.

Patients with OHS require prolonged mechanical volume ventilation until the pain of breathing resolves. One cannot expect such patients to manifest normal ABG levels, and they should be weaned to their preoperative values. This is why baseline ABG values are obtained preoperatively. The weaning process may require several days. It is important that these patients remain in the reverse Trendelenburg position to maximize diaphragmatic excursion. Positive end-expiratory pressure (PEEP) ventilation may be detrimental in patients with OHS because it can overdistend alveoli, thereby leading to capillary compression, decreased cardiac output, and increased dead space, all of which can exacerbate retention of carbon dioxide.

Swan-Ganz catheters, inserted preoperatively in patients with severe OHS, are useful in monitoring postoperative intravascular volume and oxygen delivery status. Excessive diuresis or restriction of fluids should be avoided [see Discussion, *below*].

It is extremely important to encourage early postoperative ambulation for the morbidly obese patient. These patients have surprisingly little pain, and it is not unusual to see them walking in the afternoon or early evening after a major abdominal procedure. If the patients have been advised preoperatively of the merits of early postoperative ambulation and know it is for their own welfare, they are usually willing to cooperate.

Complications of Gastric Surgery for Obesity

Current gastric procedures for obesity include open and laparoscopic gastric bypass (GBP), gastroplasty, and laparoscopic adjustable gastric banding. The procedures themselves are described in more detail elsewhere [see 5:19 **Bariatric Procedures**]; the following are some of the main complications associated with any abdominal operation in a severely obese patient.

ABDOMINAL CATASTROPHE

It may be very difficult to recognize an abdominal catastrophe in patients who are very young, very old, or morbidly obese or who are receiving high doses of steroids. The obese patient, for example, may present in the emergency room with a perforated duodenal ulcer or a ruptured diverticulum, complaining of abdominal pain, and yet on abdominal examination have no evidence of peritoneal irritation (no guarding, tenderness, or rigidity). This situation has been well documented in patients in whom an anastomotic or gastric leak has developed after operation for morbid obesity.⁹ Symptoms include shoulder pain, pelvic or scrotal pain, back pain, tenesmus, urinary frequency, and, of great importance, marked anxiety. Signs of infection (e.g., fever, tachypnea, and tachycardia) may be absent, though tachycardia is often the first sign of a significant problem. Patients with peritonitis often have clinical symptoms and signs suggesting a massive pulmonary embolus: severe tachypnea, tachycardia, and sudden hypotension. Such acute pulmonary failure is probably secondary to sepsis-induced acute respiratory dis-

stress syndrome (ARDS). Thus, peritonitis must be suspected in any morbidly obese patient with acute respiratory failure. Patients who have undergone a laparoscopic bariatric procedure may be reexplored without much difficulty if there is concern about a possible leak.

Because a high index of suspicion of peritonitis is required to detect the condition in morbidly obese patients, radiographic contrast studies with water-soluble agents such as diatrizoate meglumine (Gastrografin) may be indicated even when there are few clinical signs. If a perforated viscus is suspected, an exploratory laparotomy may be necessary despite normal findings on radiographic contrast study.

INTERNAL HERNIA

GBP places patients at risk for internal hernia with a closed-loop obstruction, leading to bowel strangulation. There are three potential locations for these internal hernias: the Roux-en-Y anastomosis; the opening in the transverse mesocolon through which the retrocolic Roux limb is brought; and the Petersen hernia, which is located behind the retrocolic Roux limb. The primary symptom of an internal hernia is periumbilical pain, usually in the form of cramping consistent with visceral colic. These internal hernias may be very difficult to diagnose. Upper gastrointestinal radiographic series and abdominal CT scans are often normal, providing a false sense of security. The resulting assumption that no problem exists may be devastating for the patient should bowel infarction occur as a consequence of closed-loop obstruction. One should always carefully inspect the plain abdominal radiograph for the abnormal placement or spreading of the Roux-en-Y anastomotic staples. The safest course of action in patients with recurrent attacks of cramping periumbilical pain is abdominal surgical exploration. The frequency of this complication seems to have increased with the advent of laparoscopic GBP, presumably because of the difficulty of closing the potential hernia spaces completely. Some attribute the problem to the decreased tendency toward adhesion formation after laparoscopic surgery.

ACUTE GASTRIC DISTENTION

After GBP, massive gaseous distention occasionally develops in the distal bypassed stomach; this can lead to a gastric perforation or disruption of the gastrojejunostomy. The primary symptoms of this complication are hiccups and a bloated feeling. Massive gastric dilatation can lead to severe left shoulder pain and shock. The problem is usually secondary to edema at the Roux-en-Y anastomosis but can also be secondary to a mechanical problem. The diagnosis is made by means of an urgent upright abdominal radiograph, which reveals the markedly dilated and air-filled bypassed stomach. Occasionally, the stomach is filled with fluid, and the diagnosis may be more difficult. In those few cases in which the dilatation is primarily caused by air, the problem can be relieved by percutaneous transabdominal skinny-needle decompression with subsequent passage of gas and gastric and biliopancreatic juices through the Roux-en-Y anastomosis. Should the dilatation recur or the patient be in serious difficulty, an emergency laparotomy with insertion of a gastrostomy tube should be performed and the jejunostomy evaluated. If a patient has extensive adhesions from previous abdominal surgery, a gastrostomy tube should be inserted at the time of GBP to prevent gastric dilatation.

Diabetes Mellitus

Type 2 (non-insulin-dependent) diabetes mellitus, a nonketotic form of diabetes that is usually noted after age 40, is markedly ex-

acerbated by obesity. Patients with this type of diabetes often require large amounts of insulin for blood glucose control because of a significant reduction in insulin receptors. It is not unusual, however, to note a complete absence of the requirement for insulin in the immediate postoperative period in morbidly obese patients. Therefore, insulin should be withheld on the morning of operation. There is often a marked reduction in the requirement for insulin throughout the postoperative period and even at discharge in morbidly obese patients who have undergone GBP, probably because of increased release of gastric inhibitory peptide (GIP) from the proximal small bowel. Therefore, regular subcutaneous insulin should be administered to GBP patients according to a sliding scale after operation until insulin requirements can be determined. Before discharge, the patient should be taking an appropriate dose of neutral protamine Hagedorn (NPH) or Lente insulin but must perform frequent finger-stick blood glucose determinations afterward, given that the need for insulin will decrease progressively with weight loss.

In one study of 23 patients with diabetes mellitus who underwent gastric bariatric operation, the average requirement for insulin decreased from 74 units/day before operation to 8 units/day after operation.¹⁰ Fourteen of the 23 patients were able to discontinue insulin completely, 11 by the time of discharge from the hospital 1 week after operation. These benefits were maintained during long-term follow-up to 39 months and were a result of a major decrease in insulin resistance that was associated with decreased food intake as well as weight loss.

Wound Care

Morbidly obese patients have been reported to have an increased risk of wound infection and dehiscence. However, the incidence of these complications in this group of patients can be very low. In a randomized, prospective trial comparing a running, continuous absorbable No. 2 polyglycolic acid suture with a No. 28 stainless-steel wire in morbidly obese patients who weighed an average of 320 lb, there was no significant difference in complications, including the incidence of incisional hernia, between the types of closure.¹¹ However, the running absorbable suture closure required significantly less time. Similar results comparing continuous with interrupted sutures have been noted by others.¹² Subcutaneous sutures should not be used, because the subcutaneous fat becomes reapproximated during skin closure, and subcutaneous sutures have been found to increase the risk of wound infection.¹³ Obese patients undergoing clean-contaminated intestinal procedures should be given a parenteral antibiotic immediately before the operation and for only 24 hours after the operation¹⁴; it is important to note that morbidly obese patients should receive a double dose of prophylactic antibiotics because of the increased volume of distribution. If a gastric or gallbladder operation is planned, only aerobic bacterial coverage is necessary; a colon operation will necessitate anaerobic coverage as well.

It has been our experience that the incidence of incisional hernia is much higher in morbidly obese patients than in thin patients with ulcerative colitis who are taking large doses of corticosteroids and who undergo the same fascial wound closure with running No. 2 polyglycolic acid sutures.¹⁵ This increased risk in morbidly

obese patients is probably secondary to the increased intra-abdominal pressures (IAP) present in patients with central, or android, obesity.¹⁶

Obese diabetic patients are at risk for rapidly spreading panniculitis secondary to mixed aerobic and anaerobic organisms.¹⁷ Subcutaneous gas and extensive necrosis, which usually does not involve the underlying muscle, are often present. It is uncommon to culture clostridia from these wounds. Even after extensive and repeated debridement, mortality remains high [*see 3:2 Soft Tissue Infection*].

Other Obesity-Related Diseases

GALLSTONES

Approximately one third of morbidly obese patients either have had a cholecystectomy or may have had gallstones noted at the time of another intra-abdominal operative procedure, such as gastric operation for morbid obesity. Preoperative evaluation of the gallbladder may be technically quite difficult in morbidly obese patients because gallstones may be missed with either ultrasonography or oral cholecystography. Intraoperative sonography is probably much more accurate. Should stones be present in a patient undergoing gastric operation for obesity, the gallbladder should be removed. In the past, obese patients with intermittent attacks of biliary colic were told to lose weight before an elective cholecystectomy for fear of significant morbidity and mortality from an elective operation. This attitude is no longer valid, because among the large numbers of obese patients who now undergo major elective abdominal procedures, morbidity is similar to that seen in thin patients if appropriate precautions are taken. Furthermore, obese patients have great difficulty losing large amounts of weight by diet alone and should be allowed to undergo definitive corrective operative procedures before weight reduction.

Rapid weight loss may lead to the development of gallstones in 25% to 40% of patients who undergo GBP. The risk of cholelithiasis in this setting can be reduced to 2% by administering ursodeoxycholic acid, 300 mg orally twice daily.¹⁸

PSEUDOTUMOR CEREBRI

Pseudotumor cerebri is an unusual complication of morbid obesity that is associated with benign intracranial hypertension, papilledema, blurred vision, headache, and elevated cerebrospinal fluid pressures.¹⁹ It has been our experience that patients with pseudotumor cerebri are not at any additional perioperative risk and that cerebrospinal fluid does not have to be removed before anesthesia and major abdominal operation. Weight reduction will cure pseudotumor cerebri.^{20,21}

DEGENERATIVE OSTEOARTHRITIS

Degenerative osteoarthritis of the knees, hips, and back is a common complication of morbid obesity. Weight reduction alone may greatly reduce the pain and immobility that afflict these patients, although the damage may be so extensive that a total joint replacement may be desirable. However, joint replacement in patients who weigh more than 250 lb is associated with an unacceptable incidence of loosening.²² Weight reduction by means of a gastric bariatric operation may be the most sensible initial approach, to be followed by joint replacement after weight loss if pain and dysfunction persist.

Discussion

Morbidity Associated with Central Fat Deposition

Much has been written about the increased health risks inherent in central, or android, fat deposition as compared with peripheral, or gynoid, fat deposition. It is thought that in the former, the increased metabolic activity of mesenteric fat is associated with increased metabolism of amino acids to sugar, which leads to hyperglycemia and hyperinsulinism. Hyperinsulinism gives rise to increased sodium absorption and hypertension. Furthermore, central obesity has been linked to hypercholesterolemia. Hence, these patients have a significantly higher incidence of diabetes, hypertension, hypercholesterolemia, and gallstones²³—which explains the higher mortality of the apple distribution of body fat as compared with the pear distribution. In the past, fat distribution was measured on the basis of the waist-to-hip ratio; however, computed tomography scans have shown that abdominal circumference is a more accurate measurement of central fat distribution.²⁴ We have found that morbidly obese women have significantly increased IAP and that this is associated with stress and urge overflow urinary incontinence.²⁵ With weight loss comes a significant decrease in bladder pressure and correction of incontinence. We have found IAP, as reflected in bladder pressure, to be closely correlated with sagittal abdominal diameter and waist circumference but not with waist-to-hip ratio (many morbidly obese patients have both central and peripheral obesity). We have also found that the increased IAP associated with central obesity may cause additional comorbid factors, including venous stasis ulcers, OHS, gastroesophageal reflux, and inguinal and incisional hernias.

Respiratory Insufficiency of Obesity

Obese patients are at risk for respiratory difficulties, which may be present before operation or may be exacerbated by an operation. The term pickwickian syndrome (which derives from *The Posthumous Papers of the Pickwick Club*, by Charles Dickens) was resurrected from the late 1800s to describe a morbidly obese man 52 years of age who fell asleep in a poker game while holding a hand containing a full house.² He was taken to the hospital by friends who presumed he was ill. The pickwickian syndrome is now known to comprise two pulmonary syndromes associated with morbid obesity: obstructive SAS and OHS.³

Patients with SAS suffer from repeated attacks of upper airway obstruction during sleep. The cause is probably related to a large, fat tongue as well as to excessive fat deposition in the uvula, pharynx, and hypopharynx. The normal genioglossus reflex is depressed, but this depression may be secondary to the excessive weight of the tongue. These patients are notorious snorers. As a result of inadequate stage IV and rapid eye movement (REM) sleep, they are markedly somnolent during the day.

Patients with SAS are at great risk for acute upper airway obstruction and respiratory arrest after operation and general anesthesia. A high index of suspicion is necessary before operation. Patients with severe SAS often have ventricular arrhythmias and sinus arrest during their apneic episodes, thereby placing them at even greater risk. A history of heavy snoring, early morning headaches, frequent awakening at night with shortness of breath, severe daytime somnolence (including falling asleep at the wheel), and frequent headaches should prompt further study. The syndrome is confirmed by sleep polysomnography, which is available at sleep centers in most major cities.

In most instances, severe SAS can be treated with nocturnal nasal CPAP. With this technique, air flowing through a nasal mask

against a constant airway resistance enters the nasal pharynx and pushes the tongue forward to prevent recurrent obstruction.²⁶ The pressure can be adjusted for each patient. Unfortunately, many patients cannot tolerate the device, because it is cumbersome and noisy and tends to dry out the upper airway, although dryness can be prevented with an inexpensive room humidifier. If nasal CPAP cannot be tolerated by the patient, or if it is ineffective and the problem is severe (i.e., causing cardiac arrhythmias or severe hypoxia), tracheostomy is indicated. This procedure can be very difficult and dangerous and therefore should not be relegated to the youngest house officer in a surgical residency program. Because of the extremely deep neck in obese patients, a standard tracheostomy tube is usually inadequate, and a special tube with a deep bend should be used.

OHS is a condition associated with morbid obesity in which an individual suffers from hypoxemia and hypercapnia when breathing room air while awake but resting.²⁷ Spirometry reveals decreases in forced vital capacity, residual lung volume, expiratory reserve volume, functional residual capacity, and maximum minute volume ventilation, usually without obstruction to airflow [see Figure 1]. The most profound decrease is that in expiratory reserve volume; it is probably secondary to increased intra-abdominal pressure and a high-riding diaphragm. Thus, these patients have a restrictive rather than an obstructive pulmonary disease. The decreased expiratory reserve volume implies that many alveolar units are collapsed at end-expiration, which leads to perfusion of unventilated alveoli, or shunting. Patients with OHS often are heavy smokers or have additional pulmonary problems, such as asthma, sarcoidosis, idiopathic pulmonary fibrosis, or recurrent pulmonary emboli. One study of patients who underwent operation for morbid obesity showed no statistically significant difference in weight between those who had OHS and those who did not.³

As a result of chronic and severe hypoxemia, patients with OHS are often markedly polycythemic. The polycythemia further increases their already significant risk for venous thrombosis and pulmonary embolism. Because we have had several patients who later had a subclavian venous thrombosis and one patient who probably had a transient sagittal sinus thrombosis, patients with OHS should probably undergo phlebotomy to a hemoglobin concentration of 15 g/dl before elective operation.

Chronic hypoxemia also leads to pulmonary arterial vasoconstriction and severe pulmonary hypertension^{1,28} and eventually to

* $P < 0.01$ Compared with Preoperative Values

Figure 1 Impaired pulmonary function in the morbidly obese improved significantly after weight loss induced by gastric operation.³

right-sided heart failure or cor pulmonale with neck vein distention, tricuspid valvular insufficiency, right upper quadrant tenderness secondary to acute hepatic engorgement, and massive peripheral edema. Such patients may also have significantly elevated PAWP, which suggests left ventricular dysfunction.¹ Morbidly obese patients with a history of pulmonary disease or a BMI higher than 50 kg/m² should have preoperative determinations of blood gas values. If ABG measurement reveals severe hypoxemia (i.e., P_aO₂ ≤ 55 mm Hg), severe hypercapnia (P_aCO₂ ≥ 47 mm Hg), or both, the patient should undergo Swan-Ganz catheterization. If PAWP is 18 mm Hg or greater, intravenous furosemide should be administered for diuresis before elective operation. However, some patients may require a high ventricular filling pressure. A low cardiac output and hypotension may follow diuresis, necessitating volume reexpansion. If mean PAP is 40 mm Hg or greater, consideration should be given to the prophylactic insertion of a Greenfield inferior vena caval filter [see Thrombophlebitis, Venous Stasis Ulcers, and Pulmonary Embolism in the Morbidly Obese Patient, below].

It is highly probable that some of the elevated PAP and PAWP measurements are caused by the increased IAP in the morbidly obese [see Figure 2].^{16,29} This leads to an elevated diaphragm, which in turn increases intrapleural pressure and thereby PAP and PAWP; if the pleural pressure is measured with an esophageal transducer, the transmural pressure can be estimated. For this reason, these patients may require a markedly elevated PAWP to maintain an adequate cardiac output, and excessive diuresis may lead to hypotension. The same reasoning may be applied to a patient with a distended abdomen resulting from peritonitis and pancreatitis in whom what seem to be unusually high cardiac filling pressures are necessary. Therefore, one must rely on relative changes in cardiac output in response to either volume challenge or diuresis to determine the optimal PAWP in morbidly obese patients.

Patients with OHS respond rapidly to supplemental oxygen. However, oxygen administration is occasionally associated with significant CO₂ retention, which necessitates intubation and mechanical ventilation. Because their pulmonary disease is restrictive rather than obstructive, these patients are usually easy to ventilate without high peak airway pressures. Arterial blood gases need not return to normal before extubation; it is only necessary that they return to their preoperative values. These values are achieved, on average, 4 days after major upper abdominal operation, when the patients no longer have abdominal pain.³

It is important to emphasize that morbidly obese patients, especially those with respiratory insufficiency, should be placed in the reverse Trendelenburg's position to maximize diaphragmatic excursion and to increase residual lung volume.⁸ These patients will often complain of air hunger and respiratory distress when they lie supine. So-called breaking of the bed at the waist may exacerbate the problem by pushing the abdominal contents into the chest, thereby raising the diaphragm and further reducing lung volumes. Placing these patients in the leg-down position may predispose them to venous stasis, phlebitis, and pulmonary embolism, which should be offset with intermittent venous compression boots [see Thrombophlebitis, Venous Stasis Ulcers, and Pulmonary Embolism in the Morbidly Obese Patient, below].³⁰

Both SAS and OHS can be completely corrected with weight reduction after gastric operation for morbid obesity: the nocturnal apneas resolve, the P_aO₂ rises, and the P_aCO₂ falls to normal as lung volumes improve.³

Cardiac Dysfunction in the Morbidly Obese Patient

Cardiac dysfunction in the morbidly obese patient is usually as-

Figure 2 In a porcine model,²⁹ raising IAP caused cardiac index to fall and PAWP to rise. At an IAP of 25 mm Hg, saline was given to restore intravascular volume; cardiac index returned to baseline levels, but PAWP remained elevated. (IAP—intra-abdominal pressure; PAWP—pulmonary arterial wedge pressure)

sociated with respiratory insufficiency of obesity, especially OHS.² Elevated PAP in these patients may be secondary to hypoxemia-induced pulmonary arterial vasoconstriction, to elevated left atrial pressures secondary to left ventricular dysfunction, or to a combination of these; they may also be secondary to the increased pleural pressures arising from an elevated diaphragm secondary to increased IAP.^{1,29,30} It is unusual for morbidly obese patients without respiratory insufficiency to experience significant cardiac dysfunction in the absence of severe coronary artery disease. Morbidly obese patients often have systemic hypertension, which can aggravate left ventricular dysfunction; however, mild left ventricular dysfunction can be documented in many morbidly obese patients in the absence of systemic hypertension.^{31,32} Circulating blood volume, plasma volume, and cardiac output increase in proportion to body weight.³² Massively obese patients may occasionally present with acute heart failure: it is reasonable to assume that the enormous metabolic requirements of such patients can present a greater

Figure 3 Mean pulmonary arterial pressure was significantly improved in 18 patients 3 to 9 months after gastric surgery—induced weight loss of 42% ± 19% of excess weight.¹

demand for blood flow than the heart can provide. Vigorous diuresis will often correct such acute heart failure. Significant weight loss will correct pulmonary hypertension [see Figure 3] as well as left ventricular dysfunction associated with respiratory insufficiency.^{1,33}

Thrombophlebitis, Venous Stasis Ulcers, and Pulmonary Embolism in the Morbidly Obese Patient

Morbidly obese individuals have difficulty walking; tend to be sedentary; have a large amount of abdominal weight resting on their inferior vena cava; and have increased intrapleural pressure, which impedes venous return.^{28,29} All of these conditions increase the tendency toward phlebothrombosis. Patients are most at risk when immobilized in the supine position for long periods in the OR. These patients have also been shown to have low levels of antithrombin, which may increase their tendency toward venous thrombosis.³⁴ It has also been suggested that starvation, particularly in the postoperative period, may be associated with high levels of free fatty acids, which may predispose to perioperative thrombotic complications.³⁵

Intermittent venous compression boots have been shown in randomized trials to reduce the incidence of deep vein thrombosis.³⁰ Administration of low-dose subcutaneous heparin must be started immediately before operation. However, because morbidly obese patients show a significant improvement in pulmonary function when placed in the reverse Trendelenburg position,⁸ and because this position further increases venous pressure in the legs and the tendency toward stasis, it is preferable to use this position and intermittent venous compression boots. All patients, but especially the morbidly obese, should make every attempt to walk during the evening after operation.

Because pulmonary embolism is quite unusual when the appropriate precautions have been taken, acute air hunger, tachypnea, and hypoxemia should suggest the equal likelihood that sepsis-induced ARDS is present secondary to an intra-abdominal anastomotic leak.

Patients with severe OHS often have noticeably elevated PAP, which can lead to right-sided heart failure and can increase the risk of venous stasis and thrombosis. Investigators have noted that patients with primary idiopathic pulmonary hypertension are at significant risk for fatal PE.⁵ For this reason, it has been our policy to place a prophylactic Greenfield vena caval filter in patients with respiratory insufficiency of obesity and a mean PAP of 40 mm Hg or greater. With this approach (in which a vena caval filter was used in 15 patients), we have had one fatal pulmonary embolus in 156 patients with respiratory insufficiency of obesity who have undergone gastric bariatric procedures. The fatality was a patient whose mean PAP was initially 40 mm Hg but fell to 35 mm Hg with diuresis and who was not considered to require a filter.

Venous stasis ulcers can be quite difficult to treat in a thin individual; they are almost impossible to cure in a patient with morbid obesity [see Figure 4]. The most important goal in management of these ulcers is weight loss, which almost invariably leads to healing of the ulcer, probably as a result of decreased IAP.⁷ Patients with venous stasis ulcers also are at high risk for fatal PE and should be considered for prophylactic placement of a vena caval filter.

Pseudotumor Cerebri in the Morbidly Obese Patient

Pseudotumor cerebri (also known as idiopathic intracranial hypertension) associated with obesity is almost certainly secondary to increased IAP. The rise in IAP causes a rise in intrathoracic pressure, which in turn raises central venous pressure and PAWP [see Figure 2], thus decreasing venous drainage from the brain.²⁹ This se-

Figure 4 This chronic venous stasis ulcer was present for several years in a morbidly obese patient. Healing promptly followed weight loss induced by a gastric operation.

quence of events has been reproduced in a porcine model.³⁶ The elevated intracranial pressure (ICP) can be prevented by means of median sternotomy and pleuropericardiectomy [see Figure 5].³⁷ In humans studied 3 years after weight-reduction surgery, surgically induced weight loss was associated with a significant decrease in ICP (from 353 ± 35 mm H₂O to 168 ± 12 mm H₂O; $P < 0.001$) and with relief of headache and pulsatile tinnitus.^{20,21}

Conclusion

Although the morbidly obese patient is potentially at risk for significant perioperative morbidity and mortality, attention to detail in preoperative preparation as well as in postoperative management

Figure 5 In a porcine model,³⁷ IAP was increased to 25 mm Hg in 12 animals, of which three underwent median sternotomy and pleuropericardiectomy (red line) and nine did not (black line). Sternotomy and pleuropericardiectomy prevented the expected increase in ICP. (ICP—intracranial pressure)

should reduce this risk almost to that of the general population. A high index of suspicion for peritonitis must be maintained after an intra-abdominal procedure or when the patient complains of abdominal pain in the emergency room. Awareness of the problems associated with respiratory insufficiency in obese patients should enable the surgeon to avoid pitfalls when managing the patient with obstructive SAS or OHS. These patients may require preoperative pulmonary arterial catheterization for optimal fluid management before and after operation. The risks of venous thrombosis and PE are high, but the use of intermittent compression boots and early ambulation can minimize the dangers. The obese patient with non-insulin-dependent diabetes has been surprisingly easy to manage after major operation.

Weight reduction by diet is associated with a 95% incidence of recidivism. The average morbidly obese patient can be expected to

lose two thirds of the excess weight within 1 year after a standard GBP or, if superobese, after a long-limb gastric bypass. Furthermore, recent reports note that this weight loss is long-lasting and averages 60% of excess weight at 5 years and more than 50% of excess weight up to 10 years after operation. This weight loss is associated with the correction of insulin-dependent diabetes, obstructive SAS, OHS, pseudotumor cerebri, hypertension, chronic venous stasis ulcers, stress incontinence, gastroesophageal reflux, and female sex hormone abnormalities, which may be related to dysmenorrhea, infertility, hirsutism, and an increased risk of endometrial carcinoma. Weight loss can markedly improve the patient's self-image and employability. Because techniques for operation for morbid obesity continue to change as understanding of pathophysiology improves, it is important for surgeons to keep abreast of the latest developments.

Gastric Adenocarcinoma

The incidence of gastric carcinoma exhibits significant geographic variability. The disease is most common in Japan and China, and high rates of occurrence have also been reported in Central and South America, Eastern Europe, and parts of the Middle East.¹ In most of the more developed nations, however, gastric carcinoma is relatively uncommon. The overall incidence of this condition has decreased in the past few decades, but gastric carcinoma remains the second leading cause of cancer death worldwide. The reported reductions in gastric cancer mortality may be linked to better refrigeration and a concomitant decrease in the intake of salted, pickled, smoked, and chemically preserved foods; however, this link remains controversial. An inverse association with the consumption of fresh fruits and vegetables has also been noted.²

Gastric cancer occurs 1.5 to 2.5 times more frequently in males than in females. It is rarely diagnosed before the age of 40, and its incidence peaks in the seventh decade of life. African Americans, Hispanic Americans, and Native Americans are two times more likely to have gastric cancer than white Americans are.³

In the United States in particular, the incidence of stomach cancer has fallen substantially over the past 70 years.⁴ Whereas this disease was once a leading cause of cancer-related death in the United States, it now ranks 13th among major causes. Unfortunately, the decline in incidence has not translated into an improvement in the 5-year survival rate.⁵ Across all races, the 5-year relative survival was 23% for the period extending from 1992 to 1999.³ This result is probably related to the advanced stage at which most patients present. A 1995 study from the Commission on Cancer of the American College of Surgeons (ACS) found that 66% of patients with gastric cancer presented with locally advanced or metastatic disease.⁶ Resection rates ranged from 30% to 50%, and 5-year survival rates after resection with curative intent were directly related to stage at presentation. For stage I disease, the survival rate was 43%; for stage II, 37%; for stage III, 18%; and for stage IV, 20%.

Another relevant change in the epidemiology of gastric cancer is a shift in the distribution of primary lesion sites within the stomach. In the first quarter of the 20th century, two thirds of gastric cancers were located in the antrum and the prepyloric area, and only 10% arose in the cardia or the esophagogastric junction. Since the 1970s, however, adenocarcinoma of the proximal stomach has become increasingly common. In one study, the incidence of adenocarcinoma of the gastric cardia rose from 29.1% to 52.2% in the period between 1984 and 1993.⁷ In another, which included 18,365 gastric cancer patients from ACS-approved hospitals, a full 31% of tumors were found to be in the proximal stomach, compared with only 26% in the distal third.⁸ In the United States, carcinoma of the cardia occurs primarily in whites, with a male-to-female ratio of approximately 2:1. Cancer of the cardia appears to be distinct from adenocarcinoma of the distal esophagus, which frequently arises in the setting of Barrett's esophagus.⁹ Associations have also been

reported between cancer of the gastric cardia and infection with *Helicobacter pylori* or Epstein-Barr virus.^{10,11}

CLASSIFICATION

Adenocarcinoma of the stomach may be divided into two histologic subtypes, intestinal and diffuse.¹² Each subtype has unique pathologic, epidemiologic, etiologic, and prognostic features. The intestinal (or glandular) subtype usually arises in the distal stomach (often after a long precancerous phase), is more common in elderly patients, and has been closely associated with atrophic gastritis and diets high in nitrates and nitroso compounds.¹³ The characteristic histologic finding is cohesive neoplastic cells that form glandlike tubular structures. The diffuse subtype occurs more frequently in younger patients and has no identifiable precursor lesion. It may develop in any part of the stomach but shows a predilection for the cardia. Cell cohesion is absent; thus, individual cancer cells infiltrate and thicken the stomach wall without forming a discrete ulcer or mass.

In general, the prognosis for the diffuse subtype is worse than that for the intestinal subtype. Whereas intestinal lesions are seen more frequently in regions with a high incidence of gastric cancer, the incidence of diffuse lesions is constant among various populations throughout the world.¹⁴ Accordingly, the overall decline in gastric cancer over the past century has been attributed to a decline in intestinal lesions and to a decline in the incidence of *H. pylori* infection (see below).

RISK FACTORS

Historical studies of specimens obtained during operation or at autopsy suggest that gastric carcinoma, especially of the intestinal subtype, frequently develops in the presence of chronic atrophic gastritis and associated intestinal metaplasia. It has generally been assumed that adenocarcinoma of the distal stomach progresses from chronic gastritis to metaplasia through the teratogenic influence of environmental factors. The most commonly studied environmental factors are the nitrates and nitroso compounds present in high levels in salted, smoked, or pickled foods consumed in areas where gastric cancer is endemic.¹⁵ To date, however, no prospective studies have conclusively demonstrated that modern refrigeration practices and the subsequent decline in the salting, smoking, and pickling of food have been responsible for the relative decline in intestinal gastric cancer. Furthermore, the intestinal subtype may arise in the absence of metaplasia. Finally, the emergence of chronic infection with *H. pylori* as the dominant risk factor for gastric adenocarcinoma has challenged the paradigm of the atrophic gastritis–intestinal metaplasia–gastric cancer sequence.

Epidemiologic studies across various populations worldwide have consistently demonstrated a strong association between *H. pylori* infection and gastric cancer.¹⁶ Prospective serologic studies have confirmed that persons with evidence of such infection are three to six times more likely to have gastric cancer than persons

Table 1 American Joint Committee of Cancer TNM Clinical Classification of Gastric Carcinoma

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ: intraepithelial tumor without invasion of lamina propria
	T1	Tumor invades lamina propria or submucosa
	T2	Tumor invades muscularis propria or subserosa
		T2a: tumor invades muscularis propria
		T2b: tumor invades subserosa
Regional lymph nodes (N)	T3	Tumor penetrates serosa (visceral peritoneum) without invasion of adjacent structures
	T4	Tumor invades adjacent structures
	NX	Regional lymph node(s) cannot be assessed
Distant metastasis (M)	N0	No regional lymph node metastasis
	N1	Metastasis in 1–6 regional lymph nodes
	N2	Metastasis in 7–15 regional lymph nodes
	N3	Metastasis in > 15 regional lymph nodes
Distant metastasis (M)	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis

who are seronegative.¹⁷ Still, only a very small fraction of infected persons have gastric cancer. It has been estimated that more than half of the world's inhabitants may be infected with *H. pylori*—a number that dwarfs the actual incidence of gastric cancer. What is clear is that *H. pylori* infection of the gastric mucosa leads to a state of chronic active inflammation that lasts for decades. This inflammatory process appears to be modulated by multiple forces, including genetic and environmental factors.¹⁸ Inherited traits may confer susceptibility or resistance to carcinogenesis. Indeed, first-degree relatives of gastric cancer patients have a two to three times higher relative risk of contracting the disease.¹⁹ Gastric irritants may act as promoters, and antioxidants may have a protective effect (which may be part of the reason for the reduced risk of gastric cancer associated with diets rich in fruits and vegetables).²⁰

Unlike intestinal cancers, diffuse cancers appear not to be associated with *H. pylori* infection. Diffuse adenocarcinoma of the stomach is more common in young patients and has no known precursor lesion.⁹ The incidence of genetically associated diffuse cancers is estimated to be in the range of 5% to 10%.¹⁹ Familial cases of diffuse gastric cancer occur at an average age of 38 years and are inherited in an autosomal dominant fashion with 70% penetrance.²¹ Patients with blood group A have a 16% to 20% increased risk of gastric cancer.²²

CLINICAL EVALUATION

In high-risk areas (e.g., Japan), mass screening programs have been successful in identifying early gastric cancer, which is generally amenable to surgical cure.²³ In fact, in some Japanese studies, as many as 40% of newly diagnosed patients had early gastric cancer. Unfortunately, in Western countries, the disease is almost always diagnosed relatively late, when it is locally advanced or metastatic. When it is superficial, gastric cancer typically produces no symptoms. As it progresses, however, a constellation of vague, nonspecific symptoms may develop, including anorexia, fatigue, weight loss, and epigastric discomfort. Dysphagia, early satiety, vomiting, and hematemesis also are seen, albeit rarely; when present, they often indicate advanced disease. Indeed, early gastric cancer has no characteristic physical findings, and many patients are not diagnosed until they present with jaundice, ascites, or a palpable mass, all of which signal incurable disease.

INVESTIGATIVE STUDIES

Until comparatively recently, an upper gastrointestinal series was often the first diagnostic test ordered to evaluate symptoms related to the upper GI tract. However, even with double-contrast techniques, which allow improved visualization of mucosal detail, false negative rates as high as 25% were reported, especially with small lesions (i.e., 5 to 10 mm).²⁴ Accordingly, in most large series, fiberoptic endoscopy with biopsy has replaced contrast radiography as the primary diagnostic technique.²⁵ Upper GI endoscopy with biopsy has been reported to have a diagnostic accuracy of 95%.²⁰ However, false negatives have been reported, especially in the context of inadequate biopsies. Thus, it is recommended that at least four biopsy specimens taken from the region of any atypical findings.²⁶

STAGING

Two major classification systems are available for staging gastric cancer. The first is the one used in Japan, where gastric cancer is staged according to the general rules for gastric study in surgery and pathology published by the Japanese Research Society for Gastric Cancer (JRS GC).²⁷ This elaborate system focuses on the anatomic involvement of specifically numbered lymph node stations. The second system is the one generally used in Western countries—namely, the familiar tumor-node-metastasis (TNM) system developed by the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (UICC) [see Tables 1 and 2].²⁸ The AJCC/UICC staging system is based on a gastric cancer database and classifies lesions according to the depth to which the primary tumor penetrates the gastric wall, the extent of lymph node involvement, and the presence or absence of distant metastases.

The primary goal in the evaluation of gastric cancer patients is to stratify them into two clinical stage groups: those with locoregional disease (AJCC stages I to III) and those with systemic disease (AJCC stage IV).²⁹ The National Comprehensive Cancer Network (NCCN) has developed consensus guidelines for the clinical evaluation and staging of patients with possible gastric cancer. These guidelines are accessible to any practitioner via

Figure 1 Shown are CT scans of a patient with a T3 carcinoma involving the posterior wall of the gastric antrum, taken with the patient supine (*a*) and prone (*b*). By placing the patient in the prone position and distending the stomach with water, better definition of the extent of the tumor and clearer delineation of the interface between the stomach and the pancreas is achieved.

the Internet (http://www.nccn.org/professionals/physician_gls/PDF/gastric.pdf) and are updated annually. Multidisciplinary evaluation is recommended for all patients. A careful history is obtained and a thorough physical examination performed, with special attention paid to comorbid conditions that might preclude operative intervention. Initial laboratory studies include a complete blood cell count with a platelet count; determination of serum electrolyte, blood urea nitrogen, creatinine, and glucose concentrations; and a liver function panel. Chest radiography is performed, along with computed tomography of the abdomen and pelvis.

Whereas CT is invaluable for detecting ascites, bulky adenopathy, and significant visceral metastases, its overall accuracy in staging tumors is modest: only 70% for advanced lesions and 44% for early lesions.³⁰ CT assesses lymph node involvement primarily on the basis of node size. Thus, its sensitivity for N1 and N2 disease is low, ranging from 24% to 43%; however, its specificity is high, approaching 100%. Technical advances, such as spiral (helical)

CT with intravenous contrast plus appropriate gastric distention with 600 to 800 ml of water (a negative contrast agent), have allowed modest improvements in overall staging with CT [see *Figure 1*]. Nevertheless, CT is still limited in its ability to evaluate peritoneal disease and liver metastases smaller than 5 mm.³¹

Given the limitations of CT, we believe that in the absence of obvious metastatic disease, locoregional staging with endoscopic ultrasonography (EUS) is vital for accurately assessing tumor penetration through the gastric wall (T stage) and ascertaining whether regional nodes (N stage) or even mediastinal or para-aortic lymph nodes may be involved (which would be considered M1 disease) [see *Figure 2*]. EUS is unique among imaging modalities in its ability to image the gastric wall as a five-layer structure, with each layer correlating with an actual histologic layer.³² The overall accuracy of EUS in determining the extent of infiltration ranges from 67% to 92%.³³ EUS features that suggest lymph node metastasis include a rounded shape, hypoechoic patterns, and a

Figure 2 (*a*) Shown is an EUS image of a T3 gastric neoplasm. (*b*) EUS reveals the presence of suspicious perigastric (N1) nodes, later confirmed as malignant at operation.

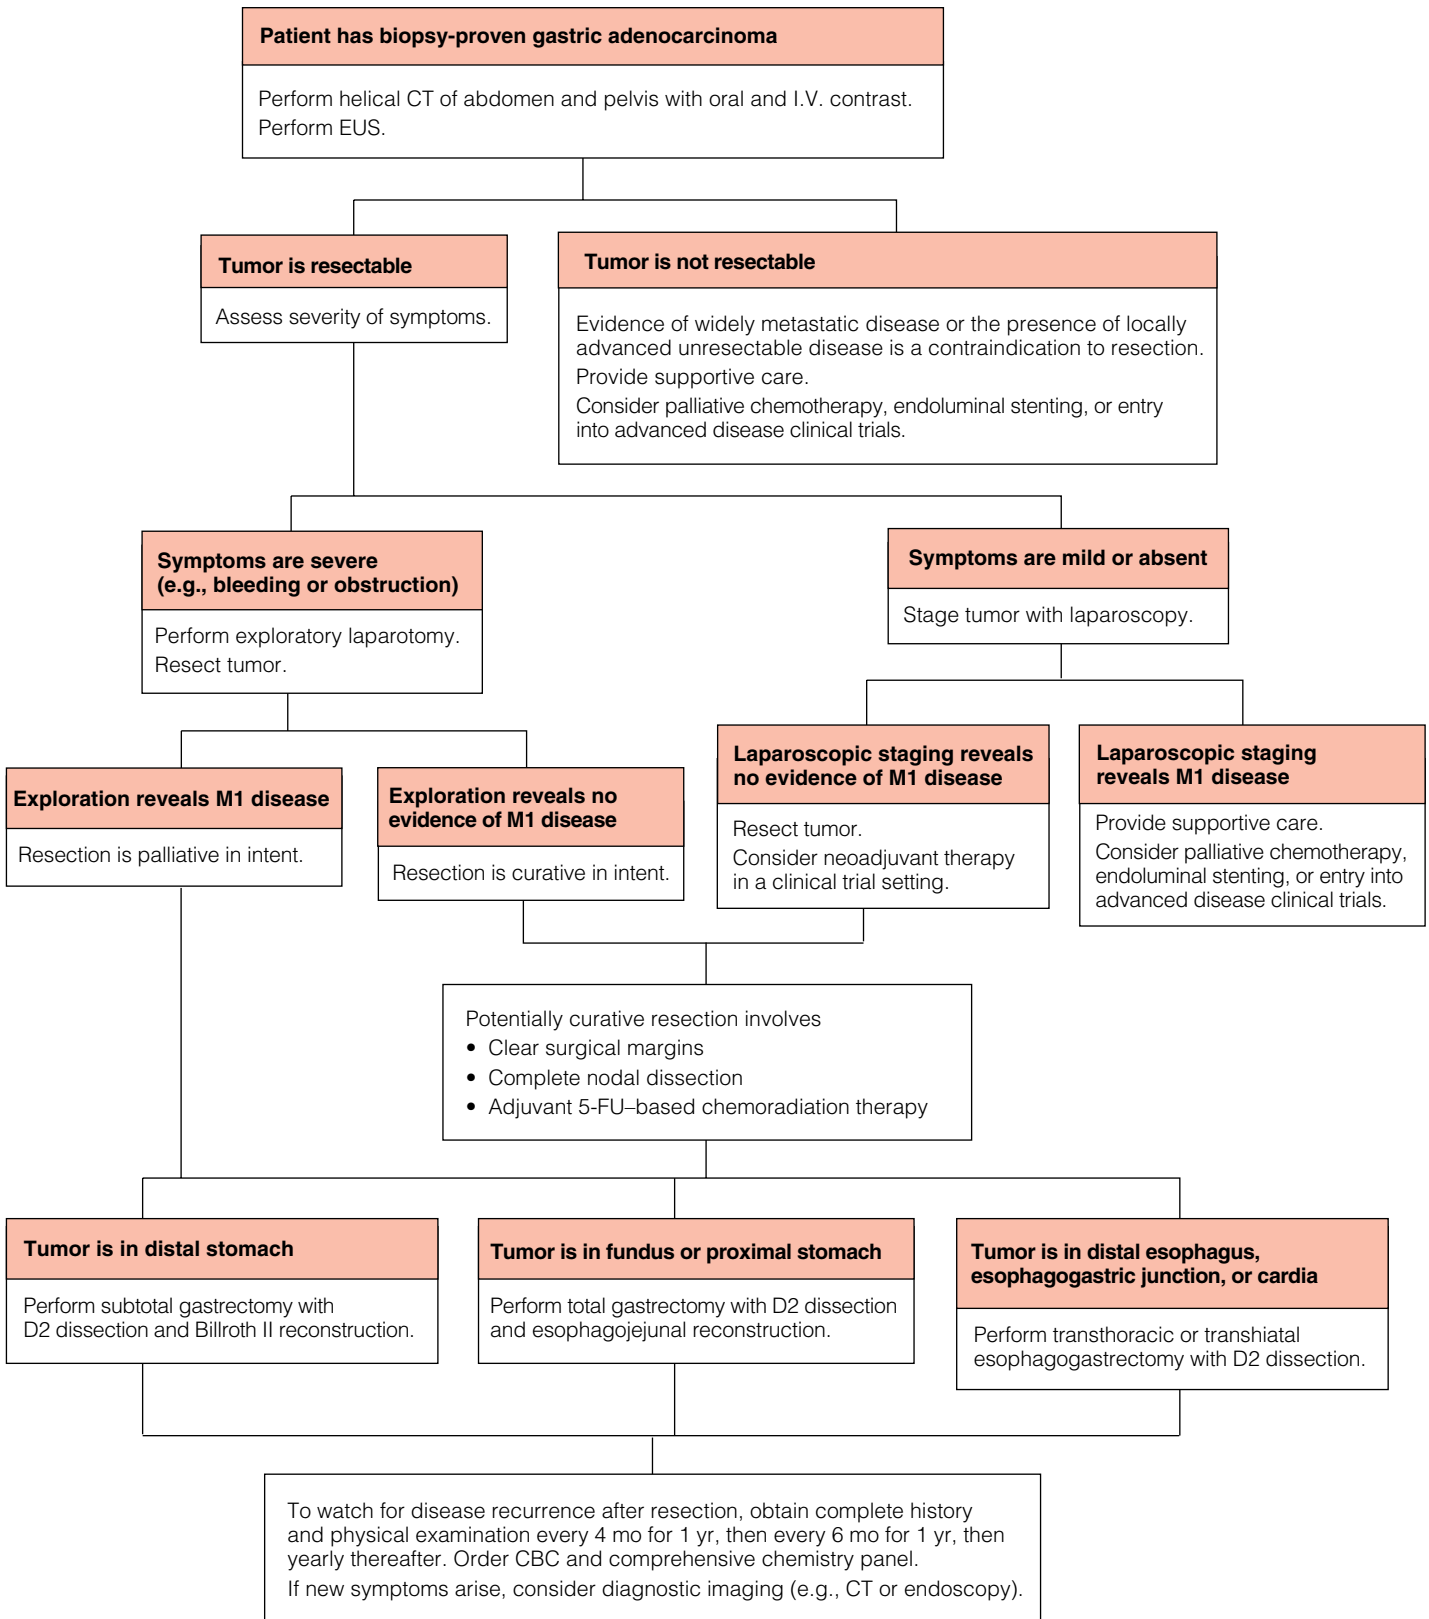

Figure 3 Algorithm illustrates workup and treatment of patient with gastric carcinoma.

size larger than 1 cm. In one study comparing preoperative findings from EUS with pathologic findings at operation, EUS was 100% sensitive for N0 disease and 66.7% sensitive for N1 disease.³⁴ EUS also allows identification and aspiration of small-vol-

ume ascites. If cytologic study of the ascitic fluid so obtained confirms the presence of malignant cells, the patient is considered to have metastatic disease and therefore is not eligible for curative-intent surgery. For all of these reasons, EUS is now widely accept-

ed as superior to conventional CT in the regional staging of gastric cancer.⁹

Role of Laparoscopy

The ultimate goal of any staging evaluation is to ensure that patients with metastatic disease are not treated with nontherapeutic laparotomy or other local therapies (e.g., radiation therapy), which are generally ineffective against advanced disease. Even small-volume metastatic disease identified on the surface of the liver or the peritoneum at laparotomy is associated with poor survival: in one study, patients with such disease had a life expectancy of only 6 to 9 months.³⁵ In these situations, there is little to be gained from attempts at palliative resection.

Staging laparoscopy [see 5:20 *Gastroduodenal Procedures*] has proved to be highly relevant to the evaluation of patients with gastric cancer. In a study from the Memorial Sloan-Kettering Cancer Center (MSKCC), the investigators performed laparoscopic exploration on 110 of 111 patients with newly diagnosed gastric cancer.³⁶ Of these 110 patients, 94% were accurately staged, with a sensitivity of 84% and a specificity of 100%, and 37% were found to have subclinical metastatic disease. Hospital stay was substantially shorter in the 24 patients who underwent diagnostic laparoscopy with biopsy only (average, 1.4 days) than in comparable patients who underwent exploratory laparotomy without resection (average, 6.5 days). Finally, at the time the data were reported, none of the patients who underwent laparoscopy had required palliative surgery. Subsequent single-institution series confirmed the utility of staging laparoscopy, reporting accuracy rates ranging from 95% to 97% and occult M1 disease rates approaching 30%.^{37,38} Taken as a whole, the data, though derived from relatively small single-institution experiences, are compelling, and they have led the NCCN to encourage laparoscopic staging strongly, either before or at the time of the planned resection.³⁹

MANAGEMENT

Surgical Therapy

Surgical resection [see 5:20 *Gastroduodenal Procedures*] remains the only potentially curative therapy for localized gastric cancer [see Figure 3]. Cure requires removal of all gross and microscopic disease. More specifically, a margin-negative (R0) resection entails wide local excision of the primary tumor with en bloc removal of all associated lymphatic vessels and any local or regional extension of disease. The downside of surgical resection as a sole modality of therapy is that it is associated with a high rate of relapse. Consequently, several areas of surgical treatment of stomach cancer remain subject to controversy. In particular, the extent of gastric resection, the extent of lymph node dissection, the optimal approach to proximal stomach lesions, and the role of splenectomy and adjacent organ resection continue to generate significant debate.

Extent of gastric resection R0 resection (i.e., resection of all gross disease with microscopically negative margins) has been shown to have a clear impact on overall survival after potentially curative surgery. In the German Gastric Cancer Study, a prospective multicenter observational trial, the calculated 10-year survival rate in the entire population was 26.3%, compared with 36.1% in patients who underwent an R0 resection.⁴⁰ In a large multi-institutional adjuvant therapy trial, 19% of patients underwent an R1 resection (i.e., had resection-line involvement); only 9% of patients with stage I, II, or III disease and resection-line involvement survived beyond 5 years, compared with 27% of those who underwent

an R0 resection.⁴¹ Given the propensity of tumor for submucosal spreading, many authors consider proximal margins of 5 to 6 cm, with routine frozen-section analysis, to be optimal.^{42,43}

In an effort to lower the positive margin rate, some surgeons have proposed that total gastrectomy be considered the operation of choice for all operable gastric cancers. This approach, originally based on historical data from single institutions, has been tested in three clinical trials. In the first trial, elective total gastrectomy was compared with subtotal gastrectomy as curative-intent therapy for adenocarcinoma of the antrum.⁴⁴ Elective total gastrectomy did not increase mortality, but it also did not improve 5-year survival (which was 48% in both treatment arms). In the second trial, patients with antral cancer were randomly assigned to undergo either subtotal gastrectomy or total gastrectomy with extended lymph node dissection (ELND) and en bloc distal pancreatectomy and splenectomy.⁴⁵ Total gastrectomy was associated with increased operative time, greater transfusion requirements, and longer hospital stay; however, median survival was significantly better in the subtotal gastrectomy group (1,511 days versus 922 days). In the third trial, the investigators concluded that subtotal gastrectomy should be the procedure of choice for cancer of the distal half of the stomach, provided that an adequate negative proximal margin could be achieved.⁴⁶ This conclusion was based on their finding that 5-year survival probabilities were essentially equivalent in the two groups studied (65.3% in the subtotal gastrectomy group versus 62.4% in the total gastrectomy group).

Options for proximal gastric cancer As noted (see above), adenocarcinoma of the gastric cardia and the esophagogastric junction appears to be clinically distinct from adenocarcinoma of the distal stomach,⁴⁷ and its incidence is currently escalating across all races and age groups. Accordingly, it is imperative that surgeons understand the surgical options for treatment of proximal gastric cancer.⁴⁸

For tumors originating from the distal esophagus, esophagectomy—either transhiatal esophagectomy with a cervical anastomosis or transthoracic (Ivor-Lewis) esophagectomy with a thoracic anastomosis—is clearly the procedure of choice [see 4:4 *Open Esophageal Procedures*]. For tumors of the cardia, it has been suggested that esophagogastrectomy might offer a survival advantage over total gastrectomy with an esophagojejunal anastomosis. This suggestion was evaluated in a study of 1,002 patients with adenocarcinoma of the esophagogastric junction.⁴⁹ The investigators divided tumors into three types on the basis of the location of the tumor center—cancers of the distal esophagus (type I), cancers of the cardia (type II), and cancers of the subcardial fundus (type III)—and analyzed the demographic and long-term survival data. Operative mortality proved to be higher with esophagogastrectomy than with extended total gastrectomy. Furthermore, R0 resection and lymph node status were found to be the dominant prognostic factors influencing survival. Finally, in patients with type II lesions, the pattern of lymphatic spread was primarily to paracardial, lesser curvature, and left gastric node groups. These data, taken together, led the authors to conclude that total gastrectomy is preferable to esophagogastrectomy in this setting if a margin-negative resection can be achieved.

An alternative approach to treating proximal gastric cancer is to perform a proximal subtotal gastrectomy. To date, no prospective studies have compared this method with total gastrectomy or transhiatal esophagogastrectomy for esophagogastric junction tumors, but surgeons from MSKCC have published their retrospective experience with 98 patients who underwent either total gas-

trectomy or proximal subtotal gastrectomy for proximal gastric cancer over a 10-year period.⁵⁰ There were no significant differences between the groups with respect to morbidity, mortality, or 5-year survival. It remains to be seen whether such excellent results can be achieved at other centers.

Thus, the evidence at present does not support routine performance of total gastrectomy for lesions of the distal fundus or antrum, provided that histologically negative margins are achievable without compromise of the gastric inlet. Our current practice is to perform a subtotal gastrectomy with Billroth II reconstruction for tumors of the distal stomach, a total gastrectomy with Roux-en-Y esophagojejunostomy for most cancers of the fundus and the proximal stomach [see 5:20 *Gastroduodenal Procedures*], and either a transthoracic esophagogastrectomy or a transhiatal esophagogastrectomy with gastric interposition for tumors of the esophagogastric junction and the cardia [see 4:4 *Open Esophageal Procedures*].

Extent of lymph node dissection Over the past decade, few topics in the surgical literature have generated more debate than the optimal extent of regional lymphadenectomy for gastric cancer. In Japan, where radical surgery for gastric cancer is now universally accepted, the JRS GC has codified the extent of lymphatic dissection according to the level of nodes dissected.⁵¹ A D1 lymph node dissection involves resection of the perigastric lymph nodes along the greater and lesser curvature of the stomach. A D0 dissection is anything less than a D1 dissection. A D2 dissection entails resection of the D1 nodes along with nodes along the common hepatic artery, the left gastric artery, the celiac axis, and the splenic artery. A D3 lymph node dissection adds resection of nodes in the hepatoduodenal ligament and the root of the mesentery. Finally, a D4 resection calls for a D3 dissection plus resection of the retroperitoneal para-aortic and paracolic lymph nodes.⁵² The JRS GC defines a curative operation as a gastric resection that includes lymph nodes one level beyond the level of pathologic nodal involvement. Thus, in Japan, a D2 lymph node dissection is considered the standard resection for even relatively early cancers, and numerous studies have cited the benefits of D3 and even D4 lymphadenectomy for advanced carcinoma.⁵³⁻⁵⁵

Western surgeons have been reluctant to embrace radical lymphadenectomy, arguing that it has yet to demonstrate an unequivocal survival advantage in any prospective, randomized trial from a Western institution or cooperative group. Detractors further argue that the survival advantage associated with more radical procedures simply reflects stage migration, a higher incidence of early gastric cancers, and differences in tumor biology and body habitus between Japanese and Western populations, and they point to the increases in operating time and morbidity that often accompany extended gastric resections. One retrospective review of the tumor registries of over 2,000 hospitals in the United States found that D2 lymph node dissection had no survival advantage over D1 lymph node dissection in terms of either the median survival time or the 5-year survival rate.⁵⁶

Two prospective trials from Western Europe examined this issue further in an effort to evaluate the safety and efficacy of ELND. In the Dutch Gastric Cancer Group trial, 711 patients were randomly assigned to undergo either D1 or D2 lymphadenectomy as part of a potentially curative gastrectomy for biopsy-proven adenocarcinoma.⁵⁷ This trial was unique in its use of extensive quality control measures, which included instruction and operative supervision by an expert gastric cancer surgeon from Japan (who also assisted with the processing and pathologic examination of the surgical specimens). Patients without evidence of disseminat-

ed metastases underwent either total gastrectomy or, if 5 cm proximal margins could be obtained, distal gastrectomy. In this study, a D2 lymph node dissection entailed distal pancreatectomy and splenectomy. Both morbidity and mortality were significantly higher in the D2 group than in the D1 group, and D2 dissection conferred no demonstrable survival advantage at a median follow-up of 72 months.

In a trial from the Medical Research Council in the United Kingdom, 400 patients with stage I to IIB disease were randomly assigned to undergo either a D1 or a D2 lymph node dissection.⁵⁸ There was no significant difference in overall 5-year survival between the two arms, but multivariate analysis demonstrated that clinical stages II and III, advanced age, male sex, and removal of the pancreas and the spleen were independently associated with poor outcome. The authors concluded that the classic Japanese D2 dissection offered no survival advantage over D1 dissection. However, they hypothesized that D2 dissection with preservation of the distal pancreas and the spleen might lead to decreased morbidity and mortality within the extended resection group and thus potentially to superior outcomes.

Further support for this hypothesis was provided by two non-randomized trials from specialized centers. The Italian Gastric Cancer Study Group (IGCSG) completed a phase II multicenter trial designed to evaluate the safety and efficacy of pancreas-preserving D2 lymph node dissection.⁵⁹ Quality control measures included supervision by a surgeon who had studied the technique of D2 lymph node dissection at the National Cancer Center Hospital in Tokyo. At a median follow-up time of 4.38 years, the overall morbidity rate for D2 dissection in the 191 patients enrolled was 20.9%, and the in-hospital mortality was 3.1%. The 5-year survival rate for eligible patients was 55%. In a prospective series of 125 patients undergoing standardized D2 lymph node dissection at a single Western center, the investigators reported a mortality of 1.37% and an overall morbidity of 33.5%.⁶⁰ As in the IGCSG study, distal pancreatectomy was avoided in all cases, except when direct extension was suspected on the basis of macroscopic findings (5.5% of cases). Overall 5- and 10-year survival rates for this highly selected cohort were 52.3% and 40%, respectively. These studies suggest D2 lymph node dissection may be safely performed in Western centers, when accompanied by careful selection of patients, strict standardization of technique, and a strategy of pancreatic preservation.

Current AJCC guidelines state that pathologic examination of at least 15 lymph nodes is required for adequate staging.²⁸ In an effort to confirm the benefit of this staging system, investigators from MSKCC reviewed their experience with 1,038 patients who underwent R0 resection for gastric cancer.⁶¹ The location of positive lymph nodes (within 3 cm of the primary tumor versus more than 3 cm away) did not significantly affect median survival; however, the number of positive lymph nodes had a profound effect on survival. Furthermore, in cases in which at least 15 nodes were examined (27% of the total), the median survival for patients with N1 (metastasis in one to six regional lymph nodes), N2 (metastasis in seven to 15 regional lymph nodes), and N3 disease (metastasis in more than 15 regional lymph nodes) was significantly longer than the median survival reported in cases in which 14 or fewer nodes were resected with the specimens. These findings are consistent with published data from our own institution (Northwestern University Feinberg School of Medicine), which indicate that the number of positive lymph nodes is a highly significant predictor of survival.⁶² In our series of 110 patients, those with N2 or N3 disease (seven or more positive lymph nodes) had a median disease-free survival (DFS) of 17.6 months, whereas those with

Table 3 Survival after Curative Resection of Gastric Cancer According to AJCC Lymph Node Status

Lymph Node Status	Roder et al ¹		Kodera et al ¹⁰⁵		Karpeh et al ⁶¹	
	Cases (% of Total)	5-Year Survival (%)	Cases (% of Total)	5-Year Survival (%)	Cases (% of Total)	5-Year Survival (%)
N1 (1–6 positive nodes)	258 (54)	45	306 (62)	70	392 (62)	38
N2 (7–15 positive nodes)	137 (29)	30	94 (19)	39	178 (28)	12
N3 (> 15 positive nodes)	82 (17)	10	93 (19)	24	65 (10)	5

N0 or N1 disease (six or fewer positive nodes) had a median DFS of 44 months. Data from other centers support this view as well [see Table 3].

It is our current practice to perform a D2 lymph node dissection, with resection of all perigastric lymph nodes along the greater and lesser curvatures of the stomach, as well as those along the common hepatic artery, the left gastric artery, the celiac axis, and the splenic artery [see 5:20 *Gastroduodenal Procedures*]. We make every attempt to preserve the tail of the pancreas and spleen, with multivisceral resection reserved for cases of overt direct extension of malignant disease in the absence of disseminated metastasis. This strategy should provide adequate staging in terms of the AJCC guidelines, minimize morbidity, and possibly confer a survival advantage on certain patient subgroups, as suggested by the results of the trials mentioned.

Role of splenectomy Routine splenectomy has been proposed as a means of facilitating clearance of metastatic nodes along the splenic artery and in the splenic hilum, but there is little evidence to support this practice in the treatment of proximal gastric cancers. Indeed, numerous studies have documented the deleterious effect of splenectomy when it is performed as part of an extended gastric resection.

In a retrospective study of 392 patients who underwent curative gastrectomy at a high-volume cancer center, the impact of splenectomy on survival and postoperative morbidity was evaluated.⁶³ Splenectomy was not predictive of death on multivariate analysis, but complications were far more frequent in patients who underwent splenectomy as part of surgical treatment than in those who did not (45% versus 21%). Specifically, the incidence of infectious complications was far higher in the splenectomy group than in the nonsplenectomy group (75% versus 47%).

In a review of data from an American College of Surgeons Pattern of Care Study, the investigators reported that the operative mortality was 9.8% in patients who underwent splenectomy during gastric resection, compared with 8.6% for those who did not.⁶⁴ More significantly, the 5-year observed survival rate was 20.9% in the splenectomy group, compared with 31% in the nonsplenectomy group.

In a randomized, prospective trial, early and late results of total gastrectomy alone were compared with those of total gastrectomy plus splenectomy in patients being treated for cancers of the upper third of the stomach.⁶⁵ All patients underwent a D2 lymph node dissection. The operative mortalities and the 5-year survival rates were similar in the two groups, but the splenectomy group had more infectious complications. Specifically, the splenectomy group had higher incidences of pulmonary complications, postoperative fever higher than 38° C (100° F), and subphrenic abscess formation. We agree with the conclusions of the authors of this study:

routine splenectomy does not increase survival, and it should be reserved for situations in which the gastric tumor directly invades the splenic hilum or there is evidence of gross nodal metastases along the splenic artery.

Nonsurgical Therapy

Adjuvant therapy As noted (see above), the majority of patients who present with gastric carcinoma and undergo potentially curative surgical treatment will experience locoregional failure, distant metastasis, or both and will succumb to their disease. Accordingly, numerous adjuvant approaches—including chemotherapy, radiotherapy, chemoradiation, immunochemotherapy, and intraperitoneal chemotherapy—have been tried in gastric cancer patients with the aim of improving overall survival and DFS. The results, for the most part, have been disappointing.

Results from prospective, randomized, controlled trials of adjuvant radiation therapy in this setting have failed to establish a survival benefit. In a multi-institutional trial from 1994, patients were randomly assigned to undergo surgery alone, surgery plus adjuvant radiation, or surgery plus adjuvant multiagent chemotherapy.⁶⁶ There was no significant benefit to either adjuvant regimen: overall 5-year survival was 20% for surgery alone, compared with 12% for surgery plus radiation therapy and 19% for surgery plus chemotherapy.

Results from trials of chemotherapy alone have been equally unsatisfactory. Because of the established inefficacy of single-agent 5-fluorouracil (5-FU) therapy, combination chemotherapy regimens have been employed. Such regimens have included nitrosourea compounds, mitomycin-C, anthracyclines, and members of the cisplatin family.²³ In a meta-analysis of 13 trials comparing adjuvant chemotherapy with observation in non-Asian countries, the odds ratio for death in the treated group was 0.8, corresponding to a relative risk of 0.94.⁶⁷ This result did not, however, reflect a statistically significant improvement. Most oncologists have now abandoned the use of chemotherapy by itself in the adjuvant setting.

In an effort to derive greater therapeutic benefit than can be achieved with either radiation therapy or chemotherapy alone, combinations of the two have been used in the adjuvant setting. In Intergroup Trial 0116, 556 patients who had undergone R0 resection of adenocarcinoma of the stomach or the esophagogastric junction were randomly assigned to treatment with either surgery alone or surgery plus postoperative chemoradiotherapy.⁶⁸ Patients with tumors ranging from stage IB to stage IVM0 were included; the majority had T3 tumors and node-positive disease. The therapeutic regimen consisted of 5-FU and leucovorin administered concomitantly with 45 Gy of external-beam irradiation over a period of 5 weeks. Median overall survival in the surgery-only group was 27 months, compared with 36 months in the surgery-chemoradiation group. In addition, the 3-year survival rate was 41% in the

surgery-only group, compared with 50% in the surgery-chemoradiation group. The hazard ratio for death in the surgery-only group as compared with the surgery-chemoradiation group was 1.35.

In the United States, the results of Intergroup Trial 0116 have led to the acceptance of chemoradiotherapy as standard adjuvant therapy for patients who have undergone curative-intent resection of gastric cancer. Nonetheless, numerous criticisms of this trial have been expressed. Specifically, a review of the operative and pathology reports of 453 of the patients revealed a lack of surgical standardization.⁶⁹ When the extent of lymphadenectomy was categorized, the majority (54.2%) of the patients were found to have undergone a D0 dissection; 38.1% underwent a D1 dissection, and only 7.5% underwent a D2 or D3 dissection. These findings suggest that the main effect of the chemoradiation therapy may have been simply to compensate for inadequate surgery. This suggestion is supported by the observation that the number of patients with local and regional recurrences was higher in the surgery-only group (178 versus 101), whereas the number of patients with distant failure was slightly higher in the adjuvant-therapy arm (40 versus 32). Furthermore, when the Maruyama Index of Unresected Disease (a computer model developed for accurate prediction of nodal station involvement in gastric cancer) was applied to the 556 patients eligible for the Intergroup Trial, the median Maruyama Index was 70.⁷⁰ This value was far above the level considered to represent optimal surgical therapy (i.e., Maruyama Index < 5) and led the authors to conclude that the vast majority of patients in the trial had been surgically undertreated.

Currently, physicians, especially in Europe, generally eschew adjuvant therapy after R0 resection of gastric cancer, except under the auspices of a clinical trial.⁹ The Radiation Therapy Oncology Group has initiated a phase II trial of adjuvant chemoradiotherapy using 45 Gy of external beam radiation with cisplatin and paxitaxel, with or without 5-FU. If promising results are found, a phase III trial will follow. It is to be hoped that ongoing trials will shed further light on this complex management issue.

Neoadjuvant therapy As a response to the disappointing results of adjuvant therapy and the inability of many patients to regain adequate performance status after radical gastric surgery, neoadjuvant therapy protocols have been proposed.⁷¹ The theoretical benefits of a neoadjuvant treatment strategy include treatment-induced tumor downstaging, which may enhance resectability, and early administration of systemic therapy, which allows almost all patients to receive and complete the prescribed treatment. Furthermore, because treatment is administered when measurable disease is present, response to therapy may be assessed and continued only in patients who are likely to benefit. Finally, patients who are found to have rapidly progressive disease during preoperative chemotherapy may be spared having to undergo a nontherapeutic gastrectomy.⁷²

In a report of three phase II trials from the M. D. Anderson Cancer Center, encompassing 83 patients who received neoadjuvant chemotherapy before planned surgical resection, clinical response rates ranged from 24% to 38%, with three patients (4%) exhibiting a complete pathologic response.⁷² Sixty-one patients (73%) were able to undergo a curative-intent resection, and the response to chemotherapy was the only significant predictor of survival on multivariate analysis.

Preoperative chemoradiation therapy has also been shown to be feasible in phase II trials. In a 2001 trial that included 23 patients, 96% of the study population received combined-modality therapy.⁷¹ Nineteen patients (83%) were able to undergo sur-

gical resection with D2 lymphadenectomy; four patients (17%) had progressive disease and did not undergo resection. Morbidity and death rates were acceptable (32% and 5%, respectively), and 11% of patients exhibited complete pathologic responses. Overall, 63% of patients showed pathologic evidence of a significant treatment effect.

Newer neoadjuvant treatment strategies employ multiagent induction chemotherapy followed by chemoradiotherapy and planned gastric resection in patients with locally advanced but potentially resectable gastric cancer.⁷³

FOLLOW-UP AND MANAGEMENT OF RECURRENT DISEASE

Even after gross resection of all disease with microscopically negative margins (R0 resection), recurrence of gastric carcinoma is common. Adenocarcinoma of the stomach may spread through direct extension, via lymphatic channels to regional and distant lymph nodes, or via the bloodstream to distant sites. Furthermore, once tumors have penetrated the serosa (T3), peritoneal metastasis becomes a possibility. Through autopsy series and clinical studies, certain definite patterns of locoregional failure and distant metastasis have been established. Locoregional recurrences are common in the gastric bed and the adjacent lymph nodes. Clinical and reoperative evaluation have documented recurrent disease at the anastomosis, in the retroperitoneum, or in the regional lymph nodes in 3% to 69% of patients; the incidence of recurrence may vary, depending on whether the patients had received adjuvant therapy.²³ One autopsy series documented a locoregional recurrence rate of 94% in patients treated with surgery alone. The peritoneum is ultimately involved in 17% to 50% of all patients. The most common sites of visceral metastases are the liver and the lungs.

In view of the high recurrence rates, all patients who have undergone resection should be seen for routine surveillance examinations. Currently, the NCCN recommends that a complete history and physical examination be conducted every 4 months for 1 year, then every 6 months for 1 year, and then yearly thereafter.³⁹ A complete blood count, serum electrolyte concentrations, and liver function studies should also be considered. Imaging studies (e.g., CT and endoscopy) are ordered as indicated, usually in response to new symptoms. In addition, long-term vitamin B₁₂ supplementation should be initiated for patients who have undergone a proximal or subtotal gastrectomy.

Other Gastric Malignancies

GASTRIC LYMPHOMA

Gastric lymphoma is the second most common malignancy of the stomach, accounting for 2% to 9% of gastric tumors in the United States. Lymphomas of the stomach are of the non-Hodgkin type. The stomach is the most common site of extranodal involvement of non-Hodgkin lymphoma (NHL) and accounts for nearly 50% of all such cases.⁷⁴

Clinical Evaluation

The presenting symptoms of gastric lymphoma, like those of gastric adenocarcinoma, are nonspecific and include loss of appetite, weight loss, vomiting, and bleeding. Overt clinical symptoms (e.g., fever and night sweats) are relatively rare: in one multicenter trial concerned with primary gastric lymphoma, they occurred in fewer than 12% of patients enrolled.⁷⁵ Risk factors for gastric lymphoma include *H. pylori* infection, immunosuppression

after solid-organ transplantation, celiac disease, inflammatory bowel disease, and HIV infection.⁷⁶

Investigative Studies

The diagnosis of gastric lymphoma is most frequently established by means of endoscopy with biopsy. Staging studies include a comprehensive blood count, a lactate dehydrogenase (LDH) level, and a comprehensive chemistry panel; CT of the chest, the abdomen, and the pelvis; and, often, a bone marrow biopsy. All pathology slides should be reviewed by an experienced hematopathologist.⁷⁷

Staging and Prognosis

Numerous staging systems have been employed to stage NHL of the GI tract. Of these, the one most commonly applied is a modification of the Ann Arbor staging system for lymphoma.⁷⁶ For surgeons, the most important determination is often whether the NHL (1) is confined to the stomach and the perigastric nodes (stage I and II disease), (2) involves other intra-abdominal nodes and organs (stage III), or (3) extends outside the abdomen (stage IV).⁷⁸

Management

Over the past decade, the management of patients with gastric lymphoma has undergone significant changes. Generally, there has been a shift away from surgical management, even in relatively localized cases (stages I and II).⁷⁹ This shift is the result not only of the documented success of chemotherapy alone for more advanced cases (stages III and IV) but also of a better understanding of the etiology of gastric lymphoma.⁸⁰ Approximately 45% of all gastric lymphomas are low-grade mucosa-associated lymphoid tissue (MALT) lymphomas.⁷⁵ The gastric mucosa is normally devoid of lymphoid tissue. It is hypothesized that MALT develops in the stomach in response to chronic *H. pylori* infection.⁸¹

Nonsurgical therapy Low-grade MALT lymphoma usually presents as stage I or II disease and has an indolent course. Since 1993, when regression of low-grade MALT lymphoma after eradication of *H. pylori* was first reported, numerous trials have documented the efficacy of anti-*H. pylori* therapy, with complete remission rates ranging from 50% to 100%.⁷⁹ In the German MALT Lymphoma Study, the complete remission rate was 81%; 9% of patients exhibited partial responses, and 10% showed no response.⁸² Low-grade lymphomas that are more advanced or do not regress with antibiotic therapy may be treated with *H. pylori* eradication and radiation (with or without chemotherapy).⁸³ For localized persistent disease, modest doses of radiation, on the order of 30 Gy, may be employed. When chemotherapy is required, multiagent regimens, such as cyclophosphamide-vincristine-prednisolone (COP), are often used.

Approximately 55% of gastric lymphomas are high-grade lesions, which can occur with or without a low-grade MALT component.⁷⁵ These lymphomas are treated with chemotherapy and radiation therapy according to the extent of the disease. The cyclophosphamide-doxorubicin-vincristine-prednisolone (CHOP) regimen is the one most frequently employed. In some studies, the anti-CD20 monoclonal antibody rituximab has been either added to standard therapy or used alone, with encouraging results.⁸⁴

Surgical therapy Surgical resection, once thought to be essential for the diagnosis, staging, and treatment of early-stage gastric lymphoma, now is used mainly in patients who experience

bleeding or perforation. In the German Multicenter Study Group trial, 185 patients with stage I or II gastric lymphoma were treated either with gastrectomy followed by radiation or (in the case of high-grade lesions) chemotherapy plus radiation or with chemotherapy and radiotherapy alone.⁷⁵ There was no significant difference in survival between the group receiving surgical treatment and the group receiving nonoperative therapy: overall 5-year survival rates were 82.5% and 84%, respectively. There were no perforations, and there was only one hemorrhage (in a patient treated with chemotherapy alone). Similarly, in a single-institution, prospective, randomized trial comparing chemotherapy alone with chemotherapy plus surgery for stage I and II lymphoma, there were no instances of perforation and only three instances of GI bleeding in the chemotherapy group, compared with two bleeding episodes in the surgery plus chemotherapy group.⁷⁹

Currently, patients with early-stage high-grade gastric lymphomas are treated primarily with chemotherapy or radiation therapy; only rarely do they require surgical intervention for complications encountered during therapy. Patients with locally advanced (stage III) or disseminated (stage IV) gastric lymphoma are clearly best treated with chemotherapy, with or without radiation. Occasionally, surgery is indicated in such patients to treat residual disease confined to the stomach or to palliate bleeding or obstruction that does not resolve with nonoperative therapy. Primary surgical therapy is to be avoided in these patients because of the significant risk of complications and the delay in initiating systemic therapy.

GASTROINTESTINAL STROMAL TUMOR

Gastrointestinal stromal tumor (GIST), though relatively rare in absolute terms, is the most common sarcoma of the GI tract,⁸⁵ with approximately 6,000 cases reported each year in the United States alone. The stomach is the most common site of involvement, accounting for 60% to 70% of cases⁸⁶; the small intestine (25%), the rectum (5%), the esophagus (2%), and a variety of other locations account for the remainder. On the basis of their appearance on light microscopy, GISTs were once thought to be of smooth muscle origin, and most were classified as leiomyosarcomas.⁸⁷ Thus, extended gastric resection, often including contiguous organs, was advised. Recurrence developed after R0 resection in approximately 50% of cases.⁸⁸ With the advent of immunohistochemistry and electron microscopy, it became clear that GIST has both smooth muscle and neural elements, and the cell of origin is now believed to be the interstitial cell of Cajal, an intestinal pacemaker cell.⁸⁹ The diagnosis of GIST is secured by immunohistochemical staining for the tyrosine kinase receptor KIT (CD117), which highlights the presence of interstitial cells of Cajal. More than 95% of GISTs exhibit unequivocal staining for KIT.⁸⁶ Approximately two thirds of GISTs also express CD34. Histologically, these tumors may exhibit a spindle cell pattern, an epithelioid pattern, or a mixed subtype.

Clinical Evaluation

The median age of incidence is 63 years, and tumors are generally between 0.5 and 44 cm in diameter at the time of diagnosis (median diameter, 6 cm).⁸⁶ Mass-related symptoms (e.g., abdominal pain, bloating, and early satiety) may be present. Melena or anemia from overlying mucosal ulceration may be present as well. A small subset of patients have peritonitis as a consequence of tumor rupture and subsequent hemorrhage. Finally, many GISTs are discovered incidentally during operation, abdominal imaging, or endoscopy.

Investigative Studies

When a GIST is suspected, abdominal and pelvic imaging with either CT or MRI is indicated. Chest imaging is performed as well. Endoscopy, with or without EUS, may occasionally help with surgical planning, but because of the infrequency of mucosal involvement, it is rarely diagnostic.⁹⁰ Surgical consultation should be obtained to determine whether the lesion can be resected. If the tumor is resectable, biopsy should not be performed, because of the risk of tumor rupture and intra-abdominal dissemination. Biopsy may be required, however, if the patient has widespread disease or may be enrolling in a trial of neoadjuvant therapy. In such cases, biopsy may be performed percutaneously or at the time of EUS.

Staging and Prognosis

Although the majority of gastric GISTs have a benign course, a wide spectrum of biologic behavior has been observed. Of the prognostic factors examined to date, tumor size and mitotic rate appear to be the most valuable. If the tumor is less than 2 cm in diameter and the mitotic count is lower than five per high-power field (HPF), the risk of an aggressive disease course is considered to be very low. Conversely, if the tumor is larger than 10 cm, if the mitotic count is higher than 10/HPF, or if the tumor is larger than 5 cm with a mitotic count higher than 5/HPF, the risk of aggressive clinical behavior is considered to be high. For all other tumors, the risk of aggressive disease is considered to be intermediate.⁸⁶

Management

Surgical therapy The role of surgery in the treatment of a GIST is to resect the tumor with grossly negative margins and an intact pseudocapsule. Lymph node involvement is rare with GISTs, and thus, no effort is made to perform ELND. The tumor must be handled with care to prevent intra-abdominal rupture. Formal gastric resection is rarely required: as a rule, it is indicated only for lesions in close proximity to the pylorus or the esophago-gastric junction.

Nonsurgical therapy If the tumor has metastasized or has advanced locally to the point where surgical therapy would result in excessive morbidity, the patient is treated with the tyrosine kinase inhibitor imatinib mesylate. Imatinib is a selective inhibitor of a family of protein kinases that includes the KIT-receptor tyrosine kinase, which is expressed in the majority of GISTs. Originally indicated for the treatment of chronic myelocytic leukemia, imatinib was approved for the treatment of KIT-positive GIST in 2002, when phase II clinical trials documented sustained objective responses in a majority of patients with advanced unresectable or metastatic GIST.⁹¹ Patients with borderline resectable lesions should be treated with imatinib until they exhibit a maximal response as documented by CT and positron emission tomography (PET); surgery may then be undertaken to resect any residual foci of disease. Similarly, whereas patients with metastatic disease are unlikely to manifest a complete response to imatinib therapy, they should be periodically reevaluated and considered for resection should surgical treatment become technically feasible.⁹⁰

After an R0 resection of a GIST, no adjuvant therapy is indicated unless the patient is participating in a clinical trial. The American College of Surgeons Oncology Group is currently conducting two trials of imatinib in the postoperative setting. A phase II trial (Z9000) of imatinib, 400 mg/day, for patients with high-risk GIST, has reached accrual, and a phase III trial (Z9001) comparing 1 year of imatinib, 400 mg/day, with placebo in patients with intermediate-risk GIST is currently under way.

GASTRIC CARCINOID

Gastric carcinoid tumors are rare, accounting for fewer than 11% to 30% of all GI carcinoids and fewer than 1% of all gastric tumors.⁹² The median age at diagnosis is 62, and tumors are equally distributed between men and women.

Clinical Evaluation and Investigative Studies

Gastric carcinoid tumors are often discovered during endoscopic examination of patients experiencing chronic abdominal pain; patients may also complain of vomiting and diarrhea. These tumors are rarely associated with symptoms of the carcinoid syndrome. Diagnosis is usually confirmed by endoscopic biopsy, and EUS is helpful in determining the extent of gastric wall penetration and the degree of regional lymph node involvement.

Gastric carcinoid tumors have been divided into three types, primarily on the basis of their association (or lack thereof) with hypergastrinemia. Type I tumors are associated with chronic atrophic gastritis, are generally small (< 1 cm), and are often multiple and polypoid. They grow slowly and only rarely metastasize to regional nodes or distant sites. Type II tumors are associated with the Zollinger-Ellison syndrome and multiple endocrine neoplasia type I (MEN I) and, like type I tumors, are usually small and multiple. They also grow slowly, but they are more likely to metastasize than type I gastric carcinoids are. Type III (sporadic) gastric carcinoid tumors are the most biologically aggressive type. They are often large (> 1 cm) at the time of diagnosis and are not associated with hypergastrinemia. Type III lesions frequently metastasize to regional nodes (54%) or the liver (24%).⁹²

Management

For patients with small, solitary type I tumors, endoscopic polypectomy [see 5:18 *Gastrointestinal Endoscopy*] or open resection via gastrotomy (local excision) [see 5:20 *Gastroduodenal Procedures*] is the procedure of choice. For patients with multiple or recurrent tumors, antrectomy [see 5:20 *Gastroduodenal Procedures*] is indicated to remove the source of the hypergastrinemia. For patients with type II lesions, treatment is similar to that for patients with type I lesions, with the extent of gastric resection determined by the size and number of lesions. For patients with type III lesions, however, either distal or total gastrectomy with ELND is required.⁹³ All patients undergoing a less than total gastrectomy should be followed with serial endoscopy at regular intervals.⁹⁴

Table 4 American Joint Committee of Cancer TNM Clinical Classification of Small Bowel Carcinoma

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ
	T1	Tumor invades lamina propria or submucosa
	T2	Tumor invades muscularis propria
	T3	Tumor penetrates < 2 cm into subserosa or into nonperitonealized perimuscular tissue (mesentery for jejunum or ileum, retroperitoneum for duodenum)
T4	Tumor penetrates visceral peritoneum or directly invades > 2 cm into adjacent structures	
Regional lymph nodes (N)	NX	Regional lymph node(s) cannot be assessed
	N0	No regional lymph node metastasis
	N1	Regional lymph node metastasis
Distant metastasis (M)	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis

Stage II	T3, T4	N0	M0
Stage III	Any T	N1	M0
Stage IV	Any T	Any N	M1

Small Bowel Malignancies

Malignant tumors of the small intestine are rare, accounting for fewer than 5% of all GI tract malignancies. In the United States, only a few thousand new cases of small bowel cancer are reported each year.⁹⁵ The majority of small bowel malignancies are adenocarcinomas, lymphomas, or carcinoid tumors,⁹⁶ though GISTs are being noted with increasing frequency in the small intestine. Treatment of lymphomas, carcinoid tumors, and GISTs in the small bowel is nearly identical to treatment of the same lesions in the stomach [see Other Gastric Malignancies, above] and thus will not be covered further in this chapter. Our focus here is on the presentation, diagnosis, and treatment of adenocarcinoma of the small bowel. Like gastric adenocarcinoma, small bowel adenocarcinoma is usually staged according to the AJCC/UICC TNM classification system [see Tables 4 and 5].

CLINICAL EVALUATION

Between 46% and 55% of small bowel adenocarcinomas occur in the duodenum.^{96,97} Patients frequently present with nausea, vomiting, abdominal pain, weight loss, and GI bleeding⁹⁸; occasionally, they present with iron deficiency anemia or a positive fecal occult blood test result. In rare cases, small bowel obstruction, often with the tumor serving as a lead point for intussusception, is the first manifestation of the disease.⁹⁷

INVESTIGATIVE STUDIES

When an adenocarcinoma is located in the duodenum, the diag-

nosis is often made by means of esophagogastroduodenoscopy (EGD). Lesions within the first 100 cm of the small bowel may be evaluated with push enteroscopy. When the adenocarcinoma is situated elsewhere in the small bowel, it is localized with small bowel radiographs. Some authors consider enteroclysis to be superior to the more commonly used small bowel follow-through in this setting, in that enteroclysis is better able to demonstrate fine mucosal detail.⁹⁹ In experienced hands, enteroclysis may therefore be more sensitive.¹⁰⁰ Some lesions are identified when CT or MRI is performed to evaluate complaints of abdominal pain. Furthermore, abdominal imaging may yield complementary staging information (e.g., the presence of regional adenopathy or metastatic disease). One promising new method for the identification of small bowel tumors is wireless capsule endoscopy.¹⁰¹ This minimally invasive technique may be particularly useful in identifying small lesions in the distal jejunum and ileum that cannot be identified radiographically.

MANAGEMENT

Aggressive surgical resection remains the cornerstone of therapy for adenocarcinoma of the small intestine.¹⁰² For periampullary lesions, pancreaticoduodenectomy is typically required to achieve a margin-negative resection. For lesions in the distal duodenum, a segmental sleeve resection with a duodenojejunostomy is appropriate. For lesions in the jejunum or the ileum, segmental resection may be performed with a wide mesenteric resection to encompass potentially involved regional lymph nodes. Contiguous organs are resected en bloc as necessary.⁹⁸

Because the presenting signs and symptoms are often vague and nonspecific, diagnosis is often delayed. In one series, only 6 (11%) of the 53 patients were suspected of having a small bowel tumor at admission.¹⁰² In a retrospective review of patients with small bowel tumors treated at our institution, the mean duration of symptoms before surgical management was 110 months, and more than 50% of the patients were found to have stage III or IV disease.⁹⁸

The 5-year survival rate continues to be low (24% to 37%).^{98,103,104} Significant predictors of good overall survival include complete (R0) resection and low AJCC tumor stage.^{98,103,104} The available evidence indicates that all patients with small bowel neoplasms should be offered an oncologically sound surgical resection. In one series, curative (R0) resection was accomplished in 51% of cases.¹⁰³

9 TUMORS OF THE PANCREAS, BILIARY TRACT, AND LIVER

Steven M. Strasberg, M.D., F.A.C.S., and David C. Linehan, M.D., F.A.C.S.

Numerous types of tumors affect the pancreas, the biliary tree, and the liver. Each year, hundreds of papers are published on the topics of pancreatic, biliary, and hepatic cancer. Accordingly, in this chapter, we concentrate on essential principles rather than details. In particular, we focus on common malignant tumors, addressing benign tumors and uncommon tumors only insofar as they are important in differential diagnosis.

When a patient presents with an apparent cancer of the pancreas, the biliary tree, or the liver, the surgeon must attempt to answer the following three important questions:

1. What is the diagnosis?
2. What is the surgical stage of the disease—that is, is the tumor resectable?
3. What is the operative rationale that will encompass the disease and produce a margin-free resection (and, for pancreatobiliary cancers, an N1 resection)?

These questions form the underpinning for the process of investigation and management. In what follows, we describe our approach to each of the cancers in these terms.

Pancreatic Cancer

DUCTAL ADENOCARCINOMA

Adenocarcinoma of Head of Pancreas

Adenocarcinoma of the pancreatic head is common (with 30,000 new cases occurring annually in the United States) but remains one of the hardest GI cancers to cure. In the past 25 years, the efficacy of surgical treatment has improved dramatically, but 5-year actual survival rates in patients who have undergone resection are still low (about 15%).¹ Cancer of the head of the pancreas is the prototypical tumor that causes painless jaundice; however, other cancers that obstruct bile ducts also cause jaundice, including extrahepatic bile duct cancers, gallbladder cancers, ampullary malignancies, and some duodenal cancers. Some of the following discussion is generalized with an eye to determining the diagnosis in patients presenting with obstructive jaundice [see 5:3 *Jaundice*].

Clinical evaluation *History.* The classic presentation of cancer of the head of the pancreas is unremitting jaundice, usually accompanied by dark urine, light stool, and pruritus. Darkening of the urine or pruritus is often the first symptom, and scleral icterus frequently is first noted by family members or coworkers. The pruritus is often severe. The jaundice sometimes is painless but more frequently is associated with epigastric pain. This pain usually is not severe; severe, acute pain is more often associated with other conditions that may cause jaundice (e.g., choledocholithiasis and pancreatitis). Back pain suggests that the tumor has invaded tissues outside the pancreas and is unresectable.

Significant weight loss ($\geq 10\%$ of body weight) is common even when the pancreatic cancer is resectable.

In some patients, steatorrhea or diarrhea from obstruction of the pancreatic duct, weight loss, pain, or a combination of these is the presenting symptom, rather than jaundice. A presentation with steatorrhea or diarrhea is usually the result of a tumor in the uncinate process that obstructs the pancreatic duct but not the bile duct. Often, these symptoms are overlooked until the tumor extends and causes jaundice. About 5% of patients have a history of diabetes of recent onset. Migratory thrombophlebitis (the Trousseau sign) is uncommon and usually signifies metastatic disease. Pancreatobiliary malignancies cause biliary obstruction, but such obstruction is not commonly associated with biliary tract infection before instruments have been employed in the biliary tree. Therefore, in patients presenting with cholangitis who have not undergone biliary tract instrumentation, other diagnoses should be suspected. Patients with pancreatic cancer may also present with acute pancreatitis as the first manifestation. Vomiting and GI bleeding are uncommon presenting symptoms and suggest the presence of advanced tumors that are obstructing or eroding the duodenum.

Physical examination. Examination reveals scleral icterus. In some cases, the distended gallbladder may be palpable. In advanced cases, signs of metastatic disease (e.g., hepatomegaly and ascites) may be detected.

Investigative studies *Laboratory tests.* Liver function tests (LFTs) are of limited value in diagnosis. The serum bilirubin level is elevated in jaundiced patients, with the direct fraction exceeding 50%. The serum alkaline phosphatase level is almost always elevated when the bile duct is obstructed, and levels three to five times normal are common. Aminotransferase levels usually are moderately elevated as well. Very high aminotransferase levels suggest a hepatocellular cause of jaundice, usually viral, though impaction of a stone in the bile duct can cause transient rises in serum aspartate aminotransferase (AST) to levels higher than 1,000 IU/ml. By themselves, LFTs cannot effectively distinguish among jaundice arising from a hepatocellular cause (e.g., viral hepatitis or drug-induced cholestasis), jaundice resulting from a disease of microscopic bile ducts (e.g., primary biliary cirrhosis), and jaundice caused by any of the malignancies that obstruct the major bile ducts. To make this distinction, radiologic imaging tests are required [see *Imaging, below*].

Serum concentrations of the tumor marker CA 19-9 are often elevated in patients with pancreatic or biliary adenocarcinomas.² The upper limit of the normal range is 37 U/ml. Concentrations higher than 100 U/ml are highly suggestive of malignancy, but elevations between 37 and 100 U/ml are less specific. Serum levels generally reflect the extent of the tumor: small tumors (< 1 cm in diameter) are rarely associated with levels higher than 100 U/ml,

Figure 1 Shown is a typical hypoattenuating cancer of the pancreatic head. The tumor is invading the right side of the portosplenic confluence, as evidenced by the “beaking” of the vein at that point.

Figure 2 In the same patient as in Figure 1, pancreatic duct dilation is apparent in the body of the pancreas, with atrophy of the parenchyma.

whereas very high levels ($> 1,000$ U/ml) suggest metastatic disease. High levels may also accompany cholangitis. Measurement of CA 19-9 concentrations may be employed to detect recurrences in patients who have elevated CA 19-9 levels that return to normal after tumor resection; a second rise in the CA 19-9 level in the follow-up period is indicative of recurrence in most cases.

Imaging. Several different imaging tests may be used for diagnostic purposes in jaundiced patients, including computed tomography, magnetic resonance imaging, endoscopic retrograde cholangiopancreatography (ERCP), endoscopic ultrasonography (EUS), and transabdominal ultrasonography. The technical advances in imaging achieved over the past few years are remarkable. CT and MRI, which only a few years ago were limited to axial images, on one hand, and fuzzy MRI cholangiopancreatography (MRCP), on the other, can now provide high-quality images of blood vessels and ducts and their anatomic relation to tumors. These images can even be projected in three dimensions if desired.

Selection of appropriate imaging tests in a jaundiced patient is influenced by patient characteristics and by the symptoms observed. For instance, the type and order of investigations appropriate for an older patient presenting with obstructive jaundice, who is likely to have a malignancy, differ from those appropriate for a young woman with severe pain, who is more likely to have choledocholithiasis. The best initial imaging test in a patient in whom malignancy is suspected is either a fine-cut (3 mm between slices) three-phase (no-contrast phase, arterial phase, and venous phase) helical (spiral) CT scan or a high-quality MRI scan. Although MRI has the advantage of being able to provide a cholangiogram (i.e., with MRCP), small and medium-sized radiologic facilities currently tend to be more skilled at CT than at MRI; this difference should be taken into account when the first test is ordered. High-quality MRI scanners and the very latest generation of CT scanners are capable of providing cholangiograms and angiograms, as well as axial images.

The typical pancreatic cancer appears as a lucent zone in the pancreatic head [see Figure 1], associated with upstream dilatation of the bile ducts and the gallbladder. Often, the pancreatic duct is

also obstructed. As a result, the pancreatic duct may be dilated in the tail, body, and neck of the pancreas, with dilatation terminating sharply at the edge of the tumor. Pancreatic duct dilatation is often accompanied by atrophy of the body and the tail of the pancreas [see Figure 2].

When a jaundiced patient is discovered to have a typical-appearing localized cancer of the pancreatic head on CT scanning, no further diagnostic tests are needed, and operative management should be the next step. Tissue diagnosis is unnecessary. Negative biopsy results rarely change the therapeutic approach, and in that they are sometimes falsely negative, they are potentially misleading. Furthermore, omitting biopsy eliminates the small risk of tumor implantation in the needle tract. Selection of axial imaging as the first test often renders diagnostic ERCP, which is a more invasive test, unnecessary as well. Cholangiography also is not required for staging pancreatic head tumors [see Surgical Staging, below]. The advantages of starting with axial imaging in jaundiced patients with suspected cancer are discussed in greater detail elsewhere [see Biliary Tract Cancer, Extrahepatic Cholangiocarcinoma, Upper-Duct Cholangiocarcinoma, Investigative Studies, below].

Additional diagnostic imaging for atypical CT or MRI findings. In many patients with adenocarcinoma of the pancreatic head, the typical CT findings are absent and additional diagnostic imaging is required. Such patients may be categorized into two groups: those with an atypical mass and those with no mass on axial imaging. In either case, before ordering additional tests, it is appropriate to determine whether the CT scan is of adequate quality. For example, the scan may have been performed without contrast, the arterial and venous phases may not have been captured appropriately, or the slice thickness may have been too great for precise visualization of the head of the pancreas. Small adenocarcinomas may be missed when the venous phase is timed poorly, especially if slice thickness is 5 mm or greater, and masses that appear atypical initially may exhibit a typical appearance when the CT scan is optimized. Neuroendocrine cancers commonly display arterial-phase enhancement, which will be missed if the scan is mistimed. In our experience, about 40% of referred patients who underwent

CT scanning before arrival require a so-called pancreas protocol CT scan (i.e., a fine-cut three-phase helical scan) when they are first seen; in many of these cases, the second CT scan yields important diagnostic findings.

When no mass is present in a jaundiced patient with a perampullary tumor or another focal obstructing process (e.g., pancreatitis), the CT scan usually shows bile duct dilatation extending down to the intrapancreatic portion of the duct. The dilatation may terminate anywhere from the upper border of the pancreas to the duodenum, depending on the site of the tumor and the nature of the process obstructing the bile duct. In these conditions, ERCP is a good choice as the second test.

ERCP provides an endoscopic view of the duodenum that allows identification and biopsy of ampullary and duodenal tumors that may be blocking the bile duct and producing jaundice. It confirms the presence of a bile duct stricture and displays its form, which is helpful in diagnosis. Focal strictures, especially those with shoulders, suggest malignancy. Long, tapering strictures limited to the intrapancreatic portion of the bile duct suggest chronic pancreatitis. Concomitant narrowing of the pancreatic duct in the head of the pancreas (the double-duct sign) suggests the presence of a small pancreatic cancer that is not visible on the CT scan. Longer or multiple pancreatic strictures suggest chronic pancreatitis. A single focal bile duct stricture in the absence of pancreatic duct abnormalities is the hallmark of cancer of the lower bile duct. Infiltrating cancers of the bile duct may cause more than one stricture along the bile duct, but when more than one stricture is present, other diagnoses (e.g., primary sclerosing cholangitis) should be considered. Both pancreatic and bile ducts may be assessed with brush cytology. This test has a 45% to 50% sensitivity for cancer³; therefore, only a positive test result is significant.

ERCP findings in a patient with no mass must be evaluated in the light of findings from other investigations. Patients with the classic double-duct sign or single focal shouldered bile duct strictures are likely to have small pancreatic or bile duct tumors. Further diagnostic support is usually not needed before laparotomy, though such support may be reassuring when the CA 19-9 concentration is higher than 100 U/ml. When doubt persists, EUS often helps resolve it. EUS may identify a small mass that was not seen on the CT scan, and biopsies may then be done. Occasionally, EUS reveals enlarged lymph nodes, which may also undergo biopsy. However, negative EUS-guided biopsy results in patients who present with painless jaundice do not exclude malignancy. When such patients have an identifiable mass on EUS, pancreaticoduodenectomy is recommended, even if EUS-guided biopsy yields negative results. If a non-operative approach is taken, short-term follow-up at 4 to 6 weeks with repeat imaging and biopsy is mandatory. If the findings persist, laparotomy is advisable.

Occasionally, preoperative testing reveals no mass, but a mass is subsequently discovered by intraoperative palpation or intraoperative ultrasonography (IOUS). A mass palpated in the head of a pancreas that is otherwise normal or near normal in texture is highly suggestive of malignancy and constitutes sufficient justification for resection. The same is true of a mass detected by IOUS if the mass has characteristics of malignancy (i.e., is hypoechoic). If the IOUS findings are inconclusive, biopsy with frozen-section examination is a reasonable approach. In many such cases, the whole pancreas is diffusely firm or hard, and IOUS demonstrates a diffuse change in the normal texture of the gland. When the pancreas is diffusely firm and no localized process is seen on IOUS, biopsies should be directed toward the stent in the bile duct at the point where the bile duct narrows (as seen on ultrasonography).

The ultimate diagnostic test is pancreaticoduodenectomy. If there is a strong suspicion of cancer before laparotomy or the findings at laparotomy are strongly suggestive, this procedure should be performed without preliminary biopsy. When this approach is followed, a small number of patients with suspected malignant disease will ultimately turn out to have benign disease when operated on; this possibility should be explained to patients who do not undergo confirmatory tissue diagnosis before operation. Because of the limited negative predictive value of currently available tests, pancreaticoduodenectomy is sometimes still required to make a definitive diagnosis.

The finding of an atypical pancreatic head mass on a CT scan poses an additional challenge. Atypical masses may take different forms. In some cases, they exhibit attenuation that differs only slightly from that of the surrounding pancreas; in others, they have a ground-glass appearance. They may extend into the body and tail of the pancreas, or they may be localized to the head. With atypical masses, the most common problem is how to differentiate focal pancreatitis from adenocarcinoma. This differentiation can be very difficult to achieve. Pancreatitis may be present without antecedent acute attacks; without a history of alcoholism, gallstones, or hyperlipidemia; without diabetes or steatorrhea; and without calcifications in the gland. Cancer appears to be more common in patients who have had chronic pancreatitis, and the diseases may coexist. Therefore, one cannot feel confident that cancer is absent simply because chronic pancreatitis is present. Cancer should be suspected in patients with an established diagnosis of chronic pancreatitis who undergo a rapid change in status (e.g., weight loss). Diabetes is common in patients with chronic pancreatitis, but it may also be the first sign of pancreatic cancer in patients without chronic pancreatitis. Chronic pancreatitis can cause painless jaundice. A rare immune form of chronic pancreatitis, known as lymphoplasmacytic sclerosing pancreatitis, has been recognized that is particularly hard to differentiate from cancer.⁴

EUS is becoming increasingly important in the management of patients with atypical pancreatic head masses.⁵ When jaundice is present, ERCP followed by EUS is our usual approach; when it is absent, EUS without ERCP is preferred. EUS-guided biopsy is superior to CT-guided transabdominal biopsy, in that access to the head of the pancreas is easier and the chance of needle tracking is reduced (because the biopsy is taken through the duodenal wall, which is resected if a Whipple procedure is done).

At the conclusion of all of the preceding investigations, it still may not be clear whether a malignancy is present. Clinical judgment must be exercised in deciding whether to operate or to repeat investigative studies after an interval of 2 to 3 months. Operation is favored in patients who are jaundiced, who have less pain, who have elevated CA 19-9 levels, and whose mass is suspicious for cancer. Elevation of the CA 19-9 concentration beyond 100 U/ml should be regarded as a very important finding. When EUS is inconclusive, ultrasound-guided diagnostic laparoscopy may be performed to obtain core tissue biopsies from several areas of the mass. This technique is especially useful when chronic pancreatitis is strongly suspected,⁶ in that the multiple long core biopsies obtainable with this procedure provide a greater degree of assurance against false-negative findings for cancer. Even this test, however, is not 100% accurate in this regard. The penultimate diagnostic test is laparotomy with mobilization of the pancreatic head and IOUS-guided transduodenal core biopsies of the mass. The ideal outcome with this approach is to perform pancreaticoduodenectomy in all patients who actually have cancer while reducing to a reasonable minimum resec-

tion in patients with benign disease, who in most cases are better served by biliary bypass.

Surgical staging The term staging is currently used to denote the process by which the surgeon determines whether a tumor is resectable. We prefer to use the term surgical staging for this process so as to distinguish it from those staging classifications that define the life history and prognosis of tumors and provide the basis for comparison of results—namely, the TNM classifications developed by the American Joint Committee on Cancer (AJCC). These latter systems are also of great importance to the surgeon dealing with pancreatic tumors.

Surgical staging is started preoperatively and completed intraoperatively. Preoperative staging tests determine operability—that is, whether the tumor appears resectable after preoperative testing. However, the final decision regarding resectability is made only during the operation, on the basis of intraoperative staging. A tumor of the head of the pancreas is deemed unresectable when it is determined to have extended beyond the boundaries of a pancreaticoduodenectomy. Common reasons for unresectability include (1) vascular invasion (i.e., invasion of the superior mesenteric vein, the portal vein, the superior mesenteric artery, or, less commonly, the hepatic artery); (2) lymph node metastases that fall outside the scope of a pancreaticoduodenectomy (e.g., metastases to para-aortic and celiac lymph nodes); (3) hepatic metastases; (4) peritoneal metastases; and (5) extra-abdominal metastases (usually pulmonary). Limited vascular invasion of the superior mesenteric vein and the portal vein may be overcome by resection and reconstruction and thus is only a relative contraindication to resection. This is especially true when the tumor is small and has arisen in the vicinity of the veins. In a series from our institution (Washington University in St. Louis), about 20% of resections done for pancreatic cancer involved resection of these veins.⁷

The tests used to establish the diagnosis and those used to accomplish surgical staging go hand in hand. Abdominal CT scans, abdominal MRI, thoracic CT scans, and chest radiographs are obtained to detect hepatic metastases, vascular invasion, and pulmonary metastases. To assess vascular invasion, fine-cut three-phase helical CT scans or MRI scans are required. These tests may detect enlarged lymph nodes, but it should be remembered that nodes may be enlarged for reasons other than cancer. Sometimes, ascitic fluid collections or peritoneal or omental nodules are iden-

Table 2 American Joint Committee on Cancer Staging System for Pancreatic Cancer

Stage	T	N	M
Stage 0	Tis	N0	M0
Stage IA	T1	B0	M0
Stage IB	T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T1, T2, T3	N1	M0
Stage III	T4	Any N	M0
Stage IV	Any T	Any N	M1

tified; ascitic fluid may be sent for cytologic analysis, and omental nodules may undergo ultrasound-guided biopsy. Invasion of the mesentery, the mesocolon, or retroperitoneal tissues may also be detected by CT scanning. In the view of some surgeons, such invasion may render the tumor unresectable, but in our experience, this is rarely the case in the absence of concomitant vascular invasion: the resection may still be accomplished with clear margins by resecting the portion of the mesocolon or the mesentery that was locally invaded.

EUS may be used to guide biopsy of suspicious lymph nodes when these lie outside the planned resection zone. It has also been employed to assess vascular invasion, but in our experience, it has no advantage over CT scanning in this regard; what is more, it is highly operator dependent. Staging laparoscopy is particularly effective at finding small hepatic and peritoneal nodules. About 20% of patients thought to have resectable pancreatic adenocarcinoma of the head of the pancreas before staging laparoscopy are found to have liver or peritoneal metastases upon laparoscopy.⁸ Staging is completed intraoperatively by carefully inspecting the intra-abdominal contents, opening the lesser sac, mobilizing the head of the pancreas, performing biopsies of suspicious nodules or nodes outside the planned resection zone, and attempting dissection of the superior mesenteric vein or the portal vein. Formal clinicopathologic staging according to the AJCC's TNM system is useful for establishing the prognosis and planning additional treatment [see Tables 1 and 2].

All authorities agree that axial imaging of the abdomen and chest (or roentgenography of the chest) is standard practice for staging pancreatic cancer; however, not all agree on the value of other staging tests. Many authorities advocate omission of staging laparoscopy or EUS-guided biopsy of nodes, on the grounds that patients are better served by palliative surgery than by endoscopic stenting of the bile duct. There is no advantage in knowing whether small liver metastases or celiac node metastases are present if laparotomy is to be undertaken anyway. The literature on this issue is unclear regarding what constitutes best practice. The two randomized trials published to date reported differing outcomes, with one favoring surgical bypass⁹ and the other endoscopic stenting. We continue to recommend staging laparoscopy in patients with adenocarcinoma of the pancreas. In those considered likely to have a short life expectancy because of peritoneal or hepatic metastases discovered upon laparoscopy, the procedure is discontinued, and endoscopic stenting with metal stents is performed. We no longer advocate using staging laparoscopy with ultrasonography to determine if the tumor is unresectable solely because of local vascular invasion; these patients are likely to have a longer life

Table 1 American Joint Committee on Cancer TNM Clinical Classification of Pancreatic Cancer

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ
	T1	Tumor limited to pancreas, ≤ 2 cm in greatest dimension
	T2	Tumor limited to pancreas, > 2 cm in greatest dimension
	T3	Tumor extends beyond pancreas but without involvement of celiac axis or SMA
	T4	Tumor involves celiac axis or SMA
Regional lymph nodes (N)	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Regional lymph node metastasis
Distant metastasis (M)	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis

SMA—superior mesenteric artery

expectancy and are treated with a double-bypass procedure. Finally, ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG-PET) may be useful in staging pancreatic cancer, but at present, its role is unclear. Given that inflammation is frequently confused with cancer, the major role of this modality will probably be in the detection of distant metastases.

Management *Preoperative preparation.* All jaundiced patients should receive vitamin K, a fat-soluble vitamin whose absorption is reduced by biliary or pancreatic duct obstruction. Routine preoperative bile duct decompression is unnecessary, except when jaundice has been prolonged or operative treatment will be delayed (e.g., for correction of cardiac or other comorbid conditions). Several studies have shown that surgical outcome is not improved by routine preoperative decompression in jaundiced patients. In fact, stent placement may increase the incidence of postoperative infection.¹⁰

Rationale for pancreaticoduodenectomy. The technical details of pancreaticoduodenectomy are discussed more fully elsewhere [see 5:24 *Pancreatic Procedures*]. Therapeutic decision-making necessarily includes consideration of the extent of the procedure. The operative goal is to remove the tumor with clear margins, as well as the N1 regional lymph nodes. Numerous attempts have been made to improve results by extending the operation, either through more extensive lymph node dissections¹¹ or through resection of the superior mesenteric artery.¹² None of these attempts have been successful in improving overall survival. The lesson is that invasion of additional lymph node regions or the superior mesenteric artery signals an aggressive tumor biology that is unlikely to be overcome by wider resections. Except for resection of the portal vein or the superior mesenteric vein to address invasion of these structures by otherwise favorable tumors, extended resections are no longer recommended. Even these recommended venous resections are probably best restricted to tumors that have arisen close to the veins and involved them while still small; resections of large adenocarcinomas that have grown over time to involve long stretches of the veins are best avoided.

There is also continuing controversy regarding the respective merits of the standard version of the operation and its pylorus-preserving variant. There is no evidence that the two procedures differ with respect to overall survival. Pylorus preservation is associated with gastric-emptying problems in the postoperative period, but overall, it seems to be associated with less postoperative GI dysfunction.¹³ We employ pylorus preservation selectively in older, thinner patients, with the aim of minimizing disruption of GI function.

Adenocarcinoma of Body and Tail of Pancreas

Adenocarcinoma of the body and tail of the pancreas is less common than adenocarcinoma of the head. Because it does not produce jaundice, it tends to be recognized relatively late. Accordingly, patients are often in an advanced stage of disease at presentation. Tumors of the midbody tend to invade posteriorly to involve the superior mesenteric artery or the celiac axis, even when these lesions are only 2 to 3 cm in diameter. As a result, tumors of the tail are more likely to be resectable than tumors of the midbody when they are discovered. Many resectable tumors are discovered incidentally; by the time the tumors give rise to symptoms, they are frequently unresectable.

Clinical evaluation Symptoms are nonspecific, consisting of abdominal and back pain (which is usually relieved by sitting up and leaning forward), weight loss, and diabetes of recent onset.

Figure 3 Shown is a typical hypoattenuating cancer of the tail of the pancreas with invasion of the hilum of the spleen and the splenic flexure of the colon. Peritumoral stranding suggests inflammation or invasion of peripancreatic fat.

Investigative studies The CA 19-9 concentration may be elevated. CT usually shows a lucent mass [see *Figure 3*], often with extension outside the pancreas and dilatation of the distal pancreatic duct, when the tumor is proximal to the tail of the gland. EUS is very useful for assessing indeterminate lesions.

Surgical staging Surgical staging of cancers of the body and the tail is similar to that of cancers of the pancreatic head and is based primarily on CT scanning of the abdomen and the thorax. Unresectability by reason of local invasion is usually attributable to the involvement of the superior mesenteric artery or the celiac artery and less commonly to the involvement of the portal vein, the superior mesenteric vein, or the aorta. Another indicator of unresectability is enlarged para-aortic nodes, which sometimes appear along the aorta below the pancreas. Invasion of the spleen, the stomach, the left adrenal gland, the mesocolon, the colon, the retroperitoneum, or even the left kidney is not a contraindication to resection, provided that clear margins may be expected.¹⁴ Staging laparoscopy is of great value in this context: between 20% and 50% of patients are found to have unresectable tumors with this modality.¹⁵ Cancer of the body and the tail differs from cancer of the head in that there is no effective palliation and therefore no rationale for laparotomy if the lesion is unresectable. Celiac nerve block, which is very helpful in reducing the use of narcotics for pain control, may also be performed laparoscopically or endoscopically.

Management *Rationale for radical antegrade modular pancreatosplenectomy.* Logically, the goal of resection of tumors of the body and tail should be the same as that of resection of tumors of the head—namely, excision of the tumor with clear margins, along with the N1 lymph nodes. In practice, this goal generally is not achieved by the traditional retrograde distal pancreatectomy, in which the spleen is taken first and which is not based on the lymph node drainage of the pancreas. Lymph node counts have been low with the traditional procedure, and positive posterior margin rates have been high. As an alternative, we have developed a technique referred to as radical antegrade modular pancreatosplenectomy

Figure 4 Illustrated is the pattern of lymphatic drainage of the pancreas. The darker nodes are N1 nodes for the body and tail of the pancreas. The lighter nodes on the aorta to the left side of the celiac artery and the superior mesenteric artery are N1 for the central part of the pancreas and N2 for other regions.

(RAMPS), which accomplishes the desired goals by performing the resection in an antegrade manner from right to left and which is based on the established lymph node drainage of the gland [see Figure 4].¹⁶ RAMPS also allows early control of the vasculature.

Mucinous Adenocarcinoma

Mucin-producing cancers are special variants of adenocarcinoma of the pancreas that often arise in preexisting lesions. The two main types are mucinous cystic neoplasm (MCN) and intraductal papillary mucinous neoplasm (IPMN) (also referred to as intraductal papillary mucinous tumor [IPMT]).¹⁷ A complete discussion of pancreatic cyst disease is beyond the scope of this chapter. Accordingly, we briefly address such disease as it relates to cancer of the pancreas, omitting discussion of less common cystic malignancies of the pancreas.

MCN MCN occurs most often in middle-aged women, typically in the body and tail of the pancreas. MCNs are unilocular or septated cysts whose diameter ranges from subcentimeter size to 15 cm or larger. Occasionally, calcium is present in the wall. Excrescences may be present on the inner wall; if so, malignancy is likely. Most symptomatic MCNs are between 4 and 7 cm in diameter.

Clinical evaluation and investigative studies. Patients with MCNs typically present with left-side pain, often in the flank and the back, though these lesions also are frequently discovered incidentally. Pancreatitis is rare and jaundice is uncommon, even when the lesions are situated in the head of the pancreas. MCNs must be differentiated from pseudocysts and from serous cystadenomas (SCAs), which are benign cysts. Differentiation between MCNs and pseudocysts is based on the history, imaging studies, and cyst fluid analysis. The diagnosis of pseudocyst is supported by a history of pancreatitis; a thick-walled, uncalcified cyst with associated radiologic signs of pancreatitis; and cyst fluid with high levels of amylase and lipase and a relatively low level of carcinoembryonic antigen (CEA) (< 500 ng/ml).

SCAs have the same clinical presentation as MCNs. SCAs are more frequently polycystic than MCNs are, but this difference is not a certain means of discriminating between the two. In a minority (25%) of cases, SCAs have a pathognomonic central calcification

with radiating arms ringed by multiple grape-sized cysts. When the cysts are tiny (honeycomb pattern), SCAs may also appear to be solid tumors. Unlike pseudocysts and IPMNs, neither MCNs nor SCAs communicate with the pancreatic duct, though they may compress it. Measurement of the CEA level in cyst fluid is a good means of distinguishing MCN from SCA. SCAs have very low levels of CEA, with the cutoff being 5 ng/ml.¹⁸ In MCNs, the cyst fluid is often mucinous, and cytologic assessment may show mucin-producing cells; typically, the fluid is high in CEA. The CA 19-9 concentration may also be used to distinguish MCNs from SCAs, but it is not as reliable as the CEA concentration for this purpose.¹⁸

Surgical staging. Surgical staging is required when MCNs are malignant, and essentially the same methods are used as for any pancreatic adenocarcinoma (see above). Malignancy is suggested by a solid intracystic or extramural component. Sometimes, a mucinous tumor is frankly malignant with a large or dominant solid component. Such a tumor is better termed a mucinous adenocarcinoma, and it should be evaluated and treated from the outset in the same manner as any other adenocarcinoma of the pancreas.

Management. In symptomatic patients, preoperative differentiation between MCNs and SCAs is unnecessary, because resection is the treatment for both. In asymptomatic patients, MCNs more than 2 cm in diameter should be excised because of the possibility of malignant degeneration. The standard procedure has been open distal pancreatectomy with splenectomy, though lesser procedures, such as spleen-sparing distal pancreatectomy,¹⁹ laparoscopic distal pancreatectomy,²⁰ central pancreatectomy, and enucleation,²¹ have all been used as well. These procedures appear to be reasonable choices, provided that there is no suggestion of invasive malignancy on imaging (i.e., that there are no excrescences on the inner lining and that the surrounding pancreas appears normal). Enucleation may be associated with a higher incidence of postoperative fistula. If invasive cancer is not detected in the resected specimen, the chances that the malignancy will recur are small; in fact, we have never seen such a recurrence.

The 2 cm cutoff for treatment of MCNs in asymptomatic patients is arbitrary. It is still possible that malignant degeneration could occur in a cyst smaller than 2 cm, but many cysts of this size

are found in the course of axial imaging performed for other reasons. Such cysts are difficult to diagnose because of the small volume of cyst fluid present, and the benefit to be gained from performing a large number of pancreatectomies for these small cysts is questionable, even when they are diagnosable as MCNs. Some authorities feel that large SCAs should also be excised because of rare instances of malignant degeneration. Occasionally, MCNs or symptomatic SCAs are located in the head of the pancreas and must be treated with pancreaticoduodenectomy.

IPMN IPMN begins as the cells lining the pancreatic ducts undergo a metaplastic alteration from a low cuboidal serous type of cell to a mucin-producing type. These cells are prone to dysplasia and eventual malignant transformation. Overall, IPMNs appear to undergo malignant transformation much more regularly than MCNs do. There are two recognized types of IPMN, which may occur either separately or together. The more common type affects the main pancreatic duct [see Figure 5], which becomes dilated and filled with mucin. As the disease progresses toward malignancy, papillary processes may project into the lumen. The less common type, so-called side-branch IPMN, affects the smaller ducts and presents as multiple (usually small) pancreatic cysts. In either type of IPMN, the disease may be either diffuse or focal; when it is focal, the head of the pancreas is the site of disease in the majority (60%) of cases. About 20% of IPMN patients have a malignancy at the time of diagnosis, though the cancer may not be evident until the specimen is examined pathologically.

Clinical evaluation and investigative studies. IPMN occurs predominantly in males and usually affects patients in their 60s. Pain (usually attributable to pancreatitis arising from mucous obstruction of the pancreatic duct) is a common presenting symptom. Another common presentation is pancreatic insufficiency with diabetes or steatorrhea. Accordingly, it is not surprising that formerly, many IPMN patients were diagnosed as having chronic pancreatitis. IPMN may also be discovered incidentally or may present as a cancer with signs and symptoms similar to those of other pancreatic cancers, depending on the part of the gland in which they arise. On rare occasions, cholangitis from obstruction of the common channel by mucus is the presenting problem.

The diagnosis is made on the basis of the presentation and the findings from axial imaging and ERCP. ERCP sometimes shows mucus bulging from the mouth of the pancreatic duct when the duodenum is inspected. In main duct disease, the pancreatic duct is dilated, but sometimes, the mucus prevents complete filling. In this situation, CT scans or MRI with MRCP may be quite useful for detecting ductal dilatation and atrophy of the pancreas. MRCP is best at detecting excrescences emanating from the surface of the duct, which signal progression of the disease toward neoplasia. In side-branch IPMN, ERCP typically demonstrates communication between the cysts and the main duct, which is often normal in size; this finding is not present in MCN or SCA and is very useful for distinguishing side-branch IPMN from these other types of cysts.

Management. IPMN is treated by resecting the involved portion of the gland. In about 50% of patients, the resection margin is involved with atypia or cancer, and the planned resection may have to be extended.²² In some cases (about 20%), total pancreatectomy is required; in others, partial pancreatectomy and close follow-up of the pancreatic remnant with MRCP and serum CA 19-9 measurement are indicated. Most patients who require total pancreatectomy tolerate the procedure well when they are enrolled in a program keyed to this operation. The mucinous cancers associated with IPMN have a better prognosis than ductal adenocarcinomas do.²³ Frank mucinous cancers may appear in patients with IPMN as well; they should be managed in much the same fashion as other adenocarcinomas, with the additional requirement that the resection should encompass the entire IPMN-bearing portion of the pancreas.

NEUROENDOCRINE CANCERS

In most large centers, neuroendocrine cancers account for fewer than 5% of surgically treated pancreatic malignancies. Some of these cancers are functional tumors, which produce hormones leading to paraneoplastic syndromes. Examples include gastrinoma, insulinoma, glucagonoma and vasoactive intestinal polypeptide-secreting tumor (VIPoma), all of which are associated with characteristic clinical syndromes. These syndromes are often produced while the tumors are still small. A detailed discussion of functional neuroendocrine tumors is beyond the scope of this chapter.

Figure 5 (a) CT scan of a patient with main duct IPMN involving the entire length of the pancreatic duct reveals substantial distention of the duct. (b) Shown is a cross-section through the resected specimen.

Other neuroendocrine tumors are nonfunctional and, as a result, reach a larger size before giving rise to symptoms. These lesions present with symptoms caused by the mass effect and must be differentiated from ductal adenocarcinomas. Nonfunctional neuroendocrine cancers are slow-growing tumors that tend to push rather than invade structures but are capable of metastasizing to lymph nodes, as well as to the liver and other organs. Pain is the most common presenting symptom. Jaundice, pancreatitis, and systemic symptoms (e.g., weight loss) are less common with these tumors than with adenocarcinoma of the pancreas. Because of the propensity of neuroendocrine tumors to deflect rather than invade the bile duct, jaundice may be absent even when tumors are located in the head of the gland.

Diagnosis, surgical staging, and treatment rationale are essentially the same for neuroendocrine cancers as for ductal adenocarcinomas. On CT scans, these lesions characteristically show enhancement in the arterial phase and are seen to push on bile ducts and vascular structures rather than encase them. Complete resection by means of pancreatoduodenectomy or distal pancreatectomy [see 5:24 *Pancreatic Procedures*] is indicated. Given the slow growth rate of neuroendocrine cancers and their relatively favorable prognosis (50% to 60% 5-year survival rate), removal of the primary lesion and any hepatic secondary lesions is justified if all tumor tissue can be removed with clear margins.

Biliary Tract Cancer

EXTRAHEPATIC CHOLANGIOCARCINOMA

Extrahepatic cholangiocarcinoma (CCA) may be subdivided into lower-duct CCA and upper-duct CCA, with the former arising in the intrapancreatic or retroduodenal portion of the bile duct and the latter arising above it. In practice, most upper-duct CCAs (also referred to as hilar CCAs or Klatskin tumors) arise just below the union of the right and left hepatic ducts, at the union of the ducts, or in the main right or left hepatic ducts. Cancer of the midportion of the bile duct at the cystic duct's usual insertion point is more likely to be an extension of a gallbladder cancer than a primary CCA. AJCC staging criteria for these tumors are useful

Table 3 American Joint Committee on Cancer TNM Clinical Classification of Extrahepatic Bile Duct Cancer

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ
	T1	Tumor confined to bile duct histologically
	T2	Tumor invades beyond wall of bile duct
	T3	Tumor invades liver, gallbladder, pancreas, or unilateral branches of portal vein or hepatic artery
	T4	Tumor invades any of the following: main portal vein or branches bilaterally, coronary artery, or other adjacent structures (e.g., colon, stomach, duodenum, or abdominal wall)
Regional lymph nodes (N)	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Regional lymph node metastasis
Distant metastasis (M)	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis

Table 4 American Joint Committee on Cancer Staging System for Extrahepatic Bile Duct Cancer

Stage III	T4	Any N	M0
Stage IV	Any T	Any N	M1

for establishing the prognosis and planning further treatment [see *Tables 3 and 4*].

Lower-Duct Cholangiocarcinoma

Clinical evaluation and investigative studies Much of what the surgeon needs to know about lower-duct CCA has already been addressed elsewhere [see *Pancreatic Cancer, Adenocarcinoma of Head of Pancreas, above*]. By far the most common presentation is painless jaundice with its constellation of associated symptoms (especially pruritus). Laboratory tests reveal the characteristic pattern of obstructive jaundice. A serum CA 19-9 concentration higher than 100 U/ml facilitates the diagnosis. Axial imaging reveals dilation of the intrahepatic bile ducts, the gallbladder (in most cases), and the extrahepatic bile ducts down to the level of the pancreatic head, where the dilatation terminates abruptly. Usually, no mass is visible. ERCP or MRCP shows a focal stricture, and ERCP brushings are positive in about 50% of cases. EUS may be helpful, in that it is more sensitive for small tumors than CT scanning is. Needle biopsy is directed toward the mass or, if no mass is visible, toward the narrowest segment of the bile duct. A negative biopsy result does not rule out a small bile duct cancer.

The differential diagnosis includes other potential causes of focal strictures of the bile duct.²⁴ The most common cause of a benign stricture of the intrapancreatic bile duct is pancreatitis, which may be diffuse or focal. Other causes of benign stricture include iatrogenic injury, choledocholithiasis, sclerosing cholangitis, and benign inflammatory pseudotumors [see *Upper-Duct Cholangiocarcinoma, Investigative Studies, Imaging, below*]. Iatrogenic injuries rarely involve the intrapancreatic portion of the bile duct, though such injuries can occur in this area as a consequence of forceful instrumentation. Sclerosing cholangitis may affect this section of the bile duct but usually affects other areas of the biliary tree as well. The diagnostic steps for differentiating benign neoplasms from malignant tumors are essentially the same for lower-duct CCA as for pancreatic cancer. As noted, resection may be required to make the diagnosis. In any patient presenting with jaundice and a focal stricture of the bile duct, lower-duct CCA should be strongly suspected.

Surgical staging Surgical staging of lower-duct CCAs is usually straightforward. These tumors are usually remote from major vascular structures and thus are not subject to the same local staging considerations as adenocarcinomas of the pancreatic head are. The exception is a tumor that extends to the top of the retroduodenal portion of the bile duct. At this point, the bile duct is apposed to the portal vein and the hepatic artery, and these structures may be invaded by bile duct tumors in this location.

Management The treatment for resectable lesions is pancreaticoduodenectomy.

Upper-Duct Cholangiocarcinoma

Upper-duct (or hilar) CCA is a sporadically occurring tumor that may also be seen in patients with primary sclerosing cholangitis, ulcerative colitis, or parasitic infestation. It is characteristically slow growing and locally invasive, and it metastasizes more readily to lymph nodes than systemically, though intrahepatic and peritoneal metastases are not uncommon. Most hilar CCAs are cicatrizing diffusely infiltrating cancers, but some are nodular, and others present as papillary ingrowths. These tumors are divided into four types according to the Bismuth classification, which is based on the upper extent of the tumor [see Figure 6].²⁵

When the CCA originates in one of the hepatic ducts, that duct may be obstructed for a considerable period before the tumor causes jaundice by growing into the other hepatic duct or the common bile duct. Such prolonged unilateral obstruction before the onset of the presenting symptom of jaundice may result in atrophy of the obstructed side of the liver, which may affect subsequent management. For example, because the disease is more advanced on the obstructed side, it is the atrophied half of the liver that will be removed in almost all cases where resection is indicated. In addition, when one side of the liver undergoes atrophy, the other side undergoes hypertrophy. These changes lead to rotation of the liver, which in turn may cause the structures in the hepatoduodenal ligament to be rotated out of their normal anatomic location. For instance, if hypertrophy of

the left hemiliver develops, the hepatic artery may come to lie directly in front of the bile duct.

Clinical evaluation The usual presentation of hilar CCA consists of painless jaundice with its accompanying symptoms (especially pruritus), though some pain may be present. Cholangitis before instrumentation of the bile duct is uncommon. In patients who present in the late stages of the disease, general manifestations of cancer (e.g., malaise, weight loss, or ascites) may be noted.

Investigative studies *Laboratory tests.* Laboratory testing follows the pattern previously described for obstructive jaundice [see Pancreatic Cancer, above]. Again, the most helpful diagnostic laboratory test is the serum CA 19-9 concentration: levels higher than 100 U/ml are strongly suggestive of cancer. In patients with primary sclerosing cholangitis, the presence of CCA is often suggested by a rapid deterioration in condition. It is not unusual for patients with hilar CCA to have undergone a cholecystectomy in the recent past; the symptoms of pain and jaundice may be mistaken for symptoms of gallbladder disease in patients who happen also to have gallstones.

Imaging. Earlier [see Pancreatic Cancer, Ductal Adenocarcinoma, Adenocarcinoma of Head of Pancreas, above], the point was made that it is preferable to employ axial imaging rather than ERCP as the first imaging test in the jaundiced patient because doing so will often render ERCP, an invasive test, unnecessary. This point carries even more force in the setting of hilar CCA. Injection of dye

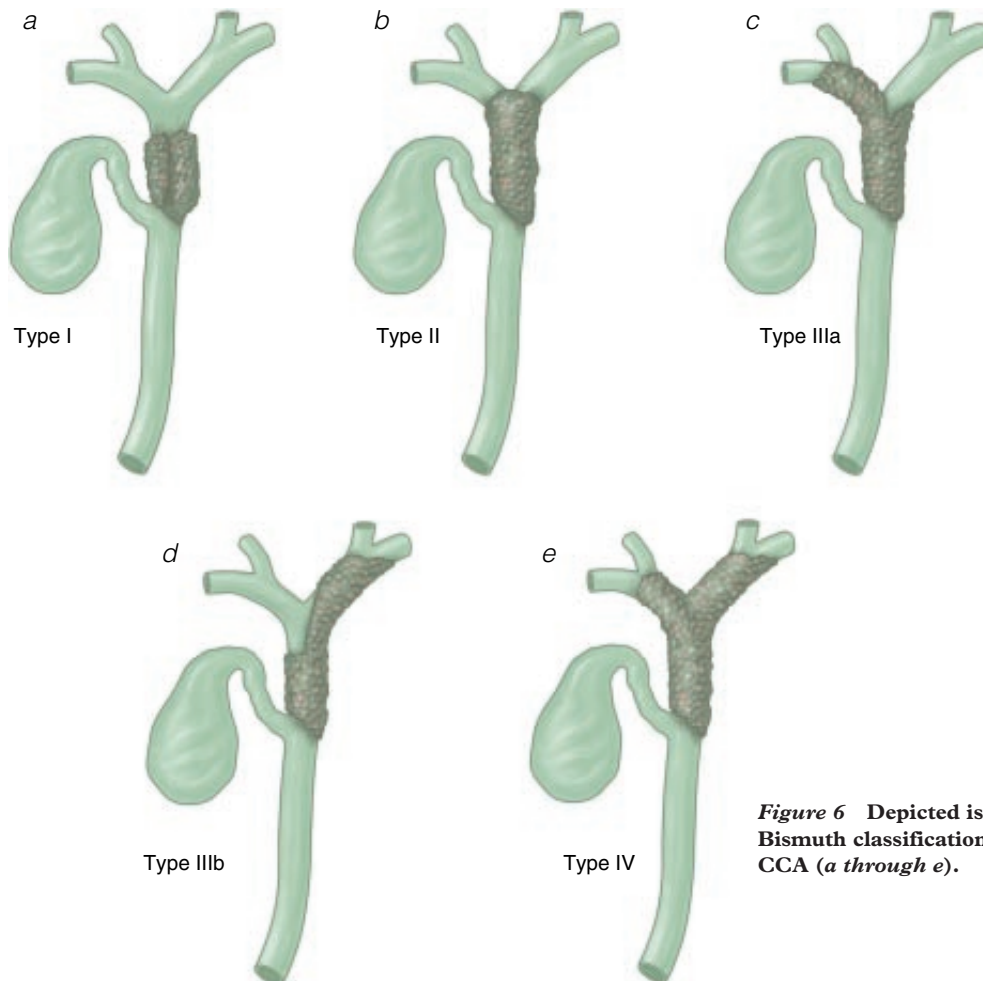

Figure 6 Depicted is the Bismuth classification of hilar CCA (a through e).

Figure 7 Shown is Bismuth type II CCA. The right and left hepatic ducts are dilated (upper arrows), whereas the common hepatic duct is normal sized.

above the malignant stricture is an integral part of ERCP. Once the dye has been injected, stents must be placed to prevent post-ERCP cholangitis. This process may involve insertion of bilateral stents, including a stent in the atrophic hemiliver. Bilateral stenting is disadvantageous, because the aim is to encourage atrophy of the hemiliver to be resected and hypertrophy of the hemiliver to be retained, and insertion of a stent in the atrophic side contravenes that aim. Starting with CT or MRI rather than with ERCP allows detection of any hilar CCA present simultaneously with detection of atrophy. At this point, the patient can be evaluated by a multidisciplinary team with expertise in this disease, and a decision can be made regarding which side of the biliary tree to decompress (if either). Whether stents should be employed in treating hilar CCA is debatable, but if a stent is inserted, only the side to be retained should be intubated. MRCP now provides resolution that is close to that obtained with direct cholangiography [see *Figure 7*].

ERCP does have one significant advantage, in that it allows brushings to be obtained; however, brushings at this high level in the biliary tree are even less sensitive than those at lower levels. Bile cytology has been tried, without much success. EUS has been employed to obtain diagnostic tissue, with some degree of success; however, because the biopsy needle passes through the peritoneal cavity, concerns have been expressed regarding possible tumor seeding. Such seeding has not been an issue with lower-duct cancers, because the biopsy tract is entirely within the future resection specimen. In many cases, a tissue diagnosis cannot be obtained preoperatively, and the diagnosis is based on the presence of a focal hilar stricture that causes jaundice.

Focal strictures of the upper bile ducts are strongly suggestive of cancer, but CCAs must also be differentiated from benign inflammatory tumors (also referred to as hepatic inflammatory pseudotumors and benign fibrosing disease).²⁶ These inflammatory masses mimic upper-duct CCAs but consist of chronic inflammatory cells and fibrous material. Even today, they are very difficult to distinguish from cancers before pathologic examination of a resected specimen.²⁷ Benign inflammatory tumors appear to occur most frequently in extrahepatic upper ducts, but they also occur intrahepatically and, less commonly, in lower ducts.

Gallbladder cancer may invade the porta hepatis and appear as a CCA, especially on ERCP. Gallstones are usually present.

Axial imaging usually shows thickening of the gallbladder wall or the presence of a mass involving the infundibulum. Mirizzi syndrome is another cause of a focal stricture of the middle or upper bile duct. This syndrome results from compression of the bile duct by a large gallstone in the infundibulum and is usually associated with severe inflammation of the gallbladder and the characteristic signs and symptoms of acute cholecystitis. The duct is typically bowed to the left rather than focally narrowed, as in cancer. Iatrogenic causes should be considered if the patient has had a cholecystectomy. On occasion, a stricture appears years after the operation. In these cases, the probable cause of the stricture is ischemic injury to the bile duct. The presence of clips close to or indenting the duct is a clue that such injury is a possibility. Choledocholithiasis may also cause strictures, especially if cholangitis has occurred. Strictures are also frequent with recurrent pyogenic (oriental) cholangitis. Other rare tumors of the bile duct (e.g., neuroendocrine tumors) may mimic cholangiocarcinoma.

Surgical staging Often, the first axial imaging test reveals only the presence of intrahepatic bile duct dilatation, which stops abruptly as the ducts merge in the hepatic hilum. This finding, however, leads to MRI or CT aimed at providing high-quality cholangiograms and angiograms of the hepatic arteries and the portal veins. Surgical staging of hilar CCA, unlike that of lower-duct CCA, requires exact knowledge of the macroscopic upper extent of the tumor in the bile duct. Furthermore, invasion of hepatic arteries and portal veins is common and frequently affects resectability. Thus, surgical staging also requires accurate determination of the extent of hepatic arterial or portal venous invasion and assessment of the degree of atrophy.

Bismuth type IV tumors are not resectable, except by liver transplantation. Type I through III tumors are resectable, provided that the main portal vein and the proper hepatic artery, as well as the portal vein and the hepatic artery to the side of the liver to be retained, are not invaded by tumor and that the side to be retained is not atrophic. Involvement of the main portal vein or the hepatic artery is a relative rather than an absolute contraindication; lesser degrees of involvement can be handled by means of vascular resection and reconstruction in specialized centers. Unusual combinations of events may prelude resection (e.g., atrophy on one side of the liver and invasion of the hepatic artery supplying the other side, or invasion of the portal vein to one side and the bile duct on the other side to the level of the secondary biliary branches).

MRI (with MRCP and magnetic resonance angiography [MRA]) or CT with the latest generation of scanners can provide complete information regarding the extent of bile duct involvement and the degree of vascular invasion. Doppler ultrasonography is also excellent for evaluating vascular invasion. ERCP may be used for additional assessment of the extent of the tumor on the side to be retained if a stent on that side is deemed necessary. The use of percutaneous cholangiography is controversial, the main concern being the risk of tumor seeding along the tube, into the peritoneal cavity, and onto the surface of the liver or the abdominal wall. Nevertheless, this procedure is used extensively in Japan, where surgeons have considerable experience with selective decompression of parts of the liver as a preoperative strategy.²⁸

Assessment of distant metastases is achieved by means of axial imaging of the chest and the abdomen. Staging laparoscopy identifies 10% to 15% of cancers that are unresectable because of peritoneal or liver metastases. FDG-PET identifies about 15% of patients with distant metastases. At present, neither of these tests is routinely employed in this setting.

Table 5 American Joint Committee on Cancer TNM Clinical Classification of Gallbladder Cancer

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ
	T1	Tumor invades lamina propria or muscle layer T1a: Tumor invades lamina propria T1b: Tumor invades muscle layer
	T2	Tumor invades perimuscular connective tissue
	T3	Tumor perforates serosa (visceral peritoneum) or directly invades one adjacent organ (\leq 2 cm into liver)
	T4	Tumor extends > 2 cm into liver or invades two or more adjacent organs (e.g., duodenum, colon, pancreas, omentum, or extrahepatic bile ducts)
Regional lymph nodes (N)	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Metastasis in cystic duct, pericholedochal, or hilar lymph nodes (i.e., in hepatoduodenal ligament)
	N2	Metastasis in peripancreatic (head only), periduodenal, periportal, celiac, or mesenteric lymph nodes
Distant metastasis (M)	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis

Management *Preoperative preparation.* Unlike cancers of the lower bile duct, cancers of the upper bile duct usually necessitate major liver resection [see 5:22 *Procedures for Benign and Malignant Biliary Tract Disease*]. Consequently, it has been argued that the risk of postoperative hepatic failure may be lowered by preoperative decompression, especially decompression of the side to be retained, which has the dual purpose of allowing that side to recover function and of actually encouraging hypertrophy. On the other hand, stents may introduce bacteria and cause cholangitis. As noted (see above), selective percutaneous decompression is an accepted strategy in Japan; often, multiple stents are inserted.²⁸

A reasonable strategy is to proceed to operation if (1) the patient is relatively young (< 70 years), (2) there are no serious comorbid conditions, (3) the jaundice has been present for less than 4 weeks, (4) the serum bilirubin concentration is lower than 10 mg/dl, (5) the future remnant liver will include more than 30% of the total liver mass, and (6) the patient has not undergone biliary instrumentation (which always contaminates the obstructed biliary tract). In all other cases, we routinely decompress the side of the liver to be retained and wait until the serum bilirubin concentration falls to 3 mg/dl. When the future remnant liver will include less than 30% to 35% of the total liver mass, portal vein embolization (PVE) of the side to be resected may be performed to induce hypertrophy of the remnant. Because resection for hilar CCA is a major procedure in a somewhat compromised liver, it is contraindicated in patients who are in poor general condition or who have major organ dysfunction.

Rationale for surgery. Patients with upper-duct CCA are candidates for resection if they have no distant metastases (including intrahepatic metastases) and if the tumor can be removed in its entirety by means of bile duct resection [see 5:22 *Procedures for Benign and Malignant Biliary Tract Disease*] combined with liver resection [see 5:23 *Hepatic Resection*]. The goal of resection of upper-duct CCA is to achieve clear resection margins by removing the tumor, the portal and celiac lymph nodes, the side of the liver in which the ductal involvement is greater (via hemihepatectomy or trisectionectomy), and the caudate lobe. (The caudate

lobe is resected because cholangiocarcinomas tend to invade along the short caudate bile ducts, which enter the posterior surfaces of the main right and left bile ducts at the bifurcation of the common hepatic duct.)

Liver transplantation has been used successfully to manage Bismuth type IV tumors and is usually performed after neoadjuvant chemoradiation therapy and staging laparotomy in highly selected patients.²⁹

GALLBLADDER CANCER

The incidence of gallbladder cancer in the United States is about 9,000 cases a year. This cancer almost always arises in patients with preexisting gallstones and is most often seen in elderly patients. Like ductal adenocarcinoma of the pancreas, it is highly malignant, and it tends to spread at an early stage to lymph nodes, to peritoneal surfaces, and through the bloodstream. AJCC staging criteria are helpful for planning management of this cancer [see Tables 5 and 6].

Clinical Evaluation

Gallbladder cancer is discovered incidentally either during performance of cholecystectomy for symptomatic cholelithiasis or when the tumor causes symptoms related to invasion of the bile duct or metastatic disease. In stage I and II disease, which is confined to the wall of the gallbladder, the symptoms are usually those of the associated stones—that is, the patient has biliary colic, and the cancer is silent. In later stages of disease, jaundice, weight loss, a palpable right upper quadrant mass, hepatomegaly, or ascites may develop. Jaundice occurs in about 50% of patients. It is a poor prognostic sign because it signifies extension of the tumor beyond the gallbladder and obstruction of the extrahepatic bile ducts. Consequently, most gallbladder cancer patients with jaundice have unresectable tumors. Because the signs and symptoms of gallbladder cancer are nonspecific, delays in diagnosis are common. As a result, most gallbladder cancers are not diagnosed until they have reached stage III or IV; thus, most of these aggressive tumors are unresectable at presentation, even when the patient is not jaundiced.

Investigative Studies

Laboratory tests In stages I and II, LFTs usually yield normal results. In later stages, laboratory test abnormalities may be noted that are not diagnostic but are consistent with bile duct obstruction. Elevated alkaline phosphatase and bilirubin levels are common. An elevation in the serum CA 19-9 concentration is the most helpful diagnostic indicator.

Table 6 American Joint Committee on Cancer Staging System for Gallbladder Cancer

Imaging Because gallbladder cancer is most curable in its early stages and because the symptoms in those stages are those of cholelithiasis, it is helpful to be aware of subtle signs of gallbladder cancer that are occasionally present on sonograms. These signs include thickening of the gallbladder wall, a mass projecting into the lumen, multiple masses or a fixed mass in the gallbladder, calcification of the gallbladder wall (so-called porcelain gallbladder), and an extracholecystic mass. Displacement of a stone to one side of the gallbladder should also be viewed with suspicion.

In later stages of disease, CT scans usually show a gallbladder mass with or without invasion of the liver or other adjacent organs. Obstruction of the bile duct produces the usual features associated with obstructive jaundice. Percutaneous CT-guided biopsy is a useful technique for confirming the diagnosis in patients with unresectable tumors. Porcelain gallbladder is a premalignant condition, though there is some evidence that the incidence of cancer depends on the pattern of calcification: selective mucosal calcification apparently carries a significant risk of cancer, whereas diffuse intramural calcification does not.³⁰ It seems reasonable to resect only tumors with the former pattern, but whenever there is a question about the pattern of calcification, one should err on the side of resection.

Surgical Staging

Staging of gallbladder cancer requires knowledge of the extent of direct invasion into the liver and other adjacent organs and tissues (especially the bile duct, the portal veins, and the hepatic arteries). As in hilar CCA, this information may be obtained by means of MRCP and MRA or CT with the latest-generation scanners. Staging laparoscopy is very helpful in managing gallbladder cancer. As many as 50% of patients with this disease are found to have peritoneal or liver metastases upon staging laparoscopy,⁸ and as with carcinoma of the body of the pancreas, there are no useful palliative measures that can be undertaken at laparotomy.

Management

Rationale for surgery When early-stage gallbladder cancer is suspected on the basis of diagnostic imaging, open cholecystectomy, rather than laparoscopic cholecystectomy, is probably the procedure of choice [see 5:21 *Cholecystectomy and Common Bile Duct Exploration and 5:22 Procedures for Benign and Malignant Biliary Tract Disease*]. Intraoperatively, if there is no evidence of spread outside the gallbladder, we recommend performing an extraserosal cholecystectomy, in which the fibrous liver plate is excised along with the gallbladder so that bare liver is exposed. It is possible to perform an extraserosal resection laparoscopically; however, in our opinion, this should not be attempted, because gallbladder perforation and bile spillage are more common with the laparoscopic version of the procedure. The negative consequences of tumor implantation or incomplete excision far outweigh any benefit that a minimally invasive approach might confer.

The excised specimen should be inked and a frozen section obtained. If there is gallbladder cancer in the specimen but the resection margins are clear and the tumor is a T1 lesion (i.e., has not penetrated the muscularis), the procedure is considered complete, in that lymph node metastases are uncommon with T1 tumors (incidence < 10%). However, lymph node metastases are present in 50% of patients with T2 lesions (i.e., tumors that have invaded the muscularis). Therefore, if margins are positive or the tumor is a T2 lesion, resection of segments 4b and 5 of the liver and dissection of portal and celiac lymph nodes, along with resection of the extrahepatic bile duct and hepaticojejunostomy, are recommended. If it is already clear at the commencement of the operation that the tumor is T2, one should proceed directly to liver, lymph node, and bile duct resection.

In more advanced stages of disease (T3 and T4), the aim is still excision with clear margins and resection of portal and celiac lymph nodes. To obtain clear local margins with these tumors, in addition to what is required for T2 tumors, more extensive hepatic resections—up to a trisectionectomy (resection of segments 4 through 8) [see Liver Cancer, Anatomic Considerations, *below*]³¹—may be necessary, as well as resection of adjacent organs.

Incidentally discovered gallbladder cancer Gallbladder cancer may be an incidental finding at laparoscopic cholecystectomy, as it has been at open cholecystectomy. The incidence of this finding ranges from 0.3% to 1.0%. A concern that has arisen in the current era, in which the laparoscopic approach to cholecystectomy is dominant, is the risk of port-site implantation of tumor. Port-site implantation may simply be the result of contact between the malignancy and the tissues surrounding the port site at the time of gallbladder extraction; however, positive pressure pneumoperitoneum may also play a causative role. When evidence of gallbladder wall thickening is noted intraoperatively, the gallbladder should be extracted in a sac. The gallbladder should be inspected at the time of extraction, and any questionable areas should undergo biopsy.

If a gallbladder cancer is discovered at the time of operation, it should be treated without delay according to the principles stated earlier (i.e., depending on whether the margins on the excised gallbladder are clear and on the T stage of the tumor). From an oncologic viewpoint, it would seem ideal to resect the tissue around all trocar port sites. From a technical viewpoint, however, it would be very difficult and impractical to excise the full thickness of the abdominal wall circumferentially around four port sites, especially because the tract of the port site often is not at a 90° angle to the abdominal wall. If the gallbladder was extracted through a port site without having been placed into a bag, it is reasonable to attempt excision of that one port site.

Sometimes, cancer is suspected, but frozen-section examination is inconclusive and the definitive diagnosis of cancer is not made until the early postoperative period. More often, cancer is not suspected intraoperatively, and the diagnosis is made only when permanent sections of the gallbladder are examined. In these situations, patients with completely excised T1 lesions require no further therapy, and patients with higher-stage lesions should undergo reoperation in accordance with the principles outlined earlier (see above). Other appropriate reasons for not performing the additional surgery at the time of the cholecystectomy are (1) the desire to discuss the management scheme with the patient and (2) lack of experience with the procedure for T2 tumors. Not infrequently, patients are referred to hepatic-pancreatic-biliary (HPB) centers 10 to 14 days after surgery, which is an inopportune time for reoperation, especially if the first procedure was difficult. Surgery may then be delayed for 3 to 4 weeks. We restage patients with abdominal CT scans when they are referred with this diagnosis, and it is not unusual to find hepatic metastases when this is done. The survival rate is much higher after radical resection than after cholecystectomy, even when cholecystectomy was the first procedure.³²

Gallbladder polyps Gallbladder polyps are discovered incidentally on ultrasonograms or CT scans or are diagnosed when they cause biliary colic. They may be malignant but are rarely so when less than 1 cm in diameter, especially when they are multiple. Most gallbladder polyps are less than 0.5 cm in diameter; these are almost always benign cholesterol polyps and may be followed if they are not giving rise to symptoms. Single polyps

between 0.5 and 1 cm in diameter should probably be removed by means of cholecystectomy; multiple polyps in this size range should be followed. About one quarter of all single gallbladder polyps more than 1 cm in diameter are malignant, and such polyps should be treated as malignant as a matter of policy. Almost all polyps more than 1.8 cm in diameter are malignant.³³

Liver Cancer

ANATOMIC CONSIDERATIONS

A long-standing problem in discussing any surgical liver disease, especially liver cancer, has been the confusing terminology applied to liver anatomy and the various hepatic resections. Fortunately, a lucid and cogent terminology has emerged that is sanctioned by both the International Hepato-Pancreato-Biliary Association (IHPBA) and the American Hepato-Pancreato-Biliary Association (AHPBA).³¹ This terminology has been widely adopted around the world and translated into many languages. It may be briefly summarized as follows.

The fundamental principle is that the anatomic divisions of the liver are based on vascular and biliary anatomy rather than on surface markings [see Figure 8]. This is an important point because surgical resection is a process of isolating specific liver volumes serviced by specific vascular and biliary structures. The anatomic

ramifications of the hepatic artery and the bile duct are regular and virtually identical. Liver anatomy is best understood by first following these structures through a series of orderly divisions. The branching of the portal vein on the right side is similar to that of the bile duct and the hepatic artery, but its branching on the left side, because of the fetus's need to use the umbilical portion of the portal vein as a conduit, is unusual.

The first-order division of the proper hepatic artery and the common hepatic duct into the right and left hepatic arteries and the right and left hepatic ducts, respectively, results in division of the liver into two parts (or volumes), referred to as the right and left hemilivers (or the right and left livers) [see Figure 8 and Table 7]. In this system of terminology, the term lobe is never used to denote a hemiliver, because it bears no relation to the internal vascular anatomy. The right hepatic artery supplies the right hemiliver, and the left hepatic artery supplies the left hemiliver. The right and left hepatic ducts drain the corresponding hemilivers. The plane between these two zones of vascular supply is called a watershed. The border or watershed of the first-order division is a plane that intersects the gallbladder fossa and the fossa for the inferior vena cava and is called the midplane of the liver.

The second-order division divides each of the hemilivers into two parts [see Figure 8 and Table 7], referred to as sections. The right hemiliver comprises the right anterior section and the right

Figure 8 Illustrated are the anatomic divisions of the liver according to IHPBA/AHPBA-sanctioned terminology, including first-order divisions (hemilivers), second-order divisions (sections) and third-order divisions (segments).

Table 7 Brisbane 2000 Terminology for Hepatic Anatomy and Resections from IHPBA

Level of Division	Preferred Anatomic Term	Corresponding Couinaud Segments (Sg)	Preferred Term for Surgical Resection*	Comments
First order (hemiliver)	Right hemiliver or Right liver	Sg 5–8 (± caudate lobe [†])	Right hepatectomy or Right hemihepatectomy (stipulate ± caudate lobe)	The border or watershed separating the two hemilivers is a plane that intersects the gallbladder fossa and the inferior vena cava fossa; this plane is referred to as the midplane of the liver
	Left hemiliver or Left liver	Sg 2–4 (± caudate lobe)	Left hepatectomy or Left hemihepatectomy (stipulate ± caudate lobe)	
Second order (section)	Right anterior section	Sg 5, 8	Right anterior sectionectomy	The borders or watersheds separating the sections within the hemilivers are planes referred to as the right intersectional plane (for which there is no surface marking) and the left intersectional plane (which passes through the umbilical fissure and the attachment of the falciform ligament)
	Right posterior section	Sg 6, 7	Right posterior sectionectomy	
	Left medial section	Sg 4	Left medial sectionectomy	
	Left lateral section	Sg 2, 3	Left lateral sectionectomy	
	—	Sg 4–8 (± caudate lobe)	Right trisectionectomy (preferred) or Extended right hepatectomy or Extended right hemihepatectomy (stipulate ± caudate lobe)	
	—	Sg 2, 3, 4, 5, 8 (± caudate lobe)	Left trisectionectomy (preferred) or Extended left hepatectomy or Extended left hemihepatectomy (stipulate ± caudate lobe)	
Third order (segment)	Segments 1–9	Any Sg	Segmentectomy (stipulate Sg—e.g., segmentectomy 7)	The borders or watersheds of the segments are planes referred to as the intersegmental planes
	Two contiguous segments	Any two Sg in continuity	Bisegmentectomy (stipulate Sg—e.g., bisegmentectomy 7, 8)	

*It is also permissible to refer to any resection in terms of its third-order components. Thus, a left hemihepatectomy may be referred to as a resection Sg 2–4 (or 1–4).

[†]The caudate lobe comprises segments 1 and 9. IHPBA—International Hepato-Pancreato-Biliary Association

posterior section. These sections are supplied by a right anterior sectional hepatic artery and a right posterior sectional hepatic artery and are drained by a right anterior sectional hepatic duct and a right posterior sectional hepatic duct. The left hemiliver comprises the left medial section and the left lateral section. These sections are supplied by a left medial sectional hepatic artery and a left lateral sectional hepatic artery and are drained by a left medial sectional hepatic duct and a left lateral sectional hepatic duct.

The third-order division divides the liver into nine segments, each of which has its own segmental artery and bile duct [see Figure 8 and Table 7]. The caudate lobe, a unique portion of the liver that is separate from the right and left hemilivers, comprises segments 1 and 9. The left lateral section comprises segments 2 and 3; the left medial section comprises segment 4 (which is sometimes further divided into segments 4a and 4b); the right anterior section comprises segments 5 and 8; and the right posterior section comprises segments 6 and 7.

PRIMARY CANCERS

Hepatocellular Cancer

Hepatocellular cancer (HCC), or hepatoma, is the fifth most

common cancer in the world. About 90% of cases arise in patients with chronic liver disease, especially when the disease has progressed to cirrhosis. Although any condition that produces cirrhosis may lead to HCC, the most common cause is viral hepatitis. In the United States, some 3 million people are infected with hepatitis C virus (HCV), and more than 1 million people have liver disease associated with hepatitis B virus (HBV). HCV infection is much more likely to lead to HCC than HBV infection is. AJCC staging criteria are useful for planning the management of liver cancer [see Tables 8 and 9].

Clinical evaluation The usual presentation of sporadic HCC consists of pain, mass, and systemic symptoms of cancer, though the disease may also be discovered incidentally. HCC occurring as a complication of liver disease may present similarly, but it is often manifested first as a deterioration of liver function with the onset of jaundice, ascites, or encephalopathy.

Investigative studies Screening programs are employed in high-risk populations. These programs, which use α -fetoprotein (AFP) levels and ultrasonographic examination of the liver to detect early HCC, may detect asymptomatic tumors.

Table 8 American Joint Committee on Cancer TNM Clinical Classification of Adult Primary Liver Cancer

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	T1	Solitary tumor without vascular invasion
	T2	Solitary tumor with vascular invasion; multiple tumors, none > 5 cm in greatest dimension
	T3	Multiple tumors > 5 cm in greatest dimension or tumor involving major branch of portal or hepatic vein
Regional lymph nodes (N)	T4	Tumor or tumors with direct invasion of adjacent organs (other than gallbladder) or visceral peritoneum
	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
Distant metastasis (M)	N1	Regional lymph node metastasis
	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis

The diagnosis of sporadic HCC is based on elevation of AFP levels (an indicator with 50% to 60% sensitivity) and the presence of a hepatic mass on axial images. HCCs typically demonstrate hypervascularity, which is best seen on arterial-phase images [see Figure 9]. A pseudocapsule is often visualized, which is best seen on portal venous-phase images. Multifocality is also common in HCC, and this finding often serves to differentiate it from other hepatic neoplasms. Routine biopsy is not indicated in patients with a characteristic mass, those who have a mass and an elevated AFP level, or those who are symptomatic and require treatment for pain. HCC may be very well differentiated and difficult to distinguish from hepatic adenoma and focal nodular hyperplasia on biopsy. It may also be hard to distinguish from cirrhotic nodules. Biopsy is associated with a small risk of bleeding or tumor seeding.

Surgical staging Staging of sporadic HCC requires axial imaging of the abdomen and imaging of the chest. FDG-PET scanning is only marginally useful: HCCs are typically well differentiated, and as a result, only 50% of the tumors are visualized. Staging laparoscopy is helpful: additional tumors are found in about 15% of patients.³⁴

Staging also requires evaluation of the extent of liver disease. The Child-Pugh classification is used to determine operability. With few exceptions, resection is limited to Child class A patients with near-normal bilirubin levels (< 1.5 mg/dl), a normal or marginally raised prothrombin time (PT), and no or minimal portal hypertension. The extent of resection must be tailored to the severity of the liver

disease. For instance, resection of more than two segments is limited to patients with normal liver function. Too-extensive resection puts the patients at risk for liver failure in the postoperative period. In Japan and China, indocyanine green (ICG) clearance is used in Child class A patients to determine the possible extent of resection.

Management Rationale for surgery. The rationale for surgery is clear in patients without liver disease or in Child class B or C patients with chronic liver disease. The rationale for surgery in Child class A patients, however, remains controversial.

Partial liver resection [see 5:23 *Hepatic Resection*] is the procedure of choice for sporadic HCC in patients with normal livers. In Child class B or C patients with chronic liver disease, liver resection can be hazardous, and orthotopic liver transplantation (OLT) is the procedure of choice. To justify the use of donor organs, however, it is necessary to select patients with HCC so that the long-term outcome of OLT for HCC is similar to that of OLT for benign conditions. To achieve this goal, OLT is restricted to patients with a single tumor less than 5 cm in diameter or to patients with as many as three tumors, none of which are more than 3 cm in diameter (the Milan criteria). These criteria have been shown to be associated with OLT outcomes comparable to those for benign conditions.³⁵

In Child class A patients with liver disease, hepatic resection and OLT are options if the Milan criteria are met. The optimal therapeutic approach in this situation has been the subject of considerable debate, with proponents arguing for one of two strategies—namely, (1) primary OLT or (2) resection followed by OLT if HCC recurs, provided that the patients still meet criteria for OLT (so-called salvage OLT). A complete discussion of this controversy is beyond the scope of this chapter. Currently, it would seem that the best strategy in patients who meet the criteria for OLT is to perform primary OLT for HCV-associated disease³⁶ and to perform resection and salvage OLT for HBV-associated disease³⁷ and other HCCs of non-HCV origin. In patients who do not meet the OLT criteria, resection would be performed even if the tumor is of HCV origin. At present, there is a trend toward liberalizing the OLT criteria to include single tumors 6 or 7 cm in diameter, especially if the source of the organ is a living donor.

When OLT is to be performed, it is important that the waiting time be short; these tumors progress over a timescale of a few months, and when viewed on an intention-to-treat basis, the results of OLT deteriorate significantly if the waiting time is long.³⁸ In the United States, this concern has been dealt with by

Table 9 American Joint Committee on Cancer Staging System for Adult Primary Liver Cancer

Stage	T	N	M
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage IIIA	T3	N0	M0
Stage IIIB	T4	N0	M0
Stage IIIC	Any T	N1	M0
Stage IV	Any T	Any N	M0

Figure 9 CT scan shows a hypervascular HCC of the left liver.

the introduction of the Model for End-stage Liver Disease (MELD) scoring system, which gives priority to recipients with HCC. It is common in the United States—and usual in countries with longer waiting times—to inhibit the growth of the HCC with various bridging-to-transplantation strategies during the waiting period for OLT. Such strategies include systemic chemotherapy, local treatments (e.g., radiofrequency [RF] ablation and alcohol injection), transarterial chemoembolization (TACE), and even resection of the HCC (so-called bridge resection).

In patients with nondiseased livers, the extent of the resection depends on the size and position of the tumor. As much as 70% of the liver may be safely excised when normal liver function is present. The size of the future hepatic remnant may be determined by means of imaging. PVE of the side of the liver to be resected may be performed preoperatively to increase the size of the future remnant. It may also be used for this purpose in patients with liver disease. In these patients, PVE functions as a test of the liver's ability to regenerate. Failure to respond to PVE is itself a contraindication to surgery in patients with chronic liver disease.

As a rule, liver resections for HCC should be anatomic [see 5:23 *Hepatic Resection*]. Recurrence rates are higher with nonanatomic resections because HCCs grow along portal veins and metastasize locally within segments, sections, or hemilivers, depending on how far they reach back along the portal veins. When HCC reaches the main portal vein, resection is generally contraindicated; the results are very poor in this situation.

Intrahepatic Cholangiocarcinoma

Clinical evaluation Intrahepatic CCAs arise from intrahepatic bile ducts. There are three types: a mass-forming type (MF), a periductal infiltrating type (PI), and a type that grows as an intra-ductal papillary tumor (IG). The MF type is by far the most common. Intrahepatic CCA tumor usually occurs in normal livers. The presentation is similar to that of sporadic HCC.

Investigative studies On diagnostic imaging, the appearance of intrahepatic CCA is suggestive of a secondary tumor [see *Figure 10*]. Unlike diagnosis of HCC, diagnosis of intrahepatic CCA usually requires a biopsy, which reveals an adenocarcinoma

Figure 10 CT scan shows a mass-forming intrahepatic CCA.

that is indistinguishable from a hepatic metastasis arising from a primary adenocarcinoma in one of several intra-abdominal or extra-abdominal sites. Special stains may be helpful in differentiating this tumor from a true secondary malignancy, but the differentiation is rarely certain. An elevated CA 19-9 concentration is strongly suggestive of this diagnosis if it is higher than 100 U/ml. To make the diagnosis of intrahepatic CCA, primary tumors in other sites must be excluded by means of axial imaging of the chest, the abdomen, and the pelvis; upper and lower GI endoscopy; and mammography. FDG-PET scanning is another means by which an extrahepatic primary may be identified, but it has not been fully evaluated in this setting.

Surgical staging FDG-PET scanning appears to be a promising staging tool for identifying portal lymph node and distant metastases when the primary is actually an intrahepatic CCA. Portal lymph node metastases are a contraindication to resection in patients with MF tumors; the results of resection in this situation are very poor. Left-side tumors may metastasize to lymph nodes at the cardia of the stomach and along the lesser curvature.

Management The considerations related to resection for intrahepatic CCA are similar to those for sporadic HCC (see above). Liver transplantation generally is not performed for this tumor, because of the typically poor results.

SECONDARY CANCERS

Colorectal Metastases

Clinical evaluation and investigative studies About 50% of the 150,000 patients who are diagnosed with colorectal cancer annually in the United States either have or will have liver metastases. About 10% of patients with these colorectal metastases (CRMs) are eligible for liver resection. CRMs may be diagnosed either at the time of treatment of the primary colorectal cancer (synchronous tumors) or at a later stage (metachronous tumors).

Synchronous tumors are diagnosed by means of either preoperative CT scanning [see *Figure 11*] or intraoperative palpation. LFTs may show elevations (especially of the serum alkaline phosphatase level), but these results are not specific. CEA levels are not helpful as long as the primary tumor is in place. Metachronous tumors are most often diagnosed in the course of a postcolectomy surveillance program, either by imaging the liver with CT scans or FDG-PET scans or by detecting a rise in the CEA level. When synchronous metastases are discovered preoperatively, a FDG-PET scan should be done to complete the staging.

Surgical staging In about 25% of patients, FDG-PET scanning changes management by detecting unsuspected extrahepatic or intrahepatic disease. Sometimes, it demonstrates that apparent metastases are actually benign lesions. Second primaries are not uncommon in patients with metachronous lesions; accordingly, such patients should also be staged by means of colonoscopy, if this procedure was not done in the preceding 6 months, as well as FDG-PET scanning. Staging laparoscopy adds little to staging if an FDG-PET scan has been done.

Intraoperative staging consists of careful palpation of intra-abdominal structures, including hepatic and portal venous lymph nodes. In patients with metachronous lesions, however, palpation of the entire abdomen may be limited by adhesions from previous operations. IOUS of the liver may also detect unsuspected lesions, though this is less likely if the patient has already been staged by means of FDG-PET.

Figure 11 (a) CT scan shows a single large CRM. (b) Shown is the specimen after resection.

The main value of FDG-PET in this setting is its ability to discover unsuspected extrahepatic disease. In so doing, it helps eliminate futile hepatic resections. If a patient with extrahepatic disease is treated with hepatic resection, a “recurrence” is inevitable. Elimination of pointless resections has a positive effect on survival: a 2004 study from our institution found that the overall 5-year survival rate after FDG-PET was about 60%, compared with 40% after conventional imaging.³⁹ Furthermore, the study showed that after FDG-PET scanning, the classic prognostic factors of the secondary tumor (e.g., tumor number and tumor size) were no longer significant; rather, the most important prognostic factor was the grade of the primary tumor. FDG-PET-scanned patients with poorly differentiated primary tumors did very poorly in terms of overall survival after hepatic resection.³⁹ Currently, standard PET scanners are rapidly being replaced with CT-PET scanners, which fuse the images and provide superior diagnosis and staging. For planning surgical extirpation, however, the level of detail provided by high-quality contrast-enhanced CT or MRI is also required.

Management Rationale for surgery. The criteria that determine eligibility for resection are (1) that the primary tumor has been or can be completely resected, (2) that (with uncommon exceptions) there is no extrahepatic tumor (other than the primary), and (3) that it is possible to resect all tumors in the liver while leaving enough of a hepatic remnant to ensure that hepatic failure does not develop post-operatively. The considerations governing the extent of the resection and the use of PVE are similar to those for sporadic HCC.

Treatment of multiple tumors is much more common with CRMs than with HCC. However, nonanatomic resections are as effective as anatomic resections as long as the resection margin is microscopically clear. The traditional view has been that resection margins of 1 cm are mandatory. Whereas 1 cm margins may still be a reasonable goal, margins as narrow as 1 mm are satisfactory and are probably as effective as traditional margins, provided that they are free of microscopic and gross cancer. When close margins are expected, transection of the liver with a saline-linked RF ablation device may be useful, in that this device leaves a margin of devitalized tissue in the patient, as well as in the specimen.⁴⁰ When the margin is very close, it may be extended by painting the cut surface of the hepatic remnant with the RF device.

Synchronous resection of the primary tumor and the liver metastases has proved to be safe⁴¹ and is desired by many patients. The decision to proceed with hepatic resection should not be made until resection of the primary tumor has been completed and it has been determined that the margins are clear and the patient is stable. Some patients with a small number of lung lesions in addition to liver lesions have been cured by resection.

Ablation of colorectal metastases. In situ destruction of tumors with cryotherapy or RF ablation may expand the surgeon’s ability to eradicate CRMs localized to the liver.⁴² RF ablation has largely supplanted cryotherapy in this context as a result of its lower incidence of complications and greater ease of use. Ablation may be used either as an adjunct to operative management or as the sole treatment when there are many metastases (but usually < 10). The efficacy of RF ablation as an adjunct to surgery remains to be determined. It is doubtful, however, that using this modality alone to eradicate multiple lesions will improve overall survival significantly, because the tumor biology in such cases is likely to be that of an aggressive tumor. FDG-PET scans should be performed in all such patients; the likelihood of discovering extrahepatic tumors increases as the number of hepatic tumors increases.³⁹

RF ablation is not recommended for treatment of resectable metastases: it is not approved for this purpose, and using it in this way would mean substituting an unproven therapy of unknown efficacy for a proven therapy of known value. If a consenting patient with resectable metastases nevertheless insists on this less invasive therapy, the surgeon should document that the preceding considerations have been explained to him or her. RF ablation may be applied by means of open, laparoscopic, or percutaneous methods. There is good reason to believe that targeting ability is degraded as one moves to less invasive methods. This consideration should also be explained to patients, though undoubtedly there are some patients who, because of comorbid conditions, are candidates only for percutaneous or laparoscopic approaches.

Neuroendocrine Metastases

Neuroendocrine metastases are characteristically slow growing. Some are functional, especially if they arise from the ileum; metastatic liver disease from this source may produce carcinoid syndrome.

¹¹¹In-pentetreotide imaging (OctreoScan; Mallinckrodt Inc., Hazelwood, Missouri) provides staging information comparable to that provided by FDG-PET in patients with CRMs.

The aims of surgical treatment are (1) to eradicate the cancer and (2) to reduce hormonal symptoms. The considerations regarding tumor eradication for neuroendocrine metastases are similar to those for CRMs—that is, resection should be performed if all cancer can be removed and no extrahepatic cancer is detectable. In highly symptomatic patients in whom conservative therapy with octreotide has failed, debulking the tumor by means of either chemoembolization or surgery may provide relief. The former is more suitable for patients with multiple small, diffuse metastases, whereas the latter is preferred for patients with large localized tumors. RF ablation may also be employed, either combined with surgical treatment or alone; this is an excellent use of this procedure, in that the aim is cytoreduction rather than eradication. Debulking tumors in asymptomatic patients with the intention of extending survival is controversial.

Noncolorectal, Nonneuroendocrine Metastases

Occasionally, liver metastases from other primary sites behave like CRMs, in that they are localized to part of the liver in the absence of extrahepatic disease. Such patients can be managed according to the same approach employed for CRMs, though the outcome is somewhat less satisfactory. Tumors that have been treated in this way with acceptable results include breast cancers, renal cell cancers, gastric cancers, acinar cell cancers of the pancreas, and ovarian cancers. Liver resection for more aggressive malignancies (e.g., metastases from gallbladder cancer and pancreatic ductal adenocarcinomas) can be expected to yield very poor results.

INCIDENTALLY DISCOVERED ASYMPTOMATIC HEPATIC MASS

Now that transaxial imaging of the abdomen is commonly performed for a variety of complaints, the problem of the incidentally discovered asymptomatic hepatic mass is being encountered with increased frequency. Generally, cysts are easily distinguished from solid tumors; the main diagnostic issue is differentiation of the various solid lesions.

The differential diagnosis of the benign solid hepatic mass includes hepatic adenoma, focal nodular hyperplasia (FNH), focal fatty infiltration, cavernous hemangioma, and other rare neoplasms (e.g., mesenchymal hamartoma and teratoma)—all of which must be distinguished not only from one another but also from malignant tumors. In the past, several diagnostic tests (e.g., ultrasonography, CT, sulfur colloid scanning, and angiography) were used to differentiate these neoplasms. Currently, our usual practice is to perform MRI with gadolinium contrast enhancement, which generally allows accurate differentiation among benign tumors with a single test. Cavernous hemangiomas are usually easy to distinguish because they have a characteristic appearance on MRI (hypointense on T₁-weighted images, very intense on T₂-weighted images, and filling in from the periphery with gadolinium injection); if they are asymptomatic, they need not be resected. It is important to distinguish asymptomatic FNHs from hepatic adenomas: whereas resection is recommended for adenomas, because of their potential for hemorrhage or malignant degeneration, asymptomatic FNHs can safely be observed. An FNH is nearly isointense on T₁- and T₂-weighted images; it shows slightly more enhancement than normal liver parenchyma in the early phase after contrast injection, then becomes isointense. A central scar is often, but not always, seen. Conversely, a hepatic adenoma exhibits strong early-phase enhancement with contrast administration, and it tends to be hyperintense on T₁-weighted images.

Given that a symptomatic hepatic mass is usually treated with resection, preoperative biopsy for tissue diagnosis is rarely necessary or desirable. Modern noninvasive radiologic tests, in conjunction with a careful patient history, are often quite accurate in predicting histologic diagnosis. Biopsy of hepatic lesions should not be performed indiscriminately, because there is a small risk of complications or tumor tracking and because biopsy results often do not change management. As a rule, biopsies should be performed when definitive surgical intervention is not planned and when pathologic confirmation is necessary for institution of non-surgical therapy.

10 PORTAL HYPERTENSION

Clifford S. Cho, M.D., and Layton F. Rikkers, M.D., F.A.C.S.

Clinical strategies for managing portal hypertension have undergone significant refinements over the past half-century. This evolution has been driven by advances in our understanding of the physiology of both the disease and the therapies employed against it. Today, clinical management of the portal hypertensive patient is a truly multidisciplinary endeavor, requiring the coordinated efforts of skilled intensivists, gastroenterologists, hepatologists, interventional radiologists, and surgeons. Nevertheless, portal hypertension and its manifold complications remain some of the most vexing problems encountered in modern medicine and surgery.

In this chapter, we briefly review portal venous anatomy and the pathophysiology of portal hypertension [see *Sidebar Portal Hypertension: Anatomic and Physiologic Considerations*]; however, our main focus is on current practical approaches to managing portal hypertension and its associated sequelae (variceal bleeding, ascites, and hepatic encephalopathy). Of particular relevance to surgeons is that the role of surgical therapy has shifted significantly. Operative treatment now occupies only the final steps in modern treatment protocols for portal hypertension—that is, it serves as a form of salvage for intractable cases that are refractory to other forms of therapy.

Clinical Evaluation

The ultimate aims of diagnostic evaluation in a patient with portal hypertension are (1) to determine the cause of portal hypertension [see *Table 1*], (2) to estimate hepatic functional reserve, (3) to define the portal venous anatomy and assess hemodynamic status, and (4) to identify the site of GI hemorrhage (if present). Any history of chronic alcohol abuse, hepatitis, or exposure to hepatotoxins raises the suspicion of cirrhotic liver disease. Confirmatory evidence of chronic liver disease on physical examination may be found in the form of jaundice, chest wall spider angiomas, palmar erythema, Dupuytren contractures, testicular atrophy, or gynecomastia. Ascites, splenomegaly, caput medusae, encephalopathic alterations in mental status, and asterix are all suggestive of portal hypertension.

Investigative Studies

Laboratory studies can also provide indicators of hepatic dysfunction. The hypersplenism that often accompanies cirrhosis can produce mild to moderate pancytopenia. Anemia may also reflect variceal hemorrhage, hemolysis, or simply the chronic malnutrition or bone-marrow suppression associated with chronic alcoholism. Associated hyperaldosteronism, emesis, or diarrhea may give rise to electrolyte derangements, including hyponatremia, hypokalemia, metabolic alkalosis, and prerenal azotemia. Coagulopathy is usually attributable to chronic deficiencies in clotting factors that are normally synthesized by the liver; thus, elevation of the prothrombin time (PT) or the international normalized ratio (INR) often reflects the degree of chronic hepatic impairment. Similarly, the degree of hyperbilirubinemia can be a measure of both acute and chronic hepatic dysfunction. Hepato-

cellular necrosis results in marked elevations in serum aminotransferases that are readily observed in patients with chronic active viral or alcoholic hepatitis. An alanine aminotransferase (ALT)–aspartate aminotransferase (AST) ratio of 2 or higher is often seen in patients with alcoholic liver disease.

The Child-Pugh scoring system is a useful tool for quantifying hepatic functional reserve [see *Table 2*].¹ Based on total bilirubin and albumin levels, PT (INR), and the clinical severity of ascites and hepatic encephalopathy, the Child-Pugh score predicts both the likelihood of variceal hemorrhage and its anticipated mortality. A newer assessment tool, the Model for End-Stage Liver Disease (MELD) scoring system, which takes the degree of renal impairment and the cause of hepatic dysfunction into account, has also been used to predict outcomes in cirrhotic patients.²

Management of Variceal Bleeding

The prognosis of variceal hemorrhage depends on the presence or absence of underlying cirrhosis. In noncirrhotic patients, the mortality associated with a first episode of variceal hemorrhage ranges from 5% to 10%; in cirrhotic patients, the range is from 40% to 70%. Esophagogastric varices ultimately develop in approximately one half of cirrhotic patients, and bleeding episodes occur in approximately one third of cirrhotic patients with varices. If the initial hemorrhagic episode resolves spontaneously, 30% of patients experience rebleeding within 6 weeks, and 70% experience rebleeding within 1 year. It is noteworthy that overall mortality in patients who survive 6 weeks after an episode of variceal bleeding is statistically indistinguishable from that in persons who have never experienced such an episode.

Massive splenomegaly	Secondary biliary cirrhosis
	Posthepatic cirrhosis

Portal Hypertension: Anatomic and Physiologic Considerations

Anatomy of Portal Venous System

The 6 to 8 cm portal vein is formed by the confluence of the splenic vein and the superior mesenteric vein behind the pancreatic neck and is the most posterior component of the portal triad in the hepatoduodenal ligament. The inferior mesenteric vein, though prone to anatomic variation, typically enters the splenic vein at or near its confluence with the superior mesenteric vein. The left gastric vein drains the lesser curvature of the stomach and typically enters the portal vein near its origin.

The unique dual blood supply of the liver, consisting of the portal vein and the hepatic artery, is coordinated by a compensatory regulatory system. Total hepatic blood flow, which averages 1.5 L/min, accounts for about one quarter of cardiac output. The portal circulation typically accounts for two thirds of this hepatic blood flow but provides only one third of hepatic oxygen content. Portal blood flow is an indirect function of splanchnic arterial vasoconstriction and vasodilatation; in contrast, hepatic arterial flow is directly regulated by sympathetic innervation and circulatory catecholamines. As a result, changes in portal blood flow resulting from splanchnic circulatory changes can be compensated for by hepatic arteriolar dilatation or constriction. In this manner, hepatic arterial autoregulatory vasodilatation can preserve normal hepatic blood flow even in the setting of significant decreases in portal flow resulting from shock, hypovolemia, splanchnic vasoconstriction, or portosystemic shunting. Although hepatic oxygenation may be preserved in this fashion, augmented hepatic arterial flow does not replace the essential regulators of hepatic metabolism and growth (e.g., insulin) that are found in portal venous blood. As a consequence, prolonged restriction of portal perfusion, as is seen with portal hypertension-induced portosystemic collateralization or surgically created portosystemic shunts, results in deprivation of these hepatotropic factors, which can ultimately contribute to hepatic atrophy and failure.

Pathophysiology of Portal Hypertension

Traditionally, the various causes of portal hypertension have been categorized according to the anatomic locus of increased resistance to portal flow. In reality, this categorization is an oversimplification, in that individual causes have been shown to exert their inciting effects at multiple levels. For example, portal hypertension arising from alcoholic cirrhosis has classically been considered an intrahepatic postsinusoidal obstructive process resulting from regenerative hepatic nodules

and fibrosis causing hepatic venule compression; however, the demonstration of collagen deposition within Disse's space in cirrhotic livers suggests the presence of a concurrent sinusoidal locus as well. Similarly, the extrahepatic postsinusoidal Budd-Chiari syndrome often produces cirrhotic changes that create a secondary intrahepatic sinusoidal cause of portal hypertension.

Normal portal vein pressures range from 3 to 6 mm Hg, with daily circadian variation. Transient pressure elevations are commonly detected after eating, exercise, and Valsalva maneuvers. Sustained elevations in portal vein pressure to levels higher than 10 mm Hg can result in gradual shunting of blood from the portal circulation into the adjacent low-pressure systemic circulation via certain collateral vessels. Formation and expansion of these collaterals are thought to progress by means of active angiogenesis. The most clinically significant of these vessels are the left gastric vein and the short gastric veins, which decompress hypertensive portal flow into the azygous vein via esophageal and gastric submucosal veins, respectively. Collateral filling from the left portal vein to the epigastric veins through recanalization of the obliterated umbilical vein can result in the caput medusae pattern of dilated abdominal wall veins that is readily appreciated on physical examination. Portosystemic shunting also takes place via retroperitoneal and anorectal collateral vessels.

Long-term shunting of high-pressure portal venous blood through systemic venous vessels evolved for low-pressure capacitance can eventually result in variceal dilatation of the latter. Sustained portal pressures of 12 mm Hg or higher are necessary to produce sufficient distention of these thin-walled vessels to induce rupture. Variceal rupture presents as GI hemorrhage. Although varices can form throughout the entire length of the alimentary canal, the majority of portal hypertensive bleeding is from esophagogastric varices. Unfortunately, prediction of variceal hemorrhage can be difficult; only one third to one half of patients with portal pressures exceeding 12 mm Hg will experience bleeding episodes. On the basis of Laplace's law, one can expect variceal size, intraluminal variceal pressure, and overlying epithelial wall thickness to be predictive of the likelihood of variceal rupture. Clinically, variceal size and the presence and severity of red-wale markings on upper GI endoscopy (a marker of epithelial thickness) can be used in conjunction with the Child-Pugh score to predict the likelihood of variceal hemorrhage.⁵⁴

Further risk stratification is based on the extent of hepatic decompensation. The mortality associated with variceal hemorrhage is 5% for patients with Child class A cirrhosis, 25% for those with Child class B cirrhosis, and over 50% for those with Child class C cirrhosis. The likelihood of recurrent hemorrhage is 28% for patients with Child class A cirrhosis, 48% for those with Child class B cirrhosis, and 68% for those with Child class C cirrhosis.³

TREATMENT OF ACUTE VARICEAL HEMORRHAGE

Management of acute variceal hemorrhage [see *Figure 1*] begins with the establishment of adequate airway protection. The risk of aspiration and consequent respiratory deterioration is particularly high among patients with hepatic encephalopathy and those undergoing endoscopic therapy. Accordingly, the threshold for early endotracheal intubation should be low, particularly if endoscopic therapy is considered. As with all cases of brisk hemorrhage, adequate venous access is mandatory; placement of a central venous catheter for accurate volume assessment is particularly useful in cases of major bleeding. The presence of chronic liver

disease often necessitates vigorous replacement of circulatory volume and coagulation factors, often involving infusion of colloids and transfusion of fresh frozen plasma and packed red blood cells. Antibiotic prophylaxis therapy is recommended because of the propensity of bacterial infections to develop in patients with chronic liver disease after bleeding episodes.

Pharmacologic Therapy

First-line pharmacotherapy for acute variceal bleeding relies on the long-acting somatostatin analogue octreotide, which has been shown to decrease splanchnic blood flow and portal venous pressure. Octreotide is administered in a 250 µg I.V. bolus, followed by infusion of 25 to 50 µg/hr for 2 to 4 days.⁴ In addition, vasopressin, a strong splanchnic vasoconstrictor, has been shown to control approximately 50% of acute variceal bleeding episodes.^{4,5} Vasopressin is typically administered in a 20 U I.V. bolus over 20 minutes, followed by infusion of 0.2 to 0.4 U/min. The therapeutic benefits of octreotide and vasopressin appear to be similar, though the side-effect profile of octreotide appears to be much lower than that of vasopressin monotherapy.⁴ Adjunctive

use of nitroglycerin at an initial rate of 50 µg/min (titrated according to blood pressure tolerance) effectively reduces the cardiac complications of vasopressin and thereby facilitates its administration.⁶ The long-acting vasopressin analogue terlipressin has been shown to be approximately as effective as octreotide.⁷

Endoscopic Therapy

Endoscopic treatment, in the form of sclerosant injection or band ligation, has become a standard form of therapy for acute variceal hemorrhage. Experienced endoscopists achieve initial control of hemorrhage in 74% to 95% of cases; however, rebleeding rates ranging from 20% to 50% are typically observed.

In endoscopic sclerotherapy, a sclerosant—typically either 5% sodium morrhuate (more common in the United States) or 5% ethanolamine oleate (more common in Europe and Japan)—is injected either intravariceally to obliterate the varix or paravariceally to induce submucosal fibrosis and thereby prevent variceal rupture. Three prospective, randomized, controlled trials demonstrated that endoscopic sclerotherapy, compared with traditional balloon tamponade, achieved better initial hemorrhage control, resulted in fewer episodes of rebleeding, and, in selected cohorts of patients, led to improved long-term survival.⁸⁻¹⁰ Furthermore, routine use of balloon tamponade after sclerotherapy appeared not to confer any additional therapeutic benefit.⁸ There are, however, significant risks associated with the use of endoscopic sclerotherapy, including pulmonary complications, transient chest pain, esophageal stricture formation with recurrent sclerotherapy, iatrogenic portal vein thrombosis, hemorrhagic esophageal ulceration, bacteremia, and esophageal perforation.¹¹

Partially in response to the potential complications of endoscopic sclerotherapy, endoscopic variceal band ligation has been advocated as a sclerosant-free therapeutic alternative. The limited data comparing the two approaches suggest a trend toward fewer rebleeding episodes, fewer endoscopic interventions, and significantly lower procedure-related morbidity and overall mortality after variceal ligation.¹²

Pharmacologic versus Endoscopic Therapy

Two meta-analyses compared medical pharmacotherapy with emergency sclerotherapy as first-line treatment of acute variceal hemorrhage.^{13,14} No significant differences between the two approaches were demonstrated with respect to initial hemorrhage

Table 2 Child-Pugh System for Classifying Cirrhosis

Parameter	Score*		
	1	2	3
Total bilirubin (mg/dl)	1–2	2.1–3	≥ 3.1
Albumin (g/dl)	≥ 3.5	2.8–3.5	≤ 2.7
INR or PT (sec)	< 1.7 1–4	1.8–2.3 4.1–6	≥ 2.4 ≥ 6.1
Ascites	None	Mild	Moderate
Hepatic encephalopathy	None	Mild	Advanced

*Class of cirrhosis is determined on the basis of total points scored: 5 to 6 points, class A; 7 to 9 points, class B; 10 to 15 points, class C.
 INR—international normalized ratio PT—prothrombin time

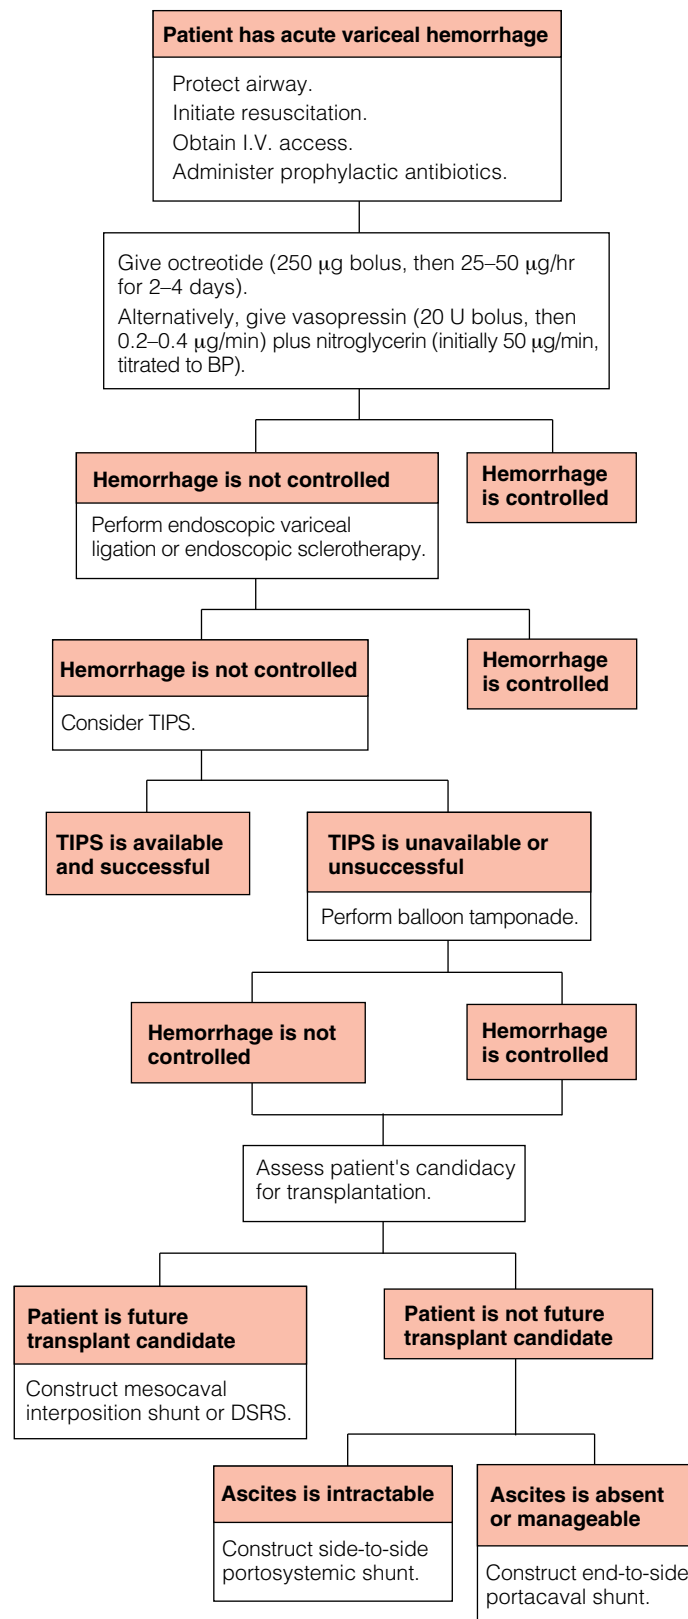

Figure 1 Algorithm outlines treatment of acute variceal bleeding.

control or mortality, though treatment-related complications appeared to be significantly more common after sclerotherapy. On the basis of these studies, it has been suggested that endoscopic treatment should be reserved for cases of pharmacotherapeutic failure or that pharmacologic therapy should be initiated in situa-

tions where endoscopy is not immediately available. At present, however, it is more common for the two forms of treatment to be employed concurrently. Pharmacotherapy is often initiated in preparation for endoscopy; early mitigation or control of variceal hemorrhage can make endoscopic visualization and intervention easier, safer, and more effective. Indeed, administration of somatostatin before and after endoscopic sclerotherapy has been shown to improve treatment efficacy and decrease transfusion requirements in comparison with endoscopic sclerotherapy alone.^{15,16}

Balloon Tamponade

Although the devices used for balloon tamponade have evolved through numerous different forms over the years, all of them rely on the same basic principle—application of direct upward pressure against varices at the esophagogastric junction. Patients for whom balloon tamponade is considered should be intubated endotracheally to prevent airway occlusion and aspiration. The tube is inserted into the stomach, and the gastric balloon is partially inflated with 40 to 50 ml of air [see Figure 2]. An abdominal radiograph is obtained to ensure that the gastric balloon is correctly positioned within the stomach and below the diaphragm. This balloon is then further inflated until it holds 300 ml of air, and the tube is pulled upward with external traction. If hemorrhage is not controlled at this point, the esophageal balloon is inflated to a pressure of 35 to 40 mm Hg. Suction drainage is applied to both the esophageal port and the gastric port to minimize aspiration risk and monitor for recurrent hemorrhage.

When properly applied, direct tamponade therapy is 90% effective in controlling acute hemorrhage. The primary limitation of such therapy is that bleeding resumes in as many as 50% of patients after takedown and removal of the balloon. Furthermore, serious potential complications (e.g., gastric or esophageal perforation, aspiration, and airway obstruction) result in treatment-related mortalities as high as 20%.^{17,18} Nevertheless, in cases of brisk variceal hemorrhage refractory to pharmacologic and endoscopic therapy, balloon tamponade may have a role to play as a bridge therapy to more definitive forms of treatment, such as transjugular intrahepatic portosystemic shunting (TIPS) (see below) or operative intervention.

Transjugular Intrahepatic Portosystemic Shunting

A nonoperative technique for creating an intrahepatic portosystemic fistula for decompression of portal hypertension was proposed in 1969¹⁹ and first performed in 1982.²⁰ As currently practiced, TIPS is performed by (1) cannulating a hepatic vein (usually the right hepatic vein) via the internal jugular vein, (2) passing a needle from the hepatic vein through the liver parenchyma and into a portal vein branch, (3) passing a guide wire through the needle, (4) dilating the needle tract with a balloon passed over the guide wire, and (5) stenting the tract to a desired diameter, thus effectively constructing a nonselective side-to-side portosystemic shunt [see Figure 3].

Experience with TIPS in the setting of acute variceal hemorrhage is limited. However, one meta-analysis of studies comparing the efficacy of conventional endoscopic therapy (with or without pharmacotherapy) with that of TIPS in treating acute hemorrhagic episodes demonstrated a significant improvement in hemorrhage control with TIPS.²¹ Unfortunately, this improvement came at the cost of increased rates of hepatic encephalopathy as a consequence of the nonselective shunting of portal venous flow into the systemic venous circulation. Furthermore, the meta-analysis failed to demonstrate a significant improvement in overall mortality with TIPS.²¹

Figure 2 The Sengstaken-Blakemore tube permits tamponade of both the distal esophagus and the gastric fundus. An accessory nasogastric tube permits aspiration of secretions from above the esophageal balloon.

Given the relative paucity of data on the use of TIPS as first-line therapy for acute variceal hemorrhage, it is logical to recommend that TIPS be employed in cases of pharmacotherapeutic and endoscopic failure; the efficacy of TIPS as salvage therapy in this setting is well documented.²² Contraindications to TIPS include right heart failure and polycystic liver disease. Portal vein thrombosis is a relative contraindication.

Surgical Therapy

The role of surgical management in the treatment of acute variceal bleeding has changed considerably over the past 50 years. At present, operative intervention is reserved for cases that have proved refractory to pharmacotherapy, endoscopy, balloon tamponade, and TIPS. Numerous operations have been developed, each with its own merits and flaws.

Esophageal transection with an end-to-end anastomosis (EEA) stapler has been employed as a means of interrupting blood flow into bleeding esophageal varices. In this technique, the esophagus is mobilized, and the EEA stapler is passed into the distal esophagus through a gastrotomy. With care taken not to injure the vagus nerves and the external periesophageal veins that may be providing collateral venous drainage, a full-thickness segment of the esophagus is transected. When this technique is used on an emergency basis in a patient with acutely bleeding varices, operative mortality is as high as 76%, and the rate of operative complications (e.g., esophageal perforation, stricture, esophagitis, and infection) is approximately 26%.²³ Accordingly, esophageal transection is not commonly advocated as a useful form of surgical therapy for acutely bleeding esophageal varices.

In contrast, portosystemic shunting operations have been widely used to treat acute variceal hemorrhage. The largest single body of data on this practice comes from Orloff and associates,²⁴ who reported remarkable outcomes—71% survival at 10 years—in 400 consecutive patients undergoing emergency portacaval shunt

operations (mostly side-to-side) over a 28-year period. Unfortunately, these investigators' experience stands in stark contrast to that of most other groups, who uniformly reported operative mortalities of about 40% and 5-year survival rates of about 30%.

Another potential drawback to urgent operative shunting is the manipulation and dissection that are often necessary in the region of the porta hepatis: these measures can result in adhesions and scarring, which can complicate future orthotopic liver transplantation. For this reason, some surgeons have advocated using the mesocaval interposition shunt [see Prevention of Recurrent Variceal Hemorrhage, Surgical Therapy, Portosystemic Shunts, Nonselective Shunts, *below*] in the emergency setting because of its ability to lower portal pressure without complicating the hilar dissection that will be necessary if transplantation is carried out later.²⁵ In addition, surgeons familiar with the distal splenorenal shunt (DSRS) can employ this selective shunt in some cases of acute variceal hemorrhage unaccompanied by refractory ascites.

PREVENTION OF RECURRENT VARICEAL HEMORRHAGE

Pharmacotherapy

Without further treatment, the likelihood that hemorrhage will recur within 1 year after control of an acute episode of variceal bleeding is approximately 70%.²⁶ The pharmacologic maneuver that has been used most extensively to prevent recurrent variceal bleeding [see *Figure 4*] is nonselective beta-adrenergic blockade, most commonly with propranolol. Although beta blockade has been shown to lower portal pressure and hepatic vein wedge pressure, its ability to induce this effect is variable and unpredictable.²⁷ Nevertheless, a meta-analysis of multiple trials studying the effectiveness of nonselective beta blockade demonstrated a significant decline in recurrent bleeding and a trend toward improved overall survival.⁴ Patients with decompensated hepatic function appear to derive less benefit from beta blockade, possibly because of the downregulation of beta-adrenergic receptors

Figure 3 Depicted is the procedure for performing TIPS. (a) A needle is passed under radiologic guidance from a hepatic vein into a major portal venous branch, and a guide wire is advanced through this needle. (b) A balloon is passed over the guide wire, creating a tract in the hepatic parenchyma. (c) An expandable stent is placed through this tract. (d) The effective result is a nonselective portosystemic shunt.

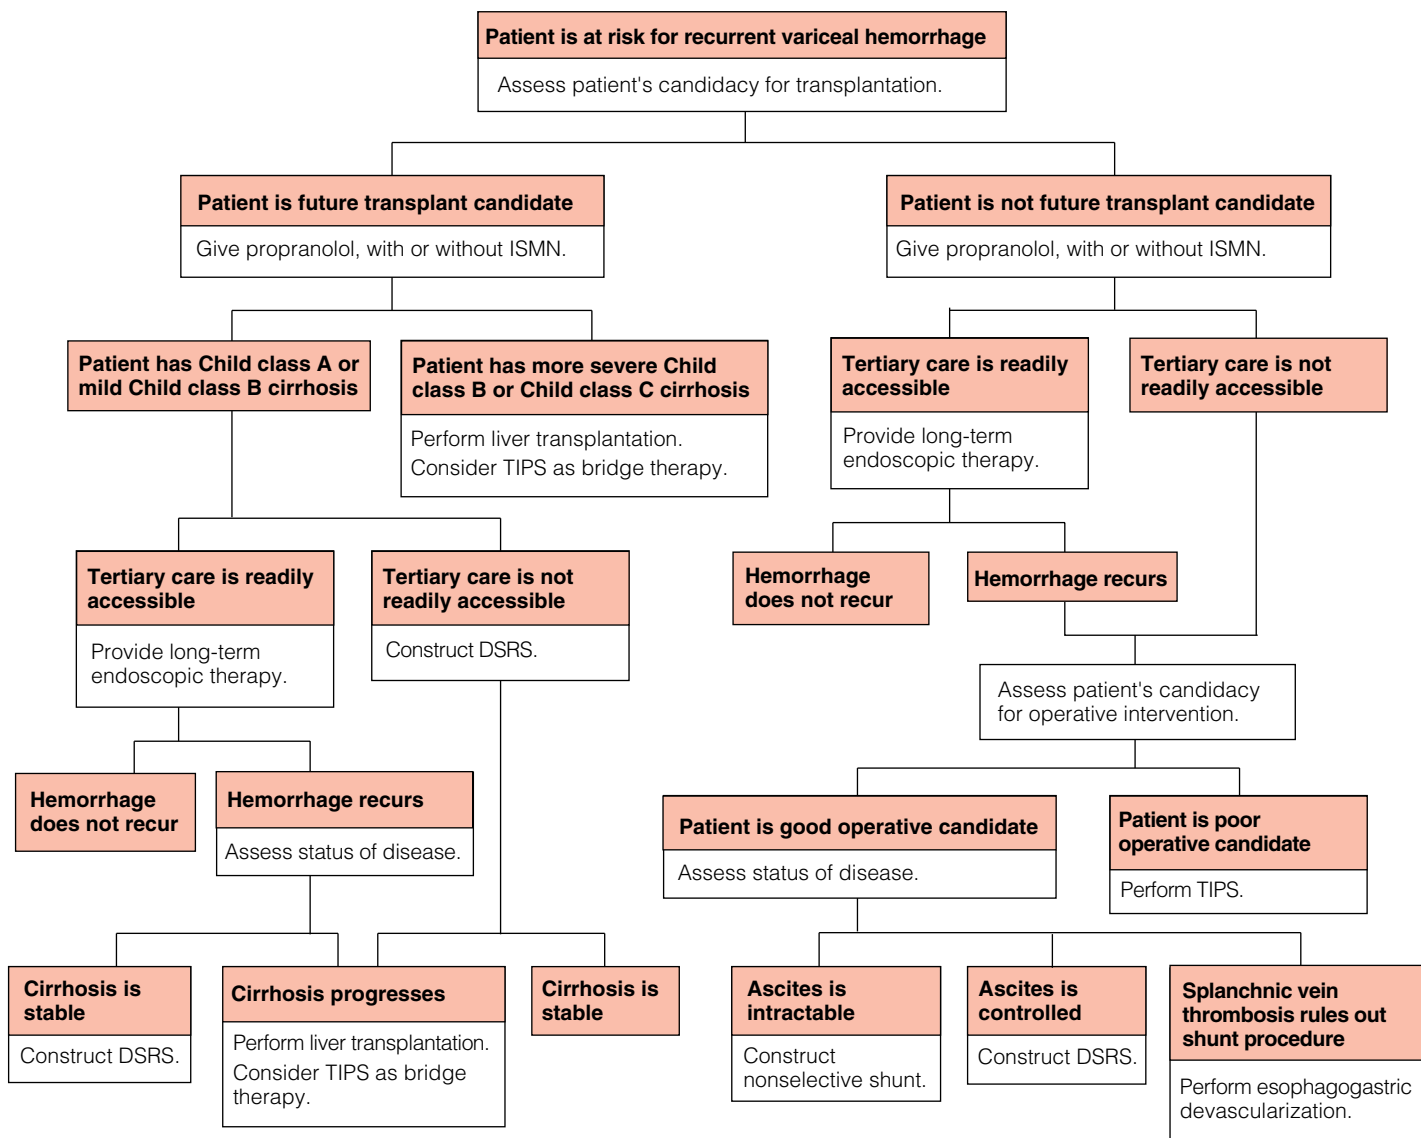

Figure 4 Algorithm outlines prevention of recurrent variceal bleeding.

associated with cirrhosis.²⁸ Adjunctive use of the long-acting vasodilator isosorbide 5-mononitrate (ISMN) appears to potentiate the efficacy of propranolol therapy.²⁹

Endoscopic Therapy

Repeated endoscopic therapy with sclerosant injection or band ligation has been advocated as a means of completely eradicating esophageal varices. Once the varices are eliminated, routine endoscopy is performed at 6- to 12-month intervals to prevent recurrent hemorrhage. Compared with medical treatment, long-term endoscopic therapy results in fewer rebleeding episodes.⁴ Nevertheless, approximately one half of endoscopically treated patients eventually experience recurrent hemorrhage, usually within the first year. Approximately one third of patients treated with repeated endoscopy ultimately must be converted to another form of therapy because of unrelenting major bleeding.^{30,31} For this reason, such extended endoscopic surveillance and treatment should be reserved for compliant patients who live in proximity to tertiary medical care and should be administered with the understanding that conversion to a more definitive form of therapy may be necessary if endoscopy fails.

Transjugular Intrahepatic Portosystemic Shunting

TIPS [see Figure 3] has been employed to prevent recurrent episodes of variceal hemorrhage, particularly as a form of bridge therapy for patients awaiting orthotopic liver transplantation. The potential advantage TIPS has over surgical portosystemic shunting is the ability to decompress the portal system without the risks associated with general anesthesia and without postoperative complications. The major limitation of TIPS is the shunt stenosis (caused by neointimal hyperplasia or thrombosis) that occurs in as many as 50% of patients in the first year after the procedure. Fortunately, most such episodes of stenosis are amenable to balloon dilatation or secondary shunt insertion; however, 10% to 15% of TIPS recipients experience total shunt occlusion that cannot be reversed. Furthermore, TIPS functions as a nonselective shunt, leading to hepatic encephalopathy in approximately one third of patients.³²

Meta-analytic comparison of TIPS with endoscopic therapy indicates that rebleeding episodes are markedly reduced in patients treated with TIPS, but at the cost of a higher incidence of encephalopathy and a shunt malfunction rate of at least 50%. That the efficacy of TIPS is relatively short-lived makes this modality an ideal form of bridge therapy for patients who are awaiting ortho-

topic liver transplantation or those who have severe hepatic decompensation and thus are unlikely to live long enough to experience failure of TIPS. TIPS can reduce the number of bleeding episodes for patients on the transplant waiting list. In addition, the significant reduction in portal pressure produced by TIPS technically facilitates future liver transplantation. Finally, unlike surgical shunts, TIPS is completely removed at the time of recipient native hepatectomy.

Surgical Therapy

Surgical therapy is the most effective method of controlling portal hypertension and preventing recurrent variceal hemorrhage. The operative procedures available to the surgeon have undergone numerous modifications and become more effective over the years. Review of the surgical experience reveals that with the onset of alternative modalities (e.g., TIPS and transplantation), the risk status of patients undergoing surgical therapy (as predicted by Child's classification) and the frequency of emergency operations have steadily declined. As a result, the incidence of postoperative hepatic encephalopathy has gradually fallen and overall survival has gradually improved.³³ Surgical options for the prevention of recurrent variceal hemorrhage in patients with portal hypertension may be divided into three categories: (1) portosystemic shunt procedures, (2) esophagogastric devascularization, and (3) orthotopic liver transplantation.

Portosystemic shunts Surgical portosystemic shunting provides a means of decompressing the hypertensive portal venous system into the low-pressure systemic venous circulation. Diversion of portal blood flow from the liver also deprives the liver of important hepatotrophic hormones that are present in portal venous blood while routing cerebral toxins normally metabolized by the liver directly into the systemic circulation. As a result, the primary complications of surgical portosystemic shunting are accelerated hepatic dysfunction and hepatic encephalopathy. Primarily in an attempt to minimize these adverse sequelae, various forms of portosystemic shunting operations have evolved, which may be classified as nonselective shunts, selective shunts, or partial shunts.

Nonselective shunts. The classic nonselective portosystemic shunt is the end-to-side portacaval shunt (the so-called Eck fistula) [see Figure 5a]. This is the only nonselective shunt that has been rigorously compared with conventional nonoperative therapy. Several randomized, controlled trials demonstrated superior control of bleeding after operative shunting: 9% to 25% of patients experienced rebleeding after portacaval shunting (mostly related to non-variceal hemorrhage or shunt thrombosis), whereas 65% to 98% of patients experienced rebleeding after medical therapy.³⁴⁻³⁷ Markedly higher rates of spontaneous posttreatment encephalopathy were reported in the operative shunt groups; however, the overall rates of encephalopathy did not differ between the operative groups and the medical groups, because the encephalopathy seen in the medically treated patients (mainly attributable to hemorrhage and infection) eventually became equivalent to that seen in the surgically treated patients. There were trends toward improved overall survival in the surgical groups, but these trends did not attain statistical significance.

The side-to-side portacaval shunt [see Figure 5b] maintains the anatomic continuity of the portal vein as it passes into the liver. However, the high sinusoidal resistance typically present in the setting of cirrhosis effectively renders this shunt a nonselective one, with no measurable antegrade (i.e., hepatopedal) portal

blood flow into the liver. Consequently, the encephalopathy rates are no different from those observed after end-to-side portacaval shunting. Side-to-side portacaval shunting does offer the benefit of decompressing the hepatic sinusoidal pressure via reversed (i.e., hepatofugal) flow of blood from the liver into the portal vein. Because transudation of interstitial fluid from both the liver and the intestines is thought to contribute to ascites formation, better control of ascites is achieved with a side-to-side portacaval shunt, which effectively decompresses both the splanchnic veins and the intrahepatic sinusoids, than with an end-to-side portosystemic shunt, which decompresses only the splanchnic veins. The side-to-side portacaval shunt is therefore also recommended for patients with Budd-Chiari syndrome, in whom an end-to-side portacaval shunt would not relieve intrahepatic congestion resulting from hepatic venous outflow occlusion. Otherwise, no significant outcome differences between end-to-side and side-to-side portacaval shunts have been documented. The end-to-side variant is, however, technically easier to construct.

Placement of an interposition mesocaval shunt [see Figure 5c] composed of prosthetic or autogenous vein grafts offers the technical advantages of avoiding hilar dissection (thereby making future liver transplantation less complicated) and permitting intentional shunt ligation in the event of refractory postoperative encephalopathy. Like the side-to-side portacaval shunt, the interposition shunt functions physiologically as a nonselective shunt because of the hepatofugal portal venous blood flow. The major drawback to the interposition shunt is shunt thrombosis, which may develop in as many as 35% of cases.

The conventional (proximal) splenorenal shunt [see Figure 5d] was initially advocated as a means of decompressing portal venous flow while retaining hepatopedal hepatic portal perfusion. This shunt is constructed by performing a splenectomy and anastomosing the proximal splenic vein to the left renal vein. Physiologic testing of patent conventional splenorenal shunts suggests that they eventually divert all portal flow into the renal vein and therefore effectively function as nonselective shunts. Indeed, long-term rates of hepatic encephalopathy appear to be no lower after conventional splenorenal shunting than after portacaval shunting.³⁸ Shunt occlusion develops in about 18% of cases.³⁹

In short, nonselective portosystemic shunts are an effective means of controlling variceal hemorrhage in cases that are refractory to other therapeutic approaches. Given the absence of any major differences in the rate of encephalopathic complications after the various nonselective shunts, the choice of a nonselective shunting procedure should be based on the surgeon's technical familiarity with the operations and on the patient's candidacy for future transplantation. The end-to-side portacaval shunt can be constructed relatively quickly but should be avoided in patients who have intractable ascites or Budd-Chiari syndrome and those who may subsequently undergo liver transplantation. The side-to-side portacaval shunt may provide better control of ascites but is technically more challenging to construct and should also be avoided if future transplantation is an option. The interposition mesocaval shunt is relatively easy to construct and avoids hepatic hilar dissection but is associated with a relatively high rate of shunt occlusion when a nonautogenous conduit is used. The conventional splenorenal shunt also avoids hilar dissection but is associated with a high shunt occlusion rate and is technically challenging to construct.

Selective shunts. In response to the postoperative complications seen after nonselective portosystemic shunting (hepatic encephalopathy and hepatic failure), Warren and colleagues intro-

Figure 5 Nonselective portosystemic shunts either immediately or eventually divert all portal blood flow from the liver into the systemic venous circulation. Shown are the four main variants: (a) end-to-side portacaval shunt, (b) side-to-side portacaval shunt, (c) interposition shunt (portacaval [1], mesocaval [2], and mesorenal [3]), and (d) conventional (proximal) splenorenal shunt.

duced the distal splenorenal shunt in 1967.⁴⁰ The DSRS has become the prototypical selective shunt, in that it selectively decompresses the esophagogastric veins while maintaining hepatopedal flow from the mesenteric veins. It is performed by anastomosing the distal splenic vein to the left renal vein and interrupting venous collaterals (e.g., the left gastric and right gastroepiploic veins) [see Figure 6]. As a result, the DSRS effectively separates the portal system into two components: (1) a decompressed esophagogastric venous circuit and (2) a persistently hypertensive mesenteric venous circuit that continues to provide hepatopedal portal flow. Thus, the DSRS does not address the mesenteric and sinusoidal hypertension that is responsible for ascites formation. Indeed, it is believed that the extensive retroperitoneal dissection required to construct this shunt may actually contribute to ascites formation through inadvertent disruption of retroperitoneal lymphatic vessels. The DSRS is contraindicated in patients who have refractory ascites or splenic vein thrombosis, those who have previously undergone splenectomy, and those with an excessively small (< 7 mm) splenic vein diameter.

Unfortunately, perfusion studies indicate that approximately one half of patients lose hepatopedal flow within 1 year after a DSRS procedure. This is a particular problem in patients with alcoholic cirrhosis. The loss of shunt selectivity is believed to result from progressive collateral diversion of portal flow into the splenic vein via a network of pancreatic and peripancreatic veins (the so-called pancreatic siphon effect). Extensive skeletonization of the splenic vein off the pancreas (so-called splenopancreatic disconnection) has been proposed as a means of minimizing this unwanted collateralization,⁴¹ but at present, the evidence is insufficient to support routine employment of this measure.

The complications of DSRS procedures are well described. Depending on patient selection, postoperative ascites formation is seen in 7% to 98% of cases; however, in only 0% to 14% of cases is ascites clinically significant and refractory to dietary sodium restriction and diuresis.²³ Hepatic encephalopathy is reported in 0% to 32% of cases; several clinical trials comparing DSRS with nonselective shunting demonstrated significantly lower rates of encephalopathy after DSRS, whereas other trials found no statis-

tically significant difference. With respect to overall survival and hemorrhage control, DSRS and nonselective shunts appear to be equivalent.⁴²

Comparison of DSRS construction with endoscopic therapy has yielded interesting results. Two controlled trials comparing endoscopic therapy and salvage DSRS with early DSRS alone demonstrated superior hemorrhage control with early DSRS.^{30,31} Rates of hepatic encephalopathy did not differ between the two groups. One of the trials, conducted in an urban-suburban area where 85% of sclerotherapy failures could be rescued with salvage DSRS, found survival to be improved in patients treated with endoscopic therapy and salvage DSRS, compared with survival in patients treated with early DSRS alone.³⁰ The other, performed in a less densely populated region where only 31% of sclerotherapy failures could be rescued with salvage DSRS, found survival to be improved in the early DSRS group.³¹ These data suggest that early definitive surgical intervention may be preferable for patients who are too far from a tertiary medical center to be able to reach one expeditiously in the event of uncontrollable hemorrhage.

Attention is now being turned toward comparisons between the DSRS and TIPS. One uncontrolled comparative study found that with DSRS, hemorrhage control was better, the encephalopa-

thy rate was lower, and shunt occlusion was reduced, but the incidence of postoperative ascites was higher.⁴³ A National Institutes of Health-sponsored randomized comparison between DSRS and TIPS is currently under way at multiple centers.

The other main form of selective portosystemic shunt is the coronary-caval shunt, initially described in Japan in 1984.⁴⁴ This shunt is constructed by anastomosing an interposition graft to the left gastric (coronary) vein on one end and the inferior vena cava on the other. To date, the applicability of this procedure has been limited, and most surgeons have relatively little experience with it.

Partial shunts. Various small-diameter interposition portosystemic shunts have been proposed as partial shunts, designed to achieve partial decompression of the entire portal venous system while maintaining a degree of hepatopedal portal flow to the liver. The most successful of these partial shunts has been the small-diameter portacaval interposition shunt. The use of a 10 mm or smaller interposition shunt, combined with extensive disruption of portosystemic collateral venous circuits, serves to maintain some degree of hepatic portal perfusion. Early experience with the 8 mm ringed polytetrafluoroethylene graft suggests that hepatic encephalopathy rates are lower with this shunt than with nonse-

Figure 6 The distal splenoportal shunt diverts portal flow from the spleen and short gastric veins into the left renal vein. The DSRS provides selective shunting by preserving portal flow from the mesenteric circulation. Potential sites of collateralization (e.g., the left gastric vein, the gastroepiploic vein, and the umbilical vein) are routinely interrupted to preserve hepatopedal portal flow.

lective 16 mm grafts and that use of the smaller shunt yields comparable long-term survival.⁴⁵ An early comparison of the small-diameter portacaval shunt with TIPS demonstrated lower rates of shunt occlusion and treatment failure in the operative therapy group.⁴⁶

Esophagogastric devascularization The most effective nonshunt operation for preventing recurrent variceal hemorrhage is esophagogastric devascularization with esophageal transection and splenectomy, as advocated by Sugiura and associates.⁴⁷ Unlike simple esophageal transection, which has been used with limited success in the setting of acute hemorrhage, the Sugiura procedure and its subsequent modifications [see *Figure 7*] involve ligation of venous branches entering the distal esophagus and the proximal stomach from the level of the inferior pulmonary vein, combined with selective vagotomy and pyloroplasty [see **5:20 Gastrointestinal Procedures**]. A key point is that the left gastric (coronary) vein and the paraesophageal collateral veins are preserved to permit portoazygous collateralization, which inhibits future varix formation. Initial reports from Japan cited a 5.2% operative mortality and a 6.3% rate of recurrent hemorrhage (most often from nonvariceal causes).^{47,48} Unfortunately, these successes have not been easily replicated in the United States, where operative mortality with this procedure has exceeded 20%, with bleeding recurring in 35% to 55% of patients.^{49,50} Nevertheless, modifications of the Sugiura procedure continue to be performed in patients who are unable to undergo shunting procedures because of extensive splanchnic vein thrombosis.

Orthotopic liver transplantation Orthotopic liver transplantation is the most definitive form of therapy for complications of portal hypertension. The cost of cadaveric and living-donor liver transplantation and its attendant immunosuppression, as well as the paucity of available allografts, make liver replacement an option for only a select minority of patients presenting with portal hypertensive sequelae. Accordingly, careful analysis of the outcomes of transplantation procedures in comparison with those of nontransplantation procedures is necessary for optimal allocation of this limited resource.

For patients whose portal hypertension has become refractory to nonoperative management strategies, the decision whether to employ transplantation or nontransplantation operative therapy can be based on the level of hepatic functional reserve. Patients with Child class A or mild class B cirrhosis appear to do well with nontransplantation therapy as first-line operative treatment, with the understanding that liver transplantation may remain an option for salvage therapy in the event of future hepatic functional deterioration. In contrast, patients with more advanced Child class B or Child class C cirrhosis appear to benefit from early transplantation, with nonoperative strategies employed strictly as bridge therapy for maintenance during the time spent on the allograft waiting list.^{51,52}

PROPHYLAXIS OF INITIAL VARICEAL HEMORRHAGE

The significant mortality associated with variceal hemorrhage has prompted efforts to devise effective means of preventing the onset of initial variceal bleeding. The difficulty of identifying those 20% to 33% of cirrhotic patients who will experience bleeding episodes remains the primary challenge in the application of prophylaxis for variceal hemorrhage. Patient characteristics that predict an increased likelihood of variceal bleeding include alcoholic cirrhosis, active alcohol consumption, and severe hepatic dysfunction.⁵³ Certain anatomic features of varices seen at the time of

endoscopic examination have been shown to predict the likelihood of rupture: evidence of variceal wall thinning (cherry-red spots, red wales), variceal tortuosity, superimposition of varices on other varices, and the presence of gastric varices all appear to be correlated with a higher likelihood of hemorrhage.⁵⁴

At present, pharmacologic therapy is the only measure that provides effective prophylaxis against variceal hemorrhage. Nonselective beta-adrenergic blockade, either with propranolol or the long-acting agent nadolol, reduces portal venous pressure by decreasing cardiac output and favoring splanchnic vasoconstriction. Clinical trials examining the efficacy of propranolol therapy demonstrated lowered rates of initial variceal bleeding, though the ultimate influence of beta blockade on patient survival was mixed.⁵⁵⁻⁵⁷

Endoscopic sclerotherapy has not been consistently effective in preventing initial variceal bleeding. In fact, several trials found survival to be poorer in patients treated with prophylactic sclerotherapy than in those managed with prophylactic pharmacotherapy.^{4,58} This difference is probably attributable to the well-documented complications associated with endoscopic sclerotherapy.

The flaws of prophylactic endoscopic sclerotherapy have led some authorities to advocate endoscopic variceal band ligation as a more effective form of prophylaxis. One trial demonstrated that variceal band ligation achieved better prophylaxis of initial variceal bleeding than propranolol therapy did.⁵⁹ Clearly, this observation warrants further investigation.

Early trials comparing prophylactic portosystemic shunting with medical prophylaxis definitively showed that early operative intervention conferred no significant benefit. In fact, the significant morbidity associated with surgical shunting and the substantial risk of accelerated hepatic dysfunction and encephalopathy led to lower survival rates in patients treated with prophylactic surgical procedures.^{6,60} At present, the data are insufficient to recommend the use of prophylactic TIPS to prevent acute variceal hemorrhage.

Management of Ascites

The presence of ascites in a patient with portal hypertension is typically an ominous finding that is of significant prognostic importance: 1-year mortalities as high as 50% have been reported in cirrhotic patients with new-onset ascites, whereas baseline 1-year mortalities in cirrhotic patients without ascites are in the range of 10%.⁶¹ The pathogenesis of ascites formation appears to be related to the relative hypovolemia and the primary avidity of renal sodium retention that develop in patients with cirrhosis. Hypovolemia induces renin-angiotensin activation and salt and water reabsorption, which, in the setting of chronic liver dysfunction, results in excessive transudation of fluid out of the liver and the intestines and into the peritoneal cavity. The major complications of this process are spontaneous bacterial peritonitis (SBP) and hepatorenal syndrome (HRS) [see *Complications, below*], which account for the bulk of the morbidity and mortality associated with ascites in patients with portal hypertension.

NONSURGICAL THERAPY

By addressing the hyperavidity of sodium retention that drives much of ascites formation, restriction of dietary salt intake (to levels as low as 2 g of sodium a day) can resolve ascites in approximately 25% of cases. The hyperaldosteronemic state that exists can be countered by initiating diuresis with spironolactone, which, at dosages ranging from 100 to 400 mg/day, can relieve ascites in an additional 60% to 70% of patients. Although automatic addi-

Figure 7 Shown is the modified Sugiura procedure. By extensively devascularizing the esophagogastric junction, this procedure may provide a means of interrupting esophagogastric varices without portosystemic shunting.

tion of loop diuretics has not been proved to enhance the clinical efficacy of spironolactone, augmentation of spironolactone therapy with furosemide can be helpful for patients whose ascites is refractory to spironolactone monotherapy or who have hyperkalemia as a result of spironolactone treatment. Gradual diuresis is necessary to prevent potential complications (e.g., prerenal azotemia and HRS).⁶²

In cases of ascites that is refractory to medical dietary restriction and diuretic therapy, large-volume paracentesis has been employed with some success. Albumin is typically infused at a dose of 6 to 8 g per liter of ascitic fluid to prevent the hypotension that results from acute volume shifts. Patients in whom ascites recurs after multiple rounds of large-volume paracentesis should be considered for TIPS. TIPS is particularly useful in patients with ascites and a history of bleeding esophageal varices; it corrects as many as 80% of medically refractory cases of ascites.⁶³ However, the efficacy of TIPS is counterbalanced by its attendant risks (i.e., hepatic encephalopathy, shunt occlusion, and accelerated hepatic failure), especially in patients with poor hepatic functional reserve.

SURGICAL THERAPY

Operative intervention plays only a limited role in the management of ascites. Surgically inserted peritoneovenous shunts have been compared with large-volume paracentesis in patients with ascites refractory to medical therapy. No significant differences in early control of ascites have been detected, but patients treated with peritoneovenous shunting appear to benefit from faster ascites resolution, longer palliation, and fewer hospital readmis-

sions.⁶⁴ Long-term follow-up, however, indicates that shunt occlusion occurs in 47% of patients so treated and disseminated intravascular coagulation in as many as 35%.

The morbidity and mortality associated with operative therapy make routine use of side-to-side portacaval shunts a poor option for managing ascites. The exceptions to this general statement are cases in which ascites proves refractory to medical and TIPS therapy or in which concomitant refractory variceal hemorrhage is present.

COMPLICATIONS

SBP is the most common form of ascitic infection. It typically is signaled by fever and abdominal tenderness and often is also accompanied by acute hepatic and renal deterioration. The diagnosis is generally made by analyzing ascitic fluid collected through paracentesis and is defined by the presence of a positive bacterial culture and a neutrophil count higher than 250/mm³ in the absence of an obvious intra-abdominal source of infection. Unlike secondary peritonitis, SBP is typically monomicrobial, and the frequency with which enteric gram-negative rods are found with SBP suggests intestinal bacterial translocation as a potential cause. SBP carries a mortality of 25% and should therefore be treated aggressively with I.V. antibiotic therapy. Given the 70% recurrence rate after an initial episode of SBP, continuation of suppressive antimicrobial therapy until ascites resolves is warranted.⁶⁵

HRS, a poorly understood state characterized by progressive and refractory renal impairment, typically occurs in the setting of tense ascites and hepatic disease. Management of HRS is strictly supportive, in that the syndrome often responds only to correc-

tion of the underlying liver dysfunction. Accordingly, the only proven therapy for HRS is liver transplantation.

Management of Hepatic Encephalopathy

Hepatic encephalopathy is a complex of symptoms characterized by mental status changes ranging from impaired mentation to frank stupor. The classic neurologic finding associated with this symptom complex is asterixis. Typically, hepatic encephalopathy develops in the setting of significant portosystemic shunting or significant hepatic functional impairment. It is most commonly observed after the creation of a therapeutic nonselective portosystemic shunt. Its onset is usually precipitated by dehydration, GI hemorrhage, sepsis, or excessive protein intake; in fact, the spontaneous development of hepatic encephalopathy mandates work-up for these physiologic triggers. It has been speculated that the shunting of intestinally absorbed cerebral toxins (e.g., ammonia,

mercaptans, and γ -aminobutyric acid) away from hepatic metabolism is what causes hepatic encephalopathy; however, the absolute level of circulating ammonia correlates poorly with the magnitude of encephalopathic symptoms.

Correction of the triggers that cause hepatic encephalopathy often reverses the psychoneurologic disturbances. In severe cases, patients should also receive neomycin (1.5 g every 6 hours), which covers enteric urease-positive bacteria, and lactulose (20 to 30 g two to four times daily), a disaccharide GI cathartic. Both agents are believed to reduce intestinal levels of ammonia and inhibit its enteric absorption. Whereas neomycin has long-term side effects (i.e., nephrotoxicity and ototoxicity), long-term lactulose therapy is generally well tolerated. Dietary protein restriction should also be employed for long-term suppression of hepatic encephalopathy. On occasion, refractory cases of shunt-induced hepatic encephalopathy may be treated by means of intentional ligation or occlusion of the portosystemic shunt.

11 CROHN DISEASE

Susan Galandiuk, M.D., F.A.C.S., F.A.S.C.R.S.

The role of surgery in the management of Crohn disease has undergone a dramatic evolution over the past 50 years. Currently, surgical treatment of Crohn disease is seldom performed in the emergency setting; it is nearly always performed after failed medical therapy. The decision to proceed with operative management is based on careful patient evaluation, with full awareness of the potential complications and ramifications of treatment. In particular, attention must be paid to the risk of recurrent disease, the possible surgical sequelae, and the side effects of medical therapy.

Classification

There are many systems for classifying Crohn disease. One of the simplest is the classification developed by Farmer and associates,¹ which categorizes the disease on the basis of disease location alone (ileocolic, purely colonic, small bowel, and perianal). A more elaborate system is the Vienna classification, which categorizes the disease on the basis not only of location but also of age of onset and disease behavior.² In this system, there are four categories for disease location: terminal ileum (L1), colon (L2), terminal ileum and colon (L3), and any location proximal to the terminal ileum (L4). There are two categories for age of onset: less than 40 years of age (A1) and 40 years of age or older (A2). Finally, there are three categories for disease behavior: nonstricturing and nonpenetrating (B1), stricturing (B2), and penetrating (B3).

Given that there are as many types and combinations of Crohn disease as there are patients with this condition, the most sensible approach is probably to use some combination of these two classification schemes. Careful evaluation of the specifics of each case will yield the best treatment results; however, general classification of the disease can help guide therapy. Broadly speaking, Crohn disease of the small bowel has the highest recurrence rate. Because of the important function of the small bowel in digestion, surgeons tend to emphasize conserving small bowel length during operative treatment of Crohn disease. Currently, however, there is an increasing focus on colon conservation with the aims of maintaining water absorption in patients and delaying (or perhaps eliminating) the need for a stoma.

Roles of Medical Therapy and Surgical Therapy

In planning treatment of Crohn disease, it is important not to make the use of medical therapy or surgical therapy an either-or issue. Just as one tool cannot be expected to fill every household need, operative management cannot be expected to solve every problem related to Crohn disease. Overall, careful use of medical therapy, appropriately combined with surgical therapy, provides the best treatment of Crohn disease. Single-minded reliance on either therapy to the exclusion of the other often leads to inadequate patient care.

Generally speaking, except in the case of a free perforation, cancer, or dysplasia, one should not operate on a patient with Crohn disease without first attempting medical therapy. With the dramatically improved medical treatment options currently available, surgery can be avoided in many cases. This is often a desirable result, given

the known risk of disease recurrence after surgical treatment of Crohn disease and the significant associated operative morbidity. In one single-center study, the reoperation rate for Crohn disease was 34% at 10 years.³ The agents used to treat Crohn disease can be divided into several broad groups: probiotics, antibiotics, anti-inflammatory drugs, immunosuppressive drugs, and biologic agents. These can be used alone or in combination to treat disease, as well as to maintain remission [see Table 1].

Few good studies have been done on the cost-effectiveness of medical or surgical therapy^{4,5} versus that of timely surgery followed by maintenance medical therapy. There is clearly a need for such studies. The use of potent and expensive immunomodulator therapy (e.g., maintenance infliximab) for simple ileocolic disease is questionable, especially in the light of studies indicating that such treatment is not at all innocuous.^{6,7}

CHANGING CONCEPTS IN SURGERY FOR CROHN DISEASE

Although first described in the beginning of the 19th century, Crohn disease was not recognized as a discrete clinical entity until the first part of the 20th century.⁸ At one point, it was treated surgically in much the same way as cancer, with frozen-section margins obtained at the time of resection. This approach did not yield any substantial reduction in the recurrence rate.⁹ In fact, overzealous resections often resulted in Crohn patients' requiring lifelong parenteral nutritional support.¹⁰ Accordingly, conservative surgery is now the rule: only gross macroscopic disease is resected into palpably normal margins (in particular, a palpably normal mesenteric border of the bowel).

General Indications for Surgical Treatment

SIDE EFFECTS OF MEDICAL THERAPY

Significant side effects of medical therapy include those associated with failure to wean from prednisone (e.g., cataract forma-

tion, aseptic necrosis of the femoral head, and weight gain). Side effects of antimetabolite therapy include pancreatitis, neutropenia, and opportunistic infections.

COMPLICATIONS OF DISEASE

Lack of Response to Medical Therapy

Many patients with so-called toxic colitis do not respond satisfactorily to medical treatment. In severe cases of refractory disease, if surgery is not performed, colonic perforation, peritonitis, and multiple organ failure may ensue. Such cases are much less frequent now than they once were.

Obstruction

In many patients with Crohn disease, the behavior of the disease changes over time, from a more inflammatory and edematous process to one characterized more by fibrosis and scarring. Whereas anti-inflammatory drugs are ideal for treating the former, surgery is frequently necessary for the latter. Failure to refer for surgical treatment of obstruction is, unfortunately, a common error among gastroenterologists. Severe abdominal pain is always a warning sign of obstruction and should be taken seriously [see 5:1 *Acute Abdominal Pain* and 5:4 *Intestinal Obstruction*]. The importance of this point is illustrated by a case from my experience, involving a patient who had obstructing ileocolic Crohn disease with gross proximal distention of the terminal ileum [see *Figure 1*]. This patient lost 20 lb, was experiencing severe abdominal pain, and was treated for more than a year with 6-mercaptopurine before being referred for operative management. Ileocolic resection led to rapid resolution of the symptoms.

Symptomatic Fistulas

Enteroenteric fistulas, by themselves, are no longer considered an absolute indication for operation in the absence of other complicating factors. Symptomatic fistulas, such as those associated with obstruction or those associated with disabling symptoms (e.g., rectovaginal fistulas or enterocutaneous fistulas [see *Figure 2*]), may have to be treated surgically. Ileosigmoid fistulas, which effectively bypass the entire colon, may be associated with profound and refractory diarrhea (i.e., ≥ 20 bowel movements/day) and may also have to be treated operatively.

Abscess Formation

Abscesses are particularly common with ileocolic Crohn disease. If they cannot be controlled by means of computed tomography-guided drainage, surgical therapy may be indicated.

Cancer or Dysplasia

The risk of colorectal cancer is approximately three times higher in patients with Crohn disease than in the general population.¹¹⁻¹³

Failure to Grow

In children, failure to grow and develop normally is one of the main indications that medical therapy for Crohn disease has been unsuccessful. Timely surgical therapy will permit normal development. On occasion, when bone age lags significantly behind chronological age, treatment with recombinant human growth hormone is required.

Special Considerations

PREGNANCY

Persons who have Crohn disease may be less fertile than healthy age-matched persons. One possible explanation for this difference is that feeling ill may result in reduced sexual desire or decreased sexual activity. Another is that pelvic inflammation caused by Crohn disease or by scarring and adhesion formation resulting from surgery may impair fertility. To reduce the chances of the latter, hyaluronic acid sheets may be placed around the tubes and ovaries; alternatively, the ovaries may be tacked to the undersurface of the anterior abdominal wall with absorbable sutures and thereby prevented from entering the pelvis.

Figure 2 Shown is an enterocutaneous fistula that persisted for more than 1 year after an ileocolic resection (arrow). The choice of parallel incisions by the previous surgeon made selection of a temporary stoma site much more difficult.

There is no evidence that pregnancy exacerbates Crohn disease; however, there are some specific concerns that apply to pregnant patients with this condition. Because patients with Crohn disease often have more-liquid bowel movements, they have a particular need for a well-functioning anal sphincter. If there is any chance of an obstetrics-related injury (e.g., from a large baby in a primigravida or from a breech presentation), a cesarean section is advisable to minimize the risk of sphincter trauma. The same is true in the presence of severe perianal Crohn disease. During pregnancy, prednisone and 5-aminosalicylic acid (5-ASA) medications are safe, whereas drugs such as metronidazole are not. If imaging studies are needed, magnetic resonance imaging and ultrasonography are the modalities of choice.

MARKING OF STOMA SITES AND CHOICE OF INCISION

When a patient with Crohn disease is expected to need an ileostomy [see 5:30 *Intestinal Stomas*], it is extremely important to mark the site preoperatively. What looks flat when the patient is on the operating table may not be flat when he or she is upright. The patient must be asked to sit and lean over to confirm that the marked stoma site is in an area without folds, creases, or previous incisions. Stoma appliances do not adhere well to areas of previous scarring, and these should be avoided whenever possible.

Patients with Crohn disease do not react to intra-abdominal infection in a typical fashion. It is not unusual to find unsuspected abscesses that were not revealed by preoperative CT scans and other imaging studies. If there is even a remote chance of an unsuspected abscess (particularly in cases of obstructing ileocolic Crohn disease), the possibility of a temporary stoma should be raised with the patient and the proposed stoma site marked preoperatively.

A key point is the necessity of planning for the future. Many patients with Crohn disease will eventually require a stoma. Operating through a midline abdominal incision preserves all four quadrants for possible future stoma sites (if needed).

LAPAROSCOPY

Laparoscopic surgical techniques have gained acceptance in the treatment of Crohn disease. In performing a laparoscopic operation for Crohn disease, it is essential to adhere to the same technical standards that apply to corresponding open procedures. Careful intraoperative exploration of the abdomen is important, in that many patients have multifocal disease. Without such exploration, patients may experience persistent postoperative symptoms as a consequence of persistent proximal pathologic states that were not addressed. As with other treatment modalities, there are some circumstances in which laparoscopy is particularly useful and others in which it should not be used. For example, a laparoscopic approach is ideal for fecal diversion in patients with perianal Crohn disease.

Ileocolic resection for Crohn disease also lends itself well to a laparoscopic-assisted approach; compared with open resection, laparoscopic resection has been reported to result in shorter hospital stays and reduced costs.^{14,15} The ileocolic vessels originate centrally, and they only lie over the retroperitoneum. Once the lateral peritoneal attachments are divided, the colon and the small bowel mesentery can be exteriorized, and the mesentery can be divided and the anastomosis performed extracorporeally.

Many studies have shown that even fistulizing Crohn disease can be safely addressed laparoscopically, depending on the skill of the surgeon. A hand-assisted approach is often useful with cases of dense fixation, in which fistulas are common and finger dissection may facilitate definition of the anatomy. If in doubt, one should

not hesitate to convert to an open procedure. Typically, most areas that feel fibrotic or contain fibrotic adhesions are actually areas of fistulizing disease and should be treated as such until proved otherwise. In one study, patients with recurrent disease, those older than 40 years, and those with an abdominal mass were more likely to require conversion to an open procedure.¹⁶

Surgical Management of Crohn Disease at Specific Sites

ESOPHAGEAL, GASTRIC, AND DUODENAL DISEASE

Crohn disease of the upper alimentary tract can be difficult to diagnose, largely because it is relatively uncommon. Obstructing strictures due to Crohn disease in this area are unusual; the unsuspected finding of noncaseating granulomas in biopsies of erythematous areas in a patient with Crohn disease in other locations is diagnostic.

Occasionally, a patient with Crohn disease of the distal esophagus requires dilatations, but this is uncommon. Surgical treatment for Crohn disease of the upper alimentary tract is almost exclusively reserved for disease affecting the duodenum. Diagnosis of duodenal Crohn disease can be difficult and requires a certain amount of suspicion. Frequently, the diagnosis is not made until relatively late, because diagnostic imaging tends to focus on endoscopy and because the degree of duodenal obstruction is often not evident except on barium studies. The rigidity and luminal narrowing of the second portion of the duodenum is typically much more readily apparent on contrast studies than on endoscopy. Duodenal Crohn disease can lead to gastric outlet obstruction. In children, it can be mistaken for annular pancreas.

When duodenal Crohn disease does not respond to medical therapy, gastrojejunostomy with vagotomy is the preferred surgical treatment.^{17,18} Failure to perform a vagotomy may result in marginal ulcer formation and obstruction. Some surgeons have performed duodenal strictureplasty to treat duodenal Crohn disease. The results have been conflicting^{19,20}; the feasibility of this operative approach is limited by the pliability of the duodenum. Many patients experience prompt and full recovery of normal gastric emptying after operation, but some patients with long-standing gastric outlet obstruction continue to experience impaired emptying. The latter may benefit from administration of a prokinetic agent (e.g., metoclopramide or erythromycin).

JEJUNOILEAL DISEASE

Short Bowel Syndrome

Although Crohn disease of the small bowel is not common and accounts for a relatively small proportion of all cases, disease in this area is associated with one of the highest overall recurrence rates. Resection of large portions of the small bowel can result in short bowel syndrome. For this reason, before proceeding with any type of small bowel or ileocolic resection, one should measure the length of the existing small bowel to determine the patient's "bowel resource." One naturally would more readily perform a resection in a patient who has 400 cm of normal small bowel than in one who has only 200 cm.

Resection versus Strictureplasty

The major advance in the surgical treatment of Crohn disease over the past quarter-century has been the technique of small bowel strictureplasty, first proposed by Lee and subsequently popularized by Williams, Fazio, and others.^{17,18} Currently, the two most prevalent strictureplasty techniques are Heineke-Mikulicz

strictureplasty [see Figure 3] and Finney strictureplasty [see Figure 4]. The former is best suited for strictures up to 5 to 7 cm long [see Figure 5], the latter for strictures up to 10 to 15 cm long. The side-to-side strictureplasty described by Michelassi²¹ is suitable for longer areas of stricture; however, this technique involves longer suture lines and is mainly considered for patients who already have, or are at high risk for, short bowel syndrome.

The short, isolated strictures characteristic of diffuse jejunoileal Crohn disease are more frequently described in patients with long-standing Crohn disease. It has been postulated that over time, Crohn disease progresses from an edematous condition to a more fibrotic, stricturing condition.²² It is the fibrotic strictures characteristic of the later stage of the disease that are amenable to treatment with strictureplasty. Patients with these short fibrotic strictures typically have obstructive symptoms and often are unable to tolerate solid food, experiencing dramatic weight loss as a result. Although strictureplasty leaves active disease in situ, it usually leads to prompt resolution of obstructive symptoms, regaining of lost body weight, and restoration of normal nutritional status.

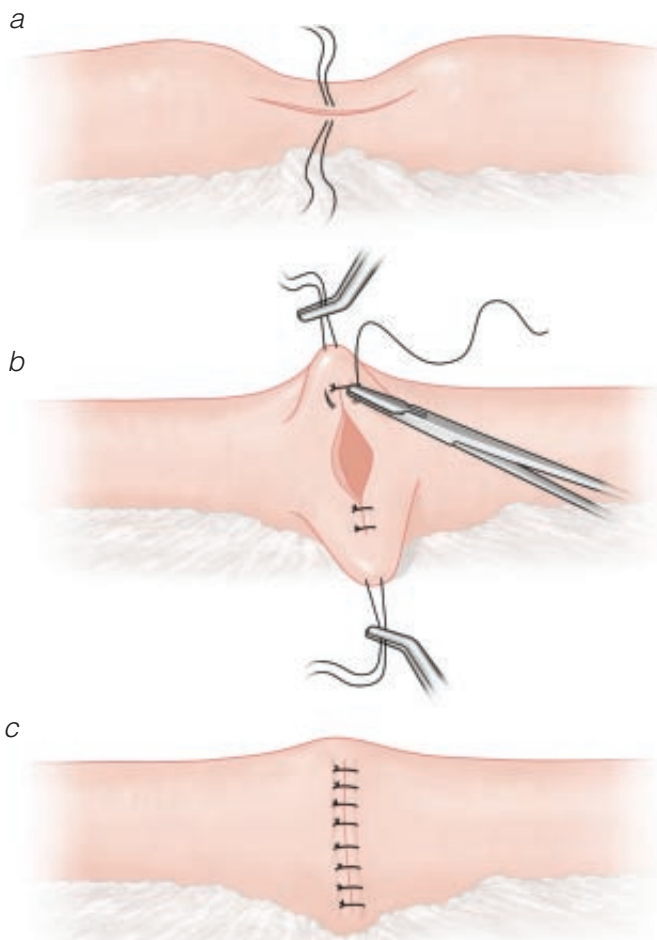

Figure 3 Heineke-Mikulicz strictureplasty. Stay sutures are placed parallel to each other on the antimesenteric border of the bowel over the area of the stricture. (a) The antimesenteric border of the bowel is then opened with the electrocautery over the area of the stricture, and the opening is extended for approximately 1 to 2 cm on either side of the stricture. (b, c) Traction is placed on the stay sutures, and the original longitudinal enterotomy is closed in a horizontal fashion in one or two layers.

Figure 4 Finney strictureplasty. (a) This procedure is suitable for longer areas of stricture (up to 10 to 15 cm). (b) The strictured bowel is bent into the shape of an inverted U. Stay sutures are placed at the apex of the U, which is at the midpoint of the stricture, and at the far ends, which lie 1 to 2 cm proximal and distal to the stricture. A longitudinal enterotomy is made on the antimesenteric border of the bowel with the electrocautery. A side-to-side anastomosis is then performed, with the posterior wall done first. (c) Shown is the completed anastomosis.

A significant concern with strictureplasty is the possibility that small bowel adenocarcinoma may develop; several cases have been reported.^{23,24} I have treated a patient in whom a poorly differentiated jejunal adenocarcinoma developed at the site of a strictureplasty that had been performed 10 years earlier. Accordingly, many surgeons advocate routine biopsy of the active ulcer on the mesenteric side of the bowel at the time of strictureplasty [see Figure 6]. Another concern has to do with the number of strictureplasties that can safely be performed in a single patient in the course of a single operation. As many as 19 strictureplasties have been performed during one procedure without increased morbidity.²⁵

Strictureplasty can be performed with either a single-layer or a double-layer anastomosis. It should not be performed in the presence of an abscess, a phlegmon, or a fistula; and like any other anastomosis, it should not be performed proximal to an existing obstruction that is not treated at the time of operation.

Areas of small bowel Crohn disease that are too long to be treated with strictureplasty can be treated with segmental resection.

Figure 5 Shown is a short fibrotic stricture that is ideally suited to treatment with Heineke-Mikulicz stricturoplasty.

The area to be resected should be as short as possible. There is no need to obtain frozen-section margins to determine the extent of resection; doing so leads to unnecessary loss of small bowel length.²⁶ The resection should extend into palpably normal areas of small bowel. The easiest way of determining the area to be resected is to feel the mesenteric margin of the bowel until palpably normal tissue is reached. Because Crohn disease is generally more severe on the mesenteric side of the bowel, palpation in this area gives the most accurate impression of the intraluminal character of the bowel. Because it is not uncommon for patients to have multifocal Crohn disease, the entire small bowel should always be inspected at the time of operation. Operating on one area of disease while failing to treat a more proximal lesion is clearly not in the patient's interest.

Because of the high rate of recurrence in patients with isolated small bowel disease, postoperative chemoprophylaxis should be strongly considered. In these patients, I prefer to use a more potent agent, such as an antimetabolite, rather than a 5-ASA agent.

ILEOCOLIC DISEASE

Approximately half of those diagnosed with Crohn disease have ileocolic disease. Ileocolic resection is, in fact, the operation most frequently performed to treat Crohn disease. Currently, there is a trend toward more aggressive medical management of Crohn disease; at the same time, surgeons are seeing more complicated disease at the time of operation. These developments have implications for management. An easy ileocolic resection is an experience that a patient generally tolerates well and recovers from very quickly; however, delaying operative management with years of aggressive medical therapy can lead to more complicated disease associated with enterenteric fistulas, which can be difficult to treat. Ileosigmoid fistulas are among the most common fistulas associated with ileocolic Crohn disease, along with fistulas between the terminal ileum and the ascending colon and fistulas between the terminal ileum and adjacent loops of small bowel.

Disease recurrence is common after ileocolic resection. Colonoscopy is the most accurate modality for postoperative surveillance and the easiest to use; it is more sensitive than either small bowel follow-through or air-contrast barium enema. For this reason, I favor an end-to-end anastomosis after ileocolic resection. In the event of recurrent disease, an end-to-side, side-to-end, or side-to-side anastomosis may be difficult to intubate. There is some evidence in the lit-

erature to suggest that the postoperative recurrence rate may be lower with a wider anastomosis.²⁷ The anastomosis can be performed in either one or two layers. If the bowel is thicker, a handsewn anastomosis is preferred to a stapled one.

The incidence of reoperation for recurrent disease after ileocolic resection is high and increases with the number of resections.²⁸ Postoperative chemoprophylaxis with mesalamine can significantly reduce the recurrence rate.²⁹ Patients who smoke should be strongly encouraged to stop: the rate and severity of recurrence are increased in smokers.²⁰

Special Circumstances

Ileocolic Crohn disease is often associated with intra-abdominal abscesses or fistulas. If an associated abscess is known to be present, CT-guided drainage should be done preoperatively so that a single-stage procedure can then be performed. If an unsuspected abscess is identified at the time of operation, the safest approach is to proceed with bowel resection, perform the posterior wall of the anastomosis, and exteriorize the anastomosis as a loop ileostomy. This loop ileostomy can then be safely closed, often without a formal laparotomy, 8 weeks after operation if there are no signs of ongoing sepsis. If the abscess or the terminal ileal loop is adherent to the sigmoid colon, an ileosigmoid fistula may be present. The decision whether to resect the sigmoid colon is dictated by the appearance and feel of the sigmoid in the involved areas. If only a portion of the anterior colon wall is involved, that portion can be excised in a wedgelike fashion and the excision site closed primarily. If the entire circumference of the sigmoid colon at that point is indurated and woody feeling, a short segmental resection with anastomosis is the best option.

Figure 6 A large ulcer is nearly always present on the mesenteric luminal border of small bowel strictures.

COLONIC DISEASE

Colonic involvement is present in 29% to 44% of patients with Crohn disease.³⁰ One of the challenges in treating colonic Crohn disease is obtaining the correct diagnosis. Whereas Crohn disease of the small bowel is fairly easy to diagnose, colonic disease often is not. Because granulomas are not present in most cases of colonic Crohn disease and because this condition can look very similar to ulcerative colitis both endoscopically and macroscopically, differentiation between Crohn colitis and ulcerative colitis can be difficult in the absence of small bowel or anal disease. Colonic Crohn disease appears to be more frequently associated with cutaneous manifestations (e.g., pyoderma gangrenosum) [see Figure 7].

Indications for Surgical Treatment

The main indications for operative management of colonic Crohn disease are stricture [see Figure 8], malignancy, side effects of medical therapy, and failure of medical therapy. In children, failure to recognize and treat this condition promptly may result in growth retardation. It is important to monitor both bone age and insulinlike growth factor-1 levels. If these are abnormal, timely institution of human growth hormone therapy, operative management of inflammatory bowel disease, or both may still permit normal growth and development.

Side effects of medical therapy can be substantial. They may include such varied complications as aseptic necrosis of the femoral head and cataract formation (both related to steroid use), as well as an increased incidence of opportunistic infections (from immunosuppression secondary to antimetabolite therapy).

Failure of medical therapy can refer to continuing severe disease activity or, at worst, to so-called toxic megacolon. The term toxic megacolon is actually a misnomer, in that not all patients with this condition actually have a true megacolon [see Figure 9a]. In common usage, the term toxic megacolon refers to any condition associated with colitis that is severe enough to result in sloughing of the

colonic mucosa; such sloughing permits endotoxins to enter the circulatory system and evoke a septic response. The signs and symptoms of toxic megacolon include those characteristic of sepsis—leukocytosis, fever, tachycardia, and hypoalbuminemia. These patients are very ill and often manifest ileus, which is an ominous development that frequently signals impending perforation. Emergency surgical intervention is required. At operation, the colon is often distended, and when the specimen is opened, the colon may appear almost autolytic [see Figure 9b]. In this state, the bowel frequently does not hold staples well; accordingly, it is often helpful to sew the distal Hartmann stump between the left and right halves of the anterior inferior rectus fascia at the lower abdominal incision and then to close the skin over it.³¹ Thus, if the staple line is disrupted, the result is essentially a surgical site infection that can be opened and drained, rather than the pelvic abscess [see Figure 9c] that could develop if the rectal stump were located deep within the pelvis.

Types of Disease

Segmental disease In a 2003 review of 92 consecutive cases of patients with Crohn colitis, the number of patients with segmental colonic Crohn disease and the number of those with pancolonic disease were nearly equal.³⁰ Approximately 63% of those with segmental colitis had other disease involvement as well (e.g., jejunoileal, ileocolic, or perianal), compared with only 12% of those with pancolitis. The recurrence rate, however, was higher in patients with segmental colitis than in those with pancolitis. In addition, the risk of recurrence was higher in patients who had granulomatous disease than in those who did not.

Pancolonic disease In cases of pancolonic Crohn disease with associated perianal, jejunoileal, or ileocolic involvement, diagnosis is not difficult. However, most patients with Crohn pancolitis do not have other sites of disease involvement, nor do they have granulomas.³⁰ Consequently, differentiation of Crohn pancolitis

Figure 7 (a) Shown is pyoderma gangrenosum affecting the peristomal and incisional area 6 months after creation of a loop ileostomy in a 16-year-old girl who had undergone colectomy with IPAA for a presumed initial diagnosis of ulcerative colitis. (b) Shown is peristomal gangrenosum of the breast in an otherwise asymptomatic patient with Crohn colitis and perianal Crohn disease who had a diverting loop ileostomy.

Figure 8 Shown is a sigmoid colon stricture secondary to Crohn disease that caused obstructing symptoms refractory to medical therapy.

from ulcerative colitis can be very difficult. Many patients with Crohn disease have been inappropriately subjected to colectomy with ileal pouch–anal anastomosis (IPAA) because they were initially presumed to have ulcerative colitis.

Operative Procedures

Total proctocolectomy with end ileostomy The traditional procedure for colonic Crohn disease is total proctocolectomy with end ileostomy, which is associated with an 8% to 15% rate of recurrence in the bowel proximal to the stoma.^{32–34} This operation remains the best choice in patients with severe rectal and anal Crohn disease (e.g., those with so-called watering-can perineum [see Figure 10]) and carries the lowest risk of disease recurrence. In contrast to the approach taken in patients with rectal cancer, which involves excising the external anal sphincter and a large portion of the levator muscles, the approach taken in those with colonic Crohn disease is intersphincteric, with dissection performed in the plane between the internal and external anal sphincters to reduce the size of the perineal wound and facilitate healing. Even with the intersphincteric approach, delayed healing of the perineal wound is common, occurring in as many as 30% of patients.

Subtotal colectomy with ileorectal or ileosigmoid anastomosis Because many patients with Crohn disease are young, surgeons have long been interested in operations that do not involve an ileostomy. In the absence of significant rectal and anal disease, subtotal colectomy with ileorectal or ileosigmoid anastomosis is an option. Unfortunately, this operation is associated with high recurrence rates (up to 70%)³⁵; however, with the advent of more effective immunosuppressive and biologic therapy, it is hoped that these rates can be reduced. As much palpably normal distal rectum and colon as possible should be spared. The anastomosis can be stapled, though if the bowel wall is thickened, many surgeons would feel more secure with a handsewn anastomosis in either one or two layers.

Segmental resection Currently, more surgeons are advocating colon-sparing procedures [see 5:34 *Laparoscopic Colectomy*] for Crohn disease. Although this is a relatively new approach,

Figure 9 (a) Shown is toxic megacolon in a 17-year-old girl with Crohn colitis. The colon is massively distended and near perforation at the time of operation. (b) When the specimen is opened, it is apparent that large segments of the mucosa have sloughed off, leaving denuded muscle wall. (c) The distal rectosigmoid is incorporated between the left and right halves of the anterior inferior rectus fascia at the lower abdominal incision and placed underneath the skin, which is then closed over it. Thus, in the event of disruption of the distal stump, the contents drain harmlessly through the wound.

Figure 10 Shown is so-called watering-can perineum secondary to severe perianal Crohn disease.

there have already been some reports documenting the safety of segmental resection in cases of limited disease.³⁶ In patients with colonic strictures resulting in obstruction, segmental resection into palpably normal areas of the bowel yields prompt resolution of symptoms. Because the colon performs an important water-absorbing function, many patients with a limited amount of small bowel can still live without intravenous supplementation if a significant segment of the colon is left in situ. However, patients with segmental Crohn disease appear to have a higher recurrence rate than those with pancolitis, as do patients with granulomas.³⁰ Surgical treatment of Crohn disease continues to undergo reevaluation and reassessment of results on the basis of the availability of newer medical therapies.

Colectomy with IPAA Although colectomy with IPAA [see 5:33 *Procedures for Ulcerative Colitis*] is not an operation that one

Figure 11 Vessel loops can be used as setons for drainage of abscesses caused by perianal Crohn disease. They can be left in as long as necessary and help prevent recurrent abscess formation.

would knowingly perform in a patient with Crohn disease, every year there are many such patients who undergo this procedure as treatment of colonic inflammatory bowel disease that initially is incorrectly presumed to be ulcerative colitis but later is diagnosed as Crohn disease (on the basis of either final pathologic analysis of the resected specimen or the disease's clinical behavior). Generally speaking, in the absence of fistulizing disease, most of these patients are able to maintain their pouch, but they require medical therapy for disease control.^{30,37-40}

ANAL DISEASE

Types of Disease

With stenosis For patients with anal strictures that are not regularly dilated, the outlook is poor. Such strictures pose functional obstructions and typically lead to continuing problems with fistulas and suppurative disease. They frequently become more and more fibrotic over time and often extend proximally. Most of these patients eventually require fecal diversion. Management generally involves self-dilation, which can often be done with Hegar dilators. If the stenosis is not dealt with, all other treatment of the Crohn disease is doomed to failure; obstruction at the level of the anal canal inevitably results in the persistence of anorectal disease.

Without stenosis Anal Crohn disease without stenosis is much easier to treat medically. Long-term oral metronidazole therapy is often helpful; other medications (e.g., anti-tumor necrosis factor antibody) may be useful as well. Broad fissures are usually asymptomatic. Surgical treatment should be avoided unless the lesions are causing symptoms. Because they tend to have more liquid bowel movements, patients with Crohn disease need an optimally functioning anal sphincter; hence, fistulotomies, which divide portions of the sphincter, should be avoided if at all possible. Placement of setons through fistula tracts can often prevent abscess formation, provide drainage, and thereby prevent perianal pain while minimizing sphincter trauma. Silk sutures, vessel loops, or Penrose drains also can be used as setons [see *Figure 11*]. Rectovaginal fistulas pose a particular challenge. In the presence of active Crohn disease, advancement flap repair of such fistulas has a low success rate.⁴¹ Laparoscopic-assisted loop ileostomy improves the success rate, but unfortunately, the fistulas may recur when intestinal continuity is reestablished.

Postoperative Management

CHEMOPROPHYLAXIS

In 1995, a prospective, randomized study showed that patients who underwent ileocolic resection and were given mesalamine postoperatively had a significant reduction in both the symptomatic and the endoscopic rate of recurrence.²⁹ Not all of the work done since then has confirmed these results, but several studies and a meta-analysis have indicated that mesalamine does reduce the postoperative recurrence rate of Crohn disease.⁴² Many patients undergoing surgical treatment of Crohn disease are advised to take some type of postoperative preventive medical therapy—either a 5-ASA derivative (e.g., mesalamine) or a stronger immunosuppressive agent (e.g., 6-mercaptopurine or azathioprine). Better studies are required to document the efficacy of the latter agents in preventing recurrence. It is hoped that chemoprophylaxis will reduce the anticipated recurrence rates by 30% to 40%.

SURVEILLANCE

At present, there are no clear guidelines for surveillance after operative treatment of Crohn disease. In my opinion, however, given the increased risk of colorectal cancer in this setting, patients with Crohn disease who retain some colon should undergo colonoscopy every 2 years, not only to detect any development of colonic neoplasia but also to identify any recurrence of disease in a timely manner. If recurrent Crohn disease is detected, appropriate medical therapy should be promptly instituted, with the aim of avoiding subsequent operation if possible.

BEHAVIORAL MODIFICATION

Exposure to cigarette smoke is known to exacerbate the symptoms of Crohn disease. Smoking has been reported to affect the overall severity of the disease, with smokers having a 34% higher recurrence rate and a higher rate of reoperation than nonsmokers.⁴³⁻⁴⁵ A 1999 study of 141 Crohn disease patients who had undergone ileocolic resection, of whom 79 were nonsmokers and the remainder were smokers, found that the respective 5- and 10-year recurrence-free rates were 65% and 45% in smokers and 81% and 64% in nonsmokers. The recurrence rates were higher in heavy smokers (≥ 15 cigarettes/day) than in moderate smokers.⁴⁶

12 DIVERTICULITIS

John P. Welch, M.D., F.A.C.S., and Jeffrey L. Cohen, M.D., F.A.C.S., F.A.S.C.R.S.

Diverticula are small (0.5 to 1.0 cm in diameter) outpouchings of the colon that occur in rows at sites of vascular penetration between the single mesenteric taenia and one of the antimesenteric taeniae. At the sites of most diverticula, the muscular layer is absent [see Figure 1]. Technically, such lesions are really pseudodiverticula; true diverticula (which are much less common than pseudodiverticula) involve all layers of the bowel wall. Nevertheless, both pseudodiverticula and true diverticula are generally referred to as diverticula.

The sigmoid colon is the most common site of diverticula: in 90% of patients with diverticulosis, the sigmoid colon is involved.¹ If a diverticulum becomes inflamed as a result of obstruction by feces or hardened mucus or of mucosal erosion, a localized perforation (microperforation) may occur—a process known as diverticulitis. The incidence of diverticulitis is about 10% to 25% in patients with colonic diverticula.¹ Both diverticulosis and variants of diverticulitis may be subsumed under the more encompassing term diverticular disease.

The incidence of diverticular disease increases with age. Diverticula are quite common in elderly patients, being present in more than 80% of patients older than 85 years.² Consequently, as the population of the United States continues to age, the overall risk of diverticular complications continues to increase.³ Before the 20th century, diverticular disease was rare in the United States. By 1996, however, 131,000 patients were being admitted to hospitals with diverticulitis each year.⁴

A diet containing refined carbohydrates and low-fiber substances, such as is currently widespread in many developed countries (especially in the West), has been associated with the emergence of this disease entity.^{5,6} A low-residue diet facilitates the development of constipation, which can lead to increased intraluminal pressure in the large bowel. In addition, elevated elastin levels are commonly noted at colon wall sites containing diverticula,⁷ and this change causes shortening of the taeniae.¹ High-pressure zones or areas of segmentation may develop [see Figure 2], usually in the sigmoid colon, and diverticula begin to protrude at these locations. If microperforation of a thin-walled diverticulum takes place, local or, sometimes, widespread contamination with fecal organisms may ensue. The pericolonic tissue (typically, the mesentery and the pericolonic fat) thus becomes inflamed while the mucosa tends to remain otherwise normal.

Several factors appear to promote the development of diverticular disease and its complications, including decreased physical activity,⁸ intake of nonsteroidal anti-inflammatory drugs (NSAIDs),^{9,10} smoking,¹¹ and constipation from any cause (e.g., diet or medications). The well-known Western afflictions cholelithiasis, diverticulosis, and hiatal hernia frequently occur together (Saint's triad). Obesity has been associated with the intake of low-fiber diets,¹² and growing numbers of young, obese patients with diverticulitis are being seen by physicians.

Clinical Evaluation

HISTORY

Uncomplicated (Simple) Diverticulitis

The classic symptoms of uncomplicated acute diverticulitis are left lower quadrant abdominal pain, a low-grade fever, irregular bowel habits, and, possibly, urinary symptoms if the affected colon is adjacent to the bladder. If the sigmoid colon is highly redundant, pain may be greatest in the right lower quadrant. Diarrhea or constipation may occur, together with rectal urgency.

The differential diagnosis includes gynecologic and urinary disorders, perforated colon carcinoma, Crohn disease, ischemic colitis, and, sometimes, appendicitis. Chronic diarrhea, multiple areas of colon involvement, perianal disease, perineal or cutaneous fistulas, or extraintestinal signs are suggestive of Crohn disease. Rectal bleeding should raise the possibility of inflammatory bowel disease, ischemia, or carcinoma; such bleeding is uncommon with diverticulitis alone. Given the prevalence of diverticula, it is not surprising that colon carcinoma may coexist with diverticular disease [see Figure 3].

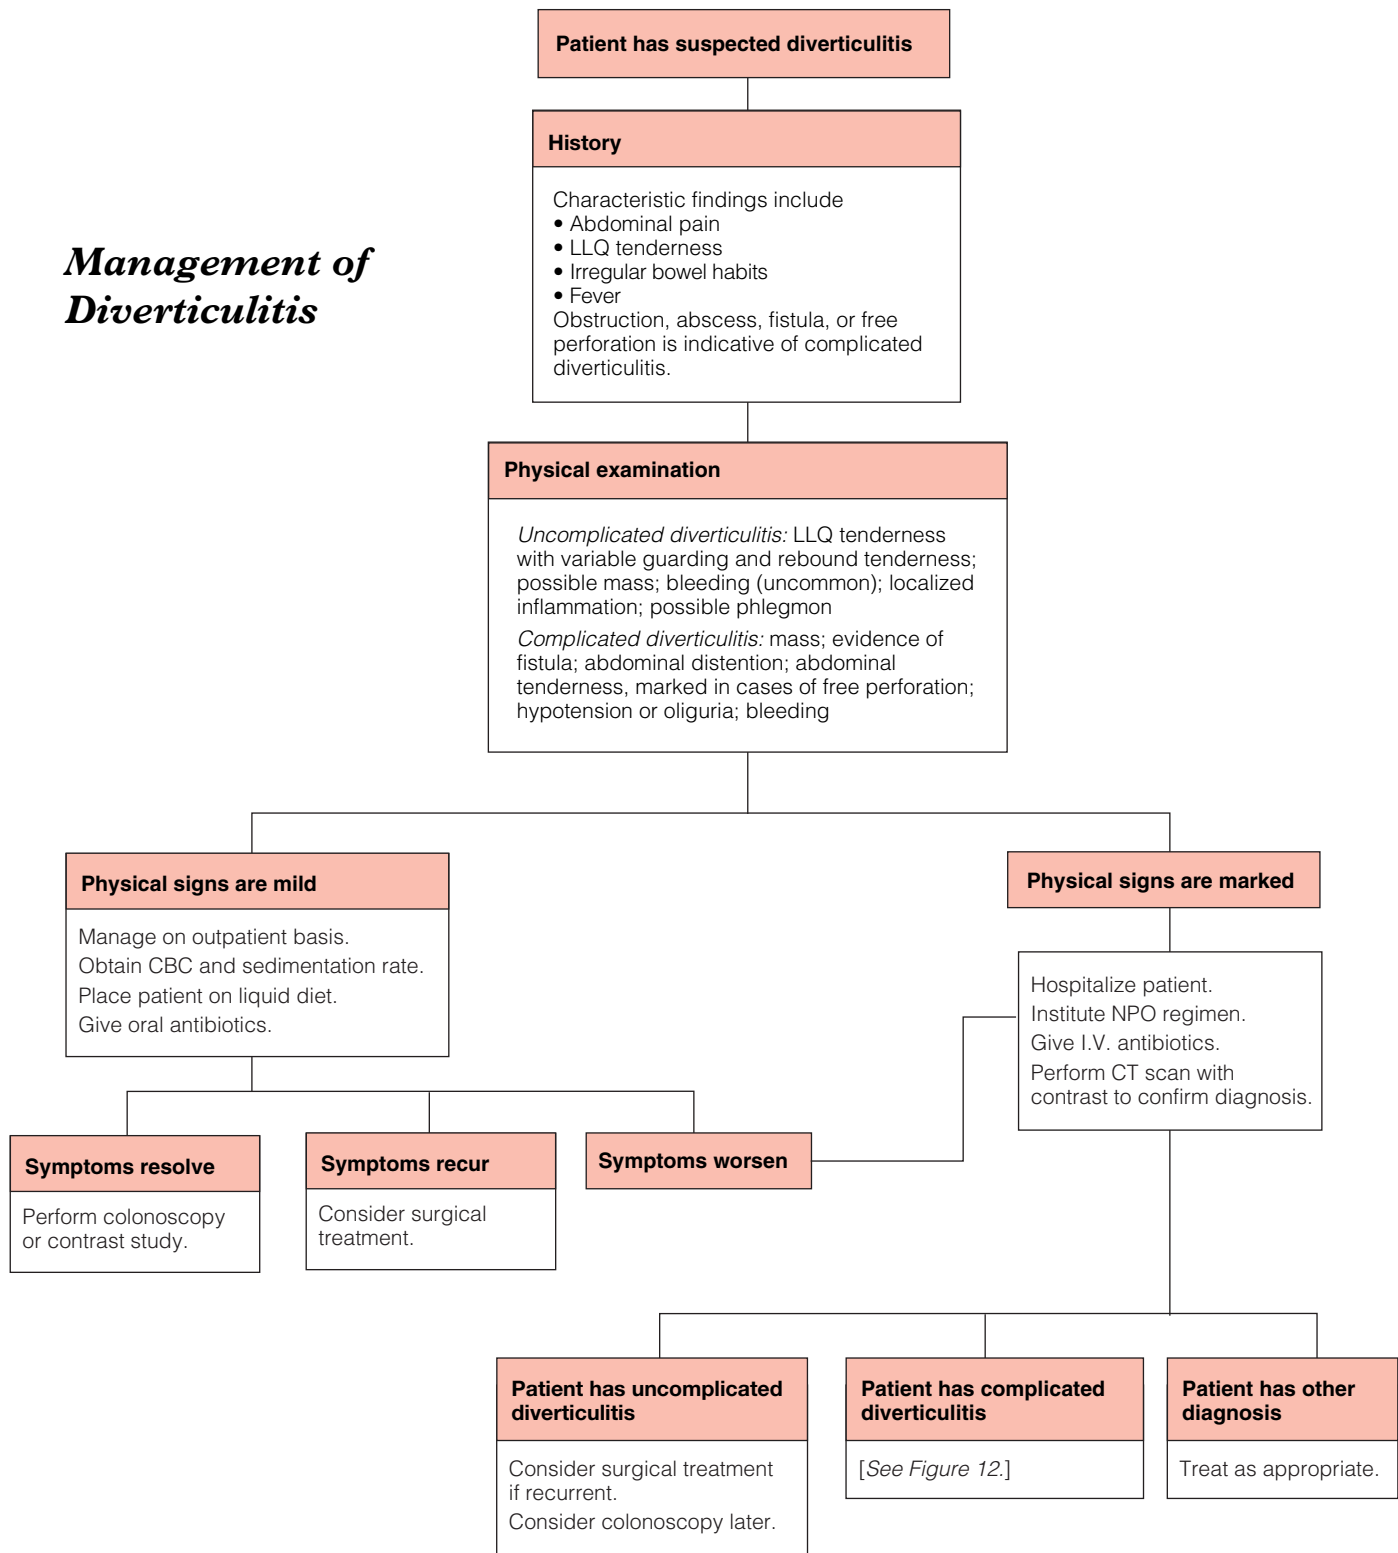

Figure 1 Illustrated are anatomic findings in a segment of colon containing diverticula. Diverticula are located at sites where blood vessels enter the colonic wall.⁸⁷

Management of Diverticulitis

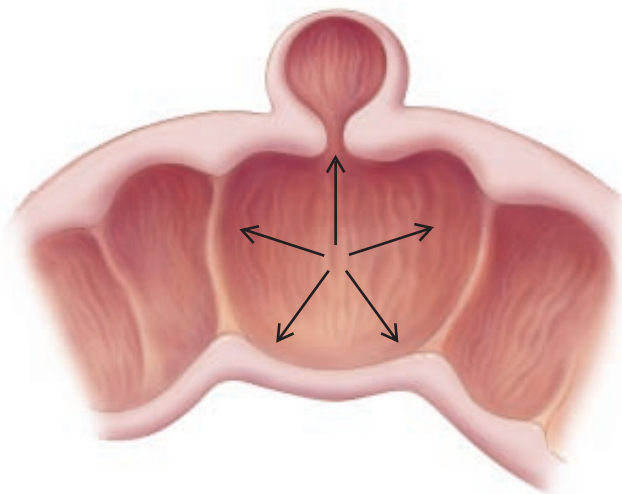

Figure 2 Depicted is a schematic representation of the process termed segmentation in the colon. It has been theorized that high-pressure compartments lead to the development of diverticula.⁸⁸

Complicated Diverticulitis

Some cases of diverticulitis are classified as complicated, meaning that the disease process has progressed to obstruction, abscess or fistula formation, or free perforation [see Figure 4]. Complicated diverticulitis may be particularly challenging to manage,^{13,14} especially because patients may have no known history of diverticular disease.¹⁵ Lower gastrointestinal bleeding is also a complication of diverticular disease in 30% to 50% of cases¹⁶; in fact, diverticula are the most common colonic cause of lower GI bleeding.¹⁶ When diverticular hemorrhage occurs [see

Figure 3 Barium enema shows a napkin-ring carcinoma (arrow) in the middle of multiple diverticula in a redundant sigmoid colon.

Figure 4 Shown are major complications of diverticular disease of the sigmoid colon.⁸⁹

5:6 Lower Gastrointestinal Bleeding], it is usually associated with diverticulosis rather than with diverticulitis. Approximately 50% of diverticular bleeding originates in the right colon, despite the low incidence of diverticula in this segment of the colon. Patients tend to be elderly¹³ and to have cardiovascular disease and hypertension. Regular intake of NSAIDs may increase the risk of this complication. Although patients may lose 1 to 2 units of blood, the bleeding usually ceases spontaneously,¹⁷ and expeditious operative treatment generally is not necessary.

The most common form of complicated diverticulitis involves the development of a pericolic abscess, typically signaled by high fever, chills, and lassitude. Such abscesses may be small and localized or may extend to more distant sites (e.g., the pelvis). They may be categorized according to the Hinchey classification of diverticular perforations,¹⁸ in which stage I refers to a localized pericolic abscess and stage II to a larger mesenteric abscess spreading toward the pelvis [see Figure 5]. On rare occasions, an abscess forms in the retroperitoneal tissues, subsequently extending to distant sites such as the thigh or the flank. The location of the abscess can be defined precisely by means of computed tomography with contrast.

Some abscesses rupture into adjacent tissues or viscera, resulting in the formation of fistulas. The fistulas most commonly seen in this

Figure 5 The Hinchey classification divides diverticular perforations into four stages. Mortality increases significantly in stages III and IV.¹⁸

setting (50% to 65% of cases) are colovesical fistulas. This complication is less common in women because of the protection afforded by the uterus. Symptoms of colovesical fistulas tend to involve the urinary tract (e.g., pneumaturia, hematuria, and urinary frequency). Fecaluria is diagnostic of colovesical or enterovesical fistulas. Colovaginal fistulas (which account for 25% of all diverticular fistulas) are usually seen in women who have undergone hysterectomies.¹⁹ The diseased colon is adherent to the vaginal cuff. Most commonly, patients complain of a foul vaginal discharge; however, some patients present with stool emanating from the vagina.

About 10% of colon obstructions are attributable to diverticulitis. Acute diverticulitis can cause colonic edema and a functional obstruction that usually resolves with antibiotic infusion and bowel rest. Stricture formation is more common, usually occurring as a consequence of recurrent attacks of diverticulitis. Circumferential pericolic fibrosis is noted, and marked angulation of the pelvic colon with adherence to the pelvic sidewall may be seen. Patients complain of constipation and narrowed stools. Colonoscopy can be difficult and potentially dangerous in this setting. Differentiating a diverticular stricture from carcinoma may be impossible by any means short of resection.

The term malignant diverticulitis has been employed to describe an extreme form of sigmoid diverticulitis that is characterized by an extensive phlegmon and inflammatory reaction extending below the peritoneal reflection, with a tendency toward obstruction and fistula formation.²⁰ Malignant diverticulitis is seen in fewer than 5% of patients older than 50 years who are operated on for diverticulitis.²⁰ The process is reminiscent of Crohn disease, and CT scans demonstrate extensive inflammation. In this setting, a staged resection might be preferable to attempting a primary resection through the pelvic phlegmon. The degree of pelvic inflammation may subside significantly after diversion.²⁰

A dangerous but rare complication of acute diverticulitis (occurring in 1% to 2% of cases) is free perforation,²¹ a term that includes both perforation of a diverticular abscess throughout the abdomen leading to generalized peritonitis (purulent peritonitis; Hinchey stage III) and free spillage of stool through an open diverticulum into the peritoneal cavity (fecal peritonitis; Hinchey stage IV). The incidence of free perforations may be increasing, at least in the southwestern United States.²² The overall mortality in this group is between 20% and 30%; that for purulent peritonitis is approximately 13%, and that for fecal peritonitis is about 43%.²¹

PHYSICAL EXAMINATION

Uncomplicated Diverticulitis

Physical examination reveals localized left lower quadrant abdominal tenderness with variable degrees of guarding and rebound tenderness. A mass is occasionally felt. The stool may contain traces of blood, but gross bleeding is unusual. Localized inflammation of the perforated diverticulum and the adjacent mesentery is present, and a phlegmon may be seen as well. Depending on the severity of the physical findings, patients may be managed either as inpatients or outpatients.

Complicated Diverticulitis

In a patient with a pericolic abscess, a mass may be detectable on abdominal, rectal, or pelvic examination. In a patient with a

colovaginal fistula, a site of granulation tissue and drainage is seen at the apex of the vaginal cuff. In a patient with obstruction, there may be marked abdominal distention, usually of slow onset; abdominal tenderness may or may not be present, but if tears develop in the cecal taeniae, right lower quadrant tenderness is typically seen. In a patient with a free perforation, there is marked abdominal tenderness, usually commencing suddenly in the left lower quadrant and spreading within hours to the remainder of the abdomen. Hypotension and oliguria may develop later. Patients with rectal bleeding usually have no complaints of abdominal pain or tenderness, and they may be hypovolemic and hypotensive, depending on the rapidity of the bleeding.

Investigative Studies

IMAGING

The most useful diagnostic imaging study in the setting of suspected diverticulitis is a CT scan with oral and rectal contrast.²³ Localized thickening of the bowel wall or inflammation of the adjacent pericolic fat is suggestive of diverticulitis; extraluminal air or fluid collections are sometimes seen together with diverticula [see Figure 6]. The most frequent findings (seen in 70% to 100% of cases) are bowel wall thickening, fat stranding, and diverticula.²⁴ In some cases, small abscesses in the mesocolon or bowel wall are not detected. The diagnosis of carcinoma cannot be excluded definitively when there is thickening of the bowel wall [see Figure 7].²

Although CT scanning has tended to replace contrast studies in the evaluation of diverticulitis, the latter may be more useful in differentiating carcinoma from diverticulitis. A contrast study can also be complementary when the CT scan raises the suspicion of carcinoma.²³ When diverticulitis is suspected, water-soluble contrast material should be used instead of barium because of the complications that follow extravasation of barium [see Figures 8 and 9]. Furthermore, in the acute setting, only the left colon should be evaluated. Carcinoma is suggested by an abrupt transition to an abnormal mucosa over a relatively short segment; diver-

Figure 6 CT scan shows thickening of the sigmoid colon (arrow) caused by acute diverticulitis.

Figure 7 (a) CT scan shows a thickened left colonic wall and diverticulum (arrow). Diverticulitis was considered the most likely diagnosis. (b) CT scan through an adjacent plane shows deformity of the mucosa, suggesting a possible apple-core lesion (arrow). Subsequent endoscopy revealed a carcinoma that was obstructing the colon almost completely.

Figure 8 Contrast study shows local extravasation from the sigmoid colon (arrow); a diverticulum is visible.

Figure 9 Shown is extravasation into an abscess cavity (arrow) from diverticulitis at the sigmoid colon–descending colon junction in a postevacuation film.

Figure 10 Colonoscopic view of several sigmoid diverticula reveals no evidence of active diverticulitis (e.g., edema or narrowing).

Diverticulitis is usually characterized by a gradual transition into diseased colon over a longer segment, with the mucosa remaining intact. If the contrast study reveals extravasation of contrast outlining an abscess cavity [see Figure 9], an intramural sinus tract, or a fistula, diverticulitis is likely.¹

Colonoscopy is avoided when acute diverticulitis is suspected, because of the risk of perforation. It may, however, be done 6 to 8 weeks after the process subsides to rule out other disorders (e.g., colon cancer) [see Figure 10]. If diverticular disease is advanced, the endoscopic procedure may be difficult; the diverticular segment must be fully traversed for the examiner to be able to exclude a neoplasm with confidence. When major lower GI bleeding occurs, colonoscopy is done to search for polyps, carcinoma, or a site of diverticular bleeding. In the case of massive bleeding, selective arteriography is useful for localizing the source, and superselective embolization frequently quells the hemorrhage. The actual risk of bowel ischemia is low when superselective techniques are employed. Bleeding at the time of arteriography may be facilitated by the infusion of heparin or urokinase; however, this is a risky approach that should be taken only when other attempts at localization have failed and recurrent bouts of bleeding have occurred.

When a colovesical fistula occurs, contrast CT with narrow cuts in the pelvis can be very helpful. The classic findings are sigmoid diverticula, thickening of the bladder and the colon, air in the bladder, opacification of the fistula tract and the bladder, and, possibly, an abscess [see Figure 11]. Cystoscopy is less specific, showing possible edema or erythema at the site of the fistula. A contrast enema helps rule out malignant disease. The diagnostic tests that are most useful for detecting colovaginal fistulas are contrast CT and vaginography via a Foley catheter. Charcoal ingestion helps confirm the presence of colovesical or colovaginal fistulas. On rare occasions, colocutaneous fistulas may develop, causing erythema and breakdown of the skin. Colouterine fistulas may occur as well; these are also quite rare.²⁵

Management

MEDICAL

Uncomplicated diverticulitis is usually managed on an outpatient basis by instituting a liquid or low-residue diet and administering an oral antibiotic combination that covers anaerobes and gram-negative organisms (e.g., ciprofloxacin with metronidazole or clindamycin) over a period of 7 to 10 days. Provided that symptoms and signs have subsided, the colon may be evaluated more fully several weeks later with a contrast study or colonoscopy if the diagnosis of diverticular disease has not already been established. If symptoms worsen, hospitalization should be considered. Over the long term, patients should be maintained on a high-fiber diet, though it may take months for the diet to have an effect on symptoms.²⁶

If more significant physical findings and symptoms of toxicity develop, hospitalization is warranted [see Figure 12]. Patients are placed on a nihil per os (NPO) regimen, and intravenous fluids and antibiotics are administered (e.g., a third-generation cephalosporin with metronidazole) until abdominal pain and tenderness have resolved and bowel function has returned. As a rule, resolution occurs within several days. If there is clinical evidence of intestinal obstruction or ileus, a nasogastric tube is placed. In most cases, ileus-related symptoms resolve with antibiotic treatment. CT scans are useful for establishing the correct diagnosis in

Figure 11 (a) CT scan in a patient with a colovesical fistula shows air in the thickened tract (arrow) adjacent to the sigmoid colon. (b) CT scan through an adjacent plane shows air in the bladder (arrow) as a result of the fistula. No contrast is present in the bladder.

the emergency department²⁷; furthermore, the severity of diverticulitis on CT scans predicts the risk of subsequent medical failure.²⁸ Following the sedimentation rate may be helpful in assessing the effectiveness of treatment. It has been estimated that 15% to 30% of patients admitted with acute diverticulitis will require surgical treatment during the same admission.¹

If fever and leukocytosis persist despite antibiotic therapy, the presence of an abscess should be suspected. Small (< 5 cm) abscesses may respond to antibiotics and bowel rest. Larger abscesses that are localized and isolated may be accessible to percutaneous drainage [see Figure 13].²⁸ Generally, this technique is reserved for abscesses greater than 5 cm in diameter in low-risk patients who are not immunocompromised. It often leads to resolution of sepsis and the resulting symptoms and signs (e.g., abdominal pain and tenderness and leukocytosis), usually within 72 hours, thereby facilitating subsequent elective surgical resection of the colon. In addition, percutaneous drainage offers cost advantages, in that it reduces the number of operative procedures required and shortens hospital stay.

Access to a pelvic collection may be difficult to obtain, and the drainage procedure typically must be done with the patient in a prone or lateral position. If the catheter drainage amounts to more than 500 ml/day after the first 24 hours, a fistula should be suspected. Before the catheter is removed, a CT scan is done with injection of contrast material through the tube to determine whether the cavity has collapsed. If this approach fails (as it usually does in patients with multiple or multiloculated abscesses), an expeditious operation may be necessary.²² An initial surgical procedure is required in about 20% of cases.²⁹

SURGICAL

Overall, approximately 20% of patients with diverticulitis require surgical treatment.^{2,30} Most surgical procedures are reserved for patients who experience recurrent episodes of acute diverticulitis that necessitate treatment (inpatient or outpatient) or who have complicated diverticulitis. The most common indication for elective resection is recurrent attacks—that is, several episodes of acute diverticulitis documented by studies such as CT. Estimates of the risk of such attacks range from 30% to 45%. A task force of the American Society of Colon and Rectal Surgeons recommended sigmoid resection after two attacks of diverticulitis.³¹ A cost analysis using a Markov model suggested that cost savings can be achieved if resection is done after three attacks.³² Efforts are made

to time surgical treatment so that it takes place during a quiescent period 8 to 10 weeks after the last attack. Barium enema or colonoscopy may be employed to evaluate the diverticular disease and rule out carcinoma. The bowel can then be prepared mechanically and with antibiotics (e.g., oral neomycin and metronidazole on the day before operation).

Elective resection is a common sequel to successful percutaneous drainage of a pericolic abscess in an otherwise healthy, well-nourished patient. The timing of surgery may be guided by the extent of the inflammatory changes (as documented by CT scanning) and the patient's clinical course. Most patients can be operated upon within 6 weeks. Elective resection is the preferred approach to diverticular fistulas as well. Colovesical fistulas are usually resected because of the risk of urinary sepsis and the concern that a malignancy might be overlooked. Preferably, the operation is done when the acute inflammation has subsided.

Elective resection is done via either the open route or, increasingly, the laparoscopic route³³; a few telerobotic-assisted laparoscopic colectomies have also been attempted.³⁴ The learning curve for laparoscopic colectomy is 20 to 50 cases.³⁵ Obese patients with severe colonic inflammation are poorer candidates for laparoscopic resection.³³ In our institution, the development of hand-assisted procedures has widened the opportunities for utilizing minimally invasive surgery [see 5:32 Procedures for Diverticular Disease], allowing all types of diverticular resections to be performed more safely. Minimally invasive procedures have several advantages over conventional procedures: decreased intraoperative trauma, fewer postoperative adhesions, reduced postoperative pain, shorter duration of ileus, quicker discharge from the hospital, and earlier return to work.³⁶⁻³⁸ Such procedures can be done safely in obese patients,³⁸ and the conversion rate is now low.^{35,39} Technical details of the procedures are addressed elsewhere [see 5:32 Procedures for Diverticular Disease].^{40,41}

Some patients with complicated diverticulitis require emergency resection because of free perforation and widespread peritonitis. In such patients, the American Society of Anesthesiologists (ASA) physical status score and the degree of preoperative organ failure may be significant predictors of outcome.^{42,43} Unfavorable systemic factors (e.g., hypotension, renal failure, diabetes, malnutrition, immune compromise, and ascites) play a vital role in determining patient outcome,⁴³ as does the severity of the peritonitis (i.e., extent, contents, and speed of development).^{44,45} One of the unfortunate limitations of the Hinchey classification is that

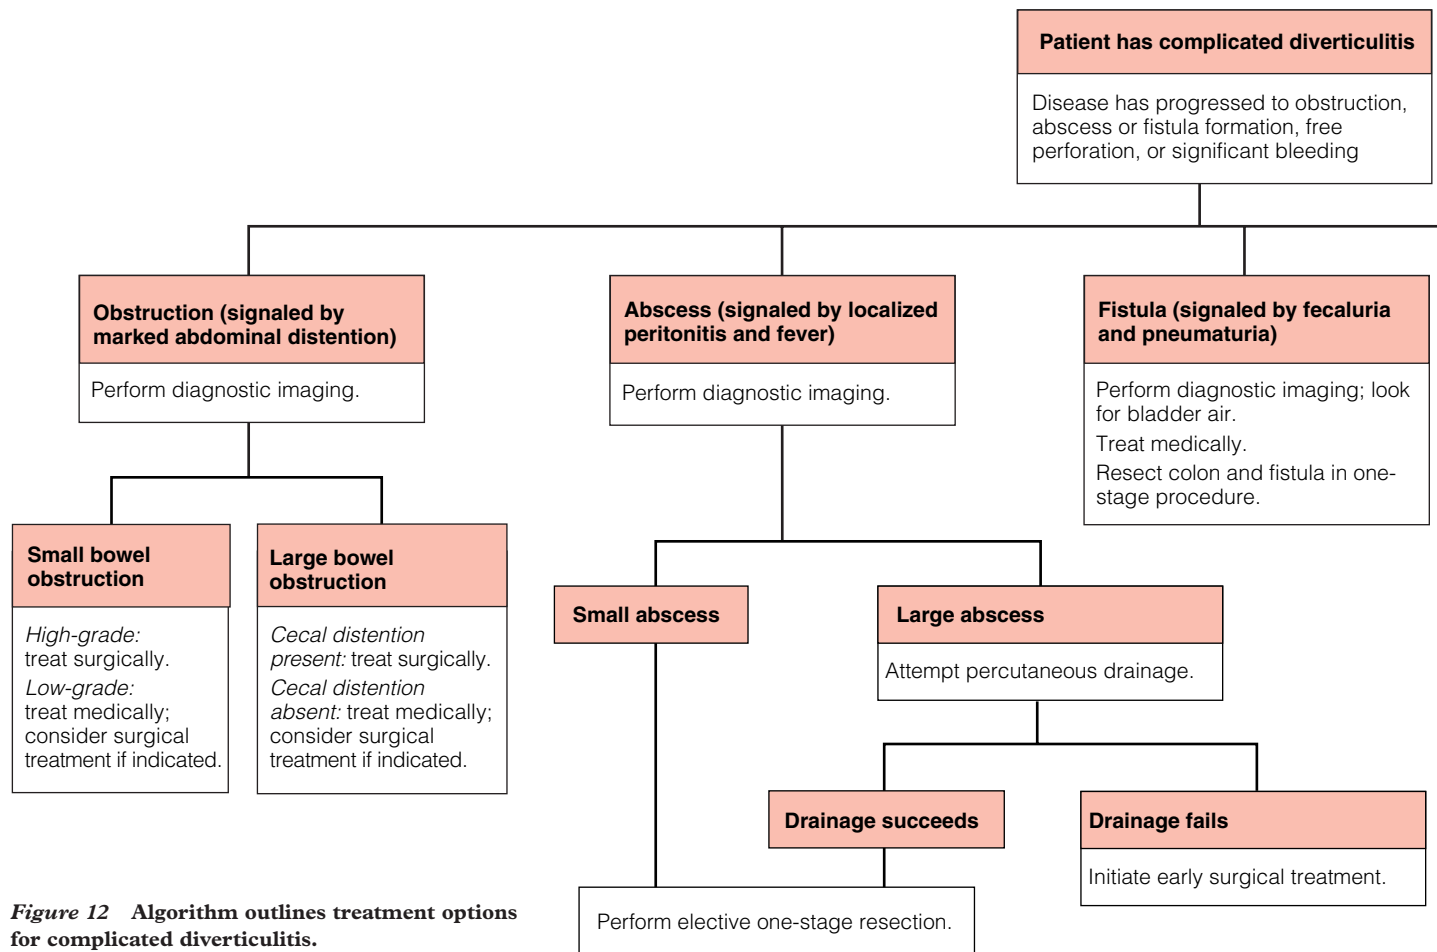

Figure 12 Algorithm outlines treatment options for complicated diverticulitis.

it does not take comorbidities into account.⁴⁴ Because the bowel is not prepared before operation, the surgeon may feel uncomfortable doing an anastomosis. On-table lavage may be considered if contamination is minimal, but it adds to the time spent under anesthesia during an emergency procedure.

As a general rule, resection and immediate anastomosis are suitable for Hinchey stage I and perhaps stage II diverticular perforations, whereas resection with diversion (the Hartmann proce-

dure) is the gold standard for stage III and especially stage IV.⁴⁶⁻⁴⁸ This recommendation is based on the finding that an anastomosis involving the left colon is risky when performed under emergency conditions.⁴⁹ The once-popular three-stage procedures are now of historic interest only. There are some reports of successful outcomes for type III and type IV cases after extensive abdominal lavage and two-layer anastomoses⁵⁰ or after on-table lavage of the colonic contents to allow primary anastomosis.⁵¹ Grading of

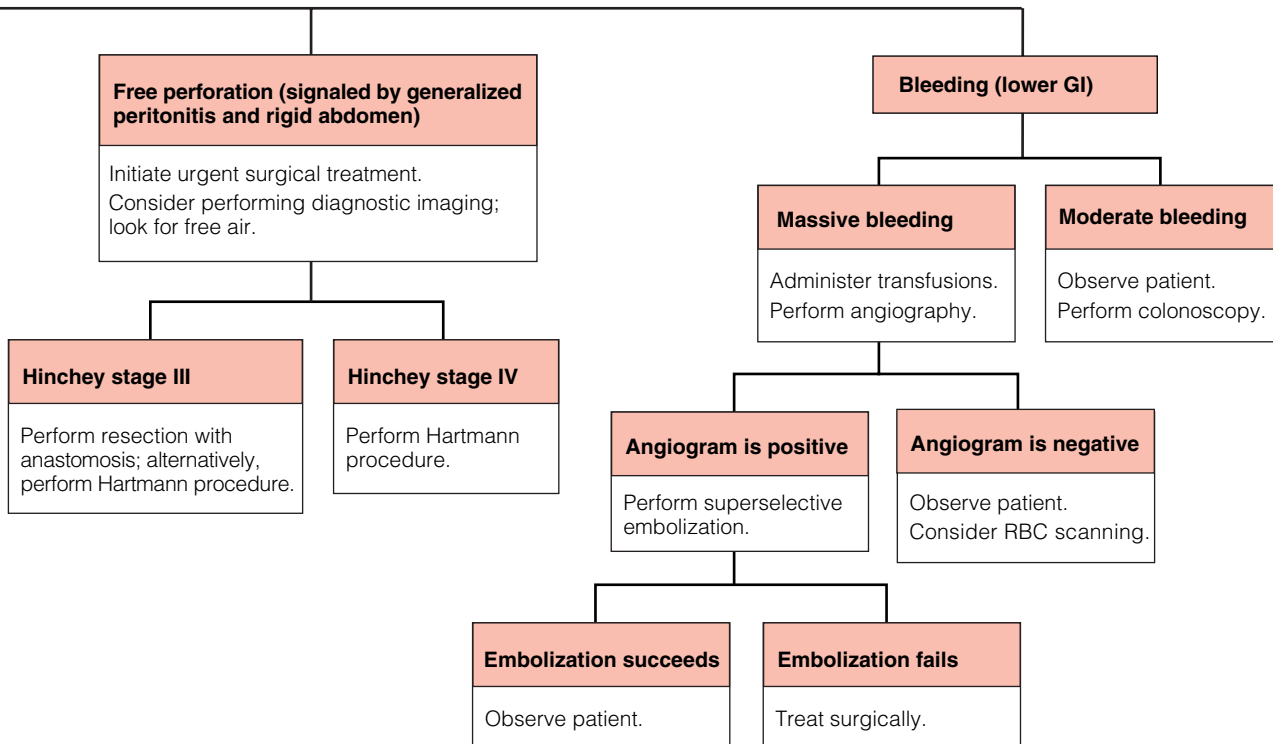

Figure 13 (a) CT scan shows a pericolic abscess (arrow) caused by a contained perforation arising from sigmoid diverticulitis. (b) A pigtail catheter (arrow) has been placed into the abscess cavity by the interventional radiologist.

comorbidities with classification systems such as APACHE II or the Mannheim peritonitis index can facilitate decision-making with respect to the question of anastomosis versus diversion.⁵² The surgeon's decision must be individualized on the basis of each patient's condition and needs. The literature on this topic is confusing, in that most of the published reports are small and retrospective, with only limited classification of disease severity.

Currently, surgeons encountering acute diverticulitis are more likely to do one-stage resections, as opposed to Hartmann procedures, than they once were.^{43,53} The advantage of the one-stage approach is that the colostomy takedown and the attendant 4% mortality are avoided.⁵⁴ Furthermore, at least 30% of patients who undergo a Hartmann procedure never return for colostomy closure. A primary anastomosis can be protected with a proximal ileostomy as well.^{46,55,56} Transverse colostomy and loop ileostomy appear to be equally safe, though skin changes may be more problematic after a colostomy⁵⁷ and an ileostomy closure tends to be less complex than a colostomy closure. On-table lavage may also be used as an adjunct to anastomosis.⁵⁸

The risk of complications inherent in operations on the colon should always be kept in mind, especially in the relatively few patients undergoing emergency procedures. In this setting, the bowel is unprepared and systemic sepsis may be present. Potential complications include ureteral injuries; anastomotic leakage, anastomotic stricture, and postoperative intra-abdominal abscesses; perioperative bleeding involving the mesentery; adhesions, the splenic capsule, or the presacral venous plexus; postoperative small bowel obstruction; stomal complications; wound infection,

wound dehiscence, and abdominal compartment syndrome; the acute respiratory distress syndrome (ARDS); and the multiple organ dysfunction syndrome (MODS).

Large bowel obstruction secondary to diverticulitis can lead to considerable morbidity and may necessitate surgical intervention.⁵⁵ The obstruction is usually partial [see Figures 14 and 15], allowing preparation of the bowel in many cases. High-grade obstruction represents a complex problem. If the cecum is dilated to a diameter of 10 cm or greater and there is tenderness in the right lower quadrant, expeditious surgery is necessary because of the risk of cecal necrosis and perforation. High-grade obstruction with fecal loading of the colon is usually managed by performing a Hartmann procedure, though on-table lavage may be considered.²² A survey of GI surgeons in the United States indicated that 50% would opt for a one-stage procedure in low-risk patients with obstruction, whereas 94% would opt for a staged procedure in high-risk patients.⁵⁹

Small bowel obstruction may also complicate the clinical picture. Mechanical small bowel obstruction may occur as a consequence of adherence of the small bowel to a focus of diverticulitis, especially in the presence of a large pericolic abscess. Whereas small bowel obstruction tends to cause periumbilical crampy abdominal pain and vomiting, these characteristic manifestations may be obscured in part by pain attributed to diverticulitis. The concern in this situation is that ischemic small bowel may be ignored, with potentially disastrous consequences. Diarrhea should trigger the suspicion of colonic disease, and formation of a fistula into the small bowel should raise the possibility of Crohn

Figure 14 CT scan shows marked thickening of the sigmoid wall (arrows) in a patient with diverticular disease who presented with symptoms of intractable constipation. No contrast is present in the lumen (curved arrow).

Figure 15 Contrast study shows high-grade retrograde obstruction, multiple diverticula, and a long proximal sigmoid stricture. A tiny extraluminal tract (possibly intramural) from a diverticulum (arrow) is seen.

disease. CT scanning often helps the surgeon differentiate between primary and secondary small bowel obstruction, but ultimately, exploratory surgery may be required both for diagnosis and for treatment.

Lower GI bleeding caused by diverticular disease rarely calls for emergency resection, because the bleeding is self-limited in most patients (80% to 90%). Furthermore, active diverticulitis is rare when active bleeding is the presenting symptom. Attempts are made to establish the active bleeding site by means of colonoscopy, tagged red blood cell nuclear scans, or angiography; barium contrast studies have no role to play in this situation. Emergency resection is indicated if the bleeding is life-threatening and if

colonic angiography and attempted superselective embolization prove unsuccessful. In an unstable patient, total abdominal colectomy is necessary if the site of bleeding is unknown, though identification of the bleeding site with intraoperative colonoscopy has been reported. In a stable patient with ongoing bleeding, repeat angiography at a later time is appropriate, or so-called pharmacangiography (infusion of heparin) can be employed in an attempt to induce bleeding.

Special Types of Diverticulitis

CECAL DIVERTICULITIS

In the United States, diverticulitis rarely involves the cecum or the right colon. Right-side diverticula occur in only 15% of patients in Western countries, compared with 75% in Singapore.¹ The incidence of cecal diverticulitis appears to be related to the number of diverticula present.⁶⁰ A classification system has been proposed that divides cecal diverticulitis into four grades [see Figure 16] to facilitate comparisons between different clinical series and to help surgeons formulate treatment plans in the OR.⁶⁰ Some cecal diverticula are true diverticula, containing all layers of the bowel wall, but the majority are pseudodiverticula. Diverticulitis of the hepatic flexure and the transverse colon is even less common and can present with symptoms suggesting appendicitis.^{61,62}

Patients with right-side disease tend to be younger and to have less generalized peritonitis than patients with left-side diverticulitis.^{60,61} Because they typically present with right lower quadrant pain, fever, and leukocytosis, acute appendicitis is usually suspected. CT scans are helpful for differentiating cecal diverticulitis from appendicitis or colon cancer [see Figure 17].^{63,64} If cecal diverticulitis is suspected (as in a patient who has previously undergone appendectomy or in a patient with known right-side diverticulosis who has experienced similar attacks in the past), medical management with observation and antibiotics is generally the favored strategy, just as with simple sigmoid diverticulitis. In Japan, where right-side diverticulitis is more common, medical treatment has been successfully used for recurrent attacks of uncomplicated right-side diverticulitis.⁶⁵ After a few weeks, colonoscopy should be performed to rule out a colonic neoplasm.

If the patient has significant peritonitis or the diagnosis is unclear, laparoscopy or laparotomy is indicated. It is important that one or the other be done because the mortality associated with delayed treatment of perforated cecal diverticulitis is high. In our institution, laparoscopy is usually employed; if the diagnosis is unclear, laparotomy is recommended. When inflammation is localized and minimal, colectomy is unnecessary, and incidental appendectomy should be considered if the cecum is uninvolved at the base of the appendix.⁶⁶ If desired, the diverticulum may be removed as well.

Diverticulectomy should be done only if (1) carcinoma can be ruled out, (2) the resection margins are free of inflammation, (3) the ileocecal valve and the blood supply of the bowel are not compromised, and (4) perforation, gangrene, and abscess are absent.⁶⁰ Localized diverticulectomy, in general, should be reserved for grade I and grade II disease.⁶⁰ Sometimes, the ostium of the inflamed diverticulum is palpable if the cecum is mobilized surgically.⁶⁷ On-table cecoscopy thorough the appendiceal stump has also been helpful in establishing the diagnosis in the OR.⁶⁶ Grade III and IV cecal diverticulitis may be difficult to differentiate from carcinoma; resection is favored for these lesions.⁶⁷ An anastomosis may be created if contamination is limited, but generally, primary resection, ileostomy, and a mucous fistula are favored for treatment of grade IV disease.

Figure 16 Illustrated is a proposed classification of pathologic types of cecal diverticulitis. Grade I is a specific inflamed diverticulum; grade II is a cecal mass; grade III is characterized by a localized abscess or fistula; and grade IV represents a free perforation or a ruptured abscess with peritonitis.⁵⁹

DIVERTICULITIS IN YOUNG PATIENTS

Diverticulitis in patients younger than 40 years has been a focus of considerable attention in the literature, though this group only represents about 2% to 5% of the patients in large series.³¹ The incidence of diverticulitis in young patients may be increasing, and obese Latino men appear to be at particular risk.⁶⁸ This predominance in males reflects a tendency to underdiagnose acute diverticulitis in young women.⁶⁹ Some authors have asserted that diverticulitis is particularly virulent in young patients; however, current data tend not to support this concept, suggesting that patients with mild diverticulitis are misdiagnosed when hospitalized or are treated as outpatients. The high rate of early operation in young patients probably reflects misdiagnosis of diverticulitis as acute appendicitis rather than the development of particularly severe forms of diverticulitis.⁶⁸ Patients found to have uncomplicated acute diverticulitis may, if desired, undergo incidental appendectomy in conjunction with medical treatment of diverticulitis.

Unlike elderly patients, hospitalized young patients with diverticulitis tend to have few comorbidities other than obesity. Furthermore, young patients hospitalized for diverticulitis tend to have relatively advanced disease, perhaps as a consequence of delayed diagnosis,² whereas elderly patients hospitalized with an

admitted diagnosis of diverticulitis tend to exhibit a wider spectrum of disease severity. Young patients appear not to have a higher rate of recurrent diverticulitis than older patients do, and thus, aggressive resection is not necessary at the time of the first attack.^{42,68} However, a finding of advanced diverticulitis on CT scans is a predictor of subsequent disease complications in this population.^{70,71}

In general, diverticulitis should be approached in the same fashion in younger patients as in older patients.⁷¹ The pathophysiology of the disease is probably identical. As in the elderly, elective resection is recommended after recurrent attacks, not after a single attack; with follow-up, the majority of patients hospitalized with acute diverticulitis do not require operation.^{71,72}

DIVERTICULITIS IN IMMUNOCOMPROMISED PATIENTS

In view of their known predisposition to infection, immunocompromised patients (e.g., chronic alcoholics, transplant patients, and persons with metastatic tumors who are receiving chemotherapy) with diverticulitis are at particular risk. There is no evidence that the incidence of diverticulitis is higher in this population than in the general population, but it is clear that

Figure 17 CT scan shows inflammation in the pericecal area (arrow) and cecal edema, which could represent cecal diverticulitis. Because the appendix is not clearly visualized, appendicitis cannot be ruled out.

immunocompromised patients have higher rates of operation once diverticulitis develops and that their postoperative mortality is higher.^{73,74} Corticosteroid intake causes a number of significant problems, such as thinning of the colonic wall, lessening of the physical findings with diverticulitis, and an attenuated inflammatory response.

Any immunocompromised patient with abdominal pain should be evaluated aggressively. Contrast-enhanced CT is the imaging study of choice. The risk of perforation is increased in this setting, as is the risk of postoperative complications such as wound dehiscence. For an immunocompromised patient who has recovered from an episode of symptomatic diverticulitis, elective surgical treatment is recommended. A renal transplant patient with asymptomatic diverticulosis, however, need not undergo prophylactic colectomy. Pretransplantation colonic screening of patients older than 50 years does not reliably predict postransplantation colonic complications.⁷⁵

ATYPICAL PRESENTATIONS

Diverticulitis may give rise to various unusual manifestations involving multiple organ systems [see Table 1]. Not surprisingly, immunocompromised patients are at particular risk.

Retroperitoneal abscesses can track into anatomic planes (e.g., along the psoas muscle) or through the obturator foramen to areas such as the neck, the thigh,⁷⁶ the knee, the groin,⁷⁷ and the genitalia.^{78,79} CT scanning is essential to outline the extent of such abscesses. Contrast enemas show the diverticula along with a sinus tract into the abscess cavity. Cultures of the abscess demonstrate the presence of colonic organisms such as *Bacteroides fragilis*. Definitive treatment consists of wide abscess drainage and colon resection. Without aggressive surgical management, mortality is high.

The protean manifestations of diverticulitis also include pylephlebitis (which causes liver abscesses), arthritis, and skin changes. Diverticulitis has in fact replaced appendicitis as the most common source of liver abscesses of portal origin. Simple abscesses may be drained percutaneously if they are not too large, and multiple loculated abscesses may be managed with open drainage. The main risk factors for mortality from liver abscesses are immunosuppression, underlying malignancy, the presence of multiple organisms, and liver dysfunction. If the decision is made to perform a colectomy, the procedure may be done after drainage of the liver abscess or simultaneously with drainage during an open procedure.

GIANT DIVERTICULA

An anatomic curiosity sometimes encountered in patients with diverticular disease is a giant diverticulum, also termed a giant gas cyst or a pneumocyst of the colon.⁸⁰ These lesions, which may reach diameters of 40 cm, are believed to develop as a consequence of a ball-valve mechanism created by intermittent occlusion of the neck by fecal material that traps air in the diverticulum. Most giant diverticula are minimally symptomatic, causing only mild abdominal pain, and perforation is rare. A mobile mass may be palpable, and the gas-filled cyst can be seen on plain abdominal films. As many as two thirds of giant diverticula are opacified during a barium enema and can thereby be differentiated from other abnormalities (e.g., a mesenteric cyst, emphysematous cholecystitis, or a colon duplication). The cyst tends to adhere densely to adjacent structures (e.g., the bladder and the small bowel). The treatment of choice is resection of the colon and the cyst; performing diverticulectomy alone can lead to the development of a colcutaneous fistula.

RECURRENT DIVERTICULITIS AFTER RESECTION

Recurrent diverticulitis is rare after a colectomy for diverticulitis, occurring in 1% to 10% of patients.⁸¹ As many as 3% of patients who have undergone resection for diverticulitis will require repeat resection.³ The differential diagnosis includes Crohn disease, irritable bowel syndrome, carcinoma, and ischemic colitis. CT imaging and colonoscopy should be carried out. Particular care should be taken to review pathologic specimens for evidence of Crohn disease.

The only significant determinant of recurrent diverticulitis is the level of the anastomosis; the high pressure in the sigmoid colon distal to the anastomosis appears to be responsible. In one study, the risk of recurrence was four times greater in patients with a colosigmoid anastomosis than in those with a colorectal anastomosis.⁸² Reoperation requires a dissection that commences in noninflamed tissue. Dissection may be particularly difficult near the pelvic sidewall because of fibrosis; ureteral stenting may facilitate identification of the ureters.

Table 1 Unusual Extra-abdominal Presentations of Diverticulitis⁹⁰

Dermatologic	Pyoderma gangrenosum
Urinary	Ureteral obstruction Coloureteral fistula
Soft tissue	Thigh abscess Necrotizing fasciitis
Orthopedic	Osteomyelitis Arthritis
Gynecologic	Colouterine fistula Ovarian tumor/abscess
Genital	Epididymitis Pneumoserotum
Neurologic	Coloepidural fistula
Vascular	Femoral vein thrombosis Mesenteric vein thrombosis Pylephlebitis Colovenous fistula
Perineal	Fournier gangrene Complex anal fistula

SUBACUTE AND ATYPICAL DIVERTICULITIS

A small number of patients experience recurrent episodes of left lower quadrant abdominal pain that are not accompanied by the classic findings of acute diverticulitis (e.g., fever and leukocytosis). The inflammatory changes associated with diverticula in this subgroup have been referred to as atypical, subacute, or smoldering diverticulitis.^{83,84} In this setting, there is not always a direct association between endoscopic and clinical findings; endoscopic evidence of diverticular inflammation has been seen in asymptomatic patients.⁸⁵ It has been suggested that there is a

relation between diverticular disease and colitis.⁸⁶ Patients with chronic lower abdominal pain should undergo imaging studies and endoscopic evaluation, and other disorders (e.g., irritable bowel syndrome, inflammatory bowel disease, drug-induced symptoms, and bowel ischemia) should be excluded. In most cases of atypical diverticulitis, endoscopic findings are normal.⁸⁴ In carefully selected patients, colectomy often eliminates the abdominal pain, and many of these patients are eventually found to have histologic signs of acute and chronic mucosal inflammation.⁸⁴

13 FULMINANT ULCERATIVE COLITIS

Roger D. Hurst, M.D., F.A.C.S., F.R.C.S.Ed., and Fabrizio Michelassi, M.D., F.A.C.S.

Fulminant ulcerative colitis is a potentially life-threatening disorder that must be expertly managed if optimal outcomes are to be achieved. This condition was once associated with a very high mortality,¹ but medical and surgical treatments have improved dramatically, to the point where the mortality associated with fulminant ulcerative colitis is now lower than 3%.^{2,3} Optimal management depends on close coordination between medical and surgical therapy, and multidisciplinary strategies are essential.

Classification

The most commonly applied system of classifying the severity of ulcerative colitis has been the one devised by Truelove and Witts, who identified clinical parameters by which colitis could be categorized as mild, moderate, or severe.⁴ The Truelove-Witts classification does not, however, specify a unique category for fulminant disease. Accordingly, Hanauer modified this classification scheme to include a category for fulminant colitis [see Table 1].⁵ Unfortunately, there is no universally agreed upon distinction between severe ulcerative colitis and fulminant ulcerative colitis.⁶ Some authors use the terms severe and fulminant interchangeably, whereas others, concerned about the lack of a clear distinction between the two, recommend that the term fulminant ulcerative colitis be avoided altogether.⁷ This latter recommendation has not been widely followed: the term fulminant ulcerative colitis remains an established component of the medical vernacular, the absence of a clear definition notwithstanding.⁸⁻¹⁰

Fulminant ulcerative colitis is certainly a severe condition that is associated with systemic deterioration related to progressive ulcerative colitis. Most authorities would agree that a flare of ulcerative colitis can be considered fulminant if it is associated with one or more of the following: high fever, tachycardia, profound anemia necessitating blood transfusion, dehydration, low urine output, abdominal tenderness with distention, profound leukocytosis with a left shift, severe malaise, or prostration. Patients with these symptoms should

be hospitalized for aggressive resuscitation while clinical assessment and treatment are being initiated.¹¹

Clinical Evaluation

When a patient is admitted with severe or fulminant ulcerative colitis, a complete history and a thorough physical examination are required. The abdominal examination should focus on signs of peritoneal irritation that may suggest perforation or abscess formation. Any patient admitted with severe ulcerative colitis may have already received substantial doses of corticosteroids, which can mask the physical findings of peritonitis.

Investigative Studies

LABORATORY TESTS

Initial laboratory studies should include a complete blood count with differential, a coagulation profile, and a complete metabolic profile with assessment of nutritional parameters (e.g., serum albumin concentration). Multiple stool specimens should be sent to be tested for *Clostridium difficile*, cytomegalovirus, and *Escherichia coli* 0157:H7.^{12,13} It is important to rule out the presence of opportunistic infections, particularly with *C. difficile*, even in patients with an established diagnosis of ulcerative colitis; superinfection with *C. difficile* is common in such patients.

IMAGING

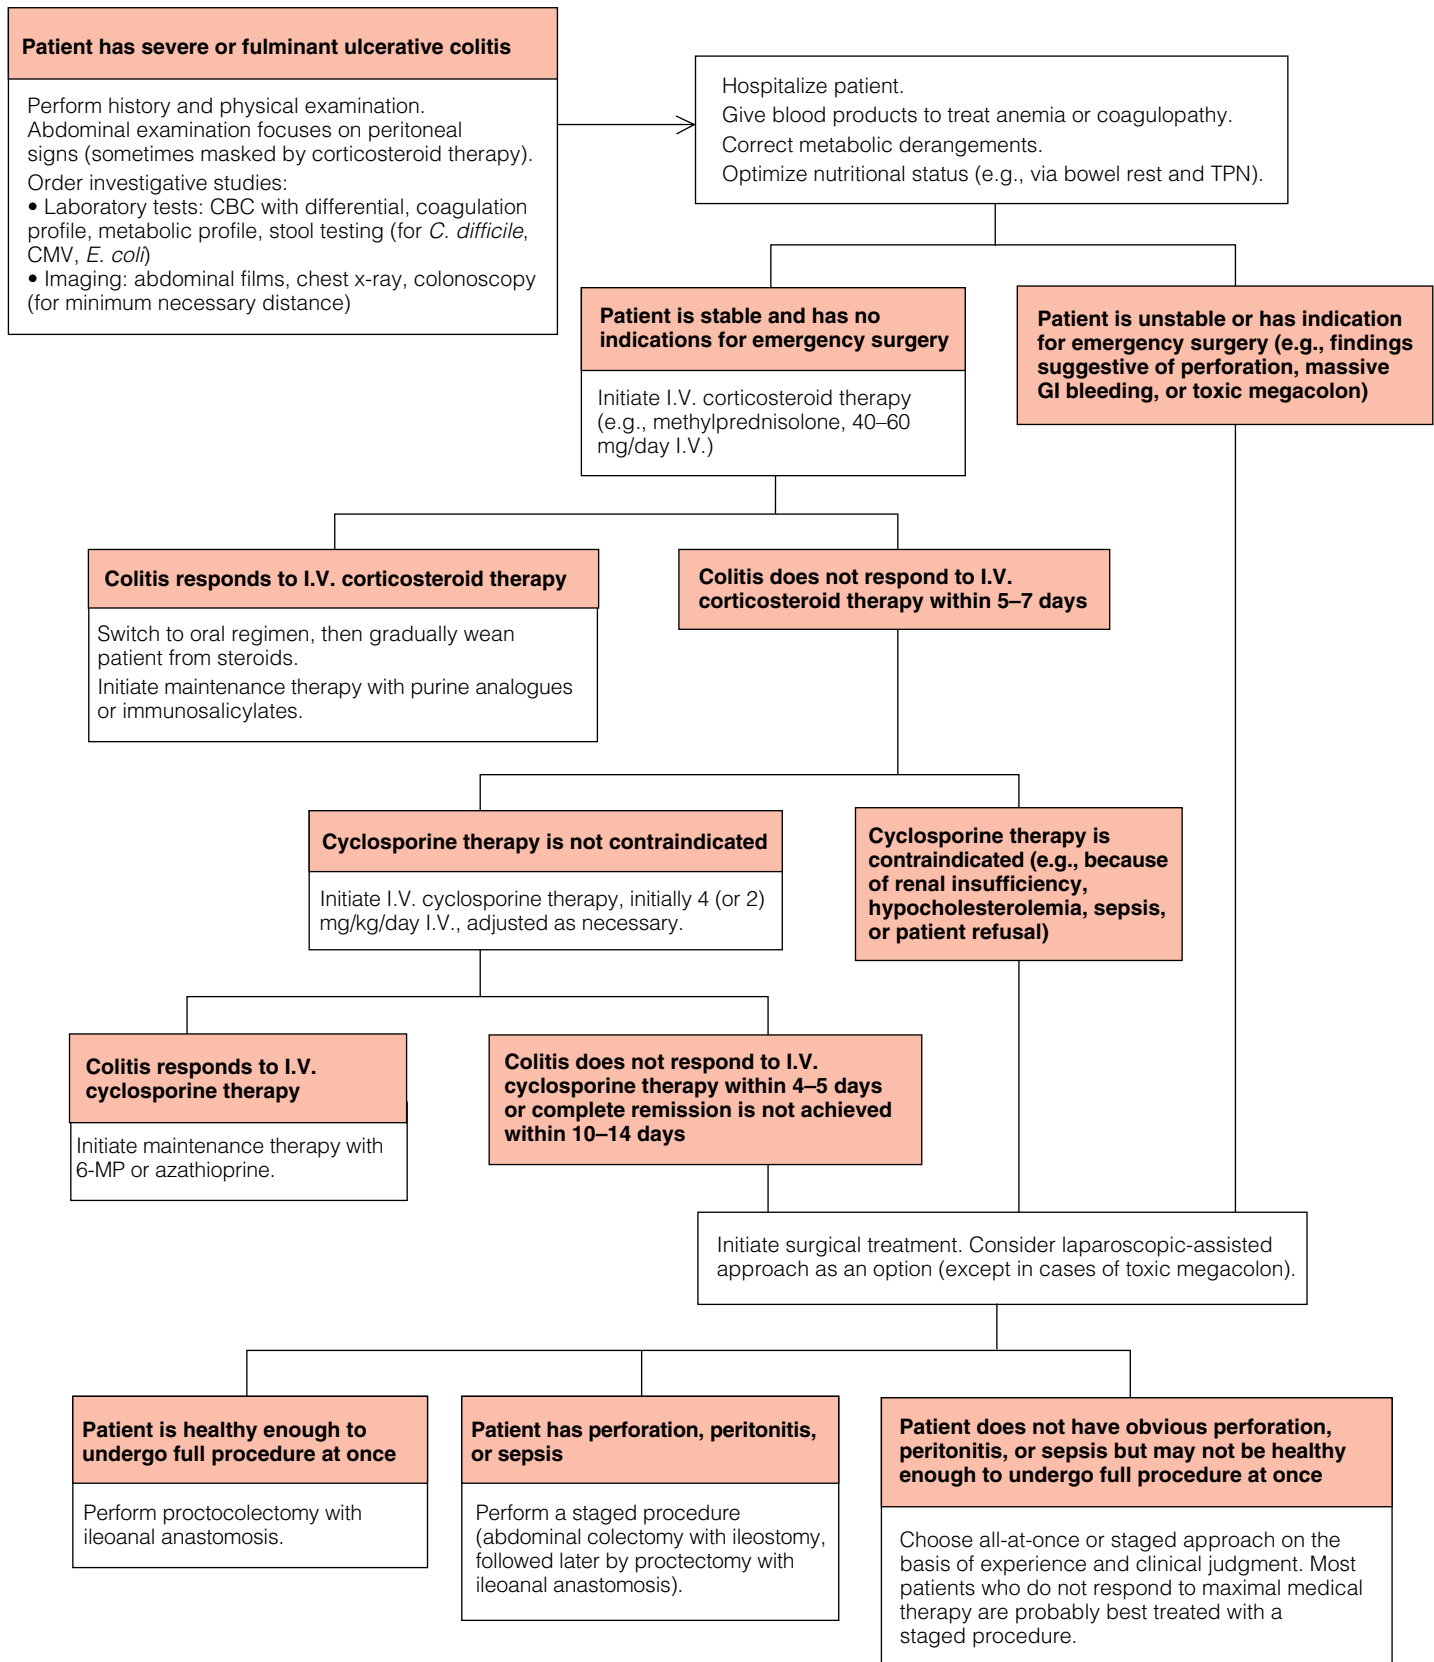

Abdominal films and an upright chest x-ray should be obtained to look for colonic distention (indicative of toxic megacolon) and free intraperitoneal air (indicative of perforation).

Endoscopic evaluation of the colon and rectum in the presence

Table 1 Criteria for Evaluating Severity of Ulcerative Colitis

Variable	Mild Disease	Severe Disease	Fulminant Disease
Stools	< 4/day	> 6/day	> 10/day
Blood in stool	Intermittent	Frequent	Continuous
Temperature	Normal	> 37.5° C	> 37.5° C
Pulse	Normal	> 90 beats/min	> 90 beats/min
Hemoglobin	Normal	< 75% of normal	Transfusion required
Erythrocyte sedimentation rate	≤ 30 mm/hr	> 30 mm/hr	> 30 mm/hr
Colonic features on radiography	—	Air, edematous wall, thumbprinting	Dilatation
Clinical signs	—	Abdominal tenderness	Abdominal distention and tenderness

Management of Fulminant Ulcerative Colitis

of fulminant ulcerative colitis is a controversial measure.¹⁴⁻¹⁶ Undoubtedly, colonoscopy with biopsy can provide useful diagnostic information in this setting, and numerous reports indicate that in experienced hands, colonoscopy poses little risk to patients with severe colitis.^{14,15} In general, however, it is recommended that endoscopic examination proceed no further than the minimum distance necessary to confirm severe colitis. If an endoscopic examination is to be performed, insufflation of air must be minimized; overdistention of the colon may lead to perforation or the development of megacolon. In addition to diagnostic information, endoscopy can provide useful prognostic information. In one study, the presence of deep, extensive colonic ulcerations indicated a low probability for successful medical treatment of fulminant ulcerative colitis: fewer than 10% of patients with such ulcerations responded to medical measures.¹⁴ Thus, an endoscopic finding of deep ulcers [see *Figure 1*] may facilitate the decision to proceed with early operative treatment if medical therapy does not lead to rapid and significant improvement.

Management

GENERAL CARE

All patients with fulminant ulcerative colitis should be hospitalized. Blood products should be administered to treat significant anemia or coagulopathy. Metabolic derangements should be corrected.¹⁷ Patients with a perforation or massive lower GI hemorrhage are taken to the operating room for emergency surgical treatment; more stable patients are initially managed with medical therapy. Narcotics, antidiarrheal agents, and other anticholinergic medications should be avoided because they can precipitate toxic dilation of the colon.

Bowel rest typically reduces the volume of diarrhea, but whether it affects the clinical course of the fulminant colitis remains to be established.^{18,19} One study of patients with acute

Figure 1 Sigmoidoscopy demonstrates deep ulcerations in a patient with fulminant ulcerative colitis.

flares of ulcerative colitis reported no significant difference in outcome between those who were managed with total parenteral nutrition (TPN) and bowel rest and those who received enteral nutrition. This study, however, included patients with colitis of varying degrees of severity, and apparently, only a small number of them had fulminant ulcerative colitis.¹⁹ A subsequent study found that bowel rest and TPN did have a potential clinical advantage in patients with fulminant ulcerative colitis.¹⁸ The most common approach to nutritional management of these patients is first to place them on bowel rest with hyperalimentation, then to initiate oral feeding once the symptoms of the fulminant attack begin to be alleviated. Whether patients are being maintained on bowel rest or are receiving oral feedings, adequate nutritional support must always be ensured. Hence, TPN, if employed, should be maintained until the patient is receiving and tolerating full enteral feedings.

MEDICAL THERAPY

The standard medical approach to fulminant ulcerative colitis involves induction of remission by means of I.V. corticosteroid therapy, followed by long-term maintenance treatment (in the form of purine analogues) once remission has been achieved. If treatment with steroids fails to induce remission, I.V. cyclosporine therapy is considered.

Steroids

For decades, steroid treatment has been the frontline therapy for acute flares of ulcerative colitis. Response rates in cases of fulminant ulcerative colitis range from 50% to 60% when the steroids are given over a period of 5 to 10 days.^{20,21} Methylprednisolone, 40 to 60 mg/day in a continuous I.V. infusion, is a common regimen.^{5,22-24}

The length of time that should be allowed for patients to respond to I.V. steroid therapy has been a subject of debate. In 1974, Truelove and Jewell recommended urgent operative treatment after 5 days if there is no response to I.V. steroid therapy.²⁵ This 5-day rule has been widely adopted, but more recent experience suggests that steroids can be safely administered for as long as 7 to 10 days to allow patients more time to respond.¹² Patients who respond to I.V. steroid therapy are switched to an oral steroid regimen (typically prednisone). It is important, however, to stress that corticosteroids should never be employed as long-term maintenance therapy.^{5,26} The toxic effects of corticosteroids are related to not only the dosage but also the duration of treatment. Severe complications are common with extended use of even modest doses of steroids. Accordingly, patients should be slowly but completely weaned from steroid therapy. Because symptomatic colitis recurs in 40% to 50% of patients who initially respond to I.V. therapy, maintenance therapy with either purine analogues or immunosalicylates should be instituted.^{5,20}

Unfortunately, corticosteroid dependency is frequently encountered in patients with ulcerative colitis. Often, the steroid dosage cannot be tapered without an increase in disease activity and exacerbation of symptoms. In such cases, if the patient cannot be weaned from steroids and switched to purine analogues within 3 to 6 months, surgical consultation is indicated. In addition, if complications related to ulcerative colitis or to corticosteroid therapy develop, the colitis must be treated surgically.

Cyclosporine

At one time, patients who did not respond to I.V. steroid treatment were invariably referred for surgical treatment. Currently, such patients are most often treated with I.V. cyclosporine therapy. Cyclosporine is an immunosuppressant macrolide that suppresses the production of interleukin-2 by activated T cells through a calcineurin-dependent pathway.²⁷ Originally employed to prevent tissue rejection after transplantation, cyclosporine has become the standard treatment of steroid-refractory severe ulcerative colitis.

The first report of the use of cyclosporine to treat ulcerative colitis was published in 1984.²⁸ It was not until 10 years later, however, that a randomized, placebo-controlled trial of cyclosporine therapy for steroid-refractory ulcerative colitis convincingly demonstrated the effectiveness of cyclosporine in this setting.²⁹ In this trial, patients with steroid-refractory ulcerative colitis who received cyclosporine (4 mg/kg) had an 82% response rate, compared with a 0% response rate in those treated with continued I.V. steroid therapy alone. Since this initial report, response rates ranging from 56% to 91% have been reported in the medical literature, confirming cyclosporine as a major advance in the treatment of severe and fulminant ulcerative colitis.³⁰⁻³²

The beneficial effects of cyclosporine therapy are not always durable: as many as 60% of patients experience recurrence of disease after initial cyclosporine-induced remission.³³ Fortunately, recurrence rates can be substantially lowered by means of maintenance therapy with 6-mercaptopurine (6-MP) or azathioprine. With appropriate maintenance therapy, the rate of early recurrence of symptoms after successful I.V. cyclosporine treatment may be reduced to levels as low as 22%.^{31,34} Even if the disease does recur, the initial success of cyclosporine therapy in aborting the acute phase of the ulcerative colitis allows patients to recover from the acute illness, so that they are in better condition to undergo elective surgical treatment at a later date if such treatment ultimately proves necessary. This is a major benefit, in that operative management of ulcerative colitis carries a much higher risk of complications when carried out on an urgent basis than when carried out in an elective setting.^{18,35,36}

The major side effects of cyclosporine treatment are renal insufficiency, opportunistic infections, and seizures. The risk of seizures appears to be highest in patients with hypocholesterolemia. Consequently, cyclosporine should not be given to patients with significant hypocholesterolemia (serum cholesterol concentration < 100 mg/dl). Hypomagnesemia is commonly seen in patients with fulminant ulcerative colitis who undergo cyclosporine treatment; accordingly, serum magnesium levels should be closely followed.

Dosing regimens for cyclosporine vary. The typical starting dosage is 4 mg/kg/day I.V., which is then adjusted to achieve a whole-blood level between 150 and 400 ng/ml, as measured by high-power liquid chromatography or radioimmunoassay.^{37,38} Whole-blood levels as high as 800 ng/ml are considered acceptable by some investigators.²⁹ If the patient shows no improvement within 4 to 5 days or if complete remission is not achieved by 10 to 14 days, surgical treatment is advised.¹² Most of the side effects of cyclosporine therapy are dose dependent. Several studies have shown that an initial dosage of 2 mg/kg/day I.V. can also be effective in achieving remission.³⁹⁻⁴¹ Some physicians prefer to begin at this lower dosage and then increase it as necessary on the basis of the measured cyclosporine levels.

Concerns have been raised about the possibility that prolonging medical therapy in patients with severe colitis who have already

Table 2 Indications for Operation in Patients with Fulminant Ulcerative Colitis

- Inability to tolerate medical treatment
- Failure to respond to medical treatment
- Inability to be weaned from corticosteroids
- Presence of complications of ulcerative colitis (e.g., perforation, peritonitis, progressive signs of sepsis, hemorrhage, and toxic megacolon)
- Development of complications related to medical treatment

received large amounts of corticosteroids may increase the risk of perioperative morbidity and mortality in those who respond to neither steroids nor cyclosporine therapy and thus require operative management. At present, however, there is no evidence that patients who do not respond to cyclosporine therapy are at increased risk for perioperative complications; such therapy does not appear to compromise surgical results.⁴²

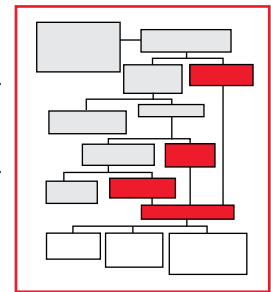

SURGICAL THERAPY

Indications

Indications for surgical treatment of fulminant ulcerative colitis have been established [see Table 2]. One such indication, of course, is the exhaustion of options for appropriate medical treatment. Because most patients with fulminant ulcerative colitis respond to aggressive medical therapy, such treatment is warranted in almost all cases. Care must be exercised, however, not to overtreat patients with fulminant ulcerative colitis who are otherwise stable. The immunosuppressive effects of high-dose corticosteroids and I.V. cyclosporine, along with the debilitation induced by prolonged severe disease, can place patients at high risk for perioperative complications. Patients who do not show significant improvement in response to I.V. steroid therapy within 5 to 7 days should be started on I.V. cyclosporine therapy or referred for operative treatment.¹² Those who do not respond to cyclosporine therapy within 4 days or in whom remission of major symptoms is not achieved within 2 weeks should be treated surgically. Patients whose symptoms progress during the course of I.V. therapy or who show no sign of improvement at all should be considered for early surgery. Patients known to have deep longitudinal ulcerations are less likely to respond to I.V. medical therapy and thus may also be referred for early surgery. The decision regarding when to abandon medical therapy for fulminant ulcerative colitis in favor of surgical therapy is difficult and requires considerable experience and special expertise. Accordingly, patients with fulminant ulcerative colitis are best managed in a center specializing in inflammatory bowel disease.

Patients with perforation or severe GI bleeding require urgent surgical treatment.⁴³ The debilitation resulting from the disease, coupled with the immunosuppression resulting from intensive medical therapy, can mask the signs and symptoms of sepsis and peritonitis associated with perforation. Perioperative mortality in cases of fulminant colitis is as much as 10 times higher when perforation occurs than when it does not.⁴⁴ For this reason, patients with high fever, marked leukocytosis, and persistent tachycardia should be referred for early surgery, regardless of whether other indications of perforation or peritonitis are noted.

Toxic megacolon, though an uncommon complication of severe ulcerative colitis, is important in that it is associated with impend-

ing colonic perforation and therefore must be watched for and aggressively managed if present. Two specific conditions must be satisfied to establish the diagnosis of toxic megacolon.⁴⁵ First, there must be colonic dilatation; second, the patient must be in a toxic state. Patients with mild symptoms of ulcerative colitis may experience a degree of colonic dilatation, perhaps in conjunction with colonic ileus. This condition is distinctly different from and considerably less worrisome than toxic megacolon. Patients admitted to the hospital with fulminant ulcerative colitis will, by definition, exhibit some degree of toxicity. Colonic dilatation in these patients is a very worrisome phenomenon, in that it completes the picture of toxic megacolon. Accordingly, in all patients with fulminant ulcerative colitis, an abdominal x-ray should be obtained to look for colonic dilatation. Those in whom abdominal distention develops or who experience a sudden decrease in the number of bowel movements without signs of significant clinical improvement should also be assessed for colonic dilatation and toxic megacolon.

In patients with toxic megacolon who are otherwise stable, conservative management, consisting of elimination of narcotics and anticholinergic agents, may be briefly tried. Changes in patient position may be tried as well: moving the patient from side to side, from supine to prone, and into the knee-elbow prone position is thought to facilitate expulsion of colonic gas.⁴⁶ Patients with toxic megacolon should be kept on a nihil per os (NPO) regimen, and broad-spectrum I.V. antibiotics should be given. Endoscopic decompression is to be avoided. Blind placement of rectal tubes is ineffective and may be harmful. Patients who do not rapidly respond to conservative management and those who show signs of peritonitis or are otherwise unstable require urgent surgical treatment.⁴⁷

Preparation for Operation

With patients who are stable but are not responding to medical therapy, there may be time for preoperative preparation. Patients who are not on NPO status should be maintained on clear liquids, then kept on an NPO regimen for 6 to 8 hours before operation. On occasion, a patient may be able to tolerate mild bowel preparation with either polyethylene glycol or Fleet Phospho-soda (Fleet Pharmaceuticals, Lynchburg, Virginia). Any bowel preparations that are used need be employed only until bowel movements are free of residue. If time allows, the patient should be counseled by an experienced enterostomal therapist, and an optimal site for the ostomy should be marked on the abdomen. Prophylactic antibiotics should be given before the the surgical incision is made, and appropriate stress-dose steroids should be administered.

Surgical Strategies

The operative strategies for treating fulminant ulcerative colitis are controversial. Ultimately, almost all patients end up undergoing a restorative proctocolectomy with ileoanal anastomosis [see 5:33 *Procedures for Ulcerative Colitis*]. In most cases, however, the final surgical goal is achieved in multiple steps. Performing an extensive resection in conjunction with a prolonged and delicate reconstruction in an acutely ill patient is a procedure of questionable safety. Accordingly, many surgeons elect first to perform a total abdominal colectomy with an ileostomy, leaving the rectal stump as either a Hartmann pouch or a mucous fistula,^{43,44} then to perform a restorative proctectomy with ileoanal anastomosis at a later date. This staged approach allows the patient to recover from the acute illness, to be

weaned from immunosuppressive agents, and to achieve improved nutritional status. Although the remaining rectal stump continues to be affected by ulcerative colitis, the fecal diversion greatly diminishes disease activity, so that almost all patients can be completely weaned from steroids and other immunosuppressive medications. It is then possible to perform the proctectomy with ileoanal anastomosis in more controlled conditions.

The exact circumstances in which it is best to follow a staged approach have not been clearly defined. It is universally accepted that a staged procedure is mandatory in patients with perforation, peritonitis, or sepsis, but beyond this point, there is no clear consensus. The studies published to date have been inconclusive on this issue: either they included only a small number of patients, they did not clearly define what constituted fulminant colitis, or they did not directly compare the results of the two alternative strategies (i.e., staged colectomy and immediate ileoanal anastomosis). A 1995 study reported excellent long-term results and acceptable short-term morbidity in 12 patients undergoing immediate restorative proctocolectomy with ileal pouch–anal anastomosis (IPAA) for fulminant colitis.⁴⁸ These 12 patients, however, represented an extraordinarily small percentage of the total number of ileoanal procedures performed by the authors. In addition, this study used a somewhat liberal definition of fulminant colitis and thus might have included a number of cases that would not have qualified as fulminant colitis—or, possibly, even as severe colitis—according to the criteria cited earlier [see Table 1]. Finally, the study provided no data on the experience of patients undergoing a staged procedure for the management of severe or fulminant colitis.

A 1994 study also reported excellent long-term results and exceptionally low perioperative morbidity in 20 patients undergoing restorative proctocolectomy with IPAA for urgent treatment of ulcerative colitis.⁴⁹ Another study from the same year, however, reported a 41% anastomotic leakage rate in 12 patients also undergoing an urgent ileoanal procedure for ulcerative colitis, compared with an 11% leakage rate in patients undergoing ileoanal anastomosis under more controlled conditions.⁵⁰ On the basis of these results, the authors counseled against ileoanal anastomosis in the urgent setting. A later study also noted a higher incidence of anastomotic leakage (36%) in patients undergoing urgent ileoanal anastomosis.⁵¹ These authors likewise advised against ileoanal anastomosis in the urgent setting.

The fact of the matter is that the distinction between severe and fulminant ulcerative colitis may be little more than an academic exercise. At one end of the disease spectrum, there is a small subset of patients who have symptoms severe enough to necessitate hospitalization yet are healthy enough to undergo a primary ileoanal anastomosis without undue risk. At the other end of the spectrum, there is a subset of severely ill patients with fulminant colitis for whom a staged procedure is mandatory. The middle of the spectrum remains something of a gray area. Because specific criteria for quantifying the risk have not been defined, the decision whether to follow a staged operative approach ultimately is made on the basis of the experienced surgeon's clinical judgment. It has been our experience, however, that the majority of patients who fit the criteria of fulminant colitis [see Table 1] and who do not respond to maximal medical therapy are best managed with a staged approach.

Technical Considerations

Surgical exploration is performed via either a midline or a transverse incision. The abdomen is carefully examined, with particular attention paid to the small intestine in an effort to detect any signs of Crohn disease. The colon often shows the changes typical of colitis: serosal hyperemia, corkscrew vessels, and edema [see Figure 2].

Figure 2 In a colon affected by fulminant ulcerative colitis, changes on the serosal aspect are typically subtle. Serosal hyperemia with small corkscrew vessels is present.

Figure 3 Shown is a Hartmann pouch constructed at the level of the sacral promontory. TA staple line is reinforced with interrupted silk Lembert sutures.

Figure 4 Surgical specimen from a patient with fulminant ulcerative colitis shows severe ulceration and inflammation.

Figure 5 Shown is mobilization of splenic flexure during laparoscopic colectomy for fulminant ulcerative colitis.

Colectomy may be performed in the standard fashion, with mesenteric division occurring at a convenient distance from the bowel; wide mesenteric resection is not necessary. If a staged colectomy is to be performed, the colon is removed, and the rectum is left either as a Hartmann pouch or as a mucous fistula. In most cases, a Hartmann pouch can safely be created. In the construction of a Hartmann pouch, it is important that the stump be of the appropriate length. If the stump is too short, the proctectomy to be performed in the second stage may prove very difficult; if it is too long, there is an increased risk of complications related to persistent disease in the rectum (e.g., bleeding, discharge, and tenesmus). Ideally, the Hartmann pouch should be made at the level of the sacral promontory [see *Figure 3*]. During the colectomy, the sigmoid branches of the inferior mesenteric artery should be divided and the terminal branches of the inferior mesenteric artery preserved. This measure ensures a good blood supply to the remaining rectal stump and helps the Hartmann closure to heal. Preservation of the terminal branches of the inferior mesenteric artery and the superior rectal artery also simplifies the subsequent proctectomy by keeping the pelvic sympathetic nerves free of surrounding scar tissue and by providing a key anatomic landmark

that will assist the surgeon in locating the appropriate presacral dissection plane for any future planned proctectomy.

To create the Hartmann pouch, the mesenteric and pericolic fat are removed from the bowel wall for a distance of approximately 2 cm. A transverse anastomosis (TA) stapler loaded with 4.8 mm staples is placed on the prepared bowel and fired to close the pouch. The bowel is then divided proximal to the staple line. The staple line should be closely examined to confirm that the staples are closed properly into two rows of well-formed Bs and that individual staples are not cutting into the muscularis propria of the bowel. To provide additional protection against dehiscence, the staple line may be oversewn with interrupted Lembert sutures [see *Figure 3*]. If sutures are employed, they should be carefully placed so that the anterior and posterior serosal surfaces are approximated without undue tension. With a well-constructed Hartmann pouch, pelvic drains are unnecessary and may even be harmful, in that they can promote dehiscence if situated close to the suture line.

In some cases, the colon at the level of the sacral promontory is affected by deep ulcerations and severe inflammation, to the point where closure of the Hartmann pouch at this level poses an unac-

ceptably high risk of dehiscence [see *Figure 4*]. If the severity of disease precludes safe closure of the Hartmann pouch, creation of a mucous fistula should be considered. A mucous fistula requires a longer segment of bowel than a Hartmann pouch does and thus is associated with a higher risk of bleeding from the retained segment. In addition, a mucous fistula is unsightly and often generates a very foul odor. As a compromise approach, some surgeons advocate creating a Hartmann pouch of moderate length and placing the proximal end of the stump through the fascia at the lower edge of the midline incision; the end of the stump is then left buried in the subcutaneous tissue. The benefit of this approach is that if dehiscence of the staple line occurs, any ensuing infection is limited to the subcutaneous space and does not result in an intra-abdominal or pelvic abscess.

If attempts to fashion a secure Hartmann closure fail and the remaining rectal stump is too short to be brought out as a mucous fistula, the proximal rectum should be resected, and closure of the Hartmann pouch should be performed just below the peritoneal reflection. In this situation, closed suction drains should be placed deep in the pelvis, and the peritoneum should be closed over the rectal stump. Such a short Hartmann pouch, however, will be more difficult to locate during the subsequent restorative proctectomy and ileoanal anastomosis.

With a staged colectomy, an end ileostomy is created in the standard fashion [see *5:30 Intestinal Stomas*], and the abdomen is closed. Placing a rectal tube to drain rectal secretions may be

beneficial in reducing the risk of dehiscence of the Hartmann pouch.

Laparoscopic Approaches

Experience has demonstrated that laparoscopic-assisted approaches to abdominal colectomy can be safely employed in patients with ulcerative colitis.⁵² Mobilization of the colon and division of the mesentery can be accomplished laparoscopically [see *Figure 5*], with the specimen being removed through a small Pfannenstiel incision. An end ileostomy can also be fashioned with the aid of inspection through the Pfannenstiel incision. Alternatively, the Pfannenstiel incision can be made early in the procedure and used for placement of a hand port, and the colon can be removed by means of a hand-assisted laparoscopic approach.

Whether a laparoscopic-assisted approach to the management of fulminate ulcerative colitis possesses any significant clinical advantages remains to be determined. However, a growing body of experience with this approach indicates that in experienced hands, laparoscopic-assisted colectomy is a safe and reasonable alternative that may well result in shorter hospital stays and decreased postoperative pain. The laparoscopic-assisted approach may therefore be considered as an option for patients with fulminant ulcerative colitis. Patients with toxic megacolon, however, should be managed by means of an open surgical approach; the instruments used to grasp the bowel in a laparoscopic-assisted colectomy are likely to cause perforation of the severely thinned walls of the dilated megacolon.

14 HEREDITARY COLORECTAL CANCER AND POLYPOSIS SYNDROMES

José G. Guillem, M.D., M.P.H., F.A.C.S., and Harvey G. Moore, M.D.

The majority of cases of inherited colorectal cancer (CRC) are accounted for by two syndromes: hereditary nonpolyposis colorectal cancer (HNPCC) and familial adenomatous polyposis (FAP). In both, the predisposition to disease is a germline mutation transmitted in an autosomal dominant fashion. Although the two syndromes are similar in some respects, differences in their phenotypic expression and in the certainty of disease development mandate distinctly different surgical approaches, including the timing and extent of prophylactic procedures in carefully selected patients. In the management of FAP, the role of prophylactic surgery is clearly defined, though the optimal procedure for an individual patient depends on a number of factors. In the management of HNPCC, the indications for prophylactic procedures are emerging, particularly for unaffected mutation-positive patients.

Two less common polyposis syndromes, Peutz-Jeghers syndrome (PJS) and juvenile polyposis syndrome (JPS), are also inherited in an autosomal dominant fashion and are associated with a significant risk of CRC. Carefully selected persons affected by these syndromes may also benefit from prophylactic surgical procedures. Current evidence supports a role for prophylactic colectomy in JPS but not in PJS.

Finally, there are a few other, less common, inherited hamartomatous polyposis syndromes, such as Cowden disease and Ruvalcaba-Myhre-Smith syndrome. At present, these syndromes appear to be associated with an exceedingly low risk of CRC; accordingly, prophylactic surgery is not indicated.¹

Familial Adenomatous Polyposis

FAP is caused by mutations in the tumor suppressor gene *APC*, located at 5q21. Nearly 80% of FAP patients belong to known FAP kindreds; 10% to 30% have new mutations.¹ More than 300 distinct mutations have been identified within the *APC* gene locus in persons manifesting the FAP phenotype. More than half of the known germline mutations associated with the classic FAP phenotype are concentrated in the 5' region of exon 15.¹ Genotype-phenotype correlative studies have revealed a wide range of phenotypic heterogeneity, ranging from the relatively mild presentation associated with attenuated FAP, which is caused by mutations in the 3' and 5' ends of the *APC* gene,² to the severe presentation associated with mutations downstream from codon 1250, particularly those in codon 1309. It has been reported that as many as 7.5% of patients with a classic FAP phenotype and no demonstrable *APC* mutation may have biallelic germline mutations in the base excision repair gene *MYH*.³

CLINICAL EVALUATION

FAP, which accounts for less than 1% of the annual CRC burden, is characterized by the presence of more than 100 adenomatous polyps of the colorectum, virtually 100% penetrance, and a nearly 100% risk of CRC by the age of 40 if prophylactic colectomy is not performed.^{1,4} Extracolonic manifestations are common and include desmoid tumors, osteomas,

odontomas, sebaceous and epidermoid cysts, congenital hypertrophy of the retinal pigment epithelium, and periampullary neoplasms.¹

INVESTIGATIVE STUDIES

Pathologic Findings

The polyps, which develop by the age of 20 years in 75% of cases, are typically less than 1 cm in size. In severe FAP, they may carpet the entire surface of the colorectal epithelium or, alternatively, may spare portions of the epithelial lining (e.g., the rectum). Adenomas may be either pedunculated or sessile and may have tubular, villous, or tubulovillous histology. Microscopic evaluation may reveal innumerable microadenomas within grossly normal-appearing colorectal mucosa. Foci of carcinoma in situ and invasive carcinoma may be found within larger polyps, and the incidence of invasive cancer is proportional to the extent of polyposis. Unlike CRC in the setting of HNPCC, CRC in the setting of FAP is more commonly located on the left side.¹

Screening and Surveillance

Screening (genetic testing or annual or biennial flexible sigmoidoscopy) for at-risk family members should begin around puberty (i.e., at 10 to 12 years of age) [see Table 1]. In families with a demonstrated *APC* mutation, informative genetic testing can be carried out with the protein truncation test [see Table 2]. This test, which detects foreshortened proteins resulting from truncating *APC* mutations, is approximately 80% sensitive⁵; however, the test results are commonly misinterpreted, even by physicians.⁶ Patients with normal protein truncation test results and a previously identified mutation in the family may be discharged from further screening with a nearly 100% certainty that the mutation is absent, but they should still undergo CRC screening starting at the age of 50 years, as is recommended for average-risk persons. When an *APC* mutation has not previously been identified in the family of an affected person, the patient should be tested first to identify the causative mutation. In families in which the protein truncation test fails to provide conclusive information on carrier status, at-risk individuals should continue with the recommended endoscopic surveillance program. Other options for detecting *APC* mutations include linkage analysis, single-stranded confirmation polymorphism, and direct sequence analysis.¹

Genetic counseling is an essential component of the evaluation of patients for FAP. Patients who have a positive genotype or who have adenomatous polyps on sigmoidoscopy should undergo full colonoscopy to establish the extent of polyposis.

MANAGEMENT

Medical Therapy

A number of nonsteroidal anti-inflammatory drugs, including sulindac, celecoxib, and the sulindac metabolite exisulind, have been shown to reduce the number and size of polyps in FAP

Table 1 Genetic Basis, Clinicopathologic Features, Diagnosis, Surveillance, and Surgical Management of Hereditary CRC and Polyposis Syndromes

Syndrome	Genetic Basis	Diagnosis	GI Manifestations	Extracolonic Manifestations	Pathologic Features	CRC Screening and Surveillance	Surgical Management
FAP	<i>APC</i> , 5q21 (> 90%); <i>MYH</i> (8%)	≥ 100 adenomatous polyps of colorectum or <i>APC</i> mutation demonstrated	Adenomatous polyps of colon and rectum 100% risk of colorectal cancer by age 40 without colectomy	Desmoids Osteomas Odontomas Sebaceous and epidermoid cysts CHRPE Periapillary neoplasms	Tubular, villous, or tubulovillous histology	Consider genetic counseling/testing Carry out early surveillance with sigmoidoscopy (at age 10–12 yr) ^{98,99} For at-risk untested individuals, perform FS every 1–2 yr	If polyposis is confirmed, colectomy is indicated Options include the following: TPC with ileostomy TAC with IRA TPC with IPAA
HNPCC	MMR genes: <i>MLH1</i> and <i>MSH2</i> (90%), <i>MSH6</i> (10%), <i>PMS1</i> , <i>PMS2</i> , <i>MLH3</i> , <i>MSH3</i>	MMR mutation demonstrated or Family meets Amsterdam I or II criteria ^{50,51}	Possibly few or no colorectal polyps Right-side tumor (60%–70%) MSI-high tumor (80%–90%) Synchronous/metachronous tumors 80% lifetime risk of CRC	Associated tumors of endometrium, small bowel, ureter, or renal pelvis	Adenocarcinoma, frequently mucinous or signet-ring cell histology Solid or cribriform growth pattern Tumor-infiltrating or peritumoral lymphocytes	Consider genetic counseling/testing If patient is mutation positive or is untested but meets criteria, perform colonoscopy at 20–25 yr (or 10 yr earlier than youngest affected individual), then every 1–2 yr, then annually after age 40 ^{98,99}	<i>Affected patient with identified mutation or meeting Amsterdam criteria:</i> Colon cancer or advanced adenoma: perform TAC with IRA or segmental colectomy with annual colonoscopy Rectal cancer: perform TPC with IPAA or LAR and annual colonoscopy <i>Unaffected patient with identified mutation or meeting Amsterdam criteria:</i> Consider TAC with IRA or colonoscopy every 1–3 yr
PJS	<i>LKB1/STK11</i> , 19p13.3 (18%–63%)	Hamartomas of GI tract and At least two of the following: Small bowel disease Mucocutaneous melanin Family history of PJS	Hamartomatous polyps throughout entire GI tract (small intestine, 90%; colon, 50%) Relative risk of CRC = 84	Mucocutaneous pigmentation (perioral and buccal areas, 95%)	Hyperplasia of smooth muscle of muscularis mucosa Arborization Pseudoinvasion	Consider genetic counseling/testing Perform colonoscopy starting between puberty and age 25, then every 2–3 yr ⁸⁸	Perform operative or laparoscopy-assisted polypectomy or segmental colectomy for polyps > 1.5 cm that are not amenable to endoscopic resection Perform segmental bowel resection for invasive cancers In the setting of laparotomy, perform intraoperative endoscopy (peroral or via enterotomy) <i>Prophylactic colectomy has no role⁸⁸</i>
JPS	<i>SMAD4/DPC4</i> , 18q21.1 (50%); <i>BMPR1A</i> , 10q22.3	≥ 3 juvenile polyps of colon and juvenile polyps throughout GI tract or Any number of polyps with family history of JPS	Multiple hamartomatous polyps throughout gastroduodenum 15% risk of CRC by age 35, 68% risk by age 65	Tumors of stomach, pancreas, duodenum	50–200 polyps Cystic, mucus-filled spaces with epithelial lining Attenuated smooth muscle layer Focal epithelial hyperplasia and dysplasia	Consider genetic counseling/testing Perform colonoscopy in middle to late teenage years, with EGD and SBS; if results are negative, repeat in 3 yr, then every 3 yr if results remain negative; if results are positive, perform biopsy of polyps and intestinal mucosa	<i>Disease is local, and no significant symptoms are present:</i> Manage endoscopically, with colonoscopic surveillance every 1–3 yr <i>Disease is diffuse or significant symptoms are present:</i> Perform TAC with IRA, and carry out rectal surveillance every 1–3 yr

CHRPE—congenital hypertrophy of retinal pigment epithelium CRC—colorectal cancer EGD—esophagogastroduodenoscopy FAP—familial adenomatous polyposis FS—flexible sigmoidoscopy HNPCC—hereditary nonpolyposis colorectal cancer IPAA—ileal pouch–anal anastomosis IRA—ileorectal anastomosis JPS—juvenile polyposis syndrome LAR—low anterior resection MMR—mismatch repair MSI—microsatellite instability PJS—Peutz-Jeghers syndrome SBS—small bowel series TAC—total abdominal colectomy TPC—total proctocolectomy

patients.⁷⁻¹⁰ However, long-term use of chemopreventive agents for primary treatment of FAP is not recommended.¹¹ In a randomized, placebo-controlled, double-blind study of genotype-positive, phenotype-negative patients, the use of sulindac had no effect on the subsequent development of colorectal polyposis.¹² Furthermore, the development of rectal cancer has been reported in patients whose rectal polyps were effectively controlled with sulindac.¹⁰ Finally, these medications necessitate continued com-

pliance⁹ and may be associated with significant side effects. Chemopreventive agents may be useful for reducing polyp load and facilitating endoscopic management of polyps in patients who have an ileal pouch or in patients who have an ileorectal anastomosis, are at high risk for polyp development, and refuse proctectomy. In such cases, however, it is still necessary to perform careful surveillance of the residual rectum or the ileoanal pouch every 6 months.¹¹

Surgical Therapy

The timing of surgical treatment depends to some degree on the extent of polyposis, in that the risk of CRC is partially dependent on the number of polyps present.¹³ Patients with mild polyposis (and thus a lower cancer risk) can undergo surgery in their midteens.¹¹ Practically speaking, the best time is usually the summer between high school and college. Patients with severe polyposis, dysplasia, adenomas larger than 5 mm, and significant symptoms should undergo surgery as soon after diagnosis as is practical.¹¹

There are three basic surgical options for treating FAP: (1) total proctocolectomy (TPC) with permanent ileostomy, (2) total abdominal colectomy with ileorectal anastomosis (IRA), and (3) proctocolectomy with ileal pouch–anal anastomosis (IPAA) [see 5:33 *Procedures for Ulcerative Colitis*]. The optimal procedure for a given patient is determined on the basis of a number of factors, including disease characteristics, differences in postoperative functional outcome, preoperative anal sphincter status, and patient preference.

TPC TPC with permanent ileostomy is rarely chosen as a primary procedure. More commonly, it is considered as an option for patients in whom a proctectomy is required but an IPAA is contraindicated (e.g., those with rectal tumors involving the sphincters or the levator complex or those with poor baseline sphincter function) or for patients in whom an IPAA is not technically feasible (e.g., those with desmoid disease and foreshortening of the small bowel mesentery). Occasionally, however, TPC is chosen as a primary procedure in patients whose lifestyle would be compromised by frequent bowel movements.

IPAA versus IRA The choice between IPAA and IRA is generally more challenging. The main considerations to be taken

into account are the risk of rectal cancer development if the rectum is left in situ and the differences in functional outcome (and associated quality of life) between procedures.

It has been estimated that the risk of rectal cancer after IRA may be as high as 4% to 8% at 10 years and 26% to 32% at 25 years.^{14,15} The true risk, however, may be somewhat lower. Most of the studies from which these figures were derived were completed before IPAA became available; thus, patients and physicians might have been more likely to choose IRA even in the setting of more extensive rectal disease, given that TPC and permanent ileostomy was the only other option at the time. The magnitude of risk in an individual patient is related to the overall extent of colorectal polyposis. IRA may be an option for patients with fewer than 1,000 colorectal polyps (including those with attenuated FAP) and fewer than 20 rectal adenomas, because these patients appear to be at relatively low risk for rectal cancer.^{11,13,16} Ideally, patients with severe rectal (> 20 adenomas) or colonic (> 1,000 adenomas) polyposis, an adenoma larger than 3 cm, or an adenoma with severe dysplasia should be treated with IPAA.^{11,13}

The risk of secondary rectal excision as a consequence of uncontrollable rectal polyposis or rectal cancer may be estimated on the basis of the specific location of the causative *APC* mutation.¹⁵⁻¹⁷ In a study of 87 FAP patients with an identified *APC* mutation who underwent IRA, those with a mutation located downstream from codon 1250 had an approximately threefold higher incidence of secondary rectal resection than those with a mutation located upstream of codon 1250.¹⁴ Furthermore, patients with a mutation located between codons 1250 and 1464 had a 6.2-fold higher risk of rectal cancer than those with a mutation before codon 1250 or after codon 1464.¹⁵

The risk of polyp and cancer development after index surgery is not limited to patients undergoing IRA. In patients undergoing IPAA, the pouch–anal anastomosis may be either handsewn after

Table 2 Availability of Commercial Genetic Testing for Autosomal Dominant Inherited CRC Syndromes

Test	Approximate Time Frame	Approximate Cost	Clinical Availability (in United States)
Protein truncation test	4–6 wk	\$1,100; if mutation known, \$475	Mayo Clinic, Rochester, Minn.; (800) 533-1710 Washington University, St. Louis, Mo.; (314) 454-7601

IHC—immunohistochemistry MMR—mismatch repair MSI—microsatellite instability

complete anal mucosectomy or stapled to a 1 to 2 cm anal transition zone. Neoplasia may occur at the site of the anastomosis, and the incidence appears to be higher after stapled anastomosis (28% to 31%) than after mucosectomy and handsewn anastomosis (10% to 14%).^{18,19} Function, however, may be better after stapled anastomosis.¹⁹ In the case of anal transition zone neoplasia after stapled anastomosis, transanal mucosectomy can often be performed, followed by advancement of the pouch to the dentate line. Of additional concern is the development of adenomatous polyps in the ileal pouch itself, which occurs in 35% to 42% of patients at 7 to 10 years.²⁰⁻²²

With respect to postoperative bowel function and associated quality of life, IPAA has been associated with a higher frequency of both daytime and nocturnal bowel movements, a higher incidence of passive incontinence and incidental soiling, and higher postoperative morbidity than IRA.²³ Accordingly, some authors recommend IRA for patients with mild rectal polyposis. Other authors, however, have found the two approaches to be equivalent in terms of functional results²⁴ and quality of life²⁵ and therefore recommend IPAA for most patients because of the risk of rectal cancer associated with IRA.

Regardless of which procedure is performed, however, lifetime surveillance of the rectal remnant (after IRA) or the ileal pouch (after IPAA) is required.¹¹ Endoscopic surveillance of the bowel at intervals of 6 months to 1 year after index surgery is recommended.^{5,11} After IRA, small (< 5 mm) adenomas may be safely observed, with biopsy performed to rule out severe dysplasia. If adenomas increase in number, the frequency of surveillance should be increased, and polyps larger than 5 mm should be removed. When fulguration and polypectomy are repeated over a period of many years, subsequent polypectomy may become difficult, rectal compliance may be reduced, and flat cancers may be hard to identify against a background of scar tissue. The development of severe dysplasia or a villous adenoma larger than 1 cm is an indication for proctectomy.¹¹

Extracolonic Disease

After total abdominal colectomy with IRA and regular surveillance, the risk of death appears to be three times higher for FAP patients than for an age- and sex-matched control population.²⁶ The main causes of death after IRA are desmoid disease and upper gastrointestinal malignancy.

Desmoid disease Desmoids are histologically benign tumors that arise from fibroaponeurotic tissue and occur in 12% to 17% of FAP patients.^{11,27,28} Unlike those in the general population, desmoids in FAP patients tend to be intra-abdominal (up to 80% of cases) and mainly occur after abdominal surgical procedures.^{27,28} Patients with *APC* mutations located between codons 1310 and 2011 are at increased risk for these tumors.²⁹ Desmoids often involve the small bowel mesentery (> 50% of cases),²⁸ making complete resection difficult or impossible, and they may also involve the ureters.²⁷ Not uncommonly, patients present with small bowel obstruction.^{27,28} Morbidity after attempted resection, which often involves removal of a significant length of small bowel, is substantial. The recurrence rate after attempted resection is also high, and the recurrent disease is often more aggressive than the initial desmoid.^{27,28}

Intra-abdominal desmoid formation may be more common after IRA than after IPAA, and the disease may be more severe after IRA as well.^{28,30} When desmoid tumors involve the small bowel mesentery, the mesentery may become foreshortened and thereby render IPAA impracticable, especially in patients under-

going a subsequent completion proctectomy after an initial IRA.¹¹ This possibility should be considered in making the choice between IRA and IPAA as the initial procedure for FAP.

Medical therapy. When desmoid tumors are clinically inert, they may be treated with sulindac.¹¹ Tamoxifen or other antiestrogens may be added for slow-growing or mildly symptomatic tumors.^{11,31,32} More aggressive desmoid tumors may be treated with chemotherapy. Vinblastin and methotrexate achieve some degree of response in 40% to 50% of patients.³³ For more rapidly growing desmoids, antineoplastic agents, such as doxorubicin and dacarbazine, may be administered.^{34,35} Radiation therapy may also be effective, but it can result in substantial small bowel morbidity.

Surgical therapy. Surgical treatment of intra-abdominal desmoid tumors should be reserved for small, well-defined lesions with clear margins.¹¹ When intra-abdominal desmoids involve the small bowel mesentery, they should be treated according to their initial presentation and rate of growth. In patients with desmoid lesions that are refractory to all medical treatment and call for surgical treatment with extensive small bowel resection, small bowel transplantation may be feasible in selected cases.³⁶

Periampullary neoplasms In approximately 80% to 90% of persons with FAP, duodenal adenomas, periampullary adenomas, or both will develop.³⁷ Of these patients, 14% to 50% will eventually exhibit advanced polyposis, and as many as 6% will eventually have invasive cancer.^{1,38-42} Although the risk of periampullary or duodenal cancer in FAP patients is relatively low, it is still several hundred times higher than that in the general population. Among FAP patients, those with *APC* mutations between codons 976 and 1067 appear to have the highest incidence of duodenal adenoma.

Surveillance should begin with side-viewing esophagogastroduodenoscopy (EGD) and biopsy of suspicious polyps either at the age of 20 years or at the time of prophylactic colectomy, whichever is earlier.¹¹ The purpose of screening is not to remove all disease but to watch for the development of high-grade dysplasia. Small, tubular adenomas without high-grade dysplasia may be biopsied and observed; adenomas that are larger than 1 cm or that exhibit high-grade dysplasia, villous changes, or ulceration should be removed. Surgical options include endoscopic removal and transduodenal excision, but both approaches have drawbacks: endoscopic ablation generally requires multiple settings,³⁸ and recurrence is high after either procedure.^{38,43} Endoscopic ablation is a reasonable initial approach for most patients without invasive cancer and is an attractive alternative for patients who are unfit for duodenal resection. For patients with persistent or recurrent high-grade dysplasia in the papilla or duodenal adenomas and for patients with Spigelman stage IV disease, pancreas-preserving duodenectomy or pancreaticoduodenectomy is recommended.¹¹ The results reported for duodenal resection in patients with pre-malignant lesions are encouraging, with good local control and low morbidity.^{38,44,45} Duodenectomy also greatly reduces the need for upper GI surveillance.

Hereditary Nonpolyposis Colorectal Cancer

HNPCC, which accounts for 5% to 7% of CRCs, results from a mutation in one of the DNA mismatch repair (MMR) genes (*MLH1*, *MSH2*, *MSH6*, *PMS1*, *PMS2*, *MLH3*, and *MSH3*).^{46,47} Two genes (*MLH1*, *MSH2*) may be responsible for as many as 90% of causative germline MMR mutations. However, only 50%

to 70% of patients meeting clinical criteria for HNPCC have an identifiable germline MMR mutation, which suggests that one or more unidentified genes may be involved. A significant percentage of cases may be attributable to large germline deletions that are difficult to detect by means of direct sequencing. It appears that genomic deletions may account for as many as 7% of HNPCC cases defined on the basis of clinical criteria.⁴⁸

CLINICAL EVALUATION

HNPCC is characterized by early-onset CRC, a predominance of lesions proximal to the splenic flexure (60% to 70% of cases), benign and malignant extracolonic tumors, and a predilection for synchronous and metachronous colorectal tumors.⁴ Microsatellite instability (MSI), reflecting a deficiency in DNA repair secondary to a mutation in the MMR genes, is noted in approximately 80% to 90% of HNPCC-related tumors.⁴ The lifetime risk of CRC in HNPCC patients is approximately 80%.^{11,49}

Establishing a clinical diagnosis of HNPCC is much more challenging than establishing a clinical diagnosis of FAP, in that it requires a careful and detailed family history. The Amsterdam II criteria [see Table 3] require that there be three relatives (of which one must be a first-degree relative of the other two) with an HNPCC-related cancer (of the colorectum, the endometrium, the small bowel, the ureter, or the renal pelvis), that two or more successive generations be involved, and that at least one relative have a CRC diagnosed before the age of 50.^{50,51} Finally, FAP should be excluded. CRC occurs in 78% to 80% of MMR mutation-positive patients at a mean age of 46 years.^{1,49,52} Endometrial cancer occurs in 43%, gastric cancer in 19%, urinary tract cancer in 18%, and ovarian cancer in 9%.⁵³

INVESTIGATIVE STUDIES

Pathologic Findings

Adenomas in HNPCC patients show high-grade dysplasia and villous changes more frequently than adenomas in sporadic CRC patients.¹ Adenomas may also appear at an earlier age and are often larger than those found in the general population. Other pathologic features reported to be more common in HNPCC-related cancers include a mucinous or poorly differentiated histology, a solid or cribriform growth pattern, signet-ring cell tumors, and the presence of tumor-infiltrating and peritumoral lymphocytes. HNPCC-related CRCs have also been shown to have a lower rate of lymph node involvement.⁵⁴

Screening and Surveillance

CRC patients who belong to known HNPCC kindreds, who have a pedigree suggestive of HNPCC, or who meet the Bethesda criteria [see Table 4]⁵⁵ should be offered screening by MSI testing. MSI evaluation will yield positive results (i.e., an MSI-high tumor) in 80% to 90% of patients belonging to families that meet the Amsterdam criteria. Patients with MSI-high tumors should undergo testing for germline MMR mutations (tests for *MSH2* and *MLH1* are available commercially [see Table 2]). If tumor tissue is not available, initial germline testing may be considered. As in FAP, a mutation in an affected individual must first be established for testing in at-risk individuals to be informative.⁵

Recommended surveillance for HNPCC includes colonoscopy, initially every 1 to 2 years beginning at the age of 20 to 25, then annually after the age of 40.⁵⁶ Given the increasing evidence of an accelerated adenoma-carcinoma sequence in HNPCC, annual colonoscopy should be strongly considered.⁴ Female patients should undergo annual transvaginal ultrasonography and mea-

Table 3 Clinical Criteria for Diagnosis of HNPCC

Amsterdam criteria I ⁵⁰	Three or more relatives with CRC One first-degree relative of the other two One CRC diagnosed at age < 50 yr Two or more successive generations FAP excluded
Amsterdam criteria II ⁵¹	Three or more relatives with an HNPCC-associated cancer (in colorectum, endometrium, small bowel, ureter, or renal pelvis) One first-degree relative of the other two Two or more successive generations One CRC diagnosed at age < 50 yr FAP excluded

surement of CA125 levels starting at 25 to 35 years of age, as well as annual endometrial aspiration.⁵⁶ Annual EGD is recommended for patients belonging to kindreds with a history of gastric cancer. Finally, ultrasonography and urine cytology every 1 to 2 years may be considered to screen for urinary tract malignancy.

MANAGEMENT

Surgical Therapy

Although the development of CRC in persons with HNPCC is not a certainty, the 80% lifetime risk,¹ the 45% rate of metachronous tumors, and the possibility of an accelerated adenoma-carcinoma sequence⁴ mandate consideration of prophylactic surgical options. Patients who have HNPCC as defined by their genotype or the Amsterdam criteria [see Table 3] and who have a colon cancer or more than one advanced adenoma should be offered either (1) prophylactic total abdominal colectomy with IRA or (2) segmental colectomy with yearly colonoscopy [see 5:34 *Laparoscopic Colectomy*].^{11,57,58} (The first option, however, is open only to patients with normal rectal and anal sphincter function.) Although the risk of metachronous colon cancers may be higher after partial colectomy than after total colectomy with IRA, intensive colonoscopic surveillance and polypectomy may minimize the number of metachronous cancers in the remaining colon.^{52,59} Careful surveillance is also necessary after total colectomy and IRA, given that the risk of metachronous rectal cancer after total colectomy is approximately 12% at 10 to 12 years.⁶⁰

HNPCC patients with an index rectal cancer that is amenable to a sphincter-preserving resection should be offered either (1) total proctocolectomy with IPAA [see 5:33 *Procedures for Ulcerative Colitis*] or (2) low anterior resection (LAR) with primary reconstruction [see 5:35 *Procedures for Rectal Cancer*].^{11,58} The rationale

Table 4 Revised Bethesda Guidelines for Testing CRC Patients for MSI⁵⁵

CRC diagnosed at age < 50 yr
Presence of synchronous or metachronous CRC or other HNPCC tumors (regardless of age)
CRC with HNPCC-like histology at age < 60 yr
CRC in one or more FDR with an HNPCC-related tumor (one diagnosed at age < 50 yr)
CRC in two or more first- or second-degree relatives with HNPCC-related tumors (regardless of age)

FDR—first-degree relative
