1 PROFESSIONALISM IN SURGERY

Wiley W. Souba, M.D., SC.D., F.A.C.S.

Over the past decade, the American health care system has had to cope with and manage an unprecedented amount of change. As a consequence, the medical profession has been challenged along the entire range of its cultural values and its traditional roles and responsibilities. It would be difficult, if not impossible, to find another social issue directly affecting all Americans that has undergone as rapid and remarkable a transformation—and oddly, a transformation in which the most important protagonists (i.e., the patients and the doctors) remain dissatisfied.¹

Nowhere is this metamorphosis more evident than in the field of surgery. Marked reductions in reimbursement, explosions in surgical device biotechnology, a national medical malpractice crisis, and the disturbing emphasis on commercialized medicine have forever changed the surgical landscape, or so it seems. The very foundation of patient care—the doctor-patient relationship—is in jeopardy. Surgeons find it increasingly difficult to meet their responsibilities to patients and to society as a whole. In these circumstances, it is critical for us to reaffirm our commitment to the fundamental and universal principles and values of medical professionalism.

The concept of medicine as a profession grounded in compassion and sympathy for the sick has come under serious challenge.² One eroding force has been the growth and sovereignty of biomedical research. Given the high position of science and technology in our societal hierarchy, we may be headed for a form of medicine that includes little caring but becomes exclusively focused on the mechanics of treatment, so that we deal with sick patients much as we would a flat tire or a leaky faucet. In such a form of medicine, healing becomes little more than a technical exercise, and any talk of morality that is unsubstantiated by hard facts is considered mere opinion and therefore carries little weight.

The rise of entrepreneurialism and the growing corporatization of medicine also challenge the traditions of virtue-based medical care. When these processes are allowed to dominate medicine, health care becomes a commodity. As Pellegrino and Thomasma remark, “When economics and entrepreneurism drive the professions, they admit only self-interest and the working of the marketplace as the motives for professional activity. In a free-market economy, effacement of self-interest, or any conduct shaped primarily by the idea of altruism or virtue, is simply inconsistent with survival.”²

These changes have caused a great deal of anxiety and fear among both patients and surgeons nationwide. The risk to the profession is that it will lose its sovereignty, becoming a passive rather than an active participant in shaping and formulating health policy in the future. The risks to the public are that issues of cost will take precedence over issues of quality and access to care and that health care will be treated as a commodity—that is, as a privilege rather than a right.

The Meaning of Professionalism

A profession is a collegial discipline that regulates itself by means of mandatory, systematic training. It has a base in a body

of technical and specialized knowledge that it both teaches and advances; it sets and enforces its own standards; and it has a service orientation, rather than a profit orientation, enshrined in a code of ethics.³⁻⁵ To put it more succinctly, a profession has cognitive, collegial, and moral attributes. These qualities are well expressed in the familiar sentence from the Hippocratic oath: “I will practice my art with purity and holiness and for the benefit of the sick.”

The escalating commercialization and secularization of medicine have evoked in many physicians a passionate desire to reconnect with the core values, practices, and behaviors that they see as exemplifying the very best of what medicine is about. This tension between commercialism on the one hand and humanism and altruism on the other is a central part of the professionalism challenge we face today.⁶ As the journalist Loretta McLaughlin once wrote, “The rush to transform patients into units on an assembly line demeans medicine as a caring as well as curative field, demeans the respect due every patient and ultimately demeans illness itself as a significant human condition.”⁷

Historically, the legitimacy of medical authority is based on three distinct claims^{2,8}: first, that the knowledge and competence of the professional have been validated by a community of peers; second, that this knowledge has a scientific basis; and third, that the professional’s judgment and advice are oriented toward a set of values. These aspects of legitimacy correspond to the collegial, cognitive, and moral attributes that define a profession.

Competence and expertise are certainly the basis of patient care, but other characteristics of a profession are equally important [see Table 1]. Being a professional implies a commitment to excellence and integrity in all undertakings. It places the responsibility to serve (care for) others above self-interest and reward. Accordingly, we, as practicing medical professionals, must act as role models by exemplifying this commitment and responsibility, so that medical students and residents are exposed to and learn the kinds of behaviors that constitute professionalism [see Sidebar Elizabeth Blackwell: A Model of Professionalism].

The medical profession is not infrequently referred to as a vocation. For most people, this word merely refers to what one does for a living; indeed, its common definition implies income-generating activity. Literally, however, the word vocation means “calling,” and the application of this definition to the medical profession yields a

Table 1 Elements of a Profession

- A profession
 - Is a learned discipline with high standards of knowledge and performance
 - Regulates itself via a social contract with society
 - Places responsibility for serving others above self-interest and reward
 - Is characterized by a commitment to excellence in all undertakings
 - Is practiced with unwavering personal integrity and compassion
 - Requires role-modeling of right behavior
 - Is more than a job—it is a calling and a privilege

more profound meaning. According to *Webster's Third New International Dictionary*,⁹ a profession may be defined as

a calling requiring specialized knowledge and often long academic preparation, including instruction in skills and methods as well as in the scientific, historical, or scholarly principles underlying such skills and methods, maintaining by force of organization or concerted opinion high standards of achievement and conduct, and committing its members to continued study and to a kind of work which has for its prime purpose the rendering of a public service[.]

Most of us went to medical school because we wanted to help and care for people who are ill. This genuine desire to care is unambiguously apparent in the vast majority of personal statements that medical students prepare as part of their application process. To quote William Osler, "You are in this profession as a calling, not as a business; as a calling which extracts from you at every turn self-sacrifice, devotion, love and tenderness to your fellow man. We must work in the missionary spirit with a breath of charity that raises you far above the petty jealousies of life."¹⁰ To keep medicine a calling, we must explicitly incorporate into the meaning of professionalism those nontechnical practices, habits, and attributes that the compassionate, caring, and competent physician exemplifies. We must remind ourselves that a true professional places service to the patient above self-interest and above reward.

Professionalism is the basis of our contract with society. To maintain our professionalism, and thus to preserve the contract with society, it is essential to reestablish the doctor-patient relationship as the foundation of patient care.

The Surgeon-Patient Relationship

The underpinning of medicine as a compassionate, caring profession is the doctor-patient relationship, a relationship that has become jeopardized and sometimes fractured over the past decade. Our individual perceptions of what this relationship is and how it should work will inevitably have a great impact on how we approach the care of our patients.²

The fundamental question to be answered is, what should the surgeon-patient relationship be governed by? If this relationship is viewed solely as a contract for services rendered, it is subject to the law and the courts; if it is viewed simply as an issue of applied biology, it is governed by science; and if it is viewed exclusively as a commercially driven business transaction, it is regulated by the marketplace. If, however, our relationship with our patients is understood as going beyond basic delivery of care and as constituting a covenant in which we act in the patient's best interest even if that means providing free care, it is based on the virtue of charity. Such a perspective transcends questions of contracts, politics, economics, physiology, and molecular genetics—all of which rightly influence treatment strategies but none of which is any substitute for authentic caring.

The view of the physician-patient relationship as a covenant does not demand devotion to medicine at the exclusion of other responsibilities, and it is not inconsistent with the fact that medicine is also a science, an art, and a business.² Nevertheless, in our struggle to remain viable in a health care environment that has become a commercial enterprise, efforts to preserve market share cannot take precedence over the provision of care that is grounded in charity and compassion. It is exactly for this reason that medicine always will be, and should be, a relationship between people. To fracture that relationship by exchanging a covenant based on

Elizabeth Blackwell: A Model of Professionalism¹⁷

Elizabeth Blackwell was born in England in 1821, the daughter of a sugar refiner. When she was 10 years old, her family emigrated to New York City. Discovering in herself a strong desire to practice medicine and care for the underserved, she took up residence in a physician's household, using her time there to study using books in the family's medical library.

As a young woman, Blackwell applied to several prominent medical schools but was snubbed by all of them. After 29 rejections, she sent her second round of applications to smaller colleges, including Geneva College in New York. She was accepted at Geneva—according to an anecdote, because the faculty put the matter to a student vote, and the students thought her application a hoax. She braved the prejudice of some of the professors and students to complete her training, eventually ranking first in her class. On January 23, 1849, at the age of 27, Elizabeth Blackwell became the first woman to earn a medical degree in the United States. Her goal was to become a surgeon.

After several months in Pennsylvania, during which time she became a naturalized citizen of the United States, Blackwell traveled to Paris, where she hoped to study with one of the leading French surgeons. Denied access to Parisian hospitals because of her gender, she enrolled instead at La Maternité, a highly regarded midwifery school, in the summer of 1849. While attending to a child some 4 months after enrolling, Blackwell inadvertently spattered some pus from the child's eyes into her own left eye. The child was infected with gonorrhea, and Blackwell contracted a severe case of ophthalmia neonatorum, which later necessitated the removal of the infected eye. Although the loss of an eye made it impossible for her to become a surgeon, it did not dampen her passion for becoming a practicing physician.

By mid-1851, when Blackwell returned to the United States, she was well prepared for private practice. However, no male doctor would even consider the idea of a female associate, no matter how well trained. Barred from practice in most hospitals, Blackwell founded her own infirmary, the New York Infirmary for Indigent Women and Children, in 1857. When the American Civil War began, Blackwell trained nurses, and in 1868 she founded a women's medical college at the Infirmary so that women could be formally trained as physicians. In 1869, she returned to England and, with Florence Nightingale, opened the Women's Medical College. Blackwell taught at the newly created London School of Medicine for Women and became the first female physician in the United Kingdom Medical Register. She set up a private practice in her own home, where she saw women and children, many of whom were of lesser means and were unable to pay. In addition, Blackwell mentored other women who subsequently pursued careers in medicine. She retired at the age of 86.

In short, Elizabeth Blackwell embodied professionalism in her work. In 1889 she wrote, "There is no career nobler than that of the physician. The progress and welfare of society is more intimately bound up with the prevailing tone and influence of the medical profession than with the status of any other class."

charity and compassion for a contract based solely on the delivery of goods and services is something none of us would want for ourselves. The nature of the healing relationship is itself the foundation of the special obligations of physicians as physicians.²

Translation of Theory into Practice

The American College of Surgeons (ACS) Task Force on Professionalism has developed a Code of Professional Conduct,¹¹ which emphasizes the following four aspects of professionalism:

1. A competent surgeon is more than a competent technician.
2. Whereas ethical practice and professionalism are closely related, professionalism also incorporates surgeons' relationships with patients and society.
3. Unprofessional behavior must have consequences.

4. Professional organizations are responsible for fostering professionalism in their membership.

If professionalism is indeed embodied in the principles discussed [see Table 1], the next question that arises is, how do we translate theory into practice? That is, what do these principles look like in action? To begin with, a competent surgeon must possess the medical knowledge, judgment, technical ability, professionalism, clinical excellence, and communication skills required for provision of high-quality patient-centered care. Furthermore, this expertise must be demonstrated to the satisfaction of the profession as a whole. The Accreditation Council on Graduate Medical Education (ACGME) has identified six competencies that must be demonstrated by the surgeon: (1) patient care, (2) medical knowledge, (3) practice-based learning and improvement, (4) interpersonal and communication skills, (5) professionalism, and (6) systems-based practice. These competencies are now being integrated into the training programs of all accredited surgical residencies.

A surgical professional must also be willing and able to take responsibility. Such responsibility includes, but is not necessarily limited to, the following three areas: (1) provision of the highest-quality care, (2) maintenance of the dignity of patients and coworkers, and (3) open, honest communication. Assumption of responsibility as a professional involves leading by example, placing the delivery of quality care above the patient's ability to pay, and displaying compassion. Cassell reminds us that a sick person is not just "a well person with a knapsack of illness strapped to his back"¹² and that whereas "it is possible to know the suffering of others, to help them, and to relieve their distress, [it is not possible] to become one with them in their torment."¹³ Illness and suffering are not just biologic problems to be solved by biomedical research and technology: they are also enigmas that can serve to point out the limitations, vulnerabilities, and frailties that we want so much to deny, as well as to reaffirm our links with one another.

Most important, professionalism demands unwavering personal integrity. Regrettably, examples of unprofessional behavior exist. An excerpt from a note from a third-year medical student to the core clerkship director reads as follows: "I have seen attendings make sexist, racist jokes or remarks during surgery. I have met residents who joke about deaf patients and female patients with facial hair. [I have encountered] teams joking and counting down the days until patients die." This kind of exposure to unprofessional conduct and language can influence young people negatively, and it must change.

It is encouraging to note that many instances of unprofessional conduct that once were routinely overlooked—such as mistreating medical students, speaking disrespectfully to coworkers, and fraudulent behavior—now are being dealt with. Still, from time to time an incident is made public that makes us all feel shame. In March 2003, the *Seattle Times* carried a story about the chief of neurosurgery at the University of Washington, who pleaded guilty to a felony charge of obstructing the government's investigation and admitted that he asked others to lie for him and created an atmosphere of fear in the neurosurgery department. According to the United States Attorney in Seattle, University of Washington

employees destroyed reports revealing that University doctors submitted inflated billings to Medicare and Medicaid. The department chair lost his job, was barred from participation in Medicare, and, as part of his plea bargain, had to pay a \$500,000 fine, perform 1,000 hours of community service, and write an article in a medical journal about billing errors. The University spent many millions in legal fees and eventually settled the billing issues with the Federal government for one of the highest Physicians at Teaching Hospitals (PATH) settlements ever.

Fortunately, such extreme cases of unprofessionalism are quite uncommon. Nevertheless, it remains our responsibility as professionals to prevent such behaviors from developing and from being reinforced. To this end, we must lead by example. A study published in 2004 demonstrated an association between displays of unprofessional behavior in medical school and subsequent disciplinary action by a state medical board.¹⁴ The authors concluded that professionalism is an essential competency that students must demonstrate to graduate from medical school. Who could disagree?

The Future of Surgical Professionalism

It is often subtly implied—or even candidly stated—that no matter how well we adjust to the changing health care environment, the practice of surgery will never again be quite as rewarding as it once was. This need not be the case. The ongoing advances in surgical technology, the increasing opportunities for community-based surgeons to enroll their patients into clinical trials, and the growing emphasis on lifelong learning as part of maintenance of certification are factors that not only help satisfy social and organizational demands for quality care but also are in the best interest of our patients.

In the near future, maintenance of certification for surgeons will involve much more than taking an examination every decade. The ACS is taking the lead in helping to develop new measures of competence. Whatever specific form such measures may take, displaying professionalism and living up to a set of uncompromisable core values¹⁵ will always be central indicators of the performance of the individual surgeon and the integrity of the discipline of surgery as a whole.

Although surgeons vary enormously with respect to personality, practice preferences, areas of specialization, and style of relating to others, they all have one role in common: that of healer. Indeed, it is the highest of privileges to be able to care for the sick. As the playwright Howard Sackler once wrote, "To intervene, even briefly, between our fellow creatures and their suffering or death, is our most authentic answer to the question of our humanity." Inseparable from this privilege is a set of responsibilities that are not to be taken lightly: a pledge to offer our patients the best care possible and a commitment to teach and advance the science and practice of medicine. Commitment to the practice of patient-centered, high-quality, cost-effective care is what gives our work meaning and provides us with a sense of purpose.¹⁶ We as surgeons must participate actively in the current evolution of integrated health care; by doing so, we help build our own future.

2 PERFORMANCE MEASURES IN SURGICAL PRACTICE

John D. Birkmeyer, M.D., F.A.C.S.

With the growing recognition that the quality of surgical care varies widely, there is a rising demand for good measures of surgical performance. Patients and their families need to be able to make better-informed decisions about where to get their surgical care—and from whom.¹ Employers and payers need data on which to base their contracting decisions and pay-for-performance initiatives.² Finally, clinical leaders need tools that can help them identify “best practices” and guide their quality-improvement efforts. To meet these different needs, an ever-broadening array of performance measures is being developed.

The consensus about the general desirability of surgical performance measurement notwithstanding, there remains considerable uncertainty about which specific measures are most effective in measuring surgical quality. The measures currently in use are remarkably heterogeneous, encompassing a range of different elements. In broad terms, they can be grouped into three main categories: measures of health care structure, process-of-care measures, and measures reflecting patient outcomes. Although each of these three types of performance measure has its unique strengths, each is also associated with conceptual, methodological, or practical problems [see Table 1]. Obviously, the baseline risk and frequency of the procedure are important considerations in weighing the strengths and weaknesses of different measures.³ So too is the underlying purpose of performance measurement; for example, measures that work well when the primary intent is to steer patients to the best hospitals or surgeons (selective referral) may not be optimal for quality-improvement purposes.

Several reviews of performance measurement have been published in the past few years.³⁻⁵ In what follows, I expand on these reviews, providing an overview of the measures commonly used to assess surgical quality, considering their main strengths and limi-

tations, and offering recommendations for selecting the optimal quality measure.

Overview of Current Performance Measures

The number of performance measures that have been developed for the assessment of surgical quality is already large and continues to grow. For present purposes, it should be sufficient to consider a representative list of commonly used quality indicators that have been endorsed by leading quality-measurement organizations or have already been applied in hospital accreditation, pay-for-performance, or public reporting efforts [see Table 2]. A more exhaustive list of performance measures is available on the National Quality Measures Clearinghouse (NQMC) Web site, sponsored by the Agency for Healthcare Research and Quality (AHRQ) (<http://www.qualitymeasures.ahrq.gov>).

To date, the National Quality Forum (NQF), the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), and the Center for Medicare and Medicaid Services (CMS) have focused primarily on preventive care and hospital-based medical care, with an emphasis on process-of-care variables. In surgery, these groups have all endorsed one process measure—appropriate and timely use of prophylactic antibiotics [see Table 2]—in partnership with the Centers for Disease Control and Prevention (CDC). In 2006, CMS, as part of its Surgical Care Improvement Program (SCIP), is also endorsing process measures related to prevention of postoperative cardiac events, venous thromboembolism, and respiratory complications.

The AHRQ has focused primarily on quality measures that take advantage of readily available administrative data. Because little information on process of care is available in these datasets, these

Table 1 Primary Strengths and Limitations of Structural, Process, and Outcome Measures

Type of Measure	Examples	Strengths	Limitations
Structural	Procedure volume Intensivist-managed ICU	Measures are expedient and inexpensive Measures are efficient—a single one may relate to several outcomes For some procedures, measures predict subsequent performance better than process or outcome measures do	Number of measures is limited Measures are generally not actionable Measures do not reflect individual performance and are considered unfair by providers
Process of care	Appropriate use of prophylactic antibiotics	Measures reflect care that patients actually receive—hence, greater buy-in from providers Measures are directly actionable for quality-improvement activities For many measures, risk adjustment is unnecessary	Many measures are hard to define with existing databases Extent of linkage between measures and important patient outcomes is variable High-leverage, procedure-specific measures are lacking
Direct outcome	Risk-adjusted mortalities for CABG from state or national registries	Face validity Measurement may improve outcomes in and of itself (Hawthorne effect)	Sample sizes are limited Clinical data collection is expensive Concerns exist about risk adjustment with administrative data

CABG—coronary artery bypass grafting

measures are mainly structural (e.g., hospital procedure volume) or outcome-based (e.g., risk-adjusted mortality).

The Leapfrog Group (<http://www.leapfroggroup.org>), a coalition of large employers and purchasers, developed perhaps the most visible set of surgical quality indicators for its value-based purchasing initiative. The organization's original (2000) standards focused exclusively on procedure volume, but these were expanded in 2003 to include selected process variables (e.g., the use of beta blockers in patients undergoing abdominal aortic aneurysm repair) and outcome measures.

Structural Measures

The term health care structure refers to the setting or system in which care is delivered. Many structural performance measures reflect hospital-level attributes, such as the physical plant and resources or the coordination and organization of the staff (e.g., the registered nurse–bed ratio and the designation of a hospital as a level I trauma center). Other structural measures reflect physician-level attributes (e.g., board certification, subspecialty training, and procedure volume).

STRENGTHS

Structural performance measures have several attractive features. A strength of such measures is that many of them are strongly related to outcomes. For example, with esophagectomy and pancreatic resection for cancer, operative mortality is as much as 10% lower, in absolute terms, at very high volume hospitals than at lower-volume centers.^{6,7} In some instances, structural measures (e.g., procedure volume) are better predictors of subsequent hospital performance than any known process or outcome measures are [*see Figure 1*].⁸

A second strength is efficiency. A single structural measure may be associated with numerous outcomes. For example, with some types of cancer surgery, higher hospital or surgeon procedure volume is associated not only with lower operative mortality but also with lower perioperative morbidity and improved late survival.^{9–11} Intensivist-staffed intensive care units are linked to shorter lengths of stay and reduced use of resources, as well as to lower mortality.^{12,13}

The third, and perhaps most important, strength of structural measures is expediency. Many such measures can easily be assessed with readily available administrative data. Although some structural measures require surveying of hospitals or providers, such data are much less expensive to collect than data obtained through review of individual patients' medical records.

LIMITATIONS

Relatively few structural performance measures are strongly linked to patients and thus potentially useful as quality indicators. Another limitation is that most structural measures, unlike most process measures, are not readily actionable. For example, a small hospital can increase the percentage of its surgical patients who receive antibiotic prophylaxis, but it cannot easily make itself a high-volume center. Thus, although some structural measures may be useful for selective referral initiatives, they are of limited value for quality improvement.

Whereas some structural measures can identify groups of hospitals or providers that perform better on average, they are not adequate discriminators of performance among individuals. For example, in the aggregate, high-volume hospitals have a much lower operative mortality for pancreatic resection than lower-volume centers do. Nevertheless, some individual high-volume hospitals may have a high mortality, and some individual low-volume centers may

Table 2 Performance Measures Currently Used in Surgical Practice

Diagnosis or Procedure	Performance Measure Developer/Endorser
Critical illness	Staffing with board-certified intensivists (LF)
Any surgical procedure	Appropriate antibiotic prophylaxis (correct approach: give 1 hr preoperatively, discontinue within 24 hr) (NQF, JCAHO, CMS)
Abdominal aneurysm repair	Hospital volume (AHRQ, LF) Risk-adjusted mortality (AHRQ) Prophylactic beta blockers (LF)
Carotid endarterectomy	Hospital volume (AHRQ)
Esophageal resection for cancer	Hospital volume (AHRQ)
Coronary artery bypass grafting	Hospital volume (NQF, AHRQ, LF) Risk-adjusted mortality (NQF, AHRQ, LF) Use of internal mammary artery (NQF, LF)
Pancreatic resection	Hospital volume (AHRQ, LF) Risk-adjusted mortality (AHRQ)
Pediatric cardiac surgery	Hospital volume (AHRQ) Risk-adjusted mortality (AHRQ)
Hip replacement	Risk-adjusted mortality (AHRQ)
Craniotomy	Risk-adjusted mortality (AHRQ)
Cholecystectomy	Laparoscopic approach (AHRQ)
Appendectomy	Avoidance of incidental appendectomy (AHRQ)

AHRQ—Agency for Healthcare Research and Quality CMS—Center for Medicare and Medicaid Services JCAHO—Joint Commission on Accreditation of Healthcare Organizations LF—Leapfrog Group NQF—National Quality Forum

have a low mortality (though the latter possibility may be difficult to confirm because of the smaller sample sizes involved).¹⁴ For this reason, many providers view structural performance measures as unfair.

Process Measures

Processes of care are the clinical interventions and services provided to patients. Process measures have long been the predominant quality indicators for both inpatient and outpatient medical care, and their popularity as quality measures for surgical care is growing rapidly.

STRENGTHS

A strength of process measures is their direct connection to patient management. Because they reflect the care that physicians actually deliver, they have substantial face validity and hence greater “buy-in” from providers. Such measures are usually directly actionable and thus are a good substrate for quality-improvement activities.

A second strength is that risk adjustment, though important for outcome measures, is not required for many process measures. For example, appropriate prophylaxis against postoperative venous thromboembolism is one performance measure in CMS's expanding pay-for-performance initiative and is part of SCIP. Because it is widely agreed that virtually all patients undergoing open abdominal procedures should be offered some form of prophylaxis, there is little need to collect detailed clinical data about illness severity for the purposes of risk adjustment.

Another strength is that process measures are generally less constrained by sample-size problems than outcome measures are. Important outcome measures (e.g., perioperative death) are relatively rare, but most targeted process measures are relevant to a much larger proportion of patients. Moreover, because process measures generally target aspects of general perioperative care, they can often be applied to patients who are undergoing numerous different procedures, thereby increasing sample sizes and, ultimately, improving the precision of the measurements.

LIMITATIONS

At present, a major limitation of process measures is the lack of a reliable data infrastructure. Administrative datasets do not have the clinical detail and specificity required for close evaluation of processes of care. Measurement systems based on clinical data, including that of the National Surgical Quality Improvement Program (NSQIP) of the Department of Veterans Affairs (VA),¹⁵ focus on patient characteristics and outcomes and do not collect information on processes of care. Currently, most pay-for-performance programs rely on self-reported information from hospitals, but the reliability of such data is uncertain (particularly when reimbursement is at stake).

A second limitation is that at present, targeted process measures in surgery pertain primarily to general perioperative care and often relate to secondary rather than primary outcomes. Although the value of antibiotic prophylaxis in reducing the risk of superficial surgical site infection (SSI) should not be underestimated, superficial SSI is not among the most important adverse events of major surgery (including death). Thus, improvements in the use of prophylactic antibiotics will not address the fundamental problem of variation in the rates of important outcomes from one hospital to another and from one surgeon to another. Except, possibly, in the case of coronary artery bypass grafting (CABG), the processes that determine the success of individual procedures have yet to be identified.

Outcome Measures

Direct outcome measures reflect the end result of care, either from a clinical perspective or from the patient’s viewpoint. Mortality is by far the most commonly used surgical outcome measure, but there are other outcomes that could also be used as qual-

ity indicators, including complications, hospital readmission, and various patient-centered measures of satisfaction or health status.

Several large-scale initiatives involving direct outcome assessment in surgery are currently under way. For example, proprietary health care rating firms (e.g., Healthgrades) and state agencies are assessing risk-adjusted mortalities by using Medicare or state-level administrative datasets. Most of the current outcome-measurement initiatives, however, involve the use of large clinical registries, of which the cardiac surgery registries in New York, Pennsylvania, and a growing number of other states are perhaps the most visible examples. At the national level, the Society for Thoracic Surgeons and the American College of Cardiology have implemented systems for tracking the morbidity and mortality associated with cardiac surgery and percutaneous coronary interventions, respectively. Although the majority of the outcome-measurement efforts to date have been procedure-specific (and largely limited to cardiac procedures), NSQIP has assessed hospital-specific morbidities and mortalities aggregated across surgical specialties and procedures. Efforts to apply the same measurement approach outside the VA are now being implemented.¹⁶

STRENGTHS

Direct outcome measures have at least two major strengths. First, they have obvious face validity and thus are likely to garner a high degree of support from hospitals and surgeons. Second, outcome measurement, in and of itself, may improve performance—the so-called Hawthorne effect. For example, surgical morbidity and mortality in VA hospitals have fallen dramatically since the implementation of NSQIP in 1991.¹⁵ Undoubtedly, many surgical leaders at individual hospitals made specific organizational or process improvements after they began receiving feedback on their hospitals’ performance. However, it is very unlikely that even a full inventory of these specific changes would explain such broad-based and substantial improvements in morbidity and mortality.

LIMITATIONS

One limitation of hospital- or surgeon-specific outcome measures is that they are severely constrained by small sample sizes. For the large majority of surgical procedures, very few hospitals (or surgeons) have sufficient adverse events (numerators) and cases (denominators) to be able to generate meaningful, proce-

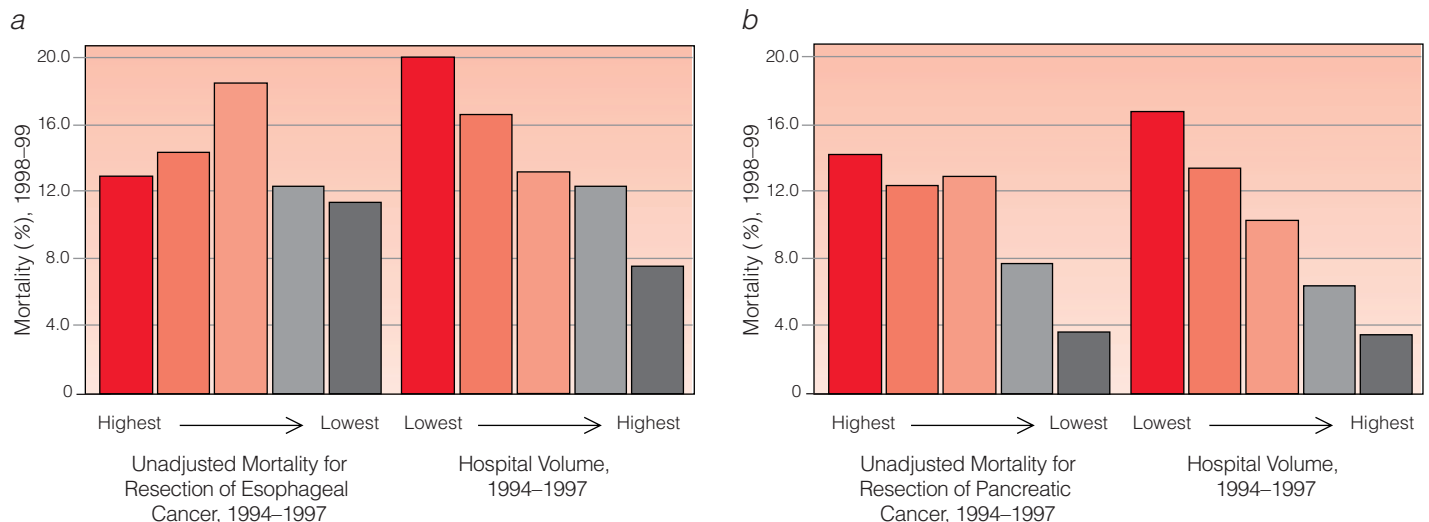

Figure 1 Illustrated is the relative ability of historical (1994-1997) measures of hospital volume and risk-adjusted mortality to predict subsequent (1998-1999) risk-adjusted mortality in Medicare patients undergoing (a) esophageal or (b) pancreatic resection for cancer.⁸

procedure-specific measures of morbidity or mortality. For example, a 2004 study used data from the Nationwide Inpatient Sample to study seven procedures for which mortality was advocated as a quality indicator by the AHRQ.¹⁷ For six of the seven procedures, only a very small proportion of hospitals in the United States had large enough caseloads to rule out a mortality that was twice the national average. Although identifying poor-quality outliers is an important function of outcome measurement, to focus on this goal alone is to underestimate the problems associated with small sample sizes. Distinguishing among individual hospitals with intermediate levels of performance is even more difficult.

Other limitations of direct outcome assessment depend on whether the assessment is based on administrative data or on clinical information abstracted from medical records. For outcome measures based on clinical data, the major problem is expense. For example, it costs more than \$100,000 annually for a private-sector hospital to participate in NSQIP.

For outcome measures based on administrative data, a major concern is the adequacy of risk adjustment. For outcome measures to have face validity with providers, high-quality risk adjustment may be essential. It may also be useful for discouraging gaming of the system (e.g., hospitals or providers avoiding high-risk patients to optimize their performance measures). It is unclear, however, to what extent the scientific validity of outcome measures is threatened by imperfect risk adjustment with administrative data. Although administrative data lack clinical detail on many variables related to baseline risk,¹⁸⁻²¹ the degree to which case mix varies systematically across hospitals or surgeons has not been determined. Among patients who are undergoing the same surgical procedure, there is often surprisingly little variation. For example, among patients undergoing CABG in New York State, unadjusted hospital mortality and adjusted hospital mortality (as derived from clinical registries) were nearly identical in most years (with correlations exceeding 0.90) [see Figure 2].²² Moreover, hospital rankings based on unadjusted mortality and those based on adjusted mortality were equally useful in predicting subsequent hospital performance.

Matching the Performance Measure to the Underlying Goal

Performance measures will never be perfect. Certainly, over time, better analytic methods will be developed, and better access to higher-quality data may be gained with the addition of clinical elements to administrative datasets or the broader adoption of electronic medical records. There are, however, some problems with performance measurement (e.g., sample-size limitations) that are inherent and thus not fully correctable. Consequently, clinical leaders, patient advocates, payers, and policy makers will all have to make decisions about when imperfect measures are nonetheless good enough to act on.

A measure should be implemented only with the expectation that acting on it will yield a net improvement in health quality. In other words, the direct benefits of implementing a particular measure cannot be outweighed by the indirect harm. Unfortunately, benefits and harm are often difficult to measure. Moreover, measurement is heavily influenced by the specific context and by who—patients, payers, or providers—is doing the accounting. For this reason, the question of where to set the bar, so to speak, has no simple answer.

It is important to ensure a good match between the performance measure and the primary goal of measurement. It is particularly important to be clear about whether the underlying goal is (1) quality improvement or (2) selective referral (i.e., directing

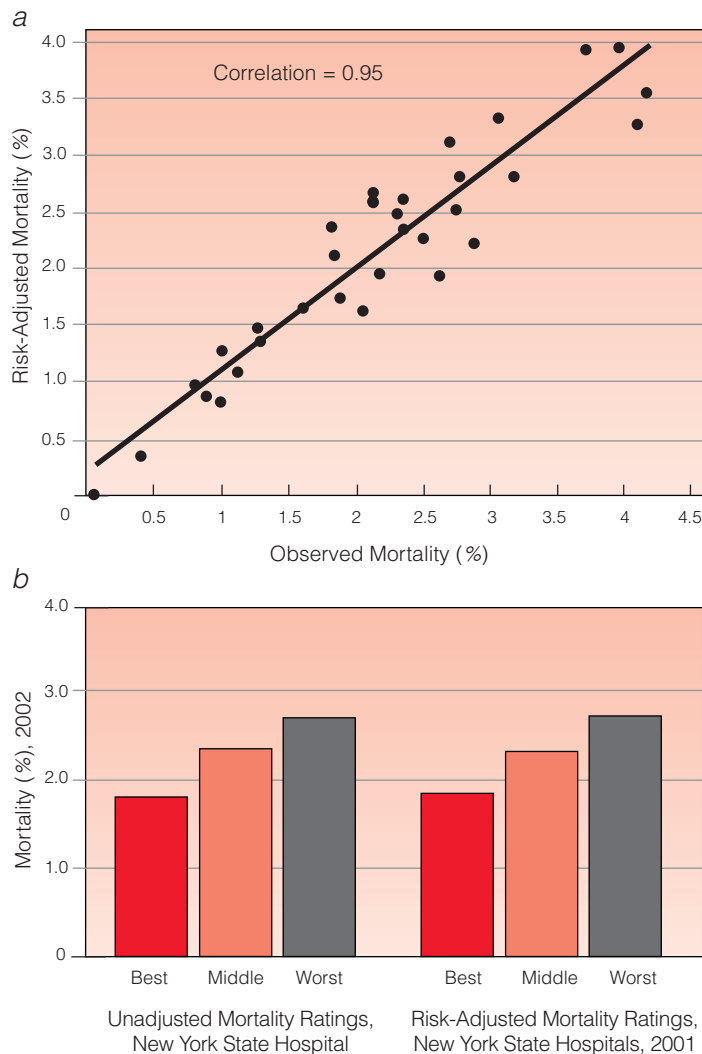

Figure 2 Shown are mortality figures from CABG in New York State hospitals, based on data from the state's clinical outcomes registry. (a) Depicted is the correlation between adjusted and unadjusted mortalities for all state hospitals in 2001. (b) Illustrated is the relative ability of adjusted mortality and unadjusted mortality to predict performance in the subsequent year.

patients to higher-quality hospitals or providers). Although some pay-for-performance initiatives may have both goals, one usually predominates. For example, the ultimate objective of CMS's pay-for-performance initiative with prophylactic antibiotics is to improve quality at all hospitals, not to direct patients to centers with high compliance rates. Conversely, the Leapfrog Group's efforts in surgery are primarily aimed at selective referral, though they may indirectly provide incentives for quality improvement.

For the purposes of quality improvement, a good performance measure—most often, a process-of-care variable—must be actionable. Measurable improvements in the given process should translate into clinically meaningful improvements in patient outcomes. Although quality-improvement activities are rarely actually harmful, they do have potential downsides, mainly related to their opportunity cost. Initiatives that hinge on bad performance measures siphon away resources (e.g., time and focus) from more productive activities.

For the purposes of selective referral, a good performance measure is one that steers patients toward better hospitals or physicians

(or away from worse ones). For example, a measure based on previous performance should reliably identify providers who are likely to have superior performance now and in the future. At the same time, a good performance measure should not provide incentives for perverse behaviors (e.g., carrying out unnecessary procedures to meet a specific volume standard) or negatively affect other domains of quality (e.g., patient autonomy, access, and satisfaction).

Measures that work well for quality improvement may not be particularly useful for selective referral; the converse is also true. For example, appropriate use of perioperative antibiotics in surgical patients is a good quality-improvement measure: it is clinically meaningful, linked to lower SSI rates, and directly actionable. This process of care would not, however, be particularly useful for selective referral purposes. In the first place, patients are unlikely to base their decision about where to undergo surgery on patterns of perioperative antibiotic use. Moreover, surgeons with high rates of appropriate antibiotic use do not necessarily do better with respect to more important outcomes (e.g., mortality). A physician's performance on one quality indicator often correlates poorly with his or her performance on other indicators for the same or other clinical conditions.²³

As a counterexample, the two main performance measures for pancreatic cancer surgery—hospital volume and operative mortality—are very informative in the context of selective referral: patients can markedly improve their chances of surviving surgery by selecting hospitals highly ranked on either measure [see Figure 1]. Neither of these measures, however, is particularly useful for quality-improvement purposes. Volume is not readily actionable, and mortality is too unstable at the level of individual hospitals (again, because of the small sample sizes) to serve as a means of identifying top performers, determining best practices, or evaluating the effects of improvement activities.

Many believe that a good performance measure must be capa-

ble of distinguishing levels of performance on an individual basis. From the perspective of providers in particular, a measure cannot be considered fair unless it reliably reflects the performance of individual hospitals or physicians. Unfortunately, as noted (see above), small caseloads (and, sometimes, variations in the case mix) make this degree of discrimination difficult or impossible to achieve with most procedures. Even so, information that at least improves the chances of a good outcome on average is still of real value to patients. Many performance measures can achieve this less demanding objective even if they do not reliably reflect individual performance.

For example, a 2002 study used clinical data from the Cooperative Cardiovascular Project to assess the usefulness of the Healthgrades hospital ratings for acute myocardial infarction (based primarily on risk-adjusted mortality from Medicare data).²⁴ Compared with the one-star (worst) hospitals, the five-star (best) hospitals had a significantly lower mortality (16% versus 22%) after risk adjustment with clinical data; they also discharged significantly more patients on appropriate aspirin, beta-blocker, and angiotensin-converting enzyme inhibitor regimens. However, the Healthgrades ratings proved not to be useful for discriminating between any two individual hospitals. In only 3% of the head-to-head comparisons did five-star hospitals have a statistically lower mortality than one-star hospitals.

Thus, some performance measures that clearly identify groups of hospitals or providers that exhibit superior performance may be limited in their ability to differentiate individual hospitals from one another. There may be no simple way of resolving the basic tension implied by performance measures that are unfair to providers yet informative for patients. This tension does, however, underscore the importance of being clear about (1) what the primary purpose of performance measurement is (quality improvement or selective referral) and (2) whose interests are receiving top priority (the provider or the patient).

3 PATIENT SAFETY IN SURGICAL CARE: A SYSTEMS APPROACH

Robert S. Rhodes, M.D., F.A.C.S.

In high-profile events such as the explosion at Chernobyl, the near meltdown at Three Mile Island, the explosion of the chemical plant in Bhopal, the collision of a U.S. submarine with a Japanese fishing boat, and the explosion of the space shuttle *Challenger*, the casualties are notable for their number and their celebrity. The differences between these events notwithstanding, each one arose in large part from faults in a complex system. Human error played a role as well, but it was generally understood to be only a relatively small part of a larger systemic failure.

In contrast, medical injuries affect one patient at a time and, until recently, rarely received much publicity. Nevertheless, there is now considerable public concern about patient safety and the overall quality of patient care.¹⁻³ It is estimated that there may be nearly 100,000 error-related deaths each year in the United States.⁴ This estimate far exceeds the casualties from more publicized nonmedical disasters and, if anywhere near correct, makes medically related injuries one of the leading causes of death, according to the Centers for Disease Control and Prevention (CDC) (<http://www.cdc.gov/scientific.htm>). Perhaps surprisingly, however, both patients and physicians still appear to place much less emphasis on system flaws as a cause of medical injury than on individual human error.² One reason for this may be that “error in medicine is almost always seen as a special case of medicine rather than as a special case of error.... The unfortunate result has been the isolation of medical errors from much of the body of theory, analysis, and application that has developed to deal with error in fields such as aviation and nuclear power.”⁵ In addition, within the field of medicine, it is accepted that complications or bad outcomes can occur even in the best circumstances. When a system is not expected to work perfectly at all times, it is difficult to distinguish problems related to individual error from those related to flaws in the system.

Various organizations—including the National Patient Safety Foundation (<http://www.npsf.org>), the National Quality Forum (NQF) (<http://www.qualityforum.org>), and the Institute of Medicine (IOM) (<http://www.iom.edu>)—are responding to the concerns about patient safety and the quality of medical care.⁶⁻⁸ In addition to the basic professional obligation to provide high-quality care, there is evidence that such care is less expensive and is therefore crucial for cost control. Moreover, the growing concern about patient safety has begun to change the way patients select providers. For example, one survey found that between 1996 and 2000, the percentage of patients who would choose a highly rated surgeon whom they had not seen before in preference to a less highly rated one whom they had seen before increased substantially.⁹ Thus, improving patient safety is also an issue of provider self-interest.

In what follows, I attempt to evaluate current information on patient safety and the quality of surgical care in the context of system failure, with a particular emphasis on indicating how and

where a systems approach might contribute to improving surgical care. In addition, I consider current obstacles to quality improvement and discuss how surgeons can take the lead in overcoming these obstacles. Finally, I consider patient safety in the broader context: the lessons learned from exploring patient safety issues are likely to be equally applicable to wider quality of care issues.

The Magnitude of the Problem

The two most widely cited estimates of adverse medical events are the Harvard Medical Practice Study (HMPS)¹⁰ and the study of adverse surgical events in Colorado and Utah.¹¹ The HMPS, a population-based study of hospitalized patients in New York State during 1984, found that nearly 4% of patients experienced an adverse event (i.e., an unintended injury caused by treatment that resulted in a prolonged hospital stay or a measurable disability at discharge) and that about half of such events occurred in surgical patients. The Colorado/Utah study, using a random sample of 15,000 nonpsychiatric discharges during 1992, found that the annual incidence of adverse surgical events was 3.0% and that 54% of these events were preventable. Nearly half of all adverse surgical events were accounted for by technique-related complications, wound infections, and postoperative bleeding. Eleven common operations were associated with a significantly higher risk of an adverse event [*see Table 1*], and eight were asso-

Table 1 Procedures Associated with a Significantly Higher Incidence of Adverse Surgical Events¹¹

Procedure	Incidence of Adverse Events (%)	Confidence Interval (%)
AAA repair	18.9	8.3–37.5
Lower extremity arterial bypass	14.1	6.0–29.7
CABG/valve replacement	12.3	7.9–18.7
Colon resection	6.8	2.9–14.8
Cholecystectomy	5.9	3.7–9.3
Prostatectomy	5.9	2.3–14.3
TURP/TURBT	5.5	2.7–10.7
Knee/hip replacements	4.9	2.9–8.4
Spinal surgery	4.5	2.8–7.3
Hysterectomy	4.4	2.9–6.8
Appendectomy	3.0	1.4–6.6

AAA—abdominal aortic aneurysm CABG—coronary artery bypass grafting
 TURP—transurethral prostatectomy TURBT—transurethral resection of bladder tumor

Table 2 Procedures Associated with a Significantly Higher Incidence of Preventable Adverse Surgical Events¹¹

Procedure	Incidence of Preventable Adverse Events (%)	Confidence Interval (%)
AAA repair	8.1	2.2–25.5
Lower extremity arterial bypass	11.0	4.2–26.1
CABG/valve replacement	4.7	2.3–9.7
Colon resection	5.9	2.4–13.8
Cholecystectomy	3.0	1.6–5.8
TURP/TURBT	3.9	1.7–8.7
Hysterectomy	2.8	1.6–4.7
Appendectomy	1.5	0.5–4.5

ciated with a significantly higher risk of a preventable event [see Table 2]. Other noteworthy studies have reported comparable or higher estimates.^{12–18}

A well-publicized 2003 report estimated that retention of sponges or surgical instruments occurred in between 1/8,801 and 1/18,760 inpatient operations at nonspecialty acute care hospitals.¹⁹ This figure is probably an underestimate.

Wrong-site surgery, brought to public attention by a wrong-sided amputation in Florida, has proved to be more than an isolated event. The Florida Board of Medicine tabulated 44 wrong-site operations in 1999–2000,²⁰ and a database begun in 1998 by the Joint Commission for Accreditation of Healthcare Organizations (JCAHO) contained 150 cases of wrong-site, wrong-person, or wrong-procedure surgery as of December 2001.²¹ The increased frequency of reports of wrong-site surgery since the initial headlines probably reflects earlier underreporting.²²

Medication errors (e.g., wrong drug, wrong dose, wrong patient, wrong time, or wrong route of administration) are alarmingly frequent.^{23–27} A study of radiopharmaceutical misadministrations showed that 68.9% of such errors involved the wrong isotope, 24% the wrong patient, 6.5% the wrong dose, and 0.6% the wrong route.²⁸ Blood transfusions continue to be plagued by patient misidentification as well. Device-related deaths and serious injuries also occur at an alarming rate, even after premarket safety testing.²⁹ In 2002, the Food and Drug Administration (FDA) received more than 2,500 such reports from clinical facilities and more than 3,500 from health professionals and consumers.

There remain significant differences of opinion regarding surgically related adverse events, with some disputing the published estimates and others arguing about the extent to which such events are preventable. Furthermore, not everyone agrees with the HMPS definition of medical error. Some argue that iatrogenic illnesses caused by conceptual error (e.g., a contraindicated, unsound, or inappropriate medical approach) should be distinguished from the side effects of an intended action that was correct in the circumstances (e.g., an indicated diagnostic or therapeutic procedure).²⁹ Others would distinguish accidents (i.e., unplanned, unexpected, and undesired events) from true side effects (which result from correct management and which are often accepted as reasonable therapeutic tradeoffs).

The HMPS attempted to address some of these issues by

characterizing adverse events as either preventable or unpreventable given the prevailing state of knowledge. Preventable errors were further subclassified as diagnostic errors or treatment errors; treatment errors included preventive errors such as failure of prophylaxis and failure to monitor and follow up treatment.^{10,30} The HMPS found preventability to vary according to the type of event: 74% of early surgical adverse events were judged preventable, compared with 65% of nonsurgical adverse events; and more than 90% of late surgical failures, diagnostic mishaps, and nonprocedural therapeutic mishaps were judged preventable.

In an attempt to make study data more directly comparable, Federal agencies developed standard definitions of the applicable terms [see Sidebar Definitions of Terms Related to Patient Safety].³¹ Even when terms are agreed on, however, differences in end points may render studies noncomparable or lead to differing conclusions. For instance, a study of Veterans Affairs (VA) hospitals reported much lower estimates of preventable deaths than those cited by the HMPS.³² The study authors noted that many of the patients who died “preventable” deaths would have died of natural causes anyway within a few months even if they had received optimal care. However, to argue that a patient would have died soon regardless of care does not mean that flaws do not exist in the care system.

Judgments of causality are affected by hindsight bias, as illustrated by a study of anesthetic care in which outcome differences significantly influenced the perception of negligence, even when the care provided was equivalent in all other respects.³³ Accordingly, there is often a tendency to focus too narrowly on adverse outcomes while paying insufficient attention to the processes that give rise to these outcomes.

The situation is further complicated by underreporting of error. Underreporting is more likely if side effects are delayed or unpredictable, if there is a longer survival or latent interval, or if a patient has been transferred from one facility to another. Inadequate doses of antibiotics or anesthetics may not be reported if they cause no immediately evident injury. The lack of detail in many medical records may contribute to underreporting as well. A major cause of underreporting is the use of a punitive

Definitions of Terms Related to Patient Safety³¹

- An *adverse event* is an injury that was caused by medical management and that results in measurable disability.
- An *error* is the failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim. Errors can include problems in practice, products, procedures, and systems.
- A *preventable adverse event* is an adverse event that is attributable to error.
- An *unpreventable adverse event* is an adverse event resulting from a complication that cannot be prevented given the current state of knowledge.
- A *near miss* is an event or situation that could have resulted in accident, injury, or illness but did not, either by chance or through timely intervention.
- A *medical error* is an adverse event or near miss that is preventable with the current state of medical knowledge.
- A *system* is a regularly interacting or interdependent group of items forming a unified whole.
- A *systems error* is an error that is not the result of an individual's actions but the predictable outcome of a series of actions and factors that make up a diagnostic or treatment process.

reporting system. In such systems, caregivers are often reluctant to discuss error out of concern that the error reports might be used against them.³⁴ If protected from disciplinary actions, however, they seem more willing to report problems.^{35,36} It is essential to recognize that when the introduction of an anonymous, nonpunitive reporting system leads to an increased number of error reports, this is more likely to be a reflection of previous underreporting than of deteriorating safety or quality.³⁷

Because of all these factors, it remains difficult to estimate the number of error-related medical injuries with precision. To some, that the rate of adverse events was lower in the Colorado/Utah study than in the HMPS suggests that safety is improving. This is encouraging if true, but there is still a great deal of room for further improvement.³⁸ Even if one accepts the more conservative estimates of error frequency, the aggregate number of fatal medical errors far exceeds that of more publicized nonmedical disasters. These lower estimates would not be tolerated in non-medical settings and should not be tolerated in patient care.

Shortcomings of Existing Quality-Improvement Methods

Clearly, there is no lack of efforts aimed at quality improvement. Unfortunately, many such efforts have notable shortcomings that prevent them from addressing current concerns about safety and quality in an optimal fashion.

Morbidity and mortality (M & M) conferences are perhaps the most traditional venue for discussion of adverse events. They do not consider all complications, however, nor are they consistently well attended.³⁹⁻⁴¹ Furthermore, M & M conferences tend to be intradepartmental, which means that there is often little opportunity to discuss system problems that may involve other departments. In addition, M & M conferences typically do not consider “near misses” (i.e., close calls), even though close calls are important in identifying both actual and potential system defects. Finally, M & M conferences have a tradition of blaming individuals rather than focusing on the circumstances within which the individuals acted. This tradition serves to perpetuate a defensive attitude among trainees that is counterproductive.

Continuing Medical Education (CME) focuses on the link between knowledge and quality of patient care. Although there is a clear relationship between CME and performance on board recertification examinations,⁴² the actual relationship between CME and better patient care is far more complex. There is evidence suggesting that performance on cognitive examinations is related to performance in practice^{43,44} and that board certification is linked with improved outcomes,⁴⁵ but the data are not conclusive. Systematic reviews of differences in the impact of various CME strategies on actual practice change have raised serious concerns about the value of some current CME.⁴⁶ The most effective change strategies (e.g., reminders, patient-mediated interventions, outreach visits, input from opinion leaders, and multifaceted activities) appear to be those that place substantial emphasis on performance change rather than just on learning.^{47,48}

Clinical pathways and guidelines, by standardizing medical processes, may help improve safety and quality, especially in high-risk procedures.⁴⁹ Some critics argue, however, that guidelines often do not apply to particular patients and can be difficult to use in patients with other, more urgent medical problems. Others suggest that guidelines are mostly beneficial in treatment and prevention and contribute little to diagnosis.^{50,51} Finally, guidelines may become outdated quickly.⁵²

Peer review, originally intended as a mechanism for professional self-evaluation, is subject to anticompetitive abuse as well

as other undesired consequences.⁵³ For instance, physicians who relinquish privileges on their own initiative may be more leniently treated than those against whom action was initiated by a peer review committee. The data reviewed by such committees often are legally discoverable, and the lack of anonymity and confidentiality of the data deters voluntary participation. Even when peer review does identify problems, it may be unable to implement solutions.

The shortcomings of hospital incident reports are similar to those of peer review. Incident reports also place limited emphasis on close calls and tend to lack systematic follow-up. Frequently, reporters are reluctant to file their reports out of fear that their employment might be jeopardized or that the reported party might seek retribution.

The present professional liability system is particularly controversial. Two of its most notable shortcomings are (1) that only a small percentage of cases of true medical injury ever become the basis of legal action and (2) that many of the claims that are brought have no merit.⁵⁴ In addition, the liability system compensates fewer than one in eight patients who are harmed; awards such compensation only after years of litigation; is based on determination of fault where experts cannot agree (often as a result of hindsight bias); and causes devastating emotional damage to physicians (and their families),^{12,55,56} which may adversely affect their problem-solving abilities. To the extent that experience with or fear of a malpractice action deters efforts at quality improvement, it is counterproductive. Yet another shortcoming of the liability system is that insurance premiums often are determined by economic factors outside the field of medicine and are not adjusted for claims experience. State legislative policy, ostensibly aimed at moderating liability crises, may have counterintuitive effects on median awards: whereas limits on awards for pain and suffering reduce total awards, limits on lawyers' fees actually increase them.⁵⁷

The National Practitioner Data Bank (NPDB) has many of the limitations of the liability system. It also contains information on settlements in which the merits of the case may not have been fully considered; to the extent that settlements may reflect monetary convenience or legal philosophy more than practitioner performance, this information may be misleading. The NPDB may also contain other inaccurate, incomplete, or inappropriate information.

Patient Care as a System

The magnitude of the medical quality problem and the shortcomings of current efforts to address this problem indicate that a change of approach is needed. Given the impressive success of systems approaches to safety and quality improvement in non-medical settings, it is worthwhile to consider taking a similar approach to patient care.

A system may be broadly defined as a regularly interacting or interdependent group of items that form a unified whole; in the context of patient safety, the term system refers to the individual components of care. A simple system may involve a specific task; a complex system may involve smaller, simpler subsystems. The complexity of a system derives both from the number of component subsystems and the interactions among them.

Systems become flawed when a problem in one or more steps or subsystems can lead to an undesired outcome. Overt problems are relatively easy to identify and correct; latent errors are more insidious. Latent errors are often introduced by people who work at the “blunt end” of the system (e.g., management or house-

keeping) but are not active participants. Such errors can then trap “sharp end” participants (e.g., anesthesiologists, nurses, or surgeons) into overt errors. A typical accident pathway is one in which organizational processes give rise to latent errors, latent errors produce system defects that may interact with external events in generating unsafe acts, and unsafe acts precipitate an active failure that then penetrates a safety barrier.⁵⁸ Indeed, in a complex system, the greatest risk of an adverse event may come not from a major subsystem breakdown or isolated operator errors but from the unrecognized accumulation of latent errors.⁵⁹⁻⁶¹ Such was the case with the explosion of the *Challenger*.⁶²

The probability that a system flaw will result in an adverse outcome reflects the probability of error within each step or component of the larger system, the total number of steps or components, and the degree of coupling among the steps or components. Errors in tightly coupled systems are more likely to propagate than those in loosely coupled systems. For example, the probability of a successful outcome in a tightly coupled, linear 20-step process with a 1% error rate per step is 0.99 factored 20 times, or 0.818. In loosely coupled systems, a successful outcome is less dependent on satisfactory completion of each step. The usual trade-off for this additional safety is greater system complexity, which can itself introduce errors. It also must be kept in mind that the presence of latent errors can make systems appear to be more loosely coupled than they actually are.

Consideration of these general characteristics of systems reveals many areas where they are applicable to medicine—in particular, to surgery and anesthesiology. Moreover, in a number of respects, the habitats of surgeons (e.g., the OR, the ICU, and the ED) resemble those seen in various high-tech, high-risk non-medical industries, and strong parallels have been noted between behavioral issues on the flight deck and observed behavior in the OR.^{63,64} It is more than coincidence that the ICU, with its emphasis on technology, is a common site of adverse events.^{65,66}

The usefulness of considering patient care as a system may be seen by examining some of the issues surrounding technology. To understand the role of technology in a system, it is necessary to understand not only the devices and techniques involved but also the people using the technology and the means by which they interact with the system. Each change in technology initiates a new learning cycle, and the resulting environment is one that is especially conducive to error.⁶⁷ It is relatively unusual, however, for an isolated error to lead to a system failure; instead, such failures typically involve multiple malfunctions, either occurring within a single element of the system or spread out across more than one element.

The potential value of a systems approach to patient care is further suggested by data associating improved outcomes associated with higher hospital or surgeon volume.^{68,69} Whether “practice makes perfect” or “perfect makes practice” remains unresolved, but in either case, it seems likely that the improved outcomes are a reflection of better care systems. That some high-volume hospitals and surgeons have below-average outcomes and many low-volume hospitals and surgeons have excellent ones is consistent with this view.⁷⁰

Additional supportive evidence comes from critical incident analyses of adverse surgical events,⁴¹ which reveal that the same types of factors that contribute to nonmedical system failures also contribute to adverse surgical events. Of these factors, the three most common are inexperience (on the part of both residents and attending surgeons), breakdowns in communication (e.g., handoffs and personnel conflicts), and fatigue or excessive workload. Often, these factors interact. For example, there seems

to be a tradeoff between problems related to fatigue and those related to handoffs: reducing the former increases the latter, and vice versa.

The similarities between medical and nonmedical systems notwithstanding, it must be recognized that medical systems are distinctive with respect to complexity of content and organizational structure. Whereas nonmedical systems are typically managed vertically through hierarchical control, patient care systems tend to comprise numerous diverse components that are only loosely aggregated.⁷¹ Within the patient care system, subsystems (including quality improvement components) tend to function in isolation, and intrasystem changes tend to be managed laterally across individual subsystems. The result, all too often, is inefficient or even contradictory policies, which increase the chances of error.

Basic Principles of Human Performance and Human Error

Systemic factors are not the sole cause of system failure; human factors play a role as well. A great deal of work has been done on analyzing human error and its relationship to performance.⁷² The overall implication of this work is that to achieve meaningful improvements in safety and quality, it is necessary to shift the focus from fallible individuals to the situational and organizational latent failures that these individuals inherit.⁵⁸

Human performance may be classified as skill-based, rule-based, or knowledge-based behavior, as follows⁷³:

1. Skill-based performance is governed by stored patterns of pre-programmed instructions, and it occurs without conscious control. Such performance makes use of long-term memory.
2. Rule-based performance involves solving problems through stored rules of the if-then variety. Like skill-based performance, it uses long-term memory; however, unlike skill-based performance, it is associated with a consciousness that a problem exists.⁵⁹ The rules are usually based on experience from previous similar situations and are structured hierarchically, with the main rules on top; their strength is an apparent function of how recently and how frequently they are used.⁷² Rule-based performance varies according to expertise: novices tend to rely on a few main rules, whereas experts have many side rules and exceptions.
3. Knowledge-based performance involves conscious analytic processes and stored knowledge. It relies on working memory, which is comparatively slow and of relatively limited capacity. Typically, people resort to knowledge-based performance when their skills are inapplicable or their repertoire of rules has been exhausted.

Successful problem solving has three main phases: planning, storage, and execution. The errors resulting from failures in performance may be classified as slips, lapses, or mistakes,⁶⁰ depending on which phase of the problem-solving sequence is involved. Slips are failures of the execution phase or storage phase, or both, and may occur regardless of whether the plan from which they arose was adequate; lapses are storage failures. Generally, slips are overt, whereas lapses are covert. Mistakes are failures of planning, reflecting basic deficiencies or failures in selecting an objective or specifying the means to achieve it, regardless of how well the plan was executed.

Specific types of errors tend to be associated with specific modes of failure [see Table 3].⁶⁰ Slips and lapses are failures of skill-based performance and generally precede recognition of a

Table 3 Common Modes of Failure Associated with Specific Types of Performance⁶⁰

Failures of Skill-Based Performance	
<i>Inattention</i>	<i>Overattention</i>

Failures of Knowledge-Based Performance	
Selectivity Workspace limitations Out of sight, out of mind Confirmation bias Overconfidence	Biased reviewing Illusory correlation Halo effects Problems with causality Problems with complexity

problem. Mistakes may be either failures of knowledge-based performance (i.e., attributable to lack of expertise) or failures of rule-based performance (i.e., attributable to failure of expertise). They typically arise during attempts to solve a problem. Mistakes tend to be more subtle, more complex, and less well understood than slips or lapses and thus more dangerous.

Two other important sources of error are underspecification of the problem and confirmation bias. Underspecification occurs when a problem seems ill-defined, whether because limited attention is paid, because the wrong cues are picked up, because the problem is truly ill-defined, or because the problem falls outside the rules known. Underspecification is more likely to occur in situations where cues change dynamically or are ambiguous— notable characteristics of surgical practice. The two most common error forms associated with underspecification are similarity matching and frequency bias (or frequency gambling). In similarity matching, a present situation is thought to resemble a previous one and consequently is addressed in the same (not necessarily appropriate) way. In frequency gambling, a course of action is chosen that has worked before; the more often that course of action has been successfully used, the more likely it is to be chosen. These behavior patterns have been confirmed among anesthesiologists, who, like many dynamic decision makers, use approximation strategies (or heuristics) to handle ambiguous situations.⁵

Confirmation bias is the propensity to stick with a chosen course of action and to either interpret new information so as to favor the original choice or else disregard such information entirely. Also referred to as cognitive fixation, cognitive lockup, or fixation error, it is often associated with knowledge-based performance.⁷⁴ Confirmation bias is particularly likely in unusual or evolving situations and when there is concomitant pressure to maintain coherence²⁵—again, notable characteristics of surgical practice.

The above classifications explain basic behavioral mechanisms but may be modified to meet specific needs.³⁴ Some authorities classify error according to whether it can be addressed by engineering, design, societal, or procedural changes; others emphasize psychological intervention and modification; and still others classify errors by their mode of appearance. As an example, classification by mode of appearance might include errors of omission, errors of insertion, errors of repetition, and errors of substitution (e.g., misadministration of lidocaine, heparin, or potassium chloride as a result of poor package labeling).

Performance and Error in Clinical Context

The application of the above concepts of performance and error to patient care is hampered by disagreements over whether human error is distinct from human performance.^{58,59,75} It has been argued (1) that assignment of error is often retrospective and subject to hindsight bias and (2) that the term error is inherently prejudicial, retarding rather than advancing understanding of system failure and tending to evoke defensiveness from physicians rather than constructive action.⁵⁹ These arguments notwithstanding, elimination of human errors is clearly an impossible goal: a more realistic goal is to understand what causes errors and to minimize or, if possible, eliminate their consequences.

There is also some disagreement about the applicability of these concepts (which derive from analysis of well-structured, well-understood technical systems) to the more complex issues of patient safety and quality of care.⁶¹ Besides the possible relationships already suggested, the concepts of performance and error can in fact be explicitly linked with two widely accepted quality-of-care paradigms. In the IOM paradigm, inappropriate care is categorized as attributable to overuse, misuse, or underuse.⁷⁶ Overuse is triggered by mistakes (sometimes rule-based but more often knowledge-based) but rarely, if ever, by slips or lapses. Underuse is triggered by mistakes or lapses, but not by slips. Misuse is caused by all three kinds of errors.⁷⁷ In the Donabedian paradigm, quality is framed in terms of structure, process, and outcome.⁷⁸ Faulty processes do not always result in adverse outcomes, but considering the process of care is as important as considering the outcome.

Regardless of which psychological construct of performance and error one may subscribe to, there is substantial evidence that performance is affected by the context of the problem. The main elements that define context are knowledge factors, attentional dynamics, and strategic factors.²⁵ The first two elements are self-explanatory. Strategic factors include an individual's physical and psychological well-being, and in this regard, the effects of sleep deprivation and fatigue on performance and learning are major concerns.^{79,80} Fatigue, by impairing vigilance, can accentuate confirmation bias. In addition, errors increase as time on task increases; no other hazardous industry permits, let alone requires, employees to regularly work the long hours common in hospitals.⁷⁴ Stress may increase the likelihood of error, but it is clearly neither necessary nor sufficient for cognitive failure.⁶⁰ Unfortunately, some physicians hold unrealistic beliefs about their ability to deal with stress and fatigue and so may not seek help when they need it.⁸¹

In situations involving a plethora of tasks, mental overload may compromise the ability to respond to secondary tasks. Errors related to loss of vigilance include not observing a data stream at all, not observing a data stream frequently enough, and not observing the optimal data stream for the existing situation. Although vigilance is essential, even vigilant practitioners may

experience failures of observation that lead to adverse events. In watching for rare occurrences, it is difficult to remain alert for longer than 10 to 20 minutes; thus, knowing when and how to verify data is an important metacognitive skill.

Psychological framing effects also play a role in error. Examples of such effects are the irrational preference for established treatments when outcomes are framed in terms of gain (e.g., survival) and the similarly irrational preference for risky treatments when outcomes are framed in terms of loss (e.g., mortality). The impetus to “do the right thing” can facilitate error.⁶²

Patient care often involves team behavior, and such behavior can affect individual performance.^{5,74} Lack of cohesion and mutual support among team members can compromise performance. Too informal a team structure may undermine patterns of authority and responsibility and hinder effective decision-making. Conversely, too strong a hierarchy may make it excessively difficult for juniors to question decisions made by those at higher levels of authority. Rigid behavior may impair the ability to cope with unforeseen events and discourage initiative.

For good teamwork, it is essential that team members share a clear understanding of what is happening and what should happen. This understanding is referred to as situational awareness.⁷⁴ Unfortunately, there is a common tendency to believe that the prevailing level of situational awareness is higher than it is. For example, the aviation industry improved its safety record when it identified and removed barriers impeding junior officers from communicating with the captain, and these improvements occurred after good communication was already thought to exist.⁸²

In the OR, teams consist of crews from nursing, surgery, and anesthesia. As an example of suboptimal situational awareness, the various crews often have fundamentally different perceptions of their respective roles. Anesthesiologists and nurse anesthetists are much more likely to feel that a preoperative briefing is important for team effectiveness than surgeons and surgical nurses are, whereas surgeons and surgical nurses are more likely to feel that junior team members should not question the decisions of senior staff members.⁸³ Such varying perceptions not only can compromise patient safety but also represent lost opportunities for teaching or learning. Unfortunately, there is often little consensus on how optimal team coordination should be achieved.

The importance of teamwork issues in the OR is illustrated by a study that analyzed time needed to learn minimally invasive cardiac surgery.⁸⁴ On the fast-learning teams, the members had worked well together in the past, they went through the early learning phase together before adding new members, they scheduled several of the new procedures close together, they discussed each case in detail beforehand and afterward, and they carefully tracked results. Of particular interest was that surgeons on the fast-learning teams were less experienced than those on the slow-learning teams but more willing to accept input from the rest of the team.

Communication and teamwork are also important in the emergency department. One study reported an average of 8.8 teamwork failures per malpractice incident, with more than half of the deaths and permanent disabilities judged to be avoidable.⁸⁵

The key message is that errors frequently are a product of the context in which they occur. It is tempting to assume that a few “bad apples” are responsible for most safety and quality problems. In reality, however, bad apples are relatively few, and they account for only a small percentage of medical errors. To achieve significant overall improvements in quality, all physicians will have to make efforts to improve the context in which patient care

is delivered. In addition, nonphysicians will have important roles to play, as illustrated by studies relating nurse staffing levels to quality of care.^{86,87}

Examples of Systems Approaches to Improving Quality

Given the complexity of health care, embarking on a systems approach to safety improvement may seem a daunting prospect. Accordingly, it is worthwhile to look at examples of successful quality improvement systems that have already been implemented.

Anesthesiologists were among the first physicians to take such an approach to safety, and the success of their efforts is irrefutable: anesthesia-related mortality has fallen from approximately 2/10,000 to the current 1/200,000 to 1/300,000⁸⁸⁻⁹⁰—a degree of safety approaching that advocated for nonmedical industries (i.e., < 3.4 defects or errors/10⁶ products or events).⁹¹ This improvement is primarily the result of a broad effort involving teamwork, practice guidelines, automation, procedure simplification, and standardization of many functions. Previously, for instance, there was no standard design for anesthesia machines, and it was not unusual for more than one type to be in use in the same hospital. This is no longer the case. It is clear that considerable benefit can be derived from a better appreciation of the human-technology interface and the ergonomics of equipment design.⁹²

Successful surgical examples exist as well, such as the Northern New England Cardiovascular Disease Study Group,⁹³ Intermountain Health Systems in Utah, and the Maine Medical Assessment Foundation.⁹⁴ These examples share four important characteristics: (1) providers responded to practice variations by participating in outcomes research; (2) voluntary, physician-initiated interventions were as effective as, if not more effective than, external regulatory mechanisms in reducing morbidity and mortality; (3) a systems approach to quality improvement produced better results than a bad-apple approach; and (4) quality-improvement programs successfully included groups that otherwise might have been competitors. None of these efforts increased liability exposure; often, they reduced it. Because the practice profiles were physician-initiated, there was little risk that the findings would be used to make decisions about credentialing, reimbursement, or contracting.⁹⁴ In addition, the funding parties (including insurers) usually agreed to confidentiality in return for the benefit associated with voluntary physician involvement.

Trauma care has also benefited from a systems approach. A study of 22,000 patients from a regional trauma system concluded that the most common single error across all phases of care was failure to evaluate the abdomen appropriately.⁹⁵ Errors in the resuscitative and operative phases were more common, but errors in critical care had the greatest impact on preventable mortality. The perception of preventability increased in parallel with appreciation of the importance of the system.

Another example is the Veterans Affairs National Surgical Quality Improvement Project (NSQIP),⁹⁶ which consists of comparative, site-specific, and outcomes-based annual reports; periodic assessment of performance; self-assessment tools; structured site visits; and dissemination of best practices. After the inception of data collection, 30-day mortality after major procedures decreased by 27% and 30-day morbidity by 45%. The NSQIP also identified risk factors for prolonged length of stay after major elective surgery; the most important of these were intraoperative processes of care and postoperative adverse events.⁹⁷ Other notable findings of the project were (1) that for a number of common procedures, there were no statistically significant associations between procedure or specialty volume and

30-day mortality and (2) that savings from improved surgical care far exceeded investment in the project.⁹⁸ The NSQIP is now expanding into academic medical centers with the aim of achieving comparable results there.

The conspicuous success of these large-scale examples should not obscure the fact that most successful efforts have been on a smaller scale in single institutions.^{77,99} Thus, individual efforts at quality improvement are not incidental but essential.

Identifying Systems and System Failures

The intensive systematic investigation of quality problems is known as root cause analysis (RCA). The first step in such analysis is to identify the specific area to be studied. One approach is to focus on an area of recurring concern (e.g., habitual misuse of medical devices) or on the result of a particular critical incident that should never have happened or must never happen again. Both the JCAHO and the NQF have identified some of these “never” events and suggested methods for avoiding them; the NQF has also drafted additional proposals suitable for evidence-based practices. Another approach is to monitor an area where there is no immediate concern but where a recent change in policy or equipment might introduce unanticipated problems. A useful source for specific topics is the online journal created by the Agency for Healthcare Research and Quality, *AHRQ WebM&M* (www.webmm.ahrq.gov). This free site includes expert analysis of medical errors in five specialty areas (including surgery), as well as interactive learning modules on patient safety.

In the absence of a specific safety or quality concern, it may be worthwhile to focus on an area where quality-improvement efforts are likely to be fruitful—for instance, patient notification systems,⁷⁷ patient safety systems,¹⁰⁰ analyses of system failures in laparoscopic surgery,¹⁰¹ or analyses of medical microsystems.¹⁰² Critical analyses of evidence-based practices identified 11 surgically relevant quality-improvement practices for which the data are strong enough to support more widespread implementation [see Table 4].^{103,104} It has been argued, however, that exclusive

emphasis on evidence-based data might lead to skewed prioritization of safety measures and thus might prevent relatively few adverse events.¹⁰⁵

Finally, one might focus on an area where there is unexplained variation in a relevant outcome measure. Such variation might exist in reference to either an internal or an external benchmark (the latter being preferable).⁴⁹

An area for evaluation having been identified, the second step is to identify the relevant subsystems and all of their components. This can be challenging, particularly with complex systems. It is advisable to start by assembling a team whose members represent all the possible components. Being inclusive rather than exclusive minimizes the chances of missing latent errors; it also, at least potentially, maximizes the number of possible solutions.

The next step is to determine the appropriate data source. Medical-record audits yield far greater detail than claims data do, but such audits are expensive, labor-intensive, and time-consuming. Moreover, the information the records contain on environment or behavior may be irrelevant or even contradictory. Screening criteria can help identify and reduce some of these problems.¹⁰⁶ Use of administrative data can help avoid many of the shortcomings of medical-record review, but such data often lack the requisite accuracy. In either type of analysis, it is important to remember that the process is evolutionary: it is rare that one starts with a perfect set of measures.

It may be difficult to generate interest in analyses of a critical incident whose causes are so unusual that they are unlikely ever to combine in the same way again in a given institution. Although the findings from such an analysis might seem to be of little use, the incident might occur frequently enough at a regional or national level to make the analysis worthwhile. Thus, it is important to tabulate such seemingly rare incidents (including near misses) even if there is little direct or immediate institutional benefit. Besides their potential value in larger contexts, such data might help the institution predict, and thereby avoid, other forms of errors (especially latent ones) and system failures. The strategy of making potential adverse consequences of latent errors visible to those who manage and operate similar systems is the basis of the highly successful Aviation Safety Reporting System.⁵⁸

Some industries have modified RCA to meet particular needs, including health care.^{67,73} A manual for RCA use in patient care is available through the JCAHO, and various centers and hospitals have reported on RCA use.^{107,108} RCA can be automated,¹⁰⁹ but the potential advantages of automation may be offset by dependence on the developer’s interpretation of the risk reduction process or by the factors identified as the principal event.

General Techniques for Safety Improvement

Many safety-improvement techniques derived from nonmedical systems have been successfully applied to medical systems [see Table 5].^{110,111} Other successful strategies include prioritization of tasks, distribution of the work load over time or resources, changing the nature of the task, monitoring and checking all available data, effective leadership, open communication, mobilization and use of all available resources, and team building.⁵ The general idea is to redesign the problem space to reduce the cognitive work load.^{73,112}

A key step in improving patient safety is the establishment of a safety culture throughout the workplace. An appropriate culture views errors as they are viewed in control theory—namely, as signals for needed changes. The focus should be on learning rather than on accountability. If the team or organization is designed to

Table 4 Surgically Relevant Quality-Improvement Practices Appropriate for Widespread Implementation¹⁰³

- Appropriate use of prophylaxis to prevent venous thromboembolism in patients at risk
- Use of perioperative beta blockers in appropriate patients to prevent perioperative morbidity and mortality
- Use of maximum sterile barriers while placing central venous catheters to prevent infection
- Appropriate use of antibiotic prophylaxis to prevent postoperative infections
- Requesting that patients recall and state what they have been told during the informed consent process
- Continuous aspiration of subglottic secretions to prevent ventilator-associated pneumonia
- Use of pressure-relieving bedding materials to prevent pressure ulcers
- Use of real-time ultrasound guidance during central line placement to prevent complications
- Patient self-management for warfarin to achieve appropriate outpatient anticoagulation and prevent complications
- Appropriate provision of nutrition, with particular emphasis on early enteral nutrition in critically ill and surgical patients
- Use of antibiotic-impregnated central venous catheters to prevent catheter-related infections

Table 5 Nonmedical System Techniques Also Applicable to Medical Systems

Simplify or reduce handoffs	Adjust work schedules
Reduce reliance on memory	Adjust the environment
Standardize procedures	Improve communication and teamwork
Improve information access	Decrease reliance on vigilance
Use constraining or forcing functions	Provide adequate safety training
Design for errors	Choose the right staff for the job

learn from and benefit from experience, its collective wisdom should be greater than the sum of its individual members. Needed changes often involve difficult choices among strategic factors, and sometimes, they introduce new latent errors.^{41,102} Accordingly, once a change in procedure or policy has been implemented, its impact must be closely monitored.¹¹³

Some unintended consequences may result from the inherent limitations of a safety-improvement strategy. For example, simplification is desirable, but oversimplification can itself generate problems.²⁵ As another example, tightly coupled high-risk industries (e.g., aviation and nuclear power) commonly use redundant processes to enhance reliability; yet the benefits of such redundancy are frequently offset by greater complexity and a consequent increase in the risk of human failure.⁷⁴ In addition, the more complex the system, the greater the chance that a change will have effects beyond the local. A central problem in error management is how to control particular errors without relaxing control over others.^{74,114}

Computer-based technology is often touted as a valuable tool for improving safety and quality.^{74,115} For instance, there is strong evidence that computers can reduce medication errors¹¹⁶ and facilitate weaning from ventilators.¹¹⁷ Nevertheless, acceptance of computerization has been neither easy nor universal. Computerized ventilator weaning, though ultimately successful, was initially resisted,¹¹⁸ and programs developed for hematology and rheumatology appear not to have gained clinical favor.¹¹⁵ A greater emphasis on computer literacy during training might facilitate effective incorporation of computer technology into subsequent practice.

One concern that has arisen with respect to computer technology in medical systems is that if computerized advice-giving systems become widespread, caregivers might become excessively dependent on them, perfunctorily acceding to the computer's advice at the expense of their own judgment. Issues of legal liability might then arise as to how much computer advice is too much and whether relying on such advice is tantamount to abandoning responsibility for critical independent thought.

Many patient care tasks may in fact be too complex for computerization and therefore better suited to human performance. The trade-off for retaining human ability to deal with such complexity is human susceptibility to error, which means that systems relying on error-free human performance are destined to experience failures. Because the kinds of transitory mental states that cause errors are both unintended and largely unpredictable, they are the last and least manageable links in the error chain.

Obstacles to Safety Improvement

It has been observed, perhaps somewhat cynically, that every system is perfectly designed to achieve the results it gets.

Accordingly, it is not surprising that the variable incentives and structure of health care in the United States lead to highly variable patterns of care and a widespread failure to implement evidence-based practice.¹¹⁹ The result has been described as a cycle of unaccountability, in which no component of the system is willing to take substantial responsibility for safety and quality. Each component defers to another: regulators to accreditors, accreditors to providers, providers to insurers, insurers to purchasers, purchasers to consumers, and consumers to regulators, completing the cycle.

Specific obstacles to improving patient safety in the United States include (1) unawareness that a problem exists; (2) a traditional medical culture based on individual responsibility and blame; (3) vulnerability to legal discovery and liability; (4) primitive medical information systems; (5) the considerable time and expense involved in defining and implementing evidence-based practice; (6) inadequate resources for quality improvement and error prevention; (7) the absence of a demand for improvement; (8) the local nature of health care; and (9) the perception of a poor return on investment (i.e., the lack of a business case).^{120,121} Several of these obstacles are worth addressing in greater detail.

The traditional paradigm of surgical care is founded on the concept of physician autonomy and holds the individual surgeon accountable as the “captain of the ship.” Undoubtedly, this paradigm has enabled great achievements in surgical care; however, it has also, in some cases, become associated with a dangerous sense of infallibility. With this paradigm as a conceptual backdrop, errors tend to be equated with negligence, and questions of professional liability tend to involve blaming individuals. Indeed, the very willingness of professionals to accept responsibility for their actions makes it convenient for lawyers to chase individual errors rather than collective ones.⁵⁸ Moreover, an individual surgeon is a more satisfactory target for an individual's anger and grief than a faceless organization is. The point is not that surgeons should avoid responsibility but rather that focusing on individual errors does not address underlying system flaws.

With the evolution of contemporary surgical practice, this paradigm may have to be rethought. The burgeoning growth of knowledge, the attendant increase in specialization, the expanding role of technology, and the rising complexity of practice are making surgeons more and more dependent on persons or factors beyond their immediate control. As a result, surgeons are finding it more and more difficult to appreciate, let alone manage, the larger context within which they provide care, and they are finding that the traditional paradigm, once so successful, is becoming less useful [see Table 6].¹²² In an apparent paradox, improving patient safety demands an understanding of patient care systems—at the very time when those systems are becoming increasingly difficult to understand.

Table 6 Contrasting Characteristics of Medical Practice in the 20th and 21st Centuries¹²²

20th-Century Characteristics	21st-Century Characteristics
Autonomy	Teamwork/systems
Solo practice	Group practice
Continuous learning	Continuous improvement
Infallibility	Multidisciplinary problem solving
Knowledge	Change

The current system of professional liability is frequently cited as an obstacle to quality improvement. Unfortunately, there is little incentive for change among many of the vested interests involved. The many millions of dollars spent on public advertising and political lobbying are likely to produce little change and could be better spent in direct efforts to improve safety. No-fault compensation, no-fault reporting systems, and a program of research have been proposed as alternatives,^{123,124} but all of these proposals appear to have shortcomings.¹²⁵ Moreover, patients' loss of trust in many health care providers has allowed lawyers to gain leverage with the argument that they act on behalf of the "little guy."

Many physicians believe that for significant improvements in quality to be achieved, a major reform of the professional liability system is essential. Certainly, tort reform is necessary, but the real prerequisite for better identification and management of system failures is increased protection for privileged discussion of such failures.¹²² Indeed, the Quality Interagency Coordination Task Force argues that RCAs undertaken to determine the internal shortcomings of hospital care systems should not be subject to discovery in litigation and that appropriate legislation should be enacted in conjunction with or before the implementation of any reporting systems.³¹ The IOM supports a larger federal role in these efforts.

The importance of liability reform notwithstanding, the issues involved in enhancing safety and quality are more involved than can be addressed solely by changes in the liability system. For instance, safety and quality problems are known to exist in nations where professional liability is not an issue. In addition, it is clear that physicians still tend to act defensively even in a no-fault liability system. Minimizing such defensiveness requires that greater emphasis be placed on measurement for improvement than on measurement for judgment.^{126,127}

Fortunately, there appears to be a growing sense that open discussion of medical errors is appropriate.⁶⁰ Moreover, it seems that such open communication may both reduce the probability of legal action and enhance public confidence in providers. Nevertheless, some hospitals continue to separate risk management from quality-assurance issues, to the detriment of both.¹²⁸

Building a strong business case for quality improvement is complicated because even when there is good evidence that improving quality is cost-effective, the parties involved may disagree on who should be rewarded and what the reward should be.^{119,120,129} Thus, if physician-related quality improvements financially benefit a managed care company rather than a physician, physicians might have little incentive to implement them—or even some incentive not to. Accordingly, it would seem sensible to focus initial quality-improvement efforts on areas where the various interests are aligned.¹³⁰ Even then, however, caution is needed. For example, one study found that 24% of physicians faced incentives derived from patient-satisfaction surveys, 19% faced incentives derived from quality-of-care measures, and 14% faced incentives derived from profiling based on use of medical resources.¹³¹ Patient satisfaction is important from the perspective of continuity of care, but it is not clear how improved patient satisfaction alone might address problems of overuse and misuse.

Some have suggested that aggressive quality-improvement efforts might make health care costs more difficult to control. It must be acknowledged, however, that to date, neither voluntary action by the health care industry, managed care, nor market competition appears to have achieved such control. For the most part, the emphasis has been on managing cost rather than reducing waste. Yet waste is essentially a synonym for poor quality, and

it is by no means evident that improving quality would cost more. Correcting underuse might increase costs, but such increases might well be outweighed by savings from correcting overuse and misuse. Given that current market approaches to health care have yet to contain costs, it would seem appropriate to at least attempt quality improvement before resorting to rationing.

Other economic considerations also factor into the lack of a coherent business case for quality improvement. For instance, sophisticated medical information systems are a necessity today; however, such systems often remain in a relatively primitive state because the fear of technical obsolescence makes buyers reluctant to capitalize new systems. Thus, while potentially usable data accumulate, the ability to extract meaningful information may deteriorate, making it more difficult and costly to define and implement evidence-based practice.

Future Implementation of Quality-Improvement Efforts

Given that quality improvement is both necessary and possible, the question then becomes, who should spearhead this process? Although consumers, purchasers, government, insurers, academic medicine, organized medicine, and health care providers all hold stakes in the process, it is physicians, with their history of patient advocacy and scientific innovation, who are best situated to provide the needed leadership.^{121,128} Such advocacy and innovation are a primary basis of the trust placed in the medical profession; to decline the challenge to improve health care quality may seriously undermine this trust. When trust is forfeited, the consequences can be dire, as the recent history of the accounting industry illustrates.

Excellent examples of physician-led efforts at quality improvement exist, but they remain relatively isolated. Unless physicians act to expand such efforts significantly, groups outside the profession are likely to fill the void and possibly close the window of opportunity for physician leadership. For instance, the Leapfrog Group (<http://www.leapfroggroup.org>), which represents more than 26 million Americans, has already conducted hospital surveys regarding computerized drug orders, ICU physician staffing, coronary artery bypass surgery, coronary angioplasty, abdominal aortic aneurysm repair, carotid endarterectomy, esophageal cancer surgery, high-risk obstetrics, and neonatal critical care, with a particular eye to identifying preventable adverse events and evaluating the relation between volume and outcome.

One potential policy implication of these findings is that health care purchasers might adopt policies that transfer patients needing a particular procedure to high-volume providers with demonstrated good outcomes.¹³² Such policies might affect the overall distribution of health care services and unfairly penalize low-volume, high-quality providers, while teaching us little or nothing about precisely which system components are relevant to improved outcome. The data on volume-outcome relations are intriguing, but many of the studies done to date have major methodological problems.^{68-70,102} Moreover, the majority of patients and physicians are not convinced that such regionalization would be effective.² For now, at least, it seems premature to adopt such a policy.

For any successful improvement in patient safety, an effective reporting system is vital. It is generally agreed that such systems should be being nonpunitive and strictly confidential (if not anonymous).¹³³ There is some debate, however, as to whether they should be voluntary or mandatory. On one hand, voluntary reporting has a high inaccuracy rate even when mandated by state or federal regulations. On the other hand, many surgeons

believe that mandatory reporting may increase the pressure to conceal errors rather than analyze them; that it is unworkable in the current legal system; and that it may result not in constructive error-reducing solutions but merely in more punishment or censure.¹³⁴

There is also some debate as to whether patient-safety efforts should (at least initially) focus on medical injuries or on medical errors.^{135,136} An approach focusing on injuries recognizes the difficulty of identifying medical errors and is based on a public health improvement model that has proved useful in addressing other types of injuries; it also recognizes that most medical injuries are not caused by negligence. Such an approach seems more compatible with the current liability system and may help restore physicians' stature as patient advocates. An approach focusing on errors suggests that focusing on injuries diverts attention from cases where there is an underlying system flaw, with the result that the flaw is not corrected. Although this is probably true, the first approach is likely to achieve greater initial buy-in on the part of physicians and thus may be a more pragmatic first step.

Successful change requires not only agreement that a change is necessary and desirable but also agreement on what the change should be. In that regard, the aviation industry is frequently proposed as a model for health care. However, aviation safety is enhanced by the availability of various monitors (e.g., flight data recorders) that supply information on aircraft position and flight conditions. A model applying these techniques to surgery has been described,¹⁰¹ but independent confirmation of relevant factors still seems impractical in most clinical surgical situations. Actually, surgery may be more akin to the maritime industry, in which the ship captain makes judgments about circumstances that are difficult to verify, than it is to the aviation industry. If so, it is probably relevant that the maritime industry has been less successful at safety improvement than the aviation industry has. In any case, there are many underutilized opportunities for quality improvement in health care, and the training lessons of aviation, whereby pilots are forced to deal with unusual situations that help reveal gaps or errors in their understanding, are one such opportunity. Even if the aviation model does not fully apply, its level of success should remain a goal.

Particular attention should be paid to incorporating current concepts of performance and error into surgical education.¹³⁷ An optimal structure for such education might be an objective-based curriculum that provides residents with defined skills, rules, and knowledge.^{138,139} The blame-and-shame approach must be eliminated from the learning atmosphere. Once made aware of their

tendencies in the presence of uncertainty, residents (like pilots) may develop better responses to underspecified situations. Residents should also be monitored to ensure that they learn to assess and address knowledge deficits as well as learn healthy habits in responding to errors. In this way, the learning curve can be made less painful for all concerned.¹⁴⁰

Conclusion

Error in medicine is a dauntingly complex topic, and the progress made in reducing such errors has, in many cases, been disappointingly slow. Unfortunately, changing the traditional paradigm is a far more complex task than the simplistic solutions often made by the popular media would suggest. A call for surgeons to report results, issued roughly 100 years ago, was largely ignored.¹⁴¹ At that time, however, the basic principles of human performance and error were not as well understood as they now are, and the tools necessary for systems analysis did not exist.

It is crucial for all parties involved in health care to acknowledge that most medical errors are attributable to system flaws rather than to incompetence or neglect. Moreover, it is important for physicians to lead the changes needed to make systems-based practice the norm. Support for such initiatives, if needed, will come from multiple sources, including patients, public and private sector purchasers, and specialty boards and societies.¹⁴² Making efforts to improve surgeon performance, patient safety, and the overall quality of surgical care not only is the right thing to do but also is in surgeons' own best interests.⁹ There is little doubt that performance assessment will increase; surgeons who do not assess their performance will be at a disadvantage to those who do.

Part of what is at stake is physicians' authority, in more than one sense of the word. Physicians do continue to enjoy unchallenged authority, in the sense of being conceded to possess specialized knowledge. However, in the sense of being able to control one's destiny, physicians' authority often seems to be slipping away into the hands of outside agencies. Much of the decline in the latter type of authority is a reflection of a decline in the public's overall trust in the profession. If physicians turn down the opportunity to lead the necessary efforts to improve patient safety and quality of care, they may anticipate further erosion of public trust and further loss of their remaining autonomy. The growing demand for accountability seems unstoppable. If surgeons provide the requisite leadership now, their ability to control their destiny is likely to be enhanced rather than further diminished.

4 RISK STRATIFICATION, PREOPERATIVE TESTING, AND OPERATIVE PLANNING

Cyrus J. Parsa, M.D., Andrew E. Luckey, M.D., Nicolas V. Christou, M.D., F.A.C.S., and Alden H. Harken, M.D., F.A.C.S.

In the midst of [the lungs] is seated a hot organ, the heart, which is the origin of life and respiration. It imparts to the lungs the desire of drawing in cold air, for it raises a heat in them; but it is the heart which attracts. If, therefore, the heart suffer primarily, death is not far off.

—Aretaeus of Cappadocia

Although no one truly wants to undergo a surgical procedure, the results of surgery can be highly gratifying to both patient and surgeon when the right operation is performed for the right reasons, accurately and expeditiously, on the right patient at the right time. In attempting to bring about this state of affairs, surgeons must consciously and honestly balance the physiologic, psychological, social, and financial insults of surgery against the anticipated benefits.¹ Of course, surgeons are not the only medical professionals who must perform this kind of balancing act; however, they are probably the most conspicuous.

Currently, the measures of both anticipated surgical risk and expected outcome are being assessed in an increasingly sophisticated manner under the umbrella of health care quality.² Mortality alone is no longer considered a sufficient indicator of the success or failure of treatment. Cost is no longer addressed only in absolute terms but is (appropriately) related to years of life saved. Therapeutic morbidity is now taken into account in figuring the cost of each quality-adjusted life year (QALY) saved. Age is considered not merely in terms of distance from the beginning of life but also, more importantly, in terms of proximity to the end of life.

It goes without saying that in balancing risks against benefits, surgeons as a group should make use of the best available evidence (e.g., from rigorous prospective trials). In the end, however, it is the responsibility of the individual surgeon to examine, digest, and individualize the morass of medical material relevant to each patient's disease and expected surgical outcome. This is key for developing not only the surgeon's ability to provide care but also the patient's ability to respond to it. Sensitive communication of the nature and severity of the disease and clear explanation of the proposed treatment are integral parts of the therapeutic process. A knowledgeable patient who participates in his or her treatment will get better faster. Finally, it is also incumbent on the surgeon to honor the extraordinary trust inherent in his or her relationship with the patient by providing ongoing psychological and social support during surgical therapy—even after such support might be deemed excessive. A patient must not be allowed to give up hope.

Our main aims in this chapter are (1) to assess approaches to the delineation of surgical risk, (2) to outline current thinking on the appropriate use of preoperative testing, (3) to highlight the importance of the patient's mental and emotional satisfaction with care as a component of outcome, and (4) to describe ways of reducing perioperative cardiac risk.

Assessment of Surgical Risk

Continuing refinement of the tools used to delineate levels of preoperative risk is permitting surgeons to “handicap” both patients and surgical procedures with greater and greater precision.^{3,4} It is clear, for example, that outcome assessment must incorporate a so-called sickness quotient—typically expressed in terms of the ratio of observed outcome to expected outcome (O/E)—into the assessment of therapeutic value.⁵ Obviously, if a surgeon operates only on Olympic-level athletes with single organ disease (or no disease at all), his or her patients will almost always do very well (or at least survive); one who operates on a more varied group of patients will have quite different results.

The most universally used classification system is the one developed by the American Society of Anesthesiologists (ASA), which is based on the patient's functional status and comorbid conditions (e.g., diabetes mellitus, peripheral vascular disease, renal dysfunction, and chronic pulmonary disease) [see Table 1].⁶ The ASA index generally associates poorer overall health with increased postoperative complications, longer hospital stay, and higher mortality. ASA classes I and II correspond to low risk, class III to moderate risk, and classes IV and V to high risk.

Besides functional capacity and comorbid conditions, age has also been shown to be a determinant of operative risk, as has the type of operation being performed (with vascular procedures and prolonged, complicated thoracic, abdominal, and head and neck procedures carrying higher levels of risk).

HISTORY AND PHYSICAL EXAMINATION

The initial history, physical examination, chest x-ray, and electrocardiographic assessment should focus on the identification of potential respiratory or cardiac disorders [see Table 2],⁷ emphasizing evaluation of the patient's cardiac status. High-risk cardiac conditions include recent myocardial infarction (MI), decompensated heart failure, unstable angina, symptomatic dysrhythmias, and symptomatic valvular heart disease. Underlying less acute cardiac conditions, though apparently stable at the time of assessment, may become manifest during perioperative stresses.⁸ Such conditions include stable angina, distant MI, previous heart failure, and moderate valvular disease. The review of symptoms should identify serious comorbid conditions such as diabetes, stroke, renal insufficiency, blood dyscrasias, and pulmonary disease.

Smoking

According to the American Heart Association, smokers made up a 40% smaller percentage of the U.S. population in 2003 than they did in 1965.⁹ Nevertheless, approximately one third of surgical patients are still smokers. Smoking is clearly a risk factor for perioperative complications,¹⁰ including pulmonary complications, circulatory complications, and an increased incidence of

Table 1 American Society of Anesthesiologists' Physical Status Classification: Nonemergency Surgery⁶

Classification	Description	Examples
Class I	Normal, healthy patient	An inguinal hernia in a fit patient or a fibroid uterus in a healthy woman
Class II	Patient with mild systemic disease—a mild to moderate systemic disorder related to the condition to be treated or to some other, unrelated process	Moderate obesity, extremes of age, diet-controlled diabetes, mild hypertension, chronic obstructive pulmonary disease
Class III	Patient with severe systemic disease that limits activity but is not incapacitating	Morbid obesity, severely limiting heart disease, angina pectoris, healed myocardial infarction, insulin-dependent diabetes, moderate to severe pulmonary insufficiency
Class IV	Patient with incapacitating systemic disease that is life threatening	Organic heart disease with signs of cardiac insufficiency; unstable angina; refractory arrhythmia; advanced pulmonary, renal, hepatic, or endocrine disease
Class V	Moribund patient not expected to survive 24 hr without an operation	Ruptured aortic aneurysm with profound shock, massive pulmonary embolus, major cerebral trauma with increasing intracranial pressure

surgical site infection. Numerous mechanisms contribute to the deleterious effects of smoking: smoking inhibits clearance of pulmonary secretions, adversely affects the immune system and collagen production, and contributes to wound hypoxia (thereby increasing susceptibility to infection).¹¹ Some studies have suggested that even passive smoking can reduce blood flow velocity in the coronary arteries of healthy young adults.¹²

A 2002 trial demonstrated that preoperative smoking cessation reduced the incidence of postoperative complications from 52% to 18%.¹⁰ A 2003 study reported similar results: patients who stopped smoking 4 weeks before operation had significantly lower postoperative wound infection rates than patients who continued to smoke up to the time of operation.¹¹ Ideally, cessation of smoking at least 4 to 6 weeks before operation is recommended.

Alcohol Abuse

The effects of chronic alcohol abuse on perioperative risk are not as well studied as those of smoking. Alcohol abuse has been defined as the consumption of at least five drinks (containing more than 60 g of ethanol) daily for several months or years.¹³ (These numbers are probably appropriate for 70 kg men but may be modified in other populations.) The pathogenic mechanism is certainly multifactorial but is postulated to involve ethanol-mediated suppression of the immune system; this immune suppression is reversible, at least during abstinence in nonsurgical patients. Other deleterious effects of chronic alcohol ingestion include alcoholic cardiomyopathy, decreased platelet count and function, reduced fibrinogen level, and compromised wound healing. Various alcohol abstinence periods, ranging from 1 week to 3 months, have been reported to decrease these adverse effects.¹⁴

Long-term abuse of alcohol is often associated with central nervous system impairment and hepatic dysfunction, as well as malnutrition. Alcohol abusers, even those who exhibit no overt alcohol-related organ dysfunction, experience greater morbidity than nonabusers and exhibit longer recovery times.¹⁴

PREOPERATIVE TESTING

It was once generally agreed that surgical patients should undergo a series of routine screening tests before operation. This approach has proved not only unhelpful but also confusing and expensive. Perhaps predictably, it has been observed that the more tests are ordered, the more abnormal values are obtained. On the reasonable assumption that a test performed in a healthy person will yield an abnormal result 5% of the time, when 10

such tests are ordered, there is a 50% probability of an abnormal test result.¹⁵ When an SMA-20 is ordered, the probability of an abnormal test result is quite high. Moreover, although these abnormalities are reported, they rarely alter the physician's behavior or result in cancellation or postponement of the operation [see Table 3].¹⁵ Accordingly, current practice is to take a much more selective approach to preoperative laboratory evaluation.

FACTORS AFFECTING CARDIAC RISK

Previous and Current Cardiovascular Disease

In the United States, approximately 30% of the 27 million patients scheduled to undergo anesthesia for surgical procedures yearly are known to have risk factors for coronary artery disease (CAD).⁸ Given that cardiovascular disease is the leading cause of death in the United States,⁹ it is not altogether surprising that cardiovascular factors account for the greatest proportion of operative risk. Significant cardiovascular risk factors include angina pectoris, dyspnea and evidence of right-side or left-side heart failure, any cardiac rhythm other than sinus rhythm, more than five ectopic ventricular beats per minute, aortic stenosis with left ventricular hypertrophy, mitral regurgitation, and previous MI. An estimated 1 million patients scheduled to undergo elective noncardiac surgical procedures experience a perioperative complication each year in the United States, and another

Table 2 Minimal Preoperative Test Requirements* at the Mayo Clinic⁷

Age (yr)	Tests Required
< 40	None
40–59	Electrocardiography, measurement of creatinine and glucose
≥ 60	Complete blood cell count, electrocardiography, chest roentgenography, measurement of creatinine and glucose

*In addition, the following guidelines apply. (1) A complete blood cell count is indicated in all patients who undergo blood typing and who are crossmatched. (2) Measurement of potassium is indicated in patients taking diuretics or undergoing bowel preparation. (3) Chest roentgenography is indicated in patients with a history of cardiac or pulmonary disease or with recent respiratory symptoms. (4) A history of cigarette smoking in patients older than 40 years who are scheduled for an upper abdominal or thoracic surgical procedure is an indication for spirometry (forced vital capacity).

Table 3 Effect of Abnormal Screening Test Results on Physician Behavior¹⁵

Screening Test	Abnormal Test Results (%)	Resulting Management Change (%)
Hemoglobin level	5 (for < 10 g/dl; < 9 g/dl was rare)	Abnormal result rarely led to change
Total leukocyte count	< 1	Abnormal result rarely led to change
Bleeding time	3.8	Abnormal result rarely led to change
Coagulation time	4.8	
Partial thromboplastin time	15.6	
Chest x-ray	2.5–3.7	2.1
ECG	4.6–31.7	0–2.2
Sodium, potassium	1.4 2.5 5.2	Abnormal result rarely led to change
Urinalysis	1–34.1	0.1–2.8

50,000 have a perioperative MI. The risk of intraoperative or postoperative MI is much higher in patients who have suffered heart muscle damage within the preceding 6 months. In large retrospective reviews, 37% of patients experienced reinfarction when they underwent operation within 3 months of an infarction; however, the incidence of reinfarction decreased to 16% when the operation was performed between 3 and 6 months after the first infarction and to 4.5% when the operation was performed more than 6 months afterward.¹⁶ The estimated economic impact of these complications is \$20 billion annually.⁸

There is currently a trend toward more aggressive surgery in sicker patients, among whom the prevalence of ischemic heart disease is increasing. As a result, there is a growing need for expert guidance in the preoperative evaluation of patients who are known to have or to be at risk for CAD. Although the literature is replete with suggested management algorithms, no firm consensus has been reached. Much of the continuing controversy is related to the obvious difficulties of conducting large randomized, controlled clinical trials on this topic, as well as to the relatively low incidence of perioperative cardiac events (< 10%). The incidence of postoperative MI is 0.7% in male general surgery

Table 4 MET Scores for Selected Activities (Duke Activity Status Index)

MET Score	Activity
1–4	Light activities of daily home life (e.g., eating, getting dressed, using the toilet, cooking, washing dishes) Walking 1–2 blocks on level ground at 2–3 mph
5–9	Climbing one flight of stairs Walking up a hill Walking on level ground at rate > 4 mph Running a short distance More strenuous household chores (e.g., scrubbing floors, moving furniture) Moderate recreational activities (e.g., hiking, dancing, golf)
> 10	Strenuous athletic activities (e.g., tennis, running, basketball, swimming) Heavy professional work

patients older than 50 years, but it is 3.1% in comparable vascular surgery patients, in whom the prevalence of asymptomatic CAD is predictably high.¹⁷

Functional Capacity

Patients who are able to exercise on a regular basis without limitations generally have sufficient cardiovascular reserve to allow them to withstand stressful operations. Those with limited exercise capacity often have poor cardiovascular reserve, which may become manifest after noncardiac surgery. Poor functional status (and exercise capacity) is associated with worse short- and long-term outcomes in patients undergoing noncardiac operations, as well as with shorter nonoperative lifespans.¹⁸

Functional capacity is readily expressed in terms of metabolic equivalents (METs). One MET is equivalent to the energy expended (or the oxygen used) in sitting and reading (3.5 ml O₂/kg/min). For a 70 kg person, one MET amounts to 245 ml O₂/min. Multiples of the baseline MET value can then be used to quantify the aerobic demands posed by specific activities, as in the Duke Activity Status Index [see Table 4].¹⁹

Energy expenditures for activities such as eating, dressing, walking around the house, and dishwashing range from 1 to 4 METs. Climbing a flight of stairs, walking on level ground at 6.4 km/hr, running a short distance, scrubbing floors, and playing golf represent expenditures of 4 to 10 METs. Strenuous sports (e.g., swimming, singles tennis, and football) often demand expenditures exceeding 10 METs. It has been established that perioperative cardiac and long-term risks are increased in patients unable to meet the 4-MET demand associated with most normal daily activities. Thus, the surgeon's assessment of the patient's exercise capacity is a practical, inexpensive, and gratifyingly accurate predictor of that patient's ability to tolerate a surgical stress.

Type of Surgical Procedure

The procedure-specific cardiac risk associated with a noncardiac operation is related almost exclusively to the duration and intensity of the myocardial stressors involved. Procedure-specific risk for noncardiac surgery can be classified as high, intermediate, or low [see Table 5].²⁰ High-risk procedures include major emergency surgery, particularly in the elderly; aortic and other major vascular operations; peripheral vascular surgery; and any operation that is expected to be prolonged and to be associated with large fluid shifts or substantial blood loss. Intermediate-risk procedures include intraperitoneal and intrathoracic operations, carotid endarterectomy, head and neck procedures, orthopedic surgery, and prostate operations. Low-risk procedures include endoscopic and superficial procedures, cataract operations, and breast surgery.

Despite the prevalence of cardiovascular disease, many patients presenting for noncardiac surgery have never received a meticulous (or even a superficial) cardiovascular evaluation. Furthermore, the proposed operations themselves may create sustained cardiovascular stresses that are quite beyond what patients may have experienced in daily life. It is therefore crucial for the cardiovascular consultant to identify underlying conditions and to evaluate and treat them using cost-effective and evidence-based guidelines, thereby benefiting patients both in the short term and in the long term. The goal of the consultation is to determine the most appropriate testing and treatment strategies for optimizing patient care while avoiding unnecessary testing.

Specialized Testing

Recognition of the limitations of routine testing [see Preopera-

Table 5 Selected Surgical Procedures Stratified by Degree of Cardiac Risk

Degree of Cardiac Risk	Type of Procedure
Low (< 1%)	Endoscopic procedures Ambulatory procedures Ophthalmic procedures Aesthetic procedures
Intermediate (1%–5%)	Minor vascular procedures (e.g., carotid endarterectomy) Abdominal procedures Thoracic procedures Neurosurgical procedures Otolaryngologic procedures Orthopedic procedures Urologic procedures
High (> 5%)	Emergency procedures (intermediate or high risk) Major vascular procedures (e.g., peripheral vascular surgery, AAA repair) Extensive surgical procedures with profound estimated blood loss, large fluid shifts, or both Unstable hemodynamic situations

AAA—abdominal aortic aneurysm

tive Testing, *above*] led to suggestions in favor of specialized preoperative cardiac testing instead.²¹ Since the 1980s, innumerable studies have attempted to establish the utility of this approach, but results have differed markedly across studies, making interpretation and recommendation difficult.²² It is now understood that no single test can replicate all of the components of surgical stress. This being the case, the challenge is to develop a preoperative assessment approach that makes appropriate use of specific tests tailored to specific patients undergoing specific procedures.

In general, indications for further cardiac tests and treatments are the same in the operative setting as in the nonoperative setting. The timing of these interventions, however, depends on the urgency of the noncardiac procedure, the risk factors present, and specific considerations associated with the procedure. Coronary revascularization before noncardiac surgery has sometimes been advocated as a way of enabling the patient to get through a noncardiac procedure, but it is appropriate only for a small subset of very high risk patients.²³

Exercise treadmill testing Increases in heart rate are common during and after operation; nearly one half of all perioperative ischemic events are associated with tachycardia.²⁴ Use of exercise treadmill testing (ETT) therefore appears reasonable, and it is supported by several studies demonstrating that a positive ischemic response and low exercise capacity predict an untoward outcome after noncardiac surgery.⁸ A level II study of intermediate-risk patients confirmed that ST segment depression of 0.1 mV or greater during exercise was an independent predictor of perioperative ischemic events.²⁵ Early studies indicated that perioperative myocardial infarction occurred in 37% of vascular surgery patients who demonstrated a positive ischemic response on ETT but in only 1.5% of those who did not.⁸ In patients whose anticipated risk of CAD is low, however, the sensitivity of an exercise ECG may be as low as 45%.²⁶ Notably, other studies reported that routine 12-lead resting preoperative ECG and evaluation of exercise capacity were independent and superior predictors of perioperative cardiac morbidity.^{8,18} Like all other components of preoperative risk evaluation, ETT should never be considered in a vacuum.

Ambulatory electrocardiography Preoperative ambulatory ECG (Holter monitoring) is relatively inexpensive, but the recordings may be difficult to analyze because of electrocardiographic abnormalities, which preclude adequate interpretation in as many as 50% of patients.²⁴ Several studies have suggested an association between ST segment changes detected during normal daily activities and subsequent cardiac events in patients with stable or unstable angina and previous or recent MI.²⁷ Some 33% of surgical patients who have or are at risk for CAD experience frequent ischemic episodes before operation, with most (> 75%) of these episodes being clinically silent.²⁸ Several investigators have suggested an association between these electrocardiographically silent changes and adverse outcomes.²⁴ Unfortunately, a nonischemic ambulatory ECG does not preclude the diagnosis of cardiac muscle damage as identified by perfusion imaging.²⁹ If myocardial perfusion scanning is taken as the standard, ambulatory ECG has both low sensitivity and low specificity for the detection of ischemic heart disease.³⁰

Radionuclide ventriculography Initial results in patients undergoing vascular surgery suggested that the ejection fraction, as determined by preoperative multiple gated acquisition (MUGA) scanning, was an independent predictor of perioperative cardiac morbidity. Subsequently, a study of 457 patients undergoing abdominal aortic surgery found that a depressed ejection fraction (50%) predicted postoperative left ventricular dysfunction but not other cardiac complications.³¹ Thus, quantification of the resting ejection fraction by means of radionuclide (technetium-99m) ventriculography appears not to contribute a great deal beyond the information already supplied by the routine history and physical examination, though exercise radionuclide ventriculography does appear to have some prognostic value.

Echocardiography Precordial echocardiography has been suggested as a means of identifying high-risk patients. In a study of 334 patients,³² however, preoperative transthoracic echocardiography had limited incremental value for predicting ischemic outcomes (cardiac death, MI, or unstable angina) in comparison with routine clinical evaluation and intraoperative ECG, and the echocardiographic findings served only as a univariate predictor of congestive heart failure (CHF) and ventricular tachycardia. In a multivariate analysis that included clinical information (e.g., a history of CHF or CAD), none of the preoperative echocardiographic measurements were significantly associated with heart failure or ventricular tachycardia. Thus, until subsets of patients who may benefit are identified, the indications for preoperative echocardiography in surgical patients appear to be similar to those in nonsurgical patients and are restricted to focused evaluation of ventricular or valvular function.

Stress echocardiography, on the other hand, may offer unique prognostic information: it appears to be as successful as radionuclide stress imaging at identifying jeopardized zones of ischemic myocardial tissue.³³ The strength of stress cardiac imaging is its ability to differentiate healthy from ischemic from scarred myocardium. Patients demonstrating extensive ischemia (more than five left ventricular segments involved) with exercise provocation experience 10 times more cardiac events than patients with limited stress-induced ischemia (fewer than four segments involved).³⁴ An increase in oxygen demand after dobutamine infusion may elicit wall-motion abnormalities pathognomonic of ischemic myocardium. A study of 1,351 consecutive patients who underwent major vascular procedures found that dobutamine stress echocardiography effectively identified the 2% of patients

at high ischemic risk for whom consideration of coronary angiography and possible revascularization was appropriate.³⁴ Patients at moderate ischemic risk (fewer than four segments) were able to proceed with surgery under beta-blockade therapy. In a study of 136 patients undergoing vascular surgery, all 15 postoperative complications occurred in the 35 patients who had a positive response to dobutamine stress echocardiography.³⁵ Other investigators subsequently confirmed that stress echocardiography using either dobutamine or dipyridamole offered useful prognostic information that facilitated the development of treatment algorithms.⁸

Thallium scintigraphy Radionuclide scanning with thallium-201 after exercise or pharmacologically induced stress is a useful method of identifying zones of potential ischemia; provocative coronary perfusion imaging studies provide a great deal of valuable data. The highest-risk patients undergoing noncardiac surgery, however, are those with exercise limitations, who typically have peripheral vascular, orthopedic, or neurologic disease. As a result, various pharmacologic methods of modeling the effects of exercise have been developed, including those that induce coronary vasodilation (using dipyridamole or adenosine) or increase heart work (using dobutamine or arbutamine). The most extensively investigated of these methods is dipyridamole thallium scintigraphy.³⁶

In the mid-1980s, the usefulness of scintigraphy was assessed in vascular surgical patients. It was found that nearly all perioperative adverse events occurred in patients with redistribution defects; few, if any, occurred in patients without preoperative redistribution abnormalities. These findings led to widespread use of dipyridamole thallium, generating more than \$500 million in national health care costs annually.⁸ In the early 1990s, investigators challenged previous findings in a prospective, triple-blinded study that assessed both adverse outcome and perioperative MI (by means of continuous ECG and transesophageal echocardiography).³⁷ In contrast to previous reports, no association between redistribution defects and perioperative ischemia or adverse events was noted, and the majority of episodes occurred in patients without redistribution defects. These findings provoked a more extensive study involving 457 consecutive unselected patients undergoing abdominal aortic surgery.²⁹ The investigators found that thallium redistribution was not significantly associated with perioperative MI, prolonged ischemia, or other adverse events. The current consensus is that routine thallium scintigraphy has no real screening value when applied to a large unselected vascular or nonvascular population or to patients already classified clinically as low- or high-risk candidates for noncardiac surgery.

Coronary angiography Coronary angiography is an invasive procedure that even today is associated with a mortality of 0.01% to 0.05% and a morbidity rate of 0.03% to 0.25%.³⁸ It is indicated only for patients who have unstable coronary syndromes, those who are undergoing intermediate- or high-risk noncardiac procedures after equivocal noninvasive test results, and those who may have an indication for elective coronary revascularization.²³ Although antecedent myocardial revascularization appears to reduce the risk associated with subsequent noncardiac surgery,⁸ the efficacy of elective preoperative revascularization remains controversial. This latter measure probably is not beneficial; in fact, the incidence of complications during or after revascularization is often comparable to that during or after the noncardiac surgical procedure itself. Routine angiography is indicat-

ed only when invasive delineation of CAD would be indicated in the absence of the noncardiac surgical problem.

ACC/AHA Guidelines

Comprehensive identification of patients who are at substantial risk for perioperative cardiac morbidity remains a difficult task. As noted [*see Preoperative Testing, above*], routine preoperative testing has significant inherent limitations. An evaluation strategy that avoids these limitations has been proposed by combined task forces from the American College of Cardiology and the AHA.³⁹ This strategy bases diagnostic and therapeutic approaches on clinical screening for disease state and functional capacity. It employs specialized testing conservatively—that is, only when the additional information provided by the proposed test is likely to have an impact on outcome. The ACC/AHA strategy has proved efficient and cost-effective in vascular surgery patients.

The ACC/AHA guidelines take the form of an eight-step algorithm for patient risk stratification and subsequent determination of appropriate cardiac evaluation; this algorithm is available on the ACC's web site (www.acc.org/clinical/guidelines/perio/update/fig1.htm). Steps 1 through 3 of the algorithm are concerned with assessing the urgency of the operation and determining whether a cardiac evaluation or intervention has recently been performed. If there has been no recent cardiac evaluation or intervention and the operation is elective, steps 4 through 7 are activated. These steps are concerned with identifying clinical predictors of cardiac risk, assessing functional status, and estimating the risk of the proposed operation. Specifically, the surgeon must determine whether the patient has a major clinical predictor of cardiac risk. As defined by the ACC/AHA task force,³⁹ major clinical predictors include unstable coronary syndrome, decompensated CHF, significant arrhythmias, and severe valvular disease. Intermediate clinical predictors include mild angina pectoris, diabetes mellitus, chronic renal failure with serum creatinine levels higher than 2 mg/dl, and a history of MI or CHF. Poor functional status is defined as inability to perform activities involving energy expenditures greater than 4 METs. Step 8 of the algorithm—noninvasive cardiac testing for further determination of cardiac risk—is employed in accordance with the information gained from steps 1 through 7 [*see Table 6*].³⁹ The purpose is to identify patients who need further cardiac evaluation and aggressive cardiac stabilization in the perioperative period.

FACTORS AFFECTING NONCARDIAC RISK

Respiratory Status

Testing of pulmonary function may be indicated on the basis of physical findings (e.g. cough, wheezing, dyspnea on exertion, rales or rhonchi) or a history of cigarette smoking. Limited pulmonary reserve may be revealed by observing the patient for dyspnea while he or she is climbing one or two flights of stairs. Forced expiratory volume can be directly measured with a handheld spirometer whenever there is a question of possible pulmonary compromise.⁴⁰ Once identified, patients with pulmonary insufficiency [*see 8:4 Pulmonary Insufficiency*] may benefit from a preoperative program that includes smoking cessation,⁹ use of bronchodilators, physiotherapy, and specific antibiotics.

Nutritional Status

In 1936, Studley demonstrated that weight loss was a robust predictor of operative risk.⁴¹ Loss of more than 15% of body weight during the previous 6 months is associated with an increased incidence of postoperative complications, including

Table 6 Predictors of Cardiac Risk for Noncardiac Surgical Procedures³⁹

Minor risk factors (probable CAD)	Uncontrolled hypertension Family history of CAD Hypercholesterolemia Smoking history ECG abnormalities (dysrhythmia, bundle branch block, LVH) Peripheral vascular disease MI > 3 mo previously, asymptomatic without treatment CABG or PTCA > 3 mo but < 6 yr previously, without anginal symptoms or anginal medications
Intermediate risk factors (stable CAD)	Angina class I or II Compensated or previous heart failure, ejection fraction < 0.35 Physiologic age > 70 yr Diabetes mellitus Ventricular arrhythmia History of perioperative ischemia Absence of symptoms after infarction with maximal therapy CABG or PTCA > 6 wk but < 3 mo previously, or > 6 yr previously, or with antianginal therapy MI > 6 wk but < 3 mo previously
Major risk factors (unstable CAD)	Clinical ischemia plus malignant arrhythmia Clinical ischemia plus congestive heart failure Residual ischemia after MI Angina class III or IV CABG or PTCA within past 6 wk MI within past 6 wk

CABG—coronary artery bypass grafting CAD—coronary artery disease LVH—left ventricular hypertrophy MI—myocardial infarction PTCA—percutaneous transluminal coronary angioplasty

delayed wound healing, decreased immunologic competence, and inability to meet the metabolic demand for respiratory effort. Peripheral edema and signs of specific vitamin deficiencies are suggestive of severe malnutrition. A huge multicenter Veterans Affairs hospital study found that hypoalbuminemia was consistently the most reliable indicator of morbidity and mortality [see Table 7].⁴² A decrease in serum albumin concentration from greater than 4.6 g/dl to less than 2.1 g/dl was associated with an increase in mortality from less than 1% to 29% and an increase in morbidity rate from 10% to 65%. Again, in these regression models, albumin concentration was the strongest predictor of mortality and morbidity after surgery.⁴²

A global nutrition assessment has been shown to identify patients who are increased risk as a result of nutritional deficiencies.⁴³ Persons with macronutrient deficiencies may benefit from preoperative nutritional supplementation⁴⁴ [see 8:23 *Nutritional Support*]; however, such supplementation should be employed selectively and tailored to the particular patient population involved.⁴⁵ A trial done by a study group from the VA determined that preoperative nutritional intervention was necessary only in the most severely nutritionally depleted patients (i.e., those who had lost more than 15% of their body weight).⁴⁶

Endocrine Status

The endocrine-related conditions most relevant in the perioperative period are hypothyroidism, hyperthyroidism, diabetes mellitus, pheochromocytoma, and adrenal insufficiency (in particular, iatrogenic adrenocortical insufficiency secondary to steroid use within the preceding 6 months). All of these conditions should be normalized to the extent possible before elective surgery, whether by hormone replacement, by adrenergic block-

ade, or by administration of stress-dose steroids [see 8:10 *Endocrine Problems*].

Diabetes mellitus As of 2003, 10.9 million persons were known to have diabetes mellitus in the United States, and another 5.7 million were estimated to be harboring the disease without being aware of it.⁹ In diabetic patients, the risk of CAD is two to four times higher than it is in the general population.⁴⁷ Diabetic autonomic neuropathy is associated with an impaired vasodilator response of coronary resistance vessels to increased sympathetic stimulation.⁴⁸ Moreover, diabetes is frequently associated with silent ischemia; if detected by Holter monitoring, it has a positive predictive value of 35% for perioperative cardiac events.⁴⁹ The incidence of ischemic events in asymptomatic diabetic patients is similar to that in patients with stable CAD.⁵⁰ Accordingly, clinicians should lower their threshold for cardiac testing when managing diabetic patients.

Asymptomatic diabetic patients with two or more cardiac risk factors should be evaluated by means of stress testing if their functional capacity is low or if they are to undergo a vascular procedure or any major operation. Only those diabetics who have good functional capacity and are undergoing minor or intermediate-risk procedures should proceed directly to operation. This is a more aggressive interventional approach than is followed for the general population. It should be kept in mind that, common assumptions notwithstanding, perioperative beta blockade is not precluded in diabetic patients and can offer substantial protection against ischemia. A 2003 study reported a 50% reduction in cardiovascular and microvascular complications in diabetic patients who underwent intensive glucose control, exercise therapy, and preventive medical management.⁵¹

Hematologic States

The most practical tool for detecting hypocoagulable or hypercoagulable states [see 1:4 *Bleeding and Transfusion* and 6:6 *Venous Thromboembolism*] is a careful history. Risk factors for postoperative phlebotrombosis and possible pulmonary embolism include Virchow's well-known triad: hypercoagulability (e.g., from antithrombin deficiency, oral contraceptives, or malignancy), stasis (e.g., from venous outflow obstruction, immobility, or CHF), and endothelial injury (e.g., from trauma or operation). A thromboe-

Table 7 Preoperative Predictors of Morbidity and Mortality in General Surgical Patients^{2,4}

Rank	Predictor of Morbidity	Predictor of Mortality
1	Albumin concentration	Albumin concentration
2	ASA class	ASA class
3	Complexity of operation	Emergency operation
4	Emergency operation	Disseminated cancer
5	Functional status	Age
6	History of COPD	DNR status
7	BUN > 40 mg/dl	Platelet count < 150,000/mm ³
8	Dependency on ventilator	Weight loss > 10%
9	Age	Complexity of operation
10	WBC count > 11,000/mm ³	BUN > 40 mg/dl

lastogram is an effective screening tool in patients with suspected abnormalities. Prothrombin time, partial thromboplastin time, and platelet count constitute sufficient preoperative testing in a patient with a suspected bleeding problem. Antithrombin, protein C, protein S, and factor V Leiden levels constitute sufficient preoperative screening in a patient with suspected hypercoagulable disease.

Assessment of Physical and Mental Happiness

Calculation of the risks and benefits of surgical (or, indeed, any) therapy has become a much more complex process than it once was. Simple assessment of survival or basic quality of life is no longer sufficient: more sophisticated measures are required.

Generic instruments now exist that are aimed at evaluating a patient's level of productive assimilation into his or her environment. The Short Form-36 (SF-36) is designed to assess physical and mental happiness in eight domains of health: (1) physical function (10 items); (2) physical role limitations (4 items); (3) bodily pain (2 items); (4) vitality (4 items); (5) general health perceptions (5 items); (6) emotional role limitations (3 items); (7) social function (2 items); and (8) mental health (5 items). The underlying assumption is that mental and physical functions are readily separable aspects of health, but of course, this is not really the case.^{52,53} Predictably, patients' responses on the SF-36 tend to be strongly influenced by the type of operation they had. For example, a patient who has undergone total hip arthroplasty will feel better immediately; one who has undergone lung resection for cancer may not feel particularly well immediately afterward but, ideally, will be relieved of a cancer scare; and one who has undergone abdominal aneurysm repair will feel worse immediately, though conscious of an improved life expectancy. Less predictably, however, patients' perceptions of their own surgical outcomes are equally strongly influenced by when in the postoperative period the questions are asked.⁵⁴ The answers obtained 6 months after operation will differ from those obtained at 1 month or 12 months. If the questions are asked several times, the answers change; indeed, the mere asking of the question may change the answer.⁵⁵ For an outcome measure to be effective by current standards, it must be not only feasible, valid, and reliable but also sensitive to change.^{56,57}

An outcome tool that has been further refined to focus specifically on cardiovascular capacity and disease is the Specific Activity Scale (SAS). Unfortunately for assessment purposes, attempts to use the SAS and the SF-36 simultaneously have yielded significantly divergent results. Such results underscore the complexities of standardizing tests of ability, intelligence, and happiness.⁵⁸

Quality is subjective. Some patients are happy when they seemingly have every reason to be unhappy; others are unhappy when they seemingly have every reason to be happy. Scientific tools for collectively examining psychosocial productivity in groups of patients may still be largely lacking, but this does not mean that surgeons have no methods of evaluating and enhancing a given patient's prospects for comfort. Indeed, any surgeon whose contribution to patient management stops with superb operative technique, or even with exemplary perioperative care added to technique, is not making optimal use of his or her privileged position. By incorporating a patient's values into the anticipated outcome, surgeons are uniquely positioned to achieve the best possible outcome-to-value ratios.

PATIENT EDUCATION

Education of the patient about the postoperative care plan plays a major role in modifying his or her response to the operative

experience. Classic studies have shown that well-informed patients require less analgesia in the postoperative period and experience significantly less pain than less well informed patients.⁵⁹ Subsequent investigations have supported these conclusions. Perioperative information facilitates coping, reduces preoperative anxiety, and may enhance postoperative recovery.⁶⁰ Such information can be provided orally or in the form of booklets or videotapes.

Reduction of Perioperative Cardiac Risk

A number of trials have indicated that perioperative beta blockade can reduce the risk of perioperative cardiac complications in patients with known or suspected CAD who are undergoing major noncardiac procedures.⁶¹⁻⁶³ One prospective study randomly assigned 200 noncardiac surgical patients to receive either atenolol or placebo.⁶⁴ Atenolol was administered intravenously before and after surgery, then continued orally until hospital discharge. Of the original 200 patients, 194 survived hospitalization, and 192 were followed for 2 years. Mortality, even after hospital discharge and discontinuance of beta blockade, was significantly lower in atenolol-treated patients than in control subjects both at 6 months and at 2 years. These findings, though somewhat puzzling, have sparked considerable enthusiasm for perioperative beta blockade. Some clinicians, however, have expressed reservations.⁶³

In 1999, a Dutch echocardiographic cardiac risk evaluation study group published a prospective, randomized, multicenter study of perioperative beta blockade in extremely high risk vascular surgical patients.⁶¹ Of the 1,351 patients screened, 846 exhibited cardiac risk factors that would have made them moderate- or high-risk patients according to either Goldman's or Lee's classification system. Of these 846 patients, 173 had positive results on dobutamine stress echocardiography, and 112 of the 173 agreed to undergo randomization. Of these 112 patients, 59 were randomly assigned to perioperative beta blockade with bisoprolol, and 53 served as control subjects. Of the patients undergoing beta blockade, 3.4% died of cardiac causes or experienced a nonfatal MI, compared with 34% of the control subjects. Admittedly, this is a study of very high risk patients; nonetheless, the conclusions are striking, and it is tempting to extrapolate them to lower-risk noncardiac surgical patients. In the human heart, α_1 -, β_1 -, and β_2 -adrenergic receptors promote inotropy, chronotropy, myocyte apoptosis, and direct myocyte toxicity.⁶³ Expanded use of beta-adrenergic receptor inhibition in the perioperative period has been supported by several groups of investigators.⁶⁵⁻⁶⁸

Prophylactic use of other agents (e.g., aspirin, α_2 -adrenergic agents, nitroglycerin, and calcium channel blockers) has been studied, but at present, the data are insufficient to support routine use of any of these.^{69,70} Risk reduction should focus on strategies for which there is good evidence (e.g., maintenance of normothermia, avoidance of extreme anemia, control of postoperative pain, and perioperative beta blockade). A stepwise approach to preoperative assessment allows judicious use of both noninvasive and invasive procedures while preserving a low rate of cardiac complications [see Figure 1].²³

Epidemiology of Surgical Risk

In a 1999 prospective study, a team of VA investigators examined the outcomes of surgical procedures in an effort to identify variables related to poor surgical results. Initial results were reported from 23,919 patients who underwent one of 11 noncardiac operations performed by surgeons from five specialties (gen-

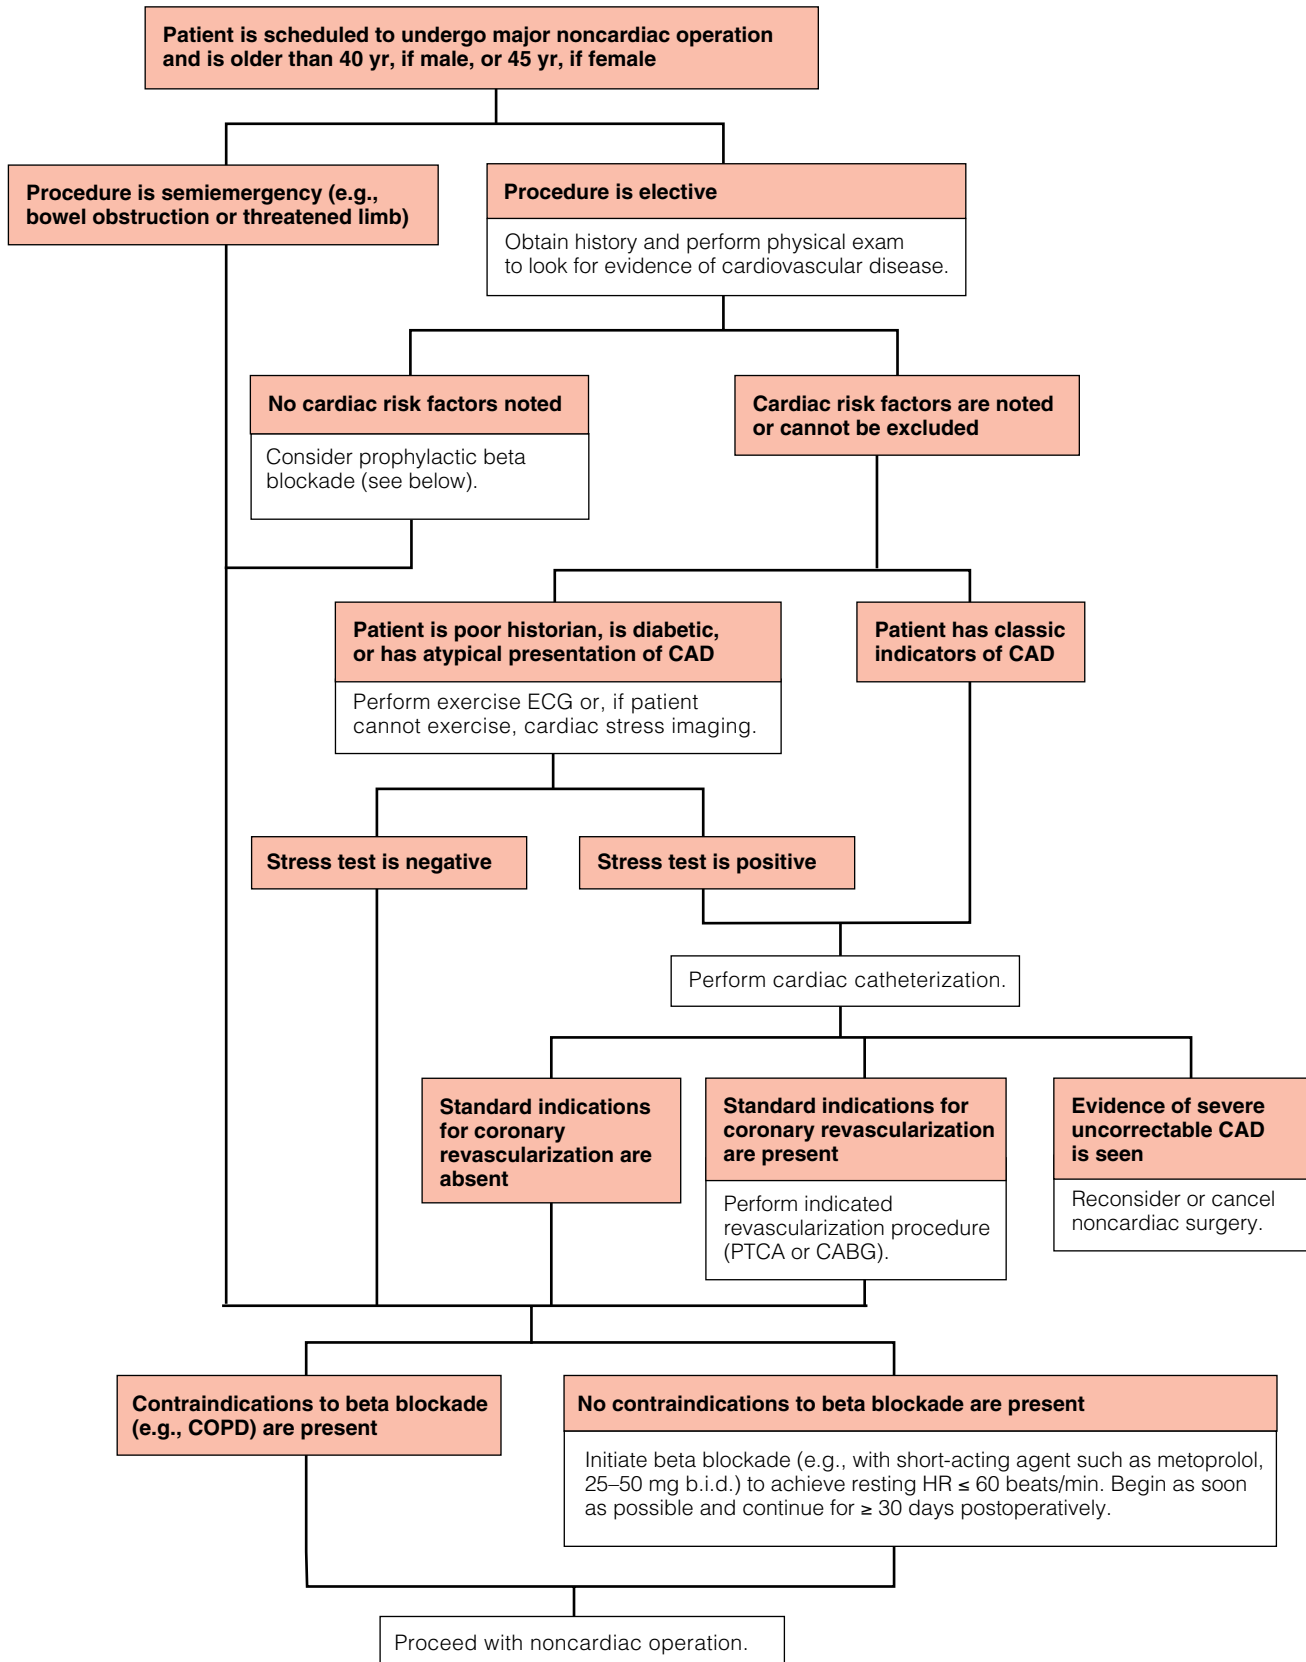

Figure 1 Algorithm depicts recommended approach to cardiac assessment before noncardiac surgery. (CAD—coronary artery disease; CABG—coronary artery bypass grafting; PTCA—percutaneous transluminal coronary angioplasty)

eral surgery, urology, orthopedic surgery, vascular surgery, and neurosurgery).⁷¹ The authors concluded that prolonged hospital stay could be related to advanced age, diminished functional status, and higher ASA class. Other preoperative patient characteristics were associated with increased morbidity and mortality [see Table 7].⁷²

Changing Paradigms of Cost-effectiveness

It is now clear that postoperative survival, by itself, is no longer an adequate assay of surgical success. Risk must be stratified before operation, and the degree of risk must be evaluated in the light of both the quantity and the quality of life to be expected after operation. Cost must then be appropriately factored in: a modern health care system will want to know the cost of a risk-stratified, quality-adjusted postoperative year of life. A 1999 study assessed the cost-effectiveness of various cardiac diagnostic strate-

gies in terms of cost in relation to each QALY saved.⁷³ Although the question this study was designed to answer was slightly different from what surgeons typically address before noncardiac surgery, several instructive findings emerged:

1. For a 55-year-old man with typical chest pain, the incremental cost-effectiveness ratio for routine coronary angiography versus exercise echocardiography was \$36,400/QALY saved.
2. For a 55-year-old man with atypical chest pain, the incremental cost-effectiveness ratio for exercise electrocardiography versus no testing was \$57,700/QALY saved.
3. The incremental cost-effectiveness ratio for exercise echocardiography versus stress electrocardiography was \$41,900/QALY saved.

The literature makes it very clear, however, that none of the available diagnostic strategies are more cost-effective than communication with the patient.

5 OUTPATIENT SURGERY

Richard B. Reiling, M.D., F.A.C.S., and Daniel P. McKellar, M.D., F.A.C.S.

A safe and cost-effective approach to elective surgery begins with a careful history, a thorough physical examination, well-chosen laboratory tests, and consultation as appropriate and proceeds to selection of the optimal procedure, assessment of patient suitability, and choice of the most appropriate site in which to perform the procedure. In what follows, we address these issues specifically as they pertain to outpatient surgery: from selection of suitable patients and procedures to determination of appropriate outpatient settings in which to perform the procedures, to perioperative management (e.g., premedication, anesthesia, monitoring, and immediate postoperative care), to discharge and postoperative pain control.

Accumulating evidence indicates that outpatient surgery can offer significant advantages over inpatient surgery. For example, patients who undergo breast surgery with same-day dismissal are not at a disadvantage; on the contrary, they report faster recovery and better psychological adjustment.¹ Moreover, the pronounced shift toward outpatient surgery has been accompanied by an equally impressive technological revolution, which has led to the development of operative approaches that require less postoperative care.

Selection of Patients for Inpatient and Outpatient Procedures

Just as inpatient and outpatient procedures must be carefully selected with an eye to difficulty and severity of illness, so too should patients be carefully selected. The following six questions should be asked:

1. Is the facility adequately equipped and appropriate for the intended procedure, and are quality standards maintained?
2. Can the procedure routinely be performed safely without hospital admission?
3. Is the patient at risk for major complications if the operation is performed in the facility?
4. Do concomitant or comorbid conditions present unacceptable risks in the intended setting?
5. Will the patient require any special instructions or psychological counseling before the operation?
6. Do the patient and the family understand their own obligations regarding postoperative care in an outpatient setting?

Surgeons and anesthesiologists have gained an immense amount of experience in outpatient management of many difficult procedures that were once considered to be best suited for more controlled inpatient environments. Procedures that were regarded as unsafe in an outpatient setting as late as the mid-1990s are now being performed in ambulatory centers, and there is evidence that this shift has not increased patient risk.²⁻⁴ Ambulatory centers are integrated with or based in hospitals, and the transfer of surgical care from the inpatient to the ambulatory

setting was accompanied by a transfer of all the measures designed to ensure patient safety, including peer review. However, this same transfer has not occurred in the office-based setting, where at least 15% of outpatient surgical procedures are currently being performed.⁵ There is a growing concern that better regulation is needed for office-based surgical units. Surgery conducted in office settings has been found to pose about a 10-fold higher risk of adverse incidents and death than surgery conducted in ambulatory centers.⁶

Certain relative contraindications to outpatient surgical procedures have been identified, but these vary depending on the patient, the physician, and the setting [see Table 1]. The surgeon is responsible for detecting undiagnosed and unsuspected acute and chronic conditions before operation. The anesthesiologist shares the responsibility for uncovering potential preoperative problems if the patient will require complex anesthesia that must be given by an anesthesiologist; otherwise, the surgeon is also responsible for this aspect of care. In addition, the surgical unit plays a role in determining which types of patients can be treated. Likewise, these determinations should be made in the office-based practice before undertaking any surgical intervention. This is best accomplished in a well-thought-out governance plan. Hospital-affiliated units or units in immediate proximity to a full-service hospital that have an agreement for rapid transfer are better able to accept patients with more serious concomitant illnesses than facilities physically separated from the acute care hospital. Surgeons also tend to select certain apparently higher-risk patients for treatment in hospital outpatient or ambulatory surgical units rather than in freestanding day surgical units, as reflected in the higher rate of admission for hospital-based units [see Tables 2 through 4].⁷

Some reimbursement plans, including the Center for Medicare and Medicaid Services (CMS), possess a curious feature by which patients are considered outpatients if they are discharged from the facility within 24 hours. Obviously, an outpatient who

Table 1 Relative Contraindications to Outpatient Surgery

Procedures with an anticipated significant blood loss
Procedures associated with significant postoperative pain
Procedures necessitating extended postoperative I.V. therapy
ASA class IV (or III if the systemic disease is not under control, as with unstable angina, asthma, diabetes mellitus, and morbid obesity)
Known coagulation problems, including the use of anticoagulants
Inadequate ability or understanding on the part of caretakers with respect to requirements for postoperative care

Table 2 Surgical Categories

Category 1

Generally noninvasive procedures with minimal blood loss and with minimal risk to the patient independent of anesthesia

Anticipated blood loss less than 250 ml

Limited procedure involving skin, subcutaneous, eye, or superficial lymphoid tissue

Entry into body without surgical incision

Excludes the following:

Open exposure of internal body organs, repair of vascular or neurologic structures, or placement of prosthetic devices

Entry into abdomen, thorax, neck, cranium, or extremities other than wrist, hand, or digits

Placement of prosthetic devices

Postoperative monitored care setting (ICU, ACU)

Category 2

Procedures limited in their invasive nature, usually with minimal to mild blood loss and only mild associated risk to the patient independent of anesthesia

Anticipated blood loss less than 500 ml

Limited entry into abdomen, thorax, neck, or extremities for diagnostic or minor therapy without removal or major alteration of major organs

Extensive superficial procedure

Excludes the following:

Open exposure of internal body organs or repair of vascular or neurologic structures

Placement of prosthetic devices

Postoperative monitored care setting (ICU, ACU), with no open exposure of abdomen, thorax, neck, cranium, or extremities other than wrist, hand, or digits

Category 3

More invasive procedures and those involving moderate blood loss with moderate risk to the patient independent of anesthesia

Anticipated blood loss 500–1,500 ml

Open exposure of the abdomen

Reconstructive work on hip, shoulder, knees

Excludes the following:

Open thoracic or intracranial procedure

Major vascular repair (e.g., aortofemoral bypass)

Major orthopedic reconstruction (e.g., spinal fusion)

Planned postoperative monitored care setting (ICU, ACU)

Category 4

Procedures posing significant risk to the patient independent of anesthesia or in one or more of the following categories:

Procedure for which postoperative intensive care is planned

Procedure with anticipated blood loss greater than 1,500 ml

Cardiothoracic procedure

Intracranial procedure

Major procedure on the oropharynx

Major vascular, skeletal, or neurologic repair

stays overnight is effectively an inpatient, even if the length of stay is less than 24 hours. Outpatient facilities exist that are physically separated from an inpatient hospital but that also can accept patients for this 24-hour arrangement. Such freestanding facilities must clearly ensure safety and quality in the unit to the same extent as facilities approved by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO).

In addition, the concept of recovery care has been introduced for facilities that provide postoperative care. In this concept, facilities are classified according to the defined length of stay (e.g., extended recovery and 23-hour care).⁸ The idea of classifying

units according to level of service, in the same way as the American College of Surgeons (ACS) has classified units according to type of surgery performed and level of anesthesia available, is a sensible one that is likely to be more fully developed and more widely applied in the coming years.

Patient acceptance is critical in outpatient surgery for reasons of safety and liability. If the patient or any responsible relative of the patient does not accept or is extremely critical of nonadmission surgical care and cannot be easily assured of its advantages and safety, inpatient treatment is indicated, regardless of the policy of the third-party payor or other regulatory bodies. Certain

Table 3 American Society of Anesthesiologists' Physical Status Classification

Classification	Description	Examples
Class I	Normal, healthy patient	An inguinal hernia in a fit patient or a fibroid uterus in a healthy woman
Class II	Patient with mild systemic disease—a mild to moderate systemic disorder related to the condition to be treated or to some other, unrelated process	Moderate obesity, extremes of age, diet-controlled diabetes, mild hypertension, chronic obstructive pulmonary disease
Class III	Patient with severe systemic disease that limits activity but is not incapacitating	Morbid obesity, severely limiting heart disease, angina pectoris, healed myocardial infarction, insulin-dependent diabetes, moderate to severe pulmonary insufficiency
Class IV	Patient with incapacitating systemic disease that is life threatening	Organic heart disease with signs of cardiac insufficiency; unstable angina; refractory arrhythmia; advanced pulmonary, renal, hepatic, or endocrine disease
Class V	Moribund patient not expected to survive 24 hr without an operation	Ruptured aortic aneurysm with profound shock, massive pulmonary embolus, major cerebral trauma with increasing intracranial pressure
Emergency (E)	Emergency surgery—the suffix “E” is added to denote the poorer status of any patient in one of these five categories who is operated on in an emergency	

Table 4 Guidelines for Selection of Outpatient versus Inpatient Surgery

ASA Class	Surgical Category			
	1	2	3	4
I	Outpatient procedure with local anesthesia	Outpatient procedure with general or regional anesthesia	Inpatient procedure	Inpatient procedure
II	Outpatient procedure with local anesthesia*	Outpatient procedure with local, regional, or general anesthesia*	Inpatient procedure	Inpatient procedure
III	Inpatient procedure (unless operation can be done with local anesthesia)*	Inpatient procedure	Inpatient procedure	Inpatient procedure
IV	Inpatient procedure (unless operation can be done with local anesthesia)*	Inpatient procedure	Inpatient procedure	Inpatient procedure

*Patient must be watched carefully.

ASA—American Society of Anesthesiologists

complicating factors, such as substantial distance from the facility, the lack of sufficient support at home, and the presence of significant comorbid illnesses, also call for inpatient treatment regardless of the payor's policy. It then becomes the responsibility of the surgeon to notify the third-party payor of these contingencies in a simple and nonconfrontational manner, as well as to explain to the patient and family why it is necessary to deviate from the more usual outpatient approach for which the payor would more readily provide reimbursement. Efforts to coerce the patient or the family to accept outpatient surgery not only engender bad will between physician and patient but also tend to give rise to more postoperative problems (either real or factitious).

Third-party payors, for their part, must understand and accept that some patients, for whatever reason, will refuse nonadmission surgery. It is the responsibility of third-party payors and their customers (i.e., corporations or employers) to provide adequate information to those covered (i.e., employees and families) about the advantages and safety of outpatient surgery. Such education should be provided well before surgical intervention is sought or needed. Too often, the patient and the family are unaware of the payor's guidelines. Finally, patients and their families must also realize the need for cost-effective care and be willing to play their part in achieving it. It is reassuring that patients and families are increasingly accepting the concept of same-day discharge, which is becoming more widely prevalent.

SPECIFIC PATIENT RISK FACTORS

Careful monitoring and improvement of the patient's physical status before operation reduce mortality and morbidity. Therefore, one should accept a patient with a poor preoperative physical status for outpatient treatment only when it is clear that concomitant disease is well controlled and that the patient will have adequate postoperative monitoring and treatment at home.

In evaluating the risk factors for any surgical intervention, the following variables should be considered: (1) the patient's age, (2) the proposed anesthetic approach (type and duration), (3) the extent of the surgical procedure (including the surgical site), (4) the patient's overall physiologic status, (5) the presence or absence of concomitant diseases, (6) baseline medications, and (7) the patient's general mental status. The aim is to return the patient to the preoperative functional level with respect to respiration, cardiovascular stability, and mental status; no deviations should be acceptable.

Several studies aimed at determining reasons for admission after ambulatory surgical procedures indicate that many admis-

sions are for problems related to the patient's preoperative cardiovascular and respiratory status, but the major reason for admission is still uncontrollable nausea and vomiting.⁴ Moreover, most complications are related to factors other than the setting of the surgical procedure (outpatient or inpatient). Admission to the hospital after ambulatory surgery because of urinary retention, for example, is related to the use of general anesthesia, the age of the patient, and the administration of more than 1,200 ml of I.V. fluids before, during, and after the operation.⁹

Patients in American Society of Anesthesiologists (ASA) class III (or even class IV) [see Table 3] are appropriate candidates for ambulatory surgery if their systemic diseases are medically stable and the intended procedure will be relatively short. A report on patient morbidity and mortality within 1 month after ambulatory surgery showed only eight morbid events in over 10,500 ASA III patients and two deaths, both occurring in ASA II patients.²

Age

Extremes of age by themselves automatically increase the ASA classification from I to II. Even though age is not correlated with hospital admission after ambulatory surgery, elderly patients often have concomitant conditions that may have gone unrecognized but should have been brought to light before the operation. This is the obvious justification for the higher ASA classification—that is, to make the surgical team aware of the potential increased risk. In addition, the family or social support networks available to elderly patients are often of questionable value and may even pose their own risks after the operation. Most studies have failed to show age-related increases in complications or recovery. Fine motor skills and cognitive function diminish with age, however, so elderly patients require closer surveillance in the postanesthesia period.

Young children, especially neonates, present separate problems that must be independently evaluated by the surgeon and the anesthesiologist.

Drug Therapy for Preexisting Disease

Two questions must be answered about a patient taking medication for preexisting disease. First, should the drug or drugs be discontinued or the dosage altered before operation [see Table 5]? Second, do the medications necessitate special laboratory evaluations before operation (e.g., a prothrombin time and international normalized ratio [INR] for patients taking anticoagulants)?

Whereas dosages of some medications, such as adrenocorticosteroids, may have to be temporarily increased, certain oral

Table 5 Disposition of Current Medications before Outpatient Surgery⁹⁷

MAO inhibitors (controversial)	
Corticosteroids	
Thyroid preparations	
Anxiolytics	

ACE—angiotensin-converting enzyme MAO—monoamine oxidase

agents may have to be replaced during the immediate perioperative period with agents that can be delivered intravenously. In particular, oral antiarrhythmic drugs (e.g., quinidine sulfate, procainamide, and disopyramide) should be discontinued 8 hours before the operation.¹⁰ Patients taking aspirin should be instructed to stop at least 1 week before elective operation because aspirin's antiplatelet effect lingers for the life of the affected platelets. Patients receiving warfarin require uninterrupted anticoagulation; hence, the drug should be stopped only in the immediate preoperative period. Fresh frozen plasma may be required intraoperatively if excessive bleeding occurs. If warfarin is to be discontinued for a longer period, I.V. or subcutaneous heparin can be given.

In a study of nearly 18,000 ambulatory surgical patients in a major surgical center, almost 2,000 patients had preexisting systemic disease, and more than 900 of them were taking specific drugs for their disease.¹¹ Nearly half of these patients were taking at least one antihypertensive medication; a significant number were taking one or more cardiovascular medications, including cardiac glycosides, beta blockers, diuretics, antiarrhythmics, vasodilators, and anticoagulants. Other drugs that were being used included insulin and asthma medications. However, none of the complications recorded were related to preoperative drug use.

In any case, patients should bring all of their medications on the day of the operation. This instruction includes transdermal patches and pills and both prescribed and self-administered medications. Herbals and other over-the-counter medications are often overlooked and underreported by patients, yet some of these medications may well influence the procedure and subsequent recovery.

Hypertension

In general, hypertension should be under control before the operation. It is advisable to discontinue monoamine oxidase (MAO) inhibitors, if possible, 2 weeks before operation because these agents have unpredictable cardiac effects and may lead to hypertension in patients receiving meperidine or vasopressors; however, whether preoperative discontinuance of MAO inhibitors is absolutely necessary remains somewhat controversial. All antihypertensive agents should be continued until the day before the operation; beta blockers can be taken on the day of the operation.

Abrupt withdrawal of clonidine, which is used to treat chronic essential hypertension, is particularly dangerous because it is often associated with an increase in the plasma catecholamine level. Accordingly, clonidine should be continued throughout the perioperative period.

Heart Disease and Congestive Heart Failure

Patients with serious heart disease or congestive heart failure fall into ASA class III or IV and thus should not be considered for outpatient surgery unless the procedure is a minor one necessitating only local or regional anesthesia. Patients with less serious heart disease should take any prescribed cardiac glycosides, beta blockers, or antiarrhythmics with a small amount of water when they awake on the day of the operation.

Bronchopulmonary Disease

Patients with bronchopulmonary disease must be evaluated individually. The degree of impairment is determined by means of a careful history and appropriate testing; a chest x-ray should always be obtained. The history should also reveal factors that initiate attacks of asthma or bronchospasm, as well as identify the medications being taken. Many patients with bronchopulmonary disease need corticosteroids and antibiotics preoperatively.

Diabetes Mellitus

Patients whose diabetes is controlled with oral hypoglycemics or with low dosages of insulin (i.e., < 25 U/day) can be adequately managed by withholding the medication on the day of the operation. In general, patients with more severe insulin-dependent diabetes mellitus should not undergo outpatient procedures. Those who do undergo such procedures are best managed by the administration of a fraction of the insulin dose on the day of the operation in conjunction with I.V. infusion of a dextrose solution (usually 5%), beginning shortly after the patient's arrival at the surgical facility. Ideally, such administration should be scheduled as early in the day as possible. Patient status is monitored by measuring either the blood glucose level or the urine glucose level, both of which can be easily and rapidly determined at the bedside.

Obesity

In general, moderately to severely obese patients should not undergo outpatient surgery. The hazards and risks of surgery in the obese are often unrecognized. Morbid obesity stresses the cardiopulmonary system, and morbidly obese patients easily become, or already are, hypoxemic. In addition, these patients usually have comorbid disorders such as diabetes, hypertension, liver disease, or cardiac failure. Moderate obesity increases the ASA classification from I to II; morbid obesity increases it to III. Careful consideration is essential before a morbidly obese patient is released from skilled observation after major anesthesia. Obese children often are not recognized as being at risk. There is some controversy over whether the ability to swallow water in a recovering obese pediatric patient is an acceptable condition for discharge. Minor procedures have ended in tragedy after a seemingly recovered obese patient was discharged.

Adrenocortical Steroid Therapy

Patients taking adrenocortical steroids for 6 to 12 months before operation should usually receive supplemental steroids in the preoperative period. It should be remembered that many patients fail to inform the surgeon of transdermal corticosteroid use. Short-term steroid overdosage has virtually no complications, but inadequate adrenocortical support may have serious repercussions.

Alcohol and Drug Abuse

Alcohol and drug abusers (a category that may also include self-medicated patients and those who are taking a large number of physician-directed medications) are also poor candidates for outpatient surgery. Chronic alcoholism is associated with a number of serious metabolic disorders, and chronic drug abusers often have many medical problems that are related to the habit (e.g., endocarditis, superficial infections, hepatitis, and thrombophlebitis).

Psychotropic Drug Therapy

Except for MAO inhibitors, most psychotropic drugs do not interact with anesthetics. Continuation of anxiolytics probably has a beneficial effect overall.

Psychiatric Illness

Mental instability is a potential problem even in the best of circumstances. A competent adult must be available to provide care for a mentally unstable patient after operation. One benefit of outpatient surgery for such patients, as for very young and very old patients, is that it allows them to return quickly to a familiar environment, which is desirable when safety can be ensured. If safety cannot be ensured, admission is indicated.

Selection of Appropriate Site for Procedure

The following are the four main types of facilities used in the performance of outpatient surgical procedures:

1. Office surgical facilities (OSFs). These include individual surgeons' offices and larger group-practice units.
2. Freestanding day surgical units. These are often used by managed health care systems and independent contractors.
3. In-hospital day surgical units. These are often associated with inpatient units.
4. In-hospital inpatient units.

At times, these facilities are collectively referred to as ambulatory surgical centers (ASCs); however, the term ASC also has a specific meaning to third-party payors (especially Medicare) for billing purposes.

The primary influences on the choice of setting are the type of procedure to be performed and the condition of the patient. There is an increasingly recognized need to implement standards and guidelines for surgery performed in the office. Many states have already enacted standards to regulate such surgical procedures, especially in regard to the level of anesthesia administered. The ACS, in cooperation with a coalition under the umbrella of the American Medical Association, has issued 10 core principles for patient safety in office-based surgery [see Table 6].¹²

It is clear that many individually operated units are delivering cost-efficient, safe, and effective care. The imposition of costly regulations and accreditation processes on such units may be fiscally prohibitive. It is equally clear, however, that many such units may well be delivering substandard care, and at present, there is no way of determining quality and safety in these units. Several institutions are currently involved in devising guidelines, standards, and even regulations. Already, some payors, such as Medicare, do not provide reimbursement for care delivered in nonaccredited facilities.

Accordingly, it is wise to have an outpatient surgical facility accredited by JCAHO or another major outpatient surgical accrediting organization. At present, besides JCAHO, the following accrediting organizations are approved by Medicare: the

Table 6 Core Principles of Patient Safety for Office-Based Procedures¹²

1. Guidelines or regulations should be developed by states for office-based surgery according to levels of anesthesia defined by the American Society of Anesthesiologists' (ASA's) "Continuum of Depth of Sedation" statement dated October 13, 1999, excluding local anesthesia or minimal sedation.
2. Physicians should select patients by criteria including the ASA patient selection Physical Status Classification System and so document.
3. Physicians who perform office-based surgery with moderate sedation/analgesia, deep sedation/analgesia, or general anesthesia should have their facilities accredited by JCAHO, the American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF), AOA, or a state recognized entity, or are state licensed and/or Medicare certified.
4. Physicians performing office-based surgery with moderate sedation/analgesia, deep sedation/analgesia, or general anesthesia must have admitting privileges at a nearby hospital, or a transfer agreement with another physician who has admitting privileges at a nearby hospital, or maintain an emergency transfer agreement with a nearby hospital.
5. States should follow the guidelines outlined by the Federation of State Medical Boards (FSMB) regarding informed consent.
6. For office surgery with moderate sedation/analgesia, deep sedation/analgesia, or general anesthesia, states should consider legally-privileged adverse incident reporting requirements as recommended by the FSMB and accompanied by periodic peer review and a program of Continuous Quality Improvement.
7. Physicians performing office-based surgery must be currently board certified/qualified by one of the boards recognized by the American Board of Medical Specialties, American Osteopathic Association, or a board with equivalent standards approved by the state medical board. The procedure must be one that is generally recognized by that certifying board as falling within the scope of training and practice of the physician providing the care.
8. Physicians performing office-based surgery with moderate sedation/analgesia, deep sedation/analgesia, or general anesthesia may show competency by maintaining core privileges at an accredited or licensed hospital or ambulatory surgical center, for the procedures they perform in the office setting. Alternatively, the governing body of the office facility is responsible for a peer review process for privileging physicians based on nationally-recognized credentialing standards.
9. For office-based surgery with moderate sedation/analgesia, deep sedation/analgesia, or general anesthesia, at least one physician who is currently trained in advanced resuscitative techniques (ATLS, ACLS, or PALS), must be present or immediately available with age and size-appropriate resuscitative equipment until the patient has been discharged from the facility. In addition, other medical personnel with direct patient contact should at a minimum be trained in Basic Life Support (BLS).
10. Physicians administering or supervising moderate sedation/analgesia, deep sedation/analgesia, or general anesthesia should have appropriate education and training.

American Association for Accreditation of Ambulatory Surgery Facilities (AAAASF) and the Accreditation Association for Ambulatory Health Care (AAAHC). The CMS requires certification by one of these bodies before a facility can be classified as an ASC for reimbursement purposes. Thus, if reimbursement for Medicare patients is a goal, appropriate certification should be a priority. It is merely a matter of time before the lead taken by those states that already require accreditation of outpatient facilities is followed by most, if not all, of the remaining states. It is hoped and anticipated, however, that the states will be guided by the ACS's 10 core principles.

The ACS has developed guidelines for office-based surgery and continues to reevaluate these guidelines periodically.¹³ (The third edition is currently available from the ACS.) In contrast to its accrediting activities in cancer and trauma, however, the ACS

does not certify outpatient surgery facilities. The goal of the ACS initiative is simply to present readily acceptable guidelines that meet a minimum standard for surgical care without the necessity of a costly and time-consuming accreditation process. The guidelines are “intended to ensure and maintain superior quality of care for the surgical patient who undergoes an outpatient procedure in an office-based or ambulatory surgical facility.”¹³

The concept of governance in an ASC is key to quality. In effect, governance comprises the rules and regulations that determine how the facility does business. The ultimate authority and responsibility reside with the governing body. The processes outlined in the governance manual should include the following¹³:

1. Specifying mission and goals, including the types of services provided.
2. Defining organizational structure.
3. Adopting policies and procedures for the orderly conduct of the ASC.
4. Adopting a quality-assurance (QA) program.
5. Reviewing and taking appropriate action on all legal affairs of the unit and its staff.
6. Ensuring financial management and accountability.
7. Establishing a policy on patients’ rights.
8. Approving all arrangements for ancillary medical care delivered in the ASC, including laboratory, radiologic, pathologic, and anesthesia services.
9. Conducting the operation of the unit without discrimination on any basis (including the presence of disabilities).

Other regulatory agencies must also be taken into account in the management of an ASC, especially if laboratory, x-ray, and pharmacy services are being offered. Examples include the Clinical Laboratory Improvement Amendments (CLIA) of 1988 and the Occupational Safety and Health Administration (OSHA) standards on hazard communication (29CFR1910.1200) and blood-borne pathogens (29CFR1910.1030). In addition, compliance with local and state fire and safety regulations and state nuclear regulatory agencies is essential.

An important aspect of the ACS guidelines is that they take into account the differing capabilities of individual facilities. The ACS classifies ambulatory surgical facilities into three categories—classes A, B, and C—on the basis of the level of anesthesia provided, the types of procedures performed, and the degree of sedation employed.¹³ The suggested guidelines for each class of unit differ; for example, less resuscitation equipment would be required in a class A facility than in a class C facility. This differentiation makes it easier for a small OSF to demonstrate compliance with reasonable guidelines, in that the relevant requirements are not as extensive as they would be for a more comprehensive center.¹³

Hospital-based ambulatory care units that are extensions of inpatient facilities obviously have many advantages for the surgeon and the patient, but they are often less efficient and convenient than other ambulatory facilities. On the other hand, it is easier to assess the safety and quality of hospital-based units, in that the QA functions of the hospital must extend to such units. JCAHO is now well established in the voluntary accreditation process for ambulatory health care facilities, as well as for inpatient facilities. Even though accreditation is still voluntary, it is clear that a mandate already exists for some sort of QA for ambulatory facilities.

In 1993, the Office of the Inspector General (OIG) reported on the appropriateness of the surgical setting, the medical necessity of the surgical procedure, and the quality of care performed

Table 7 Premedications

Class	Drug (Trade Name)	Recommended Dose and Route of Administration	Onset (min)
Anxiolytics	Midazolam* (Versed)	Titrate in 0.5–1.0 mg aliquots I.V. (total, ~ 2–3 mg) 7.5–15 mg p.o.	1–5 15–30
	Diazepam (Valium)	4–10 mg (0.05–0.15 µg/kg) I.V. 5–10 mg p.o.	1–5 15–40
Narcotics†	Fentanyl (Sublimaze)	0.5–1.0 µg/kg I.V. or I.M.	—
	Sufentanil (Sufenta)	0.1–0.25 µg/kg	—

*Drug of choice. Oral administration allows children to be separated from parents as early as 15 min after ingestion, with no prolongation of recovery.

†Long-acting narcotics such as meperidine and morphine are usually not recommended for use in outpatient surgery.

in physicians’ offices.¹⁴ The data were obtained from the 1989 Part B Medicare Annual Data and thus are somewhat dated; however, it is likely that the situation has not changed greatly over the succeeding years. The 1993 report contained disturbing findings: in 20% of the medical records, reasonable quality of care was not documented; in 13%, an indication for surgery was not documented; for a small number of operations, the physician’s office was not an appropriate setting; and in 16% of sample cases, procedure codes did not match the operations performed. Physicians performing surgery in the office-based setting need to pay careful attention to compliance with documentation requirements concerning safety. The headline in a surgical newspaper article about the OIG report described office-based surgery as “the Wild West of surgery”¹⁵—not the image that the surgical profession would like to project!

Performance of the Operation

PREOPERATIVE PATIENT EDUCATION

Time spent in preoperative preparation of the patient—whether by the surgeon, anesthesiologist, nurse, or other personnel—is time well spent. Surgical patients are especially susceptible to preoperative anxiety and stress during the week before the intended surgical procedure. This increased stress level continues into the postoperative period, until the patient is assured of an uneventful recovery.¹⁶ Well-informed patients have been demonstrated to have less stress perioperatively.¹⁷

Preoperative education needs to cover topics of particular concern for patients, which include intraoperative awareness, awakening after sedation, postoperative pain and nausea, and socioeconomic aspects such as return to work and loss of income. Education needs to take place sufficiently far in advance; rarely

Table 8 Premedication and Recovery Time¹⁹

Type	Number of Patients	Recovery Time* (min)
No premedication	1,015	179 ± 113
Diazepam	98	168 ± 104
Pentobarbital	25	231 ± 88
Narcotics (meperidine, morphine)	388	208 ± 101
Hydroxyzine	92	192 ± 120

*Values are ± SD.

does discussion immediately before the procedure, such as in the preoperative area, lessen stress levels.

Preoperative teaching for children is a special case. Such teaching must be age appropriate, and it should address sources of particular distress in children, especially separation from caregivers and changes in dietary habits.

ORAL-INTAKE GUIDELINES

Prolonged fasting does not guarantee an empty stomach. In contrast, liquids pass through the stomach quite quickly; the half-time of clear liquids is 10 to 20 minutes. There is less content in the stomach of patients 2 hours after consuming small amounts of clear liquids than in the fasting patient.¹⁸ The risk of dangerous hypoglycemia should be more of a concern than stomach volume. For that reason, patients should be permitted small quantities of clear liquids up to 2 hours before the procedure, and the old standard of “NPO past midnight” should be abandoned. These recommendations are especially applicable to infants and children, but they also apply to elderly patients and debilitated patients with diabetes or other metabolic diseases.

PREMEDICATION

Premedication is an important adjunct to local and regional general anesthesia [see Table 7].¹⁹ It can facilitate performance of the procedure by alleviating fear and anxiety, supplementing analgesia, reducing gastric acidity and volume, reducing oral and airway secretions, decreasing histamine effects in patients with multiple allergies, limiting postoperative nausea and vomiting (PONV), and controlling infection.

On the other hand, premedication, especially with narcotics, can also delay recovery; in fact, patients may actually take longer to recover from premedication and local anesthesia than from general anesthesia. Still, no patient should be denied premedication out of fear that it might delay discharge. Some studies have shown that premedication with agents other than long-acting narcotics does not prolong recovery time [see Table 8].²⁰ Narcotic premedications are the usual cause of PONV and one of the major reasons for admission of outpatients to the hospital.

The five major categories of agents used for premedication are (1) anticholinergic drugs, (2) narcotics, (3) anxiolytics, (4) antinauseants and antiemetics, and (5) antacids and histamine antagonists.

Anticholinergic Drugs

Atropine and scopolamine are not routinely indicated for outpatient premedication, because newer anesthetics are less irritating than older ones and because use of anticholinergic agents may increase the incidence of cardiac irregularities. If an anticholinergic is needed, glycopyrrolate, 0.2 to 0.3 mg I.M. or I.V., is a better alternative in that it does not cross the blood-brain barrier and causes less tachycardia than atropine does.

Narcotics

The primary effect of narcotics is the relief of pain; however, they also have significant side effects that limit their usefulness for outpatient procedures. Fentanyl is appropriate for outpatient surgery because of its short duration of action and its limited side effects; it should be given within 30 minutes of the actual induction of anesthesia. Long-acting narcotics, especially meperidine and morphine, are usually not indicated in the outpatient setting.

As outpatient surgical procedures become more lengthy and complex, larger doses of short-acting narcotics such as fentanyl are being used. As the doses are increased, however, the advantages of short-acting drugs over long-acting drugs become less

pronounced. Newer short-acting narcotics are now available, but they have side effects of their own.

Anxiolytics

Most barbiturates are long-acting agents and thus are not indicated for outpatient procedures. Very short acting barbiturates, such as thiopental, are occasionally used during anesthesia. Nonbarbiturate tranquilizers, such as midazolam or diazepam, are being used more often, primarily because they do not cause much sleepiness and because they may reduce the amount of anesthetic required. Midazolam has become the medication of choice because of its ease of administration (it is nonirritating as a parenteral injection), rapid onset, and flexibility (an oral formulation is now available, and is especially useful for children). In addition, these benzodiazepines are useful in stopping convulsions.

Antinauseants

Administration of antinauseants is often begun in the preoperative setting.²¹ Given that PONV is a common cause of prolonged recovery and of subsequent hospital admission, preventive measures aimed at high-risk patients are preferable to treatment.

Antacids and Histamine Antagonists

Antacids and histamine antagonists are sometimes used in an effort to diminish the risk of gastric aspiration and the consequent deleterious effects of acidic gastric contents on the respiratory tract, but they have not been proved to be beneficial in this respect. It is important to remember that most of the commonly used antacid preparations are composed of particulate matter, so aspiration of the antacid can itself be a serious problem. Patients who are assumed to be at high risk for aspiration (e.g., diabetic, obese, or pregnant patients or patients with gastroesophageal reflux disease [GERD], stroke, or swallowing difficulties) should be premedicated with an H₂ receptor antagonist on the evening before and the morning of the operation. Alternatively, these high-risk patients may be premedicated with a nonparticulate (i.e., clear) antacid, such as sodium citrate; a 50 ml dose of sodium citrate 1 hour before the operation raises the pH to a safe level, albeit at the expense of a slightly increased gastric residual volume.²² Rapid infusions of H₂ inhibitors at the time of surgery are discouraged because of the possibility that bradycardia will result.

ANESTHESIA

It is beyond the scope of this chapter to address general anesthesia in depth. We merely note that one should be prepared to meet all of the contingencies that can accompany general anesthesia, especially when anesthesia is delivered by someone other than an anesthesiologist and is not immediately supervised by an anesthesiologist. The patient's cardiac activity, blood pressure, temperature, respiration, and neuromuscular activity should be properly monitored. The incidence of postoperative complications is related to the anesthetic technique²³: one of 268 patients who receive local anesthesia experience postoperative complications, compared with one of 106 patients who undergo sedation. Obviously, the anesthetic technique used reflects the invasiveness of the surgical procedure.

Local Anesthetics for Local and Regional Anesthesia

As outpatient surgery has become more popular, so too has the use of local anesthetics for local and regional control of pain [see 1:5 *Postoperative Pain*]. Local anesthetics are usually administered by the surgeon. It is crucial that the patient accept this type of anesthesia and be psychologically suited for it; obviously, local or

Table 9 Local Anesthetics for Infiltration

Drug		Plain Solutions		Epinephrine-Containing Solutions	
		Maximum Adult Dose (mg)	Duration (min)	Maximum Adult Dose (mg)	Duration (min)
Short-acting	Procaine 1%–2%	800	15–30	1,000	30–90
Intermediate-acting	Lidocaine 0.5%–2.0%	300	30–60	500	120–360
	Mepivacaine 1%–2%	300	45–90	500	120–360
Long-acting	Bupivacaine* 0.25%–5.0%	175	180+	225	240+

*Not recommended for children younger than 12 yr.

regional anesthesia can be very disturbing and disruptive when administered inadequately or when given to an emotionally unstable patient. During the preoperative conference or the patient education session, the surgeon, the anesthesiologist, or both should make a point of describing how the anesthetic will be administered and what sensations will ensue.

Local anesthetics can be classified into three groups according to their potency and duration of action: (1) low potency and short duration (e.g., procaine and chlorprocaine), (2) moderate potency and intermediate duration (e.g., lidocaine, mepivacaine, and prilocaine), and (3) high potency and long duration (e.g., tetracaine, bupivacaine, and etidocaine) [see Table 9].

Most local anesthetics are administered by infiltration into the extravascular space. In some areas, especially the hands, intravascular (I.V. regional) infiltration has been used with considerable success; however, inadvertent intravascular administration of epidural doses of the high-potency agents can lead to life-threatening complications [see Toxicity and Allergy, below]. Although such complications have not been reported in association with inadvertent intravascular administration during infiltration for local anesthesia, it is advisable to check carefully to be sure that the injecting needle is not located in an intravascular site. Intravascular injection can usually be prevented by constantly aspirating during infiltration and by infiltrating only while withdrawing the needle.

Mixing local anesthetics is an effective means of obtaining the advantages of more than one drug at once. At the Lichtenstein Hernia Institute, in Los Angeles,²⁴ patients undergoing repair of inguinal hernias receive a 50-50 mixture of 1% lidocaine and 0.5% bupivacaine. The maximum therapeutic dose of lidocaine is 300 mg alone and 500 mg with epinephrine; the maximum therapeutic dose of bupivacaine is 175 mg alone and 225 mg with epinephrine. The addition of 1 mEq/10 ml of sodium bicarbonate to the solution shortens the onset time²⁵ and reduces discomfort by raising the pH. This combination of drugs has several advantages: (1) lidocaine has a rapid onset, whereas bupivacaine prolongs the duration of the effect; (2) the negative chronotropic and inotropic action of lidocaine may well counteract the cardiac excitability of bupivacaine; and (3) use of multiple drugs makes it less likely that the maximum therapeutic dose of any single agent will be exceeded.

Regional anesthesia, usually in the form of a regional nerve block, is generally administered by an anesthesiologist but can be adequately administered by a knowledgeable surgeon.

The use of epinephrine with local anesthetics prolongs the duration of the anesthetic effect without delaying its onset; however, epinephrine should not be used with anesthetics at sites where the vascular supply distal to the site of infusion is marginal

(e.g., the fingers, the toes, the nose, and the external ears). In addition, adrenergic agents should not be used in unstable cardiac patients unless absolutely necessary.

Administration of long-acting local anesthetics (e.g., 0.25% bupivacaine, injected in the skin edges at the end of the procedure) seems to limit postoperative pain and thus to encourage early activity and ambulation. Often, this technique not only postpones pain but reduces it as well. Bupivacaine is not, however, recommended for patients younger than 12 years.

Adjunctive Use of Local Anesthetics to Prolong Anesthetic Effect

It is clear that even when regional anesthetics, general anesthetics, or both are employed, adjunctive use of local anesthetics at the end of the procedure prolongs the anesthetic effect. In addition, once the patient realizes that ambulation is possible without discomfort, he or she is more likely to leave the hospital sooner and is less likely to need additional postoperative analgesia. Several centers are currently experimenting with administering local anesthetics before operation; the hypothesis, which is still unproven, is that preoperative administration may result in less use of postoperative analgesics and a longer anesthetic effect than administration at the end of the procedure.

Injection of joint capsules with long-acting anesthetics and narcotics (e.g., morphine sulfate) relieves a great deal of postoperative pain. Bathing of wounds with bupivacaine is a safe and effective method of decreasing postoperative pain.²⁶ The addition of epinephrine can extend the prolongation of analgesia to 12 hours after operation.

Nonsteroidal Anti-inflammatory Drugs

Some centers use nonsteroidal anti-inflammatory drugs (NSAIDs) to reduce inflammation and thus pain [see 1:5 *Postoperative Pain*]. In addition, it has been shown that NSAIDs significantly reduce the need for opioid analgesics after abdominal procedures. Administration of ketorolac over a short period (i.e., 5 days or less), first at the time of operation (60 mg I.M. in the OR; lower doses for patients weighing less than 50 kg, those older than 65 years, and those with impaired renal function) and then every 6 hours thereafter (10 to 15 mg p.o.), has improved recovery after many operations, especially perianal and inguinal procedures. (Ketorolac is, however, contraindicated as a preoperative prophylactic analgesic.) Other NSAIDs can be given in transdermal patches (which are not recommended for children) or transnasally.

Toxicity and Allergy

Whenever local anesthetics are used, especially when they are administered regionally for major nerve blockade, the possibility

of systemic toxicity should be considered. Such toxicity often results from inadvertent intravascular injection of these agents, leading to a sudden increase in systemic concentration.²⁰ The rate of injection is inversely related to the patient's tolerance of the drug: the higher the injection rate, the lower the tolerance. In general, arterial infusion is less likely to cause a toxic reaction than venous infusion because of the delay in circulation through the distal capillary network. Other factors that can lead to toxic reactions are a diminished drug detoxification rate, systemic acidosis, and individual sensitivities, which are highly variable.

In the CNS, toxic reactions range from drowsiness to frank convulsions. One study found that the incidence of mild toxic reactions to local and regional anesthetics was 0.38% and the incidence of convulsions was 0.12%.²⁷ In the cardiovascular system, toxicity is initially manifested by elevated blood pressure; eventually, depression of systemic resistance and myocardial contractility leads to cardiovascular collapse. The myocardial depression associated with intravascular injection of 0.75% bupivacaine for epidural anesthesia has been reported to be strongly resistant to treatment in pregnant women.²⁸ Systemic toxicity is also manifested by alterations in the metabolic system, such as derangement of acid-base balance. (Respiratory or metabolic acidosis leads to an increased sensitivity to local anesthetics.) All such reactions are best managed by prevention. Constant vigilance is necessary to ensure that inadvertent intravascular injection does not occur at the time of infiltration. Any serious reactions (e.g., convulsions and cardiovascular collapse) that arise despite precautions are treated with standard measures.

Many patients claim to be allergic to anesthetics (which they often refer to generically as Novocain), but true allergic reactions are rare.²⁹ A careful history of allergic drug reactions should be taken, including reactions to concomitant medications such as epinephrine. It is important to explain to a patient the nature of any reaction that occurs so that if the reaction is not in fact an allergic one, he or she will not give a history of allergy to anesthetics in the future.

Allergic reactions are mediated by the release of histamine. Previous exposure to the offending local anesthetic can lead to the production of IgE antibodies, which initiate anaphylaxis on subsequent exposure; however, anesthetics can also initiate complement-mediated release of histamine without previous exposure. Histamine release leads to characteristic symptoms: skin erythema, followed by erythema in various regions of the body and edema of the upper airway. Abdominal cramps and cardiac instability may also be present.

If an allergic reaction occurs, administration of the drug should be stopped immediately. Epinephrine, 0.3 to 0.5 ml of a 1:1,000 dilution, should immediately be given either locally (I.M. or subcutaneously) or, if the reaction is severe, systemically.³⁰ Diphenhydramine, 0.5 to 1.0 mg/kg, should also be given systemically. If bronchospasm occurs, aminophylline, 3 to 5 mg/kg I.V., should be administered. Corticosteroids have been used in this setting, but there is little evidence that such therapy is helpful [see Table 10].

One common cause of allergic reactions is sensitivity to paraben derivatives, which are preservatives used in local anesthetics. Paraben preservatives resemble para-aminobenzoic acid (PABA), a metabolic-breakdown product of ester-type anesthetics (e.g., procaine, benzocaine, and tetracaine). PABA is a member of a class of compounds that are highly allergenic. Patients sensitive to sunscreens containing PABA often show cross-sensitivity to ester-type local anesthetics. Patients who are allergic to a local anesthetic usually can be safely given a preservative-free

anesthetic of unrelated structure. An intradermal skin test, in which 0.1 ml of the anesthetic drug is injected intradermally into the volar aspect of the forearm, may be tried. A negative reaction indicates that the drug probably can be used safely; nevertheless, resources for handling major cardiopulmonary irregularities should be available when anesthetics are used in previously sensitized patients.³⁰

Control of Nausea and Vomiting

Many predisposing factors play a role in causing PONV. Not all of these factors can be managed. Nevertheless, it behooves the surgeon and the anesthesiologist to identify patients at risk so as to minimize the incidence of this debilitating syndrome, which is responsible for a large number of hospital admissions after outpatient surgical procedures.

Some of the more common causes of nausea are often overlooked. Pain is in itself capable of causing nausea and vomiting. Accordingly, adequate control of pain is essential, and the patient must not be deprived of analgesics under the false assumption that the medications are the only cause of the nausea. Changes in body activity, especially assumption of the upright position by a patient with hypotension, can also cause nausea, as is experienced before a vasovagal attack. In some patients who are prone to motion sickness, the sensation of motion is aggravated by the surgical procedure, the anesthetics, and pain. A preoperative history of frequent attacks of motion sickness is often a signal that the patient is prone to nausea and vomiting.

The use of narcotics in premedication, as well as in induction and maintenance of anesthesia, is definitely a cause of increased postoperative nausea and vomiting; however, some of the newer opioid analgesics (e.g., fentanyl, sufentanil, and alfentanil), when given judiciously as premedications [see Table 7], appear to reduce anxiety, decrease anesthetic requirements, and relieve pain in the early postoperative period.³¹ One should have a thorough understanding of the proper use of these medications before employing them in the ambulatory setting.

Benzquinamide, trimethobenzamide, promethazine, and prochlorperazine have all been used in an effort to control PONV but with only limited success.³² Droperidol had been popular for this purpose, but in December 2001, the Food and Drug Administration added a so-called black-box warning to the drug's labeling because of the potential for fatal cardiac arrhythmias; consequently, droperidol is now rarely used.³³ Metoclopramide acts specifically on the upper GI tract and is a useful premedication because it also encourages gastric emptying and prevents aspiration; however, it is a short-acting agent and thus may have to be given again after a long procedure. The usual dose of metoclopramide for the average adult patient is 10 to 20 mg.^{34,35}

Given that a history of motion sickness is a good predictor of increased risk for nausea and vomiting, it is not surprising that

Table 10 Treatment of Allergic Reactions to Local Anesthetics

Agent	Route of Administration	Recommended Dose
Epinephrine	I.M. or subcutaneously	0.3–0.5 ml of 1:1,000 dilution
Diphenhydramine	Systemically	0.5–1.0 mg/kg
Aminophylline	I.V.	3–5 mg/kg
Corticosteroids	I.V.	1 g

dimenhydrinate is effective in many cases. Indeed, in some cases, it is significantly more effective than droperidol.³⁶

Postoperative Care

The cornerstone of postoperative care in outpatient surgery is a well-instructed and well-informed patient. Many postoperative problems can be avoided if patients fully understand the nature of the proposed procedure, the potential side effects of the operation, and the role they must play in their own postoperative care. Facilitating such understanding not only helps prevent potential problems but also increases patients' overall satisfaction with the process of outpatient surgery.

RECOVERY

The process of postoperative recovery may be divided into three phases as follows.^{37,38}

Phase I

Phase I, or early recovery, includes the patient's return to consciousness and recovery of vital reflexes. Generally, phase I takes place in the postanesthesia care unit (PACU). Currently, however, as a result of increasing use of short-acting anesthetics³⁹ and conscious sedation, this phase sometimes occurs in the OR, thus eliminating the need for recovery in the PACU. This fast-track approach is being adopted more frequently in ASCs, where patients typically undergo shorter, less invasive procedures.⁴⁰ It is attractive because if patients can recover in the ASCs and avoid the PACU, they can be discharged sooner, and costs can thereby be reduced. On the other hand, more rapid recovery and discharge can mask some minor adverse symptoms, which may lead to patient dissatisfaction with ambulatory surgery.⁴¹

Several significant problems (e.g., PONV, pain, hypotension, and respiratory depression) may arise during phase I. Accordingly, the patient's vital signs, including oxygen saturation, must be closely monitored. Frequent reassessment in the PACU is indicated. A useful way of determining whether the patient is ready for discharge to phase II is to employ a scoring system such as the modified Aldrete system, which assigns scores from 0 to 2 in each of five categories (activity, respiration, circulation, consciousness, and oxygen saturation) [see Table 11].^{42,43}

Phase II

Phase II, or intermediate recovery, is the period between immediate clinical recovery and the time when the patient is ready to be discharged. This phase usually takes place in the ASC or the step-down unit. Patients still need periodic monitoring during this period because they often have not yet fully recovered from the effects of the anesthetic or the surgical procedure. As in phase I, patients must be thoroughly assessed according to predetermined criteria to determine whether they are ready to be discharged to the next phase of recovery.⁴⁴ Before discharge to phase III, patients should be provided with both verbal and written discharge instructions. A responsible adult must be present to accompany the patient home and assist in the final phase of recovery; often, the absence of such a person delays completion of phase II.

Phase III

Phase III, or late recovery, takes place outside the health care facility, usually at home. Because the anesthetic may still be affecting patients 24 to 48 hours after the procedure (and sometimes considerably longer), they should be cautioned not to drive, operate heavy machinery, or make important decisions during

Table 11 Modified Aldrete Phase I Postanesthetic Recovery Score^{42,43}

Patient Sign	Criterion	Score
Activity	Able to move 4 extremities*	2
	Able to move 2 extremities*	1
	Able to move 0 extremities*	0
Respiration	Able to breathe deeply and cough	2
	Dyspnea or limited breathing	1
	Apneic, obstructed airway	0
Circulation	BP \pm 20% of preanesthetic value	2
	BP \pm 20%–49% of preanesthetic value	1
	BP \pm 50% of preanesthetic value	0
Consciousness	Fully awake	2
	Arousable (by name)	1
	Nonresponsive	0
Oxygen saturation	SpO ₂ > 92% on room air	2
	Requires supplemental O ₂ to maintain SpO ₂ > 90%	1
	SpO ₂ < 90% even with O ₂ supplement	0

*Either spontaneously or on command.
SpO₂—pulse oximetry

this period. It is in phase III that patients may experience various postoperative problems [see Postoperative Problems, *below*] that require specific management. Patients should also be informed about warning signs and symptoms. Patients should be provided with contact numbers to call if these symptoms occur and with instructions on returning to a health care facility if necessary.

DISCHARGE INSTRUCTIONS

Ideally, ambulatory surgery patients should be given their discharge instructions during the preoperative conference in the office. A variety of patient education tools (e.g., pamphlets, detailed written instructions, and videos) may be used to help educate patients about their operations and subsequent postoperative care.³⁸ Verbal reinforcement of written instructions by the surgeon is an important component of patient education. Communications from the surgeon should be consistent with the other materials (e.g., pamphlets, brochures, and preprinted instruction sheets) provided to the patient. The instructions the patient is given before leaving the ASC must also be consistent with what the patient or family has previously been told, whether orally or in writing, by the surgeon. Providing careful perioperative instructions can yield several significant benefits, including increased patient satisfaction, improved outcomes, decreased patient anxiety, improved compliance, and even reduced costs.⁴⁵

In a multicenter British study, up to 25% of patients did not comply with postoperative instructions.⁴⁶ There are several barriers to comprehension of or adherence to instructions that the surgeon must take into account.⁴⁷ The most obvious barrier is that patients simply may not understand or remember the instructions given. It has been shown that patients' ability to understand written instructions may be a few grades lower than their actual education level⁴⁸; accordingly, instructions should be written in such a way as to be easily understood by patients. In addition, patients may not be able to remember long, detailed verbal instructions well, even if they understood them on first hearing; thus, supplemental written instructions should be provided.

Table 12 Issues to Address in Postoperative Instructions

Activity	Possible complications or side effects (of procedure, anesthesia, or medications)
Medication	Follow-up testing or treatments
Diet	Emergency contacts, including surgeon and acute care facility
Wound care	
Pain relief	

Table 13 Reasons for Notification of Surgeon³⁷

Persistent nausea and vomiting	Persistent uncontrolled pain
Bleeding	Excessive redness or drainage from incision
Fever (usually > 101° F [38.3° C])	Urinary retention

Another barrier to comprehension and compliance is that patients' perception of when postoperative recovery is complete may be inaccurate. Many patients, mistakenly believing that they are fully recovered, resume driving, working, or other strenuous activities prematurely. Surgeons must therefore stress the necessity of following discharge instructions exactly, even if patients feel that they are completely recovered.

Postoperative instructions should include several specific categories of information [see Table 12], preferably in writing. In addition, a follow-up appointment should be made, and patients should be given clear directions regarding access to postoperative care in the event of an emergency.^{37,49} As a rule, it is best to present these instructions at the time of the preoperative evaluation, but it is probably advisable to present them again at the time of discharge from the ASC.

Activity instructions should address exercise or activity level, driving or operating machinery, return to work, and showering or bathing. The importance of following postoperative instructions, especially regarding activities such as driving, must be made clear to the patient. Patients often feel that these instructions are overly cautious, and therefore, many patients are noncompliant with activity instructions.⁴⁶ If patients are likely to need someone to assist them in their routine daily activities, they should be informed well in advance, so that suitable arrangements can be made preoperatively.

Detailed wound care instructions, including directions for removing or changing dressings, applying ice or heat, and elevating the affected area, are essential. In addition, patients should be told what to do when they see signs of wound problems, such as redness, drainage, or bleeding. Patients should also be taught drain or catheter care, if pertinent, before the operation. If the outputs of these devices must be measured and recorded, patients or caretakers should be taught how to do this as well.

It is vital that patients and caretakers be advised regarding resumption of preoperative medications. In addition, patients should be provided with specific information about pain medications, including drug names, dosages, potential side effects, and drug interactions. If patients are taking analgesic preparations that contain acetaminophen, they must be cautioned not to take other acetaminophen-containing medications, because of the potential for hepatotoxicity. Diabetic patients need special in-

structions regarding medications if the surgical procedure may interfere with their usual diet.

As part of the postoperative instructions, patients or caretakers should be given a list of items that require them to notify the physician [see Table 13]. Access to postoperative care in the event of an emergency is mandatory. Whether such access is available in a given instance often plays a role in determining whether ambulatory surgery is appropriate for that patient. The patient should be given the telephone number of the surgeon and the ASC, as well as the location and telephone number of the appropriate emergency care facility.³⁷ Providing careful and thorough postoperative instructions, however, should help minimize unnecessary telephone calls to the surgeon and inappropriate visits to an emergency facility.⁵⁰

POSTOPERATIVE PROBLEMS

Delayed Discharge or Unexpected Hospital Admission

The overall rate of unanticipated hospital admission after ambulatory surgery ranges from 0.15% to 2.5%^{4,51-55} The rate may vary considerably, depending on what types of procedures are performed at the facility, how patients are selected for outpatient surgery, patient characteristics such as age, and whether the facility is hospital-based or independent. Many ASCs use unexpected hospital admission after ambulatory surgery as a quality indicator. Analysis of such admissions may be useful in helping a facility develop appropriate patient and procedure selection criteria.⁵³ It may also be helpful for developing discharge criteria and identifying patients who will require additional monitoring before discharge.

Factors leading to hospital admission from an ASC may be classified into four general categories: procedure-related factors, anesthetic-related factors, patient-related factors, and system-related factors.

Procedure-related factors Length of operation has been shown to be an independent predictor of increased admission rates after ambulatory surgery.^{45,46} Other procedure-related factors associated with increased admission rates include a procedure that is more extensive than planned, inappropriate booking of the case, the need for a subsequent procedure, and intraoperative adverse events (e.g., bleeding or bowel perforation during laparoscopy). Uncontrolled pain related to the procedure is a significant cause of unanticipated admission from an ASC.⁵² Accordingly, measures to prevent and control excessive pain should be taken [see Pain, below].

Anesthetic-related factors One of the most common of the anesthetic-related factors necessitating hospital admission is PONV [see Nausea and Vomiting, below]. Other adverse reactions to anesthesia that call for admission or observation include delayed emergence from the anesthetic, excessive drowsiness, and delayed resolution of a regional block; more serious reactions include pulmonary aspiration of gastric contents and malignant hyperthermia.

Patient-related factors Patient-related factors leading to hospital admission after ambulatory surgery may be further divided into two subcategories: medical factors and social factors.

Many of the medical factors are related to preexisting conditions⁵⁶; for example, it has been shown that patients with preexisting congestive heart failure stay longer in the ASC.⁵⁷ Such findings underscore the need for appropriate selection of patients

for ambulatory surgery and the importance of optimizing treatment of any preexisting medical conditions.

Social factors account for as many as 41% of delays in discharge from the ASC. The most common social reason for delayed discharge is the lack of an adult escort to accompany the patient home.^{58,59} To prevent this occurrence, patients should be counseled preoperatively in the office on the need for someone to accompany them home from the ASC, and the availability of the escort should be verified when the patient presents to the ASC before the scheduled procedure.

System-related factors Many system-related factors may delay discharge or increase the postoperative admission rate from the ASC. These include patient prescriptions that are not ready, nurses who are too busy to instruct and discharge patients, uncompleted paperwork, or physicians who have not discharged the patient.⁵⁹ Because the PACU may close before the patient is fully recovered, some patients need to remain in the ASC until their recovery is complete.⁵³ For an ASC to be efficient and profitable, as well as to promote patient satisfaction, these types of unnecessary delays should be anticipated and avoided.

Nausea and Vomiting

PONV is distressing to patients and is a common source of patient dissatisfaction with ambulatory surgery and anesthesia.⁶⁰⁻⁶⁴ In addition, PONV often causes delayed discharge from the ASC or unplanned hospital admission, thereby inconveniencing patients and increasing the cost to the ASC.^{37,57} Patients who experience PONV report more difficulty in resuming normal activities and may require a longer recovery period.⁶⁵ PONV may also lead to a variety of postoperative problems, including aspiration pneumonitis, dehydration, esophageal rupture, and wound dehiscence.⁶⁶

The etiology of PONV is complex and includes factors related to the procedure, the anesthetic, and the patient. Certain operations, including ophthalmic procedures, orchiectomy, and middle-ear procedures, are associated with a high incidence of PONV. Certain anesthetics (e.g., narcotics, etomidate, and ketamine) have been shown to carry a greater risk of PONV than other agents do.⁶⁰ Use of propofol as an induction agent has been shown to decrease the incidence of PONV.⁶⁷ Other anesthetic-related causes include gastric distention during mask ventilation, hypotension related to regional anesthesia, and vagal stimulation. Of the patient-related causes, younger age, anxiety, pain, underlying medical conditions such as gastroparesis, and a previous history of PONV are also known to be associated with a higher incidence of PONV.

Prevention of PONV depends on a clear understanding of the etiology and on an accurate assessment of the patient's level of risk for this complication. Given the cost and side effects of the medications required, prophylaxis for all patients undergoing ambulatory surgery is not advisable⁶⁰; however, prophylaxis for patients known to be at high risk for PONV may result in decreased cost to the patient and facility, greater patient satisfaction, and fewer associated complications.

PONV prophylaxis should include both pharmacologic and non-pharmacologic interventions. Preoperative sedation to alleviate anxiety may facilitate control of PONV, as may adequate management of postoperative pain [see Pain, below]. Judicious selection of anesthetic agents also helps reduce the incidence of PONV. Limiting patient motion after certain operations (e.g., ophthalmic procedures) may be beneficial. A more flexible approach to postoperative fluid intake may be helpful as well. One pediatric study found that patients who were required to drink liquids before being discharged

from an ambulatory surgical facility had a higher incidence of PONV.⁶⁸ A similar study of adult patients, however, did not document increased risk of PONV in patients required to drink fluids before discharge, nor did it document decreased risk in patients who were not so required.⁶⁹ Given these findings, we believe that patients should be allowed to choose whether they want to drink fluids before discharge; oral fluid intake should not be a mandatory discharge criterion.

Several categories of antiemetic agents are available for prevention and treatment of PONV, the most common of which are the antihistamines, the antidopaminergics, and the antisero-toninergics.⁶⁰

The antihistamines have long been used to treat motion sickness and other disturbances of the vestibular pathway. They may be more effective than other antiemetics after middle-ear procedures. Common side effects include dry mouth and sedation.

One of the most commonly used antidopaminergic antiemetics is promethazine. This agent possesses both antihistaminic and anticholinergic properties and is therefore useful for treating motion sickness.⁶⁰ Droperidol has also been widely used for prevention of PONV. However, because of its association with fatal cardiac arrhythmias, which prompted the December 2001 black-box warning from the FDA—the most serious warning an FDA-approved drug can carry—and because of studies documenting slower recovery from anesthesia with droperidol than with other agents, the current consensus is that the use of droperidol should be limited.⁷⁰ Side effects of antidopaminergic agents include anxiety, dizziness, drowsiness, extrapyramidal effects, and hypotension. These effects are dose related and may continue after discharge.^{60,70}

The selective serotonin receptor antagonist ondansetron is very effective in preventing and treating PONV.⁷¹ The optimal prophylactic dose for adults is 4 mg.⁷² The side effects commonly seen with antihistamines (e.g., blurred vision, dry mouth, and diplopia) are rare with ondansetron.^{70,72}

Metoclopramide reduces PONV by increasing lower esophageal sphincter pressure and increasing gastric emptying. This agent may be useful in counteracting the effects of narcotics on gastric motility. Because it does not affect the vestibular system, metoclopramide is usually employed as an adjunct to other agents in the treatment of PONV. However, its use is somewhat controversial.^{60,66}

The synthetic glucocorticoid dexamethasone is also a safe and effective agent in preventing PONV.^{73,74} The delayed onset of action and prolonged effectiveness of dexamethasone make it ideal for use in conjunction with other agents in patients who are at particularly high risk for PONV.⁷³ Dexamethasone has few side effects and is more cost-effective than other agents.⁷⁵

In summary, the management of PONV requires a systematic approach. Identifying patients who are at high risk and providing multimodal treatment can often prevent PONV.⁷⁶

Pain

Effective pain management after ambulatory surgery depends on a clear understanding of the mechanisms of pain, a careful assessment of the type and degree of pain, and appropriate selection of pain-control methods so as to optimize patient comfort while minimizing side effects. Incomplete pain control is associated with several significant complications, such as PONV, reduced mobility, and inability to cough and breathe deeply. In addition, pain is associated with delayed discharge from phase II of recovery, more frequent return visits by the patient to a health care facility, and higher rates of unplanned hospital admission.^{77,78} Postoperative pain also can be physiologically harmful, causing increased release of catecholamines with resultant eleva-

tion of blood pressure and pulse rate. Inadequate postoperative pain control is a significant source of patient dissatisfaction with ambulatory surgery.⁵⁵ By limiting mobility, postoperative pain may hamper patient recovery. Moreover, inability to manage pain adequately after certain procedures makes it difficult (or even impossible) for surgeons to perform these procedures in an ambulatory setting.⁷⁹

Assessment of postoperative pain requires good communication between the surgeon and the patient. Patients have varying sensitivity to pain and respond differently to pain medication. Use of a measurement tool such as the verbal analogue scale can facilitate assessment of postoperative pain. A 1998 study found that 40% of patients reported moderate to severe pain in the first 24 hours after ambulatory surgery and that the best predictor of severe pain at home was inadequate pain control during the first few hours after the operation.⁷⁹ It is therefore crucial to assess patients' pain and treat it aggressively before discharging them from the ASC.

A key component of pain control after ambulatory surgery is education of patients regarding the degree of postoperative pain they may experience. It is not uncommon for patients to complain that they were given no information about how much pain to expect and how to manage it. During the preoperative visit, patients should be informed about various nonpharmacologic methods of alleviating pain. Depending on the procedure to be performed, appropriate methods may include application of ice, elevation of an affected extremity, wearing of loose-fitting clothing, sitz baths, or modified sleeping positions.⁸⁰ During the same visit, patients should also be informed about the medications they will be given for pain control—specifically, names, dosages, potential side effects, drug interactions, and precautions. Finally, patients should be told how to notify their physician if they continue to experience excessive pain.

The best pharmacologic strategy for controlling postoperative pain is to employ regimens comprising multiple analgesics that work synergistically.⁷⁸ So-called balanced analgesia involves giving medications from three different analgesic groups: nonopioids, opioids, and adjuvants.⁸¹

The nonopioid agents most commonly used after outpatient surgery are the NSAIDs and acetaminophen. NSAIDs act peripherally and have anti-inflammatory, analgesic, and antipyretic effects. They are very effective against mild to moderate pain. Side effects include gastric mucosal irritation and inhibition of platelet aggregation; however, newer NSAIDs that selectively inhibit the cyclooxygenase-2 (COX-2) enzyme exhibit these effects to a much lesser degree.⁸² One of the most commonly used NSAIDs in ambulatory surgery patients is ketorolac, which may be administered either I.V. or I.M. Its onset of action occurs approximately 30 minutes after administration, with peak effect coming at about 75 minutes.⁸¹ This agent causes reversible inhibition of platelet aggregation, which resolves 24 to 48 hours after the drug is stopped; it also has an adverse effect on renal function. Accordingly, ketorolac should be used with caution in elderly patients and in patients with altered renal function.⁸³

Acetaminophen acts to alleviate pain by a central mechanism. It lacks the antiplatelet effects of NSAIDs and has few side effects. Acetaminophen should not be given to patients with liver disease or chronic alcoholism. The maximum daily dose of acetaminophen in adults is 4,000 mg; thus, as noted [see Discharge Instructions, *above*], patients must be cautioned not to take any other acetaminophen-containing medications. This is a matter of particular concern because many of the commonly used oral narcotic pain preparations already include a significant amount of acetaminophen, which patients may not realize.⁸¹

Overall, opioids are the most commonly used pain medications after ambulatory surgery. They can be delivered via many different routes, including oral, I.V., I.M., transcutaneous, intranasal, oral transmucosal, and subcutaneous. The main concerns with respect to opioid use are the side effects and the potential for abuse. Common side effects include respiratory depression, sedation, reduction of rapid-eye-movement sleep, impaired GI motility, urinary retention, PONV, and allergic reactions. PONV is a particular problem; however, if other agents (e.g., NSAIDs and adjuvants) are being used as well, the opioid dosage can be reduced and the incidence of PONV thereby lowered.⁸³ Because of the many side effects of opioid analgesics, the preoperative teaching should include instructions to patients regarding the management of these side effects. The patient should also be instructed on avoiding driving and use of heavy machinery while taking these medications.

Adjuvant methods of controlling pain include infiltration of local anesthetics (e.g., bupivacaine) into the surgical site, continuous or patient-controlled regional anesthesia (PCRA) systems, local nerve blocks, and transcutaneous electrical nerve stimulation (TENS). Often, these measures add substantially to control of pain after ambulatory surgery. In particular, PCRA is very effective in certain procedures.⁸³ In this approach, a catheter is placed in the surgical site or near local peripheral nerves and attached to an elastometric (balloon) pump containing bupivacaine; the patient can then control administration of the local anesthetic.

Infection

The incidence of postoperative infection in ambulatory surgery patients varies, depending on the procedure performed and the risk factors for infection present. Overall, however, infection rates after ambulatory surgery tend to be substantially lower than those after inpatient surgery.^{84,85} Actual infection rates can be difficult to quantify in ambulatory surgery patients but should nonetheless be measured both as an indicator of quality and as an aid to reducing the incidence of infection.⁸⁶

Patients should be given a list of potential signs of infection (i.e., redness, drainage, excessive pain around the incision, and fever) and instructed to call the physician if these appear. The presence of any of these signs is an indication for examination by a physician. Most of the postoperative surgical site infections that occur in ambulatory surgery patients can be treated in the office with local wound care.

Many other types of infection may occur in ambulatory surgery patients, of which pneumonia, urinary tract infections, and prosthetic-device infections are the most common. Generally, these infections develop several days after the procedure; thus, it is important to schedule a postoperative visit around this time.

Urinary Retention

Postoperative urinary retention occurs in 0.5% to 5% of ambulatory surgery patients.^{87,88} Patients at high risk for this complication are those who have previously experienced urinary retention and those who are undergoing particular types of procedures (e.g., herniorrhaphy and anal procedures). Other predisposing factors are advanced age,⁸⁸ spinal anesthesia,⁸⁷ use of anticholinergics, bladder overdistention, use of analgesics, unrelieved pain, preoperative use of beta blockers,⁸⁹ and a history of preoperative catheterization.

Surgeons often require ambulatory surgery patients to void before discharge; however, this practice unnecessarily delays discharge of low-risk ambulatory surgery patients. A 1999 study showed that low-risk patients could be safely discharged without

voiding and did not benefit from being required to void spontaneously before discharge.⁸⁷ The incidence of postoperative urinary retention in these patients was 0%. In low-risk patients who were discharged without voiding, the mean time to voiding after discharge was 75 minutes, indicating that discharge had been expedited by at least that length of time. In high-risk patients, however, catheterization before discharge should be considered if they are unable to void. In addition, once discharged, high-risk patients should have ready access to a medical facility and should be instructed to return if they are still unable to void 8 to 12 hours after discharge.

The presence or absence of symptoms is not a reliable indicator of urinary retention: many patients are asymptomatic even with bladder volumes greater than 600 ml.^{87,90} Alternative methods of diagnosing urinary retention, such as ultrasonography or catheterization of patients known to be at high risk for urinary retention and unable to void before discharge, are more reliable.

Bladder overdistention is a significant cause of postoperative urinary retention.^{9,87} Judicious use of fluids helps minimize postoperative urinary retention in patients at high risk. Those who are at high risk for retention and are receiving substantial amounts of I.V. fluids should be considered for early catheterization to help prevent excessive distention of the bladder with resultant retention and bladder atony.

Patients who require catheterization more than once postoperatively may be safely discharged home after placement of an indwelling catheter. The catheter should be left in place for 24 to 72 hours, after which time it can be removed in the physician's office. In the absence of any complicating circumstances, there is generally no need to admit patients to a hospital simply because of urinary retention.

Other Postoperative Problems

Other common postoperative problems that may develop in ambulatory surgery patients are headache, insomnia, constipation, bleeding, and pharyngitis. Many of these problems can be handled by providing reassurance and carrying out simple interventions; however, some problems (e.g., headache and bleeding) may necessitate direct physician intervention to ensure that they do not worsen.

Headache occurs in 10% to 38% of patients in the first 24 hours after the operation.³⁷ It may be related to caffeine withdrawal, in which case it is easily treated with caffeine-containing beverages, often before discharge. Spinal headache, or postdural puncture headache (PDPH), however, may be much more difficult to treat. This condition results from leakage of CSF from a tear in the dura during spinal anesthesia; thanks to advances in spinal-needle design, it is now less common than it once was.^{91,92} PDPH is most commonly a frontal or occipital headache that worsens with sitting or standing and lessens with recumbency. Photophobia, diplopia, auditory

Table 14 Predisposing Factors to Complications during and after Outpatient Anesthesia²³

Predisposing Factor	Incidence of Complications
Preexisting disease	
None (ASA I)	1/156
Diabetes mellitus	1/149
Asthma	1/139
Chronic pulmonary disease	1/112
Hypertension (diuretic therapy)	1/87 (1/64)*
Heart disease	1/74*
Type of anesthesia	
Local only	1/268
Regional only	1/277
Local/regional with sedation	1/106*
General (combination of techniques)	1/120*
Duration of anesthesia	
< 1 hr	1/155
1–2 hr	1/84
2–3 hr	1/54*
> 3 hr	1/35*

Significantly different from initial value for the group; $P < 0.05$.

disturbances, and PONV may be noted as well. How PDPH is treated depends on the severity of the symptoms. For mild symptoms, the patient should be instructed to take appropriate amounts of fluids, remain recumbent, decrease environmental stimuli (e.g., lights and noise), and take analgesics; caffeine may be a helpful adjuvant.³⁷ For severe, persistent symptoms, the patient may have to undergo a blood-patch procedure, in which a small amount of his or her blood is injected epidurally to patch the dural leak.⁹³

A small amount of incisional bleeding after ambulatory surgery is common. Patients must be carefully taught how to monitor for excessive bleeding and how to perform initial management of incisional bleeding with direct pressure and dressing changes. They must also be instructed to call the physician if bleeding persists.

DOCUMENTATION OF OUTCOMES

Evidence-based medicine is becoming the basis for accreditation, reimbursement, and public acceptance of the care-delivery system. Outpatient surgery is no exception to this trend. Therefore, clear documentation and follow-up are important. The Federated Ambulatory Surgery Association (FASA) has published a list of predisposing factors for complications during and after surgery [see Table 14].²³ It is imperative that the staff of any surgical unit be just as diligent in documenting outcomes as it is in documenting other parameters in preparation for surgery. National benchmarks, such as those developed by the FASA, should be used as guidelines for measuring the safety of any unit.

Discussion

Growth of Outpatient Surgery

The recent evolution of health care in response primarily to socioeconomic factors has been spectacular, and the process is by no means complete. The most striking result to date is the emergence of ambulatory surgery as the predominant mode for the

delivery of surgical health care. Just a few years ago, it was estimated that more than 40% of all operative procedures would be performed in the outpatient setting. By 2000, however, 70% of operative procedures were already being performed on an outpatient basis. In 1996, an estimated 31.5 million procedures were

performed during 20.8 million ambulatory surgical visits.⁹⁴ The majority (84%) of these visits still took place in hospitals, however, with the remainder in freestanding units.⁹⁴ Although procedures such as endoscopies and lens extraction and insertion were predominant at this time, there were also many breast biopsies, herniorrhaphies, and orthopedic procedures.

The explosive growth of ambulatory surgery was initiated by economic factors, but it has had some positive effects on patient care, for the following reasons:

1. **Development of new technology.** Newer techniques, such as laparoscopic surgery, minimize the need for hospitalization and decrease the pain and suffering that patients must endure. It is not yet clear, however, whether such developments will inevitably lead to a reduction in total health care costs. One study reported that the cholecystectomy rate increased from 1.35 per 1,000 enrollees in an HMO in 1988 to 2.15 per 1,000 in 1990 and that the total cost for cholecystectomies rose by 11.4% despite a unit cost savings of 25.1%.⁹⁵ The authors suggested that these results might be attributable to changing indications for gallbladder operations; however, it is much more likely that a significant number of patients suffering from gallbladder dysfunction who were reluctant to undergo an open procedure are now willing to accept the lesser discomfort and inconvenience characteristic of a laparoscopic procedure. What the appropriate cholecystectomy rate may be is a question for the future to answer; in the meantime, many patients are living more comfortably, having had the dysfunctional organ removed. The situation is similar in the treatment of GERD. Repairs to the esophagogastric junction can now be done without a long and difficult postoperative course. In addition, there have been major advances in anesthetic techniques and postoperative management of pain and PONV.
2. **Cost savings achieved by Medicare and other payors.** In 1987, Medicare approved over 200 procedures as suitable for ASCs. Currently, more than 1,200 procedures are so designated, with more procedures being approved every year. The endorsement of cost-efficient delivery systems by employers and the reduction of employee benefits by insurers are encouraging employees (as both consumers and patients) to be more cost-conscious. When patients are involved in the actual cost of medical care, they tend to accept more efficient modes of delivery. This is even more likely to be the case when they are at risk for the cost of care.
3. **Physician concern.** The emergence of the concept of managed care has exerted a strong influence on physician involvement in ambulatory surgery. Concerns over the safety of major surgical procedures being performed in the outpatient setting have largely been removed, and surgeons are becoming more aggressive. Clearly, surgeons have benefited from the ease and convenience of outpatient surgery, especially with respect to scheduling and protection from cancellations due to emergencies. Equally clearly, however, they will now have to be more vigilant, given that outpatient surgical facilities tend to be less well monitored and supervised.
4. **Patient awareness of quality assurance.** Today's patients (or consumers) are more medically knowledgeable than ever before and more concerned with actively seeking out institutions that deliver high-quality and cost-efficient care. Consumers are highly sensitive to the issue of quality, but their definitions of this attribute are not always based on the same criteria that surgeons use. To patients, quality is a combination of effectiveness, safety, cost, convenience, and comfort.

Economic benefits aside, the major issue in the movement of surgical activities out of the hospital and into a more convenient and economical environment is how best to ensure that patients continue to receive safe, high-quality care. This consideration must in all circumstances be the primary issue underlying the planning of elective surgery. More and more, third-party payors expect surgical care to be provided to their clients (patients, to us) in a cost-effective environment. On the whole, this is not a bad thing. If, however, they also expect that surgical care can be provided just as cost-effectively to diabetic patients, morbidly obese patients, and patients with serious cardiac or respiratory disease, there is a real danger that patients' welfare could be compromised. Accordingly, it is crucial that all third parties who are not directly involved in the care of the patient permit the surgeon and the anesthesiologist to exercise sound medical judgment in regard to what type of care is needed and where such care can best be delivered. Surgeons must not delegate their responsibility for safeguarding their patients' well-being.

The ACS has issued several statements on ambulatory surgery.⁹⁶ In their 1983 statement, the ACS approved "the concept that certain procedures may be performed in an ambulatory surgical facility" but emphasized that "a prime concern about ambulatory surgery is assurance of quality" and that "a discussion between patient and surgeon about performance of the procedure on an ambulatory basis should result in a mutually agreeable decision."⁹⁶ More than two decades later, this is still the position of the ACS. The College is continually evaluating evolving medical technology, both inpatient and outpatient.

Outpatient surgery would seem to have an obvious advantage over inpatient surgery with respect to cost savings, especially if the main focus of the comparison is the high charges for 1 or more days of inpatient care. Such a comparison may be misleading insofar as it suggests that the entire cost of inpatient care can be saved when the procedure is done on an outpatient basis. The hospital inpatient charge reflects the costs of a number of functions associated with early convalescence in the hospital, including nursing, diet, and housekeeping; some of these costs are also associated with immediate postoperative care in the outpatient recovery area and consequently will be reflected in the outpatient facility's bill as well. The comparison may also be misleading insofar as it ignores the inherent costs of outpatient surgery. In some cases, medical personnel perform functions that do not appear on the bill, such as follow-up care, care by phone, and home visits to evaluate recovery, as well as dressing changes and other services similar to those provided by family members or friends. The costs associated with buying or renting durable medical equipment (e.g., beds and commodes), preparing meals, and various other activities must also be taken into account. Clearly, there are avenues for development in the postoperative setting that might raise expenses for outpatient surgery, but certainly not to the level of an inpatient stay.

It is to be hoped that new Medicare and state regulations mandating evaluation of quality of care in outpatient surgical facilities will provide definitive statistics for determining actual cost savings. Cost data must be analyzed thoroughly if we are to assess the true contribution of outpatient surgery to cost containment. As medicine advances into the 21st century, the changes in patient care have been and will continue to be nothing but spectacular, and one can only speculate what is to come. If this century brings about the same level of innovation that was experienced in the 20th century, the future for surgery and the surgical patient is bright, exciting, and to be greatly anticipated.

6 FAST TRACK SURGERY

Henrik Kehlet, M.D., Ph.D., F.A.C.S. (Hon.), and Douglas W. Wilmore, M.D., F.A.C.S.

Over the past several decades, surgery has undergone revolutionary changes that are leading to improved treatments (involving lower risk and better outcome) for an increasing number of diseases. These salutary developments are the result of more advanced anesthetic techniques, new methods of reducing the perioperative stress response, wider application of minimally invasive techniques, improved understanding of perioperative pathophysiology, and more sophisticated approaches to the prevention of postoperative organ dysfunction. Currently, many operations that once necessitated hospitalization can readily be performed in the outpatient setting; in addition, many major procedures are now associated with a significantly reduced duration of hospitalization and a shorter convalescence.

Although these anesthetic and surgical developments are the result of basic scientific and clinical research, they have also been influenced by governmental and managed care policies aimed at encouraging more cost-effective treatments. Such extraclinical influences, coupled with new clinical developments, have resulted in novel approaches designed to enhance the cost-effectiveness of health care, such as so-called fast track surgery, critical pathways, and various types of clinical guidelines. To understand the true potential value of such approaches, it is essential to recognize that their aim is not merely to ensure that fewer health care dollars are spent but, more important, to ensure that better and more efficient health care is delivered. Although these novel approaches may reduce cost, their primary purpose is to improve surgical management by reducing complications and providing better outcomes. In what follows, we outline the basic concept, primary components, and current results of fast track surgery, which is a comprehensive approach to the elective surgical patient that is designed to accelerate recovery, reduce morbidity, and shorten convalescence.

Basic Concept

Fast track surgery involves a coordinated effort to combine (1) preoperative patient education; (2) newer anesthetic, analgesic, and surgical techniques whose aim is to reduce surgical stress responses, pain, and discomfort; and (3) aggressive postoperative rehabilitation, including early enteral nutrition and ambulation. It also includes an up-to-date approach to general principles of postoperative care (e.g., use of tubes, drains, and catheters; monitoring; and general rehabilitation) that takes into account the revisions to traditional practice mandated by current scientific findings. It is believed that by these means, fast track surgery can shorten the time required for full recovery, reduce the need for hospitalization and convalescence, and lower the incidence of generalized morbidity related to pulmonary, cardiac, thromboembolic, and infectious complications.¹⁻³

For an accelerated recovery program of this type to succeed, proper organization is essential. In general terms, fast track

surgery must be based on a process of multidisciplinary collaboration that embraces not only the surgeon, the anesthesiologist, the physiotherapist, and the surgical nurse but also the patient. More specifically, fast track surgery depends on the inclusion and integration of a number of key constituent elements (see below).

Constituent Elements

EDUCATION OF THE PATIENT

To obtain the full advantages of a fast track surgical program, it is essential to provide patients with information about their perioperative care in advance of the procedure. Such educational efforts often serve to reduce patients' level of anxiety and need for pain relief, thereby providing a rational basis for collaboration with health care personnel, a process that is crucial for enhancing postoperative rehabilitation.¹⁻³ Patients can supplement the information they receive directly from health care providers by accessing reference sources such as www.facs.org/public_info/operation/aboutbroch.html, a collection of electronic brochures on specific clinical procedures that is provided by the American College of Surgeons.

OPTIMIZATION OF ANESTHESIA

The introduction of rapid-onset, short-acting volatile anesthetics (e.g., desflurane and sevoflurane), opioids (e.g., remifentanyl), and muscle relaxants has enabled earlier recovery from anesthesia and thereby facilitated ambulatory and fast track surgery.⁴ Although use of these newer general anesthetic agents has resulted in quicker recovery of vital organ function after minor surgical procedures, it has not been shown to decrease stress responses or mitigate organ dysfunction after major procedures.

Regional anesthetic techniques (e.g., peripheral nerve blocks and spinal or epidural analgesia), on the other hand, have several advantages in addition to providing anesthesia. Such advantages include improved pulmonary function, decreased cardiovascular demands, reduced ileus, and more effective pain relief. Neural blockade is the most effective technique for providing postoperative pain relief, and it has been shown to reduce endocrine and metabolic responses to surgery [see 1:5 *Postoperative Pain*]. For a pronounced reduction in perioperative stress after a major operation, continuous epidural analgesia for 24 to 72 hours is necessary.^{5,6} A meta-analysis of randomized trials evaluating regional anesthesia (primarily involving patients undergoing operations on the lower body) found that morbidity was 30% lower with regional anesthesia than with general anesthesia.⁷ However, the effect of continuous epidural analgesia on outcome after major abdominal or thoracic procedures has been questioned in the past several years. In three large randomized trials,⁸⁻¹⁰ no beneficial effect on overall morbidity could be demonstrated, except for a slight improvement in pulmonary outcome, and the duration of hospi-

talization was not reduced. It should be remembered, however, that in these studies, either an epidural opioid regimen or a predominantly epidural opioid regimen was employed and that the perioperative care regimens either were not described or were not revised according to current scientific data regarding the use of nasogastric tubes, early oral feeding, mobilization, and other care parameters.³ We believe, therefore, that for further assessment of the role of continuous epidural local analgesic regimens that include local anesthetics in improving outcome, an integrated approach within the context of fast track surgery is required.⁶

Perioperative measures should also be taken to preserve intraoperative normothermia. Hypothermia may lead to an augmented stress response during rewarming, impaired coagulation and leukocyte function, and increased cardiovascular demands. Preservation of intraoperative and early postoperative normothermia has been shown to decrease surgical site infection, intraoperative blood loss, postoperative cardiac morbidity, and overall catabolism.¹¹

REDUCTION OF SURGICAL STRESS

The neuroendocrine and inflammatory stress responses to surgery increase demands on various organs, and this increased demand is thought to contribute to the development of postoperative organ system complications. At present, the most important of the techniques used to reduce the surgical stress response are regional anesthesia, minimally invasive surgery, and pharmacologic intervention (e.g., with steroids, beta blockers, or anabolic agents).¹²

Neural blockade with local anesthetics reduces endocrine and metabolic (specifically, catabolic) activation and sympathetic stimulation, thereby decreasing the demands placed on organs and reducing loss of muscle tissue; however, regional anesthetic techniques have no relevant effect on inflammatory responses.^{5,6}

Minimally invasive surgical techniques clearly decrease pain and lessen inflammatory responses,¹³⁻¹⁵ but they appear to have relatively little, if any, effect on endocrine and metabolic responses.

Pharmacologic intervention with a single dose of a glucocorticoid (usually dexamethasone, 8 mg) given before a minor procedure has led to reduced nausea, vomiting, and pain, as well as to decreased inflammatory responses (interleukin-6), with no observed side effects.^{16,17} This intervention may facilitate recovery from minor (i.e., ambulatory) procedures¹⁸; however, the data from major procedures are inconclusive. The use of perioperative beta blockade to reduce sympathetic stimulation and thereby attenuate cardiovascular demands has been shown to reduce cardiac morbidity,¹⁹ as well as to reduce catabolism in burn patients [see *Elements of Contemporary Practice:2 Risk Stratification, Preoperative Testing, and Operative Planning*].^{20,21} Perioperative beta blockade may therefore become an important component of efforts to facilitate recovery in fast track surgical programs.

For patients whose nutritional status is normal, oral feeding ad libitum is appropriate in the postoperative period. For patients who are elderly or nutritionally depleted, nutritional supplementation, administration of an anabolic agent (e.g., oxandrolone or another anabolic steroid,²²⁻²⁴ insulin,²⁵ or growth hormone [GH]^{26,27}) to enhance deposition of lean tissue, or both may be beneficial. Most of the studies addressing the use of anabolic agents have focused on critically ill catabolic patients, in whom both indirect effects (e.g., improved nitrogen balance²⁶) and direct effects (e.g., improved wound healing and decreased length of stay with GH in burned children²⁷ and decreased mortality with insulin in critically ill patients²⁵) on outcome have been demonstrated. In a study published in 2000, a group of elderly patients undergoing opera-

tions for hip fracture received either low-dose GH (20 mg/kg/day) or placebo.²⁸ Overall, those in the GH group were able to return to their prefracture living situation earlier than those in the placebo group. A 1999 study reported increased mortality when GH was administered to ICU patients,²⁹ but a 2001 meta-analysis failed to confirm this observation.³⁰ More work is necessary before definitive conclusions can be formed in this regard.

Postoperative insulin resistance is an important metabolic factor for catabolism. There is evidence to suggest that preoperative oral or intravenous carbohydrate feeding may reduce postoperative insulin resistance.³¹ Whether this approach yields clinical benefits in terms of improved recovery remains to be determined,^{31,32} but its simplicity, its clear pathophysiologic rationale, and its low cost make it a potentially attractive option.

CONTROL OF NAUSEA, VOMITING, AND ILEUS

The ability to resume a normal diet after a surgical procedure (whether minor or major) is essential to the success of fast track surgery. To this end, postoperative nausea, vomiting, and ileus must be controlled. Principles for rational prophylaxis of nausea and vomiting have been developed on the basis of systematic reviews³³: for example, 5-HT₃ receptor antagonists, droperidol, and dexamethasone have been shown to be effective in this regard, whereas metoclopramide is ineffective. There is some reason to think that multimodal antiemetic combinations may be superior to single antiemetic agents; unfortunately, the data currently available on combination regimens are relatively sparse. In addition, analgesic regimens in which opioids are cut back or eliminated have been shown to decrease postoperative nausea and vomiting.

Paralytic ileus remains a significant cause of delayed recovery from surgery and contributes substantially to postoperative discomfort and pain. Of the various techniques available for managing ileus,^{34,35} continuous epidural analgesia with local anesthetics is the most effective, besides providing excellent pain relief. Now that cisapride has been taken off the market, no effective anti-ileus drugs are available. In a 2001 study, however, a peripherally acting mu opioid receptor antagonist significantly reduced nausea, vomiting, and ileus after abdominal procedures, without reducing analgesia.³⁶ If further studies confirm these findings, use of peripherally acting opioid antagonists may become a popular and effective way of improving postoperative recovery; this treatment is simple and apparently has no major side effects.

ADEQUATE TREATMENT OF POSTOPERATIVE PAIN

Despite ongoing development and documentation of effective postoperative analgesic regimens—such as continuous epidural analgesia in major operations, patient-controlled analgesia (PCA), and multimodal (balanced) analgesia that includes nonsteroidal anti-inflammatory drugs as well as stronger agents³⁷⁻³⁹ [see *1:5 Postoperative Pain*]⁴⁰—postoperative pain still is too often inadequately treated. Improved pain relief, facilitated by an acute pain service,⁴⁰ is a central component of any fast track surgery program and is a prerequisite for optimal mobilization and oral nutrition, as well as a valuable aid in reducing surgical stress responses.³⁷

APPROPRIATE USE OF TUBES, DRAINS, AND CATHETERS

There is substantial support in the literature for the idea that nasogastric tubes should not be used routinely in patients undergoing elective abdominal surgery.^{1,2} Randomized trials indicated that drains offered little benefit after cholecystectomy, joint replacements, colon resection, thyroidectomy, radical hysterectomy, or

pancreatic resection^{1,3,41} but that they might limit seroma formation after mastectomy.^{1,3} Such postmastectomy drainage does not necessarily impede hospital discharge, and the patient generally may be treated on an outpatient basis. Urinary catheterization has been routinely performed after many operations, but scientific documentation of the requirement for this measure is often lacking. In general, catheterization beyond 24 hours is not recommended with colorectal procedures, except with the lowest rectal procedures, for which 3 to 4 days of catheterization may be indicated.³

Although tubes, drains, and catheters may lead to morbidity only when used for extended periods, they do tend to hinder mobilization, and they can raise a psychological barrier to the patient's active participation in postoperative rehabilitation. Therefore, such devices should be used not routinely but selectively, in accordance with the available scientific documentation.

NURSING CARE, NUTRITION, AND MOBILIZATION

Postoperative nursing care should include psychological support for early rehabilitation, with a particular focus on encouraging the patient to resume a normal diet and become ambulatory as soon as possible. Early resumption of an oral diet is essential for self-care; furthermore, according to a 2001 meta-analysis of controlled trials, it may reduce infectious complications and shorten hospital stay after abdominal procedures, without increasing the risk of anastomotic dehiscence.⁴² In addition, early resumption of enteral feeding may reduce catabolism and may be facilitated by the methods used to reduce postoperative nausea, vomiting, and ileus (see above).

Postoperative bed rest is undesirable because it increases muscle loss, decreases strength, impairs pulmonary function and tissue oxygenation, and predisposes to venous stasis and thromboembolism.³ Accordingly, every effort should be made to enforce postoperative mobilization; adequate pain relief is a key adjuvant measure in this regard.

Organization is essential for good postoperative nursing care: a prescheduled care map should be drawn up, with goals for rehabilitation listed for each day.

DISCHARGE PLANNING

Given that a primary result of fast track surgery is reduced length of hospitalization, discharge planning must be a major consideration in the preoperative patient information program, as well as during hospitalization. Careful, detailed discharge planning is essential for reducing readmissions and increasing patient safety and satisfaction. The discharge plan should include (1) detailed information on the expected time course of recovery, (2) recommendations for convalescence, and (3) encouragement of enteral intake and mobilization. For patients with a significant degree of postoperative disability, various acute care facilities are available after hospital discharge. It should be kept in mind, however, that the integrated care approach fundamental to fast track surgery is specifically intended as a way of limiting or preventing such disability, thereby reducing patients' need for and dependence on postdischarge care facilities.

Reported Results

Ongoing efforts to formulate multimodal strategies aimed at improving postoperative outcome have led to the development of a variety of fast track surgical programs [see Table 1]. Most of the studies published to date have been descriptive ones reporting consecutive patient series from single centers, the findings from which have often been confirmed by other groups using the same

or a slightly modified fast track care program. On the whole, the preliminary results from these studies are very positive: fast track surgery is associated with shorter hospital stays, reduced or at least comparable morbidities, and low readmission rates, with no apparent decrease in safety.

Studies of fast track surgery in which organ function was assessed postoperatively and compared with organ function after traditional care found fast track surgery to be associated with earlier ambulation,^{43,44} superior postoperative muscle function,⁴⁴ improved oral nutritional intake,⁴⁵ better preservation of lean body mass,^{43,45} reduced postoperative impairment of pulmonary function,⁴³ earlier recovery of GI motility,⁴⁶ and mitigation of the decrease in exercise capacity and impairment of cardiovascular response to exercise that are usually expected after an operation.⁴³ The few randomized trials performed to date (mostly involving patients undergoing cholecystectomy, colonic resection, or mastectomy) reported that fast track programs increased or at least maintained patient satisfaction while achieving major cost reductions.

Future Developments

The initial promising results from the fast track surgical programs studied suggest that such programs can achieve major care improvements in terms of reducing postoperative stay. At present, however, sufficient scientific documentation is lacking for many commonly performed major operations. Thus, there is a need for additional data—in particular, data on the potential positive effects of fast track surgery on postoperative morbidity. The necessary data would probably be best obtained through multicenter trials using identical protocols. Randomized trials within the same unit that allocate some patients to suboptimal care recommendations for pain relief, mobilization, and nutrition would be difficult to perform, if not unethical, though a few such reports have been published on colon surgery patients.^{44,47}

As yet, it has not been conclusively demonstrated that reducing the duration of hospitalization necessarily reduces morbidity,⁴⁸ though data from studies addressing colonic and vascular procedures suggest that nonsurgical (i.e., cardiopulmonary and thromboembolic) morbidity may be reduced and overall postoperative recovery (assessed in terms of exercise performance and muscle power) enhanced. More study is required in this area. Future trials should also focus on identifying any factors that might be limiting even more aggressive early recovery efforts, so that more effective fast track programs can be designed. Finally, studies are needed to identify potential high-risk patient groups for whom fast track surgery may not be appropriate or who may need to be hospitalized for slightly longer periods to optimize organ function.⁴⁷

There has been considerable interest in whether the use of critical pathways improves postoperative care. Preliminary studies involving coronary artery bypass grafting, total knee replacement, colectomy, thoracic procedures, and hysterectomy suggested that critical pathways may reduce length of hospital stay, but the reduction is no greater than can be observed in neighboring hospitals that do not use critical pathways.⁴⁹ Thus, the initial enthusiasm for critical pathways notwithstanding, conclusive evidence that they have a beneficial effect on postoperative care is still lacking. The continuously decreasing length of stay noted in hospitals without fast track programs may be partly attributable to the intense competition within the health care system, which can lead to changes in care principles even without the formal adoption of critical pathways or similar systems.⁴⁹

All of the studies on the economic implications of fast track surgical programs and critical pathways have documented substantial

Table 1 Results from Selected Fast Track Surgical Programs

Type of Operation	Postoperative Hospital Stay	Comments and Other Findings
Abdominal procedures		
Inguinal hernia repair ^{59,61}	1.5–6 hr	Large consecutive series using local infiltration anesthesia in > 95%, with one series ⁵⁹ using unmonitored anesthesia; documented low morbidity, with no urinary retention; patient satisfaction ~90%, cost reduction > \$250 with local anesthesia
Cholecystectomy (laparoscopic, ⁶²⁻⁶⁷ mini-incision ⁶⁸)	> 80% discharge on same day	Large consecutive series, with documented safety and patient satisfaction > 80%; cost reduction of \$750/patient in randomized study ⁶⁴ ; recovery of organ functions within 2–3 days, with <1 wk convalescence ⁶⁷ ; similar results with mini-incision in consecutive series ⁶⁸
Fundoplication ^{69,70}	> 90% < 23 hr	Large consecutive series with documented safety ⁷⁰
Open ^{43,44,46,47,56,71-76} and laparoscopic ^{72,77-79} colorectal procedures	2–4 days	Consecutive series including high-risk patients; reduced cardiopulmonary morbidity, readmission rates 0%–15%; no documented advantages of laparoscopy-assisted colonic resection, though costs may be reduced ⁷² ; ileus reduced to < 48 hr in > 90% of patients, ^{46,56} with improved muscle and pulmonary function in fast track patients and better preservation of postoperative body composition ⁴³ ; one randomized study showed similar morbidity, readmissions, and satisfaction with fast track versus traditional care ⁴⁷
Complex pelvic-colorectal procedures ^{80,81}	3–6 days	Short stay ⁸⁰ (~4–6 days) even with additional stoma; low readmission rate (7%)
Rectal prolapse ⁸²	80% < 24 hr	Consecutive series (N = 63) with Altemeier repair; 5% readmission rate (nonserious indications)
Pancreaticoduodenectomy, ^{83,84} complex biliary tract procedures ⁸⁵	—	Hospital stay decreased by implementation of clinical pathway
Mastectomy ⁸⁶⁻⁹⁰	90% < 1 day	Large cumulative series; documented safety and major cost reduction with high patient satisfaction; no increased morbidity with fast track, but less wound pain and improved arm movement and no increase in risk of psychosocial complications
Vascular procedures		
Carotid endarterectomy ⁹¹⁻⁹⁴	90% < 1 day	Surgery done with local anesthesia; specialized nurses and wards
Lower-extremity arterial bypass ⁹⁵	2–3 days	Large series (N = 130); documented safety
Abdominal aortic aneurysmectomy ^{96,97}	~3 days	Preliminary studies (N = 50 ⁹⁶ and N = 77 ⁹⁷); documented early recovery and safety; one study with epidural analgesia, ⁹⁷ one without ⁹⁶
Urologic procedures		
Radical prostatectomy ⁹⁸	~75% 1 day	Large consecutive series (N = 252); documented safety and patient satisfaction
Laparoscopic adrenalectomy ⁹⁹⁻¹⁰¹	< 1 day	Small series; safety and low morbidity suggested
Cystectomy ^{102,103}	7 days	Improved mobilization, bowel function, and sleep recovery with fast track surgery ¹⁰² ; low mortality; ileus a problem ^{102,103}
Laparoscopic donor nephrectomy ¹⁰⁴	< 1 day	Preliminary study (N = 41); low readmission rate (2%)
Open donor nephrectomy ¹⁰⁵	2 days	—
Pulmonary procedures ¹⁰⁶⁻¹¹⁰	~1 day in some series, ^{106,107} ~4–5 days in others	Shortest stay with fast track protocol including revision of drainage principles ^{106,107} ; safety with very early discharge suggested
Other procedures		
Craniotomy ¹¹¹	~40% < 24 hr	Large consecutive series (N = 241) including tumor surgery; local anesthesia used; low readmission rate; safety suggested
Parathyroid procedures ¹¹²	~90% ambulatory	Selected consecutive series (N = 100); regional anesthesia and intraoperative adenoma localization employed; documented safety
Vaginal procedures ¹¹³	~1 day	Consecutive series (N = 108); surgery done with local anesthesia

cost savings. It should, however, be borne in mind that the last portion of a hospital stay is much less expensive than the initial portion; thus, the cost savings in this area may turn out to be smaller than they would at first appear.⁵⁰⁻⁵² This caveat should not hinder further development and documentation of fast track surgery, because inherent in the concept is the idea that revision and optimization of perioperative care may also reduce morbidity,

thereby achieving additional cost savings. As noted, the large-scale data with detailed patient description and stratification that are needed to clarify the improvements achieved by fast track surgery are, unfortunately, lacking at present, but so far, all indications are that postoperative morbidity is comparable or reduced.

A commonly expressed concern is that fast track surgery might increase the burden on general practitioners and other parts of the

nonhospital care system. The evidence currently available clearly indicates that increased use of ambulatory surgery is safe and is associated with a very low readmission rate.^{53,54} After major procedures such as colorectal surgery, however, readmissions are often unpredictable, and the readmission rate is not significantly reduced by keeping patients in the hospital for an additional 2 to 3 days.^{55,56} Moreover, in some studies of patients who have undergone coronary bypass⁵⁷ and hip replacement,⁵⁸ earlier discharge and hospital cost savings have been offset by increased use of postacute rehabilitation services. Thus, any assessment of the costs associated with fast track surgery should include the total period during which care (including both hospital care and rehabilitation care) is delivered.

Again, however, it should be emphasized that the basic concept of fast track surgery implies control of perioperative pathophysiology with the aim of enhancing recovery and thereby reducing the need for postdischarge care. The relatively few published studies that

addressed patient functional status after fast track colonic surgery suggested that muscle function, exercise capacity, and body composition are better preserved with this approach than with traditional care, in which surgical stress, insufficient nutrition, and prolonged immobilization typically lead to significant deterioration of organ function. Accordingly, an optimal fast track surgery regimen should aim at early recovery of organ function, not just early discharge.

In summary, the basic concept of fast track surgery, which could be expressed as multimodal control of perioperative pathophysiology, seems to be a highly promising approach to improving surgical outcome. We believe that the principles and techniques embodied in this approach will eventually be integrated into the care of all surgical patients. To this end, resources should be allocated for evaluation and documentation of the effects of fast track surgery and related systems on cost, postoperative morbidity, safety, and overall patient well-being.

7 INFECTION CONTROL IN SURGICAL PRACTICE

Vivian G. Loo, M.D., M.Sc., and A. Peter McLean, M.D., F.A.C.S.

Surgical procedures, by their very nature, interfere with the normal protective skin barrier and expose the patient to microorganisms from both endogenous and exogenous sources. Infections resulting from this exposure may not be limited to the surgical site but may produce widespread systemic effects. Prevention of surgical site infections (SSIs) is therefore of primary concern to surgeons and must be addressed in the planning of any operation. Standards of control have been developed for every step of a surgical procedure to help reduce the impact of exposure to microorganisms.¹⁻³ Traditional control measures include sterilization of surgical equipment, disinfection of the skin, use of prophylactic antibiotics, and expeditious operation.

The Study on the Efficacy of Nosocomial Infection Control (SENIC), conducted in United States hospitals between 1976 and 1986, showed that surgical patients were at increased risk for all types of infection. The nosocomial, or hospital-acquired, infection rate at that time was estimated to be 5.7 cases out of every 100 hospital admissions.⁴ These infections included SSIs as well as bloodstream, urinary, and respiratory infections. Today, the increased use of minimally invasive surgical procedures and early discharge from the hospital necessitates postdischarge surveillance⁵ in addition to in-hospital surveillance for the tracking of nosocomial infections. With the reorganization of health care delivery programs, nosocomial infections will appear more frequently in the community and should therefore be considered a part of any patient care assessment plan.

Care assessment programs designed to help minimize the risk of nosocomial infections were first introduced in 1951 by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). Since then, as medical technology has changed, JCAHO has redesigned the survey process. In its plan for infection control programs, JCAHO strongly recommends that the survey, documentation, and reporting of infections be made mandatory for the purpose of hospital accreditation.⁶

Effective infection control and prevention requires an organized, hospital-wide program aimed at achieving specific objectives. The program's purpose should be to obtain relevant information on the occurrence of nosocomial infections both in patients and in employees. The data should be documented, analyzed, and communicated with a plan for corrective measures. Such surveillance activities, combined with education, form the basis of an infection control program.

Data relating to host factors are an integral part of infection data analysis. Documentation of host factors has made for a better appreciation of the associated risks and has allowed comparative evaluation of infection rates. Development of new surgical equipment and technological advances have influenced the impact of certain risk factors, such as lengthy operation and prolonged hospital stay. Clinical investigations have helped improve the understanding of host factors and have influenced other aspects of surgical practice.⁷⁻¹² Excessive use of and reliance on antibiotics have led to problems not previously encountered in practice—for

example, the emergence of drug-resistant microorganisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA), glycopeptide-intermediate *S. aureus* (GISA), multidrug-resistant *Mycobacterium tuberculosis*, and multidrug-resistant *Enterococcus* strains.¹³⁻¹⁶ Such complications reemphasize the need to focus on infection control as an essential component of preventive medicine.

Besides the impact of morbidity and mortality on patients, there is the cost of treating nosocomial infections, which is a matter of concern for surgeons, hospital administrators, insurance companies, and government planners alike. Efforts to reduce the occurrence of nosocomial infections are now a part of hospital cost-control management programs.^{17,18} The challenge to clinicians is how to reduce cost while maintaining control over, and preventing spread of, infection.

The Surgical Wound and Infection Control

Nosocomial infections are defined as infections acquired in the hospital. There must be no evidence that the infection was present or incubating at the time of hospital admission. Usually, an infection that manifests 48 to 72 hours after admission is considered to be nosocomially acquired. An infection that is apparent on the day of admission is usually considered to be community acquired, unless it is epidemiologically linked to a previous admission or to an operative procedure at the time of admission.

IDENTIFICATION OF RISK FACTORS

The risk of development of an SSI depends on host factors, perioperative wound hygiene, and the duration of the surgical procedure. The risk of development of other nosocomial infections depends on these and other factors, including length of the hospital stay and appropriate management of the hospital environment [see Activities of an Infection Control Program, *below*]. Identification of host and operative risk factors can help determine the potential for infection and point toward measures that might be necessary for prevention and control.

Host Risk Factors

Host susceptibility to infection can be estimated according to the following variables: older age, severity of disease, physical-status classification (see below), prolonged preoperative hospitalization, morbid obesity, malnutrition, immunosuppressive therapy, smoking, preoperative colonization with *S. aureus*, and coexistent infection at a remote body site.¹⁹

A scale dividing patients into five classes according to their physical status was introduced by the American Society of Anesthesiologists (ASA) in 1974 and tested for precision in 1978.²⁰ The test results showed that the ASA scale is a workable system, although it lacks scientific definition [see *Table 1*].

Significant differences in infection rates have been shown in patients with different illnesses. In one prospective study, the severity of underlying disease (rated as fatal, ultimately fatal, or

Table 1 American Society of Anesthesiologists
Physical-Status Scale

Class 1	A normally healthy individual
Class 2	A patient with mild systemic disease
Class 3	A patient with severe systemic disease that is not incapacitating
Class 4	A patient with incapacitating systemic disease that is a constant threat to life
Class 5	A moribund patient who is not expected to survive 24 hr with or without operation
E	Added for emergency procedures

nonfatal) was shown to have predictive value for endemic nosocomial infections: the nosocomial infection rate in patients with fatal diseases was 23.6%, compared with 2.1% in patients with nonfatal diseases.²¹

Operative Risk Factors

Several factors related to the operative procedure may be associated with the risk of development of an SSI [see 1:2 *Prevention of Postoperative Infection*]. These include method of hair removal (and likelihood of consequent skin injury), inappropriate use of antimicrobial prophylaxis, duration of the operation, and wound classification. The influence of hair removal methods on SSI has been examined by many investigators. Lower infection rates were reported with the use of depilatory agents and electric clippers than with razors.^{7,8} Antimicrobial prophylaxis is used for all operations that involve entry into a hollow viscus. Antimicrobial prophylaxis is also indicated for clean operations in which an intra-articular or intravascular prosthetic device will be inserted and for any operation in which an SSI would have a high morbidity.¹⁹ A comprehensive study determined that there is considerable variation in the timing of administration of prophylactic antibiotics, but that the administration within 2 hours before surgery reduces the risk of SSI.⁹

Operative wounds are susceptible to varying levels of bacterial contamination, by which they are classified as clean, clean-contaminated, contaminated, or dirty.²² In most institutions, the responsibility for classifying the incision site is assigned to the operating room circulating nurse; one assessment suggests that the accuracy of decisions made by this group is as high as 88%.²³

Composite Risk Indices

The Centers for Disease Control and Prevention (CDC) established the National Nosocomial Infections Surveillance (NNIS) system in 1970 to create a national database of nosocomial infections.²⁴ The NNIS system has been used to develop indices for predicting the risk of nosocomial infection in a given patient.

NNIS basic risk index NNIS developed a composite risk index composed of the following criteria: ASA score, wound class, and duration of surgery. Reporting on data collected from 44 United States hospitals between 1987 and 1990, NNIS demonstrated that this risk index is a significantly better predictor for development of SSI than the traditional wound classification system alone.^{25,26} The NNIS risk index is a useful method of risk adjustment for a wide variety of procedures.

The NNIS risk index is scored as 0, 1, 2, or 3. A patient's score is determined by counting the number of risk factors present from among the following: an ASA score of 3, 4, or 5; a surgical wound that is classified as contaminated or dirty/infected;

and an operation lasting over T hours (where T represents the 75th percentile of distribution of the duration of the operative procedure being performed, rounded to the nearest whole number of hours).

Modified NNIS basic risk index for procedures using laparoscopes For cholecystectomy and colon surgery procedures, the use of a laparoscope lowered the risk of SSI within each NNIS risk index category.²⁷ Hence, for these procedures, when the procedure is performed laparoscopically, the risk index should be modified by subtracting 1 from the basic NNIS risk index score. With this modification, the risk index has values of M (or -1), 0, 1, 2, or 3. For appendectomy and gastric surgery, use of a laparoscope affected SSI rates only when the NNIS basic risk index was 0, thereby yielding five risk categories: 0-Yes, 0-No, 1, 2, and 3, where Yes or No refers to whether the procedure was performed with a laparoscope.²⁷

Operation-specific risk factors It is likely that operation-specific logistic regression models will increasingly be used to calculate risk. For example, in spinal fusion surgery, Richards and colleagues identified diabetes mellitus, ASA score greater than 3, operation duration longer than 4 hours, and posterior surgical approach as significant independent predictors of SSI.²⁸ Other logistic regression models have been developed for craniotomy and cesarean section.^{29,30} These models should permit more precise risk adjustment.

PREVENTIVE MEASURES

In any surgical practice, policies and procedures should be in place pertaining to the making of a surgical incision and the prevention of infection. These policies and procedures should govern the following: (1) skin disinfection and hand-washing practices of the operating team, (2) preoperative preparation of the patient's skin (e.g., hair removal and use of antiseptics), (3) the use of prophylactic antibiotics, (4) techniques for preparation of the operative site, (5) management of the postoperative site if drains, dressings, or both are in place, (6) standards of behavior and practice for the operating team (e.g., the use of gown, mask, and gloves), (7) special training of the operating team, and (8) sterilization and disinfection of instruments.

Hand Hygiene

Although hand washing is considered the single most important measure for preventing nosocomial infections, poor compliance is frequent.³¹ Role modeling is important in positively influencing this behavior. One study showed that a hand-washing educational program contributed to a reduction in the rate of nosocomial infections.³² Good hand-washing habits can be encouraged by making facilities (with sink, soap, and towel) visible and easily accessible in patient care areas [see 1:2 *Prevention of Postoperative Infection*].

Cleansers used for hand hygiene include plain nonantimicrobial soap, antimicrobial soaps, and waterless alcohol-based hand antiseptics. Plain soaps have very little antimicrobial activity; they mainly remove dirt and transient flora.³³ Compared with plain soaps, antimicrobial soaps achieve a greater log reduction in eliminating transient flora and have the additional advantage of sustained activity against resident hand flora.³³ Alcohol-based hand antiseptics have an excellent spectrum of antimicrobial activity and rapid onset of action, dry rapidly, and do not require the use of water or towels.³⁴ Therefore, they are recommended for routine decontamination of hands during patient care except when hands are visibly soiled. Emollients are often added to alcohol-based

waterless hand antiseptics because of these antiseptics' tendency to cause drying of the skin.³⁴

Sterilization and Disinfection

Spaulding proposed in 1972 that the level of disinfection and sterilization for surgical and other instruments be determined by classifying the instruments into three categories—critical, semi-critical, and noncritical—according to the degree of infection risk involved in their use.³⁵

Critical items include objects or instruments that enter directly into the vascular system or sterile areas of the body. These items should be sterilized by steam under pressure, dry heat, ethylene oxide, or other approved methods. Flash sterilization is the process by which surgical instruments are sterilized for immediate use should an emergency situation arise (e.g., to sterilize an instrument that was accidentally dropped). This is usually achieved by leaving instruments unwrapped in a container and using a rapid steam cycle.³⁶ Instruments must still be manually cleaned, decontaminated, inspected, and properly arranged in the container before sterilization. Implantables should not be flash sterilized. Flash sterilization is not intended to replace conventional steam sterilization of surgical instruments or to reduce the need for adequate instrument inventory.³⁶

Semicritical items are those that come into contact with mucous membranes or skin that is not intact (e.g., bronchoscopes and gastroscopes). Scopes have the potential to cause infection if they are improperly cleaned and disinfected. Transmission of infection has been documented after endoscopic investigations, including infection with *Salmonella typhi*³⁷ and *Helicobacter pylori*.³⁸ Such incidents emphasize the need for sterilization of the endoscopic biopsy forceps. Semicritical items generally require high-level disinfection that kills all microorganisms except bacterial spores.³⁹

Glutaraldehyde 2% is a high-level disinfectant that has been used extensively in flexible endoscopy. Before disinfection, scopes should receive a thorough manual cleaning to eliminate gross debris. To achieve high-level disinfection, the internal and external surfaces and channels should come into contact with the disinfecting agent for a minimum of 20 minutes.³⁹ Glutaraldehyde has certain disadvantages. In particular, it requires activation before use; moreover, it is irritating to the skin, eyes, and nasal mucosa, and thus, its use requires special ventilation or a ducted fume hood.³⁹

An alternative to glutaraldehyde is orthophthalaldehyde (OPA), a newer agent approved by the Food and Drug Administration (FDA) for high-level disinfection. OPA is odorless and nonirritating and does not require activation before use.⁴⁰

Noncritical items are those that come in contact with intact skin (e.g., blood pressure cuffs). They require only washing or scrubbing with a detergent and warm water or disinfection with an intermediate-level or low-level germicide for 10 minutes.

The reuse of single-use medical devices has become a topic of interest because of the implied cost saving. The central concerns are the effectiveness of sterilization or disinfection according to category of use, as well as maintenance of the essential mechanical features and the functional integrity of the item to be reused. The FDA has issued regulations governing third-party and hospital reprocessors engaged in reprocessing single-use devices for reuse.⁴¹ These regulations are available on the FDA's web site (www.fda.gov/cdrh/comp/guidance/1168.pdf).

Hair Removal

An infection control program should have a hair-removal policy for preoperative skin preparation [*see 1:2 Prevention of Post-operative Infection*].

Operating Room Environment

Environmental controls in the OR have been used to reduce the risk of SSI [*see 1:1 Preparation of the Operating Room*]. The OR should be maintained under positive pressure of at least 2.5 Pa in relation to corridors and adjacent areas. In addition, there should be at least 15 air changes per hour, of which three should involve fresh air.⁴²

HEALTH STATUS OF THE HEALTH CARE TEAM

The health care team has a primary role in the prevention of infection. Continued education and indoctrination of policies are essential: the team must be kept well informed and up to date on concepts of infection control. Inadvertently, team members may also be the source of, or the vector in, transmission of infection. Nosocomial infection outbreaks with MRSA have been traced to MRSA carriers among health care workers.⁴³ Screening of personnel to identify carriers is undertaken only when an outbreak of nosocomial infection occurs that cannot be contained despite implementation of effective control measures and when a health care worker is epidemiologically linked to cases.

Protecting the health care team from infection is a constant concern. Preventive measures, such as immunizations and pre-employment medical examinations, should be undertaken at an employee health care center staffed by knowledgeable personnel.⁴⁴ Preventable infectious diseases, such as chickenpox and rubella, should be tightly controlled in hospitals that serve immunocompromised and obstetric patients. It is highly recommended that a record be maintained of an employee's immunizations. Knowledge of the employee's health status on entry to the hospital helps ensure appropriate placement and good preventive care.

When exposure to contagious infections is unavoidable, susceptible personnel should be located, screened, and given prophylactic treatment if necessary. Infection control personnel should define the problem, establish a definition of contact, and take measures to help reduce panic.

Isolation Precautions

CDC guidelines have been developed to prevent the transmission of infections.⁴⁵ These isolation guidelines promote two levels of isolation precautions: standard precautions and transmission-based precautions.

Standard precautions The standard precautions guidelines—which incorporate the main features of the older universal precautions and body substance isolation guidelines—were developed to reduce the risk of transmission of microorganisms for all patients regardless of their diagnosis.⁴⁵⁻⁴⁷ Standard precautions apply to blood, all body fluids, secretions and excretions, and mucous membranes.

Transmission-based precautions Transmission-based precautions were developed for certain epidemiologically important pathogens or clinical presentations. These precautions comprise three categories, based on the mode of transmission: airborne precautions, droplet precautions, and contact precautions.⁴⁵ Precautions may be combined for certain microorganisms or clinical presentations (e.g., both contact and airborne precautions are indicated for a patient with varicella).

Airborne precautions are designed to reduce transmission of microorganisms spread via droplets that have nuclei 5 μm in size or smaller, remain suspended in air for prolonged periods of time,

and have the capability of being dispersed widely.⁴⁵ Airborne precautions include wearing an N95 respirator, placing the patient in a single room that is under negative pressure of 2.5 Pa in relation to adjacent areas, keeping the door closed, providing a minimum of 6 to 12 air changes per hour, and exhausting room air outside the building and away from intake ducts or through a high-efficiency particulate air (HEPA) filter if recirculated.^{45,48} Airborne precautions are indicated for patients with suspected or confirmed infectious pulmonary or laryngeal tuberculosis; measles; varicella; disseminated zoster; and Lassa, Ebola, Marburg, and other hemorrhagic fevers with pneumonia. Varicella, disseminated herpes zoster, and hemorrhagic fevers with pneumonia also call for contact precautions (see below).

Droplet precautions are designed to reduce the risk of transmission of microorganisms spread via large-particle droplets that are greater than 5 µm in size, do not remain suspended in the air for prolonged periods, and usually travel 1 m or less.⁴⁵ No special ventilation requirements are required to prevent droplet transmission. A single room is preferable, and the door may remain open. Examples of patients for whom droplet precautions are indicated are those with influenza, rubella, mumps, and meningitis caused by *Haemophilus influenzae* and *Neisseria meningitidis*.

Contact precautions are designed to reduce the risk of transmission of microorganisms by direct or indirect contact. Direct contact involves skin-to-skin contact resulting in physical transfer of microorganisms.⁴⁵ Indirect contact involves contact with a contaminated inanimate object that acts as an intermediary. Contact precautions are indicated for patients colonized or infected with multidrug-resistant bacteria that the infection control program judges to be of special clinical and epidemiologic significance on the basis of recommendations in the literature.⁴⁵

Exposure to Bloodborne Pathogens

The risk of transmission of HIV and hepatitis B virus (HBV) from patient to surgeon or from surgeon to patient has resulted in a series of recommendations governing contact with blood and body fluids.⁴⁸ The risk of acquiring a bloodborne infection—such as with HBV, hepatitis C virus (HCV), or HIV—depends on three factors: type of exposure to the bloodborne pathogen, prevalence of infection in the population, and the rate of infection after exposure to the bloodborne pathogen.⁴⁹ Postexposure management has been discussed in CDC guidelines (www.cdc.gov/mmwr/pdf/rr/rr5011.pdf).⁵⁰

Protection of the face and hands during operation has become important. A study of 8,502 operations found that the rate of direct blood exposure was 12.4%, whereas the rate of parenteral exposure via puncture wounds and cuts was 2.2%. Parenteral blood contacts were twice as likely to occur among surgeons as among other OR personnel.⁵¹ These findings support the need for OR practice policies and the choice of appropriate protective garments for the OR staff. OR practice policy should give particular attention to methods of using sharp instruments and to ways of reducing the frequency of percutaneous injuries: sharp instruments should be passed in a metal dish, cautery should be used, and great care should be taken in wound closures. It is important that masks protect the operating team from aerosolized fluids. Researchers have shown that for ideal protection, a mask should be fluid-capture efficient and air resistant.⁵²

For invasive surgical procedures, double gloving has become routine. However, there are recognized differences among the gloves available. Latex allergy is an important issue; nonlatex alternatives are available for those who are allergic.⁵³

Table 2 CDC Recommendations for Prevention of HIV and HBV Transmission during Invasive Procedures⁴⁸

- Health care workers with exudative lesions or weeping dermatitis should cover any unprotected skin, or they should not provide patient care until the damaged skin has healed.
- Hands should be washed after every patient contact.
- Health care workers should wear gloves when contact with blood or body substances is anticipated; double gloves should be used during operative procedures; hands should be washed after gloves are removed.
- Gowns, plastic aprons, or both should be worn when soiling of clothing is anticipated.
- Mask and protective eyewear or face shield should be worn if aerosolization or splattering of blood or body substances is expected.
- Resuscitation devices should be used to minimize the need for mouth-to-mouth resuscitation.
- Disposable containers should be used to dispose of needles and sharp instruments.
- Avoid accidents and self-wounding with sharp instruments by following these measures:
 - Do not recap needles.
 - Use needleless systems when possible.
 - Use cautery and stapling devices when possible.
 - Pass sharp instruments in metal tray during operative procedures.
- In the case of an accidental spill of blood or body substance on skin or mucous membranes, do the following:
 - Rinse the site immediately and thoroughly under water.
 - Wash the site with soap and water.
 - Document the incident (i.e., report to Occupational Safety and Health Administration or to the Infection Control Service).
- Blood specimens from all patients should be considered hazardous at all times.
- Prompt attention should be given to spills of blood or body substances, which should be cleaned with an appropriate disinfectant.

Hepatitis B virus For active surgeons and other members of the health care team, HBV infection continues to pose a major risk. Hepatitis B vaccination has proved safe and protective and is highly recommended for all high-risk employees; it should be made available through the employee health care center.

Despite the efficacy of the vaccine, many surgeons and other personnel remain unimmunized and are at high risk for HBV infection.⁴⁸ HBV is far more easily transmitted than HIV and continues to have a greater impact on the morbidity and mortality of health care personnel. An estimated 8,700 new cases of hepatitis B are acquired occupationally by health care workers each year; 200 to 250 of these cases result in death.⁵⁴ The risk of seroconversion is at least 30% after a percutaneous exposure to blood from a hepatitis B e antigen-seropositive source.⁵⁰ Given that a patient's serostatus may be unknown, it is important that health care workers follow standard precautions for all patients.

With HBV infection, as with HIV (see below), the approach to prevention and control is a two-way street—that is, protection should be afforded to patients as well as health care personnel. In addition to standard precautions, the CDC has developed recommendations for health care workers that are designed to prevent transmission of HBV and HIV from health care worker to patient or from patient to health care worker during exposure-prone invasive procedures [see Table 2]. Cognizant of the CDC recommendations, the American College of Surgeons has issued additional recommendations regarding the surgeon's role in the prevention of hepatitis transmission [see Table 3].⁵⁴

Hepatitis C virus The average incidence of seroconversion after percutaneous exposure from an HCV-positive source is 1.8% (range, 0% to 7%).⁵⁵⁻⁵⁷ Mucous membrane exposure to blood rarely results in transmission, and no transmission has been documented from exposure of intact or nonintact skin to blood.^{50,58} There is no recommended postexposure prophylaxis regimen for HCV. The use of immunoglobulin has not been demonstrated to be protective.⁵⁰ There are no antiviral medications recommended for postexposure prophylaxis.⁵⁰

Human immunodeficiency virus Exposure to blood and body substances of patients who have AIDS or who are seropositive for HIV constitutes a health hazard to hospital employees. The magnitude of the risk depends on the degree and method of exposure [see 8:21 *Acquired Immunodeficiency Syndrome*].

The presence of HIV infection in a patient is not always known. Because the prevalence of HIV in the North American patient population is less than 1% (range, 0.09% to 0.89%), and because a caregiver's risk of seroconversion after needlestick injury is likewise less than 1%, the CDC recommends taking standard precautions [see 8:20 *Viral Infection*] and following in all patients the same guidelines for invasive procedures that one would use in cases of known HBV-infected patients [see Table 2].⁴⁸ Infection control personnel have introduced realistic control measures and educational programs to help alleviate fears that health care workers might have about coming in contact with patients infected with HIV.

Exposure to Tuberculosis

In studies of health care workers, positive results on tuberculin skin testing have ranged from 0.11% to 10%.^{59,60} Health care workers who are immunocompromised are at high risk for development of disease postexposure.⁵⁹

The CDC recommendation for tuberculosis prevention places emphasis on a hierarchy of control measures, including administrative engineering controls and personal respiratory protection

(www.cdc.gov/mmwr/pdf/rr/rr4313.pdf). The following measures should be considered:

1. The use of risk assessments and development of a written tuberculosis control protocol.
2. Early identification and treatment of persons who have tuberculosis.
3. Tuberculosis screening programs for health care workers.
4. Training and education.
5. Evaluation of tuberculosis infection control programs.⁶¹

Activities of an Infection Control Program

SURVEILLANCE

The cornerstone of an infection control program is surveillance. This process depends on the verification, classification, analysis, reporting, and investigation of infection occurrences, with the intent of generating or correcting policies and procedures. Five surveillance methods can be applied^{62,63}:

1. Total, or hospital-wide, surveillance—collection of comprehensive data on all infections in the facility, with the aim of correcting problems as they arise. This is labor intensive.
2. Surveillance by objective, or targeted surveillance, in which a specific goal is set for reducing certain types of infection. This concept is priority-directed and can be further subdivided into two distinct activities:
 - a. The setting of outcome objectives, in which the objectives for the month or year are established and all efforts applied to achieve a desired rate of infection. As with the hospital-wide approach, a short-term plan would be made to monitor, record, and measure results and provide feedback on the data.
 - b. The setting of process objectives, which incorporates the patient care practices of doctors and nurses as they relate to outcome (e.g., wound infections and their control).
3. Periodic surveillance—intensive surveillance of infections and patient-care practices by unit or by service at different times of the year.
4. Prevalence survey—the counting and analysis of all active infections during a specified time period. This permits identification of nosocomial infection trends and problem areas.
5. Outbreak surveillance—the identification and control of outbreaks of infection. Identification can be made on the basis of outbreak thresholds if baseline bacterial isolate rates are available and outbreak thresholds can be developed. Problems are evaluated only when the number of isolates of a particular bacterial species exceeds outbreak thresholds.

Surveillance techniques include the practice of direct patient observation⁷ and indirect observation by review of microbiology reports, nursing Kardex, or the medical record to obtain data on nosocomial infections. The sensitivity of case finding by microbiology reports was found to be 33% to 65%; by Kardex, 85%; and by total chart review, 90%.⁶² These methods may be used either separately or in combination to obtain data on clinical outcomes.

One use of surveillance data is to generate information for individual surgeons, service chiefs, and nursing personnel as a reminder of their progress in keeping infections and diseases under control. This technique was used by Cruse in 1980 to show a progressive decrease in infection rates of clean surgical wounds to less than 1% over 10 years.⁸ In other settings, endemic rates of bloodstream, respiratory, and urinary tract infections were cor-

Table 3 ACS Recommendations for Preventing Transmission of Hepatitis⁵⁴

Surgeons should continue to utilize the highest standards of infection control, involving the most effective known sterile barriers, universal precautions, and scientifically accepted measures to prevent blood exposure during every operation. This practice should extend to all sites where surgical care is rendered and should include safe handling practices for needles and sharp instruments.

Surgeons have the same ethical obligations to render care to patients with hepatitis as they have to render care to other patients.

Surgeons with natural or acquired antibodies to HBV are protected from acquiring HBV from patients and cannot transmit the disease to patients. All surgeons and other members of the health care team should know their HBV immune status and become immunized as early as possible in their medical career.

Surgeons without evidence of immunity to HBV who perform procedures should know their HBsAg status and, if this is positive, should also know their HBeAg status. In both instances, expert medical advice should be obtained and all appropriate measures taken to prevent disease transmission to patients. Medical advice should be rendered by an expert panel composed and convened to fully protect practitioner confidentiality. The HBeAg-positive surgeon and the panel should discuss and agree on a strategy for protecting patients at risk for disease transmission.

On the basis of current information, surgeons infected with HCV have no reason to alter their practice but should seek expert medical advice and appropriate treatment to prevent chronic liver disease.

rected and reduced by routine monitoring and reporting to medical and nursing staff.²¹

The increasing practice of same-day or short-stay surgical procedures has led to the need for postdischarge surveillance. This may be done by direct observation in a follow-up clinic, by surveying patients through the mail or over the telephone, by reviewing medical records, or by mailing questionnaires directly to surgeons. The original CDC recommendation of 30 days for follow-up was used by one hospital to randomly screen post-joint arthroplasty patients by telephone. This screening identified an infection rate of 7.5%, compared with 2% for hospitalized orthopedic patients.⁶⁴ Results from another medical center suggested that 90% of cases would be captured in a 21-day postoperative follow-up program.⁵ Infections that occur after discharge are more likely with clean operations, operations of short duration, and operations in obese patients and in nonalcoholic patients. The use of prosthetic materials for implants requires extending the follow-up period to 1 year.

Definition of Surgical Site Infections

The CDC defines an incisional SSI as an infection that occurs at the incision site within 30 days after surgery or within 1 year if a prosthetic implant is in place. Infection is characterized by redness, swelling, or heat with tenderness, pain, or dehiscence at the incision site and by purulent drainage. Other indicators of infection include fever, deliberate opening of the wound, culture-positive drainage, and a physician's diagnosis of infection with prescription of antibiotics. To encourage a uniform approach among data collectors, the CDC has suggested three categories of SSIs, with definitions for each category [see Table 4].⁶⁵ The category of organ or space SSI was included to cover any part of the anatomy (i.e., organs or spaces) other than the incision that might have been opened or manipulated during the operative procedure. This category would include, for example, arterial and venous infections, endometritis, disk space infections, and mediastinitis.⁶⁵

There should be collaboration between the physician or nurse and the infection control practitioner to establish the presence of an SSI. The practitioner should complete the surveillance with a chart review and document the incident in a computer database program for later analysis. The data must be systematically recorded; many commercial computer programs are available for this purpose. One group reported that their experience with the Health Evaluation through Logical Processing system was useful for identifying patients at high risk for nosocomial infections.⁶⁶

Verification of Infection

A complete assessment should include clinical evaluation of commonly recognized sites (e.g., wound, respiratory system, urinary tract, and intravenous access sites) for evidence of infection, especially when no obvious infection is seen at the surgical site. Microbiologic evaluation should identify the microorganism. Such evaluation, however, depends on an adequate specimen for a Gram stain and culture. For epidemiologic reasons, DNA fingerprinting may be required, especially for outbreak investigation.

A system of internal auditing should alert the infection control service to multiresistant microorganisms—for example, to the presence of MRSA or vancomycin-resistant *Enterococcus* (VRE) in a patient. Differentiation between infection and colonization is important for the decision of how to treat. Regardless of whether infection or colonization is identified, verification of MRSA or VRE should generate a discussion on control measures.

Data Interpretation

The predictive value of data is deemed more useful when it is applied to specific situations. According to CDC experts, the scoring for infections depends on specified, related denominators to interpret the data, especially when there is to be interhospital comparison.⁶⁷

Data Analysis

The original practice of presenting overall hospital-wide crude rates provided little means for adjustment of variables (e.g., risk related to the patient or to the operation). The following three formulas, however, are said to offer more precision than traditional methods⁶⁷:

$$(\text{Number of nosocomial infections/Service operations}) \times 100$$

$$[\text{Number of site-specific nosocomial infections/Specific operations (e.g., number of inguinal hernias)}] \times 100$$

$$[\text{Number of nosocomial infections/Hospital admissions (patient-days)}] \times 1,000$$

Data on infections of the urinary tract, respiratory system, and circulatory system resulting from exposure to devices such as Foley catheters, ventilators, and intravascular lines can be illustrated as device-associated risks according to site, as follows:

$$(\text{Number of device-associated infections of a site/Number of device days}) \times 1,000$$

Reporting

Infection notification to surgeons has been shown by Cruse and Foord to have a positive influence on clean-wound infection rates.^{7,8} In a medical setting, Britt and colleagues also reported a reduction in endemic nosocomial infection rates for urinary tract infections, from 3.7% to 1.3%, and for respiratory tract infections, from 4.0% to 1.6%, simply by keeping medical personnel aware of the rates.²¹

Outbreak Investigation

There are 10 essential components to an outbreak investigation:

1. Verify the diagnosis and confirm that an outbreak exists. This is an important step, because other factors may account for an apparent increase in infections. These factors may include a reporting artifact resulting from a change in surveillance methodology, a laboratory error or change in laboratory methodology, or an increase in the denominator of the formula used for data analysis (if this increase is proportionate to the rise in the numerator, the infection rate has not changed).
2. Formulate a case definition to guide the search for potential patients with disease.
3. Draw an epidemic curve that plots cases of the disease against time of onset of illness. This curve compares the number of cases during the epidemic period with the baseline. In addi-

tion, the epidemic curve helps to determine the probable incubation period and how the disease is being transmitted (i.e., a common source versus person to person).

4. Review the charts of case patients to determine demographics and exposures to staff, medications, therapeutic modalities, and other variables of importance.
5. Perform a line listing of case patients to determine whether there is any common exposure.
6. Calculate the infection rate. The numerator is the number of infected patients and the denominator is the number of patients at risk.
7. Formulate a tentative hypothesis to explain the reservoir and the mode of transmission. A review of the literature on similar outbreaks may be necessary.
8. Test the hypothesis, using a case-control study, cohort study, prospective intervention study, or microbiologic study. A case-control study is usually used, because it is less labor intensive. For a case-control study, control subjects should be selected from an uninfected surgical population of patients who were hospitalized at the same time as those identified during the epidemic period and matched for age, gender, service operation, operation date, and health status (ASA score). Two or three control patients are usually selected for every case patient. The cases and controls are then compared with respect to possible exposures that may increase the risk of disease. Patient, personnel, and environmental microbiologic isolates (if any) should be kept for fingerprinting (e.g., pulsed-field gel electrophoresis, random amplified polymorphic DNA polymerase chain reaction).
9. Institute infection control measures. This may be done at any time during the investigation. The control measures should be reviewed after institution to determine their efficacy and the possible need for changing them.
10. Report the incident to the infection control committee and, at the completion of the investigation, submit a report. The administrators, physicians, and nurses involved should be informed and updated as events change.⁶⁸

ANTIMICROBIAL-RESISTANT MICROORGANISMS

Hospitals and communities worldwide are facing the challenge posed by the spread of antimicrobial-resistant microorganisms. Strains of MRSA are increasing in hospitals and are an important cause of nosocomial infections; in the United States in the year 2002, the proportion of *S. aureus* isolates resistant to methicillin or oxacillin was more than 55%.⁶⁹ MRSA strains do not merely replace methicillin-susceptible strains as a cause of hospital-acquired infections but actually increase the burden of nosocomial infections.⁷⁰ Moreover, there are reports that MRSA may be becoming a community-acquired pathogen.^{71,72} A proactive approach for controlling MRSA at all levels of health care can result in decreased MRSA infection rates.^{73,74}

Strains of GISA, an emerging pathogen, exhibit reduced susceptibility to vancomycin and teicoplanin. The first GISA strain was isolated in 1996 in Japan.⁷⁵ DNA fingerprinting suggests that these GISA strains evolved from preexisting MRSA strains that infected patients in the months before the GISA infection. Contact precautions are indicated for patients infected or colonized with GISA; infection control guidelines to prevent the spread of GISA are available.⁷⁶

VRE accounts for 31% of all enterococci in the NNIS system.⁷⁰ Transmission usually occurs through contact with the contaminated hands of a health care worker. The environment is an important reservoir for VRE, but it is not clear whether the environment plays a significant role in transmission.⁷⁷ Risk factors for VRE

acquisition include length of hospital stay, liver transplantation, presence of feeding tubes, dialysis, and exposure to cephalosporins.⁷⁸ Contact precautions are indicated for patients infected or colonized with VRE.⁷⁹

Strategies to prevent and control the emergence and spread of antimicrobial-resistant microorganisms have been developed. These include optimal use of antimicrobial prophylaxis for surgical procedures; optimizing choice and duration of empirical therapy; improving antimicrobial prescribing patterns by physicians; monitoring and providing feedback regarding antibiotic resistance; formulating and using practice guidelines for antibiotic usage; developing a system to detect and report trends in antimicrobial resistance; ensuring that caregivers respond rapidly to the detection of antimicrobial resistance in individual patients; incorporating the importance of controlling antimicrobial resistance into the institutional mission and climate; increasing compliance with basic infection control policies and procedures; and developing a plan for identifying, transferring, discharging, and readmitting patients colonized or infected with specific antimicrobial-resistant microorganisms.⁸⁰

Severe Acute Respiratory Syndrome

The severe acute respiratory syndrome (SARS) first emerged in Guangdong Province, China, in November 2002. SARS is caused by a novel coronavirus (SARS-CoV) that may have originated from an animal reservoir.⁸¹ It is characterized by fever, chills, cough, dyspnea, and diarrhea and radiologic findings suggestive of atypical pneumonia.⁸² As of August 7, 2003, a total of 8,422 probable cases, with 916 deaths (11%), had been reported from 29 countries.⁸³

The incubation period is estimated to be 10 days, and patients appear to be most infectious during the second week of illness.⁸³ Available evidence suggests that SARS-CoV is spread through contact, in droplets, and possibly by airborne transmission.⁸³ Accordingly, health care workers must adhere to contact, droplet, and airborne precautions when caring for SARS patients. Included in such precautions are the use of gloves, gowns, eye protection, and the N95 respirator.⁸³ A comprehensive review of SARS is available at the WHO web site (www.who.int/csr/sars/en/WHOconsensus.pdf).

ENVIRONMENTAL CONTROL

Control of the microbial reservoir of the patient's immediate environment in the hospital is the goal of an infection control program. Environmental control begins with design of the hospital's physical plant. The design must meet the functional standards for patient care and must be integrated into the architecture to provide traffic accessibility and control. Since the 1960s, the practice of centralizing seriously ill patients in intensive care, dialysis, and transplant units has accentuated the need for more careful analysis and planning of space. The primary standards for these special care units and ORs require planning of floor space, physical surfaces, lighting, ventilation, water, and sanitation to accommodate easy cleaning and disinfecting of surfaces, sterilization of instruments, proper food handling, and garbage disposal. These activities should then be governed by workable policies that are understandable to the staff. Preventive maintenance should be a basic and integral activity of the physical plant department.

Surveillance of the environment by routine culturing of operating room floors and walls was discontinued in the late 1970s. Autoclaves and sterilization systems should, however, be continuously monitored with routine testing for efficiency and performance. The results should be documented and records maintained.

Investigations of the physical plant should be reserved for specific outbreaks, depending on the organism and its potential for

causing infection. This was demonstrated by the incident of a cluster outbreak of sternal wound *Legionella* infections in post-cardiovascular surgery patients after they were exposed to tap water during bathing.⁸⁴ Because outbreaks of nosocomial respiratory infections caused by *L. pneumophila* continue to be a problem,⁸⁵ the CDC includes precautionary measures for this disease in its pneumonia prevention guidelines.⁸⁶ In addition, several water-treatment measures are available to help eradicate or clear the water of these bacteria.⁸⁷

Hospital-acquired aspergillosis is caused by another ubiquitous type of microorganism that is often a contaminant of ambient air during construction. The patients most at risk are usually immunosuppressed (i.e., neutropenic). It is recommended that preventive measures be organized for these patients when construction is being planned.⁸⁸ The provision of clean (i.e., HEPA-filtered) air in positive pressure-ventilated rooms, with up to 12 air exchanges an hour, is the basic requirement for these patients.⁴²

A comprehensive review of environmental infection control in health care facilities is available at the CDC Web site (www.cdc.gov/mmwr/pdf/rr/rr5210.pdf). This review contains recommendations for preventing nosocomial infections associated with construction, demolition, and renovation.

EDUCATION

A strategy for routine training of the health care team is necessary at every professional level. The process may vary from institution to institution, but some form of communication should be established for the transmittal of information about the following:

1. Endemic infection rates.
2. Endemic bacterial trends.
3. Updates on infection prevention measures (especially during and after an outbreak).
4. Updates on preventive policies pertaining to intravenous line management, hand washing, isolation precautions, and other areas of concern.

Although members of the infection control team are the responsible resource persons in the hospital system, each member of the health care team also has a responsibility to help prevent infection in hospitalized patients. Under the JCAHO guidelines,⁶ education of patients and their families should become a part of teaching plans, as well.

RESEARCH

Infection control policies are constantly being evaluated and remodeled because most traditional preventive measures are not scientifically proved but are based on clinical experience. Although infection data are useful, research in infection control requires microbiologic support to conduct realistic studies. Very few infection control programs have the personnel and resources for these activities.

PUBLIC HEALTH AND COMMUNITY HEALTH SERVICE

According to existing public health acts, certain infectious diseases must be reported by law. Differences exist between the reporting systems of one country and those of another, but on the whole, diseases such as tuberculosis and meningococcal meningitis are reported for community follow-up.

Open communication with community hospitals and other health care facilities provides for better management of patients with infections, allowing for notification and planning for additional hospitalization or convalescence as the patient moves to and from the community and hospital.

Benefits of an Infection Control Program

The establishment of an infection control program can greatly benefit a hospital. An infection control program supports patient care activities and is a means for continuous quality improvement in the care that is given, in addition to being an accreditation requirement. In Canada and the United States, the need for infection control programs is supported by all governing agents, including the Canadian Council on Hospital Accreditation, JCAHO, the American Hospital Association (AHA), the Canadian Hospital Association, the Association for Practitioners in Infection Control (APIC), the Society of Hospital Epidemiologists of America (SHEA) Joint Commission Task Force, and the Community and Hospital Infection Control Association—Canada (CHICA-Canada).

An infection control program requires a multidisciplinary committee that includes an infection control practitioner, who may be a nurse or a technician. In the original concept, Infection Control Officer was the title given to the person in charge of the program. As the practice has expanded into research and more sophisticated data analysis, physicians and nurses have had to update their epidemiologic skills, and some hospitals have acquired the services of an epidemiologist. The historical development of infection control programs in hospitals dates to the late 1970s. The SENIC project endorsed the use of nurses⁸⁹ because of their patient care expertise; the literature contains many examples of collaboration between infection control officers and nurse practitioners.

Controlling and preventing the spread of infections in health care facilities has taken many forms:

1. Prevention of cross-infection between patients.
2. Monitoring environmental systems (e.g., plumbing and ventilation).
3. Procedures for sterilization of equipment and instruments.
4. Policies and procedures for the implementation of sterile technique for surgical and other invasive procedures.
5. Procedures for nursing care activities for the postoperative patient.
6. Policies and procedures for dietary, housekeeping, and other ancillary services.
7. Policies for the control of antibiotics.
8. Policies and procedures for occupational health prevention.
9. Educational strategies for the implementation of isolation precautions.

At present, infection control practices have developed into a sophisticated network that does not allow for hospital-wide surveillance as it was once practiced. However, the use of surveillance by objective and the use of indicators to monitor select groups of patients or select situations provide information that will benefit the entire hospital. For example, monitoring bloodborne infections in an intensive care setting will provide data to support an intravenous care plan for general use. Accomplishing a high-quality infection control program requires organization and the dedicated service of all health care employees.

Organization of an Infection Control Program

INFECTION CONTROL COMMITTEE

The chair of the infection control committee should have an ongoing interest in the prevention and control of infection. Members should represent microbiology, nursing, the OR, central supply, medicine, surgery, pharmacy, and housekeeping. This multidisciplinary group becomes the advocate for the entire hospital. The members

work with the infection control service to make decisions in the following areas: (1) assessing the effectiveness and pertinence of infection control policies and protocols in their areas and (2) raising infection control-related concerns.

INFECTION CONTROL SERVICE

Collecting surveillance data on nosocomial infections and taking actions to decrease nosocomial infections are the benchmarks of the infection control service. In the traditional sense, the service provides information on all types of endemic infections (e.g., wound, urinary tract, and bloodstream) to the benefit of the health care system. The cost-effectiveness of data collection was demonstrated by the SENIC study.⁹⁰ Since then, other studies have shown that there are benefits in reducing nosocomial infection.^{17,18,50} Cruse and Foord presented data to show that clean-wound infection rates could be brought below 0.8%.⁸ Such reductions bring multiple benefits because nosocomial infections have a substantial impact on morbidity, mortality, length of stay, and cost⁹⁰; for example, the extra costs of treating bloodstream infections in an intensive care setting were recently estimated to be \$40,000 per survivor.⁹¹

INFECTION CONTROL PRACTITIONERS

The reshaping of hospitals because of cost constraints will have an effect on the work of infection control practitioners. Already, some institutions have regrouped responsibilities and changed the role of these professionals. Given the accreditation mandate, the need to continue an active program may be reviewed. Many training pro-

grams are available to assist with professional and organizational development (see below), and the APIC certification program supports continuous professional improvement. A viable and useful program for surveillance and collection of data requires a computer database program networked to microbiology, the OR, and nursing units. Methods for collecting, editing, storing, and sharing data should be based on the CDC's NNIS system,²⁶ which promotes the use of high-quality indicators for future monitoring and comparison among health care institutions.

Training programs for infection control practitioners are available through the following organizations:

Society of Hospital Epidemiologists of America (SHEA)

8 MINIMIZING THE RISK OF MALPRACTICE CLAIMS

Grant H. Fleming, Esq., and Wiley W. Souba, M.D., Sc.D., F.A.C.S.

Of all the challenges that surgeons face, perhaps none can be so threatening and draining—on an emotional, personal, and professional level—as being a defendant in a medical malpractice claim. This is especially true when the individual initiating the claim is the very patient the defendant physician was earnestly trying to help. The purpose of this chapter is to provide the practicing surgeon with practical information about the genesis and mechanics of malpractice suits. Application of this knowledge may decrease the likelihood of being named in a malpractice suit or having to endure the ordeal of a jury trial.

The Malpractice Climate

Record verdicts are now commonplace. Our state, Pennsylvania, has contributed its share: the year 2001 saw a \$100 million malpractice award in Philadelphia—the third highest ever in the United States. Just 1 month before that award came two others: one for \$55 million and another for \$49.6 million. In 1998, Philadelphia paid out more malpractice case settlement awards and jury verdicts than the entire state of California. In 1999, there were 33 medical malpractice verdicts in Philadelphia that exceeded \$1 million, compared with 19 the previous year. Statewide, by the end of 2001, settlements in Pennsylvania had risen 15% to 20%.

The adverse malpractice environment has taken its toll on insurers, and a number of them have gone into bankruptcy.¹ St. Paul Companies, for years a mainstay for physicians' professional liability coverage, has announced its intention to drop its medical malpractice business nationwide. Despite some effort at tort reform on the state level, physicians are leaving Pennsylvania and other states because the practice of medicine has found itself embroiled in a war with patients, the court system, and political lobby interests influenced by trial lawyers who have built powerful law firms by profiting from the system.

Personal Issues for the Defendant Physician

How physicians cope personally with being a defendant in a medical malpractice suit varies, but a number of factors come to bear on the amount of stress that litigation inflicts. These factors include the physician's previous exposure to litigation claims, degree of familiarity with the legal system and the litigation process, and previous experience testifying in the courtroom or in depositions; the size of the claim as measured by the seriousness of the alleged injury; and the presence or absence of a claim for punitive damages—which, of course, are not insured by professional liability policies. Some physicians experience a sense of profound isolation when they are first named in a suit, particularly when service of suit papers is accompanied by the standard instruction from their risk management office or legal counsel not to discuss the case with anyone.

Allegations of negligence or substandard care, in and of themselves, are bitter pills to swallow, but they are all the more painful

when they are accompanied with a claim for punitive damages. Such claims, announced in the formal complaint, are then typically followed promptly with a grim letter to the defendant physician from the insurers involved, reminding the physician that there is no coverage for punitive damages awarded. The allegations in the plaintiff's complaint necessary to support a claim for punitive damages are hurtful and sometimes outrageous; the physician is accused of willful, reckless, and wanton behavior bordering on intent to injure the plaintiff. The awards sought in such cases reach far beyond fair compensation for the injured plaintiff. Rather, punitive damages are calculated to punish the defendant physician—the perceived wrongdoer—and to serve as public sanctions. The physician against whom punitive damages are sought then undergoes pretrial discovery, sometimes shortly after suit is filed. This process involves requests (interrogatories) for detailed accounting of personal assets that might be available to be attached in the event of a judgment in the plaintiff's favor.

Whether or not punitive damages are sought, it is difficult for most physicians to regard being harpooned by a medical malpractice claim as merely a cost of doing business, and for many, the arduous and seemingly never-ending nature of the claim is distracting and potentially debilitating.

Who Brings Medical Malpractice Claims?

Despite the self-aggrandizing proclamations of trial lawyer associations, professional negligence has little to do with whether claims are brought for patient injuries. Nor has any research established that a higher incidence of medical malpractice litigation has brought about a better quality of medical care delivery. Brennan and colleagues have shown that there is no relationship between the occurrence of adverse events and the assertion of claims, nor is there any association between adverse events and negligent or substandard care.² These authors did, however, find a relationship between the degree of disability and the payment of claims.

Only a small fraction of patients who are injured through substandard care or treatment actually bring claims or suits.³ Localio and colleagues concluded that although 1% of hospitalized patients suffer a significant injury as a result of negligence, fewer than 2% of these patients initiate a malpractice claim.⁴ Other authors have found that only 2% to 4% of patients injured through negligence file claims, yet five to six times as many patients who suffered injuries that are not legally compensable also file malpractice claims.⁵

Who Are the Defendants in Medical Malpractice Cases?

The experience one of us (G.H.F.) has acquired in defending malpractice claims for over 25 years at the same teaching hospital vouches for the contention that those targeted in medical malpractice suits are not the incompetent, the unskilled, or the care-

less. Entman and colleagues studied the quality of care rendered to 446 obstetric patients and performed a blinded comparison of adverse outcomes, with physicians grouped according to frequency of medical malpractice claims against them.⁶ The authors found no relationship between the number of adverse outcomes and the frequency of claims experienced. In addition, other research has shown that no relationship exists between the presence or absence of claims history and traditional indicators of physician ability, such as board certification, status, prestige of medical school attended, country of medical school, medical school ranking, or solo practice.^{7,8} An examination of the files of the National Practitioners Data Base, which lists those on whose behalf either jury awards or monetary settlements were paid, would reveal the names of some of the most highly regarded physicians in the United States.

Reducing Malpractice Claims

Clearly, some suits cannot be prevented. When catastrophic injuries follow surgery or treatment, the emotional impact of the tragedy, coupled with overwhelming economic pressures, can create an environment in which a claim is assured. On the other hand, not all adverse outcomes from treatment result in claims. Why is it that some patients and families sue for adverse outcomes and some do not? Why do some patients sue for adverse outcomes that are expected and that occur in the context of high-quality care? The answers to those questions typically have to do with physician-patient relationships rather than with professional skill.

It has become increasingly clear that surgeons can reduce the likelihood of litigation by adopting a few key habits and practices with their patients and their patients' families. These include building trust through open communication, making effective use of informed consent, keeping accurate and complete medical records, and educating office staff.

COMMUNICATION AND INTERPERSONAL SKILLS IN THE PHYSICIAN-PATIENT RELATIONSHIP

Although advancing medical technology has elevated patients' level of expectation regarding treatment outcome, easy public access to medical information on the Internet has encouraged patients to become partners with their physicians in their own care. Experience with juries over the past few decades continues to support the belief that in general, laypersons have a high regard for physicians and a deep respect for their superior level of knowledge and training. At the same time, patients expect and deserve to receive intelligible and thorough explanations from their physicians regarding their diagnosis, their treatment plan, and the risks and benefits of their treatment. Even when the disease process is beyond the physician's control, the physician can still create an environment for effective communication with the patient. Years of listening to patients and their family members tell about their experiences at depositions and trials has confirmed for us that the quality of communication and trust between physician and patient is the most important contributing factor in the patient's decision to prosecute a medical malpractice suit.

Several researchers have analyzed physician-patient communication and its relationship to claims for damages for alleged professional negligence. Beckman and colleagues studied 45 deposition transcripts of plaintiffs in settled malpractice suits, focusing on the question of why these plaintiffs decided to bring malpractice actions.⁹ These authors concluded that the process of care,

rather than the adverse outcome, determined the decision to bring the claim. They found that 71% of the depositions revealed problems with physician-patient communication in four major categories: (1) perceived unavailability ("you never knew where the doctor was," "you asked for a doctor and no one came," "no one returned our calls"); (2) devaluing of the patient's or the family's views (e.g., perceived insensitivity to cultural or socioeconomic differences); (3) poor delivery of medical information (e.g., lack of informed consent, failure to keep patients informed during care, or failure to explain why a complication occurred); and (4) failure to understand the patient's perspective.

Levinson and colleagues studied specific communication behaviors associated with malpractice history.¹⁰ Although they did not discover a relationship between those two factors in the surgeons they studied, they found that primary care physicians who had no claims filed against them used more statements of orientation (i.e., they educated patients about what to expect), used humor more with their patients, and employed communication techniques designed to solicit their patients' level of understanding and opinions (i.e., they encouraged patients to provide verbal feedback).

Hickson and colleagues studied specific factors that led patients to file malpractice claims after perinatal injuries by surveying patients whose claims had been closed after litigation.¹¹ Dissatisfaction with physician-patient communication was a significant factor: 13% of the sample believed that their physicians would not listen, 32% felt that their physicians did not talk openly, 48% believed that their physicians had deliberately misled them, and 70% indicated that their physicians had not warned them about long-term developmental problems.

In our own experience with defending malpractice suits, we have seen instances in which attending physicians who had developed a positive rapport with their patients were not named in a suit, whereas other physicians involved in the patient's care were named. In suits that progressed through pretrial discovery, we have observed instances in which patients were willing to drop from the suit physicians with whom they had a good rapport, leaving in the suit others with whom they had a less positive relationship—or with whom they had had no communication. Patients apparently made these decisions without regard to the extent of each defendant's factual involvement in the case.

A component of the motivation to sue may be simply an unsatisfactory or incomplete explanation of how and why an adverse outcome occurred. Patients who remain uninformed often assume the worst—that their physician is uncomfortable talking about the complication because he or she made a mistake, was careless, or is hiding something. In our experience, malpractice plaintiffs have sometimes claimed that when they sat through the process of jury education during the trial, it was the first time they received any explanation of the complication for which they had brought suit.

When children suffer injuries, parents often seek desperately to avoid blaming themselves and so may attempt to transfer the responsibility to the health care providers. It is therefore critical that after a complication or adverse event arises in a pediatric case, whenever possible the physician should speak openly with the parents about inappropriate feelings of guilt. The discussion should cover possible or known causes or mechanisms of the injury or death that are independent of any care rendered by the parents, including prenatal care or home care of a chronically ill child. Similarly, the physician should make a point of explaining to adult patients and their families how and why adverse conditions arose, independent of any possible deficiencies in the qual-

ity of care received at home or in patient compliance. Patients and their families are keenly sensitive to unintended inferences that blame for the bad outcome rests with them.

The principles of good communication are the same, whether an adverse event has occurred or not. They include the following:

1. **Content.** Convey medical information in descriptive terms that patients can understand, using illustrations, sketches, and diagrams. Ask about the response to the therapeutic regimen. Provide counseling and instruction if no improvement is observed. Inform the patient about specific steps in the examination or treatment plan.
2. **Process.** Ask patients whether they understand what they have been told; check the understanding by listening to the patient after providing an explanation. Demonstrate respect for any cultural or socioeconomic differences that may be impeding the patient's understanding.
3. **Emotional affect.** Demonstrate concern and understanding of the patient's complaints. Express empathy; use humor where appropriate. Demonstrate awareness of the patient's occupation, social circumstances, hobbies, or interests.
4. **Follow-up.** Return telephone calls. Explain the protocol for substitute or resident coverage, and introduce patients to other personnel who may be following their care. During longer hospitalizations, keep the patient and the family informed of the patient's progress or treatment plan. Keep the referring physician promptly informed by providing treatment or discharge summaries. In the event of a patient's death, meet with the family to review and explain autopsy findings.

Further guidelines apply when an adverse outcome occurs. In the hospital setting, prompt disclosure of an untoward or unexpected event that causes injury or harm is mandated by the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO). JCAHO standards require disclosure of unanticipated outcomes "whenever those outcomes differ significantly from the anticipated outcome." The responsibility to communicate lies with both the attending physician and, in the case of a complication incident to surgery, the person accountable for securing consent for the procedure.

When possible, it may be advisable to invite other responsible caregivers to take part in the discussion of the adverse event with the patient and the family. Consideration should also be given to inviting other persons who may be sources of support for the patient and could benefit from the disclosure. During the discussion, express regret for the occurrence, without ascribing blame, fault, or neglect to oneself or any other caregiver. Describe the decisions that led to the adverse event, including those in which the patient participated. Explain and outline the course of events, using factual, nonspeculative, nontechnical language, without admitting fault or liability or ascribing blame to anyone else. State the nature of the mistake or error if one was made, and highlight the expected consequences and prognosis, if known. Outline the plan of corrective action with respect to the patient. In the event that certain information is unknown at the time of the discussion (e.g., the etiology of the condition, suspected equipment malfunction in the absence of controlled testing, or pending laboratory test results), tell the patient and family that such information is currently unknown and offer to share the information with them when it becomes available.

INFORMED CONSENT

Effective informed consent can reduce the risk of litigation.

Informed consent is merely an extension of good communication practices, albeit one that is mandated by law. The tort of informed consent is derived from the concept of battery—for example, unauthorized touching. Patients are deemed not to have consented to a procedure unless they have been advised of all the risks involved in it and all the alternatives to it. In most jurisdictions, the standard is objective rather than subjective. In other words, the risks and alternatives that must be disclosed are those that a "reasonable patient, in similar circumstances"—not necessarily the plaintiff—would regard as material to the decision whether to undergo the surgery in question. With procedures for which the statistical incidence of risks has been published or is known, the physician has a duty to quantify for the patient the likelihood of the risk being realized. If the patient's particular condition or situation is such that the likelihood of the risk occurring is higher than average, the physician has the duty to so inform the patient.

Many physicians ignore another critical element in the required informed consent discussions: describing the range of reasonable alternative procedures or modalities other than the procedure in question that are available to the patient. The hazard that such omissions entail is illustrated by a case in which the physician performed a transesophageal balloon dilatation of the esophagus to address achalasia that had not responded to conservative medical therapy. The risk of esophageal perforation was disclosed as part of informed consent, and the procedure was performed totally within the standard of care, but the patient suffered perforation of the esophagus with serious permanent and long-term disability. Although an alternative approach, via thoracotomy, was known to be followed at other institutions, it was not used at the defendant hospital, and the informed consent discussion therefore did not include the surgical alternative as a disclosed option. The defendants were forced to settle the case for a significant amount of money, even though there had been no negligence and the patient acknowledged that the risk of esophageal perforation had been thoroughly disclosed. A breach of informed consent was easily established because one of the reasonable alternatives was not disclosed to the patient. The argument that a reasonable person would probably have rejected the surgical alternative had it been disclosed was not a valid defense; nondisclosure of a reasonable alternative, in and of itself, created strict liability.

Some surgeons regard the informed consent discussion as an inconvenient imposition on their time. However, the few minutes needed for this discussion pales in comparison with the time needed to defend a lawsuit involving a breach of informed consent, either as the central or an ancillary claim. In addition, given that the surgeon's personal interaction with a patient may be significantly limited in comparison with that of the primary care physician, obstetrician, gynecologist, or medical specialist, the informed consent discussion presents an important opportunity for the surgeon to develop rapport and a positive relationship with the patient. Such rapport can be invaluable in the event of a later complication or adverse outcome. An effective informed consent discussion may decrease the likelihood of a claim for a particular adverse outcome if the patient remembers that the risk of its occurrence was disclosed and discussed.

Informed consent is not the consent form. The form is merely a piece of evidence documenting that informed consent occurred; the critical factor is the content of the discussion. For the form to be effective, it must cogently summarize the disclosures in a manner that makes it difficult for the patient to later refute, in a "he said, she said" controversy, the version of the discussion that the physician may be rendering in the courtroom under oath.

An effective informed-consent discussion based on custom and habit is essential because of the slow pace of the legal system. In most jurisdictions, the statute of limitations for bringing claims involving adult patients is 2 years. By the time the defendant physician's pretrial deposition is taken, another 1 to 3 years may have elapsed, and after that, even more time passes before the conversation will have to be relayed under oath if the claim goes to trial. It is exceedingly rare that physicians can actually recall the informed consent discussion in question at the time of suit. However, the content of the communication can be proved more reliably by means of custom and habit than by direct recollection, particularly when the elements of the discussion are corroborated with a comprehensive but clear form signed by the patient.

In some cases, physicians encourage the showing of a patient education video that explains the intended procedure. Such videos should also communicate the risks of the procedure. The use of such videos can provide additional evidence to support the defense that the patient gave informed consent. Each version of the video should be labeled with the dates when it was routinely used, and it should not be discarded when it is replaced with updated versions. The patient's chart should reflect that the patient watched the video and had no questions after a review of its contents.

The physician who will perform the procedure, not the nurse or resident who will assist at it, has the duty to secure the patient's consent. Information provided by other health care providers can be used by the defense as evidence, however.

DOCUMENTATION

Along with effective communication techniques and informed consent protocols, good documentation practices can minimize a surgeon's risk of becoming a defendant in a medical malpractice suit, or at least provide a more effective defense if litigation is commenced. Although the purpose of keeping medical records is to provide subsequent caregivers with important information relevant to the patient's condition and treatment, in the context of litigation, medical records are used to demonstrate what care was or was not rendered. A standard question that plaintiffs' attorneys ask defendants at pretrial depositions is whether the defendant agrees with the adage, "If it is not documented, it wasn't done." Time and time again, otherwise defensible cases are compromised because of inadequate documentation, such as failure to document an order, the time an order was given, a critical telephone call from the patient or patient's family, a critical informal consultation, or critical symptoms reported by a patient during the course of an examination or clinic visit.

A current trend in tort reform legislation, designed to discourage frivolous suits, is to require that any claim being brought must be accompanied by a certification of merit, which establishes that a qualified expert has reviewed the records and is supportive of the claim. If the chart is well documented in defensible cases, many reputable experts will be loath to give an opinion that substandard care was provided. On the other hand, absence of adequate documentation sometimes prejudices expert case reviewers in favor of the plaintiff, even though subsequent deposition testimony may provide a cogent and defensible explanation for how and why the adverse event or complication occurred.

Ensure that telephone conversations are documented. Cases have been saved in the courtroom simply because a resident who received a call jotted a short note of the patient's complaint and the advice given and pasted it in the patient's chart. Keep logbooks of appointments, cancellations of appointments, and reasons for cancellations. If printed images of bedside ultrasound

scans are of relevance, be sure the printed copy is stapled and placed into the progress notes of the patient's chart. A surgeon who has provided the patient with a sketch to help explain an operative procedure should place the sketch in the patient's chart and write the date on it. In one case involving an informed consent issue, the defense was able to produce a sketch of the operation that the surgeon had made on the reverse side of a lab report in the patient's chart, refuting the patient's contention that no explanation of the procedure had ever been given. If equipment malfunction is involved in an adverse outcome, such as a death in which a postmortem examination was conducted, insist that the risk management office provide a secure place to store the specimen or equipment in question for later testing or use as a trial exhibit. If an anomalous condition has contributed to an adverse outcome in a death case, make sure the pathologist at autopsy at least photographs the abnormality if the specimen is not going to be preserved for later use.

If an untoward outcome or event occurs, document the event in the chart purely with facts. Avoid expressions of opinion or suggestions of blame of other health care providers. In the event relevant information becomes available at a later point, it can be helpful to make a late entry in the chart, documenting the time of the entry.

If one realizes that an error in documentation has been made in the patient's chart (e.g., inaccurate information recorded), do not remove the page and start over and do not scratch out or "white out" the mistake. The appropriate way of handling such an error is to draw a single line through the inaccurate information, record the correct information, and initial and date the amendment. Clearly, a medical record should never be altered in an attempt to cover something up. In the event of a suit, this act could lead to the loss of an otherwise defensible case.

EDUCATING AND INFORMING OFFICE STAFF

More than ever before, every practicing surgeon must recognize that his or her office staff must also be well informed and well educated about malpractice issues. The Health Insurance Portability and Accountability Act (HIPAA) of 1996, which began taking effect in 2003, regulates the use of an individual's protected health information and, for the first time, authorizes specific federal penalties if a patient's right is violated. All practice employees must be trained in compliance with the law and must know how to deal with privacy requirements stated in the law.

In-service training of office staff is pivotal to reducing the risk of being sued. All office personnel should be well informed and educated on issues of confidentiality, including how to answer the phone, what kinds of conversations are inappropriate, and the giving out of medical information. Good patient relations is also critical; many avoidable lawsuits have arisen simply because a member of the physician's office staff was rude to a patient on the phone, or the patient waited too long to see the doctor without an explanation. In the event that patients or family members call or write to express displeasure with service they received—whether that service was provided by the surgeon, the resident, the clinic staff, or the nursing team—courtesy and common sense decree that the dissatisfied customers be contacted and allowed to vocalize their complaints, by telephone or in person. Willingness to listen to these persons indicates a genuine interest in improving the delivery of patient care and may well prevent some claims.

ADDITIONAL POINTERS

Be vigilant for litigious patients; such individuals exist. They should receive the same high-quality medical care as any other

patient, but extra attention should go into documentation and informed consent. Avoid becoming paranoid, but inform the staff of any concerns. Such patients may feel short-changed by the medical system, or they may be looking for any derogatory statements about another physician's advice or treatment. Steer clear of criticizing another physician.

With the enormous pressure on minimizing health care expenditures, virtually all surgeons feel pressure to reduce length of stay and decrease the use of diagnostic tests and medications. These constrictions should never influence patient care decisions. Cutting corners may result in litigation. In dealing with health care plan denials, it can often be helpful to talk directly with the medical director.

What Can Surgeons Do to Assist in Their Defense if They Are Sued?

First, one should assemble all of the relevant records, phone logs and messages, and e-mail correspondence or other notes and should cooperate fully with the claims representative of the insurer and the representative of the hospital risk management team if the hospital is involved in the case. Under no circumstances should one alter, amend, or discard records when a suit is initiated. Do not discuss the facts of the case with any colleagues until legal counsel is involved, because anyone involved in those discussions may be asked to repeat the substance of the conversation

at the time of pretrial depositions. Review the available records and prepare a confidential summary of the case; address this summary only to legal counsel, with no copies to anyone. If the media is involved at the outset of the suit, under no circumstances should the defendants attempt to be spokespersons on their own behalf; they should leave this task to others who are equipped to determine how much information to provide to the media about the controversy.

Defendants should find out the name of the lawyer who will be assigned to represent them and arrange an initial meeting to familiarize the lawyer with the medical issues in the case. Defendants who conduct any medical research to assist themselves and their counsel with the issues should do so with the understanding that the research is in the context of communication with counsel. Independent research conducted for the defendant's own edification, not for communication with counsel, is discoverable by the plaintiff. Defendants should take the time necessary to educate their attorney on the medical issues involved so that the attorney can gather more information effectively. Defendants can recommend and discuss with counsel certain fact-gathering tasks to be done by counsel on the defendants' behalf. Both can begin thinking about whom to engage as an outside expert to assist in identifying weak points or issues in the case before the defendant submits to a deposition by the plaintiff's lawyer. However, after defendant and counsel have agreed on an expert, only counsel should approach or contact the expert.

9 ELEMENTS OF COST-EFFECTIVE NONEMERGENCY SURGICAL CARE

Robert S. Rhodes, M.D., F.A.C.S., and Charles L. Rice, M.D., F.A.C.S.

The citizens of industrialized nations generally enjoy a high level of health, and the positive correlation between life expectancy and per capita income is one of the best-known relationships in international development.¹ Yet many of these nations also face major challenges in controlling the cost and improving the quality of health care. The United States has attempted to control these costs through price controls (in the Nixon era), prospective payment (in the Reagan era), and managed care (in the Clinton era), but none of these measures have had any long-term success [see Table 1].^{2,3}

A consequence of the ongoing growth in health care expenditures is that health care then increasingly competes with other social goals (e.g., education) for some of the same funds. The anguish of having to choose one social goal over another can be rationalized when the expenditures on the chosen goal produce demonstrable improvements. Thus, if increased health spending generates measurably better health, it seems worthwhile, but if it does not, it seems wasteful. In the United States, unfortunately, the latter scenario appears to prevail. Even though the United States spends a larger fraction of its gross domestic product (GDP) on health care than other industrialized nations do [see Table 2], U.S. citizens seem less healthy—often by wide margins—than citizens in other nations [see Table 3].⁴ Of further concern are the data indicating that the greater U.S. spending is attributable largely to higher prices for health care goods and services.⁵

Controlling health care costs and improving health care outcomes have multiple interwoven perspectives that range from the macrostructure of the health care system to the wide variety of individual patient-provider interactions. The relevance of these interactions is underscored by the fact that physician decision-making accounts for 75% of overall health care costs. The pronounced impact of physicians' choices on health care costs also explains why those who pay the bills naturally seek to identify the most cost-effective physicians.

Surgery is a particularly suitable subject for cost-effectiveness analysis because surgical illnesses are usually of relatively short duration, surgical outcomes are readily quantified, and surgical costs often involve global fees. In what follows, we explore some basic principles of cost-effective surgical care and address some of the complex issues involved in defining such care. We define cost-effectiveness as cost divided by net benefit, with the numerator (cost) expressed in dollars and the denominator (net benefit) expressed as beneficial outcomes minus adverse outcomes. Since cost-effectiveness is integrally related to quality of care issues, we consider recent changes in the concepts of quality, address the complex issues associated with cost, and examine the relation of quality to cost. Perhaps most important, we also focus on specific skills and attributes that can help surgeons become more cost-effective.

Demise of “Appropriateness” as Indicator of Quality

DRAWBACKS OF TRADITIONAL VIEW OF QUALITY

To achieve cost-effective care, it is necessary first to develop a suitable definition of quality—a task that is considerably more problematic than it seems.^{6,7} The traditional definition of quality focused on the appropriateness of the care provided, and the authority (in terms of knowledge) for such appropriateness was viewed as exclusively the province of physicians. By the end of the 20th century, however, several factors had begun to erode appropriateness (and physician authority) as the traditional indicator of quality.

One such factor was the realization that per capita health care expenditure was not necessarily positively correlated with life expectancy. Another factor—one that directly challenged the authority of the physician as the arbiter of quality of care—was the finding that some procedures have a relatively high incidence of

Table 1 U.S. Health Care Expenditures: Selected Years, 1960–2000^{2,184}

Year	Expenditure for Health Services and Supplies (\$ billion)	U.S. Population (million)	Expenditure per Capita (\$)	GDP (\$ billion)	Expenditure as Percentage of GDP (%)
1960	25.2	190	141	527	5.1
1970	67.9	215	341	1,036	7.1
1980	245.8	230	1,067	2,796	8.8
1990	696.0	254	2,738	5,803	12.0

inappropriate indications. For instance, a Rand Corporation study found that 32% of carotid endarterectomies, 17% of coronary arteriograms, and 17% of upper GI endoscopies lacked appropriate indications.⁸ In another study, one in six hysterectomies were deemed inappropriate.⁹ Caesarean section is also frequently performed for unclear indications.

A third factor was the differences in judgments of appropriateness often noted when decisions were made for groups rather than for individuals.¹⁰ In addition, retrospective assessments often judged appropriateness on the basis of outcome alone, without considering processes of care.¹¹

Yet another factor was the recognition of the great disparities in the frequency of surgical procedures among small geographic areas.^{12–14} These frequency variations are procedure specific, and their degree is often related to the degree of consensus regarding indications.¹⁵ Procedures with highly specific indications (e.g., repair of fractured hips, inguinal herniorrhaphy, and appendectomy) often exhibit little frequency variation, whereas procedures with less definite indications (e.g., carotid endarterectomy, hysterectomy, and coronary angiography) often exhibit a great deal of variation.¹⁶

The lack of consensus about the appropriateness of surgical interventions is often related to a lack of evidence. Indeed, a study from the 1970s estimated that only about 15% of common medical practices had documented foundations in any sort of medical research.¹⁷ This conclusion does not necessarily mean that only 15% of care is effective, but it does raise concerns about the lack of hard evidence for most care.

Variations in procedure frequency also appear to be related to provider capacity (usually expressed as the number of hospital beds per 1,000 persons): one study noted a close relation between

the intensity of local diagnostic testing and the number of invasive cardiac procedures subsequently performed.¹⁸ Indeed, some communities seem to have distinct “practice signatures”—a finding that supports the idea that many medical decisions are based on opinion rather than on evidence.¹⁹ It may be tempting to attribute such variations to the inherent potential conflict of interest in a fee-for-service system, but in fact, economic incentives appear to have relatively little influence on physicians in this regard. Comparable variations in utilization rates exist among Veterans Health Administration medical facilities,²⁰ as well as in countries that do not have fee-for-service reimbursement.

Whether the high utilization rates observed are too high or the low utilization rates are too low is still a matter of debate. The possibility that low frequency of use may reflect restricted access to care is a particular concern, given the association between variation and the ratio of hospital beds to population.²¹ To date, studies that have attempted to find evidence supporting other possible explanations of these variations (e.g., differences in disease incidence and differences in the appropriateness of use) have not found such evidence.²² The current belief that the high utilization rates are too high is supported by findings of comparable health status among patients from widely disparate areas of usage, which have led to the conclusion that “marked variability in surgical practices and presumably in surgical judgment and philosophy must be considered to reflect absent or inadequate data by which to evaluate surgical treatment...”²³

In addition to these concerns about selection and utilization of surgical interventions, specific concerns have been raised about quality of care. For instance, studies suggested that as many as one fourth of hospital deaths might be preventable,²⁴ that one third of hospital procedures might be exposing patients to unnecessary

Table 3 Health Status and Outcomes in Selected Countries: 1999

risk, that one third of drugs might not be indicated, and that one third of abnormal laboratory test results were not followed up.²⁵ Large reviews of medical records also revealed alarming error rates and showed that approximately half of the adverse events were associated with errors in surgical care.^{26,27} The report on medical error issued by the Institute of Medicine (IOM) brought these issues directly into the public spotlight.²⁸ There were also concerns that physicians might be ignoring therapies of proven value (e.g., beta blockade after a myocardial infarction).

An important consequence of the difficulty of measuring quality in traditional terms was that the lack of clear data on quality led to a buyer's market. Health care purchasers began to use the apparent similarity in quality, despite variations in frequency and cost, to justify contracting for less expensive care. As a result, the medical profession, whose authority was once strong enough to forestall system change, now bears the burden of proof. In some cases, the pendulum may have even swung too far in one direction: purchasers assume that even in an atmosphere of decreasing income and increasing professional constraints, health care providers will not knowingly or willingly sacrifice quality. Indeed, some believe that competition may spark in physicians a drive to exceed their patients' expectations.

EMERGENCE OF NEW CONCEPT OF QUALITY

Perhaps the final blow to appropriateness as the indicator of quality was the emergence of a new concept of quality that overcame many of the shortcomings of the traditional concept.²⁹ This new concept characterized quality in terms of (1) structure (facilities, equipment, and services), (2) process (content of care), and (3) outcomes. Moreover, it made use of the quality-control techniques pioneered by W. Edwards Deming in industry, which involved minimizing quality variations by examining production systems. In health care, the production systems are the systems of care, with the structure and process of such systems being independent variables and the outcomes being a dependent variable. Good systems predispose to good outcomes (e.g., high quality), and vice versa.

This new concept of quality is also compatible with IOM's view of quality in terms of overuse, underuse, and misuse.³⁰ Although the new concept is gaining a strong foothold, the traditional concept continues to hold sway in some quarters, and this persistence, in our view, is at least partly responsible for the fears commonly expressed by patients and health care professionals that managed care will adversely affect quality. Nonetheless, the concepts of total quality management and continuous quality improvement are increasingly being applied to health care.

Application of New Concept of Quality

Of the three main components of the new concept of quality, outcome assessments have received the most attention. It is important to remember, however, that outcomes are very dependent on the structure and the processes of care. Moreover, improvement of both the structure and the processes of care requires a commitment to evidence-based medical practice. This commitment, in turn, depends on a capability for critical analysis of the medical literature. Such analysis then becomes the basis of skills that are applied to quality improvement: technology assessment (structure), efficient use of diagnostic testing (process), and clinical decision analysis (process). These skills often are not emphasized during formal medical education and thus warrant review here.

CRITICAL LITERATURE ANALYSIS

The ability to evaluate the literature critically is essential for cost-effective care because it enables one both to identify the evidence relevant to the decision being made and to judge the quality of that evidence. Today, the Internet is indispensable in this process. Three Web sites that are particularly valuable in retrieving and assessing evidence are MEDLINE (<http://www.ncbi.nlm.nih.gov/PubMed/medline.html>), together with other National Library of Medicine databases; the Cochrane Collaboration³¹ (<http://www.cochrane.org>), an international network of clinicians and epidemiologists that systematically reviews the best available medical evidence; and the Oxford Centre for Evidence-Based Medicine (<http://www.cebm.net>). Each of these sites has its advantages and disadvantages. For example, the Cochrane Collaboration includes sources not always accessible through MEDLINE, but the former requires a subscription, whereas the latter is freely accessible. Recent reviews from the Cochrane Collaboration are also abstracted monthly in the *Journal of the American College of Surgeons*.

Randomized, controlled trials (RCTs) are considered the gold standard of evidence-based medicine, and the number of surgery-related RCTs has grown rapidly. Meta-analysis of individual RCTs further improves their utility. Unfortunately, RCTs do have potential drawbacks. One is that the reporting methods still are not standardized.³² Another is that the stringent inclusion criteria of RCTs may limit the applicability of their results to very specific subsets of patients. That is, the results may not apply well or at all outside the conditions specified by the RCT. Even when the study findings are seemingly applicable to a particular patient, it may be difficult to reproduce the expected results in a setting that differs from the carefully controlled conditions imposed by the original RCT. Thus, a test or treatment that is efficacious under ideal circumstances may not be effective under less than ideal circumstances. Study types other than RCTs are associated with lower evidence levels; the hierarchy of evidence levels was well summarized in a 2003 review.³³

Carotid endarterectomy is a good example of a procedure that demonstrates the crucial distinction between efficacy and effectiveness. RCTs have shown this procedure to be efficacious when performed by surgeons with low rates of perioperative stroke and death.^{34,35} The effectiveness of carotid endarterectomy, however, depends on whether the incidence of complications can be kept low: as the incidence of stroke and other complications rises, the procedure becomes less effective or even ineffective.³⁶⁻³⁸ Because effectiveness may vary over a relatively narrow range of outcomes, there are strong ethical reasons why surgeons ought to be familiar with their own results. If patients are to give truly informed consent, they should have access to information about their surgeon's outcomes in similar patients.

The generalizability of results is a concern for all types of studies, not just for RCTs. For instance, in a prospective study of computed tomography in the diagnosis of appendicitis, the clinical likelihood of appendicitis in 100 patients was estimated by the referring surgeon and assigned to one of four categories: (1) definitely appendicitis (80% to 100% likelihood), (2) probably appendicitis (60% to 79%), (3) equivocally appendicitis (40% to 59%), and (4) possibly appendicitis (20% to 39%).³⁹ These estimates were then compared with the estimated probability of appendicitis determined by CT, and the pathologic condition (or absence thereof) was then confirmed by operation or recovery. The actual incidences of appendicitis in the four categories were 78%, 56%, 33%, and 44%, respectively. The CT interpretations had a sensitivity of 98%, a specificity of 98%, a positive predictive value of 98%, a negative predictive value of 98%, and an accuracy of 98% for either diagnosing or ruling out appendicitis. The

difference between the true incidences and the initial clinical estimates indicates the potential for inaccuracy in surgeons' estimation of outcomes.

The results of this study seem relatively clear-cut, but they may be considerably less so when applied to other institutions. For instance, the authors calculated a savings of \$447 per patient. However, costs (and any savings therein) are likely to vary from one institution to another in conjunction with a number of factors, including surgeons' differing estimates of the clinical likelihood of appendicitis, the availability of less expensive alternatives to in-hospital observation, and the use of the emergency department for triage. In this report, 53% of the patients studied had appendicitis, but in other studies, as few as 30% of patients with an admitting diagnosis of appendicitis eventually underwent appendectomy.⁴⁰

Proper assessment of the literature also requires an awareness of the distinction between relative and absolute risk reduction. For instance, a treatment that reduces the incidence of an undesired outcome from 5% to 4% and a treatment that reduces it from 50% to 40% can both be said to achieve a 20% relative reduction in risk. Reporting effectiveness in terms of relative improvement can be misleading if the baseline outcome is ignored.⁴¹ Patients' participation in adjuvant cancer therapy (and their willingness to tolerate side effects) may be affected more by absolute reductions in risk than by relative reductions.

Another potential pitfall in assessing evidence can arise when an advance in diagnostic technology allows earlier symptomatic diagnosis or a new or improved screening test allows diagnosis at an asymptomatic stage of a disease. As a result of such developments, studies intended to compare different treatments of the same disease may actually be comparing treatments of different stages of the disease process. Earlier diagnosis may appear to improve long-term survival while in fact only serving to identify the condition for a longer time. The apparent extended survival with earlier diagnosis is referred to as lead-time bias, and such bias can lead to overestimation of disease prevalence.⁴²

Further information on critical analysis of the medical literature is available elsewhere,¹⁹ particularly in the excellent series produced by the Evidence-Based Medicine Working Group.⁴³⁻⁶⁰

A final argument for the value of critical literature analysis is physicians' need to keep pace with patients' growing access to medical information. There are now more than 15,000 health-related Web sites,⁶¹ and it is estimated that tens of millions of adults find health information online. In addition, patients may get information from completely unmonitored sources, such as disease-specific bulletin-boards. Given that at least some of this information is inaccurate, misleading, or unconventional,⁶² it is vital that surgeons be aware of what their patients may know or believe. Survey results published in 2003 suggest that patient use of the Internet may be somewhat less than previous estimates suggested and that further patient use may be dependent on subsequent interactions with the physician.⁶³ Issues of reimbursement for Internet-based health care services also need to be resolved.⁶⁴

TECHNOLOGY ASSESSMENT

The prevailing societal attitude that equates the latest with the best—the so-called technological imperative—creates considerable pressure to acquire the newest equipment and techniques, even before their value is completely evident. With the explosive growth of technology in recent years, this behavior has been a major contributor to the rapid growth of health care costs.

It is undeniable that many technological advances have improved surgical care; however, not every new technology proves successful.

Accordingly, it is incumbent on surgeons to know how decisions about technology acquisition contribute to excess capacity and cost within the health care system. The process begins with providers who, out of a compulsion to be the first to have a new technology, acquire it before its value is fully known. Other providers, fearing to be left behind, then follow suit. If the new technology is successful, the capacity within a community can exceed the needs; if it is unsuccessful, health care cost increases without any increase in benefit to the community. Competition among providers is advocated as a way of restraining health care costs, but when competition is driven by the technological imperative, it can contribute to inflationary increases in these same costs.

Special challenges result from practice innovations that do not involve the introduction of new technology but, rather, involve the application of existing technology in new ways.⁶⁵ In this setting, methodologic problems may prevent surgeons from appreciating potential harm before the innovation has become widely disseminated. Laparoscopic cholecystectomy is a particularly good example of an innovation that diffused rapidly into surgical practice before its safety had been fully assessed. Although laparoscopic cholecystectomy is now relatively safe, the learning curve was associated with an increased number of bile duct injuries—an outcome that might have been avoided had the procedure been introduced in a more systematic fashion. The following four questions, formulated by the American College of Surgeons,⁶⁶ should be asked whenever a new technology or an innovation in surgical care is being considered for introduction into widespread use:

1. Has the new technology been considered adequately tested for safety and efficacy?
2. Is the new technology at least as safe and effective as existing, proven techniques?
3. Is the individual proposing to perform the new procedure fully qualified to do so?
4. Is the new technology cost-effective?

EFFICIENT USE OF DIAGNOSTIC TESTING

Laboratory tests and imaging studies are responsible for a large share of health care costs and account for much of the reported cost variations. Traditionally, the value of a test rested on its sensitivity (i.e., its ability to identify patients with a disease) and specificity (i.e., its ability to identify patients without a disease).⁶⁷ However, the cost-effectiveness of a test also depends on disease prevalence. For instance, if a test with a 98% sensitivity and a 98% specificity is applied to a group of patients with a disease prevalence of 50% (i.e., a group in which half the patients have the disease being tested for), 245 of every 500 patients tested ($500 \times 0.98 \times 0.5$) will have true positive results and five ($500 \times 0.02 \times 0.5$) will have false positive results. If, however, this same test is applied to 500 members of a population with a disease prevalence of 10%, 49 patients ($500 \times 0.98 \times 0.1$) will have true positive results and nine ($500 \times 0.02 \times 0.9$) will have false positive results. Thus, for any given sensitivity, the ratio of true positives to false positives increases with increasing prevalence of disease in a given patient population. In the above example, the incidence of false positives was 2.0% (5/245) in the first group and 18.4% (9/49) in the second. Given that most tests are not 98% sensitive and 98% specific, the incidence of false positives in the real world is likely to be that much greater. This relation between disease prevalence and the incidence of false positives serves to establish a test's value or utility and explains why a test may have relatively little value as a screening test in general practice (where the disease prevalence may be low) but may have relatively high value in a specialist's practice (where referrals may increase the relative prevalence of the disease).

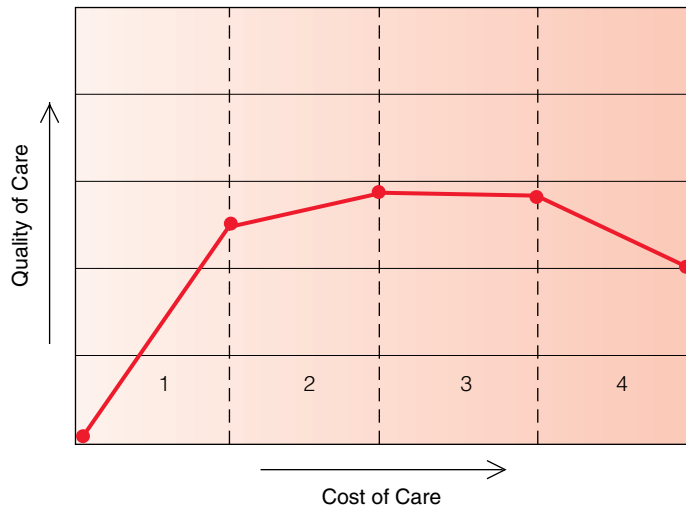

Figure 1 Illustrated is the new concept of quality and cost.⁷² A positive relation between quality and cost still exists in zones 1 and 2, but the slope of the curve flattens in zone 3 and actually becomes negative in zone 4. Here, further cost increases are associated with decreasing quality because increased use of sophisticated (albeit riskier) technology in earlier (or even just suspected) stages of disease may result in a flat slope (zone 3) or even a negative one (zone 4).

An example of the role of test utility in clinical decision making is found in the functional assessment of incidental adrenal masses.⁶⁸ Physicians encountering such masses often feel compelled to engage in an elaborate workup; however, in the absence of concrete signs and symptoms, measurement of specific hormone levels may be of little value. Close inspection of many other routine preoperative tests reveals that they, too, may have little value.^{69,70}

As noted [see Demise of “Appropriateness” as Indicator of Quality, *above*], increases in diagnostic testing tend to parallel increases in clinically relevant downstream procedures.⁷¹ An example is the known association between the intensity of diagnostic testing and the frequency of subsequent invasive cardiac procedures.¹⁸ A consequence of this association is that increases in the number of patients who undergo cardiac catheterization as a result of false positive screening tests also lead to increases in the number of patients with negative findings who may have complications of catheterization, because complications of catheterization occur just as frequently in patients with false positive indications as in those with true positives. The net effect is to flatten the cost-benefit curve and steepen the cost-harm curve.²⁹ Thus, the relative frequency of false positives affects both the numerator and the denominator of cost-effectiveness.

The possibility of a relative reduction in benefit coupled with a relative increase in harm is the basis of the new relation between quality and cost. In the context of the appropriateness concept, the relation between health care cost and quality was seen exclusively as positive: increasing expenditure was considered to improve quality, and vice versa. In the light of our current understanding, however, differential effects on the cost-benefit and the cost-harm curves can be seen to alter the relation of quality to cost [see *Figure 1*].⁷²

CLINICAL DECISION ANALYSIS

Analysis of clinical decision making involves quantifying the effect or impact of each option involved in a medical decision. The outcome of each decision thereby acquires a probability, and each component of the decision tree carries an explicit assumption that

allows an appreciation of the impact of specific factors on that outcome. Some factors may then receive greater consideration, and others may be discounted.⁷³ This process is exemplified by analyses of the management of penetrating colon trauma⁷⁴ and asymptomatic carotid artery stenosis.⁷⁵ Reductions in uncertainty are reflected in increased cost-effectiveness.⁷⁶⁻⁷⁸

Some may find the mathematics of such analyses intimidating; others may perceive it as a cookbook approach to health care. Nonetheless, it is clear that formal clinical decision analysis yields estimates of the importance of specific facets of health care that might be difficult to obtain otherwise.⁷⁹

Understanding Systems of Care

The analytical skills described (see above) are important for improving cost-effectiveness, but they may not be sufficient by themselves. An additional critical element that must be in place is a solid understanding of the systems of care within which one practices. These systems reflect the processes of care, and the measures of these processes (i.e., what is done to a patient) may be a more sensitive indicator of quality of care than measures of outcome (i.e., what happens to a patient). After all, poor outcomes do not occur every time an incorrect decision is made.⁸⁰ Systems of care are reflected in critical pathways, coordination of care, and disease management.

CRITICAL PATHWAYS

Critical pathways, also referred to as practice guidelines, are increasingly used to standardize treatments and are particularly helpful for high-volume diagnoses. Although criticized by some as embodying a “cookie cutter” approach, they minimize variation by displaying optimal goals for both patients and providers. Critical pathways have been developed by a number of groups and organizations and are available commercially, through surgical societies,⁸¹ and in focused publications.⁸² The Agency for Healthcare Research and Quality (AHRQ) has also established practice guidelines, which are available online (<http://www.ahrq.gov> or <http://www.guideline.gov>) or through evidence-based practice centers. The guideline.gov site is part of the National Guideline Clearinghouse and is a comprehensive repository for clinical practice guidelines and related materials.

Critical pathways, though valuable as explicit expressions of the processes of care, do have limitations. One is that the focus on quality and efficiency of care is often adopted after the decision has already been made to admit the patient or perform a procedure. A second is that standardization does not automatically result in quality improvement. Accordingly, critical pathways must be considered flexible and subject to modification on the basis of experience. Indeed, critical pathways are perhaps best understood not as rigid rules but as ways of codifying experience that can help others avoid mistakes. A third limitation is that some guidelines do not adhere to established methodologic standards.⁸³⁻⁸⁶ A great deal of additional information on pathway development, implementation, and troubleshooting is readily available in published sources.^{87,88}

COORDINATION OF CARE

By preventing duplication of tests and unnecessary delays, coordination of care both improves patient satisfaction and saves money. The most frequent causes of delay are scheduling of tests (31%), followed by unavailability of postdischarge facilities (18%), physician decision making (13%), discharge planning (12%), and scheduling of surgery (12%).⁸⁹ The growing complexity of health care makes teamwork increasingly essential.

DISEASE MANAGEMENT

Comprehensive management of disease goes beyond coordination of care and emphasizes preventive measures. Disease management is most applicable to a relatively large group of patients with a given health problem within a given health system or practice. Such management uses an explicit, systematic population-based approach to identify patients at risk, intervene with specific programs of care, and measure clinical and other outcomes.⁹⁰

Analysis of Cost-Effectiveness

In simple terms, cost-effectiveness reflects the cost of a health care intervention (usually expressed in dollars) in relation to outcome. It is distinct both from the cost-benefit ratio, which measures return on investment (with both the numerator and the denominator expressed in dollars), and from efficiency, which measures productivity (with outputs divided by inputs). Analysis of cost-effectiveness, by definition, compares two approaches to a given problem, with the numerator reflecting any difference in cost and the denominator reflecting any difference in quality. The comparison can be between two interventions, between an intervention and no intervention, or between early and delayed treatment.⁹¹ Beneficial changes in one component of the cost-effectiveness ratio can be outweighed by adverse changes in the other, and vice versa. For example, a study of appendicitis noted that for each 10% increase in diagnostic accuracy, there was a 14% increase in the perforation rate.⁹² In this case, the cost (i.e., increased morbidity from perforation) might be the price paid for the benefit derived (i.e., greater diagnostic accuracy). Any savings achieved up front might be lost in the long run because of more advanced or complicated illness.

MEASUREMENT OF QUALITY

To calculate cost-effectiveness, it is necessary to understand the principles underlying the measurement of both quality and cost. Under the new concept of quality, the preferred outcome measure is health care–related quality of life, typically expressed in terms of quality-adjusted life years (QALYs),^{93,94} which reflect the length of time for which a patient experiences a given health status. There are several methods of quantifying QALYs.⁹⁵ Some of these methods include objective measures (e.g., functional status), whereas others are based entirely on subjective estimates of well-being. The objective measures emphasize patient-desired outcomes and the

meaningfulness of a given functional status. For instance, patient A may not be able to walk as far as patient B, but whether patient A actually has a poorer quality of life depends on the context in which that poorer functional status is placed.⁹⁶

Calculation of QALYs is confounded by several factors.^{80,97} For instance, estimates of the future value of an outcome measure may vary with the circumstances prevailing at the time of assessment (e.g., acute pain) or with the patient’s age (e.g., the elderly often place great value on the ability to live independently). Thus, quality of life may be more important than longevity.⁹⁸ Calculation of QALYs may also be affected by gender, ethnicity, socioeconomic status, religious beliefs, and other factors that affect attitudes about health care. Adjusting outcome measures to account for health status and severity of illness before treatment can also be difficult.⁹⁹

Still another factor confounding determination of QALYs is that patients, providers, and health care purchasers may have different perspectives on the experiential, physiologic, and resource-related dimensions of QALYs. These differences may be reflected in different views about which measure is best for judging the outcome of a given intervention. Thus, the hospital administration is likely to emphasize length of stay and cost, whereas the surgeon and the patient are more likely to emphasize morbidity, mortality, and subsequent quality of life. When these various perspectives disagree about the outcome of a decision (as when an outcome deemed successful by a provider does not satisfy the patient), the disagreement further complicates the assessment of quality.

DETERMINATION OF COST

Definition and attribution of cost are also complex issues. Practice costs are relatively easy to identify. Hospital costs, however, are much more intricate; as has been well said, “cost is a noun that never really stands alone.”¹⁰⁰

A first step in unraveling the complexity of cost is to understand the distinction between costs and charges. Charges reflect price structure but are a poor reflection of actual costs. Costs can be calculated as an aggregate fraction of charges, and this aggregate ratio is often relatively constant among institutions. Nevertheless, substantial variations exist among institutions regarding the relation between charges and costs for specific goods and services. Such variations result partly from differences in accounting systems and partly from contractual differences with payors. However, they also arise as a consequence of substantial differences in cost attribution, and these differences are evident even with the relatively standardized accounting standards required by the Centers for Medicare and Medicaid

Table 4 Categories and Types of Hospital Costs

Category	Type	Example or Definition
Traceability to the object being costed	Direct	Salaries, supplies, rents, and utilities
	Indirect	Depreciation and employee benefits
Behavior of cost in relation to output or activity	Variable	Supply
	Fixed	Depreciation
	Semivariable	Utilities
	Semifixed	Number of full-time equivalents per step in output
Management responsibility for control	—	Often limited to direct, variable costs
Future versus historical	Avoidable costs	Costs affected by a decision under consideration
	Sunk costs	Costs not affected by a decision under consideration
	Incremental costs	Changes in total costs resulting from alternative courses of action
	Opportunity costs	Value forgone by using a resource in a particular way instead of in its next best alternative way

Services (CMS) (formerly the Health Care Financing Administration [HCFA]). For instance, data from 1996 indicated that best practice for expense per 100 minutes of OR time was \$511, but the national median was \$938—a 46% variance.¹⁰¹ It is difficult to determine how much of this variation is due to differences in accounting and how much to differences in efficiency.

To better understand cost behavior, it is useful to recognize that health-related costs commonly fall into one of four general categories [see Table 4]. For surgeons, the first two—the behavior of cost in relation to output or activity and the traceability of costs—are perhaps the most important. Within these general categories, there are several types of costs that are worth considering in further detail.

Variable costs, such as supplies, change in a constant proportional manner with changes in output; fixed costs do not change in response to changes in volume. Semivariable costs (e.g., utilities) include elements of both fixed and variable costs; there is a fixed basic cost per unit of time and a direct, proportional relation between volume and cost. Semifixed costs (also known as step costs) may change with changes in output, but the changes occur in discrete steps rather than in a constant proportional manner. An example of a semifixed cost is the number of full-time equivalents (FTEs) required for a particular output. If one FTE can produce 2,000 widgets, every 2,000-unit change in widget output will be associated with a change in labor cost: for every 2,000-unit increment in output, one more FTE is needed (with a concomitant increase in costs), and for every 2,000-unit decrement, one fewer FTE is needed (with a concomitant decrease in costs). Unless the step threshold is attained, costs do not change. Thus, a semifixed cost might be considered either a variable cost or a fixed cost, depending on the size of the steps relative to the range of output. Unfortunately, standard protocols for reporting this information often are not available,¹⁰² and the lack of such protocols makes it more difficult to compare cost analyses of clinical interventions.

Cost traceability is classified as direct or indirect. Examples of direct costs are salaries, supplies, rents, and utilities; examples of indirect costs are depreciation and administrative costs associated with regulatory compliance. However, not all costs classified as indirect are necessarily indirect in all circumstances. In some situations, they could be defined as direct costs, with the specific classification depending on the given cost objective.

One technique that can help clarify costs is the creation of a matrix in which cost type is plotted against cost traceability. Thus, variable costs can be direct or indirect, and direct costs can be variable, semivariable, semifixed, or fixed. More often than not, costs are categorized according to a decision maker's specific needs. The subcategory to which a given cost is assigned, however, often depends on whose point of view is assumed—the purchaser, the provider, or the patient.^{103,104} A key point is that physicians primarily affect costs via their impact on variable costs (e.g., fully variable or semifixed costs), yet these costs typically constitute no more than 15% to 35% of hospital costs.^{104,105}

The interval between the intervention and the point of measurement can also affect estimates of cost-effectiveness.^{106,107} Whereas patients are likely to view outcomes over the long term, providers and purchasers tend to focus on the short term (e.g., the term of a health care contract). This difference in perspective affects the calculation of QALYs, which, in turn, affects the determination of cost-effectiveness.

It is also useful to distinguish between per-procedure costs at the hospital level and aggregate procedure costs at the insurer level. This distinction was clearly an issue with the advent of laparoscopic cholecystectomy,¹⁰⁸ which saw lower costs per pro-

cedure being offset by an increase in procedure volume and an actual increase in aggregate costs. Given such results, it is understandable that patients, providers, purchasers, and investigators might all reach differing opinions about the value of new technology. Similarly, the added costs of a complication in a single patient can be considered with respect to the frequency of that complication in the entire population undergoing a given treatment.¹⁰⁹ Priorities for quality improvement efforts to prevent complications should consider both the incidence of the complication and its independent contribution to resource use.

Perspectives on cost-saving can vary among the different components of the health care system. A 1996 consensus statement recommended adoption of better standards to improve the comparability of cost and quality.^{94,110,111} The panel advocated that calculations be based on the perspective of society as a whole rather than on that of patients, providers, or purchasers. Otherwise, the panel concluded, costs incurred by patients or others, such as outpatient medication or home care after hospital discharge, might be deemed irrelevant from the purchaser's perspective.

A unilateral perspective may also disregard some outcomes. For example, how soon patients return to work after an illness may matter little to a health maintenance organization (HMO) or a government program but may matter a great deal to the patients themselves, their employers, or the government agency responsible for disability payments—and probably to most surgeons.

QUANTIFICATION OF COST-EFFECTIVENESS

Because it is a ratio, cost-effectiveness may be affected by changes in either the numerator (cost) or the denominator (quality) [see Table 5]. Thus, changes in cost-effectiveness can occur through either a relative reduction in cost or a relative improvement in quality. Moreover, quality improvements will be a function of both the extent and the duration of the improvement.

The various confounding factors notwithstanding, good data are available on the relative cost-effectiveness of some common medical interventions [see Table 6].¹¹² The median medical intervention cost is \$19,000/year of life. The figure of \$50,000/year of life saved has often been put forward as a threshold for cost-effectiveness; however, any such thresholds remain both arbitrary and relative and are not necessarily indicative of an intervention's societal value. For instance, the Oregon state health plan prioritized benefits on the basis of broad input from stakeholders rather than a stratified list of \$/QALYs.¹¹³ Physician leadership is particularly crucial in this context because the majority of health care costs are related to the decision to provide care, not to the question of which options for care should be selected.

Implications of Outcome Variations

Although it is human nature for each surgeon to believe that he or she is among the best, the data clearly show considerable variation in resource use and outcomes among surgeons and among hospitals.¹¹⁴ These variations are often relatively large, sometimes exceeding 200% or even 300%. Some of the discrepancies reported can be accounted for by the natural variability of biologic processes, and some by differences in disease severity; however, the majority of the variations are unexplained.

Health care purchasers are well aware of these variations and use claims data to create performance profiles of hospital and physician costs and outcomes and to establish benchmarks toward which providers are expected to strive. The potential problem with such benchmarks is that they tend to reflect an ideal or excep-

Table 5 Cost-Effectiveness Studies of Selected Surgical Procedures

Procedure	\$/QALY	Δ QALY	Comment
Carotid endarterectomy in asymptomatic patients ⁷⁴	8,000	+0.25	The initial cost of endarterectomy is offset by the high cost of care after a major stroke; the relative cost of surgical treatment increases substantially with increasing age, increasing perioperative stroke rate, and decreasing stroke rate during medical management
Routine radiation therapy after conservative surgery for early breast cancer ¹⁸⁶	28,000	+0.35	The ratio is heavily influenced by the cost of radiation therapy and the quality-of-life benefit that results from a decreased risk of local recurrence
Total hip arthroplasty for osteoarthritis of the hip: 60-year-old woman ¹⁸⁷	117,000 in cost savings	+6.9	The cost savings result from the high cost of custodial care associated with dependency
Total hip arthroplasty for osteoarthritis of the hip: 85-year-old man ¹⁸⁷	4,600	+2	—
Endoscopic versus open carpal tunnel release ¹⁸⁸	195	+0.235	Cost-effectiveness is very sensitive to a major complication such as median nerve injury
Lumbar discectomy ¹⁸⁹	29,200	+0.43	Cost-effectiveness results from the moderate costs of lumbar discectomy and its substantial effect on quality of life

tional patient population.¹¹⁵ Thus, efforts to meet the mandated performance levels might actually increase the risk of adverse outcomes in complicated patients who need more extensive care.

A significant limitation of practice profile comparisons is that they cannot fully account for disease-severity factors that affect outcome. Adjustments for disease severity are difficult to make on the basis of claims data because in many cases, the requisite data either is not collected or is miscoded.¹¹⁶ Medical-record review is much better at accounting for severity, but it is also significantly more cumbersome and costly. Even with medical-record review, the effects of comorbid conditions on cost and outcome can be difficult to sort out; as a result, much of the cost variation will still be unaccounted for.¹¹⁷ Moreover, some differences in cost and length of stay are related to factors that are not under surgeons' direct control, such as patient age, patient gender, and various cultural, ethnic, or socioeconomic factors extrinsic to the medical care system.¹¹⁸⁻¹²⁰ Selection bias may affect outcome reporting as well.¹²¹ High rates of functional health illiteracy can also have an adverse effect on compliance (and hence on outcomes).¹²²

Current methods, therefore, can result in very different estimates of cost-effectiveness for the same intervention. Despite the shortcomings of these methods, it is likely that health care purchasers will continue to use claims data and medical record review to assess cost-effectiveness. The issue, then, is not whether such assessments will be made but rather to what extent they will be used and for what purposes. The Leapfrog Group (<http://www.leapfroggroup.org>) has taken the lead in this area. This organization increasingly focuses on the differences in cost and outcome evidence and uses these data to recommend referral patterns. A 1995 national survey found that 39% of managed care organizations were moderately or largely influenced in initial physician selection by the physician's previous patterns of costs or utilization, and nearly 70% profiled their member physicians.¹²³ At least one HMO recognized that practices with high scores on service and quality indicators attracted significantly more new enrollees than practices with lower scores did.¹²⁴

A somewhat controversial step has been the distribution of provider outcomes directly to the public in the form of report cards. In an early effort, HCFA (now CMS) calculated mortality data for individual hospitals using a risk-adjustment model based on DRGs. After many years, however, HCFA acknowledged the flaws in the associated mortality model and stopped releasing these data. Subsequently, both HCFA (using Medicare data) and

some states publicly disclosed provider-specific data on outcomes of cardiac surgery. Their intent was to educate the public regarding the choice of health care providers. Although these efforts used more criteria than were available through DRGs alone,^{125,126} the profiles remained highly controversial because they still did not adequately account for all the differences in case severity. Because current severity adjustments may not reflect differences attributable to patient selection, surgeons operating on truly high-risk patients will, all other factors being equal, have poorer outcomes than surgeons operating on lower-risk patients. However, all other factors may not be equal. If the latter group of surgeons operated on the former group's patients, the outcomes might even be worse, and if the former group operated on the latter group's patients, the outcomes might even be better. Such patient selection among practices is a well-recognized phenomenon.¹²⁷

Public release of provider outcome data may also have unintended consequences. For instance, it has been suggested that publicizing provider outcomes creates incentives to reduce risk-adjusted mortality by avoiding high-risk patients.^{128,129} In a 1996 study, although consumer guides containing provider-specific outcome data appeared to improve quality of care, they also appeared to have limited credibility among cardiovascular specialists.¹²⁹ Surveys also indicated that the data were of limited value to the target audience (i.e., patients undergoing cardiac surgery).

The success of provider report cards in prompting quality improvement depends on several factors.¹³⁰ The added value of such reports is likely to result in an increase in their availability to the public.¹³¹ As examples, one Web site (<http://www.healthgrades.com>) contains hospital specialty data on cardiac, orthopedic, neurologic, pulmonary, and vascular surgery; transplantation outcomes are available from the United Network for Organ Sharing (<http://www.unos.org>). There are numerous other Web sites that focus on health care quality [see Table 7].

In contrast to the equivocal results of payor-based efforts, physician-based quality-improvement efforts have had unquestioned success. Perhaps the most notable of these latter efforts is that initiated by the Northern New England Cardiovascular Disease Study Group, which has developed a multi-institutional regional model for the continuous improvement of surgical care.¹³² The success of this group's approach rests on several key characteristics: there is no ambiguity of purpose, the data are not owned by any member or subgroup of members, members have an estab-

lished safe place to work, a forum is set up for discussion, and regular feedback is provided. Using a systems approach, the group effected a 24% reduction in hospital mortality for cardiac surgery and reduced variation in outcomes among group members. The decrease in mortality was considerably greater than that reported by HCFA and by state report cards for similar procedures. Despite concerns that releasing such findings would lead to unfavorable publicity, no such reaction occurred. It is noteworthy that the process the group developed did not involve personal criticism or attempt to identify the proverbial bad apples. Three important conclusions can be drawn from the results reported: (1) physician-initiated interventions are likely to be more effective than external review in improving quality, (2) a systems approach to quality improvement is better than the bad-apple approach, and (3) it is possible to conduct quality-improvement programs involving practice groups that might otherwise be viewed as competitors.

Although self-assessment of quality and cost-effectiveness may seem daunting, the most difficult step may be the willingness to initiate the process. Studies of practice change in relation to continuing medical education (CME) consistently emphasize that

effective change strategies include reminders, patient-mediated interventions, outreach visits, input from opinion leaders, and multifaceted activities. Specific factors reported to increase the probability of a practice change are peer interaction, commitment to change, and assessment of the results of change.¹³³ Additional evidence suggests that improvement in care is more likely to occur with CME activity that is directly linked to processes of care.¹³⁴⁻¹³⁸ Indeed, many of these features of practice change were employed both in the model developed by the Northern New England Cardiovascular Disease Study Group and in the subsequent national study by the Society of Thoracic Surgeons, which used process measures to improve outcomes from coronary artery bypass graft (CABG) surgery.¹³⁹

The current interest in assessing surgeons' performance is not new, nor is the plea for that assessment from surgeons. In the early years of the 20th century, Ernest A. Codman, a Boston surgeon, crusaded for hospitals and surgeons to publicize their results; his efforts typically met with varying degrees of disinterest or even defensiveness.¹⁴⁰ Today, in the early years of the 21st century, it is clear that efforts to profile surgeons, despite their methodologic shortcomings, are unlikely to go away. Surgeons who respond to such efforts dismissively or defensively (e.g., by attempting to explain away any outcome variations simply by stating, "My patients are sicker") will be forgoing the opportunity to reestablish the authority of the medical profession on the issue of quality. Surgeons who preemptively familiarize themselves with their own outcome data, on the other hand, will be better positioned to respond appropriately to external review.

One must accept from the outset that self-assessment is an ongoing process akin to peeling an onion: initial steps inevitably lead to deeper analyses. Even simple data charts may reveal changes or patterns in a surgeon's outcomes or resource consumption that might not otherwise be obvious.¹⁴¹ Sometimes, merely standardizing a process is enough to improve outcomes significantly. With time, strategies for optimal practice emerge.^{142,143} An important concept in looking at outcome measures and processes of care is that for any given outcome measure to be a valid index of improved quality, it should also be intimately related to the processes of care.³⁰

Relation of Volume to Outcome

An emerging aspect of cost-effective surgery is the finding, reported in numerous studies, that outcome appears to be positively correlated with volume: surgeons and hospitals that do an operation more frequently tend to do it better.¹⁴⁴⁻¹⁴⁹ This finding led the National Cancer Policy Board of the Institute of Medicine and the National Research Council to conclude that patients requiring complicated cancer operations or chemotherapy should be treated at high-volume facilities. There also appears to be an inverse relation between volume and cost.^{150,151} Thus, high volume may have a positive effect on both the numerator and the denominator of the cost-effectiveness ratio. Similar arguments have been made with regard to the issue of surgical subspecialty training.¹⁵² These findings form the basis of the Leapfrog Group's recommendations regarding the minimum numbers of CABG procedures, esophagectomies, carotid endarterectomies, and aortic aneurysmectomies required for acceptable outcomes.

It must be kept in mind, however, that the data in these studies represent associations and probabilities, not cause-and-effect relationships.¹⁵³ Thus, one cannot conclude that low volume is always associated with poorer outcomes and high volume with better outcomes. Because some measures can be convincingly assessed only in

Table 6 Cost-Effectiveness of Common Surgical Interventions⁹²

Intervention	Cost-Effectiveness (\$/QALY)
Mammography and breast exam (versus exam alone) annually for women 40-49 yr of age	95,000
Mammography and breast exam (versus exam alone) annually for women 40-64 yr of age	17,000
Postsurgical chemotherapy for premenopausal women with breast cancer	18,000
Bone marrow transplant and high (versus standard) chemotherapy for breast cancer	130,000
Cervical cancer screening every 3 yr for women older than 65 yr	≤ 0*
Cervical cancer screening annually (versus every 3 yr) for women older than 65 yr	49,000
Cervical cancer screening annually for women beginning at age 20	82,000
One stool guaiac colon cancer screening for persons older than 40 yr	660
Colonoscopy for colorectal cancer screening for persons older than 40 yr	90,000
Left main coronary artery bypass graft surgery (versus medical management)	2,300
Coronary artery bypass surgery for octogenarians ¹⁹⁰	10,424
Exercise stress test for asymptomatic men 60 yr of age	40
Compression stockings to prevent venous thromboembolism	≤ 0*
Preoperative chest x-ray to detect abnormalities in children	360,000

*Saves more resources than it consumes.
QALY—quality-adjusted life year

Table 7 Selected Web Sites Focusing on Health Care Quality

Organization (Web Address)	Comment
National Committee for Quality Assurance (NCQA) (www.ncqa.com)	The NCQA accredits managed health care plans and develops and refines the Healthplan Employer Data and Information Set (HEDIS). Many of the measures involve screening (e.g., mammography) and/or prevention (e.g., smoking cessation).
Foundation for Accountability (FACCT) (www.facct.org)	FACCT is a national organization dedicated to improving health care by advocating for an accountable and accessible system.
National Forum for Health Care Quality Measurement and Reporting (www.nfqf.org)	NQF is a private, not-for-profit membership organization created to develop and implement a national strategy for health care quality measurement and reporting.
The Leapfrog Group (www.leapfroggroup.org)	Leapfrog is composed of more than 140 public and private organizations that provide health benefits. The group works with medical experts to identify problems and to propose solutions that it believes will improve hospital safety. It represents more than 34 million health care consumers in all 50 states.
Joint Commission on Accreditation of Healthcare Organizations (JCAHO) (www.jcaho.org)	The JCAHO develops standards and accredits health care organizations throughout the United States.
Institute for Healthcare Improvement (www.ihl.org)	The institute offers resources and services to help health care organizations make dramatic and long-lasting improvements that enhance outcomes and reduce costs.
Institute for Health Policy (www.mgh.harvard.edu/healthpolicy)	The institute is dedicated to conducting world-class research on central health care issues.
QualityCounts (www.qualitycounts.org)	This organization was created to build consumer demand by providing information on quality ratings for medical groups and hospitals in its network; tips for choosing doctors or hospitals; and information on dealing with medical errors.
The Commonwealth Fund (www.cmwf.org)	The Commonwealth Fund supports and publishes studies in the broad area of health care quality. The study results are available on its Web site.
National Patient Safety Foundation (www.npsf.org)	The NPSF identifies and creates a core body of knowledge; identifies pathways to apply that knowledge; develops and enhances the culture of receptivity to patient safety; and raises public awareness and fosters communications about patient safety.
Agency for Healthcare Research and Quality (www.ahrq.org)	AHRQ is a branch of the Department of Health and Human Services that focuses on funding and reporting health services research. Its Web site is an excellent resource of knowledge.
Center for Medical Consumers (www.medicalconsumers.org)	A nonprofit advocacy organization active in both state (primarily New York) and national efforts to improve the quality of health care. Its Web site is regularly updated with articles on issues of health care quality, including a report on volume-outcomes in carotid endarterectomy.

large patient populations, outcome comparisons can be highly problematic when one is dealing with unusual or infrequent cases. Moreover, the relative importance of hospital volume and surgeon volume may vary with specific procedures: complex, team-dependent procedures (e.g., CABG surgery) may be more dependent on hospital volume, whereas less complicated procedures may be more dependent on surgeon volume. In the Veterans Administration National Surgical Quality Improvement Project's large study of eight common surgical procedures, which used medical-record data rather than claims data, no correlation could be established between institutional operative volume and postoperative mortality.¹⁵⁴ It remains unclear, therefore, whether practice makes perfect or perfect makes practice. The announced thresholds for given procedures are also fraught with methodologic problems.¹⁵⁵

The empirical relation between surgical volume and outcome has led to proposals for regionalization of care.¹⁵⁶ Regionalization has proved effective in trauma care, but the basis of the improved quality in this setting may be better systems of care, not higher volume per se. This view is consistent with the findings that not every high-volume provider has better outcomes and not every low-volume provider has poor outcomes. Regionalization of care without a solid understanding of the basis of the volume-outcome relationship has the potential to create unintended or even adverse consequences for other types of care. Consequently, many believe that it is too soon to use these volume-outcome data as surrogates for quality or as criteria for establishing policy.¹⁵⁷ Nonetheless, the pressure to reduce cost remains strong; if suitable (preferably

physician-initiated) alternatives do not emerge, then other, less desirable options are likely to be imposed.

Practical Issues in Improving Cost-Effectiveness

The OR is a frequent target for improved efficiency, and specific guidelines for achieving this end are available.¹⁵⁸⁻¹⁶⁰ Perceived delays in room turnover are a common complaint, for which the responsibility is variously assigned to nurses, anesthesiologists, and surgeons themselves. Maintaining large inventories to satisfy individual surgeon preferences also contributes to higher costs, and the growth of minimally invasive surgery has added new dimensions to this challenge [see 1:1 *Preparation of the Operating Room*].¹⁶¹ Key issues in this setting include reusable versus disposable equipment, the varying costs of different types of equipment used to accomplish the same task, and just-in-time inventory. Major pieces of equipment are often duplicated to allow similar cases to be performed simultaneously in different rooms, but this duplication often means that the equipment may be idle for relatively long periods. More efficient use of such equipment reduces costs, but it requires levels of cooperation and coordination among surgical staff members that can be hard to achieve.

To improve efficiency, the surgical team must think of the OR less as a workshop and more as a factory. Surgeons, having been steeped in the view that they are the "captain of the ship," often have a hard time embracing the view that all members of the surgical team have interdependent goals for quality maintenance and

cost reduction. However, these two perspectives are not mutually exclusive. Successful team efforts have led to cost reductions in trauma care^{162,163} and to the use of protocols to guide ventilator weaning.^{164,165} Moreover, the relative contributions of individual and institutional cost-effectiveness are such that improving the former may have little impact if the latter is not improved as well.

Ambulatory surgical units are often heralded as a cost-saving measure. However, the aggregate savings are likely to depend on existing OR capacity and on specific payor issues.¹⁶⁶

It is worthwhile for surgeons to familiarize themselves with the broader organizational efforts aimed at improving quality in health care [see Table 7].¹⁶⁷⁻¹⁶⁹ Such efforts may indeed help improve care significantly; however, the most meaningful improvements in care are likely to arise from efforts initiated at the grassroots level.

Ethical and Legal Concerns

Efforts to improve cost-effectiveness are often seen as forcing health professionals to face conflicts between the ethic of patient advocacy, on one hand, and pressures to make clinical decisions for societal purposes and on behalf of third parties, on the other. Although resolving these tensions may seem difficult,¹⁷⁰ the medical profession is no stranger to such potential conflicts. The vast majority of physicians successfully avoid the temptations inherent in fee-for-service care, and at least as many appear to avoid incentives to undertreat. Although some believe that evidence-based practices derived from large populations may not be readily applicable to individual patients, the rationale for this belief is not clear.

One area that frequently generates controversy is the high costs of the terminal stages of life, particularly among patients who require intensive care. To mitigate the dilemma faced by physicians involved in making life-ending decisions, increasing emphasis is being placed on patient self-determination. However, even when physicians and institutions make efforts to comply with the choices of patients or their families in the setting of terminal illness, costs are not always reduced, nor are outcomes always improved.¹⁷¹ The actual savings may be small.¹⁷²

The Future

Physicians undoubtedly have a role to play in the ongoing discussion and debate on the future of the health care system in the United States. The extent of their input in this debate is likely to depend on

how effectively they can address the issues of quality and cost. In particular, it is essential that they address both variations in intervention rates and variations in outcomes. Medical decision making must increasingly be evidence based. Financial constraints will place growing pressure on payors to reimburse surgeons and hospitals only for those procedures with clear indications, suitably low morbidity and mortality, or both. This has already occurred with lung reduction surgery for end-stage chronic obstructive pulmonary disease (COPD). Although this procedure was being performed more and more frequently, there was little hard evidence indicative of long-term efficacy. As a result, HCFA announced that it would pay for the procedure only if it was performed as part of a clinical trial aimed at confirming such efficacy; other payors quickly followed suit.¹⁷³ Only in the past few years did the results of an RCT clarify the role of lung reduction surgery for COPD.¹⁷⁴

Academic medical centers are no more immune to the current changes in health care than nonacademic centers are. In fact, they face special challenges.¹⁷⁵ Teaching hospitals are under growing pressure to subsidize education and research from their clinical incomes, even while reimbursement is being increasingly restricted.¹⁷⁶ A 1997 study examining the relation between National Institutes of Health awards and managed care penetration in academic medical centers found the two to be inversely related.¹⁷⁷ Other studies indicated that increased competitiveness within health care markets seemed to hinder the capacity of academic health centers to conduct clinical research and foster the careers of young faculty members.^{178,179} Nevertheless, despite higher costs, teaching hospitals continue to demonstrate better outcomes, even for rather low-technology interventions.^{180,181}

A concern for the future is that academic medical centers may lose the capacity for producing the evidence on which cost-effective practice must be based—circumstances that would be tantamount to eating the proverbial seed corn.¹⁸²

It is curious that despite the frequently expressed concerns about quality, competition over price still appears to be a much more urgent issue than competition over quality is.¹⁸³ It seems logical, however, that at some point, concerns about how much is being paid out will give way to questions about why something is being paid for. Physicians are the only participants in the health care system who have the knowledge and skills needed to address the challenges of identifying cost-effective care. If they can respond constructively to these challenges, rather than simply ignore or dismiss them, they stand a good chance of recapturing much of their lost status and autonomy.

10 HEALTH CARE ECONOMICS: THE LARGER CONTEXT

Charles L. Rice, M.D., F.A.C.S., and Robert S. Rhodes, M.D., F.A.C.S.

In another chapter [see *ECP:9 Elements of Cost-Effective Non-emergency Surgical Care*], we review the principles of cost-effective surgical care and discuss the implications of such principles for health care spending. Our primary focus there is on the interaction between an individual surgeon and an individual patient. In this chapter, we explore some of the issues surrounding health care spending on a larger (i.e., national) scale. Although the data presented come from the United States, many of the challenges identified are faced by other industrialized nations as well. We believe that it is important for surgeons to have a broad understanding of these issues, in particular because such concerns are increasingly becoming the subject of political debate.

United States Health Care Expenditures

SPENDING LEVELS

In 2002, U.S. National Health Expenditures (NHE) amounted to \$1.6 trillion (approximately 14.9% of the gross domestic product [GDP]).¹ According to data from the World Bank (<http://www.worldbank.org/data/databytopic/GDP.pdf>), if the current level of U.S. health care spending were viewed as a separate economy, it would be the fourth largest economy in the world, surpassing the GDP of the United Kingdom. This level of spending translates into a per capita expenditure of \$5,440, which surpasses the per capita expenditure for the next highest-spending country, Switzerland, by almost 30%.

Between 2000 and 2002, the average annual growth rate for per capita health care spending was 7.1%, a rate that, if sustained, would result in a figure of \$3.1 trillion (17.7% of the GDP) for total NHE by 2012 [see *Table 1*]. This high growth rate is the cur-

rent reflection of a long-term trend in which health care costs in the United States have risen continuously since 1966 (the year in which Medicare and Medicaid were implemented) [see *Figure 1*].

Economists differ on whether such spending represents a risk to the overall economic well-being of the United States. Those who are concerned about both the amount that is spent on health care and the rate at which this amount is growing cite the following concerns:

1. In spending more on health care, society spends less on other goods and services—a process referred to as displacement. Thus, health care consumes resources that might otherwise have been allocated to services such as education or public safety.
2. The health care market is imperfect; therefore, some health care spending is inevitably wasteful [see *ECP:9 Elements of Cost-Effective Nonemergency Surgical Care*].
3. The health care sector of the economy is so large—not only in terms of the amounts of money involved but also in terms of the number of people employed—that short-term changes in its growth rate (in either direction) necessarily exert substantial and painful economic effects.
4. As costs increase, voluntary participation by employers in the provision of health insurance to employees and retirees comes under increasing pressure, with the result that employers either shift more and more of the costs of insurance to employees or decide to stop providing health insurance altogether.²

A major concern about the considerable swings in the rate of growth is that it creates the appearance of a health care system in constant crisis.³ One need look no further than the news stories in

Table 1 Average Annual Growth from Previous Year:
United States, 2000–2002

Category	2000	2001	2002
	Total (Growth)	Total (Growth)	Total (Growth)
National health expenditures (NHE) (\$ billion)	1,309.4 (6.2%)	1,420.7 (8.5%)	1,553.0 (9.3%)
Hospital care expenditures (\$ billion)	413.2 (4.0%)	444.3 (7.5%)	486.5 (9.5%)
Physician and clinical services expenditures (\$ billion)	290.3 (6.4%)	315.1 (8.6%)	339.5 (7.7%)
Prescription drug expenditures (\$ billion)	121.5 (17.1%)	140.8 (15.9%)	162.4 (15.3%)
Population (million)	280.4 (0.9%)	282.9 (0.9%)	285.5 (0.9%)
Per capita NHE (\$)	4,670 (5.2%)	5,021 (7.5%)	5,440 (8.3%)
Gross national product (GDP) (\$ billion)	9,825 (5.7%)	10,082 (2.6%)	10,446 (3.6%)
NHE as percentage of GDP (%)	13.3	14.1	14.9

Figure 1 Shown is the increase in per capita national health care spending between 1966 and 2001.²

the press in the United States to read of bankrupt hospital systems on one hand and cases of excessive profit-taking on the other.

Those who do not hold this pessimistic view of current health care spending argue that the health care share of GDP has no natural limit and that the only issue is whether the value of health care spending is higher or lower than that of the spending it displaces.⁴ Intrinsic to this argument is the notion that the appropriateness of spending can be judged only by taking the long view. Proponents of this viewpoint assert that it is alarmist to be overly concerned about short-term changes in the rate of growth and maintain that over the long term, the current growth rate is sustainable. According to this school of thought, it is health care spending in the economy as a whole that ought to be the focus, not the fraction of the total cost borne by a specific sector.⁵

Regardless of which perspective is closer to the truth, it is abundantly clear that to date, no approach by either the public or the private sector has significantly reduced—much less reversed—the rate at which health care spending is growing [see Figure 2].⁶

SERVICES PURCHASED

Elsewhere [see ECP:9 *Elements of Cost-Effective Nonemergency Surgical Care*], we discussed the appropriateness (or lack thereof) of a variety of services purchased with health care dollars. We also pointed out that the United States ranks well behind other industrialized countries in a number of well-accepted indicators of a population's health.

However, we need not look beyond the United States for evidence that increased health care expenditures are not invariably associated with demonstrable improvements in health outcomes. Several major studies have shown that patients treated in higher-spending regions of the United States do not have either better health outcomes or greater satisfaction with their care than patients treated in lower-spending regions.⁷ One such study reported that the differences in spending were largely attributable to the higher frequency of physician visits, the tendency to consult specialists more readily, the ordering of more tests, the performance of more minor procedures, and the more extensive use of hospital and intensive care services in the higher-spending regions. The authors could find no evidence that these types of increased utilization resulted in improved survival, better functional status, or enhanced satisfaction with care. These findings

have profound implications for efforts aimed at constraining further growth in health care spending.

In 1996, almost half (44.2%) of total NHE was accounted for by just 15 conditions [see Table 2].⁸ Even a casual glance at this short list of conditions reveals how many of them are potentially avoidable; obvious examples include motor vehicle accidents, chronic obstructive pulmonary disease, and respiratory malignancies. These findings illustrate how public policy decisions (or the lack of them) can result in costs that are attributed to the health care system. Another study found that in 1998, 9.1% of total NHE (\$78.5 billion) was related to obesity and overweight—a percentage comparable to that related to smoking.⁹

It is also noteworthy that a small fraction of the population accounts for the majority of health care spending. An analysis of data from the 1987 National Medical Expenditure Survey and the 1996 Medical Expenditure Panel Survey revealed that for both periods surveyed, 5% of the population accounted for more than half (55%) of total spending and 10% of the population for nearly 70%.¹⁰ One implication of these findings is that any efforts to constrain health care spending that focus on the 90% of the population responsible for only one third of expenditures are unlikely to have a major impact.

Factors Influencing Demand for Health Care

AGING OF POPULATION

Although many believe that the aging of the United States population is a key factor driving the increase in HCE, several studies suggest otherwise. A 1992 study estimated that total NHE in 2030 would be \$16 trillion, reflecting an estimated average growth rate of 8.3% (a rate that proved to be remarkably close to the observed increase over the subsequent decade).¹¹ Only 0.5% of this \$16 trillion could be attributed to the aging of the population. A subsequent report estimated that less than 1 percentage point of the annual growth through the 1990s could be accounted for by aging.¹² Studies involving the Canadian population¹³ and multiple national populations¹⁴ reached similar conclusions.

The implications of these findings for health policy are not entirely clear. It has been argued, however, that if the gradual aging of the United States population over the coming three decades is accompanied by a change in practice patterns from those

Figure 2 Depicted are the percentage changes in per capita private health care spending between 1961 and 2000.⁶

Table 2 The 15 Most Costly Medical Conditions in the United States

Condition	Estimated No. of Patients (Million)	National Cost (\$ Billion)
Ischemic heart disease	3.4	21.5
Motor vehicle accident	7.3	21.2
Acute respiratory infection	44.5	17.9
Arthropathy	16.8	15.9
Hypertension	26.0	14.8
Back problem	13.2	12.2
Mood disorder	9.0	10.2
Diabetes	9.2	10.1
Cerebrovascular disease	2.0	8.3
Cardiac dysrhythmias	2.9	7.2
Peripheral vascular disease	3.4	6.8
COPD	12.4	6.4
Asthma	8.6	5.7
Congestive heart failure	1.1	5.2
Respiratory malignancy	0.3	5.0

COPD—chronic obstructive pulmonary disease

employed in higher-cost regions to those employed in lower-cost regions, the United States health care system should be able to accommodate the retiring baby-boom generation with minimal disruption.¹⁵

PRESCRIPTION DRUGS

The cost of prescription drugs is increasing much faster than the cost of any other major component of health care spending [see Figure 3]. It is noteworthy that spending on prescription drugs has risen sharply since the introduction of direct-to-consumer (DTC) marketing. Drug companies spend approximately \$20 billion per year on advertising and promotion—roughly the same amount that they spend on research and development.¹⁶ Few physicians have escaped the pressure brought to bear by patients who have heard the promise of a better life in advertisements, and few have been able to resist the ensuing demand for prescriptions. How this category of spending will be affected by the Medicare prescription drug provision enacted in 2003 remains to be seen, but this provision is not generally expected to slow the rate of growth. On the basis of projections developed before the enactment of this law, prescription drug expenditures were expected to account for one seventh of total health care expenditures by 2012.¹⁷

HOSPITAL SERVICES

Spending on hospital services accounts for nearly a third (31.3%) of all NHE. Since 2001, growth in spending on hospital services has slowed somewhat, though it continues to outpace inflation and growth in GDP.¹⁸ The current growth in hospital inpatient

spending is a reversal of a trend seen in the mid-1990s, in which such spending actually declined. Hospital prices increased by 5.1% in 2002, a rise fueled in part by the increased payment rates hospitals have negotiated with health plans and in part by increased demand for services.

Projecting future spending on hospital services is difficult. Some authorities assert that because of declining disability rates, the rate at which spending grows will fall over the next several years.¹⁹ Others argue that the factors responsible for the recent and current increases in spending growth are more likely to continue than to lessen. Advances in technology are a major factor, but so too is the current capacity constraint.²⁰

A factor that is likely to play an increasingly important role in the higher cost of hospital services is the growing cost of labor. From 2001 to 2002, hospital payrolls rose by nearly 8%, a much greater increase than was seen in other industries. This pronounced rise is probably attributable to the well-publicized shortage of nursing and other skilled personnel, which is predicted to persist for a considerable period despite rising wages. Several factors have been implicated in the reluctance of high-school graduates to pursue careers in health care, including (1) the perception that health care is a low-tech industry, (2) the hierarchical nature of health care, and (3) the regular hours required by health care professions.

TECHNOLOGY

In virtually every sector of the economy, the introduction of new technology tends to reduce the cost of a particular service or good. Health care is one of the few exceptions to this general rule. A 2003 analysis of the relationship between the availability of advanced technologies and health care spending found that for certain technologies (e.g., diagnostic imaging, cardiac catheterization facilities, and intensive care facilities), increased availability was often accompanied by increased usage (and,

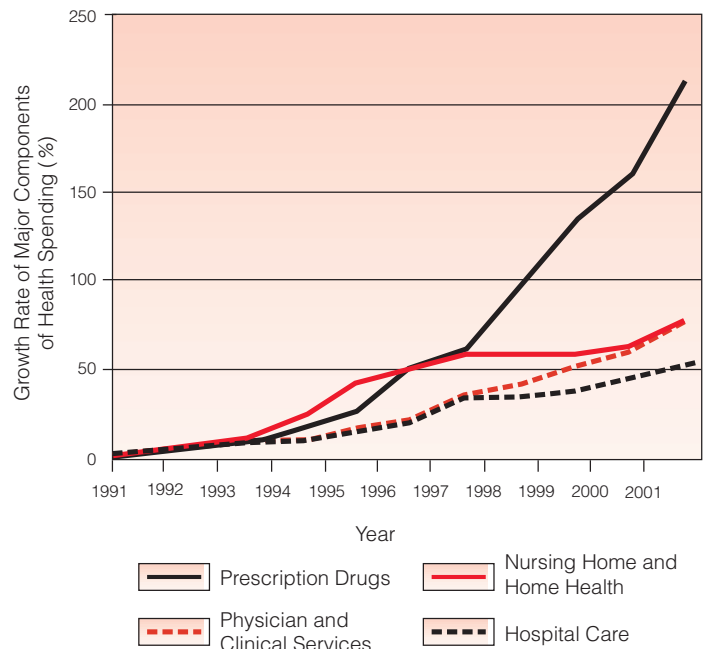

Figure 3 Shown are the growth rates for major components of health care spending between 1991 and 2001. Data from the Centers for Medicare and Medicaid Services (www.cms.hhs.gov/statistics/nhe/historical).

hence, increased spending).²¹ Although this relationship is not uniform across all technologies, the data reinforce the increasing evidence that technological change is the key driver of increased health spending.

From a policy perspective, it might be tempting to conclude that one way of constraining the growth of health care spending would be to restrain the introduction or dissemination of new technologies. For political reasons, however, such a step might prove difficult, if not impossible, to implement. In a survey contrasting the interest in new medical technologies demonstrated by Americans with that demonstrated by Europeans, Americans were found to be more interested in such technologies and to have higher expectations regarding medicine's capacity for managing illness or disability.²² To curb Americans' appetite for new technologies would require a considerable change in public opinion and perception of the value of such technologies, extensive education of the public regarding realistic expectations, or a willingness on the part of United States political leaders to impose such a restraint in the face of public opposition. The last scenario is difficult to imagine, given current campaign financing.

FAILURE OF MARKET FORCES

Some economists—and a considerable number of politicians—believe that unleashing market forces will suffice to constrain the cost of health care. It appears, however, that health care does not behave like other sectors of the economy, for a number of reasons. For one thing, it is difficult for health care consumers to become fully informed. For another, health services have the characteristics of public goods. In addition, health insurance leads to the so-called moral-hazard effect. This term moral hazard warrants a brief discussion here. It originated with the purchase of fire insurance in the 19th century, when it was recognized that the owner of a property that was insured might have an incentive to incur a loss either by deliberately setting a fire (a moral hazard) or by not taking steps to reduce the likelihood of fire. The implication of the moral hazard effect for health care spending is that those who are insured (or more generously insured) will tend to use more health services. (There is an obvious contrast with automobile insurance: no one would argue that insured drivers are more likely to deliberately wreck their cars.) In the health care setting, such behavior is logical in economic terms because for fully insured persons, the cost of additional health services is borne by all those who pay insurance premiums. As a consequence, there may be substantial demand for services that are of only minimal benefit. Because minimally beneficial services may cost as much as any other service, the overall benefit derived may be vastly overshadowed by the cost.

A complete exposition of this important topic is beyond the scope of this chapter. Further discussion may be found in two excellent texts on health economics.^{23,24}

Inefficiencies in Health Care

INEFFECTIVE OR INAPPROPRIATE CARE

In another chapter [see *ECP-9 Elements of Cost-Effective Non-emergency Surgical Care*], we explored a number of considerations related to either the delivery of services of limited or nonexistent value or the failure to employ services of demonstrated benefit. The actual cost incurred by these factors is difficult to estimate but is certainly large. In a study that compared utilization of medical resources by Medicare beneficiaries in various regions of the United States, per capita spending in 1996 was \$3,341 in the

Minneapolis area but more than twice that amount (\$8,414) in the Miami area.²⁵ Despite the sizable difference in expenditures, the authors found no differences in outcomes on a risk-adjusted basis. A strong case can be made that if no differences in quality, access, or satisfaction can be demonstrated, much of the difference in spending may be unnecessary, inappropriate, or ineffective.

It is unclear precisely what proportion of total health care expenditures represents costs that are greater than the benefits that result. Some authors argue the figure is at least one third,²⁶ but others doubt whether it is that high.²⁷ No one, however, maintains that this figure is zero. Unfortunately, no system has yet been devised that will eliminate such unproductive spending.

COST OF REGULATION AND ADMINISTRATION

The United States health care system is notable for its bewildering array of insurers and contracts. Virtually every physician in the United States has had to expend considerable time and effort on dealing with complicated, arcane, and apparently deliberately confusing rules and practices. As a reaction to this state of affairs, some critics of the system in the United States have asserted that the adoption of a simplified Canadian-style single-payor health insurance system would yield large savings in administrative costs that could then be used to expand coverage to those who are currently uninsured.

A 2003 study compared administrative health care costs in the United States with those in Canada. In 1999, per capita health administration costs amounted to \$1,059 in the United States (for a total cost of \$294 billion), contrasted with \$307 in Canada [see *Table 3*].²⁸ The authors arrived at these figures by analyzing data from governments, hospitals, insurance companies, and physicians. They argued that much of the difference between the two countries was accounted for by the multiple sources of health coverage in the United States, as opposed to the single source in the Canadian system.

In an editorial accompanying this report,²⁹ Aaron raised three questions²⁹: (1) Are the differences reported accurate? (2) Would the difference in administrative costs cover the costs for additional services under universal coverage? (3) What are the implications for the answers for health policy? Aaron argued that the significance of the differences in administrative spending were exaggerated—first, because of the methodology used to compare purchasing power between the two currencies, and second, because the original analysis assumed that the relative compensations of clinical and administrative employees were the same in the two countries. He further argued that there was no reason to believe that any costs potentially saved by simplifying administration in the United States would be used to extend coverage. Aaron was certainly no defender of the current U.S. system:

I look at the U.S. health care system and see an administrative monstrosity, a truly bizarre mélange of thousands of payers with payment systems that differ for no socially beneficial reason, as well as staggeringly complex public systems with mind-boggling administered prices and other rules expressing distinctions that can only be regarded as weird.

Nevertheless, he concluded, as have most other observers of the United States system, that the administrative structure of any nation's health care system evolves from its political history and institutions and that to be durable, a health care system must reflect prevailing political values.

COSTS OF MEDICAL INJURY

The Institute of Medicine has produced two reports that have received considerable attention in both the scientific and the lay

Table 3 Administrative Costs of Health Care: United States versus Canada

Administrative Cost Category	United States		Canada	
	Total Cost (\$ billion)	Per Capita Cost (\$)	Total Cost (\$ billion)	Per Capita Cost (\$)
Insurance overhead	72	259	1.43	47
Employer costs	15.9	57	0.257	8
Hospital administration	87.6	315	3.1	103
Practitioners	89.9	324	3.3	107
Total	294.3	1,059	9	307

press. The first, *To Err Is Human*,³⁰ concluded that mistakes were frequently made in the health care system and that the consequences of these mistakes were considerable in both human and economic terms. The second, *Crossing the Quality Chasm*,³¹ outlined steps that must be taken to ensure that patients are not injured by the care intended to help them. Although the magnitude of the problem identified in the two reports has been vigorously debated, the existence of the problem is undeniable. A 2003 analysis based on a review of 7.5 million hospital discharge abstracts from nearly 1,000 hospitals in 28 states documented sizable variations in length of stay and expenditure related to medical injury.³² The authors concluded that despite this variability, medical injuries both pose significant risks for patients and result in considerable cost to society. It is difficult to argue with the proposition that systems for minimizing these risks and reducing the associated cost must be developed and implemented.

COST OF MEDICAL MALPRACTICE

Physicians have long argued that the tort system of compensation for alleged medical injuries or adverse outcomes is expensive, punitive, and arbitrary. Furthermore, they assert that the threat of litigation induces them to practice defensive medicine. As a concrete example, a 2002 report from the American Academy of Orthopaedic Surgeons indicated that concerns about liability had caused nearly half of the surgeons surveyed to alter their practice and nearly two thirds to order more diagnostic tests.³³

The sharp rise in premiums for medical malpractice liability insurance over the past several years has led many professional associations to lobby Congress and state legislatures for caps on noneconomic damages, as well as for other changes in the tort liability system. Proponents of such changes point to the loss of access to care in the only level 1 trauma center in Las Vegas in 2002; the difficulty of providing on-call surgical care to emergency rooms in Jacksonville, Florida, and in Mississippi in 2003; and the loss of neurosurgical services in the northern panhandle of West Virginia in 2002. Concerned about continued increases, the reform advocates cite the reduced rates of increase in premiums reported in states that have imposed caps on noneconomic losses (e.g., California, Colorado, and Montana).

Two reports cast doubt on these arguments, however. A study conducted by the General Accounting Office was unable to confirm the existence of any widespread access problems that could be attributed to concerns about malpractice premiums.³⁴ A report from the Congressional Budget Office (CBO) concluded that any savings resulting from a federally imposed cap on damage awards would not have a significant impact on total health care spend-

ing.³⁵ According to the CBO's estimates, malpractice costs amounted to \$24 billion in 2002, or less than 2% of overall national health spending; thus, even a 25% reduction in malpractice costs would lower health care costs by only about 0.4%. Because of the political interests invested in the issue, however, malpractice liability is certain to remain the subject of public discussion for the foreseeable future.

Implications for Surgeons

In a now-classic article describing the consequences of continued population growth, Hardin first articulated the notion of the tragedy of the commons³⁶:

Picture a pasture open to all. It is to be expected that each herdsman will try to keep as many cattle as possible on the commons. Such an arrangement may work reasonably satisfactorily for centuries because tribal wars, poaching, and disease keep the numbers of both man and beast well below the carrying capacity of the land. Finally, however, comes the day of reckoning, that is, the day when the long-desired goal of social stability becomes a reality. At this point, the inherent logic of the commons remorselessly generates tragedy. As a rational being, each herdsman seeks to maximize his gain. [H]e asks, "What is the utility to me of adding one more animal to my herd?"

[T]he rational herdsman concludes that the only sensible course for him to pursue is to add another animal to his herd. And another; and another.... But this is the conclusion reached by each and every rational herdsman sharing a commons. Therein is the tragedy. Each man is locked into a system that compels him to increase his herd without limit—in a world that is limited. Ruin is the destination toward which all men rush, each pursuing his own best interest in a society that believes in the freedom of the commons. Freedom in a commons brings ruin to all.

The comparison with health care may seem far-fetched at first glance, but as practitioners continue to seek to maximize utility for themselves or their patients, the eventual outcome—assuming that the resources available for health care are, like the commons, finite—may well turn out to be as tragic as the one described by Hardin. Surgeons can help avert this fate by helping to develop, and then adhering to, evidence-based approaches such as the one we outline elsewhere [see *ECP:9 Elements of Cost-effective Non-emergency Surgical Care*], thereby minimizing the likelihood that procedures that are of limited value or whose benefit is less than their cost will be performed. The importance of one-on-one education in the context of surgical care must also be emphasized. Such education, by placing patient interests ahead of surgeon interests, truly defines professionalism.

11 BENCHMARKING SURGICAL OUTCOMES

Emily V. A. Finlayson, M.D., M.S., and John D. Birkmeyer, M.D., F.A.C.S.

Currently, there is growing interest in obtaining information about surgical outcomes. Patients and their families are increasingly looking for—and finding—hospital- and surgeon-specific quality data as they try to make informed decisions about where and from whom to receive surgical care.^{1,2} Payers, both private and public, are also seeking information about surgical performance for their value-based purchasing initiatives. For example, the Leapfrog Group (www.leapfroggroup.org), a large coalition of health-care purchasers, is collating data on hospital volume, process, and outcome measures in an effort to steer patients to the centers likely to have the best results [see *ECP:2 Performance Measures in Surgical Practice*]. As part of its Surgical Care Improvement Program (SCIP) and Centers of Excellence projects, the Centers for Medicare and Medicaid Services (CMS) is requiring that hospitals report outcome data for selected procedures, as well as other performance measures.

Surgeons should be just as interested in surgical outcome data as patients and payers are, for several reasons. First, it is essential that surgeons be able to provide patients with accurate, realistic information about the risks and benefits they can expect from specific procedures. Unfortunately, the medical literature is not always reliable for this purpose: it is limited by publication bias [see *ECP:12 Evidence-Based Surgery*], and the findings tend to be skewed by case series from large, nonrepresentative referral centers, which may not reflect outcomes in the “real world.” Second, as patients increasingly turn to the Internet for information, surgeons need to be aware of what data their patients are seeing and prepared to address their questions. Third, and most important, surgeons require information about surgical outcomes to benchmark their own performance against both national norms and the performance of their peers, as well to help guide their own efforts at improvement.

In this chapter, we review various data sources for benchmarking surgical outcomes, including ongoing public reporting programs, public-use administrative databases that can be analyzed for benchmarking purposes, and improvement-oriented clinical outcomes registries, such as the National Surgical Quality Improvement Program (NSQIP) now being promoted by the American College of Surgeons (ACS). In particular, we consider the strengths and weaknesses of these sources and provide representative surgical mortality data from some of them.

Public Reporting Programs

The most readily available sources of surgical outcome data are Internet-based public reporting programs. At present, the only such programs that are based on clinical data are in the field of cardiac surgery. Following the lead of New York State, which first initiated public reporting in 1989, state agencies in New Jersey, Pennsylvania, California, and Massachusetts now administer longitudinal clinical registries and regularly release (on the Internet and elsewhere) information on risk-adjusted mortality for coro-

nary artery bypass grafting (CABG). All of these states release hospital-specific performance data, but only some report surgeon-specific information.

Public reporting programs related to other surgical procedures generally rely on administrative data. A few states use data from their discharge abstract databases to determine and report volume and risk-adjusted mortalities for selected procedures, including major cancer resections. The most widely available providers of data on noncardiac surgical outcomes are proprietary rating firms, which rely primarily on public-use Medicare files. Of these rating firms, the most notable is probably Healthgrades (www.healthgrades.com), which currently allows users to select from 31 different procedures or conditions and to obtain data on hospitals in any specified geographic region. For each procedure, hospitals are given a ranking, ranging from 5 stars (best) to 1 star (worst), on the basis of risk-adjusted mortality and, in some cases, morbidity. Hospital-specific information is provided free of charge, but a small fee is charged for information on specific surgeons.

The clinical outcome data from the state cardiac surgery registries are generally considered robust. The other sources of publicly reported outcome data, however, have several important limitations, some of which pertain to the use of administrative rather than clinical data [see *Public-Use Administrative Databases, below*] and some of which are specific to the vendor. For example, Healthgrades is often criticized on the grounds that its methods of calculating rates and risk adjustment are insufficiently transparent.³ It is also criticized for its reliance on categorical rankings and its failure to provide actual rates (along with numerators and denominators).

Public-Use Administrative Databases

As an alternative to relying on outside analysis, surgeons can obtain administrative data and perform the analysis themselves. Although this approach requires a certain level of data skills, it may be practical for surgeons with sufficient analytic expertise (or else access to analytic support). Public-use administrative databases [see *Table 1*] are increasingly available, remain relatively inexpensive, and no longer require special equipment for data transmission or storage.

Most of the administrative databases that are useful for benchmarking surgical outcomes consist of hospital discharge abstracts, which contain information on patients admitted to acute care hospitals. The information collected includes demographic data (e.g., name, age, sex, race/ethnicity, and place of residence), admission and discharge dates, total charges, expected payment source, admission type (elective, urgent, or emergency), and discharge disposition. In addition, the abstracts may list attending physicians and surgeons, identified by means of Unique Physician Identification Numbers (UPINs). Claims for surgical admissions contain procedure-specific codes from the International Classification of Diseases, Ninth Edition, Clinical Modification (ICD-9-CM). In addition, hospital discharge abstracts contain fields for at least 10

Table 1 Public-Use Administrative Databases and Clinical Registries

Database/Registry	Patients	Participating Hospitals	Strengths	Limitations
Medicare	Medicare recipients ≥ 65 years old undergoing inpatient surgery	All U.S. hospitals treating Medicare patients	Large sample size; population-based	Limited to elderly patients; not specific for some procedure codes; no detailed clinical information for risk adjustment
Nationwide Inpatient Sample (NIS)	Patients undergoing inpatient surgery	20% sample of all U.S. nonfederal hospitals (~ 1,000 hospitals in 37 states)	All ages; large sample size	Limited to inpatient mortality; not specific for some procedure codes; no detailed clinical information for risk adjustment
National Surgical Quality Improvement Program (NSQIP)	Patients undergoing general and vascular surgery	> 100 private sector hospitals	Prospectively acquired clinical data	Costly to participate in; not designed to assess procedure-specific performance
Society of Thoracic Surgeons (STS) National Database	Patients undergoing cardiothoracic surgery	Registry participants accounting for > 70% of all adult cardiothoracic operations performed annually in the U.S.	Prospectively acquired clinical data	Historically rather than externally audited
National Cancer Data Base (NCDB)	Patients undergoing surgery for cancer	~1,400 hospitals nationwide (~ 75% of incident cancer cases in the U.S.)	Prospectively acquired clinical data; detailed cancer-specific data	Not externally audited

diagnosis codes, which are used to record preexisting medical conditions or medical complications of surgery for billing purposes.

There are a number of different administrative databases that surgeons can use for benchmarking surgical outcomes. For example, most states maintain discharge abstract databases that are available for public use (though the accessibility of these databases and other details vary widely from state to state). Moreover, surgeons can conveniently obtain data from the Nationwide Inpatient Sample (NIS) for this purpose at relatively low cost. Developed as part of the Healthcare Cost and Utilization Project (HCUP), a federal-state-industry partnership sponsored by the Agency for Healthcare Research and Quality (www.hcup-us.ahrq.gov), the NIS is an all-payer inpatient care database that collects information from approximately 8 million hospital admissions annually. It includes all patients from a 20% sample of all nonfederal hospitals (approximately 1,000 facilities) from 37 states and is designed to provide nationally representative estimates of health care utilization and outcomes. To this end, hospitals are selected to be as representative as possible with respect to ownership/control, bed size, teaching status, rural/urban location, and geographic region. Finally, surgeons can obtain public-use Medicare data for benchmarking surgical outcomes, just as some proprietary rating firms do. The Medicare inpatient database (i.e., the Medicare Provider Analysis and Review [MEDPAR] file) is the most accessible and widely used source of such data. It contains data on all fee-for-service acute care admissions for Medicare recipients, including most Americans older than 65 years, disabled patients younger than 65 years, and patients with end-stage renal disease.

Primary analysis of administrative databases has a number of advantages for surgeons interested in benchmarking outcomes. In the absence of comparable clinical databases (except for cardiac surgery), administrative databases are currently the only source of population-based outcome data. By accessing these databases directly, surgeons can obtain information on virtually any inpatient procedure of interest to them, not just those procedures currently targeted by proprietary rating firms. Because the sample sizes are so large, surgeons can effectively analyze the outcomes even of infrequently performed procedures.

Nevertheless, reliance on administrative data for benchmarking outcomes also has certain drawbacks. Some of these drawbacks are related to the specific database under consideration. For example, Medicare data apply primarily to elderly patients and thus are not useful for evaluating the outcomes of procedures that are most commonly performed in younger patients. In addition, they miss large numbers of elderly patients in regions of the United States with a high penetration of Medicare-managed care. As another example, all-payer databases, including state-level files and the NIS, provide in-hospital mortality data but not 30-day mortality data, and unlike Medicare databases, they usually do not contain codes identifying hospitals or surgeons. Thus, these databases are useful for generating national or state-level norms for specific procedures, but not for assessing the outcomes achieved by specific providers.

The most important drawbacks of administrative databases, however, are related to problems with the accuracy, completeness, and clinical precision of the data coding.^{4,5} The ICD-9-CM diagnosis codes used to identify comorbidities are often clinically imprecise, do not reflect disease severity, and cannot differentiate preadmission conditions from acute complications. For this reason, risk adjustment and measurement of postoperative complications are possible only to a limited extent when administrative databases are employed. The ICD-9-CM procedure codes, though generally much more reliable than the diagnosis codes, still lack sufficient clinical specificity, particularly in relation to the Current Procedural Terminology (CPT) codes used for physician billing. For example, they often fail to distinguish between laparoscopic and open procedures or between similar procedures that are associated with different baseline risk levels (e.g., laparoscopic antireflux surgery and repair of paraesophageal hernias).

Clinical Registries

Of course, the ideal sources of information for benchmarking surgical outcomes are clinical outcome registries containing prospectively collected data [see Table 1]. As noted [see Public Reporting Programs, *above*], several states administer such registries for cardiac surgery as part of their efforts at quality

improvement and public reporting. In the past few years, however, a number of professional organizations, including the ACS, have launched national outcome registries in other clinical areas. Outcome data from these registries are not reported publicly but are used to provide confidential feedback on performance to hospitals and surgeons for the purposes of internal quality improvement. With one prominent exception (NSQIP), the currently available outcome registries target specific specialties, conditions, or procedures.

NATIONAL SURGICAL QUALITY IMPROVEMENT PROGRAM

Perhaps the most visible and powerful source of benchmarking information is the NSQIP. Originally developed and implemented in Veterans Affairs (VA) hospitals, the NSQIP was later applied in a consortium of large academic medical centers and private sector hospitals and subsequently marketed by the ACS to all types of hospitals. As of 2006, more than 100 non-VA hospitals had enrolled. At participating hospitals, NSQIP data are collected through review of the medical records by dedicated nurse abstractors. Preoperative risk factors, intraoperative variables, and 30-day postoperative mortality and morbidity outcomes for patients undergoing major operations are submitted. Risk-adjusted morbidity and mortality results for each hospital are calculated semi-annually and are reported as observed-to-expected (O/E) ratios.

As private-sector participation grows, the NSQIP is becoming a valuable resource for benchmarking surgical outcomes. Because the clinical data are prospectively collected, robust risk adjustment is possible. In addition, participants can readily access their own outcome data on a user-friendly Web interface. Moreover, they can easily navigate through different procedures and outcomes to obtain a range of information pertaining to their own specialty and can benchmark their own results against those of community centers, academic centers, or both. Nonetheless, the NSQIP currently has several weaknesses that reduce its usefulness in benchmarking surgical outcomes. First, it is expensive to administer. Besides paying an annual fee, each center is required to hire and train a dedicated surgical clinical nurse reviewer to review and enter data. Second, the NSQIP is not designed for assessing procedure-specific performance. Risk adjustment is based on a common set of preoperative variables that apply to all procedures, not on differing sets of risk factors that are specific to individual procedures. Furthermore, the program collects data on a sample of the procedures performed at each hospital, not on all procedures. Thus, the sample sizes are relatively small, and as a result, procedure-specific outcome measures may be imprecise. Third, the NSQIP's global measures of morbidity and mortality may be limited in terms of how well they account for differences in procedure mix across hospitals.

SOCIETY OF THORACIC SURGEONS NATIONAL DATABASE

The Society of Thoracic Surgeons (STS) National Database is the best source of national data for benchmarking the outcomes of cardiac procedures.⁶ This database includes clinical data on more than 70% of all cardiothoracic operations performed in adults each year in the United States. Participating hospitals receive regular feedback on mortality after adult and congenital cardiac and general thoracic surgery. The main strengths of the STS registry are the robust and procedure-specific risk adjustment and the high hospital participation rate (which suggests that the STS outcome data should be highly generalizable). Historically, its major weakness has been the lack of external auditing to ensure that the outcome data submitted by hospitals are accurate and complete.

NATIONAL CANCER DATA BASE

A joint effort of the ACS Commission on Cancer (CoC) and the American Cancer Society, the National Cancer Data Base (NCDB) is a national registry that tracks information related to the treatment and outcome of cancer patients (www.facs.org/dept/cancer/ncdb/index.html). About 1,400 hospitals participate in the NCDB, which currently captures approximately 75% of incident cancer cases in the United States. The participating centers provide data on patient characteristics, tumor stage and grade, type of treatment, disease recurrence, and survival. Health care providers at CoC-approved cancer centers are able to access benchmark reports that summarize the data from the user's own center and compare them with state, regional, or national data, as well as with data from other individual cancer centers. Although the NCDB is undoubtedly the richest source of clinical data for benchmarking the outcomes of cancer surgery, it has certain limitations. As with the STS National Database, the data are not externally audited to ensure accuracy and completeness. Moreover, unlike most clinical outcome registries, the NCDB was not originally designed for tracking outcomes related to quality; it only recently began collecting information on comorbidity (for the purposes of risk adjustment), and it provides no information on outcomes other than mortality.

NATIONAL TRAUMA DATA BANK

The ACS, along with its Committee on Trauma, also oversees the National Trauma Data Bank (NTDB) (www.facs.org/trauma/ntdb.html). At present, approximately 556 hospitals submit data to the NTDB, including 70% of level I trauma centers and 53% of level II centers. Participating hospitals submit extensive information about comorbid conditions, patient status on arrival at the hospital, procedures performed, complications, and mortality. They also have access to the primary data, so that they can perform their own analyses. Although the NTDB captures a large percentage of trauma admissions in the United States, it should be kept in mind that data submission to NTDB is voluntary and that the data are not externally audited.

REGISTRIES FOR BARIATRIC SURGERY

In the past few years, two competing programs for tracking the outcomes of bariatric procedures have been launched: the ACS Bariatric Surgery Center Network (www.facs.org/cqi/bscn) and the Surgical Review Corporation (SRC) (www.surgicalreview.org). The details of these two clinical registries have not yet been released or even fully developed, but it is clear that these programs are intended to support hospital accreditation and "center of excellence" designations in bariatric surgery. In the ACS Bariatric Surgery Network, hospitals that are participating in the NSQIP submit all their data via their Web-based portals and compare their bariatric surgery results with those of other centers, as is done with other procedures included in the NSQIP. Hospitals that are not participating in the NSQIP submit only their bariatric outcome data and receive annual summaries of their outcomes, which are not adjusted for risk or benchmarked against the outcomes of other programs. The SRC, which is closely aligned with the American Society for Bariatric Surgery, is a nonprofit organization that assesses bariatric surgery programs, analyzes outcome data, and formulates practice guidelines. Participating centers must report their outcomes annually in order to maintain their status as SRC-approved centers. In addition to access to their own data, SRC-approved centers have access to benchmark outcome data aggregated from all participating institutions.

Table 2 Operative Mortality for Selected Procedures in Two National Databases

Operation	Database			
	Medicare (2003)		NIS (2003)	
	N	Mortality (%)	N	Mortality (%)
Cardiac procedures				
CABG	79,704	3.8	32,123	2.2
Aortic valve replacement	21,464	5.8	7,221	4.0
Mitral valve replacement	6,844	8.9	2,903	5.9
Vascular procedures				
Lower-extremity bypass	31,861	2.9	10,830	1.3
Elective aortic aneurysm repair	16,481	5.1	5,757	3.6
Carotid endarterectomy	67,895	0.9	21,441	0.4
Cancer procedures				
Pulmonary lobectomy	14,696	3.8	5,298	1.9
Pneumonectomy	1,184	11.7	563	8.7
Esophagectomy	2,760	7.5	1,198	5.0
Gastrectomy	5,929	6.6	2,776	3.5
Pancreaticoduodenectomy	1,424	9.1	629	5.2
Colectomy	56,669	3.5	23,074	1.5
Abdominoperineal resection	3,680	2.8	1,489	1.1
Gastric bypass	5,663	1.0	14,056	0.2

CABG—coronary artery bypass grafting NA—not available

Additional Considerations

Although it is important to understand that the various sources of surgical benchmarking data all have their own distinct strengths and weaknesses, it is also worthwhile to keep in mind that these sources all have certain limitations in common. One such limitation has to do with sample size. Whereas the benchmark data themselves usually are based on large numbers and thus are statistically robust, the outcome data of the hospitals and surgeons assessing their own performance against these benchmarks are not, particularly at the level of individual procedures. When sample sizes are too small, it may be difficult to determine whether complication rates higher than the benchmark rate reflect genuine problems or are simply the result of chance. A 2004 study considered hypothetical hospitals with operative mortalities twice the national average and estimated how many cases these hospitals

would need over a 3-year period to be reasonably confident that their higher mortality figures were real and not just statistical artifacts.⁷ The estimated minimal caseloads varied by procedure, ranging from 77 for esophagectomy to 2,668 for hip replacement. According to the authors' analysis of the NIS, the only procedure for which a majority of U.S. hospitals met these caseload criteria was CABG.

Another limitation has to do with generalizability. In this regard, it is illustrative to consider the overall reported mortalities for several procedures, determined on the basis of data from two different national databases: the Medicare Inpatient File (2003) and the NIS (2003) [see Table 2]. These databases have their own distinct characteristics (e.g., a particular patient population or method of defining mortality), and the different datasets yield different mortality estimates. For example, the predominantly elderly Medicare population had the highest mortalities across all procedures, ranging from 0.9% for carotid endarterectomy to 11.7% for pneumonectomy. In the NIS population, operative mortalities were considerably (sometimes more than 3%) lower for all procedures than in the Medicare population (e.g., 5.2% versus 9.1% for pancreaticoduodenectomy and 3.5% versus 6.6% for gastrectomy). Although neither the Medicare estimates nor the NIS estimates are wrong, they should not be considered universally applicable. Surgeons must recognize that risk estimates derived from any given database are dependent on the distinct composition of that database and therefore may not be generalizable to their own practice.

Our primary focus in this chapter has been on sources of information about morbidity and mortality; however, there are other measures related to surgical quality that surgeons may also be interested in benchmarking. For example, information about hospital volumes can be obtained from Healthgrades, the Leapfrog Group, and a growing number of state agencies. As another example, information pertaining to selected processes of care (e.g., processes related to preventing surgical site infection, venous thromboembolism, cardiac events, and ventilator-acquired pneumonia after operation) is now being collected by CMS as part of SCIP; although this information is not currently available, there are plans for eventual public reporting. Finally, information about patient satisfaction can be obtained from several private vendors. A large number of hospitals participate in a survey measurement program administered by Press-Ganey, a health care satisfaction survey business that has created national databases of comparative satisfaction information. In addition, both HCIA Inc. (formerly called Health Care Investment Analysts) and the Medical Group Management Association offer patient satisfaction comparison services.

12 EVIDENCE-BASED SURGERY

Samuel R. G. Finlayson, M.D., M.P.H., F.A.C.S.

Evidence-based surgery may be defined as the consistent and judicious use of the best available scientific evidence in making decisions about the care of surgical patients. It is not an isolated phenomenon; rather, it is one part of a broad movement—evidence-based medicine—whose aim is to apply the scientific method to all of medical practice. The historical roots of this broad movement lie in the pioneering work of the Scottish epidemiologist Archibald Cochrane (1909–1988), for whom the preeminent international organization for research in evidence-based medicine (the Cochrane Collaboration) is named. The term evidence-based medicine itself was popularized by a landmark article that appeared in the *Journal of the American Medical Association* in 1992.¹ This article advocated a new approach to medical education, urging physicians and educators to deemphasize “intuition, unsystematic clinical experience, and pathophysiological rationale as sufficient grounds for clinical decision making.” In essence, advocates of evidence-based medicine seek to demote so-called expert opinion from its previous relatively high standing, regarding it as being, in fact, the least valid basis for making clinical decisions. As a consequence of the growth of this movement, the discipline of surgery, once driven more by the eminence of tradition than by the evidence of science, now increasingly requires its students to adopt evidence-based scientific standards of practice.

The imperative that surgical care be delivered in accordance with the best available scientific evidence is only one facet of evidence-based surgery. Other facets include systematic efforts to establish standards of care supported by science and the movement to popularize evidence-based practice. Systematic reviews of the literature are often generated by independent researchers or collaborative study groups (e.g., Cochrane collaborations) and published as review articles in journals or disseminated as practice guidelines. The movement to popularize evidence-based surgical practice is a relatively recent phenomenon that is exemplified by the activities of the Surgical Care Improvement Project (SCIP) (http://www.medqic.org/scip/scip_homepage.html). Although researchers are charged with generating and disseminating scientific evidence, the greatest responsibility for the success of evidence-based surgery ultimately lies with individual surgeons, who must not only practice evidence-based surgery but also understand and appropriately interpret an immense surgical literature.

In this chapter, I provide a framework for evaluating the strength of evidence for surgical practices, examining the validity of scientific studies in surgery, and assessing the role of evidence-based surgery in measuring and improving the quality of surgical care. These are the basic conceptual and analytic tools that a modern evidence-based surgeon needs to navigate the surgical literature and implement practices that are based on sound science.

Evaluation of Strength of Evidence for Surgical Practices

GUIDELINES AND SECONDARY SOURCES OF SCIENTIFIC EVIDENCE

To meet the growing demand for evidence-based practice information, a market has developed around the process of pooling and

interpreting the best scientific evidence. Scientific reviews serve as secondary sources for evidence-based practice and are increasingly found in journals, in books, and on the Internet. Prominent examples include *Clinical Evidence* (published semiannually by the *British Journal of Medicine* and continually updated online [<http://www.clinicalevidence.com>]) and the Cochrane Database of Systematic Reviews (<http://www.cochrane.org>). SCIP serves as a clearinghouse for evidence-based guidelines that specifically address surgical practices.

These efforts to summarize and disseminate information about evidence-based surgery provide a convenient means of access to the surgical literature that can be very helpful to practicing surgeons. Such aids, however, are far from complete, and new evidence emerges continually. Accordingly, modern evidence-based surgeons cannot afford to rely entirely on these sources: they must also learn to assess the quality of individual scientific studies for themselves, as well as to interpret the implications of these studies for their own practices.

LEVELS OF EVIDENCE

Evidence for surgical practices comes in many forms, with varying degrees of reliability. At one end of the spectrum is an empirical impression that a practice makes physiologic sense and seems to work well; much of what surgeons actually do falls into this category and has not been formally tested. At the other end of the spectrum is evidence accumulated from multiple carefully conducted scientific experiments that yield consistent and reproducible results. The ultimate task of the evidence-based surgeon is to select practices that conform to the best evidence available; to that end, it is essential to be able to judge the reliability of scientific evidence.

In an effort to help clinicians judge the strength of scientific evidence, researchers have attempted to create hierarchies of evidence, in which the highest places are occupied by those sources that are most reliable and the lowest places by those that are least sure. With the understanding that not all practices have been subjected to the highest levels of scientific scrutiny, clinicians are advised to base practices on evidence gleaned from studies as high on the evidence hierarchy as possible.

An oft-cited example of such an evidence hierarchy is the levels-of-evidence system popularized by the United States Preventive Medicine Task Force (USPMTF) [*see Table 1*].² Since the inception of this system, the terms and concepts it employs have become common parlance among clinicians—hence, for example, the frequently heard references to level 1 evidence (i.e., evidence from well-conducted, randomized, controlled trials). However, almost as soon as the USPMTF levels-of-evidence system was released, debate about its adequacy began.³ The predominant criticism has been that the system is too simple and inflexible to provide a precise description of the strength of evidence for clinical practices. Although the system identifies the design of the study from which the evidence is drawn, it does not consider certain other important factors that influence the quality of the study. For example, in the USPMTF system, the same grade is awarded to a

randomized, double-blind, placebo-controlled trial with 50,000 subjects as to a randomized, unblinded trial with 30 subjects. Furthermore, a higher grade is awarded to the latter trial than to a well-designed, well-conducted, multi-institution, prospective cohort study with 10,000 subjects.

In response to the deficiencies of the USPMTF system, numerous alternative grading systems have been developed that take into account factors other than study design, such as quality, consistency, and completeness. Nevertheless, it is widely recognized that no grading system yet developed is perfect.⁴ Consequently, surgeons are often required to judge the quality and applicability of scientific evidence for themselves.

APPRAISING SCIENTIFIC EVIDENCE

Specific study designs are associated with different levels of confidence about cause and effect. The clinical study design that is considered to have the greatest potential for determining causation is the randomized, controlled clinical trial. However, even studies with this design can lead to erroneous conclusions if they are not performed properly. Therefore, in evaluating the quality of clinical evidence, it is not sufficient simply to ascertain the design of the study that produced the evidence: one must also take a close look at how the study was conceived, implemented, analyzed, and interpreted.

Scientific evidence from studies of clinical practice relies on two important inferences. The first inference is that the observed outcome is the result of the practice and cannot be attributed to some alternative explanation. When this inference is deemed to be true, the study is considered to have internal validity. The second inference is that what was observed in the clinical study is relevant to scenarios outside the study in which the surgeon seeks to implement the practice. The extent to which this inference is true is referred to as external validity or generalizability. Whereas internal validity is determined by how well the study is conducted and how accurately the results are analyzed, external validity is determined by how well the study plan reflects the real-world clinical question that inspired it and how well the study's conclusions apply to real-world scenarios outside the study [see Figure 1]. External validity can also refer to the difference between an intervention's efficacy (how well it works when applied perfectly) and its effectiveness (how well it works when applied generally in an uncontrolled environment); when this difference is substantial, the study's external validity is poor.

Assessment of Validity of Scientific Studies in Surgery

INTERNAL VALIDITY: EVALUATING STUDY QUALITY

Assessment of the internal validity of a study requires an understanding of the potential influence of three key factors: chance, bias, and confounding. Chance refers to unpredictable randomness of events that might mislead researchers. Bias refers to systematic errors in how study subjects are selected or assessed. Confounding refers to differences in the comparison groups (other than the intended difference that is the subject of the comparison) that lead to differences in outcomes.

Chance

In clinical studies that compare outcomes between two or more groups, the assumption that there is no difference in outcomes is called the null hypothesis. Erroneous conclusions with regard to the null hypothesis can sometimes occur by chance alone. There

Table 1 Levels of Evidence According to USPMTF Schema

Level of Evidence	Source of Evidence
I	At least one properly randomized, controlled trial
II-1	Well-designed controlled trials without randomization
II-2	Well-designed cohort or case-control analytic study, preferably from more than one center or research group
II-3	Multiple time-series with or without intervention or, possibly, dramatic results from uncontrolled trials (e.g., penicillin treatment in 1940s)
III	Opinions from respected authorities based on clinical experience, descriptive studies, and case reports or opinions from committees of experts
Category of Recommendation	Basis of Recommendation
Level A	Good and consistent scientific evidence
Level B	Limited or inconsistent scientific evidence
Level C	Consensus, expert opinion, or both

USPMTF—United States Preventive Medicine Task Force

are two types of chance-related errors: type I and type II. Type I error (also called α error) occurs when researchers erroneously reject the null hypothesis—that is, they infer that there is a difference in outcomes when no difference really exists. Type II error (also called β error) occurs when researchers erroneously confirm the null hypothesis—that is, they infer that there is no difference in outcomes when a difference really does exist.

Type I errors Statistical testing is used to quantify the likelihood of a type I error. A variable commonly employed for this purpose is the *P* value, which is a measure of the probability that observed differences between groups might be attributable to chance alone. The threshold for statistical significance is conventionally set at a *P* value of 0.05, which signifies that the likelihood that the observed differences would occur by chance alone is 5%. Although a *P* value of 0.05 falls short of absolute certainty, it is generally accepted as sufficient for scientific proof.

An alternative expression of statistical likelihood is the confidence interval, which is a measure of the probability that the observed difference would occur if the same study were repeated an infinite number of times. For example, a confidence interval of 95% indicates that the observed difference would be present in 95% of the repetitions of the study.

There are many statistical tests that can be used to calculate *P* values and confidence intervals. Which statistical test is most appropriate for a particular situation depends on several factors, including the number of observations in the comparison groups, the number of groups being compared, whether two or more groups are being compared to each other or one group is being compared to itself after some time interval, what kind of numerical data are being analyzed (e.g., continuous or categorical), and whether risk adjustment is required. It is likely that only a minority of surgeons will have a firm grasp of all the nuances of the more complex statistical analyses. Fortunately, however, most clinical surgical studies are designed simply enough to employ statistical tests that are within the reach of the nonstatistician.

Type II errors Type II errors often occur when the sample size is simply too small to permit detection of small but clinically

important differences in outcomes between comparison groups. When a study's sample size is insufficient for identification of outcome differences, the study is said to lack sufficient statistical power. Once a study is complete, no amount of analysis can correct for insufficient statistical power. Therefore, before starting a study, researchers should perform what is known as a power calculation, which involves determining the minimum size a difference must have to be meaningful, then calculating the minimum number of observations that would be required to demonstrate such a difference statistically. Surgeons should be particularly cautious when evaluating studies with null findings, particularly when no power calculation is explicitly reported. It is wise to remember that, as the adage has it, no evidence of effect is not necessarily evidence of no effect.

Bias

The term bias refers to a systematic problem with a clinical study that results in an incorrect estimate of the differences in outcomes between comparison groups. There are two general types of bias: selection bias and information bias. The former results from errors in how study subjects are chosen, whereas the latter results from errors in how information about exposures or outcomes (or other pertinent information) is obtained.

Selection bias The term selection bias applies to any imperfection in the selection process that results in a study population containing either the wrong types of subjects (i.e., persons who are not typical of the target population) or subjects who, for some reason unrelated to the intervention being evaluated, are more likely to have the outcome of interest. As an example, paid volunteer subjects may be more motivated to comply with treatment regimens and report favorable results than unpaid subjects are, and this difference may result in overestimation of the effect of an intervention. Such overestimation may involve both the internal validity and the external validity of the study. As another example,

in a trial of medical versus surgical treatment of gastroesophageal reflux disease, selecting study subjects from a group of diners at a Szechuan Chinese restaurant might lead to results favoring medical treatment (in that consumers of Szechuan Chinese food may be more likely to have well-controlled reflux). When assessing the validity of scientific evidence, surgeons must carefully consider the characteristics of the subjects selected for study.

Information bias The term information bias applies to any problem caused by the way in which outcome data or other pertinent data are obtained. As an example, in a study of sexual function after surgical treatment of rectal cancer, subjects may report symptoms differently in an in-person interview from how they would report them in an anonymous mailed survey. As another example, in a study of hernia repair outcomes, rates of chronic postoperative pain might be incorrectly reported if surgeons assess outcomes in their own patients. Also, recall bias (i.e., selective memory of past events) is a type of information bias to which retrospective clinical studies are particularly vulnerable.

Information bias is often more subtle than selection bias; accordingly, particular attention to the reported study methods is required to control this problem. Measures employed to control information bias include blinding and prospective study design.

Confounding

The term confounding refers to differences in outcomes that occur because of differences in the respective baseline risks of the comparison groups. Confounding is often the result of selection bias. For example, a comparison of mortality after open colectomy with that after laparoscopic colectomy might be skewed because of the greater likelihood that open colectomy will be performed on an emergency basis in a critically ill patient. In other words, severity of illness might confound the observed association between mortality and surgical approach.

Confounding can be effectively addressed by means of randomization. When subjects are randomized, potentially confounding variables (both recognized and unrecognized) are likely to be evenly distributed across comparison groups. Thus, even if these variables influence the baseline rates of certain outcomes in the cohort as a whole, they are unlikely to have a significant effect on differences observed across comparison groups. When randomization is not practical, confounding can be minimized by tightly controlling the study entry criteria. For instance, in the aforementioned comparison of open and laparoscopic colectomy (see above), one might opt to include only elective colectomies. It should be kept in mind, however, that restrictive entry criteria can sometimes limit generalizability. Another way to combat confounding is to use statistical risk-adjustment techniques; the downside to these is that they can reduce statistical power.

EXTERNAL VALIDITY: INTERPRETING AND APPLYING EVIDENCE TO PRACTICE

Once one is convinced that a clinical study is internally valid (i.e., that the observed outcome is the result of the exposure or intervention and cannot be attributed to some alternative explanation), the challenge is to assess the study's external validity (i.e., to determine whether the findings are applicable to a particular clinical scenario). To make an assessment of the external validity of a clinical study, it is necessary to examine several components of the study, including the patient population, the intervention, and the outcome measure. This process can be illustrated by briefly considering the example of a large, prospective, randomized clinical

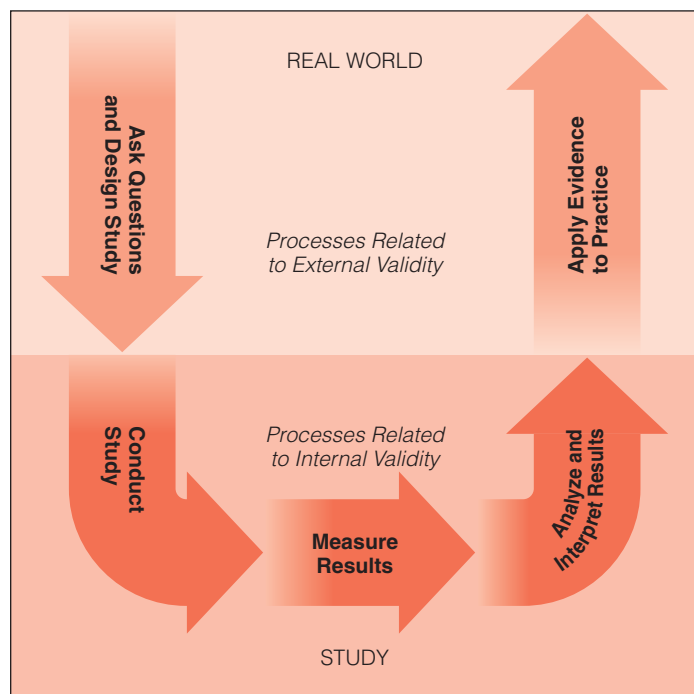

Figure 1 Schematically depicted are processes that affect the internal and external validity of a clinical study.

trial of laparoscopic versus open inguinal hernia repair performed in Veterans' Affairs (VA) medical centers.⁵

The VA trial concluded that the outcomes of open hernia repair were superior to those of laparoscopic repair. The trial was well designed and well conducted, but it generated substantial discussion about the generalizability of the results. As noted [*see Internal Validity: Evaluating Study Quality, Bias, above*], subject selection bias can adversely affect the external validity (generalizability) of a study's results: if the study population is in some important respect different from a particular population for which a surgeon is making clinical decisions, the results may not be entirely generalizable to the latter population. In the VA hernia trial, the subjects were military veterans, who tend to be, on average, older than the non-veteran general population. If older persons are more vulnerable to the risks of laparoscopic hernia repair (e.g., complications associated with general anesthesia), one might expect that any differences between open and laparoscopic herniorrhaphy with respect to morbidity outcomes would be exaggerated in a trial that included a higher number of older subjects, as the VA trial did. Accordingly, a surgeon attempting to assess the external validity of the VA trial might consider the evidence provided by the trial to be applicable to older patients but might reserve his or her judgment on the use of laparoscopy to repair hernias in younger, healthier patients.

A striking example of the potential effect of selection bias on generalizability comes from the Asymptomatic Carotid Artery Stenosis (ACAS) trial.⁶ In this large, prospective, randomized study, volunteers for the trial were substantially younger and healthier than the average patient who undergoes carotid endarterectomy. As a result, the observed perioperative mortality in the ACAS trial was considerably lower than that observed in the general population—and, for that matter, lower even than the overall perioperative mortality in the very hospitals where the trial was conducted.⁷ Although the results of the ACAS trial significantly changed practice, an argument could be made that the evidence provided by this trial, strictly speaking, was generalizable only to younger populations.

The external validity of a clinical study can also be affected by who provides the intervention. For example, in the VA hernia trial, surgeons had varying degrees of experience with the laparoscopic approach, and there were twofold differences in hernia recurrence rates between surgeons who had done more than 250 cases and surgeons who had less experience. Surgeons considering whether the evidence supports the use of laparoscopic repair will therefore have to examine their own experience with this approach before they can determine to what extent the results of the VA trial are generalizable to their own practices.

Furthermore, external validity can be influenced by what type of intervention is provided. For example, some have argued that one of the laparoscopic techniques commonly used in the VA trial, transabdominal preperitoneal repair (TAPP), is outmoded and more hazardous than the competing approach, totally extraperitoneal

repair (TEP).⁸ Surgeons who avoid using TAPP might reasonably question the generalizability of the VA study to their practices.

Finally, the type of outcome measured can affect the generalizability of clinical studies. The outcomes chosen for clinical studies may be those that are most convenient or most easily quantified rather than those that are of greatest interest to patients. In the VA hernia trial, several outcomes were studied, including operative complications, hernia recurrence, pain, and length of convalescence. Some of the outcome differences favored open repair, whereas others favored laparoscopic repair. To interpret the evidence as favoring one type of repair or the other involves making implicit value judgments regarding which outcomes are most important to patients. Surgeons interested in applying the evidence from the VA hernia trial to their own decisions about hernia repair will have to examine the specific outcomes measured before they can determine to what extent this study is generalizable to specific patients with specific values and interests.

Role of Evidence-Based Surgery in Measuring and Improving Quality of Care

In clinical studies, the efficacy of a surgical practice is measured in terms of the resulting patient outcomes. Until relatively recently, efforts to assess the quality of surgical care have focused almost exclusively on clinical outcomes. In the past few years, however, the evidence-based surgery movement has begun to promote an alternative measure of surgical quality—namely, adherence to processes of care supported by the best available scientific evidence.

The question of whether efforts to assess quality should focus on evidence-based processes of care or clinical outcomes is as much practical as philosophical. The practical argument against outcome measures is largely driven by a growing recognition that when hospitals and surgeons are considered on an individual basis, adverse outcomes generally are not numerous enough to allow identification of meaningful differences between providers.⁹ In other words, outcome-based studies of the quality of care supplied by individual providers tend to have insufficient statistical power. The practical argument against evidence-based process-of-care measures is driven by the paucity of high-leverage, procedure-specific processes for which sound evidence is available, as well as by the logistical challenge of measuring such processes. The issues surrounding assessment of quality of care are discussed in greater detail elsewhere [*see ECP:2 Performance Measures in Surgical Practice*].

Given its current momentum, the evidence-based surgery movement is likely to play a progressively larger role in efforts to assess and improve quality of surgical care. Furthermore, as payers increasingly turn to pay-for-performance strategies to improve quality and control costs, the demand for evidence-based practice guidelines is likely to grow. Ultimately, it is certain that identification and implementation of evidence-based surgical practices will provide patients with safer, better care.

De Maria, M.D., F.A.C.S., and Lena M. Napolitano, M.D., F.A.C.S., for the American College of Surgeons Committee on Perioperative Care

Today's operating room is a complex environment wherein a variety of health care providers are engaged in the sacred ritual of surgery, controlling and modifying nature's complicated orchestra of disease entities. In what follows, we discuss certain key aspects of the OR environment—design, safety, efficiency, patient factors, and the multidisciplinary team—with the aim of improving surgeons' understanding and comprehension of this complex world. In particular, we focus on emerging technologies and the special OR requirements of the burgeoning fields of endovascular surgery and minimally invasive surgery.

General Principles of OR Design and Construction

PHYSICAL LAYOUT

The basic physical design and layout of the OR have not changed substantially over the past century. In the past few years, however, major changes have occurred in response to continuing technological developments in the areas of minimally invasive surgery, intraoperative imaging, invasive nonsurgical procedures (e.g., endoscopic, endovascular, and image-guided procedures), patient monitoring, and telemedicine.

The exact specifications for new construction and major remodeling of ORs in the United States depend, first and foremost, on state and local regulations, which often incorporate standards published by the Department of Health and Human Services.¹ The American Institute of Architects publishes a comprehensive set of guidelines for health care facility design that includes a detailed discussion of OR design.² The design of new ORs must also take into account recommendations generated by specialty associations and regulatory agencies.³⁻⁶ Finally, there are numerous articles and books that can be consulted regarding various aspects of OR design.⁷⁻¹¹

The architectural design process for modern ORs should include knowledgeable and committed representatives from hospital clinical services, support services, and administration. Important design considerations include the mix of inpatient and outpatient operations, patient flow into and out of the OR area, the transportation of supplies and waste materials to and from the OR, and flexibility to allow the incorporation of new technologies. This planning phase benefits greatly from the use of architectural drawings, flow diagrams, computer simulations, and physical mockups of the OR environment.

For an operation to be successful, multiple complex tasks must be carried out, both serially and in parallel, while care is exercised to ensure the safety of both the patient and OR personnel. To this end, it is vital that the OR be designed so as to permit patients, OR personnel, and equipment to move and be moved as necessary without being unduly hindered by overcrowding or by obstruction from cables, wires, tubes, or ceiling-mounted devices. Before and

during the operation, critical devices must be positioned so that they can readily be brought into use for monitoring and life support. The supplies and instruments likely to be needed must be easily available. Effective communication must be in place among the members of the OR team, the OR front desk, and the rest of the hospital. Built-in computer, phone, imaging, and video systems can enhance efficiency and safety by facilitating access to clinical information and decision-making support. Finally, the design of the OR must facilitate cleaning and disinfection of the room as well as permit efficient turnover of needed equipment and supplies for the next procedure.

A modern OR must include adequate storage space for immediately needed supplies. Equally important, it must include adequate storage space for the multitude of equipment and devices required in current surgical practice. All too often, storage space is inadequate, with the result that equipment and supplies must be stored in hallways and in the ORs themselves, thereby creating obstructions and hazards for personnel and patients.

The basic design of today's OR consists of a quadrangular room with minimum dimensions of 20 × 20 ft. More often, the dimensions are closer to 30 × 30 ft to accommodate more specialized cardiac, neurosurgical, minimally invasive, or orthopedic procedures. Smaller rooms, however, are generally adequate for minor surgery and for procedures such as cystoscopy and eye surgery. Ceiling height should be at least 10 ft to allow mounting of operating lights, microscopes, and other equipment on the ceiling. An additional 1 to 2 ft of ceiling height may be needed if x-ray equipment is to be permanently mounted.

VOICE, VIDEO, AND DATA COMMUNICATION

The operating suite should be wired to provide two-way voice, video, and data communication between the OR and the rest of the health care facility. Teleconnection of the OR to other areas of the hospital (e.g., the pathology department, the radiology department, the emergency department, conference rooms, surgeons' offices, and wet/dry laboratories) can greatly enhance both patient care and teaching by improving the exchange of crucial information while keeping noncritical traffic out of the OR environment. Two-way audio and video teleconferencing can improve surgical management by facilitating proctoring of less experienced practitioners, real-time consultation with experienced specialists or the scientific literature, and immediate viewing of x-ray images, specimens, and histologic findings. Archiving of visual data also permits efficient sharing of information with other practitioners, to the point where even the most complex operative situation can be experienced on a nearly firsthand basis. It is largely true that our newfound technological ability to share the OR environment between institutions has greatly facilitated the rapid development of advanced laparoscopic surgical procedures on a global level. The superior educational value of a shared

audio and visual environment for teaching and learning complex surgical procedures is now well established.

ACCOMMODATION OF NEW TECHNOLOGIES

In developing the OR of the future, it is essential to remain abreast of new technologies and incorporate them as appropriate; however, this should be done in such a way as to make the OR environment simpler rather than more complicated and less intimidating rather than more so. Any new technical development must undergo rigorous evaluation to ensure that the correct technology is introduced in the correct manner at the correct time.¹²

Properly utilized, technology can greatly facilitate surgical management. A potential example is the bar coding now seen in every facet of our daily lives. At a patient's first office visit, he or she can be given a bar code, which is entered into a computer. On the morning of surgery, the computer can give the patient a wake up call at 5:30 A.M. Upon arrival at the surgical center, the patient can be logged in by bar code. Each step in the process can be tracked: how many minutes it took for the patient to get to the OR, how long it took for the anesthesiologist and the resident to interview the patient in the preoperative holding area, and how long it took to position the patient. Essentially, this process is a variation on patient tracking and data acquisition that minimizes variability with respect to data entry. Tracking information can also be displayed on a video monitor, so that the patient's location and current status within the surgical care process are available on an ongoing basis.

MAXIMIZATION OF EFFICIENCY IN DESIGN AND PROCESS

With the proliferation of technology, the increased complexity of surgical procedures, and the ongoing advances in surgical capabilities, surgery today is a highly involved undertaking. As the number of potential processes and subprocesses in surgical care has increased, so too has the potential for inefficiency. Often, the organizational tendency to keep doing things the way they have always been done prevents necessary improvements from being made, even in the face of significant pressure from corporate interests to improve and simplify processes. Decreasing turnover time and increasing efficiency during procedures are essential and can be accomplished by simplifying rather than complicating the processes involved. An example of such an approach was documented in a 2002 article demonstrating that the redesign of a neurosurgical operating suite simplified processes and procedures related to neurosurgical operations, resulting in a 35% decrease in turnover time.¹³ In addition, team efficiency was significantly increased, leading to further time savings. The time commitment required of the specialist and the team members to make the necessary changes was modest, but the presence of OR administrators, staff members, surgeons, and anesthesia personnel, all cooperating to make working conditions more productive and rewarding for everyone, was deemed crucial to the success of the experiment.

Environmental Issues in the OR

TEMPERATURE AND HUMIDITY

The ambient temperature of the OR often represents a compromise between the needs of the patient and those of the staff; the temperature desired by staff itself is a compromise between the needs of personnel who are dressed in surgical gowns and those who are not. In Europe and North America, OR temperatures range from 18° to 26° C (64.4° to 78.8° F). A higher temperature is necessary during operations on infants and burn

patients because conservation of body heat is critical in these patients. Generally, surgeons who are actively working and fully gownned prefer a temperature of 18° C (64.4° F), but anesthesiologists prefer 21.5° C (70.7° F).¹⁴

Humidity in the OR is generally maintained at between 50% and 60%; humidity greater than 60% may cause condensation on cool surfaces, whereas humidity less than 50% may not suppress static electricity.

LIGHTING

Well-balanced illumination in the OR provides a surgeon with a clear view of the operative field, prevents eye strain, and provides appropriate light levels for nurses and anesthesiologists. Much of our factual knowledge of OR illumination has been gained through the efforts of Dr. William Beck and the Illuminating Engineering Society.^{15,16} A general illumination brightness of up to 200 footcandles (ft-c) is desirable in new constructions. The lighting sources should not produce glare or undesirable reflection.

The amount of light required during an operation varies with the surgeon and the operative site. In one study, general surgeons operating on the common bile duct found 300 ft-c sufficient; because the reflectance of this tissue area is 15%, the required incident light level would be 2,000 ft-c.¹⁷ Surgeons performing coronary bypass operations require a level of 3,500 ft-c.¹⁷ Whether changes in the color of light can improve discrimination of different tissues is unknown.

Another facet of OR lighting is heat production. Heat may be produced by infrared light emitted either directly by the light source or via energy transformation of the illuminated object. However, most of the infrared light emitted by OR lights can be eliminated by filters or by heat-diverting dichroic reflectors.

Basic Safety Concerns in the OR

The OR presents a number of environmental hazards to both surgical personnel and patients. Chemical hazards exist from the use of trace anesthetic gases, flammable anesthetic agents, various detergents and antimicrobial solutions, medications, and latex products.¹⁸ Other ever-present physical hazards include electrical shock and burns, exposure to radiation from x-ray equipment, and injuries caused by lasers.¹⁹ In addition to causing injury directly, the use of lasers can expose OR personnel to papillomavirus in smoke plumes.²⁰ Hazards that are less often considered include noise pollution²¹ and light hazards from high-intensity illumination.²² The most effective way of minimizing the particular hazards in a given OR is to have an active in-hospital surveillance program run by a multidisciplinary team that includes surgeons.

MINIMIZATION OF HAZARDS TO PATIENT

Patient safety, the first order of business in the OR,²³ begins with proper handling of patients and their tissues, which is particularly important where patients are in direct contact with medical devices. It is imperative that physicians, nurses, and technicians protect patients from injuries caused by excessive pressure, heat, abrasion, electrical shock, chemicals, or trauma during their time in the OR. Equipment must be properly used and maintained because equipment malfunctions, especially in life-support or monitoring systems, can cause serious harm.

Anesthetic Considerations

Surgery, by its very nature, makes demands on the body's homeostatic mechanisms that, if unchecked, would be injurious. It is the role of the anesthesiologist to anticipate these demands,

compensate for them, and protect the patient by supporting the body's own efforts to maintain homeostasis [see 1:3 *Perioperative Considerations for Anesthesia*]. Patient protection demands that concerned physicians understand the effects of their perioperative interventions, both positive and negative, and act to minimize the unintended consequences.

Even with straightforward surgical procedures, issues related to patient positioning can lead to unintended consequences. General, regional, and monitored anesthesia care render patients helpless to protect themselves from the stresses of an uncomfortable position. As the physician who renders the patient helpless, the anesthesiologist is responsible for protecting the patient from the results of the position. The surgeon, who chooses the position for the procedure that maximizes exposure and facilitates the operation, is responsible for the consequences of that choice. The OR team is responsible for procuring and maintaining whatever specialized equipment is needed to position the patient properly. The American Society of Anesthesiologists (ASA) Practice Advisory on the Prevention of Perioperative Peripheral Neuropathies recommends that when practical, the patient should be placed in the intended position before the procedure to see if it is comfortable.²⁴ If the position is uncomfortable when the patient is awake, it should be modified until it is comfortable.

The consequences of patient discomfort from positioning may include postoperative myalgias, neuropathies, and compartment syndromes. The greatest risk in the supine position, peripheral neuropathy, arises from the positioning of the upper extremity. The two most common peripheral neuropathies reported to the ASA Closed Claim Study as of 1999 were ulnar neuropathy and brachial plexopathy.²⁵ Approximately 28% of the closed claims for peripheral neuropathy were for ulnar neuropathy and 20% for brachial plexopathy.²⁵ With regard to upper-extremity positioning, the ASA Practice Advisory recommends that the arms be abducted no more than 90°.²⁴ The arms should also be positioned so as to decrease pressure on the postcondylar groove of the humerus. When the arms are tucked, the neutral position is recommended. Prolonged pressure on the radial nerve in the spiral groove of the humerus should be avoided. Finally, the elbows should not be extended beyond a comfortable range so as not to stretch the median nerve.

Approximately 80% of surgical procedures are performed with patients in the supine position.²⁶ Its ubiquity notwithstanding, the supine position has certain physiologic consequences for the patient, including gravitational effects on both the circulatory system and the pulmonary system.²⁷ The most immediate hemodynamic effect noted upon assumption of the supine position is increased cardiac output resulting from enhanced return of lower-extremity venous blood to the heart.²⁸ If this effect were unopposed, systemic blood pressure would rise. This rise does not occur, however, because baroreceptor afferent impulses lead to a reflexive change in the autonomic balance, which decreases stroke volume, heart rate, and contractility,²⁹ thereby serving to maintain blood pressure. Inhaled, I.V., and regional anesthetics all have the capacity to blunt or abolish these protective reflexes, thus causing hypotension in supine, anesthetized patients and necessitating the administration of additional fluids or, occasionally, pressors.

Immediate effects of the supine position on the respiratory system include cephalad and lateral shifting of the diaphragm and cephalad shifting of the abdominal contents, resulting in decreased functional residual capacity and total lung capacity.^{27,28} In addition, perfusion of the lung changes as the supine position is assumed. When the patient is upright, the dependent portions of the lungs receive the bulk of the blood flow²³; however, when the patient

becomes supine, the blood flow becomes essentially uniform from apex to base.²⁹ During spontaneous ventilation in the supine position, the patient can compensate for the altered flow, but when he or she is anesthetized, paralyzed, and placed on positive pressure ventilation, the weight of the abdominal contents prevents the posterior diaphragm from moving as freely as the anterior diaphragm, thus contributing to a ventilation-perfusion mismatch.³⁰

After the supine position, the lithotomy position is the next most common position for surgical procedures. Approximately 9% of operations are conducted with the patient in the lithotomy position.²⁶ Because the lithotomy position is basically a modification of the supine position, there is still a risk of upper-extremity neuropathy; however, the risk of lower-extremity neuropathy is significantly greater. The main hemodynamic consequence of the lithotomy position is increased cardiac output secondary to the gravity-induced increase in venous return to the heart caused by elevation of the lower extremities above the level of the heart.²⁸ Of greater concern is the effect on the lower extremity of the various devices used in positioning. Damage to the obturator, sciatic, lateral femoral cutaneous, and peroneal nerves after immobilization in the lithotomy position, though rare, has been reported.^{31,32} Such complaints account for only 5% of all closed claims for nerve damage in the Closed Claims Data Base.²⁵

Other patient positions can also lead to physiologic and neurologic complications, including the lateral decubitus, prone, sitting, Trendelenburg, and reverse Trendelenburg positions.

MINIMIZATION OF OCCUPATIONAL INJURIES TO HEALTH CARE TEAM

Work-related musculoskeletal injuries are a major cause of decreased productivity and increased litigation costs in the United States.²³ In the OR, occupational injuries can be caused by excessive lifting, improper posture, collision with devices, electrical or thermal injury, puncture by sharp instruments, or exposure to bodily tissues and fluids. Temporary musculoskeletal injuries resulting from poor posture (particularly static posture) or excessive straining are less commonly acknowledged by members of the surgical team but occur relatively frequently during some operations.

To reduce injuries from awkward posture and excessive straining, OR devices should be positioned in an ergonomically desirable manner, so that unnecessary bending, reaching, lifting, and twisting are minimized. Visual displays and monitors should be placed where the surgical team can view them comfortably. Devices that require adjustment during operations should be readily accessible. Placement of cables and tubes across the OR workspace should be avoided if possible. The patient and the operating table should be positioned so as to facilitate the surgeons' work while maintaining patient safety. Lifting injuries can be prevented by using proper transfer technique and obtaining adequate assistance when moving patients in the OR.

Equipment

Modern surgery uses an ever-increasing number of devices in the OR to support and protect the patient and to assist the work of the surgical team [see *Table 1*]. All OR equipment should be evaluated with respect to three basic concerns: maintenance of patient safety, maximization of surgical team efficiency, and prevention of occupational injuries.

ELECTROSURGICAL DEVICES

The electrosurgical device is a 500 W radio-frequency generator that is used to cut and coagulate tissue. Although it is both

Table 1 Devices Used in the OR

For support of patient	Anesthesia delivery devices Ventilator Physiologic monitoring devices Warming devices I.V. fluid warmers and infusers
For support of surgeon	Sources of mechanical, electrical, and internal power, including power tools and electrocautery, as well as laser and ultrasound instruments Mechanical retractors Lights mounted in various locations Suction devices and smoke evacuators Electromechanical and computerized assistive devices, such as robotic assistants Visualization equipment, including microscopes, endoscopic video cameras, and display devices such as video monitors, projection equipment, and head-mounted displays Data, sound, and video storage and transmission equipment Diagnostic imaging devices (e.g., for fluoroscopy, ultrasonography, MRI, and CT)
For support of OR team	Surgical instruments, usually packaged in case carts before each operation but occasionally stored in nearby fixed or mobile modules Tables for display of primary and secondary surgical instruments Containers for disposal of single-use equipment, gowns, drapes, etc. Workplace for charting and record keeping Communication equipment

common and necessary in the modern OR, it is also a constant hazard and therefore requires close attention.³³ When in use, the electrosurgical unit generates an electrical arc that has been associated with explosions. This risk has been lessened because explosive anesthetic agents are no longer used; however, explosion of hydrogen and methane gases in the large bowel is still a real—if rare—threat, especially when an operation is performed on an unprepared bowel.³⁴ Because the unit and its arc generate a broad band of radio frequencies, electrosurgical units interfere with monitoring devices, most notably the electrocardiographic monitor. Interference with cardiac pacemaker activity also has been reported.³⁵

The most frequently reported hazard of the electrosurgical unit is a skin burn. Such burns are not often fatal, but they are painful, occasionally require skin grafts, and raise the possibility of litigation. The burn site can be at the dispersive electrode, ECG monitoring leads, esophageal or rectal temperature probes, or areas of body contact with grounded objects. The dispersive electrode should be firmly attached to a broad area of dry, hairless skin, preferably over a large muscle mass.³⁴

LASERS

Lasers generate energy that is potentially detrimental. Lasers have caused injuries to both patients and staff, including skin burns, retinal injuries, injuries from endotracheal tube fires, pneumothorax, and damage to the colon and to arteries.³⁶ Some design changes in the OR are necessary to accommodate lasers. The OR should not have windows, and a sign should be posted indicating that a laser is in use. The walls and ceiling in the room should be nonreflective. Equipment used in the operative field should be nonreflective and nonflammable. The concentration of O₂ and N₂O in the inhaled gases should be reduced to decrease the possibility of fire. In addition, personnel should wear goggles of an appropriate type to protect the eyes from laser damage. A smoke

evacuator should be attached to the laser to improve visualization, reduce objectionable odor, and decrease the potential for papillomavirus infection from the laser smoke plume.³⁷

POWERED DEVICES

The most common powered device in the OR is the surgical table. Central to every operation, this device must be properly positioned and adjusted to ensure the safety of the patient and the efficient work of the surgical team. Manually adjustable tables are simple, but those with electrical controls are easier to manage. OR table attachments, such as the arm boards and leg stirrups used to position patients, must be properly maintained and secured to prevent injuries to patients or staff. During transfer to and from the OR table, care must be taken to ensure that the patient is not injured and that life-support, monitoring, and I.V. systems are not disconnected. Proper transfer technique, personnel assistance, and the use of devices such as rollers will help prevent musculoskeletal injuries to the OR staff during this maneuver.

Other powered surgical instruments common in the OR include those used to obtain skin grafts, open the sternum, and perform orthopedic procedures. Powered saws and drills can cause substantial aerosolization of body fluids, thereby creating a potential infectious hazard for OR personnel.^{38,39}

VIEWING AND IMAGING DEVICES

OR microscopes are required for microsurgical procedures. Floor-mounted units are the most flexible, whereas built-in microscopes are best employed in rooms dedicated to this type of procedure.⁴⁰ Microscopes are bulky and heavy devices that can cause obstructions and collision hazards in the OR. All controls and displays must be properly positioned at or below the user's line of sight to allow comfortable and unobstructed viewing.

Today's less invasive operations require more accurate intraoperative assessment of the relevant surgical anatomy through the use of x-ray, computed tomography, magnetic resonance imaging, and ultrasonography. Intraoperative fluoroscopy and ultrasonography are most commonly used for this purpose. Intraoperative ultrasonography requires a high-quality portable ultrasound unit and specialized probes. Depending on the procedure and the training of the surgeon, the presence of a radiologist and an ultrasound technician may be required. The ultrasound unit must be positioned near the patient, and the surgical team must be able to view the image comfortably. In some cases, the image may be displayed on OR monitors by means of a video mixing device. Dedicated open radiologic units are usually installed either in the OR proper or immediately adjacent to the OR to permit intraoperative imaging of the selected body area. As image-guided procedures become more commonplace, OR designers will have to accommodate such devices within the OR workplace in a user-friendly manner.

ADDITIONAL DEVICES

The use of sequential compression stockings (SCDs), with or without additional medical anticoagulation, has become the standard of care for the prevention of venous thromboembolism in the majority of operations for which direct access to the lower extremities is not required [see 6:6 *Venous Thromboembolism*].⁴¹ This is particularly true in operations lasting more than 4 hours for which the patient is in the lithotomy position. The pump often must be placed near the patient on the floor or on a nearby cart. The pressure tubing from the stockings to the pump must be routed out of the surgical team's way to prevent hazards and enlargements, particularly during operations for which perineal access is required.

Suction devices are ubiquitous in the OR, assisting the surgeon in the evacuation of blood and other fluids from the operative field. A typical suction apparatus consists of a set of canisters on a wheeled base that receive suction from a wall- or ceiling-mounted source. The surgeon's aspirating cannula is sterilely connected to these canisters. Suction tubing is a common tripping hazard in the OR, and the suction canisters fill rapidly enough to require repeated changing.

Portable OR lights or headlights are often used when the lighting provided by standard ceiling-mounted lights is insufficient or when hard-to-see body cavities prove difficult to illuminate. Headlights are usually preferred because the beam is aimed in the direction the surgeon is looking; however, these devices can be uncomfortable to wear for prolonged periods. The fiberoptic light cord from the headset tethers the surgeon to the light source, which can exacerbate crowding.

CASE CARTS AND STORAGE

In the case cart system, prepackaged sterile instruments and supplies for each scheduled operation are placed on a single open cart (or in an enclosed cart) and delivered from the central sterile supply area to the OR before the start of the procedure. Instrument sets should be sterilized according to facility policy. It is not recommended that instrument sets be flash sterilized immediately before use in order to avoid purchasing additional instrument sets.⁴² Instruments that are used less frequently or are used as replacements for contaminated items can be kept in nearby fixed or mobile storage modules for ready access when required. Replacements for frequently used items that may become contaminated (e.g., dissecting scissors and hemostats) should be separately wrapped and sterile so that they are readily available if needed during an operation.

The Endovascular OR

The field of vascular surgery has rapidly expanded over the past decade to encompass a wide variety of both established and innovative endovascular procedures that are new to the OR environment. Such procedures include complex multilevel diagnostic arteriography, balloon angioplasty (with and without stenting), and endoluminal grafting of aortic aneurysms. Many of these procedures can be performed in the radiologic intervention suite as well as in the cardiac catheterization laboratory. However, the sterile environment, the option of performing combined open surgical and endovascular procedures, and the opportunity to provide one-stop diagnostic and therapeutic care make the OR the favored location for efficient and safe management. Although most OR personnel are familiar with fluoroscopic procedures as well as simple diagnostic arteriography, the development of a comprehensive and successful endovascular program in the OR requires significant personnel training, commitment of resources, and preparation. In what follows, we review certain basic considerations in the evolution of such a program, focusing primarily on space and equipment. Technical details of endovascular procedures are addressed in more detail elsewhere [see 6:8 *Fundamentals of Endovascular Surgery*].

RADIATION SAFETY

A detailed discussion of radiation physics and safety is beyond the scope of this chapter. There are, however, certain fundamental concerns that should be emphasized here to ensure the safety of patients and staff members.

Table 2 ICRP-Recommended Radiation Dose Limits⁴³

	Dose Limit	
	Occupational	Public
Effective dose	20 mSv/yr averaged over defined periods of 5 yr	1 mSv/yr
Annual equivalent dose in		
Lens of the eye	150 mSv	15 mSv
Skin	500 mSv	50 mSv
Hands and feet	500 mSv	—

ICRP—International Commission on Radiological Protection mSv—millisievert

Units of Exposure

Radiation exposure is expressed in several ways. One of the most commonly used terms is the rad (radiation absorbed dose), defined as the amount of energy absorbed by tissue (100 erg/g = 1 rad). In the Système International, the gray (Gy) is used in place of the rad (1 Gy = 100 rad). The newest of the units in current use, the millisievert (mSv), was introduced as a measure of the effective absorbed dose to the entire body (accounting for different sensitivities of exposed tissues). The amount of radiation generated by the x-ray tube is determined by the energy generated by the beam, which in turn is determined both by the number of x-ray photons generated (measured in milliamperes [mA]) and by the power or penetration of the beam (measured in kilovolts [kV]). Most modern fluoroscopes automatically balance mA levels against kV levels on the basis of the contrast of the image so as to optimize image quality and minimize x-ray exposure.

Exposure of human beings to radiation is broadly categorized as either public (i.e., environmental exposure of the general public) or occupational. The International Commission on Radiological Protection (ICRP) has established recommended yearly limits of radiation exposure for these two categories [see Table 2].⁴³ A 2001 study determined that with appropriate protection, radiation exposure for busy endovascular surgeons fell between 5% and 8% of ICRP limits, whereas exposure for other OR personnel fell between 2% and 4%.⁴⁴ Average radiation exposure for patients undergoing endovascular aneurysm repair was 360 mSv/case (range, 120 to 860).⁴⁴

Basic Safety Rules

A few simple rules and procedures can help ensure a safe environment for patients and OR staff. The simplest rule is to minimize the use of fluoroscopy. Inexperienced operators are notorious for excessive reliance on fluoroscopy. Such overutilization results both from needing more time to perform endovascular maneuvers than a more experienced surgeon would need and, more important, from performing excessive and unnecessary (and frequently unintentional) imaging between maneuvers. The use of pulsed fluoroscopy and effective collimation of the images will also minimize the dose of radiation administered. Minimal use of high-definition fluoroscopy and unnecessary cine runs (both of which boost radiation output) are desirable. Most important, surgeons and OR staff should maximize their working distance from radiation sources. Radiation scatter drops off rapidly with increasing distance from the fluoroscope.

Safety Equipment and Monitoring

All OR personnel should wear protective lead aprons (0.25 to

0.5 mm in thickness). Wraparound designs are preferred because members of the OR team will invariably turn their backs to the radiation source on occasion. The apron should include a thyroid shield. High-level users must wear protective lead-containing lenses. A mobile shield (e.g., of lead acrylic) is a useful adjunct that may be employed to reduce exposure during cine runs. All personnel should wear radiation safety badges. Although these badges afford no direct protection, they do allow direct monitoring of individual cumulative exposure on a monthly basis.

PHYSICAL LAYOUT

The design of the endovascular OR depends on the balance of institutional and programmatic needs. For large institutions with a significant endovascular volume, a dedicated endovascular OR may be desirable. Ideally, such a room would combine fixed ceiling-mounted imaging equipment with a dedicated “floating” fluoroscopy table. The main advantage of a dedicated endovascular OR is that it provides state-of-the-art imaging techniques and capabilities in the OR setting; the main disadvantage is that it is relatively inflexible and is not useful for other procedures. For many institutions, such a room may not be cost-effective. Fortunately, with careful design, a high-quality endovascular suite can be set up that is flexible enough to allow both complex endovascular procedures and conventional open vascular and nonvascular operations to be performed. Such a room should be at least 600 sq ft in area, with sufficient length and clearance for extension tables and angiographic wires and catheters.

EQUIPMENT

Imaging Equipment

There are two fundamental physical designs for OR imaging equipment. The first is the fixed ceiling-mounted system that is also employed in catheterization laboratories and dedicated radiologic interventional suites. The second is a system using portable C-arms with dedicated vascular software packages designed for optimal endovascular imaging. Each of these systems has advantages and disadvantages.

Notable benefits of the fixed ceiling-mounted system include higher power output and smaller focal spot size, resulting in the highest-quality images. Larger image intensifiers (up to 16 in.) make possible larger visual fields for diagnostic arteriograms; thus, fewer runs need be made, and injection of dye and exposure to radiation are reduced accordingly. The variable distance between the x-ray tube and the image intensifier allows the intensifier to be placed close to the patient if desired, thereby improving image quality and decreasing radiation scatter. Fixed systems are accompanied by floating angiography tables, which allow the surgeon to move the patient easily beneath the fixed image intensifier. It is generally accepted that such systems afford the surgeon the most control and permit the most effortless and efficient imaging of patients.

Unfortunately, fixed ceiling-mounted systems are quite expensive (typically \$1 million to \$1.5 million), and major structural renovations are often required for installation in a typical OR. Perhaps more important for most ORs, however, is that these systems are not particularly flexible. The floating angiography tables and the immobility of the image intensifiers render the rooms unsuitable for most conventional open surgical procedures. Consequently, fixed imaging systems are generally restricted to high-volume centers where utilization rates justify the construction of dedicated endovascular ORs.

As endovascular procedures in the OR have become increasingly common, the imaging capability and versatility of portable

Table 3 Standard Equipment for Endovascular ORs

Diagnostic arteriography	Entry needle (16-gauge beveled) Entry wire (J wire or floppy-tip wire) Arterial sheath (5 Fr) Catheters Multipurpose nonselective (pigtail, tennis racquet, straight, etc.) Selective (cobra head, shepherd's crook, etc.) Guide wires (floppy, steerable, angled, hydrophilic, etc.) Contrast agent (nonionic preferred) Power injector
Balloon stent angioplasty	Sheaths (various lengths and diameters) Guide catheters Balloons (various lengths and diameters) Stents Balloon expandable (various lengths and diameters) Self-expanding (various lengths and diameters) Inflation device
Endovascular aneurysm repair	Large-caliber sheaths (12–24 Fr) Super-stiff guide wires Endovascular stent grafts Main body and contralateral iliac limb Aortic and iliac extension grafts Endovascular arterial coils

digital C-arms have increased dramatically. State-of-the-art portable C-arms are considerably less expensive than fixed systems (\$175,000 to \$225,000) while retaining many of their advantages. The variable image intensifier size (from 6 to 12 in.) offers valuable flexibility, with excellent resolution at the smaller end and an adequate field of view at the larger end. With some portable C-arm systems, it is possible to vary the distance between the image intensifier and the x-ray tube, as with a fixed system (see above). Pulsed fluoroscopy, image collimation, and filtration are standard features for improving imaging and decreasing radiation exposure. Sophisticated software packages allow high-resolution digital subtraction angiography, variable magnification, road mapping (i.e., the superimposition of live fluoroscopy over a saved digital arteriogram), and a number of other useful features. Improvements in C-arm design allow the surgeon to use a foot pedal to select various imaging and recording modes as well as to play back selected images and sequences.

Unlike fixed systems, which require patients to be moved on a floating table to change the field of view, C-arm systems require the image intensifier to be moved from station to station over a fixed patient. Although more cumbersome than fixed systems, the newest C-arms have increased mobility and maneuverability. Patients must be placed on a special nonmetallic carbon fiber table. To provide a sufficient field of view and permit panning from head to toe, the tables must be supported at one end with complete clearance beneath. Although these tables do not flex, they are sufficient for most operations. Furthermore, they are mobile and may be replaced with conventional operating tables when the endovascular suite is being used for standard open surgical procedures.

Interventional Equipment

The performance of endovascular procedures in the OR requires familiarity with a wide range of devices that may be unfamiliar to OR personnel, such as guide wires, sheaths, specialized catheters, angioplasty balloons, stents, and stent grafts [see Table 3]. In a busy endovascular OR, much of this equipment must be

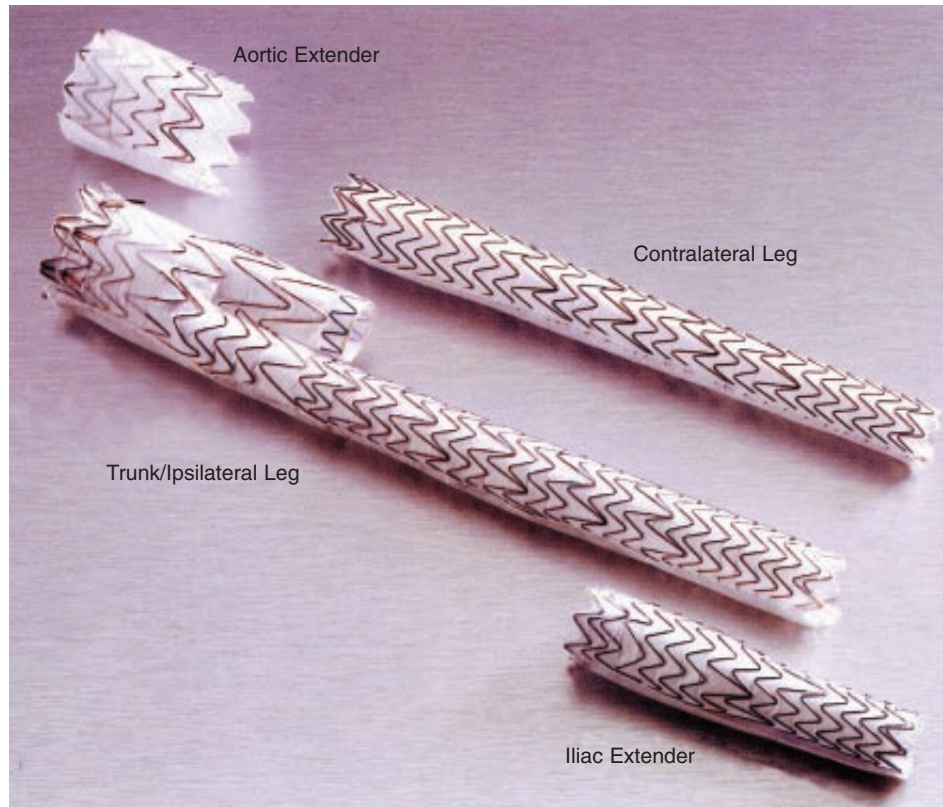

Figure 1 Shown are the component parts of a modular aortic stent graft.

stocked for everyday use, with the remainder ordered on a case-by-case basis. The expense of establishing the necessary inventory of equipment can be substantial and can place a considerable burden on smaller hospitals that are already spending sizable amounts on stocking similar devices for their catheterization laboratories and interventional suites. Fortunately, many companies are willing to supply equipment on a consignment basis, allowing hospitals to pay for devices as they are used.

Aortic Stent Grafts

Endovascular repair of an abdominal aortic aneurysm (EVAR) is the most common and important endovascular procedure performed in the OR [see 6:11 *Repair of Infrarenal Abdominal Aortic Aneurysms*]. As of spring 2003, three EVAR devices had been approved by the FDA for commercial use, with numerous others at various stages of the FDA approval process. All EVAR grafts are expensive (> \$10,000). Although busy hospitals may maintain an inventory of devices, most grafts are ordered on a case-by-base basis. The favored devices are configured as bifurcated aortoiliac grafts. Most such grafts are modular in design, comprising two main pieces [see Figure 1], though one unibody device has been approved. Nonbifurcated grafts connecting the aorta to a single iliac artery are available for special circumstances. Grafts are constructed of either polyester or polytetrafluoroethylene (PTFE) and have varying amounts of stent support. Proximal fixation is accomplished in different ways, ranging from friction fit to the use of hooks and barbs. Various extension components for both ends of the graft are available; in many cases, these components are necessary to complete the repair.

Endovascular therapy is a rapidly evolving field within the discipline of vascular surgery. Many operations traditionally performed as open surgical procedures are increasingly being sup-

planted by less invasive endovascular alternatives. Today's vascular surgery ORs must be prepared and equipped for a safe and efficient transition as this trend continues.

The Laparoscopic OR

PHYSICAL LAYOUT

With the advent of laparoscopy, it has become necessary to reevaluate traditional OR concepts with the aim of determining how best to design a surgical environment suitable for the demanding requirements of advanced minimally invasive surgical procedures.

As noted (see above), until the early 1990s, ORs were constructed in much the same way as they had been for nearly 100 years. The effect of the explosion in minimally invasive surgical procedures that occurred in that decade, along with the demonstration that patients benefited from significantly reduced recovery times, was to force OR personnel to move rapidly into a new age of technology, with little or no preparation. During the early days of laparoscopic surgery, surgeons noted significant increases in turnover time and procedural down time.⁴⁵ Adding to the problem was that the OR environment was becoming increasingly cluttered as a consequence of the addition of endoscopic video towers and other equipment. This equipment often proved to be complicated to use and expensive to repair. The increasing expenditure of money and time, coupled with an operating environment that increasingly promoted confusion rather than patient care, constituted a clear signal that the OR, as designed a century before, had been stretched beyond its capabilities and needed to be redesigned.

A key component of OR redesign for laparoscopic surgery is the placement of patient contact equipment on easily movable booms that are suspended from the ceiling. This arrangement makes rooms

easier to clean and thus speeds turnover. All patient contact equipment and monitors are placed on these booms, and all other equipment is moved to the periphery of the surgical suite, usually in a nurse's command and control center. Thus, control of all equipment is at the fingertips of the circulating nurse, and the disruption and inconvenience of manipulating equipment on carts is avoided.

Rearranging monitors is much simpler with the easily movable booms than with carts, and there are no wires to trip OR personnel, because the wiring is done through the boom structure. Furthermore, because the wiring moves with the equipment, there is less risk that settings will be accidentally changed or wires unplugged—and thus less wear and tear on equipment and staff. The booms are easily moved to the periphery of the room, allowing the room to be used for multispecialty procedures, including non-minimally invasive procedures [see Figure 2].

LAPAROSCOPIC SURGICAL TEAM

The issue of time efficiency in the OR is at the heart of 21st-century surgical practice. Prolonged operating time, excessive setup time, and slow turnover can all affect productivity adversely. As managed care continues to evolve, less productive health care providers will be left behind. The right equipment and the right room design provide the basic foundation for a more productive OR. Without the right team, however, time efficiencies cannot be optimized. To achieve quick turnover time and efficient procedural flow in the laparoscopic OR, it is critical to inculcate a team orientation in all OR personnel.⁴⁶

It is clear that a team of circulating nurses and scrub techs specially designated for minimally invasive surgical procedures can accomplish their tasks more quickly and efficiently than a random group of circulating nurses and scrub techs could. The time savings can be channeled into a larger volume of procedures and a more relaxed, patient care-driven OR environment.

Training seminars to improve the OR staff's familiarity with and performance of laparoscopic procedures should be given. Sessions in which surgeons present the technical issues involved in advanced laparoscopic procedures, including room setup, choice of equipment, and procedural steps, are beneficial. Video-tower setup and troubleshooting can be taught in small group sessions, with an emphasis on solving common technical problems by a process analogous to working through a differential diagnosis.

EQUIPMENT

In addition to having the correct room design, the laparoscopic OR must include equipment that provides the highest level of video quality and incorporates the latest developments in command and control systems.

Cameras and Scopes

No other device is as critical to the success of a laparoscopic procedure as the video camera. Without high-quality image capture and display, accurate identification and treatment of the disease process are impossible. The video cameras used for minimally invasive surgery contain solid-state light-sensitive receptors called charge-coupled devices (CCDs, or chips) that are able to detect differences in brightness at different points throughout an image. Generally, two types are available: one-chip cameras and three-chip cameras. Three-chip cameras provide the greatest resolution and light sensitivity; however, they are also the most expensive. One-chip cameras augment their single CCD with an overlay of millions of colored filters; electronics within the camera or the camera control unit then determine which filter the light hitting a specific point in the CCD is passing through. In this way, it is pos-

Figure 2 The new OR suites at the Medical College of Virginia incorporate the Endosuite design (Stryker Communications, San Jose, Calif.) for advanced laparoscopic procedures.

sible to produce cameras that are smaller and less expensive than three-chip cameras; however, resolution and sensitivity are both compromised.

The trend in laparoscopic surgery has been toward smaller scope diameters. In particular, there has been a large migration from 10 mm to 5 mm rigid scopes. As a result, it is essential to choose a camera that can perform under the reduced lighting conditions imposed by the use of 5 mm devices. The nature and intensity of the light source must be factored in as well. When a laparoscopic procedure is being performed through 5 mm ports, it is often preferable to use a xenon light source so as to maximize light throughput and optimize resolution.

Surgeon's Control of Equipment: Touch Panels, Voice Activation, and Robotics

There are some inherent shortcomings in the way OR equipment has traditionally been accessed, and those shortcomings have been exacerbated by the advent of minimally invasive procedures. Because most of the equipment needed for minimally invasive surgery resides outside the sterile field, the point person for critical controls became the circulating nurse. Often, the circulating nurse would be out of the room at the precise moment when an adjustment (e.g., in the level of the insufflator's CO₂) had to be made. Surgeons grew frustrated at the subsequent delays and at their inability to take their own steps to change things. Additionally, nurses grew weary of such responsibilities; these constant interactions with the video tower pulled them away from patient-related tasks and from necessary clerical and operational work. The answer was to improve surgeons' access to these critical devices via methods such as touchscreen control and, more recently, voice activation.

Development of voice activation began in the late 1960s. The goal was a simple, safe, and universally acceptable voice recognition system that flawlessly carried out the verbal requests of the user. However, attempts to construct a system capable of accurately recognizing a wide array of speech patterns faced formidable technological hurdles that only now are beginning to be overcome. Although voice recognition is not yet a mature technology, it is clearly here to stay, and it has begun to permeate many facets of everyday life.

In 1998, the first FDA-approved voice activation system, Hermes (Computer Motion, Santa Barbara, Calif.), was introduced into the OR. Designed to provide surgeons with direct access and control of surgical devices, Hermes is operated via either a handheld pendant or voice commands from the surgeon. The challenges of advanced laparoscopic surgery provide a fertile ground for demonstrating the benefits of voice activation [see Table 4]. Two-handed laparoscopic procedures make it very difficult for a surgeon to control ancillary equipment manually, even if touchscreens are sterile and within reach.

Voice activation gives surgeons immediate access to and direct control of surgical devices, and it provides the OR team with critical information. To operate a device, the surgeon must take approximately 20 minutes to train the recognition system to his or her voice patterns and must wear an audio headset to relay commands to the controller. The learning curve for voice control is minimal (two or three cases, on average). Many devices can now be controlled by voice activation software, including cameras, light sources, digital image capture and documentation devices, printers, insufflators, OR ambient and surgical lighting systems, operating tables, and electrocauteries.

In the future, more and more devices will be accessible to the surgeon through simple voice commands, and the time will soon arrive when telesurgical and telementoring capabilities will be an integral part of the system. The voice interface will allow surgeons to interact with the world at large in such a way that the performance of a surgical procedure is actively facilitated rather than interrupted. The OR will cease to be an environment of isolation.

Infection Control in the OR

Infection control is a major concern in health care in general, but it is a particularly important issue in the sterile environment of the OR, where patients undergo surgical procedures and are at significant risk for perioperative nosocomial infection. Even the best OR design will not compensate for improper surgical technique or failure to pay attention to infection prevention.

Surgical site infection (SSI) is a major cause of patient morbidity, mortality, and health care costs. In the United States, according to the Centers for Disease Control and Prevention (CDC), about 2.9% of nearly 30 million operations are complicated by SSIs each year. This percentage may in fact be an underestimate,

given the known inherent problems with surgeons' voluntary self-reporting of infections occurring in the ambulatory surgical setting.⁴⁷ Each infection is estimated to increase total hospital stay by an average of 7 days and add more than \$3,000 in charges.

SSIs have been divided by the CDC into three broad categories: superficial incisional SSI, deep incisional SSI, and organ/space SSI [see Table 5 and 1:2 *Prevention of Postoperative Infection*].⁴⁸ Factors that contribute to the development of SSI include (1) those arising from the patient's health status, (2) those related to the physical environment where surgical care is provided, and (3) those resulting from clinical interventions that increase the patient's inherent risk. Careful patient selection and preparation, including judicious use of antibiotic prophylaxis, can decrease the overall risk of infection, especially after clean-contaminated and contaminated operations.

HAND HYGIENE

Hand antisepsis plays a significant role in preventing nosocomial infections. When outbreaks of infection occur in the perioperative period, careful assessment of the adequacy of hand hygiene among OR personnel is recommended. U.S. guidelines recommend that agents used for surgical hand scrubs should substantially reduce microorganisms on intact skin, contain a nonirritating antimicrobial preparation, possess broad-spectrum activity, and be fast-acting and persistent.⁴⁹ In October 2002, the CDC published the most recent version of its Guideline for Hand Hygiene in Health-Care Settings.⁵⁰ The Guideline's final recommendations regarding surgical hand antisepsis included the following:

- Surgical hand antisepsis using either an antimicrobial soap or an alcohol-based hand rub with persistent activity is recommended before donning sterile gloves when performing surgical procedures (evidence level IB).
- When performing surgical hand antisepsis using an antimicrobial soap, scrub hands and forearms for the length of time recommended by the manufacturer, usually 2 to 6 minutes. Long scrub times (e.g., 10 minutes) are not necessary (evidence level IB).
- When using an alcohol-based surgical hand-scrub product with persistent activity, follow the manufacturer's instructions. Before applying the alcohol solution, prewash hands and forearms with a nonantimicrobial soap, and dry hands and forearms completely. After application of the alcohol-based product, allow hands and forearms to dry thoroughly before donning sterile gloves.

GLOVES AND PROTECTIVE BARRIERS

Because of the invasive nature of surgery, there is a high risk of pathogen transfer during an operation, a risk from which both the patient and the surgical team must be protected. The risk can be reduced by using protective barriers, such as surgical gloves. Wearing two pairs of surgical gloves rather than a single pair is considered to provide an additional barrier and to further reduce the risk of contamination. A 2002 Cochrane review concluded that wearing two pairs of latex gloves significantly reduced the number of perforations of the innermost glove.⁵¹ This evidence came from trials undertaken in low-risk surgical specialties—that is, specialties that did not include orthopedic joint surgery.

The Occupational Safety and Health Administration (OSHA) requires that personal protective equipment be available in the health care setting, and these requirements are spelled out in detail in the OSHA standard on Occupational Exposure to Bloodborne Pathogens, which went into effect in 1992. Among the require-

Table 4 Benefits of Voice Activation Technology in the Laparoscopic OR

Benefits to surgical team	Gives surgeons direct and immediate control of devices Frees nursing staff from dull, repetitive tasks Reduces miscommunication and frustration between surgeons and staff Increases OR efficiency Alerts staff when device is malfunctioning or setting off alarm
Benefits to hospital	Saves money, allowing shorter, more efficient operations Contributes to better OR utilization and, potentially, performance of more surgical procedures Lays foundation for expanded use of voice activation in ORs Allows seamless working environment
Benefit to patient	Reduces operating time, which—coupled with improved optics, ergonomics, and efficiency—leads to better surgical outcome

Table 5 Criteria for Defining a Surgical Site Infection (SSI)⁷¹**Superficial incisional SSI**

Infection occurs within 30 days after the operation, *and* infection involves only skin or subcutaneous tissue of the incisions, *and* at least *one* of the following:

1. Purulent drainage, with or without laboratory confirmation, from the superficial incision
2. Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision
3. At least one of the following signs or symptoms of infection: pain or tenderness, localized swelling, redness, or heat; *and* superficial incision is deliberately opened by surgeon, *unless* incision is culture negative
4. Diagnosis of superficial incisional SSI by the surgeon or attending physician

Do *not* report the following conditions as SSI:

1. Stitch abscess (minimal inflammation and discharge confined to the points of suture penetration)
2. Infection of an episiotomy or newborn circumcision site
3. Infected burn wound
4. Incisional SSI that extends into the fascial and muscle layers (see deep incisional SSI)

Note: Specific criteria are used for identifying infected episiotomy and circumcision sites and burn wounds

Deep incisional SSI

Infection occurs within 30 days after the operation if no implant* is left in place or within 1 yr if implant is in place and the infection appears to be related to the operation, *and* infection involves deep soft tissues (e.g., fascial and muscle layers) on the incision, *and* at least *one* of the following:

1. Purulent drainage from the deep incision but not from the organ/space component of the surgical site
2. A deep incision spontaneously dehisces or is deliberately opened by a surgeon when the patient has at least one of the following signs or symptoms: fever (> 38° C [100.4° F]), localized pain, or tenderness, unless site is culture negative
3. An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination
4. Diagnosis of a deep incisional SSI by a surgeon or attending physician

Notes:

1. Report infection that involves both superficial and deep incision sites as deep incisional SSI
2. Report an organ/space SSI that drains through the incision as a deep incisional SSI

Organ/space SSI

Infection occurs within 30 days after the operation if no implant* is left in place or within 1 yr if implant is in place and the infection appears to be related to the operation, *and* infection involves any part of the anatomy (e.g., organs or spaces), other than the incision, which was opened or manipulated during an operation, *and* at least *one* of the following:

1. Purulent drainage from a drain that is placed through a stab wound† into the organ/space
2. Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space
3. An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination
4. Diagnosis of an organ/space SSI by a surgeon or attending physician

*National Nosocomial Infection Surveillance definition: a nonhuman-derived implantable foreign body (e.g., prosthetic heart valve, nonhuman vascular graft, mechanical heart, or hip prosthesis) that is permanently placed in a patient during surgery.

†If the area around a stab wound becomes infected, it is not an SSI. It is considered a skin or soft tissue infection, depending on its depth.

ments is the implementation of the CDC's universal precautions,⁵² designed to prevent transmission of human immunodeficiency virus, hepatitis B virus, and other bloodborne pathogens. These precautions involve the use of protective barriers (e.g., gloves, gowns, aprons, masks, and protective eyewear) to reduce the risk that the health care worker's skin or mucous membranes will be exposed to potentially infectious materials. Performance standards for protective barriers are the responsibility of the FDA's Center for Devices and Radiological Health. These standards define the performance properties that these products must exhibit, such as minimum strength, barrier protection, and fluid resistance. The current CDC recommendation is to use surgical gowns and drapes that resist liquid penetration and remain effective barriers when wet.

Compliance with universal precautions and barrier protection is notably difficult to achieve. A 2001 study, however, found that educational interventions aimed at OR personnel improved compliance significantly, particularly with regard to the use of protective eyewear and double-gloving. Furthermore, such interventions were associated with a reduced incidence of blood and body fluid exposure.⁵³

INFECTION SURVEILLANCE PROGRAMS

Surveillance is an important part of infection control [see *CP:7 Infection Control in Surgical Practice*]. The success of a surveillance program depends on the ability of the infection control team to form a partnership with the surgical staff. Creating a sense of ownership of the surveillance initiative among the members of the surgical staff enhances cooperation and ensures that the best use is made of the information generated. It is not possible to eliminate

SSIs completely, but by sharing information and influencing subsequent behavior, it is certainly possible to reduce their incidence.

A 2002 study documented successful institution of a surveillance program after a period of high infection rates in an orthopedic surgical department.⁵⁴ This program contributed to a significant reduction in SSI rates after elective hip and knee replacement procedures and was successful in creating awareness of infection control practices among hospital staff members.

ANTIMICROBIAL PROPHYLAXIS

SSIs are established several hours after contamination.⁵⁵ Administration of antibiotics before contamination reduces the risk of infection but is subsequently of little value.⁵⁶ Selective use of short-duration, narrow-spectrum antibiotic agents should be considered for appropriate patients to cover the usual pathogens isolated from SSIs [see *Table 6*]. Optimal surgical antimicrobial prophylaxis is based on the following three principles: (1) appropriate choice of antimicrobial agent, (2) proper timing of antibiotic administration before incision, and (3) limited duration of antibiotic administration after operation.

Recommendations for antibiotic prophylaxis are addressed in more detail elsewhere [see *1:2 Prevention of Postoperative Infection*]. When a preoperative antibiotic is indicated, a single dose of therapeutic strength, administered shortly before incision, usually suffices.⁵⁷ (The dose may have to be increased if the patient is morbidly obese.⁵⁸) A second dose is indicated if the procedure is longer than two half-lives of the drug or if extensive blood loss occurs. Continuation of prophylaxis beyond 24 hours is not recommended.

With respect to redosing of the antimicrobial agent in lengthy procedures, consistency is important but can be difficult to obtain.

OR design can be helpful in this regard. In a 2003 study, significant improvement of intraoperative antibiotic prophylaxis in prolonged (> 4 hours) cardiac operations was achieved by employing an automated intraoperative alert system in the OR, with alarms both audible and visible on the OR computer console at 225 minutes after administration of preoperative antibiotics.⁵⁹ Intraoperative redosing of antibiotics was significantly more frequent in the reminder group (68%) than in the control group (40%; $P < 0.0001$). The use of an automatic reminder system in the OR improved compliance with guidelines on perioperative antibiotic prophylaxis.

NONPHARMACOLOGIC PREVENTIVE MEASURES

Several studies have confirmed that certain nonpharmacologic measures, including maintenance of perioperative normothermia and provision of supplemental perioperative oxygen, are efficacious in preventing SSIs.⁶⁰

Perioperative Normothermia

A 1996 study showed that warming patients during colorectal surgery reduced infection rates.⁶¹ A subsequent observational cohort study found that mild perioperative hypothermia was associated with a significantly increased incidence of SSI.⁶² A randomized, controlled trial, published in 2001, was done to determine whether warming patients before short-duration clean procedures would have the same effect.⁶³ In this trial, 421 patients scheduled to undergo clean (breast, varicose vein, or hernia) procedures were randomly assigned either to a nonwarmed group or to one of two warmed groups (locally warmed and systemically warmed). Warming was applied for at least 30 minutes before surgery. Patients were followed, and masked outcome assessments were made at 2 and 6 weeks. SSIs occurred in 19 (14%) of 139

nonwarmed patients but in only 13 (5%) of 277 warmed patients ($P = 0.001$). Wound scores were also significantly lower in warmed patients ($P = 0.007$).

The safest and most effective way of protecting patients from hypothermia is to use forced-air warmers with specialized blankets placed over the upper or lower body. Alternatives include placing a warming water mattress under the patient and draping the patient with an aluminized blanket. Second-line therapy for maintaining normothermia is to warm all I.V. fluids. Any irrigation fluids used in a surgical procedure should be at or slightly above body temperature before use. Radiant heating devices placed above the operative field may be especially useful during operations on infants. Use of a warmer on the inhalation side of the anesthetic gas circuit can also help maintain the patient's body temperature during an operation.

Supplemental Perioperative Oxygen

Destruction by oxidation, or oxidative killing, is the body's most important defense against surgical pathogens. This defensive response depends on oxygen tension in contaminated tissue. An easy method of improving oxygen tension in adequately perfused tissue is to increase the fraction of inspired oxygen (F_{I,O_2}). Supplemental perioperative oxygen (i.e., an F_{I,O_2} of 80% instead of 30%) significantly reduces postoperative nausea and vomiting and diminishes the decrease in phagocytosis and bacterial killing usually associated with anesthesia and surgery. Oxygen tension in wound tissue has been found to be a good predictor of SSI risk.⁶⁴

Avoidance of Blood Transfusion

The association between blood transfusion and increased perioperative infection rates is well documented. In a 1997 study, geriatric hip fracture patients undergoing surgical repair who received blood transfusion had significantly higher rates of perioperative infection than those who did not (27% versus 15%), and this effect was present on multivariate analysis.⁶⁵ Another 1997 study, involving 697 patients undergoing surgery for colorectal cancer, yielded similar findings: 39% of transfused patients had bacterial infections, compared with 24% of non-transfused patients, and the relative risk of infection was 1.6 for transfusion of one to three units of blood and 3.6 for transfusion of more than three units.⁶⁶

A large prospective cohort study published in 2003 evaluated the association between anemia, blood transfusion, and perioperative infection.⁶⁷ Logistic regression analysis confirmed that intraoperative transfusion of packed red blood cells was an independent risk factor for perioperative infection (odds ratio, 1.06; confidence interval, 1.01 to 1.11; $P > 0.0001$). Furthermore, transfusion of more than four units of packed red blood cells was associated with a 9.28-fold increased risk of infection (confidence interval, 5.74 to 15.00; $P < 0.0001$).

Housekeeping Procedures

FLOORS AND WALLS

Despite detailed recommendations for cleaning the OR [see Table 7],⁶⁸ the procedures that are optimal to provide a clean environment while still being cost-effective have not been critically analyzed.

Only a few studies have attempted to correlate surface contamination of the OR with SSI risk. In one study, for example, ORs were randomly assigned to either a control group or an experimental group.⁶⁹ The control rooms were cleaned with a germicidal

Table 6 Distribution of Pathogens Isolated from SSIs: National Nosocomial Infections Surveillance System, 1986–1996⁴⁸

Pathogen	Percentage of Isolates*	
	1986–1989 (N=16,727)	1990–1996 (N=17,671)
<i>Staphylococcus aureus</i>	17	20
Coagulase-negative staphylococci	12	14
<i>Enterococcus</i> species	13	12
<i>Escherichia coli</i>	10	8
<i>Pseudomonas aeruginosa</i>	8	8
<i>Enterobacter</i> species	8	7
<i>Proteus mirabilis</i>	4	3
<i>Klebsiella pneumoniae</i>	3	3
Other <i>Streptococcus</i> species	3	3
<i>Candida albicans</i>	2	3
Group D streptococci (nonenterococci)	—	2
Other gram-positive aerobes	—	2
<i>Bacteroides fragilis</i>	—	2

*Pathogens representing less than 2% of isolates are excluded.

Table 7 OR Cleaning Schedules

Areas requiring daily cleaning	Surgical lights and tracks Fixed ceiling-mounted equipment Furniture and mobile equipment, including wheels OR and hall floors Cabinet and push-plate handles Ventilation grills All horizontal surfaces Substerile areas Scrub and utility areas Scrub sinks
Areas requiring routinely scheduled cleaning	Ventilation ducts and filters Recessed tracks Cabinets and shelves Walls and ceilings Sterilizers, warming cabinets, refrigerators, and ice machines

dal agent and wet-vacuumed before the first case of the day and between cases; in the experimental rooms, cleaning consisted only of wiping up grossly visible contamination after clean and clean-contaminated cases. Both rooms had complete floor cleanup after contaminated or dirty and infected cases. The investigators found that bacterial colony counts obtained directly from the floors were lower in the control rooms but that counts obtained from other horizontal surfaces did not differ between the two OR groups. In addition, wound infection rates were the same in the control rooms and the experimental rooms and were comparable with rates reported in other series. Another study found that floor disinfectants decreased bacterial concentration on the floor for only 2 hours; colony counts then returned to pretreatment levels as personnel walked on the floor.⁷⁰ These investigators recommended discontinuing routine floor disinfection.

Even when an OR floor is contaminated, the rate of redispersal of bacteria into the air is low, and the clearance rate is high. It is unlikely, therefore, that bacteria from the floor contribute to SSI. Consequently, routine disinfection of the OR floor between clean or clean-contaminated cases appears unnecessary.

According to CDC guidelines for prevention of SSI, when visible soiling of surfaces or equipment occurs during an operation, an Environmental Protection Agency (EPA)-approved hospital disinfectant should be used to decontaminate the affected areas before the next operation.⁷¹ This statement is in keeping with the OSHA requirement that all equipment and environmental surfaces be cleaned and decontaminated after contact with blood or other potentially infectious materials. Disinfection after a contaminated or dirty case and after the last case of the day is probably a reasonable practice, though it is not supported by directly pertinent data. Wet-vacuuming of the floor with an EPA-approved hospital disinfectant should be performed routinely after the last operation of the day or night.

DIRTY CASES

Operations are classified or stratified into four groups in relation to the epidemiology of SSIs [see 1:2 *Prevention of Postoperative Infection*].⁷² Clean operations are those elective cases in which the GI tract or the respiratory tract is not entered and there are no major breaks in technique. The infection rate in this group should be less than 3%. Clean-contaminated operations are those elective cases in which the respiratory or the GI tract is entered or during which a break in aseptic technique has occurred. The infection rate in such cases should be less than 10%. Contaminated operations

are those cases in which a fresh traumatic wound is present or gross spillage of GI contents occurs. Dirty or infected operations include those in which bacterial inflammation occurs or in which pus is present. The infection rate may be as high as 40% in a contaminated or dirty operation.

Fear that bacteria from dirty or heavily contaminated cases could be transmitted to subsequent cases has resulted in the development of numerous and costly rituals of OR cleanup. However, there are no prospective studies and no large body of relevant data to support the usefulness of such rituals. In fact, one study found no significant difference in environmental bacterial counts after clean cases than after dirty ones.⁷³ Numerous authorities have recommended that there be only one standard of cleaning the OR after either clean or dirty cases.^{68,73,74} This recommendation is reasonable because any patient may be a source of contamination caused by unrecognized bacterial or viral infection; more important, the other major source of OR contamination is the OR personnel.

Rituals applied to dirty cases include placing a germicide-soaked mat outside the OR door, allowing the OR to stand idle for an arbitrary period after cleanup of a dirty procedure, and using two circulating nurses, one inside the room and one outside. None of these practices has a sound theoretical or factual basis.

Traditionally, dirty cases have been scheduled after all the clean cases of the day. However, this restriction reduces the efficiency with which operations can be scheduled and may unnecessarily delay emergency cases. There are no data to support special cleaning procedures or closing of an OR after a contaminated or dirty operation has been performed.⁷⁵ Tacky mats placed outside the entrance to an OR suite have not been shown to reduce the number of organisms on shoes or stretcher wheels, nor do they reduce the risk of SSI.⁷⁶

Data Management in the OR

In this era of capitated reimbursement and managed care, containment of health care costs is a prime concern; consequently, OR efficiency has become a higher priority for many institutions.⁷⁷ No OR environment can even function, let alone improve its efficiency, without data. Data control every facet of the activities within the OR environment. For evaluating procedural time, OR utilization and efficiency, OR scheduling, infection rates, injury prevention, and other key measures of organizational function, it is essential to have current, high-quality data.

To obtain good data, it is necessary first to determine what information is required. For example, assessment of OR utilization and efficiency depends on how utilization is measured. Before an OR can meaningfully be measured against a target figure, it is necessary to know exactly how the organization calculates utilization and how the parameters are defined. There is no accepted national standard. The future of the organization—not to mention the jobs of the people who work there—may depend on how well it understands and controls OR utilization.

It is generally agreed that 80% to 85% is the maximum utilization level that an OR can be expected to reach. At higher utilization levels, the OR loses flexibility, and the hospital should consider adding capacity. It is important that utilization of all OR resources by the various sectors of the institution be reasonable and balanced, because higher OR utilization can be achieved only when this is the case. To improve the use of OR time, it is important (1) to limit the number of ORs available to the number required to achieve good utilization, (2) to have nurses rather than attending surgeons control access to the surgical schedule, (3) to

provide good scheduling systems that allow surgeons to follow themselves, and (4) to maintain systems that enable and enforce efficient turnover between cases.⁷⁸

It has been estimated that 30% of all health care outlays are related to surgical expenditures.⁷⁹ Thus, it is likely that in a cost-conscious, competitive environment, the OR will be a major focus of change. Surgical costs are related to OR utilization, inventory levels, operative volume, supply usage, and equipment purchase, rental, and maintenance. Facility design also affects efficiency and thus the ability to reduce costs. All of these issues must be evaluated and monitored to ensure quality care at the lowest feasible cost.⁸⁰

Once good data are available, the issue then becomes how practices and procedures should change as a result. Although new information, by itself, can often affect behavior, true behavior modification in the OR requires effective leadership from the chiefs of surgery, anesthesia, and nursing, all of whom should receive monthly performance reports.

DATA ACQUISITION

The necessary data must be not only available but also accessible in a rapid and convenient manner. Total automation of OR data management is critical for ascertaining patterns, managing productivity and resources, and providing solid informational bases for future decisions. Only through automation tools can relevant, timely, and accurate statistical data be generated to facilitate problem solving, trend spotting, forecasting, and revisioning.⁸¹

A long-standing question in OR utilization was how many historical data points were necessary or ideal to make appropriate decisions regarding OR staffing via statistical methods. In a 2002 study, statistical analysis of 30 workdays of data yielded staffing solutions that had, on average, 30% lower staffing costs and 27% higher staffing productivity than the existing staffing plans.⁸² The productivity achieved in this way was 80%, and this figure was not significantly improved by increasing the number of workdays of data beyond 180. These findings suggest that in most OR environments, statistical methods of data acquisition and analysis can identify cost-lowering and productivity-enhancing staffing solutions by using 30 days of OR and anesthesia data.

OR SCHEDULING

For optimal OR utilization, it is important to have a system for releasing OR time efficiently and appropriately. Surgical services fill their OR time at different rates. In a 2002 study, the median period between the time when a patient was scheduled for surgery and the day of the operation ranged from 2 to 27 days, depending on the subspecialty.⁸³ Whereas ophthalmologic surgeons might schedule outpatient cases weeks beforehand, cardiac or thoracic surgeons might book cases the day before the operation. Consequently, it would not be logical to release allocated OR time for all services the same prespecified number of days before surgery.⁸⁴ A better approach would be to predict, as soon as a case is scheduled, which surgical service is likely to have the most underutilized OR time on the scheduled day of surgery. In practice, the OR information system would perform the forecasting and provide a recommendation to the OR scheduler. To produce reliable results, forecasting should be based on the previous 6 months of OR performance, with allowances made for vacations and meeting-related down time.

Perioperative costs can be reduced if cases are scheduled so that the workload evenly matches staffing schedules. Specifically, to minimize the cost per case, down time must be minimized. Appropriate choice of the day on which a patient will undergo surgery is the most important decision affecting OR labor costs.⁸⁴

QUALITY IMPROVEMENT

The key to increased OR efficiency is increased productivity. Standardization and streamlining of internal procedures reduces bottlenecks, and computerization speeds the flow of information so that continuous improvement of the system becomes possible. Before a desired improvement can be implemented, the proposed change must be tested quickly so that its effect can be determined. This is accomplished by means of a collaborative effort, in which the group involved in the change learns how to plan, do, check and act—the so-called PDCA cycle, which is a classic quality initiative method. During the PDCA cycle, teams are encouraged to share ideas and talk about various solutions. A change is tested quickly, and if it works, implementation is expanded and tested further. The importance of the changes that can be implemented is often secondary to the progress made in building collaboration with fellow physicians and other health care professionals.⁸⁴

2 PREVENTION OF POSTOPERATIVE INFECTION

Jonathan L. Meakins, M.D., D.Sc., F.A.C.S., and Byron J. Masterson, M.D., F.A.C.S.

Epidemiology of Surgical Site Infection

Historically, the control of wound infection depended on anti-septic and aseptic techniques directed at coping with the infecting organism. In the 19th century and the early part of the 20th century, wound infections had devastating consequences and a measurable mortality. Even in the 1960s, before the correct use of antibiotics and the advent of modern preoperative and postoperative care, as much as one quarter of a surgical ward might have been occupied by patients with wound complications. As a result, wound management, in itself, became an important component of ward care and of medical education. It is fortunate that many factors have intervened so that the so-called wound rounds have become a practice of the past. The epidemiology of wound infection has changed as surgeons have learned to control bacteria and the inoculum as well as to focus increasingly on the patient (the host) for measures that will continue to provide improved results.

The following three factors are the determinants of any infectious process:

1. The infecting organism (in surgical patients, usually bacteria).
2. The environment in which the infection takes place (the local response).
3. The host defense mechanisms, which deal systemically with the infectious process.¹

Wounds are particularly appropriate for analysis of infection with respect to these three determinants. Because many components of the bacterial contribution to wound infection now are clearly understood and measures to control bacteria have been implemented, the host factors become more apparent. In addition, interactions between the three determinants play a critical role, and with limited exceptions (e.g., massive contamination), few infections will be the result of only one factor [see Figure 1].

Definition of Surgical Site Infection

Wound infections have traditionally been thought of as infections in a surgical wound occurring between the skin and the deep soft tissues—a view that fails to consider the operative site as a whole. As prevention of these wound infections has become more effective, it has become apparent that definitions of operation-related infection must take the entire operative field into account; obvious examples include sternal and mediastinal infections, vascular graft infections, and infections associated with implants (if occurring within 1 year of the procedure and apparently related to it). Accordingly, the Centers for Disease Control and Prevention currently prefers to use the term surgical site infection (SSI). SSIs can be classified into three categories: superficial incisional SSIs (involving only skin and subcutaneous tissue), deep incisional SSIs (involving deep soft tissue), and organ/space SSIs (involving anatomic areas other than the incision itself that are opened or manipulated in the course of the procedure) [see Figure 2].^{2,3}

Standardization in reporting will permit more effective surveillance and improve results, as well as offer a painless way of achieving quality assurance. The natural tendency to deny that a surgical site has become infected contributes to the difficulty of defining SSI in a way that is both accurate and acceptable to surgeons. The surgical view of SSI recalls one judge's (probably apocryphal) remark about pornography: "It is hard to define, but I know it when I see it." SSIs are usually easy to identify. Nevertheless, there is a critical need for definitions of SSI that can be applied in different institutions for use as performance indicators.⁴ The criteria on which such definitions must be based are more detailed than the simple apocryphal remark just cited; they are outlined more fully elsewhere [see 1:1 *Preparation of the Operating Room*].

STRATIFICATION OF RISK FOR SSI

The National Academy of Sciences–National Research Council classification of wounds [see Table 1], published in 1964, was a landmark in the field.⁵ This report provided incontrovertible data to show that wounds could be classified as a function of probability of bacterial contamination (usually endogenous) in a consistent manner. Thus, wound infection rates could be validly compared from month to month, between services, and between hospitals. As surgery became more complex in the following decades, however, antibiotic use became more standardized and other risk variables began to assume greater prominence. In the early 1980s, the Study on the Efficacy of Nosocomial Infection Control (SENIC) study identified three risk factors in addition to wound class: location of operation (abdomen or chest), duration of operation, and

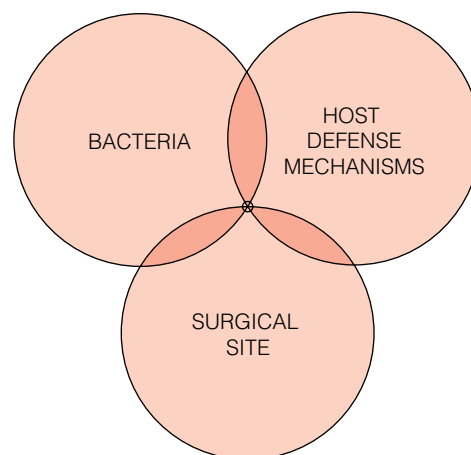

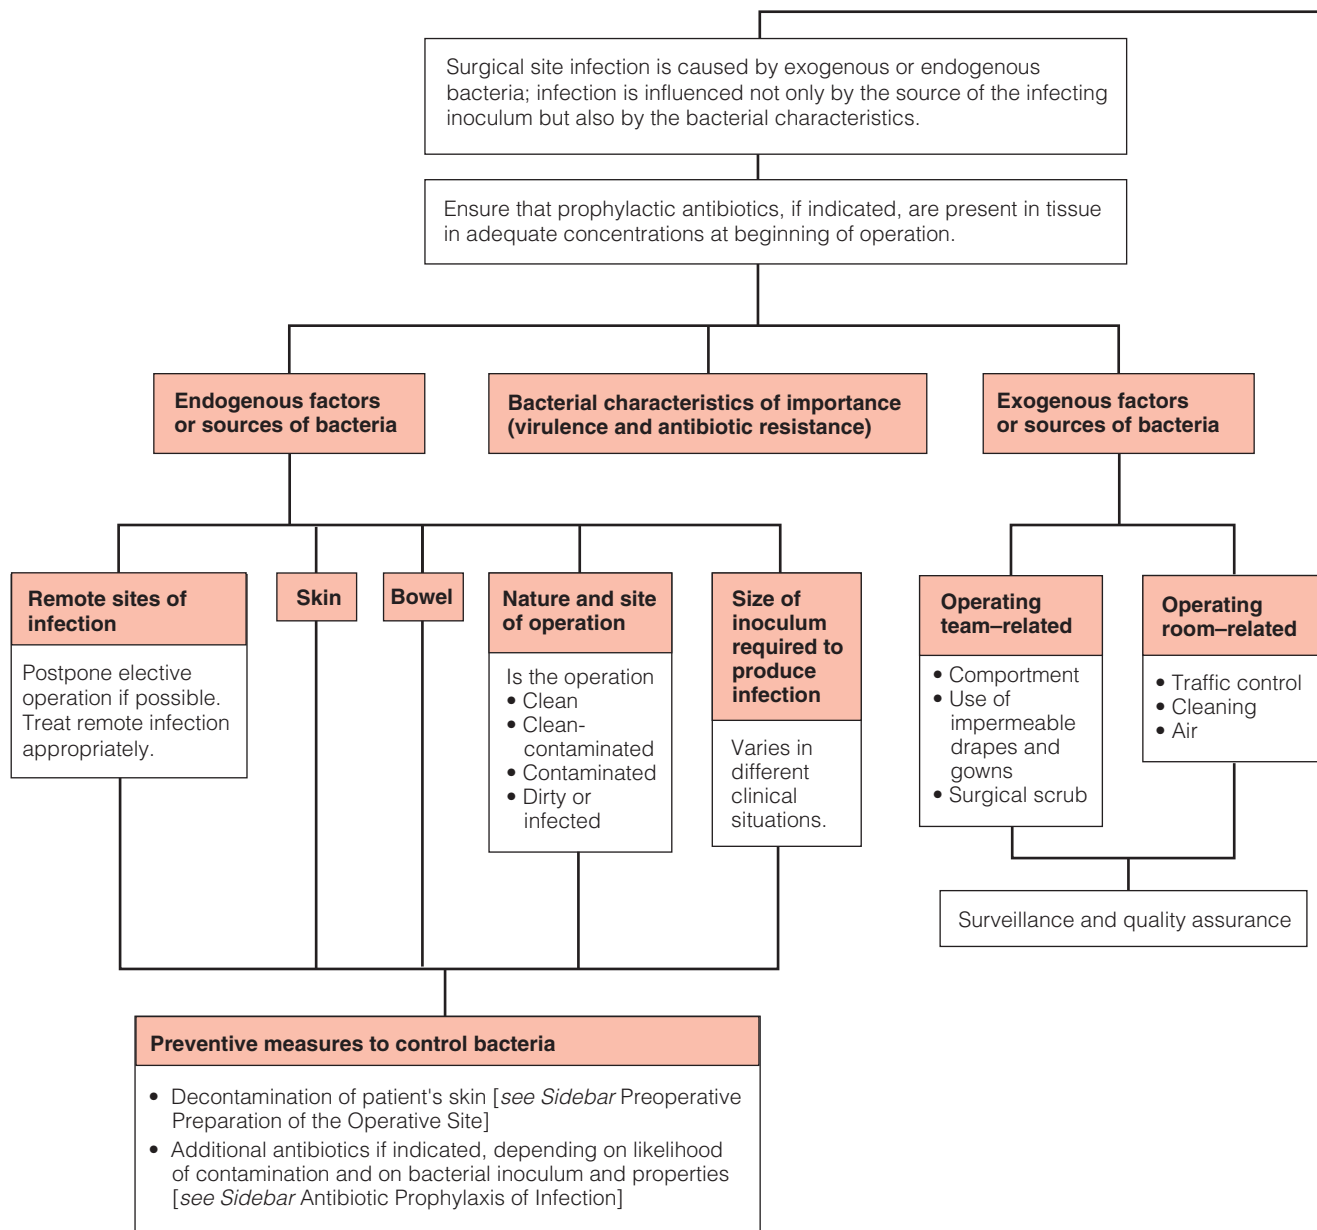

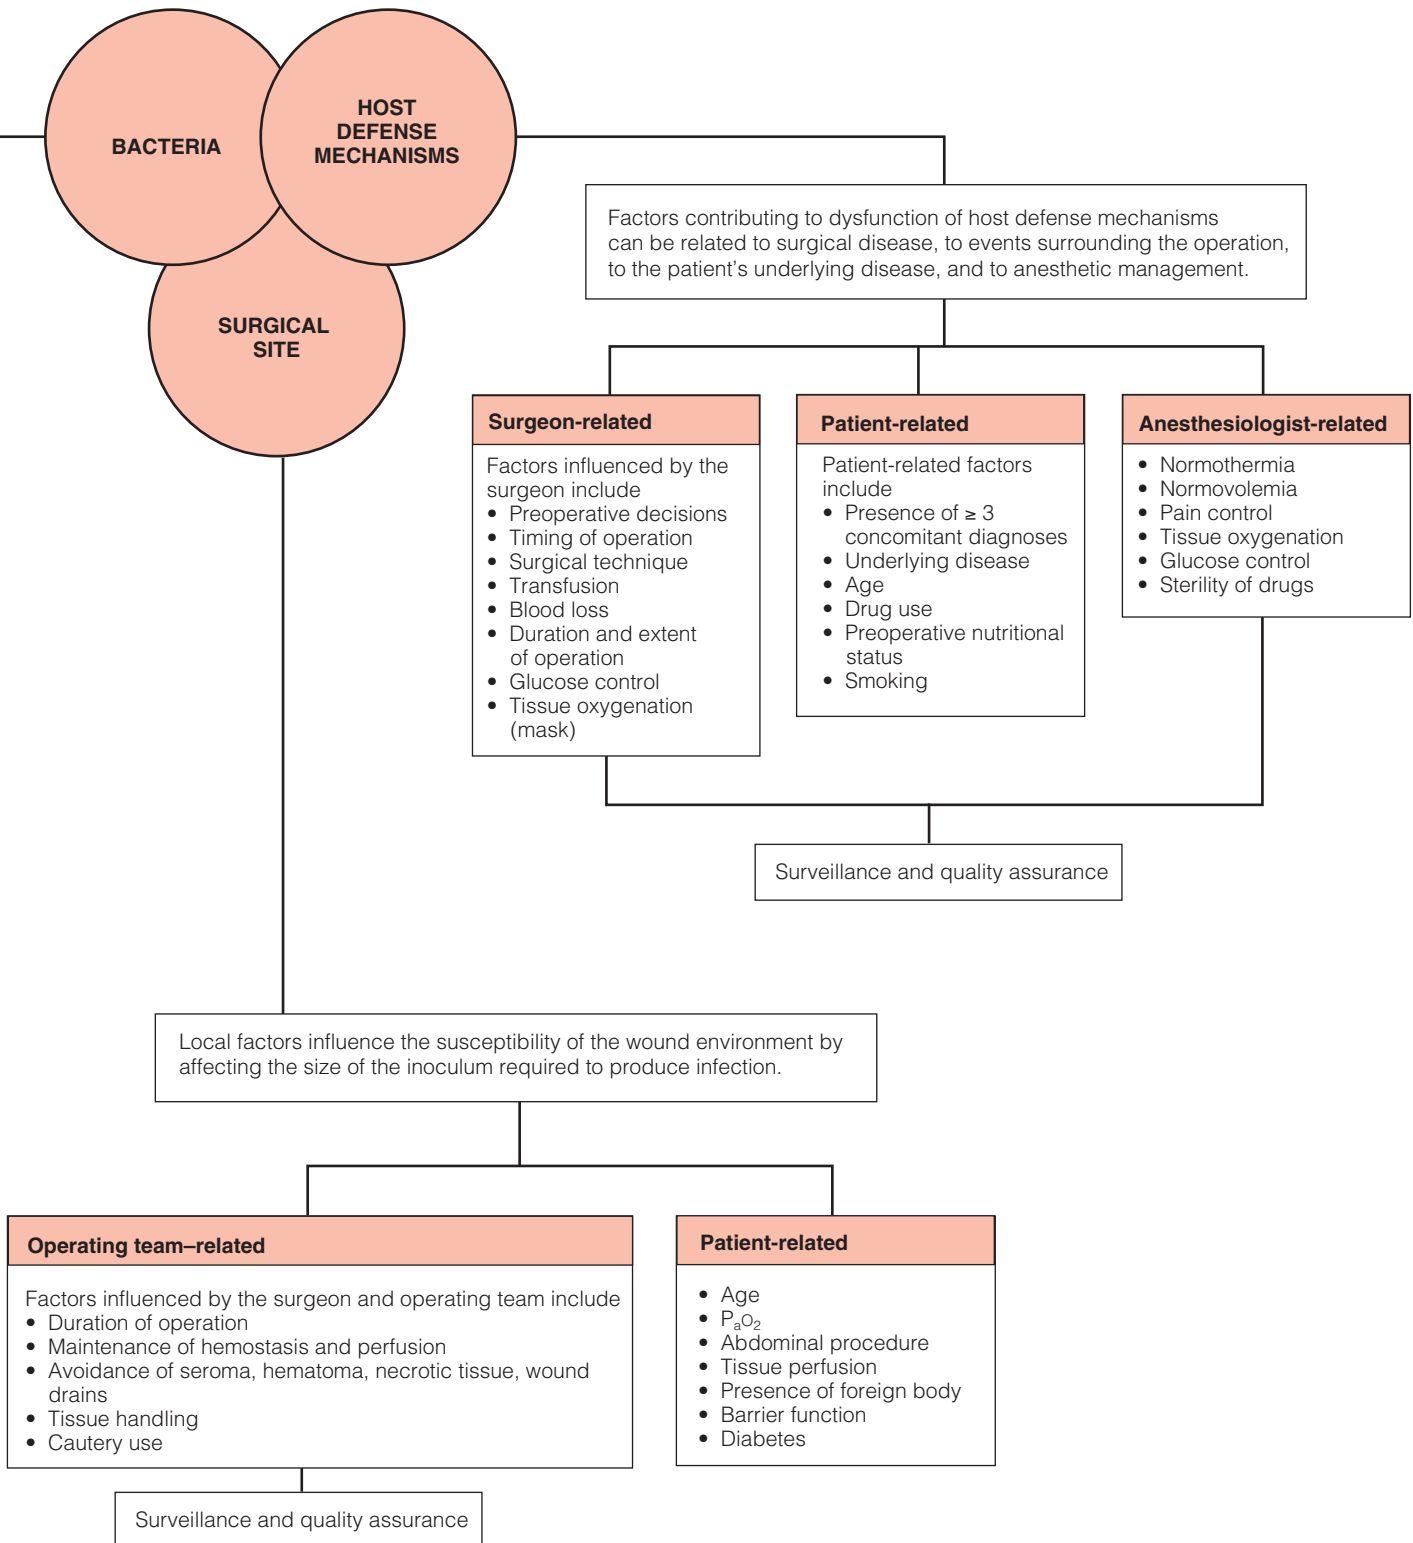

Figure 1 In a homeostatic, normal state, the determinants of any infectious process—bacteria, the surgical site, and host defense mechanisms (represented by three circles)—intersect at a point indicating zero probability of sepsis.

Epidemiology of Surgical Site Infection

Figure 2 Surgical site infections are classified into three categories, depending on which anatomic areas are affected.³

patient clinical status (three or more diagnoses on discharge).⁶ The National Nosocomial Infection Surveillance (NNIS) study reduced these four risk factors to three: wound classification, duration of operation, and American Society of Anesthesiologists (ASA) class III, IV or V.^{7,8} Both risk assessments integrate the three determinants of infection: bacteria (wound class), local environment (duration), and systemic host defenses (one definition of patient health status), and they have been shown to be applicable outside the United States.⁹ However, the SENIC and NNIS assessments do not integrate other known risk variables, such as smoking, tissue oxygen tension, glucose control, shock, and maintenance of normothermia, all of which are relevant for clinicians (though often hard to monitor and to fit into a manageable risk assessment).

Bacteria

Clearly, without an infecting agent, no infection will result. Accordingly, most of what is known about bacteria is put to use in major efforts directed at reducing their numbers by means of asepsis and antisepsis. The principal concept is based on the size of the bacterial inoculum.

Wounds are traditionally classified according to whether the wound inoculum of bacteria is likely to be large enough to overwhelm local and systemic host defense mechanisms and produce an infection [see Table 1]. One study showed that the most important factor in the development of a wound infection was the number of bacteria present in the wound at the end of an operative procedure.¹⁰ Another study quantitated this relation and provided insight into how local environmental factors might be integrated into an understanding of the problem [see Figure 3].¹¹ In the years before prophylactic antibiotics, as well as during the early phases of their use, there was a very clear relation between the classification of the operation (which is related to the probability of a significant inoculum) and the rate of wound infection.^{5,12} This relation is now less dominant than it once was; therefore, other factors have come to play a significant role.^{6,13}

CONTROL OF SOURCES OF BACTERIA

Endogenous bacteria are a more important cause of SSI than exogenous bacteria. In clean-contaminated, contaminated, and dirty-infected operations, the source and the amount of bacteria are functions of the patient's disease and the specific organs being operated on.

Operations classified as infected are those in which infected tissue and pus are removed or drained, providing a guaranteed inoculum to the surgical site. The inoculum may be as high as 10¹⁰ bacteria/ml, some of which may already be producing an infection. In addition, some bacteria could be in the growth phase rather than the dormant or the lag phase and thus could be more pathogenic. The heavily contaminated wound is best managed by delayed primary closure. This type of management ensures that the wound is not closed over a bacterial inoculum that is almost certain to cause a wound infection, with attendant early and late consequences.

Patients should not have elective surgery in the presence of remote infection, which is associated with an increased incidence of wound infection.⁵ In patients with urinary tract infections, wounds frequently become infected with the same organism. Remote infections should be treated appropriately, and the operation should proceed only under the best conditions possible. If operation cannot be appropriately delayed, the use of prophylactic and therapeutic antibiotics should be considered [see Sidebar Antibiotic Prophylaxis of Infection and Tables 2 through 4].

Preoperative techniques of reducing patient flora, especially endogenous bacteria, are of great concern. Bowel preparation, antimicrobial showers or baths, and preoperative skin decontami-

Table 1 National Research Council Classification of Operative Wounds⁵

Clean (class I)	Nontraumatic No inflammation encountered No break in technique Respiratory, alimentary, or genitourinary tract not entered
Clean-contaminated (class II)	Gastrointestinal or respiratory tract entered without significant spillage Appendectomy Oropharynx entered Vagina entered Genitourinary tract entered in absence of infected urine Biliary tract entered in absence of infected bile Minor break in technique
Contaminated (class III)	Major break in technique Gross spillage from gastrointestinal tract Traumatic wound, fresh Entrance of genitourinary or biliary tracts in presence of infected urine or bile
Dirty and infected (class IV)	Acute bacterial inflammation encountered, without pus Transection of "clean" tissue for the purpose of surgical access to a collection of pus Traumatic wound with retained devitalized tissue, foreign bodies, fecal contamination, or delayed treatment, or all of these; or from dirty source

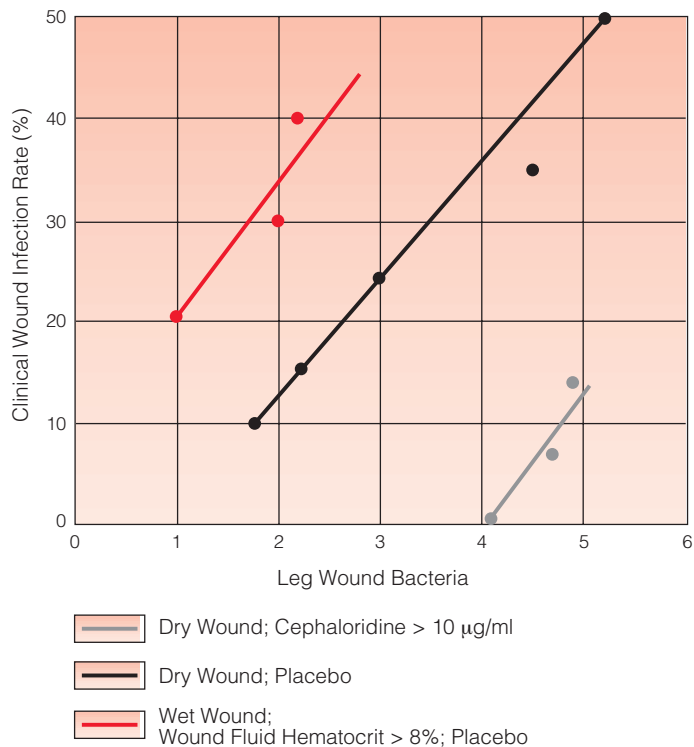

Figure 3 The wound infection rate is shown here as a function of bacterial inoculum in three different situations: a dry wound with an adequate concentration of antibiotic (cephalexin > 10 µg/ml), a dry wound with no antibiotic (placebo), and a wet wound with no antibiotic (placebo, wound fluid hematocrit > 8%).¹¹

nation have been proposed frequently. These techniques, particularly preoperative skin decontamination [see *Sidebar* Preoperative Preparation of the Operative Site], may have specific roles in selected patients during epidemics or in units with high infection rates. As a routine for all patients, however, these techniques are unnecessary, time-consuming, and costly in institutions or units where infection rates are low.

The preoperative shave is a technique in need of reassessment. It is now clear that shaving the evening before an operation is associated with an increased wound infection rate. This increase is sec-

ondary to the trauma of the shave and the inevitable small areas of inflammation and infection. If hair removal is required,^{14,15} clipping is preferable and should be done in the OR or the preparation room just before the operative procedure. Shaving, if ever performed, should not be done the night before operation.

In the past few years, the role of the classic bowel preparation [see *Table 5*] has been questioned [see *Discussion, Infection Prevention in Bowel Surgery, below*].¹⁶⁻²⁰ The suggestion has been made that selective gut decontamination (SGD) may be useful in major elective procedures involving the upper GI tract and perhaps in other settings. At present, SGD for prevention of infection cannot be recommended in either the preoperative or the postoperative period.

When infection develops after clean operations, particularly those in which foreign bodies were implanted, endogenous infecting organisms are involved but the skin is the primary source of the infecting bacteria. The air in the operating room and other OR sources occasionally become significant in clean cases; the degree of endogenous contamination can be surpassed by that of exogenous contamination. Thus, both the operating team—surgeon, assistants, nurses, and anesthetists—and OR air have been reported as significant sources of bacteria [see *1:1 Preparation of the Operating Room*]. In fact, personnel are the most important source of exogenous bacteria.²¹⁻²³ In the classic 1964 study by the National Academy of Sciences–National Research Council, ultraviolet light (UVL) was efficacious only in the limited situations of clean and ultraclean cases.⁵ There were minimal numbers of endogenous bacteria, and UVL controlled one of the exogenous sources.

Clean air systems have very strong advocates, but they also have equally vociferous critics. It is possible to obtain excellent results in clean cases with implants without using these systems. However, clean air systems are here to stay. Nevertheless, the presence of a clean air system does not mean that basic principles of asepsis and antisepsis should be abandoned, because endogenous bacteria must still be controlled.

The use of impermeable drapes and gowns has received considerable attention. If bacteria can penetrate gown and drapes, they can gain access to the wound. The use of impermeable drapes may therefore be of clinical importance.^{24,25} When wet, drapes of 140-thread-count cotton are permeable to bacteria. It is clear that some operations are wetter than others, but generally, much can be done to make drapes and gowns impermeable to bacteria. For example, drapes of 270-thread-count cotton that have been water-

Table 2 Parenteral Antibiotics Recommended for Prophylaxis of Surgical Site Infection

	Antibiotic	Dose	Route of Administration
For coverage against aerobic gram-positive and gram-negative organisms	Cefazolin	1 g	I.V. or I.M. (I.V. preferred)
If patient is allergic to cephalosporins or if methicillin-resistant organisms are present	Vancomycin	1 g	I.V.
Combination regimens for coverage against gram-negative aerobes and anaerobes	Clindamycin or Metronidazole	600 mg	I.V.
	plus	500 mg	I.V.
	Tobramycin (or equivalent aminoglycoside)	1.5 mg/kg	I.V. or I.M. (I.V. preferred for first dose)
For single-agent coverage against gram-negative aerobes and anaerobes	Cefoxitin	1–2 g	I.V.
	Cefotetan	1–2 g	I.V.

Antibiotic Prophylaxis of Infection

Selection

Spectrum. The antibiotic chosen should be active against the most likely pathogens. Single-agent therapy is almost always effective except in colorectal operations, small-bowel procedures with stasis, emergency abdominal operations in the presence of polymicrobial flora, and penetrating trauma; in such cases, a combination of antibiotics is usually used because anaerobic coverage is required.

Pharmacokinetics. The half-life of the antibiotic selected must be long enough to maintain adequate tissue levels throughout the operation.

Administration

Dosage, route, and timing. A single preoperative dose that is of the same strength as a full therapeutic dose is adequate in most instances. The single dose should be given I.V. immediately before skin incision. Administration by the anesthetist is most effective and efficient.

Duration. A second dose is warranted if the duration of the operation exceeds either 3 hours or twice the half-life of the antibiotic. No additional benefit has been demonstrated in continuing prophylaxis beyond the day of the operation, and mounting data suggest that the preoperative dose is sufficient. When massive hemorrhage has occurred (i.e., blood loss equal to or greater than blood volume), a second dose is warranted. Even in emergency or trauma cases, prolonged courses of antibiotics are not justified unless they are therapeutic.^{77,108}

Indications

CLEAN CASES

Prophylactic antibiotics are not indicated in clean operations if the patient has no host risk factors or if the operation does not involve placement of prosthetic materials. Open heart operation and operations involving the aorta of the vessels in the groin require prophylaxis.

Patients in whom host factors suggest the need for prophylaxis include those who have more than three concomitant diagnoses, those whose operations are expected to last longer than 2 hours, and those whose operations are abdominal.⁶ A patient who meets any two of these criteria is highly likely to benefit from prophylaxis. When host factors suggest that the probability of a surgical site infection is significant, administration of cefazolin at induction of anesthesia is appropriate prophylaxis. Vancomycin should be substituted in patients who are allergic to cephalosporins or who are susceptible to major immediate hypersensitivity reactions to penicillin.

When certain prostheses (e.g., heart valves, vascular grafts, and orthopedic hardware) are used, prophylaxis is justified when viewed in the light of the cost of a surgical site infection to the patient's health. Prophylaxis with either cefazolin or vancomycin is appropriate for car-

diac, vascular, or orthopedic patients who receive prostheses.

Catheters for dialysis or nutrition, pacemakers, and shunts of various sorts are prone to infection mostly for technical reasons, and prophylaxis is not usually required. Meta-analysis indicates, however, that antimicrobial prophylaxis reduces the infection rate in CSF shunts by 50%.¹⁰⁹ Beneficial results may also be achievable for other permanently implanted shunts (e.g., peritoneovenous) and devices (e.g., long-term venous access catheters and pacemakers); however, the studies needed to confirm this possibility will never be done, because the infection rates are low and the sample sizes would have to be prohibitively large. The placement of such foreign bodies is a clean operation, and the use of antibiotics should be based on local experience.

CLEAN-CONTAMINATED CASES

Abdominal procedures. In biliary tract procedures (open or laparoscopic), prophylaxis is required only for patients at high risk: those whose common bile duct is likely to be explored (because of jaundice, bile duct obstruction, stones in the common bile duct, or a reoperative biliary procedure); those with acute cholecystitis; and those older than 70 years. A single dose of cefazolin is adequate. In hepatobiliary and pancreatic procedures, antibiotic prophylaxis is always warranted because these operations are clean-contaminated, because they are long, because they are abdominal, or for all of these reasons. Prophylaxis is also warranted for therapeutic endoscopic retrograde cholangiopancreatography. In gastroduodenal procedures, patients whose gastric acidity is normal or high and in whom bleeding, cancer, gastric ulcer, and obstruction are absent are at low risk for infection and require no prophylaxis; all other patients are at high risk and require prophylaxis. Patients undergoing operation for morbid obesity should receive double the usual prophylactic dose¹¹⁰; cefazolin is an effective agent.

Operations on the head and neck (including the esophagus). Patients whose operation is of significance (i.e., involve entry into the oral cavity, the pharynx, or the esophagus) require prophylaxis.

Gynecologic procedures. Patients whose operation is either high-risk cesarean section, abortion, or vaginal or abdominal hysterectomy will benefit from cefazolin. Aqueous penicillin G or doxycycline may be preferable for first-trimester abortions in patients with a history of pelvic inflammatory disease. In patients with cephalosporin allergy, doxycycline is effective for those having hysterectomies and metronidazole for those having cesarean sections. Women delivering by cesarean section should be given the antibiotic immediately after cord clamping.

Urologic procedures. In principle, antibiotics are not required in patients with sterile urine. Patients with positive cultures should be treated. If an operative procedure is performed, a single dose of the appropriate antibiotic will suffice.

(continued)

proofed are impermeable, but they can be washed only 75 times. Economics plays a role in the choice of drape fabric because entirely disposable drapes are expensive. Local institutional factors may be significant in the role of a specific type of drape in the prevention of SSI.

PROBABILITY OF CONTAMINATION

The probability of contamination is largely defined by the nature of the operation [see Table 1]. However, other factors contribute to the probability of contamination; the most obvious is the expected duration of the operative procedure, which, whenever examined, has been significantly correlated with the wound infection rate.^{6,10,12} The longer the procedure lasts, the more bacteria accumulate in a wound; the sources of bacteria include the patient, the operating team (gowns, gloves with holes, wet drapes), the OR, and the equipment. In addition, the patient undergoing a longer operation is likely to be older, to have other diseases, and to have cancer of—or to be undergoing operation on—a structure

with possible contamination. A longer duration, even of a clean operation, represents increased time at risk for contamination. These points, in addition to pharmacologic considerations, suggest that the surgeon should be alert to the need for a second dose of prophylactic antibiotics [see Sidebar Antibiotic Prophylaxis of Infection].

Abdominal operation is another risk factor not found in the NNIS risk assessment.^{6,8} Significant disease and age are additional factors that play a role in outcome; however, because the major concentrations of endogenous bacteria are located in the abdomen, abdominal operations are more likely to involve bacterial contamination.

For some years, postoperative contamination of the wound has been considered unlikely. However, one report of SSI in sternal incisions cleaned and redressed 4 hours postoperatively clearly shows that wounds can be contaminated and become infected in the postoperative period.²⁶ Accordingly, use of a dry dressing for 24 hours seems prudent.

Antibiotic Prophylaxis of Infection (*continued*)

CONTAMINATED CASES

Abdominal procedures. In colorectal procedures, antibiotics active against both aerobes and anaerobes are recommended. In appendectomy, SSI prophylaxis requires an agent or combination of agents active against both aerobes and anaerobes; a single dose of cefoxitin, 2 g I.V., or, in patients who are allergic to β -lactam antibiotics, metronidazole, 500 mg I.V., is effective. A combination of an aminoglycoside and clindamycin is effective if the appendix is perforated; a therapeutic course of 3 to 5 days is appropriate but does not seem warranted unless the patient is particularly ill. A laparotomy without a precise diagnosis is usually an emergency procedure and demands preoperative prophylaxis. If the preoperative diagnosis is a ruptured viscus (e.g., the colon or the small bowel), both an agent active against aerobes and an agent active against anaerobes are required. Depending on operative findings, prophylaxis may be sufficient or may have to be supplemented with postoperative antibiotic therapy.

Trauma. The proper duration of antibiotic prophylaxis for trauma patients is a confusing issue—24 hours or less of prophylaxis is probably adequate, and more than 48 hours is certainly unwarranted. When laparotomy is performed for nonpenetrating injuries, prophylaxis should be administered. Coverage of both aerobes and anaerobes is mandatory. The duration of prophylaxis should be less than 24 hours. In cases of penetrating abdominal injury, prophylaxis with either cefoxitin or a combination of agents active against anaerobic and aerobic organisms is required. The duration of prophylaxis should be less than 24 hours, and in many cases, perioperative doses will be adequate. For open fractures, management should proceed as if a therapeutic course were required. For grade I or II injuries, a first-generation cephalosporin will suffice, whereas for grade III injuries, combination therapy is warranted; duration may vary. For operative repair of fractures, a single dose of cefazolin may be given preoperatively, with a second dose added if the procedure is long. Patients with major soft tissue injury with a danger of spreading infection will benefit from cefazolin, 1 g I.V. every 8 hours for 1 to 3 days.

DIRTY OR INFECTED CASES

Infected cases require therapeutic courses of antibiotics; prophylaxis is not appropriate in this context. In dirty cases, particularly those re-

sulting from trauma, contamination and tissue destruction are usually so extensive that the wounds must be left open for delayed primary or secondary closure. Appropriate timing of wound closure is judged at the time of debridement. Antibiotics should be administered as part of resuscitation. Administration of antibiotics for 24 hours is probably adequate if infection is absent at the outset. However, a therapeutic course of antibiotics is warranted if infection is present from the outset or if more than 6 hours elapsed before treatment of the wounds was initiated.

Prophylaxis of Endocarditis

Studies of the incidence of endocarditis associated with dental procedures, endoscopy, or operations that may result in transient bacteremia are lacking. Nevertheless, the consensus is that patients with specific cardiac and vascular conditions are at risk for endocarditis or vascular prosthetic infection when undergoing certain procedures; these patients should receive prophylactic antibiotics.¹¹¹⁻¹¹³ A variety of organisms are dangerous, but viridans streptococci are most common after dental or oral procedures, and enterococci are most common if the portal of entry is the GU or GI tract. Oral amoxicillin now replaces penicillin V or ampicillin because of superior absorption and better serum levels. In penicillin-allergic patients, clindamycin is recommended; alternatives include cephalexin, cefadroxil, azithromycin, and clarithromycin. When there is a risk of exposure to bowel flora or enterococci, oral amoxicillin may be given. If an I.V. regimen is indicated, ampicillin may be given, with gentamicin added if the patient is at high risk for endocarditis. In patients allergic to penicillin, vancomycin is appropriate, with gentamicin added in high-risk patients. These parenteral regimens should be reserved for high-risk patients undergoing procedures with a significant probability of bacteremia.

In patients receiving penicillin-based prophylaxis because of a history of rheumatic fever, erythromycin rather than amoxicillin should be used to protect against endocarditis.¹¹¹ There is consensus concerning prophylaxis for orthopedic prostheses and acquired infection after transient bacteremia. In major procedures, where the risk of bacteremia is significant, the above recommendations are pertinent.

BACTERIAL PROPERTIES

Not only is the size of the bacterial inoculum important; the bacterial properties of virulence and pathogenicity are also significant.

The most obvious pathogenic bacteria in surgical patients are gram-positive cocci (e.g., *Staphylococcus aureus* and streptococci). With modern hygienic practice, it would be expected that *S. aureus* would be found mostly in clean cases, with a wound infection incidence of 1% to 2%; however, it is in fact an increasingly common pathogen in SSIs. Surveillance can be very useful in identifying either wards or surgeons with increased rates. Operative procedures in infected areas have an increased infection rate because of the high inoculum with actively pathogenic bacteria.

The preoperative hospital stay has frequently been found to make an important contribution to wound infection rates.¹² The usual explanation is that during this stay, either more endogenous bacteria are present or commensal flora is replaced by hospital flora. More likely, the patient's clinical picture is a complex one, often entailing exhaustive workup of more than one organ system,

various complications, and a degree of illness that radically changes the host's ability to deal with an inoculum, however small. Therefore, multiple factors combine to transform the hospitalized preoperative patient into a susceptible host. Same-day admission should eliminate any bacterial impact associated with the preoperative hospital stay.

Bacteria with multiple antibiotic resistance (e.g., methicillin-resistant *S. aureus* [MRSA], *S. epidermidis*, and vancomycin-resistant enterococci [VRE]) can be associated with significant SSI problems. In particular, staphylococci, with their natural virulence, present an important hazard if inappropriate prophylaxis is used.

Many surgeons consider it inappropriate or unnecessary to obtain good culture and sensitivity data on SSIs; instead of conducting sensitivity testing, they simply drain infected wounds, believing that the wounds will heal. However, there have been a number of reports of SSIs caused by unusual organisms^{23,26,27}; these findings underscore the usefulness of culturing pus or fluid when an infection is being drained. SSIs caused by antibiotic-resistant organisms or unusual pathogens call for specific prophylaxis, perhaps other infection control efforts, and, if the problem persists, a search for a possible carrier or a common source.^{21-23,26,27}

SURGEONS AND BACTERIA

The surgeon's perioperative rituals are designed to reduce or eliminate bacteria from the operative field. Many old habits are obsolete [see 1:1 Preparation of the Operating Room and Discussion, Hand Washing, below]. Nonetheless, it is clear that surgeons can influence SSI rates.¹³ The refusal to use delayed primary closure or secondary closure is an example. Careful attention to the concepts of asepsis and antisepsis in the preparation and conduct of the operation is important. Although no single step in the ritual of preparing a patient for the operative procedure is indispensable, it is likely that certain critical standards of behavior must be maintained to achieve good results.

The measurement and publication of data about individuals or hospitals with high SSI rates have been associated with a diminution of those rates [see Table 6].^{12,13,28} It is uncertain by what process the diffusion of these data relates to the observed improvements. Although surveillance has unpleasant connotations, it provides objective data that individual surgeons are often too busy to acquire but that can contribute to improved patient care. For

example, such data can be useful in identifying problems (e.g., the presence of MRSA, a high SSI incidence, or clusters), maintaining quality assurance, and allowing comparison with accepted standards.

Environment: Local Factors

Local factors influence SSI development because they affect the size of the bacterial inoculum that is required to produce an infection: in a susceptible wound, a smaller inoculum produces infection [see Figure 2].

THE SURGEON'S INFLUENCE

Most of the local factors that make a surgical site favorable to bacteria are under the control of the surgeon. Although Halsted usually receives, deservedly so, the credit for having established the importance of technical excellence in the OR in preventing infection, individual surgeons in the distant past achieved remarkable results by careful attention to cleanliness and technique.²⁹ The Halstedian principles dealt with hemostasis, sharp dissection, fine sutures, anatomic dissection, and the gentle handling of tissues. Mass ligatures, large or braided nonabsorbable sutures, necrotic tissue, and the creation of hematomas or seromas must be avoided, and foreign materials must be judiciously used because these techniques and materials change the size of the inoculum required to initiate an infectious process. Logarithmically fewer bacteria are required to produce infection in the presence of a foreign body (e.g., suture, graft, metal, or pacemaker) or necrotic tissue (e.g., that caused by gross hemostasis or injudicious use of electrocautery devices).

The differences in inoculum required to produce wound infections can be seen in a model in which the two variables are the wound hematocrit and the presence of antibiotic [see Figure 3]. In the absence of an antibiotic and in the presence of wound fluid with a hematocrit of more than 8%, 10 bacteria yield a wound infection rate of 20%. In a technically good wound with no antibiotic, however, 1,000 bacteria produce a wound infection rate of 20%.¹¹ In the presence of an antibiotic, 10⁵ to 10⁶ bacteria are required.

Drains

The use of drains varies widely and is very subjective. All surgeons are certain that they understand when to use a drain. However, certain points are worth noting. It is now recognized that a simple Penrose drain may function as a drainage route but is also an access route by which pathogens can reach the patient.³⁰ It is important that the operative site not be drained through the wound. The use of a closed suction drain reduces the potential for contamination and infection.

Many operations on the GI tract can be performed safely without employing prophylactic drainage.³¹ A review and meta-analysis from 2004 concluded that (1) after hepatic, colonic, or rectal resection with primary anastomosis and after appendectomy for any stage of appendicitis, drains should be omitted (recommendation grade A), and (2) after esophageal resection and total gastrectomy, drains should be used (recommendation grade D). Additional randomized, controlled trials will be required to determine the value of prophylactic drainage for other GI procedures, especially those involving the upper GI tract.

Table 3 Conditions and Procedures That Require Antibiotic Prophylaxis against Endocarditis^{111,112}

CONDITIONS

Cardiac

- Prosthetic cardiac valves (including biosynthetic valves)
- Most congenital cardiac malformations
- Surgically constructed systemic-pulmonary shunts
- Rheumatic and other acquired valvular dysfunction
- Idiopathic hypertrophic subaortic stenosis
- History of bacterial endocarditis
- Mitral valve prolapse causing mitral insufficiency
- Surgically repaired intracardiac lesions with residual hemodynamic abnormality or < 6 mo after operation

Vascular

- Synthetic vascular grafts

PROCEDURES

Dental or oropharyngeal

- Procedures that may induce bleeding
- Procedures that involve incision of the mucosa

Respiratory

- Rigid bronchoscopy

Incision and drainage or debridement of sites of infection

Urologic

- Cystoscopy with urethral dilatation
- Urinary tract procedures
- Catheterization in the presence of infected urine

Gynecologic

- Vaginal hysterectomy
- Vaginal delivery in the presence of infection

Gastrointestinal

- Procedures that involve incision or resection of mucosa
- Endoscopy that involves manipulation (e.g., biopsy, dilatation, or sclerotherapy) or ERCP

Table 4 Antibiotics for Prevention of Endocarditis^{55,111}

Manipulative Procedure	Prophylactic Regimen*	
	Usual	In Patients with Penicillin Allergy
Dental procedures likely to cause gingival bleeding; operations or instrumentation of the upper respiratory tract	<p><i>Oral</i> Amoxicillin, 2.0 g 1 hr before procedure</p> <p><i>Parenteral</i> Ampicillin, 2.0 g I.M. or I.V. 30 min before procedure</p>	<p><i>Oral</i> Clindamycin, 600 mg 1 hr before procedure or Cephalexin or cefadroxil,[†] 2.0 g 1 hr before procedure or Azithromycin or clarithromycin, 500 mg 1 hr before procedure</p> <p><i>Parenteral</i> Clindamycin, 600 mg I.V. within 30 min before procedure or Cefazolin, 1.0 g I.M. or I.V. within 30 min before procedure</p>
Gastrointestinal or genitourinary operation; abscess drainage	<p><i>Oral</i> Amoxicillin, 2.0 g 1 hr before procedure</p> <p><i>Parenteral</i> Ampicillin, 2.0 g I.M. or I.V. within 30 min before procedure; if risk of endocarditis is considered high, add gentamicin, 1.5 mg/kg (to maximum of 120 mg) I.M. or I.V. 30 min before procedure[‡]</p>	<p>Vancomycin, 1.0 g I.V. infused slowly over 1 hr, beginning 1 hr before procedure; if risk of endocarditis is considered high, add gentamicin, 1.5 mg/kg (to maximum of 120 mg) I.M. or I.V. 30 min before procedure[‡]</p>

*Pediatric dosages are as follows: oral amoxicillin, 50 mg/kg; oral or parenteral clindamycin, 20 mg/kg; oral cephalexin or cefadroxil, 50 mg/kg; oral azithromycin or clarithromycin, 15 mg/kg; parenteral ampicillin, 50 mg/kg; parenteral cefazolin, 25 mg/kg; parenteral gentamicin, 2 mg/kg; parenteral vancomycin, 20 mg/kg. Total pediatric dose should not exceed total adult dose.

[†]Patients with a history of immediate-type sensitivity to penicillin should not receive these agents.

[‡]High-risk patients should also receive ampicillin, 1.0 g I.M. or I.V., or amoxicillin, 1.0 g p.o., 6 hr after procedure.

Duration of Operation

In most studies,^{6,10,12} contamination certainly increases with time (see above). Wound edges can dry out, become macerated, or in other ways be made more susceptible to infection (i.e., requiring fewer bacteria for development of infection). Speed and poor technique are not suitable approaches; expeditious operation is appropriate.

Electrocautery

The use of electrocautery devices has been clearly associated with an increase in the incidence of superficial SSIs. However, when such devices are properly used to provide pinpoint coagulation (for which the bleeding vessels are best held by fine forceps) or to divide tissues under tension, there is minimal tissue destruction, no charring, and no change in the wound infection rate.³⁰

PATIENT FACTORS

Local Blood Flow

Local perfusion can greatly influence the development of infection, as is seen most easily in the tendency of the patient with peripheral vascular disease to acquire infection of an extremity. As a local problem, inadequate perfusion reduces the number of bacteria required for infection, in part because inadequate perfusion leads to decreased tissue levels of oxygen. Shock, by reducing local perfusion, also greatly enhances susceptibility to infection. Fewer organisms are required to produce infection during or immediately after shock [see Figure 4].

To counter these effects, the arterial oxygen tension (P_{aO_2}) must be translated into an adequate subcutaneous oxygen level (determined by measuring transcutaneous oxygen tension)³²; this, together with adequate perfusion, will provide local protection by increasing the number of bacteria required to produce infection. Provision of supplemental oxygen in the perioperative period may

lead to a reduced SSI rate, probably as a consequence of increased tissue oxygen tension,³³ though the value of this practice has been questioned.³⁴ If the patient is not intubated, a mask, not nasal prongs, is required.³⁵

Barrier Function

Inadequate perfusion may also affect the function of other organs, and the resulting dysfunction will, in turn, influence the patient's susceptibility to infection. For example, ischemia-reperfusion injury to the intestinal tract is a frequent consequence of hypovolemic shock and bloodstream infection. Inadequate perfusion of the GI tract may also occur during states of fluid and electrolyte imbalance or when cardiac output is marginal. In experimental studies, altered blood flow has been found to be associated with the breakdown of bowel barrier function—that is, the inability of the intestinal tract to prevent bacteria, their toxins, or both from moving from the gut lumen into tissue at a rate too fast to permit clearance by the usual protective mechanisms. A variety of experimental approaches aimed at enhancing bowel barrier function have been studied; at present, however, the most clinically applicable method of bowel protection is initiation of enteral feeding (even if the quantity of nutrients provided does not satisfy all the nutrient requirements) and administration of the amino acid glutamine [see 8:23 Nutritional Support]. Glutamine is a specific fuel for enterocytes and colonocytes and has been found to aid recovery of damaged intestinal mucosa and enhance barrier function when administered either enterally or parenterally.

Advanced Age

Aging is associated with structural and functional changes that render the skin and subcutaneous tissues more susceptible to infection. These changes are immutable; however, they must be evaluated in advance and addressed by excellent surgical technique and, on occasion, prophylactic antibiotics [see Sidebar Antibiotic Prophylaxis of Infection]. SSI rates increase with aging until the age of 65 years, after which point the incidence appears to decline.³⁶

Preoperative Preparation of the Operative Site

The sole reason for preparing the patient's skin before an operation is to reduce the risk of wound infection. A preoperative antiseptic bath is not necessary for most surgical patients, but their personal hygiene must be assessed and preoperative cleanliness established. Multiple preoperative baths may prevent postoperative infection in selected patient groups, such as those who carry *Staphylococcus aureus* on their skin or who have infectious lesions. Chlorhexidine gluconate is the recommended agent for such baths.¹¹⁴

Hair should not be removed from the operative site unless it physically interferes with accurate anatomic approximation of the wound edges.¹¹⁵ If hair must be removed, it should be clipped in the OR.¹⁴ Shaving hair from the operative site, particularly on the evening before operation or immediately before wound incision in the OR, increases the risk of wound infection. Depilatories are not recommended, because they cause serious irritation and rashes in a significant number of patients, especially when used near the eyes and the genitalia.¹¹⁶

In emergency procedures, obvious dirt, grime, and dried blood should be mechanically cleansed from the operative site by using sufficient friction. In one study, cleansing of contaminated wounds by means of ultrasound debridement was compared with high-pressure irrigation and soaking. The experimental wounds were contaminated with a colloidal clay that potentiates infection 1,000-fold. The investigators irrigated wounds at pressures of 8 to 10 psi, a level obtained by using a 30 ml syringe with a 1.5 in. long 19-gauge needle and 300 ml of 0.85% sterile saline solution. High-pressure irrigation removed slightly more particulate matter (59%) than ultrasound debridement (48%), and both of these methods removed more matter than soaking (26%).¹¹⁷ Both ultrasound debridement and high-pressure irrigation were also effective in reducing the wound infection rate in experimental wounds contaminated with a subinfective dose of *S. aureus*.

For nonemergency procedures, the necessary reduction in microorganisms can be achieved by using povidone-iodine (10% available povidone-iodine and 1% available iodine) or chlorhexidine gluconate both for mechanical cleansing of the intertriginous folds and the umbilicus and for painting the operative site. Which skin antiseptic is optimal is unclear. The best option appears to be chlorhexidine gluconate or an iodophor.¹¹⁸ The patient should be assessed for evidence of sensitivity to the antiseptic (particularly if the agent contains iodine) to minimize the risk of an allergic reaction. What some patients report as iodine allergies are actually iodine burns. Iodine in alcohol or in water is associated with an increased risk of skin irritation,⁹⁰ particularly at the edges of the operative field, where the iodine concentrates as the alcohol evaporates. Iodine should therefore be removed after sufficient contact time with the skin, especially at the edges. Iodophors do not irritate the skin and thus need not be removed.

Host Defense Mechanisms

The systemic response is designed to control and eradicate infection. Many factors can inhibit systemic host defense mechanisms; some are related to the surgical disease, others to the patient's underlying disease or diseases and the events surrounding the operation.

SURGEON-RELATED FACTORS

There are a limited number of ways in which the surgeon can improve a patient's systemic responses to surgery. Nevertheless,

when appropriate, attempts should be made to modify the host. The surgeon and the operation are both capable of reducing immunologic efficacy; hence, the operative procedure should be carried out in as judicious a manner as possible. Minimal blood loss, avoidance of shock, and maintenance of blood volume, tissue perfusion, and tissue oxygenation all will minimize trauma and will reduce the secondary, unintended immunologic effects of major procedures.

Diabetes has long been recognized as a risk factor for infection and for SSI in particular. Three studies from the past decade demonstrated the importance of glucose control for reducing SSI rates in both diabetic and nondiabetic patients who underwent operation,^{37,38} as well as in critically ill ICU patients.³⁹ Glucose control is required throughout the entire perioperative period. The beneficial effect appears to lie in the enhancement of host defenses. The surgical team must also ensure maintenance of adequate tissue oxygen tension^{32,33} and maintenance of normothermia.⁴⁰

When abnormalities in host defenses are secondary to surgical disease, the timing of the operation is crucial to outcome. With acute and subacute inflammatory processes, early operation helps restore normal immune function. Deferral of definitive therapy frequently compounds problems.

PATIENT FACTORS

Surgeons have always known that the patient is a significant variable in the outcome of operation. Various clinical states are associated with altered resistance to infection. In all patients, but particularly those at high risk, SSI creates not only wound complications but also significant morbidity (e.g., reoperation, incisional hernia, secondary infection, impaired mobility, increased hospitalization, delayed rehabilitation, or permanent disability) and occasional mortality.²² SENIC has proposed that the risk of wound infection be assessed not only in terms of prob-

Table 5 Parenteral Antibiotics Commonly Used for Broad-Spectrum Coverage of Colonic Microflora

COMBINATION THERAPY OR PROPHYLAXIS	
<i>Aerobic Coverage</i>	
(to be combined with a drug having anaerobic activity)	
Amikacin	Ciprofloxacin
Aztreonam	Gentamicin
Ceftriaxone	Tobramycin
<i>Anaerobic Coverage</i>	
(to be combined with a drug having aerobic activity)	
Chloramphenicol	Metronidazole
Clindamycin	
SINGLE-DRUG THERAPY OR PROPHYLAXIS	
<i>Aerobic-Anaerobic Coverage</i>	
Ampicillin-sulbactam	Imipenem-cilastatin*
Cefotetan	Piperacillin-tazobactam
Cefoxitin	Ticarcillin-clavulanate
Ceftizoxime

Table 6 Effect of Surveillance and Feedback on Wound Infection Rates in Two Hospitals²⁸

		Period 1	Period 2*
Hospital A	Number of wounds	1,500	1,447
	Wound infection rate	8.4%	3.7%
Hospital B	Number of wounds	1,746	1,939
	Wound infection rate	5.7%	3.7%

*Periods 1 and 2 were separated by an interval during which feedback on wound infection rates was analyzed.

ability of contamination but also in relation to host factors.^{6,7,9} According to this study, patients most clearly at risk for wound infection are those with three or more concomitant diagnoses; other patients who are clearly at risk are those undergoing a clean-contaminated or contaminated abdominal procedure and those undergoing any procedure expected to last longer than 2 hours. These last two risk groups are affected by a bacterial component, but all those patients who are undergoing major abdominal procedures or lengthy operations generally have a significant primary pathologic condition and are usually older, with an increased frequency of concomitant conditions. The NNIS system uses most of the same concepts but expresses them differently. In the NNIS study, host factors in the large study are evaluated in terms of the ASA score. Duration of operation is measured differently as well, with a lengthy operation being defined by the NNIS as one that is at or above the 75th percentile for operating time. Bacterial contamination remains a risk factor, but operative site is eliminated.⁸

Shock has an influence on the incidence of wound infection [see Figure 4]. This influence is most obvious in cases of trauma, but there are significant implications for all patients in regard to maintenance of blood volume, hemostasis, and oxygen-carrying capacity. The effect of shock on the risk of infection appears to be not only immediate (i.e., its effect on local perfusion) but also late because systemic responses are blunted as local factors return to normal.

Advanced age, transfusion, and the use of steroids and other immunosuppressive drugs, including chemotherapeutic agents, are associated with an increased risk of SSI.^{41,42} Often, these factors cannot be altered; however, the proper choice of operation, the appropriate use of prophylaxis, and meticulous surgical technique can reduce the risk of such infection by maintaining patient homeostasis, reducing the size of any infecting microbial inoculum, and creating a wound that is likely to heal primarily.

Smoking is associated with a striking increase in SSI incidence. As little as 1 week of abstinence from smoking will make a positive difference.⁴³

Pharmacologic therapy can affect host response as well. Nonsteroidal anti-inflammatory drugs that attenuate the production of certain eicosanoids can greatly alter the adverse effects of infection by modifying fever and cardiovascular effects. Operative procedures involving inhalational anesthetics result in an immediate rise in plasma cortisol concentrations. The steroid response and the associated immunomodulation can be modified by using high epidural anesthesia as the method of choice; pituitary adrenal activation will be greatly attenuated. Some drugs that inhibit steroid elaboration (e.g., etomidate) have also been shown to be capable of modifying perioperative immune responses.

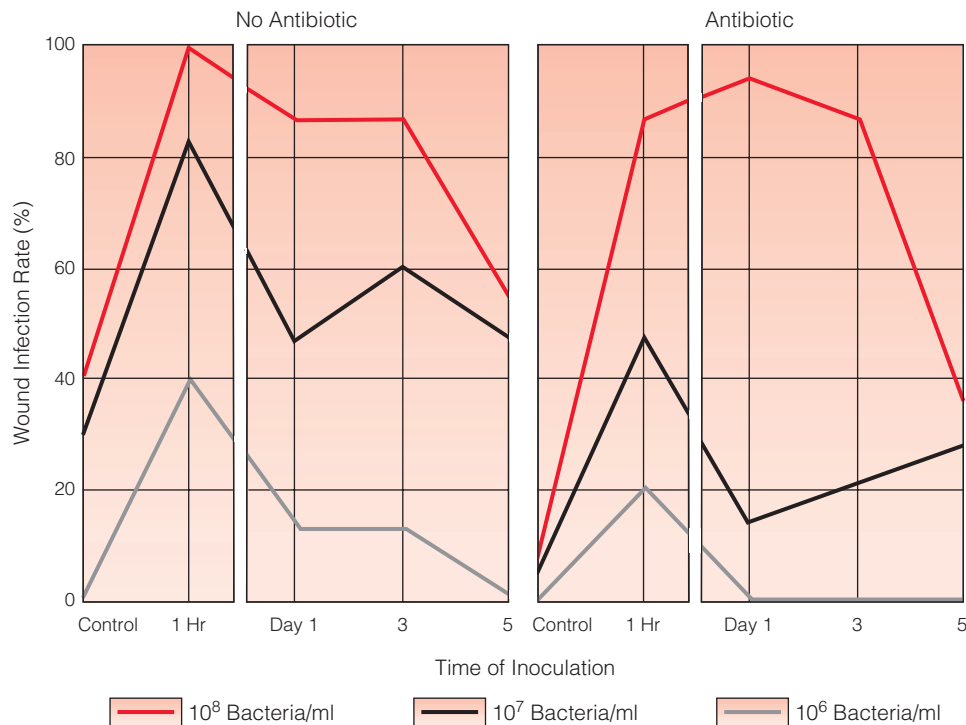

Figure 4 Animals exposed to hemorrhagic shock followed by resuscitation show an early decreased resistance to wound infection. There is also a persistent influence of shock on the development of wound infection at different times of inoculation after shock. The importance of inoculum size (10⁶/ml to 10⁸/ml) and the effect of antibiotic on infection rates are evident at all times of inoculation.¹⁰³

Table 7 Determinants of Infection and Factors That Influence Wound Infection Rates

Variable	Determinant of Infection		
	Bacteria	Wound Environment (Local Factors)	Host Defense Mechanisms (Systemic Factors)

Smoking ⁴³		B	C

ANESTHESIOLOGIST-RELATED FACTORS

A 2000 commentary in *The Lancet* by Donal Buggy considered the question of whether anesthetic management could influence surgical wound healing.⁴⁴ In addition to the surgeon- and patient-related factors already discussed (see above), Buggy cogently identified a number of anesthesiologist-related factors that could contribute to better wound healing and reduced wound infection. Some of these factors (e.g., pain control, epidural anesthesia, and autologous transfusion) are unproven but nonetheless make sense and should certainly be tested. Others (e.g., tissue perfusion, intravascular volume, and—significantly—maintenance of normal perioperative body temperature) have undergone formal evaluation. Very good studies have shown that dramatic reductions in SSI rates can be achieved through careful avoidance of hypothermia.^{40,45} Patient-controlled analgesia pumps are known to be associated with increased SSI rates, through a mechanism that is currently unknown.⁴⁶ Infection control practices are required of all practitioners; contamination of anesthetic drugs by bacteria has resulted in numerous small outbreaks of SSI.^{47,48}

terial contamination has come to be generally well managed, the importance of all members of the surgical team in the prevention of SSI has become increasingly apparent. The crux of Buggy's commentary may be expressed as follows: details make a difference, and all of the participants in a patient's surgical journey can contribute to a continuing decrease in SSI. It is a systems issue.

INTEGRATION OF DETERMINANTS

As operative infection rates slowly fall, despite the performance of increasingly complex operations in patients at greater risk, surgeons are approaching the control of infection with a broader view than simply that of asepsis and antisepsis. This new, broader view must take into account many variables, of which some have no relation to bacteria but all play a role in SSI [see Table 7 and Figure 1].

To estimate risk, one must integrate the various determinants of infection in such a way that they can be applied to patient care. Much of this exercise is vague. In reality, the day-to-day practice of surgery includes a risk assessment that is essentially a form of logistic regression, though not recognized as such. Each surgeon's assessment of the probability of whether an SSI will occur takes into account the determining variables:

$$\text{Probability of SSI} = x + a (\text{bacteria}) + b (\text{environment: local factors}) + c (\text{host defense mechanisms: systemic factors})$$

Discussion

Antibiotic Prophylaxis of Surgical Site Infection

It is difficult to understand why antibiotics have not always prevented SSI successfully. Certainly, surgeons were quick to appreciate the possibilities of antibiotics; nevertheless, the efficacy of antibiotic prophylaxis was not proved until the late 1960s.¹¹ Studies before then had major design flaws—principally, the administration of the antibiotic some time after the start of the operation, often in the recovery room. The failure of studies to demonstrate efficacy and the occasional finding that prophylactic antibiotics worsened rather than improved outcome led in the late

1950s to profound skepticism about prophylactic antibiotic use in any operation.

The principal reason for the apparent inefficacy was inadequate understanding of the biology of SSIs. Fruitful study of antibiotics and how they should be used began after physiologic groundwork established the importance of local blood flow, maintenance of local immune defenses, adjuvants, and local and systemic perfusion.⁴⁹

The key antibiotic study, which was conducted in guinea pigs, unequivocally proved the following about antibiotics:

1. They are most effective when given before inoculation of bacteria.
2. They are ineffective if given 3 hours after inoculation.
3. They are of intermediate effectiveness when given in between these times [see Figure 5].⁵⁰

Although efficacy with a complicated regimen was demonstrated in 1964,⁵¹ the correct approach was not defined until 1969.¹¹ Established by these studies are the philosophical and practical bases of the principles of antibiotic prophylaxis of SSI in all surgical arenas^{11,50}: that prophylactic antibiotics must be given preoperatively within 2 hours of the incision, in full dosage, parenterally, and for a very limited period. These principles remain essentially unchanged despite minor modifications from innumerable subsequent studies.⁵²⁻⁵⁶ Prophylaxis for colorectal operations is discussed elsewhere [see Infection Prevention in Bowel Surgery, below].

PRINCIPLES OF PATIENT SELECTION

Patients must be selected for prophylaxis on the basis of either their risk for SSI or the cost to their health if an SSI develops (e.g., after implantation of a cardiac valve or another prosthesis). The most important criterion is the degree of bacterial contamination expected to occur during the operation. The traditional classification of such contamination was defined in 1964 by the historic National Academy of Sciences–National Research Council study.⁵ The important features of the classification are its simplicity, ease of understanding, ease of coding, and reliability. Classification is dependent on only one variable—the bacterial inoculum—and the effects of this variable are now controllable by antimicrobial prophylaxis. Advances in operative technique, general care, antibiotic

use, anesthesia, and surveillance have reduced SSI rates in all categories that were established by this classification [see Table 8].^{6,12,13,51}

In 1960, after years of negative studies, it was said, “Nearly all surgeons now agree that the routine use of prophylaxis in clean operations is unnecessary and undesirable.”⁵⁷ Since then, much has changed: there are now many clean operations for which no competent surgeon would omit the use of prophylactic antibiotics, particularly as procedures become increasingly complex and prosthetic materials are used in patients who are older, sicker, or immunocompromised.

A separate risk assessment that integrates host and bacterial variables (i.e., whether the operation is dirty or contaminated, is longer than 2 hours, or is an abdominal procedure and whether the patient has three or more concomitant diagnoses) segregates more effectively those patients who are prone to an increased incidence of SSI [see Integration of Determinants of Infection, below]. This approach enables the surgeon to identify those patients who are likely to require preventive measures, particularly in clean cases, in which antibiotics would normally not be used.⁶

The prototypical clean operation is an inguinal hernia repair. Technical approaches have changed dramatically over the past 10 years, and most primary and recurrent hernias are now treated with a tension-free mesh-based repair. The use of antibiotics has become controversial. In the era of repairs under tension, there was some evidence to suggest that a perioperative antibiotic (in a single preoperative dose) was beneficial.⁵⁸ Current studies, however, do not support antibiotic use in tension-free mesh-based inguinal hernia repairs.^{59,60} On the other hand, if surveillance indicates that there is a local or regional problem⁶¹ with SSI after hernia surgery, antibiotic prophylaxis (again in the form of single preoperative dose) is appropriate. Without significantly more supportive data, prophylaxis for clean cases cannot be recommended unless specific risk factors are present.

Data suggest that prophylactic use of antibiotics may contribute to secondary *Clostridium difficile* disease; accordingly, caution should be exercised when widening the indications for prophylaxis is under consideration.⁶² If local results are poor, surgical practice should be reassessed before antibiotics are prescribed.

ANTIBIOTIC SELECTION AND ADMINISTRATION

When antibiotics are given more than 2 hours before operation, the risk of infection is increased.^{52,54} I.V. administration in the OR or the preanesthetic room guarantees appropriate levels at the time of incision. The organisms likely to be present dictate the choice of antibiotic for prophylaxis. The cephalosporins are ideally suited to prophylaxis: their features include a broad spectrum of activity, an excellent ratio of therapeutic to toxic dosages, a low rate of allergic responses, ease of administration, and attractive cost advantages. Mild allergic reactions to penicillin are not contraindications for the use of a cephalosporin.

Physicians like new drugs and often tend to prescribe newer, more expensive antibiotics for simple tasks. First-generation cephalosporins (e.g., cefazolin) are ideal agents for prophylaxis. Third-generation cephalosporins are not: they cost more, are not more effective, and promote emergence of resistant strains.^{63,64}

The most important first-generation cephalosporin for surgical patients continues to be cefazolin. Administered I.V. in the OR at the time of skin incision, it provides adequate tissue levels throughout most of the operation. A second dose administered in the OR after 3 hours will be beneficial if the procedure lasts longer than that. Data on all operative site infections are imprecise, but SSIs

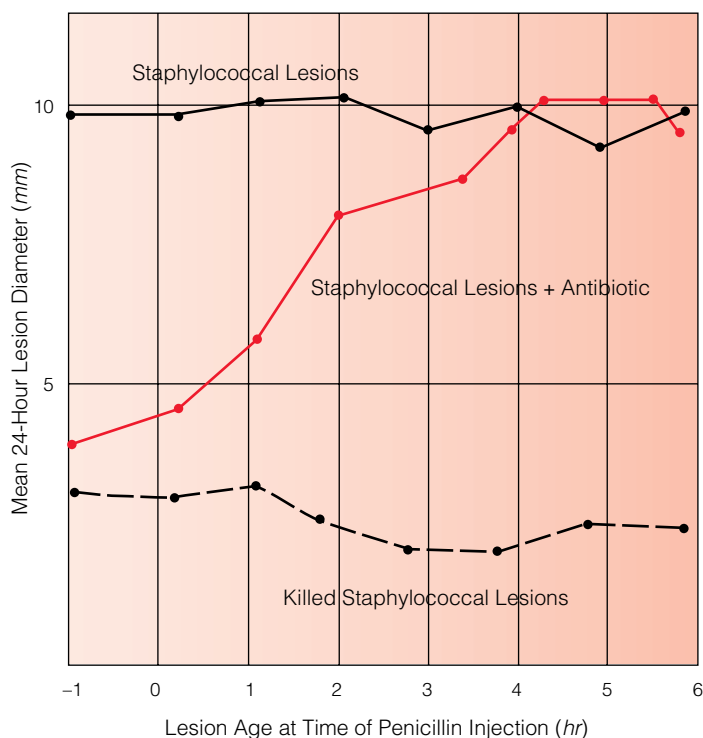

Figure 5 In a pioneer study of antibiotic prophylaxis,⁵⁰ the diameter of lesions induced by staphylococcal inoculation 24 hours earlier was observed to be critically affected by the timing of penicillin administration with respect to bacterial inoculation.

Table 8 Historical Rates of Wound Infection

Wound Classification	Infection Rate (%)				
	1960–1962 ⁵¹ (15,613 patients)	1967–1977 ¹² (62,937 patients)	1975–1976 ⁶ (59,353 patients)	1977–1981 ¹³ (20,193 patients)	1982–1986 ¹⁰⁷ (20,703 patients)
Clean	5.1	1.5	2.9	1.8	1.3
Clean-contaminated	10.8	7.7	3.9	2.9	2.5
Contaminated	16.3	15.2	8.5	9.9	7.1
Dirty-infected	28.0	40.0	12.6	—	—
Overall	7.4	4.7	4.1	2.8	2.2

can clearly be reduced by this regimen. No data suggest that further doses are required for prophylaxis.

Fortunately, cefazolin is effective against both gram-positive and gram-negative bacteria of importance, unless significant anaerobic organisms are encountered. The significance of anaerobic flora has been disputed, but for elective colorectal surgery,⁶⁵ abdominal trauma,^{66,67} appendicitis,⁶⁸ or other circumstances in which penicillin-resistant anaerobic bacteria are likely to be encountered, coverage against both aerobic and anaerobic gram-negative organisms is strongly recommended and supported by the data.

Despite several decades of studies, prophylaxis is not always properly implemented.^{52,54,68,69} Unfortunately, didactic education is not always the best way to change behavior. Preprinted order forms⁷⁰ and a reminder sticker from the pharmacy⁷¹ have proved to be effective methods of ensuring correct utilization.

The commonly heard decision “This case was tough, let’s give an antibiotic for 3 to 5 days” has no data to support it and should be abandoned. Differentiation between prophylaxis and therapy is important. A therapeutic course for perforated diverticulitis or other types of peritoneal infection is appropriate. Data on casual contamination associated with trauma or with operative procedures suggest that 24 hours of prophylaxis or less is quite adequate.⁷²⁻⁷⁴ Mounting evidence suggests that a single preoperative dose is good care and that additional doses are not required.

Trauma Patients

The efficacy of antibiotic administration on arrival in the emergency department as an integral part of resuscitation has been clearly demonstrated.⁶⁶ The most common regimens have been (1) a combination of an aminoglycoside and clindamycin and (2) cefoxitin alone. These two regimens or variations thereof have been compared in a number of studies.^{40,67,75} They appear to be equally effective, and either regimen can be recommended with confidence. For prophylaxis, there appears to be a trend toward using a single drug: cefoxitin or cefotetan.⁵⁵ If therapy is required because of either a delay in surgery, terrible injury, or prolonged shock, the combination of an agent that is effective against anaerobes with an aminoglycoside seems to be favored. Because aminoglycosides are nephrotoxic, they must be used with care in the presence of shock.

In many of the trauma studies just cited, antibiotic prophylaxis lasted for 48 hours or longer. Subsequent studies, however, indicated that prophylaxis lasting less than 24 hours is appropriate.^{73,74,76} Single-dose prophylaxis is appropriate for patients with closed fractures.⁷⁷

COMPLICATIONS

Complications of antibiotic prophylaxis are few. Although data linking prophylaxis to the development of resistant organisms are

meager, resistant microbes have developed in every other situation in which antibiotics have been utilized, and it is reasonable to expect that prophylaxis in any ecosystem will have the same result, particularly if selection of patients is poor, if prophylaxis lasts too long, or if too many late-generation agents are used.

A rare but important complication of antibiotic use is pseudomembranous enterocolitis, which is induced most commonly by clindamycin, the cephalosporins, and ampicillin [see 8:16 *Nosocomial Infection*].⁶² The common denominator among different cases of pseudomembranous enterocolitis is hard to identify. Diarrhea and fever can develop after administration of single doses of prophylactic antibiotics. The condition is rare, but difficulties occur because of failure to make a rapid diagnosis.

CURRENT ISSUES

The most significant questions concerning prophylaxis of SSIs already have been answered. An important remaining issue is the proper duration of prophylaxis in complicated cases, in the setting of trauma, and in the presence of foreign bodies. No change in the criteria for antibiotic prophylaxis is required in laparoscopic procedures; the risk of infection is lower in such cases.^{78,79} Cost factors are important and may justify the endless succession of studies that compare new drugs in competition for appropriate clinical niches.

Further advances in patient selection may take place but will require analysis of data from large numbers of patients and a distinction between approaches to infection of the wound, which is only a part of the operative field, and approaches to infections directly related to the operative site. These developments will define more clearly the prophylaxis requirements of patients whose operations are clean but whose risk of wound or operative site infection is increased.

A current issue of some concern is potential loss of infection surveillance capability. Infection control units have been shown to offer a number of benefits in the institutional setting, such as the following:

1. Identifying epidemics caused by common or uncommon organisms.^{23,26,56}
2. Establishing correct use of prophylaxis (timing, dose, duration, and choice).^{52,55,72}
3. Documenting costs, risk factors, and readmission rates.^{80,81}
4. Monitoring postdischarge infections and secondary consequences of infections.⁸²⁻⁸⁴
5. Ensuring patient safety.⁸⁵
6. Managing MRSA and VRE.⁸⁶

S. aureus—in particular, MRSA—is a major cause of SSI.⁸⁶ Cross-infection problems are a concern, in a manner reminiscent of the preantibiotic era. Hand washing (see below) is coming back into fashion, consistent with the professional behavior toward

cross-infection characteristic of that era. At present, hard evidence is lacking, but clinical observation suggests that *S. aureus* SSIs are especially troublesome and destructive of local tissue and require a longer time to heal than other SSIs do. When *S. aureus* SSIs occur after cardiac surgery, thoracotomy, or joint replacement, their consequences are significant. Prevention in these settings is important. When nasal carriage of *S. aureus* has been identified, mupirocin may be administered intranasally to reduce the incidence of *S. aureus* SSIs.⁸⁷

The benefits of infection surveillance notwithstanding, as the business of hospital care has become more expensive and financial control more rigid, the infection control unit is a hospital component that many administrators have come to consider a luxury and therefore expendable. Consequently, surveillance as a quality control and patient safety mechanism has been diminished.

It is apparent that SSIs have huge clinical and financial implications. Patients with infections tend to be sicker and to undergo more complex operations. Therefore, higher infection rates translate into higher morbidity and mortality as well as higher cost to the hospital, the patient, and society as a whole. With increasingly early discharge becoming the norm, delayed diagnosis of postdischarge SSI and the complications thereof is a growing problem.⁸²⁻⁸⁴ Effective use of institutional databases may contribute greatly to identification of this problem.⁸³

Clearly, the development of effective mechanisms for identifying and controlling SSIs is in the interests of all associated with the delivery of health care.⁸⁵ The identification of problems by means of surveillance and feedback can make a substantial contribution to reducing SSI rates [see Table 6].^{12,85}

Hand Washing

The purpose of cleansing the surgeon's hands is to reduce the numbers of resident flora and transient contaminants, thereby decreasing the risk of transmitting infection. Although the proper duration of the hand scrub is still subject to debate, evidence suggests that a 120-second scrub is sufficient, provided that a brush is used to remove the bacteria residing in the skin folds around the nails.⁸⁸ The nail folds, the nails, and the fingertips should receive the most attention because most bacteria are located around the nail folds and most glove punctures occur at the fingertips. Friction is required to remove resident microorganisms which are attached by adhesion or adsorption, whereas transient bacteria are easily removed by simple hand washing.

Solutions containing either chlorhexidine gluconate or one of the iodophors are the most effective surgical scrub preparations and have the fewest problems with stability, contamination, and toxicity.⁸⁹ Alcohols applied to the skin are among the safest known antiseptics, and they produce the greatest and most rapid reduc-

tion in bacterial counts on clean skin.⁹⁰ All variables considered, chlorhexidine gluconate followed by an iodophor appears to be the best option [see Table 9].

The purpose of washing the hands after surgery is to remove microorganisms that are resident, that flourished in the warm, wet environment created by wearing gloves, or that reached the hands by entering through puncture holes in the gloves. On the ward, even minimal contact with colonized patients has been demonstrated to transfer microorganisms.⁹¹ As many as 1,000 organisms were transferred by simply touching the patient's hand, taking a pulse, or lifting the patient. The organisms survived for 20 to 150 minutes, making their transfer to the next patient clearly possible.

A return to the ancient practice of washing hands between each patient contact is warranted. Nosocomial spread of numerous organisms—including *C. difficile*; MRSA, VRE, and other antibiotic-resistant bacteria; and viruses—is a constant threat.

Hand washing on the ward is complicated by the fact that overwashing may actually increase bacterial counts. Dry, damaged skin harbors many more bacteria than healthy skin and is almost impossible to render even close to bacteria free. Although little is known about the physiologic changes in skin that result from frequent washings, the bacterial flora is certainly modified by alterations in the lipid or water content of the skin. The so-called dry hand syndrome was the impetus behind the development of the alcohol-based gels now available. These preparations make it easy for surgeons to clean their hands after every patient encounter with minimal damage to their skin.

Infection Prevention in Bowel Surgery

At present, the best method of preventing SSIs after bowel surgery is, once again, a subject of debate. There have been three principal approaches to this issue, involving mechanical bowel preparation in conjunction with one of the following three antibiotic regimens^{55,92-97}:

1. Oral antibiotics (usually neomycin and erythromycin),^{20,96}
2. Intravenous antibiotics covering aerobic and anaerobic bowel flora,^{16,20,55,94,95} or
3. A combination of regimens 1 and 2 (meta-analysis suggests that the combination of oral and parenteral antibiotics is best).⁹⁷

The present controversy, triggered by a clinical trial,¹⁶ a review,²⁰ and three meta-analyses, relates to the need for mechanical bowel preparation,¹⁷⁻¹⁹ which has been a surgical dogma since the early 1970s. The increased SSI and leak rates noted have been attributed to the complications associated with vigorous bowel preparation, leading to dehydration, overhydration, or electrolyte abnormalities.

An observational study reported a 26% SSI rate in colorectal

Table 9 Characteristics of Three Topical Antimicrobial Agents Effective against Both Gram-Positive and Gram-Negative Bacteria⁹⁰

Agent	Mode of Action	Antifungal Activity	Comments
Chlorhexidine	Cell wall disruption	Fair	Poor activity against tuberculosis-causing organisms; can cause ototoxicity and eye irritation
Iodine/Iodophors	Oxidation and substitution by free iodine	Good	Broad antibacterial spectrum; minimal skin residual activity; possible absorption toxicity and skin irritation
Alcohols	Denaturation of protein	Good	Rapid action but little residual activity; flammable

Table 10 Comparison of Wound Classification Systems⁶

Traditional Wound Classification System	Simplified Risk Index					All from Traditional Classification
	Low Risk	Medium Risk	High Risk			
	0	1	2	3	4	
Clean	1.1	3.9	8.4	15.8		2.9
Clean-contaminated	0.6	2.8	8.4	17.7		3.9
Contaminated		4.5	8.3	11.0	23.9	8.5
Dirty-infected		6.7	10.9	18.8	27.4	12.6
All from SENIC index	1.0	3.6	8.9	17.2	27.0	4.1

SENIC—Study of the Efficacy of Nosocomial Infection Control

surgery patients.⁹⁸ Intraoperative hypotension and body mass index were the only independent predictive variables. All patients underwent mechanical bowel preparation the day before operation and received oral antibiotics and perioperative I.V. antibiotics. Half of the SSIs were discovered after discharge. Most would agree that the protocol was standard. These and other results suggest that a fresh look at the infectious complications of surgery—and of bowel surgery in particular—is required.

The recommended antibiotic regimen for bowel surgery consists of oral plus systemic agents (see above).⁵⁵ The approach to mechanical bowel preparation, however, is open. Intuition would suggest that the presence of less liquid and stool in the colon might be beneficial and perhaps that a preoperative phosphate enema with 24 hours of fluid might make sense. It is hard to throw out 30 years of apparent evidence on the basis of these three meta-analyses. These studies do, however, present data that cannot be ignored. Protocols for bowel surgery in the modern era of same-day admission, fast track surgery, and rapid discharge will require further study and clinical trials.

Integration of Determinants of Infection

The significant advances in the control of wound infection during the past several decades are linked to a better understanding of the biology of wound infection, and this link has permitted the advance to the concept of SSL.² In all tissues at any time, there will be a critical inoculum of bacteria that would cause an infectious process [see Figure 3]. The standard definition of infection in urine and sputum has been 10⁵ organisms/ml. In a clean dry wound, 10⁵ bacteria produce a wound infection rate of 50% [see Figure 3].¹¹ Effective use of antibiotics reduces the infection rate to 10% with the same number of bacteria and thereby permits the wound to tolerate a much larger number of bacteria.

All of the clinical activities described are intended either to reduce the inoculum or to permit the host to manage the number of bacteria that would otherwise be pathologic. One study in guinea pigs showed how manipulation of local blood flow, shock, the local immune response, and foreign material can enhance the development of infection.⁹⁹ This study and two others defined an early decisive period of host antimicrobial activity that lasts for 3 to 6 hours after contamination.^{50,99,100} Bacteria that remain after this period are the infecting inoculum. Processes that interfere with this early response (e.g., shock, altered perfusion, adjuvants, or foreign material) or support it (e.g., antibiotics or total care)

have a major influence on outcome.

One investigation demonstrated that silk sutures decrease the number of bacteria required for infection.¹⁰¹ Other investigators used a suture as the key adjuvant in studies of host manipulation,¹⁰² whereas a separate study demonstrated persistent susceptibility to wound infection days after shock.¹⁰³ The common variable is the number of bacteria. This relation may be termed the inoculum effect, and it has great relevance in all aspects of infection control. Applying knowledge of this effect in practical terms involves the following three steps:

1. Keeping the bacterial contamination as low as possible via asepsis and antisepsis, preoperative preparation of patient and surgeon, and antibiotic prophylaxis.
2. Maintaining local factors in such a way that they can prevent the lodgment of bacteria and thereby provide a locally unreceptive environment.
3. Maintaining systemic responses at such a level that they can control the bacteria that become established.

These three steps are related to the determinants of infection and their applicability to daily practice. Year-by-year reductions in wound infection rates, when closely followed, indicate that it is possible for surgeons to continue improving results by attention to quality of clinical care and surgical technique, despite increasingly complex operations.^{5,13,28-30} In particular, the measures involved in the first step (control of bacteria) have been progressively refined and are now well established.

The integration of determinants has significant effects [see Figures 3 and 4]. When wound closure was effected with a wound hematocrit of 8% or more, the inoculum required to produce a wound infection rate of 40% was 100 bacteria [see Figure 3]. Ten bacteria produced a wound infection rate of 20%. The shift in the number of organisms required to produce clinical infection is significant. It is obvious that this inoculum effect can be changed dramatically by good surgical technique and further altered by use of prophylactic antibiotics. If the inoculum is always slightly smaller than the number of organisms required to produce infection in any given setting, results are excellent. There is clearly a relation between the number of bacteria and the local environment. The local effect can also be seen secondary to systemic physiologic change, specifically shock. One study showed the low local perfusion in shock to be important in the development of an infection.^{99,100}

One investigation has shown that shock can alter infection rates immediately after its occurrence [see Figure 4].¹⁰³ Furthermore, if

the inoculum is large enough, antibiotics will not control bacteria. In addition, there is a late augmentation of infection lasting up to 3 days after restoration of blood volume. These early and late effects indicate that systemic determinants come into play after local effects are resolved. These observations call for further study, but obviously, it is the combined abnormalities that alter outcome.

Systemic host responses are important for the control of infection. The patient has been clearly implicated as one of the four critical variables in the development of wound infection.⁶ In addition, the bacterial inoculum, the location of the procedure and its duration, and the coexistence of three or more diagnoses were found to give a more accurate prediction of the risk of wound infection. The spread of risk is defined better with the SENIC index (1% to 27%) than it is with the traditional classification (2.9% to 12.6%) [see Table 10]. The importance of the number of bacteria is lessened if the other factors are considered in addition to inoculum. The inoculum effect has to be considered with respect to both the number of organisms and the local and systemic host factors that are in play. Certain variables were found to be significantly related to the risk of wound infection in three important prospective studies [see Table 10].^{6,10,12} It is apparent that the problem of SSI cannot be examined only with respect to the management of bacteria. Host factors have become much more significant now that the bacterial inoculum can be maintained at low levels by means of asepsis, antisepsis, technique, and prophylactic antibiotics.¹⁰⁴

Important host variables include the maintenance of normal homeostasis (physiology) and immune response. Maintenance of

normal homeostasis in patients at risk is one of the great advances of surgical critical care.¹⁰⁴ The clearest improvements in this regard have come in maintenance of blood volume, oxygenation, and oxygen delivery.

One group demonstrated the importance of oxygen delivery, tissue perfusion, and P_{aO_2} in the development of wound infection.¹⁰⁵ Oxygen can have as powerful a negative influence on the development of SSI as antibiotics can.¹⁰⁶ The influence is very similar to that seen in other investigations. Whereas a P_{aO_2} equivalent to a true fractional concentration of oxygen in inspired gas (F_{iO_2}) of 45% is not feasible, maintenance, when appropriate, of an increased F_{iO_2} in the postoperative period may prove an elementary and effective tool in managing the inoculum effect.

Modern surgical practice has reduced the rate of wound infection significantly. Consequently, it is more useful to think in terms of SSI, which is not limited to the incision but may occur anywhere in the operative field; this concept provides a global objective for control of infections associated with a surgical procedure. Surveillance is of great importance for quality assurance. Reports of recognized pathogens (e.g., *S. epidermidis* and group A streptococci) as well as unusual organisms (e.g., *Rhodococcus [Gordona] bronchialis*, *Mycoplasma hominis*, and *Legionella dumoffii*) in SSIs highlight the importance of infection control and epidemiology for quality assurance in surgical departments.^{21-23,26,27} (Although these reports use the term wound infection, they are really addressing what we now call SSI.) The importance of surgeon-specific and service-specific SSI reports should be clear [see Table 6],^{12,13,107} and their value in quality assurance evident.

3 PERIOPERATIVE CONSIDERATIONS FOR ANESTHESIA

Steven B. Backman, M.D.C.M., Ph.D., Richard M. Bondy, M.D.C.M., Alain Deschamps, M.D., Ph.D., Anne Moore, M.D., and Thomas Schrickler, M.D., Ph.D.

Ongoing advancements in modern surgical care are being complemented by alterations in anesthetic management aimed at providing maximum patient benefit. Since the early 1990s, anesthesia practice has changed enormously—through the proliferation of airway devices, the routine employment of patient-controlled analgesia (PCA), the wider popularity of thoracic epidural anesthesia, the development of computer-controlled devices for infusing short-acting drugs, the growing use of quickly reversible inhalational drugs and muscle relaxants, the availability of online monitoring of CNS function, and the increased application of transesophageal echocardiography, to name but a few examples. Our aim in this chapter is to offer surgeons a current perspective on perioperative considerations for anesthesia so as to facilitate dialogue between the surgeon and the anesthesiologist and thereby help minimize patient risk. The primary focus is on the adult patient; the special issues involved in pediatric anesthesia are beyond the scope of our review. In addition, the ensuing discussion is necessarily selective; more comprehensive discussions may be found elsewhere.^{1,2}

Perioperative Patient Management

Preoperative medical evaluation is an essential component of preoperative assessment for anesthesia. Of particular importance to the anesthesiologist is any history of personal or family problems with anesthesia. Information should be sought concerning difficulty with airway management or intubation, drug allergy, delayed awakening, significant postoperative nausea or vomiting (PONV), unexpected hospital or ICU admission, and post-dural puncture headache (PDPH). Previous anesthetic records may be requested.

The airway must be carefully examined to identify patients at risk for difficult ventilation or intubation [see Special Scenarios, Difficult Airway, *below*], with particular attention paid to teeth, caps, crowns, dentures, and bridges. Patients must be informed about the risk of trauma associated with intubation and airway management. Anesthetic options [see Choice of Anesthesia, *below*] should be discussed, including the likelihood of postoperative ventilation and admission to the hospital or the intensive care unit. When relevant, the possibility of blood product administration should be raised [see 1:4 *Bleeding and Transfusion*], and the patient's acceptance or refusal of transfusion should be carefully documented. Postoperative pain management [see 1:5 *Postoperative Pain*] should be addressed, particularly when a major procedure is planned. The risks associated with general or regional anesthesia should be discussed in an informative and reassuring manner; a well-conducted preoperative anesthesia interview plays an important role in alleviating anxiety.

The medications the patient is taking can have a substantial impact on anesthetic management. Generally, patients should continue to take their regular medication up to the time of the operation. It is especially important not to abruptly discontinue

medications that may result in withdrawal or rebound phenomena (e.g., beta blockers, alpha agonists, barbiturates, and opioids). With some medications (e.g., oral hypoglycemics, insulin, and corticosteroids), perioperative dosage adjustments may be necessary [see 8:10 *Endocrine Problems*]. Angiotensin-converting enzyme (ACE) inhibitors have been associated with intraoperative hypotension and may be withheld at the discretion of the anesthesiologist.³ Drugs that should be discontinued preoperatively include monoamine oxidase inhibitors (MAOIs) and oral anticoagulants [see *Table 1*].

Many surgical patients are taking antiplatelet drugs. Careful consideration should be given to the withdrawal of these agents in the perioperative period [see *Table 1*] because of the possibility that discontinuance may lead to an acute coronary syndrome. If increased bleeding is a significant risk, longer-acting agents (e.g., aspirin, clopidogrel, and ticlopidine) can be replaced with non-steroidal anti-inflammatory drugs (NSAIDs) that have shorter half-lives. Typically, these shorter-acting drugs are given for 10 days, stopped on the day of surgery, and then restarted 6 hours after operation. Platelet transfusion should be considered only in the presence of significant medical bleeding.⁴

The increasing use of herbal and alternative medicines has led to significant morbidity and mortality as a consequence of unexpected interactions with traditional drugs. Because many patients fail to mention such agents as part of their medication regimen during the preoperative assessment, it is advisable to question all patients directly about their use. Particular attention should be given to Chinese herbal teas, which include organic compounds and toxic contaminants that may produce renal fibrosis or failure, cholestasis, hepatitis, and thrombocytopenia. Specific recommendations for discontinuance for many of these agents have been developed [see *Table 1*].

Inpatient versus Outpatient Surgery

An ever-increasing number of operations are performed on an ambulatory basis [see *ECP:5 Outpatient Surgery*]. Operations considered appropriate for an ambulatory setting are associated with minimal physiologic trespass, low anesthetic complexity, and uncomplicated recovery.^{5,6} The design of the ambulatory facility may impose limitations on the types of operations or patients that can be considered for ambulatory surgery. Such limitations may be secondary to availability of equipment, recovery room nursing expertise and access to consultants, and availability of ICU beds or hospital beds. Patients who are in class I or class II of the American Society of Anesthesiologists (ASA) physical status scale are ideally suited for ambulatory surgery; however, a subset of ASA class III patients may be at increased risk for prolonged recovery and hospital admission [see *Table 2*].

Premedication to produce anxiolysis, sedation, analgesia, amnesia, and reduction of PONV and aspiration may be considered for patients undergoing outpatient procedures, as it may for those

Table 1 Recommendations for Preoperative Discontinuance of Drugs and Medicines⁵¹⁻⁶⁴

Type of Drug	Agent	Pharmacologic Effects	Adverse Effects	Discontinuance Recommendations
MAOIs	Isocarboxazid Phenelzine Pargyline Tranlylcypromine Selegiline	Irreversible inhibition of monoamine oxidase with the resultant increase in serotonin, norepinephrine, epinephrine, dopamine, and octamine neurotransmitters	Potential of sympathomimetic amines, possible hypertensive crisis May prolong and intensify effects of other CNS depressants Severe idiopathic hyperpyrexia reaction with meperidine and possibly other narcotics Potential catastrophic interaction with tricyclic antidepressants, characterized by high fever and excessive cerebral excitation and hypertension	<i>Elective surgery:</i> discontinue at least 2 wk in advance; consider potential for suicidal tendency—mental health specialist should be involved <i>Emergency surgery:</i> avoid meperidine; consider regional anesthesia
Oral anticoagulants	Warfarin	Inhibition of vitamin K–dependent clotting factors II, VII, IX, X	Bleeding	<i>Elective surgery:</i> discontinue 5–7 days in advance; replace with heparin if necessary
Antiplatelet agents	<i>Aspirin and NSAIDs</i> Aspirin Fenoprofen Ibuprofen Sodium meclofenamate Tolmetin Indomethacin Ketoprofen Diflunisal Naproxen Sulindac Piroxicam	Inhibition of thromboxane A ₂ 80% of platelets must be inhibited for therapeutic effect Susceptibility to aspirin varies between patients	May increase intraoperative and postoperative bleeding, but not transfusion requirement Perioperative hemorrhagic complications increase with increasing half-life of drug	Primary hemostasis normalizes in 48 hr in healthy persons; platelet activity fully recovered in 8–10 days Patients on long-term aspirin therapy for coronary or cerebrovascular pathology should <i>not</i> discontinue drug in perioperative period unless hemorrhagic complications of procedure outweigh risk of acute thrombotic event
	<i>Thienopyridines</i> Ticlopidine Clopidogrel	Inhibition of platelet aggregation Inhibition of platelet ADP–induced amplification	Synergistic antithrombotic effect with aspirin	Discontinue ticlopidine 2 wk in advance; discontinue clopidogrel 7–10 days in advance Patients with coronary artery stents must receive aspirin plus ticlopidine for 2–4 wk after angioplasty; stopping therapy considerably increases risk of coronary thrombosis; elective surgery should be delayed for 1–3 mo
	<i>Antiglycoprotein agents</i> Eptifibatid Tirofiban Abciximab	Competitive inhibition of GPIIb/IIIa receptors to prevent platelet aggregation Rapid onset of action Short half-lives Often combined with aspirin and/or heparin	Literature (mainly from cardiac surgery) shows increased hemorrhagic risk if surgery undertaken < 12 hr after discontinuance of abciximab Individual variability in recovery time of platelet function	Discontinue at least 12 hr in advance Transfuse platelets only if needed to correct clinically significant bleeding

(continued)

undergoing inpatient procedures. Such premedication should not delay discharge. Fasting guidelines [see Table 3] and intraoperative monitoring standards for ambulatory surgery are identical to those for inpatient procedures [see Patient Monitoring, below].

A number of currently used anesthetics (e.g., propofol and desflurane), narcotics (e.g., alfentanil, fentanyl, sufentanil, and remifentanyl), and muscle relaxants (e.g., atracurium, mivacurium, and rocuronium) demonstrate rapid recovery profiles. Nitrous oxide also has desirable pharmacokinetic properties, but it may be associated with increased PONV. Titration of anesthetics to indices of CNS activity (e.g., the bispectral index) may result in decreased drug dosages, faster recovery from anesthesia, and fewer complications.^{7,8} Multimodal analgesia (involving the use of local anesthetics, ketamine, α_2 -adrenergic agonists, beta blockers, acetaminophen, or NSAIDs) may reduce intraoperative and postoperative opioid requirements and accelerate patient discharge. Use of a laryngeal mask airway (LMA) rather than an endotracheal tube is ideal in the outpatient setting because lower doses of

induction agent are required to blunt the hypertension and tachycardia associated with its insertion; in addition, it is associated with a decreased incidence of sore throat and does not require muscle paralysis for insertion. On the other hand, an LMA may not protect as well against aspiration.^{5,9,10}

The benefits of regional anesthesia [see Regional Anesthesia Techniques, below] may include decreases in the incidence of aspiration, nausea, dizziness, and disorientation. Spinal and epidural anesthesia may be associated with PDPH and backache. Compared with spinal anesthesia, epidural anesthesia takes more time to perform, has a slower onset of action, and may not produce as profound a block; however, the duration of an epidural block can readily be extended intraoperatively or postoperatively if necessary. Care should be exercised in choosing a local anesthetic for neuraxial blockade: spinal lidocaine may be associated with a transient radicular irritation, and bupivacaine may be associated with prolonged motor block; narcotics may produce pruritus, urinary retention, nausea and vomiting, and respiratory depression.

Table 1 (continued)

Type of Drug	Agent	Pharmacologic Effects	Adverse Effects	Discontinuance Recommendations
Herbal medicines	Garlic (<i>Allium sativum</i>)	Irreversible dose-dependent inhibition of platelet aggregation	Increased bleeding May potentiate other platelet inhibitors	Discontinue at least 7 days in advance
	Ginkgo (<i>Ginkgo biloba</i>)	Inhibition of platelet-activating factor Modulation of neurotransmitter receptor activity	Increased bleeding May potentiate other platelet inhibitors	Discontinue at least 36 hr in advance
	Ginger (<i>Zingiber officinale</i>)	Potent inhibitor of thromboxane synthase	Increased bleeding May potentiate effects of other anticoagulants	Discontinue at least 36 hr in advance
	Ginseng (<i>Panax ginseng</i>)	Inhibition of platelet aggregation, possibly irreversibly Antioxidant action Antihyperglycemic action "Steroid hormone"-like activity	Prolonged PT and PTT Hypoglycemia Reduced anticoagulation effect of warfarin Possible additive effect with other stimulants, with resultant hypertension and tachycardia	Discontinue at least 7 days in advance
	Ephedra/ma huang (<i>Ephedra sinica</i>)	Noncatecholamine sympathomimetic agent with α_1 , β_1 , and β_2 activity; both direct and indirect release of endogenous catecholamines	Dose-dependent increase in HR and BP, with potential for serious cardiac and CNS complications Possible adverse drug reactions: MAOIs (life-threatening hypertension, hyperpyrexia, coma), oxytocin (hypertension), digoxin and volatile anesthetics (dysrhythmias), guanethedine (hypertension, tachycardia)	Discontinue at least 24 hr in advance
	Echinacea (<i>Echinacea purpurea</i>)	Immunostimulatory effect	Hepatotoxicity Allergic potential	Discontinue as far in advance as possible in any patient with hepatic dysfunction or surgery with possible hepatic blood flow compromise
	Licorice (<i>Glycyrrhiza glabra</i>)		Hypertension Hypokalemia Edema Contraindicated in chronic liver and renal insufficiency	
	Kava (<i>Piper methysticum</i>)	Dose-dependent potentiation of GABA-inhibitory neurotransmitter with sedative, anxiolytic, and antiepileptic effects	Potential of sedative anesthetics, including barbiturates and benzodiazepines Possible potentiation of ethanol effects	
	Valerian (<i>Valeriana officinalis</i>)	Dose-dependent modulation of GABA neurotransmitter and receptor function	Possible potentiation of sedative anesthetics, including barbiturates and benzodiazepines	Discontinue at least 24 hr in advance
St. John's wort (<i>Hypericum perforatum</i>)	Inhibits reuptake of serotonin, norepinephrine, and dopamine by neurons Increases metabolism of some P-450 isoforms	Possible interaction with MAOIs Evidence for reduced activity of cyclosporine, warfarin, calcium channel blockers, lidocaine, midazolam, alfentanil, and NSAIDs	Discontinue on day of surgery; abrupt withdrawal in physically dependent patients may produce benzodiazepine-like withdrawal syndrome	

ADP—adenosine diphosphate ETOH—ethyl alcohol GABA— γ -aminobutyric acid GP—glycoprotein MAOIs—monoamine oxidase inhibitors NSAIDs—nonsteroidal anti-inflammatory drugs PT—prothrombin time PTT—partial thromboplastin time

Various dosing regimens, including minidose spinal techniques, have been proposed as means of minimizing these side effects.¹¹⁻¹⁴

Monitored anesthesia care [see Choice of Anesthesia, below] achieves minimal CNS depression, so that the airway and spontaneous ventilation are maintained and the patient is able to respond to verbal commands. Meticulous attention to monitoring is required to guard against airway obstruction, arterial desaturation, and pulmonary aspiration.

In the recovery room, the anesthetic plan is continued until discharge. Shorter-acting narcotics and NSAIDs are administered for pain relief, and any of several agents may be given for control of nausea and vomiting. Criteria for discharge from the recovery

room have been established [see Table 4]. Recovery of normal muscle strength and sensation (including proprioception of the lower extremity, autonomic function, and ability to void) should be demonstrated after spinal or epidural anesthesia. Delays in discharge are usually the result of pain, PONV, hypotension, dizziness, unsteady gait, or lack of an escort.¹⁵

Elective versus Emergency Surgery

Surgical procedures performed on an emergency basis may range from relatively low priority (e.g., a previously cancelled case that was originally elective) to highly urgent (e.g., a case of

Table 2 Association between Preexisting Medical Conditions and Adverse Outcomes⁶⁵

Medical Condition	Associated Adverse Outcome
Congestive heart failure	12% prolongation of postoperative stay
Hypertension	Twofold increase in risk of intraoperative cardiovascular events
Asthma	Fivefold increase in risk of postoperative respiratory events
Smoking	Fourfold increase in risk of postoperative respiratory events
Obesity	Fourfold increase in risk of intraoperative and postoperative respiratory events
Reflux	Eightfold increase in risk of intubation-related adverse events

impending airway obstruction). For trauma, specific evaluation and resuscitation sequences have been established to facilitate patient management [see 7:1 *Initial Management of Life-Threatening Trauma*]. The urgency of the situation dictates how much time can be allotted to preoperative patient assessment and optimization. When it is not possible to communicate with the patient, information obtained from family members and paramedics may be crucial. Information should be sought concerning allergies, current medications, significant past medical illnesses, nihil per os (NPO) status, personal or family problems with anesthesia, and recent ingestion of alcohol or drugs. Any factor that may complicate airway management should be noted (e.g., trauma to the face or the neck, a beard, a short and thick neck, obesity, or a full stomach). When appropriate, blood samples should be obtained as soon as possible for typing and crossmatching, as well as routine blood chemistries and a complete blood count. Arrangements for postoperative ICU monitoring, if appropriate, should be instituted early.

Clear communication must be established between the surgical team and anesthesia personnel so that an appropriate anesthetic management plan can be formulated and any specialized equipment required can be mobilized in the OR. The induction of anesthesia may coincide with resuscitation. Accordingly, the surgical team must be immediately available to help with difficult I.V. access, emergency tracheostomy, and cardiopulmonary resuscitation. Patients in shock may not tolerate standard anesthetics, which characteristically blunt sympathetic outflow. The anesthetic dose must be judiciously titrated, and definitive surgical treatment must not be unduly delayed by attempts to “get a line.”

Choice of Anesthesia

Anesthesia may be classified into three broad categories: (1) general anesthesia, (2) regional anesthesia, and (3) monitored anesthesia care. General anesthesia can be defined as a state of insensibility characterized by loss of consciousness, amnesia, analgesia, and muscle relaxation. This state may be achieved either with a single anesthetic or, in a more balanced fashion, with a combination of several drugs that specifically induce hypnosis, analgesia, amnesia, and paralysis.

There is, at present, no consensus as to which general anesthetic regimen best preserves organ function. General anesthesia is employed when contraindications to regional anesthesia are present or when regional anesthesia or monitored anesthesia care fails to provide adequate intraoperative analgesia. In addition, there are a few situations that specifically mandate general anesthesia and

controlled ventilation: the need for abdominal muscle paralysis, lung isolation, and hyperventilation; the presence of serious cardiorespiratory instability; and the lack of sufficient time to perform regional anesthesia. Alternatives to general anesthesia should be considered for patients who are susceptible to malignant hyperthermia (MH), for those in whom intubation is likely to prove difficult or the risk of aspiration is high, and for those with pulmonary compromise that may worsen after intubation and positive pressure ventilation.

Regional anesthesia is achieved by interfering with afferent or efferent neural signaling at the level either of the spinal cord (neuraxial blockade) or of the peripheral nerves. Neuraxial anesthesia (i.e., epidural or spinal administration of local anesthetics) is commonly employed as the sole anesthetic technique for procedures involving the lower abdomen and the lower extremities; it also provides effective pain relief after intraperitoneal and intrathoracic procedures. Combining regional and general anesthesia has become increasingly popular.¹⁶ Currently, some physicians are using neuraxial blockade as the sole anesthetic technique for procedures such as thoracotomy and coronary artery bypass grafting, which are traditionally thought to require general anesthesia and endotracheal intubation.¹⁷

Neuraxial blockade has several advantages over general anesthesia, including better dynamic pain control, shorter duration of paralytic ileus, reduced risk of pulmonary complications, and decreased transfusion requirements; it is also associated with a decreased incidence of renal failure and myocardial infarction [see 1:5 *Postoperative Pain*].¹⁸⁻²¹ Contrary to conventional thinking, however, the type of anesthesia used (general or neuraxial) is not an independent risk factor for long-term cognitive dysfunction.²² Neuraxial blockade is an essential component of multimodal rehabilitation programs aimed at optimization of perioperative care and acceleration of recovery [see *ECP:6 Fast Track Surgery*].^{23,24}

For short, superficial procedures, a wide variety of peripheral nerve blocks may be considered.²⁵ For procedures on the upper or lower extremity, an I.V. regional (Bier) block with diluted lidocaine is often useful. Anesthesia of the upper extremity and shoulder may be achieved with brachial plexus blocks. Anesthesia of the lower extremity may be achieved by blocking the femoral, obturator, and lateral femoral cutaneous nerves (for knee surgery) or the ankle and popliteal sciatic nerves (for foot surgery). Anesthesia of the thorax may be achieved with intercostal or intrapleural nerve blocks. Anesthesia of the abdomen may be achieved with celiac

Table 3 Fasting Recommendations* to Reduce Risk of Pulmonary Aspiration⁶⁶

Ingested Material	Minimum Fasting Period† (hr)
Clear liquids‡	2
Breast milk	4
Infant formula	6
Nonhuman milk§	6
Light meal¶	8

*These recommendations apply to healthy patients undergoing elective procedures; they are not intended for women in labor. Following the guidelines does not guarantee complete gastric emptying.

†These fasting periods apply to all ages.

‡Examples of clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.

§Because nonhuman milk is similar to solids in gastric emptying time, amount ingested must be considered in determining appropriate fasting period.

¶A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time. Both amount and type of foods ingested must be considered in determining appropriate fasting period.

Table 4 Postanesthetic Discharge Scoring System (PADSS)⁶⁷

Category	Score*	Explanation
Vital signs	2	Within 20% of preoperative value
	1	Within 20% to 40% of preoperative value
	0	Within 40% of preoperative value
Activity, mental status	2	Oriented and steady gait
	1	Oriented or steady gait
	0	Neither
Pain, nausea, vomiting	2	Minimal
	1	Moderate
	0	Severe
Surgical bleeding	2	Minimal
	1	Moderate
	0	Severe

	1	Oral fluid intake or voiding
	0	Neither

*Total possible score is 10; patients scoring ≥ 9 are considered fit for discharge home.

plexus and paravertebral blocks. Anesthesia of the head and neck may be achieved by blocking the trigeminal, supraorbital, supra-trochlear, infraorbital, and mental nerves and the cervical plexus. Local infiltration of the operative site may provide intraoperative as well as postoperative analgesia.

Unlike the data on neuraxial blockade, the data on peripheral nerve blockade neither support nor discourage its use as a substitute for general anesthesia. Generally, however, we favor regional techniques when appropriate: such approaches maintain consciousness and spontaneous breathing while causing only minimal depression of the CNS and the cardiorespiratory system, and they yield improved pain control in the immediate postoperative period.

Monitored anesthesia care involves the use of I.V. drugs to reduce anxiety, provide analgesia, and alleviate the discomfort of immobilization. This approach may be combined with local infiltration analgesia provided by the surgeon. Monitored anesthesia care requires monitoring of vital signs and the presence of an anesthesiologist who is prepared to convert to general anesthesia if necessary. Its benefits are substantially similar to those of regional anesthesia. These benefits are lost when attempts are made to overcome surgical pain with excessive doses of sedatives and analgesics.

Table 5 Benzodiazepines: Doses and Duration of Action⁶⁸

Benzodiazepine	Dose (for Sedation)	Elimination Half-life	Comments
Midazolam	0.5–1.0 mg, repeated	1.7–2.6 hr	Respiratory depression, excessive sedation, hypotension, bradycardia, withdrawal Anticonvulsant activity
Lorazepam	0.25 mg, repeated	11–22 hr	See midazolam Venous thrombosis
Diazepam	2.0 mg, repeated	20–50 hr	See midazolam and lorazepam

Patient Monitoring

Patient monitoring is central to the practice of anesthesia. A trained, experienced physician is the only truly indispensable monitor; mechanical and electronic monitors, though useful, are, at most, aids to vigilance. Wherever anesthesia is administered, the proper equipment for pulse oximetry, blood pressure measurement, electrocardiography, and capnography should be available. At each anesthesia workstation, equipment for measuring temperature, a peripheral nerve stimulator, a stethoscope, and appropriate lighting must be immediately available. A spirometer must be available without undue delay.

Additional monitoring may be indicated, depending on the patient's health, the type of procedure to be performed, and the characteristics of the practice setting. Cardiovascular monitoring, including measurement of systemic arterial, central venous, pulmonary arterial, and wedge pressures, is covered in detail elsewhere [see 8:26 *Cardiovascular Monitoring*]. Additional information about the cardiovascular system may be obtained by means of transesophageal echocardiography.²⁶ Practice guidelines for this modality have been developed.²⁷ It may be particularly useful in patients who are undergoing valvular repair or who have persistent severe hypotension of unknown etiology.

The effects of anesthesia and surgery on the CNS may be monitored by recording processed electroencephalographic activity, as in the bispectral index or the Patient State Index. These indices are used as measures of hypnosis to guide the administration of anesthetics.^{28,29}

General Anesthesia Techniques

An ever-expanding armamentarium of drugs is available for premedication and for induction and maintenance of anesthesia. Selection of one agent over another is influenced by the patient's baseline condition, the procedure, and the predicted duration of hospitalization.

PREMEDICATION

Preoperative medications are given primarily to decrease anxiety, to reduce the incidence of nausea and vomiting, and to prevent aspiration. Other benefits include sedation, amnesia, analgesia, drying of oral secretions, and blunting of undesirable autonomic reflexes.

Sedatives and Analgesics

Benzodiazepines produce anxiolysis, sedation, hypnosis, amnesia, and muscle relaxation; they do not produce analgesia. They may be classified as short-acting (midazolam), intermediate-acting (lorazepam), or long-acting (diazepam). Adverse effects [see Table 5] may be marked in debilitated patients. Their central effects may be antagonized with flumazenil.

Muscarinic antagonists (e.g., scopolamine and atropine) were commonly administered at one time; this practice is not as popular today. They produce, to varying degrees, sedation, amnesia, lowered anesthetic requirements, diminished nausea and vomiting, reduced oral secretions, and decreased gastric hydrogen ion secretion. They blunt the cardiac parasympathetic reflex responses that may occur during certain procedures (e.g., ocular surgery, traction on the mesentery, and manipulation of the carotid body). Adverse effects include tachycardia, heat intolerance, inhibition of GI motility and micturition, and mydriasis.

Opioids are used when analgesia, in addition to sedation and anxiolysis, is required. With morphine and meperidine, the time of

Table 6 Opioids: Doses and Duration of Action⁶⁹

Agent	Relative Analgesic Potency	Dose		Time to Peak Effect	Duration of Action	Comments
		Induction	Maintenance			
Morphine	1	1 mg/kg	For perioperative analgesia: 0.1 mg/kg I.V., I.M.	5–20 min	2–7 hr	Respiratory depression, nausea, vomiting, pruritus, constipation, urinary retention, biliary spasm, neuroexcitation ± seizure, tolerance Cough suppression, relief of dyspnea-induced anxiety (common to all opioids) Histamine release, orthostatic hypotension, prolonged emergence
Meperidine	0.1	NA	For perioperative analgesia: 0.5–1.5 mg/kg I.V., I.M., s.c.	2 hr (oral); 1 hr (s.c., I.M.)	2–4 hr	See morphine Orthostatic hypotension, myocardial depression, dry mouth, mild tachycardia, mydriasis, histamine release Attenuates shivering; to be avoided with MAOIs Local anesthetic-like effect
Remifentanyl	250–300	1 µg/kg	0.25–0.4 µg/kg/min	3–5 min	5–10 min	See morphine Awareness, bradycardia, muscle rigidity Ideal for infusion; fast recovery, no postoperative analgesia
Alfentanil	7.5–25	50–300 µg/kg	1.25–8.0 µg/kg/min	1–2 min	10–15 min	See morphine Awareness, bradycardia, muscle rigidity
Fentanyl	75–125	5–30 µg/kg	0.25–0.5 µg/kg/min	5–15 min	30–60 min	See morphine and alfentanil
Sufentanyl	525–625	2–20 µg/kg	0.05–0.1 µg/kg/min	3–5 min	20–45 min	See morphine and alfentanil Ideal for prolonged infusion

onset of action and the peak effect are unpredictable. Fentanyl has a rapid onset and a predictable time course, which make it more suitable for premedication immediately before operation. Adverse effects [see Table 6] can be reversed with full (naloxone) or partial (e.g., nalbuphine) antagonists.

The α_2 -adrenergic agonists clonidine and dexmedetomidine are sympatholytic drugs that also exert sedative, anxiolytic, and analgesic effects. They reduce intraoperative anesthetic requirements, thus allowing faster recovery, and attenuate sympathetic activation secondary to intubation and surgery, thus improving intraoperative hemodynamic stability. Major drawbacks are hypotension and bradycardia; rebound hypertensive crises may be precipitated by their discontinuance.^{30,31}

Prevention of Aspiration

Aspiration of gastric contents is an extremely serious complication that is associated with significant morbidity and mortality.

Fasting helps reduce the risk of this complication [see Table 3]. When the likelihood of aspiration is high, pharmacologic treatment may be helpful [see Table 7]. H_2 -receptor antagonists (e.g., cimetidine, ranitidine, and famotidine) and proton pump inhibitors (e.g., omeprazole) reduce gastric acid secretion, thereby raising gastric pH without affecting gastric volume or emptying time. Nonparticulate antacids (e.g., sodium citrate) neutralize the acidity of gastric contents. Metoclopramide promotes gastric emptying (by stimulating propulsive GI motility) and decreases reflux (by increasing the tone of the esophagogastric sphincter); it may also possess antiemetic properties.

In all patients at risk for aspiration who require general anesthesia, a rapid sequence induction is essential. This is achieved through adequate preoxygenation, administration of drugs to produce rapid loss of consciousness and paralysis, and exertion of pressure on the cricoid cartilage (the Sellick maneuver) as loss of consciousness occurs to occlude the esophagus and so limit reflux of gastric con-

Table 7 Pharmacologic Prevention of Aspiration^{70,71}

Agent	Dose	Timing of Administration before Operation	Comments
H_2 receptor antagonists		1–3 hr	
Cimetidine	300 mg, p.o.		Hypotension, bradycardia, heart block, increased airway resistance, CNS dysfunction, reduced hepatic metabolism of certain drugs
Ranitidine	50 mg I.V.		Bradycardia
Famotidine	20 mg I.V.		Rare CNS dysfunction
Sodium citrate	30 ml p.o.	20–30 min	Increased gastric fluid volume
Omeprazole	40 mg I.V.	40 min	Possible alteration of GI drug absorption, hepatic metabolism
Metoclopramide	10 mg I.V.	15–30 min	Extrapyramidal reactions, agitation, restlessness (large doses); to be avoided with MAOIs, pheochromocytoma, bowel obstruction

Table 8 Induction Agents: Doses and Duration of Action⁶⁸

Agent	Induction Dose	Time to Peak Effect (sec)	Duration of Action (min)	Comments
Propofol	1.0–2.5 mg/kg	90–100	5–10	Hypotension, apnea, antiemetic (low dose), sexual fantasies and hallucinations, convulsions ± seizures (rare), pain on injection, thrombophlebitis
Thiopental	2.5–4.5 mg/kg	60	5–8	Hypotension, apnea, emergence delirium, prolonged somnolence, anaphylactoid reaction, injection pain, hyperalgesia Anticonvulsant effect Contraindicated with porphyria
Ketamine	0.5–2 mg/kg	30	10–15	Analgesia; increased BP, HR, CO; lacrimation and salivation; bronchial dilatation; elevated ICP Dreaming, illusions, excitement Preservation of respiration (apnea possible with high doses)
Etomidate	0.2–0.6 mg/kg	60	4–10	Minor effects on BP, HR, CO Adrenocortical suppression, injection pain and thrombophlebitis, myoclonus, nausea and vomiting

CO—cardiac output

tents into the pharynx. An alternative is the so-called modified rapid sequence induction, which permits gentle mask ventilation during the application of cricoid pressure (thereby potentially reducing or abolishing insufflation of gas into the stomach). The advantages of the modified approach are that there is less risk of hypoxia and that there is more time to treat cardiovascular responses to induction agents before intubation. Regardless of which technique is used, consideration should be given to emptying the stomach via an orogastric or nasogastric tube before induction.

INDUCTION

Induction of general anesthesia is produced by administering drugs to render the patient unconscious and secure the airway. It is one of the most crucial and potentially dangerous moments for the patient during general anesthesia. Various agents can be used for this purpose; the choice depends on the patient's baseline medical condition and fasting status, the state of the airway, the surgical procedure, and the expected length of the hospital stay. The agents most commonly employed for induction are propofol, sodium thiopental, ketamine, and etomidate [see Table 8]. The opioids alfentanil, fentanyl, sufentanil, and remifentanyl are also used for this purpose; they are associated with a very stable hemodynamic

profile during induction and operation [see Table 6].

Volatile agents [see Table 9] may be employed for induction of general anesthesia when maintenance of spontaneous ventilation is of paramount importance (e.g., with a difficult airway) or when bronchodilation is required (e.g., with severe hyperreactive airway disease). Inhalation induction is also popular for ambulatory surgery when paralysis is not required. Sevoflurane is well suited for this application because it is not irritating on inhalation, as most other volatile agents are, and it produces rapid loss of consciousness. Sevoflurane has mostly replaced halothane as the agent of choice for inhalation induction because it is less likely to cause dysrhythmias and is not hepatotoxic.

MAINTENANCE

Balanced general anesthesia is produced with a variety of drugs to maintain unconsciousness, prevent recall, and provide analgesia. Various combinations of volatile and I.V. agents may be employed to achieve these goals. The volatile agents isoflurane, desflurane, and sevoflurane are commonly used for maintenance [see Table 9]. Nitrous oxide is a strong analgesic and a weak anesthetic agent that possesses favorable pharmacokinetic properties. It cannot be used as the sole anesthetic agent unless it is adminis-

Table 9 Volatile Drugs^{72,73}

Agent	Oil/Gas Coefficient*	MAC [†] (atm)	Blood/Gas Coefficient [‡]	Rank Order (F _A /F _I) [§]
Halothane	224	0.0074	2.5	6
Enflurane	96.5	0.0168	1.8	5
Isoflurane	90.8	0.0115	1.4	4
Desflurane	18.7	0.060	0.45	2
Sevoflurane	47.2	0.0236	0.65	3
Nitrous oxide	1.4	1.04	0.47	1

*Lipid solubility correlates closely with anesthetic potency (Meyer-Overton rule).

†Correlates closely with lipid solubility.

‡Relative affinity of an anesthetic for blood compared to gas at equilibrium. The larger the coefficient, the greater the affinity of the drug for blood and hence the greater the quantity of drug contained in the blood.

§Rise in alveolar anesthetic concentration towards the inspired concentration is most rapid with the least soluble drugs and slowest with the most soluble.

F_A/F_I—alveolar concentration of gas/inspired concentration MAC—minimum alveolar concentration to abolish purposeful movement in response to noxious stimulation in 50% of patients

Table 10 Neuromuscular Blocking Agents: Doses and Duration of Action⁷⁴

Agent	Dose (mg/kg)	Duration of Action ¹ (min)	Metabolism	Elimination	Comments
Succinylcholine chloride	0.7–2.5	5–10	Plasma cholinesterase	Renal < 2%, hepatic 0%	Fasciculations, elevation of serum potassium, increased ICP, bradycardia, MH trigger; prolonged effect in presence of atypical pseudocholinesterase
Pancuronium	0.04–0.1	60–120	Hepatic 10%–20%	Renal 85%, hepatic 15%	Muscarinic antagonist (vagolytic), prolonged paralysis (long-term use)
Rocuronium	0.6–1.2	35–75	None	Renal < 10%, hepatic > 70%	Minimal histamine release
Vecuronium	0.08–0.1	45–90	Hepatic 30%–40%	Renal 40%, hepatic 60%	Prolonged paralysis (long-term use)
Atracurium	0.3–0.5	30–45	Hoffman elimination, nonspecific ester hydrolysis	Renal 10%–40%, hepatic 0%	Histamine release; laudanosine metabolite (a CNS stimulant)
Cisatracurium	0.15–0.2	40–75	Hoffman elimination	Renal 16%, hepatic 0%	Negligible histamine release; laudanosine metabolite
Mivacurium	0.15–0.2	15–20	Plasma cholinesterase	Renal < 5%, hepatic 0%	Histamine release; prolonged effect in presence of atypical pseudocholinesterase

tered in a hyperbaric chamber; it is usually administered with at least 30% oxygen to prevent hypoxia. Nitrous oxide is commonly used in combination with other volatile agents. All of the volatile agents can trigger malignant hyperthermia in susceptible patients.

The I.V. drugs currently used to maintain general anesthesia, whether partially or entirely, feature a short context-sensitive elimination half-life; thus, pharmacologically significant drug accumulation during prolonged infusion is avoided. Such agents (including propofol, midazolam, sufentanil, and remifentanil) are typically administered via computer-controlled infusion pumps that use population-based pharmacokinetic data to establish stable plasma (and CNS effector site) concentrations. Because of the extremely rapid hydrolysis of remifentanil, its administration may be labor intensive, necessitating frequent administration of boluses and constant vigilance. Its short half-life also limits its usefulness as an analgesic in the postoperative period and may even contribute to acute opioid intolerance. To help circumvent these problems, various dosing regimens have been proposed in which the patient is switched from remifentanil to a longer-acting narcotic.

NEUROMUSCULAR BLOCKADE

The reversible paralysis produced by neuromuscular blockade improves conditions for endotracheal intubation and facilitates surgery. Neuromuscular blocking agents are classified as either depolarizing (succinylcholine) or nondepolarizing (pancuronium,

rocuronium, vecuronium, atracurium, cisatracurium, and mivacurium) and may be further differentiated on the basis of chemical structure and duration of action [see Table 10]. The blocking effect of nondepolarizing muscle relaxants is enhanced by volatile drugs, hypothermia, acidosis, certain antibiotics, magnesium sulfate, and local anesthetics and is reduced by phenytoin and carbamazepine. Patients with weakness secondary to neuromuscular disorders (e.g., myasthenia gravis and Eaton-Lambert syndrome) may be particularly sensitive to nondepolarizing muscle relaxants.

EMERGENCE

General anesthesia is terminated by cessation of drug administration, reversal of paralysis, and extubation. During this period, close scrutiny of the patient is essential, and all OR personnel must coordinate their efforts to help ensure a smooth and safe emergence. In this phase, patients may demonstrate hemodynamic instability, retching and vomiting, respiratory compromise, and, occasionally, uncooperative or aggressive behavior.

Reversal of neuromuscular blockade is achieved by administering anticholinesterases such as neostigmine and edrophonium. These drugs should be given in conjunction with a muscarinic antagonist (atropine or glycopyrrolate) to block their unwanted parasympathomimetic side effects. Neostigmine is more potent than edrophonium in reversing profound neuromuscular blockade. It is imperative that paralysis be sufficiently reversed before

Table 11 Pharmacology of Anticoagulant Agents

 LMWH—low-molecular-weight heparin t-PA—tissue plasminogen activator

extubation to ensure that spontaneous respiration is adequate and that the airway can be protected. Reversal can be clinically verified by confirming the patient's ability to lift the head for 5 seconds. Reversal can also be assessed by measuring muscle contraction in response to electrical nerve stimulation.

Causes of failure to emerge from anesthesia include residual neuromuscular blockade, a benzodiazepine or opioid overdose, the central anticholinergic syndrome, an intraoperative cerebrovascular accident, preexisting pathophysiologic conditions (e.g., CNS disorders, hepatic insufficiency, and drug or alcohol ingestion), electrolyte abnormalities, acidosis, hypercarbia, hypoxia, hypothermia, and hypothyroidism. As noted, the effects of narcotics and benzodiazepines can be reversed with naloxone and flumazenil, respectively. Physostigmine may be given to reverse the reduction in consciousness level produced by general anesthetics. Electrolyte, glucose, blood urea nitrogen, and creatinine levels should be measured; liver and thyroid function tests should be performed; and arterial blood gas values should be obtained. Patients should be normothermic. Unexplained failure to emerge from general anesthesia warrants immediate consultation with a neurologist.

Regional Anesthesia Techniques

Neuraxial (central) anesthesia techniques involve continuous or intermittent injection of drugs into the epidural or intrathecal space to produce sensory analgesia, motor blockade, and inhibition of sympathetic outflow. Peripheral nerve blockade involves inhibition of conduction in fibers of a single peripheral nerve or plexus (cervical, brachial, or lumbar) in the periphery. Intravenous regional anesthesia involves I.V. administration of a local anesthetic into a tourniquet-occluded extremity. Perioperative pain control may be facilitated by administering local anesthetics, either infiltrated into the wound or sprayed into the wound cavity.^{32,33} Procedures performed solely under infiltration may be associated with patient dissatisfaction caused by intraoperative anxiety and pain.³⁴

CONTRAINDICATIONS

Strong contraindications to regional (particularly neuraxial) anesthesia include patient refusal or inability to cooperate during the procedure, elevated intracranial pressure, anticoagulation, vascular malformation or infection at the needle insertion site, severe hemodynamic instability, and sepsis. Preexisting neurologic disease is a relative contraindication.

ANTICOAGULATION AND BLEEDING RISK

Although hemorrhagic complications can occur after any regional technique, bleeding associated with neuraxial blockade is the most serious possibility because of its devastating consequences. Spinal hematoma may occur as a result of vascular trauma from placement of a needle or catheter into the subarachnoid or epidural space. Spinal hematoma may also occur spontaneously, even in the absence of antiplatelet or anticoagulant therapy. The actual incidence of spinal cord injury resulting from hemorrhagic complications is unknown; the reported incidence is estimated to be less than 1/150,000 for epidural anesthesia and 1/220,000 for spinal anesthesia.³⁵ With such low incidences, it is difficult to determine whether any increased risk can be attributed to anticoagulant use [see Table 11] without data from millions of patients, which are not currently available. Much of our clinical practice is based on small surveys and expert opinion.

Antiplatelet Agents

There is no universally accepted test that can guide antiplatelet therapy. Antiplatelet agents can be divided into four major classes: (1) aspirin and related cyclooxygenase inhibitors (nonsteroidal anti-inflammatory drugs, or NSAIDs); (2) ticlopidine and selective adenosine diphosphate antagonists; (3) direct thrombin inhibitors (e.g., hirudin); and (4) glycoprotein IIb/IIIa inhibitors. Only with aspirin is there sufficient experience to suggest that it does not increase the risk of spinal hematoma when given at clinical dosages.³⁶ Caution should, however, be exercised when aspirin is used in conjunction with other anticoagulants.³⁷

Oral Anticoagulants

Therapeutic anticoagulation with warfarin is a contraindication to regional anesthesia.³⁸ If regional anesthesia is planned, oral warfarin can be replaced with I.V. heparin (see below).

Heparin

There does not seem to be an increased risk of spinal bleeding in patients receiving subcutaneous low-dose (5,000 U) unfractionated heparin [see 6:6 *Venous Thromboembolism*] if the interval between administration of the drug and initiation of the procedure is greater than 4 hours.³⁹ Higher doses, however, are associated with increased risk. If neuraxial anesthesia or epidural catheter removal is planned, heparin infusion must be discontinued for at least 6 hours, and the partial thromboplastin time (PTT) should be measured. Recommendations for standard heparin cannot be extrapolated to low-molecular-weight heparin (LMWH), because the biologic actions of LMWH are different and the effects cannot be monitored by conventional coagulation measurements. After the release of LMWH for general use in the United States in 1993, more than 40 spinal hematomas were reported during a 5-year period. LMWH should be stopped at least 24 hours before regional blockade, and the first postoperative dose should be given no sooner than 24 hours afterward.³⁷

COMPLICATIONS

Drug Toxicity

Systemic toxic reactions to local anesthetics primarily involve the CNS and the cardiovascular system [see Table 12]. The initial symptoms are light-headedness and dizziness, followed by visual and auditory disturbances. Convulsions and respiratory arrest may ensue and necessitate treatment and resuscitation.

The use of neuraxial analgesic adjuncts (e.g., opioids, clonidine, epinephrine, and neostigmine) decreases the dose of local anesthetic required, speeds recovery, and improves the quality of analgesia. The side effects of such adjuncts include respiratory depression (with morphine), tachycardia (with epinephrine), hypotension (with clonidine), and nausea and vomiting (with neostigmine and morphine).

Neurologic Complications

The incidence of neurologic complications ranges from 2/10,000 to 12/10,000 with epidural anesthesia and from 0.3/10,000 to 70/10,000 with spinal anesthesia.⁴⁰ The most common serious complication is neuropathy, followed by cranial nerve palsy, epidural abscess, epidural hematoma, anterior spinal artery syndrome, and cranial subdural hematoma. Vigilance and routine neurologic testing of sensory and motor function are of paramount importance for early detection and treatment of these potentially disastrous complications.

Table 12 Local Anesthetics for Infiltration Anesthesia: Maximum Doses* and Duration of Action

Drug	Without Epinephrine		With Epinephrine (1:200,000)	
	Maximum Dose (mg)	Duration of Action (min)	Maximum Dose (mg)	Duration of Action (min)
Chloroprocaine	800	15–30	1,000	3–90
Lidocaine	300	30–60	500	120–360
Mepivacaine	300	45–90	500	120–360
Prilocaine	500	30–90	600	120–360
Bupivacaine	175	120–240	225	180–420
Etidocaine	300	120–180	400	180–420

*Recommended maximum dose can be given to healthy, middle-aged, normal-sized adults without toxicity. Subsequent doses should not be given for at least 4 hr. Doses should be reduced during pregnancy.

Transient neurologic symptoms The term transient neurologic symptoms (TNS) refers to backache with pain radiating into the buttocks or the lower extremities after spinal anesthesia. It occurs in 4% to 33% of patients, typically 12 to 36 hours after the resolution of spinal anesthesia, and lasts for 2 to 3 days.⁴¹ TNS has been described after intrathecal use of all local anesthetics but is most commonly noted after administration of lidocaine, in the ambulatory surgical setting, and with the patient in the lithotomy position during operation. Discomfort from TNS is self-limited and can be effectively treated with NSAIDs.

Post-Dural Puncture Headache

Use of small-gauge pencil-point needles for spinal anesthesia is associated with a 1% incidence of PDPH. The incidence of PDPH after epidural analgesia varies substantially because the risk of inadvertent dural puncture with a Tuohy needle is directly dependent on the anesthesiologist's training. PDPH is characteristically aggravated by upright posture and may be associated with photophobia, neck stiffness, nausea, diplopia, and tinnitus. Meningitis should be considered in the differential diagnosis. Although PDPH is not life-threatening, it carries substantial morbidity in the form of restricted activity. Medical treatment with bed rest, I.V. fluids, NSAIDs, and caffeine is only moderately effective. An epidural blood patch is the treatment of choice: the success rate is approximately 70%.

Recovery

Admission to the postanesthetic care unit (PACU) is appropriate for patients whose vital signs are stable and whose pain is adequately controlled after emergence from anesthesia. Patients requiring hemodynamic or respiratory support may be admitted to the PACU if rapid improvement is expected and appropriate monitoring and personnel are available. Hemodynamic instability, the need for prolonged respiratory support, and poor baseline condition mandate admission to the ICU. Common complications encountered in the PACU include postoperative pulmonary insufficiency, cardiovascular instability, acute pain, and nausea and vomiting [see Table 13]. These complications are discussed in greater detail elsewhere [see 8:4 *Pulmonary Insufficiency*, 8:2 *Acute Cardiac Dysrhythmia*, 1:5 *Postoperative Pain*, and ECP:5 *Outpatient Surgery*].

Special Scenarios

DIFFICULT AIRWAY

Airway management is a pivotal component of patient care because failure to maintain airway patency can lead to permanent disability, brain injury, or death. The difficult airway should be managed in accordance with contemporary airway guidelines, such as the protocols established by the ASA, to reduce the risk of adverse outcomes during attempts at ventilation and intubation. (The ASA protocols may be accessed on the organization's Web site: <http://www.asahq.org/publicationsandservices/difficult%20airway.pdf>.) The emphasis on preserving spontaneous ventilation and the focus on awake intubation options are central themes whose importance cannot be overemphasized.

It is crucial that all patients who are undergoing difficult or prolonged airway instrumentation be appropriately treated with topical anesthesia, sedation, and monitoring so as to ensure adequate ventilation and to attenuate, detect, and treat harmful neuroendocrine responses that can cause myocardial ischemia, bronchospasm, and intracranial hypertension. Extubation is stressful as well and may be associated with intense mucosal stimulation and exaggerated glottic closure reflexes resulting in laryngospasm and, possibly, pulmonary edema secondary to vigorous inspiratory efforts against an obstructed airway. Laryngeal incompetence and aspiration can also occur after extubation. Removal of an endotracheal tube from a known or suspected difficult airway should ideally be performed over a tube exchanger so as to facilitate emergency reintubation.

Alternatives to standard oral airways, masks, introducers, exchangers, laryngoscopes, and endotracheal tubes now exist that offer more options, greater safety, and better outcomes. It would be naive to believe that any single practitioner could master every new airway protocol and device. To keep up with technical and procedural advances, university hospital program directors should consider incorporating technical skill laboratories and simulator training sessions into their curricula.

MORBID OBESITY

Morbid obesity represents the extreme end of the overweight spectrum and is usually defined as a body-mass index higher than 40 kg/m² [see 5:7 *Morbid Obesity*].⁴² It poses a formidable challenge

to health care providers in the OR, the postoperative recovery ward, and the ICU. The major concerns in the surgical setting are the possibility of a difficult airway, the increased risk of known or occult cardiorespiratory compromise, and various serious technical problems related to positioning, monitoring, vascular access, and transport. Additional concerns are the potential for underlying hepatic and endocrine disease and the effects of altered drug pharmacokinetics and pharmacodynamics. For the morbidly obese patient, there is no such thing as minor surgery.

Initial management should be based on the assumptions that (1) a difficult airway is likely, (2) the patient will be predisposed to hiatal hernia, reflux, and aspiration, and (3) rapid arterial desaturation will occur with induction of anesthesia as a consequence of decreased functional residual capacity and high basal oxygen consumption. Often, the safest option is an awake fiberoptic intubation with appropriate topical anesthesia and light sedation.⁴³ In expert hands, this technique is extremely well tolerated and can usually be performed in less than 10 minutes. Morbidly obese patients often are hypoxemic at rest and have an abnormal alveolar-arterial oxygen gradient caused by ventilation-perfusion mismatching. The combination of general anesthesia and the supine position exacerbates alveolar collapse and airway closure. Mechanical ventilation, weaning, and extubation may be difficult and dangerous, especially in the presence of significant obstructive sleep apnea. Postoperative pulmonary complications (e.g., pneumonia, aspiration, atelectasis, and emboli) are common.

Morbid obesity imposes unusual loading conditions on both sides of the heart and the circulation, leading to the progressive development of insulin resistance, atherogenic dyslipidemias, systemic and pulmonary hypertension, ventricular hypertrophy, and a high risk of premature coronary artery disease and biventricular heart failure. Perioperative cardiac morbidity and mortality are therefore significant problems. Untoward events can happen suddenly, and resuscitation is extremely difficult. Cardiorespiratory compromise may be attenuated by effective postoperative pain control that permits early ambulation and effective ventilation. Surgical site infection and dehiscence may result in difficult reoperation and prolonged hospitalization.

MALIGNANT HYPERTHERMIA

MH is a rare but potentially fatal genetic condition characterized by life-threatening hypermetabolic reactions in susceptible individuals after the administration of volatile anesthetics or depolarizing muscle relaxants.⁴⁴ Abnormal function of the sarcoplasmic

reticulum calcium release channel in skeletal muscle has been identified as a possible underlying cause.

In making the diagnosis of MH, it is important to consider other possible causes of postoperative temperature elevation. Such causes include inadequate anesthesia, equipment problems (e.g., misuse or malfunction of heating devices, ventilators, or breathing circuits), local or systemic inflammatory responses (either related or unrelated to infection), transfusion reaction, hypermetabolic endocrinopathy (e.g., thyroid storm or pheochromocytoma), neurologic catastrophe (e.g., intracranial hemorrhage), and reaction to or abuse of a drug.

Immediate recognition and treatment of a fulminant MH episode are essential for preventing morbidity and mortality. Therapy consists of discontinuing all triggers, instituting aggressive cooling measures, giving dantrolene in an initial dose of 2.5 mg/kg, and administering 100% oxygen to compensate for the tremendous increase in oxygen utilization and carbon dioxide production. An indwelling arterial line, central venous access, and bladder catheterization are indispensable for monitoring and resuscitation. Acidosis, hyperkalemia, and malignant dysrhythmias must be rapidly treated, with the caveat that calcium channel blockers are contraindicated in this setting. Maintenance of adequate urine output is of paramount importance and may be facilitated by the clinically significant amounts of mannitol contained in commercial dantrolene preparations. When the patient is stable and the surgical procedure is complete, monitoring and support are continued in the ICU, where repeat doses of dantrolene may be needed to prevent or treat recrudescence of the disease.

MASSIVE TRANSFUSION

Massive blood transfusion, defined as the replacement of a patient's entire circulating blood volume in less than 24 hours, is associated with significant morbidity and mortality. Management of massive transfusion requires an organized multidisciplinary team approach and a thorough understanding of associated hematologic and biochemical abnormalities and subsequent treatment options.

Patients suffering from shock as a result of massive blood loss often require transfusions of packed red blood cells, platelets, fresh frozen plasma, and cryoprecipitate to optimize oxygen-carrying capacity and address dilutional and consumptive loss of platelets and clotting factors [see 8:3 *Shock and 1:4 Bleeding and Transfusion*]. Transfusion of large amounts of blood products into a critically ill patient can lead to coagulopathies, hyperkalemia, acidosis, citrate intoxication, fluid overload, and hypothermia.⁴⁵ Therapy should be

Table 13 Pharmacologic Treatment of PONV⁵

Agent	Dose	Comments
Propofol	10 mg I.V., repeated dose	[See Table 8]
Ondansetron	4.0–8.0 mg I.V.	Highly effective, costly; headache, constipation, transiently increased LFTs
Dexamethasone	4.0–8.0 mg I.V.	Adrenocortical suppression, delayed wound healing, fluid retention, electrolyte disturbances, psychosis, osteoporosis
Droperidol	0.5–1.0 mg I.V.	Sedation, restlessness, dysphoria, ?dysrhythmia
Metoclopramide	10–20 mg I.V.	Avoid in bowel obstruction, extrapyramidal reactions
Scopolamine	0.1–0.6 mg s.c., I.M., I.V.	Muscarinic side effects, somnolence
Dimenhydrinate	25–50 mg I.V.	Drowsiness, dizziness

LFTs—liver function tests

guided by vital signs, urine output, pulse oximetry, electrocardiography, capnography, invasive hemodynamic monitoring, serial arterial blood gases, biochemical profiles, and bedside coagulation screens. Fluids should be administered through large-bore cannulas connected to modern countercurrent warming devices. Shed blood should be salvaged and returned to the patient whenever possible. In refractory cases, transcatheter angiographic embolization techniques should be considered for control of bleeding.

Newer hemostatic agents, such as aprotinin and recombinant factor VIIa, should also be considered [see 1:4 *Bleeding and Transfusion*]. Aprotinin is a serine protease inhibitor with unique antifibrinolytic and hemostatic properties. It is used during surgery to decrease blood loss and transfusion requirements as well as to attenuate potentially harmful inflammatory responses and minimize reperfusion injury. Recombinant factor VIIa was originally approved for hemophiliacs who developed antibodies against either factor VIII or factor IX; it may prove useful for managing uncontrolled hemorrhage deriving from trauma or surgery.

HYPOTHERMIA

Significant decreases in core temperature are common during anesthesia and surgery as a consequence of exposure to a cold OR environment and of disturbances in normal protective thermoregulatory responses. Patients lose heat through conduction, convection, radiation, and evaporation, especially from large wounds and during major intracavitary procedures. Moreover, effective vasoconstrictive reflexes and both shivering and nonshivering thermogenesis are severely blunted by anesthetics.⁴⁶ Neonates and the elderly are particularly vulnerable.

Hypothermia may confer some degree of organ preservation during ischemia and reperfusion. For example, in cardiac surgery, hypothermic cardiopulmonary bypass is a common strategy for protecting the myocardium and the CNS. Intentional hypothermia has also been shown to improve neurologic outcome and survival in comatose victims of cardiac arrest. Perioperative hypothermia can have significant deleterious effects as well, however, including myocardial ischemia, surgical site infection, increased blood loss and transfusion requirements, and prolonged anesthetic recovery and hospital stay.

The sensation of cold is highly uncomfortable for the patient, and shivering impedes monitoring, raises plasma catecholamine levels, and exacerbates imbalances between oxygen supply and demand by consuming valuable energy for involuntary muscular activity. It is therefore extremely important to measure the patient's temperature and maintain thermoneutrality. Increasing the ambient temperature of the OR and applying modern forced-air warming systems are the most effective techniques available. In addition, all I.V. and irrigation fluids should be heated. After the patient has been transferred from the OR, aggressive treatment of hypothermia with these techniques should be continued as necessary. Shivering may also be reduced by means of drugs such as meperidine, nefopam, tramadol, physostigmine, ketamine, methylphenidate, and doxapram.⁴⁷

INTRAOPERATIVE AWARENESS

One of the goals of anesthesia is to produce a state of unconsciousness during which the patient neither perceives nor recalls noxious surgical stimuli. When this objective is not met, awareness occurs, and the patient will have explicit or implicit memory of intraoperative events. In some instances, intraoperative awareness develops because human error, machine malfunction, or technical problems result in an inappropriately light level of anesthesia. In others (e.g., when the patient is severely hemodynamically unstable

or efforts are being made to avoid fetal depression during cesarean section), the light level of anesthesia may have been intentionally chosen. Regardless of the cause, intraoperative awareness is a terrifying experience for the patient and has been associated with serious long-term psychological sequelae.⁴⁸ Prevention of awareness depends on regular equipment maintenance, meticulous anesthetic technique, and close observation of the patient's movements and hemodynamic responses during operation. CNS monitoring may reduce the risk of intraoperative awareness.

ANAPHYLAXIS

Allergic reactions range in severity from mild pruritus and urticaria to anaphylactic shock and death. Inciting agents include antibiotics, contrast agents, blood products, volume expanders, protamine, aprotinin, narcotics, induction agents, muscle relaxants, latex,⁴⁹ and, rarely, local anesthetic solutions. Many drug additives and preservatives have also been implicated.

True anaphylaxis presents shortly after exposure to an allergen and is mediated by chemicals released from degranulated mast cells and basophils. Manifestations usually include dramatic hypotension, tachycardia, bronchospasm, arterial oxygen desaturation, and cutaneous changes. Laryngeal edema can occur within minutes, in which case the airway should be secured immediately. Anaphylaxis can mimic heart failure, asthma, pulmonary embolism, and tension pneumothorax. Treatment involves withdrawing the offending substance and administering oxygen, fluids, and epinephrine, followed by I.V. steroids, bronchodilators, and histamine antagonists. Prolonged intubation and ICU monitoring may be required until symptoms resolve. Appropriate skin and blood testing should be done to identify the causative agent.

PERIOPERATIVE DYSRHYTHMIAS

In 2005, current scientific developments in the acute treatment of cerebrovascular, cardiac, and pulmonary disease were merged with the evolving discipline of evidence-based medicine to produce the most comprehensive set of resuscitation standards ever created: a 14-part document from the American Heart Association entitled "2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care."⁵⁰ This document addresses a wide array of key issues in both in-hospital and out-of-hospital resuscitation, including a recommendation for confirmation of tube position after endotracheal intubation and a warning about the danger associated with unintentional massive auto-PEEP.

As regards the impact the new guidelines have on the management of cardiopulmonary resuscitation, an increase in compression:ventilation ratios (to 30:2) and an emphasis on effective chest compressions ("push hard, push fast") are suggested. In addition, early chest compressions before defibrillation, a one-shock sequence for defibrillation as opposed to a three-shock sequence, and avoidance of prolonged interruption of chest compressions are recommended. For wide QRS dysrhythmias, amiodarone continues to be the drug of choice. It may also be administered for ventricular fibrillation or for pulseless ventricular tachycardia that does not respond to cardiopulmonary resuscitation, cardioversion, and a vasopressor.

Amiodarone is a complex, powerful, and broad-spectrum agent that inhibits almost all of the drug receptors and ion channels conceivably responsible for the initiation and propagation of cardiac ectopy, irrespective of underlying ejection fraction, accessory pathway conduction, or anatomic substrate. It does, however, have potential drawbacks, such as its relatively long half-life, its toxicity to multiple organs, and its complicated administration scheme.

Furthermore, amiodarone is a potent noncompetitive alpha and beta blocker, which has important implications for anesthetized, mechanically ventilated patients who may be debilitated and experiencing volume depletion, abnormal vasodilation, myocardial depression, and fluid, electrolyte, and acid-base abnormalities. That said, no other drug in its class has ever demonstrated a significant benefit in randomized trials addressing cardiac arrest in humans.

Amiodarone is effective in both children and adults, and it can be used for prophylaxis as well as treatment. The recommended cardiac arrest dose is a 300 mg I.V. bolus. In less acute situations (e.g., wide-complex tachycardia), an initial 150 mg dose should be administered slowly over 10 minutes, and one or two additional

boluses may be given similarly. A loading regimen is then initiated, first at 1 mg/min for 6 hours and then at 0.5 mg/min for 18 hours.

Vasopressin (antidiuretic hormone) continues to be listed as an alternative to epinephrine in the ventricular tachycardia/ventricular fibrillation protocol. Vasopressin is an integral component of the hypothalamic-pituitary-adrenal axis and the neuroendocrine stress response. The recommended dose for an adult in fibrillatory arrest is 40 units in a single bolus. For vasodilatory shock states associated with sepsis, hepatic failure, or vasomotor paralysis after cardiopulmonary bypass, infusion at a rate of 0.01 to 0.04 units/min may be particularly useful. Vasopressin is neither recommended nor forbidden in cases of pulseless electrical activity or asystolic arrest, and it may be substituted for epinephrine.

4 BLEEDING AND TRANSFUSION

John T. Owings, M.D., F.A.C.S., Garth H. Utter, M.D., M.Sc., and Robert C. Gosselin, M.T.

Approach to the Patient with Ongoing Bleeding

A surgeon is often the first person to be called when a patient experiences ongoing bleeding. To treat such a patient appropriately, the surgeon must identify the cause or source of the bleeding. Causes fall into two main categories: (1) conditions leading to loss of vascular integrity, as in a postoperative patient with an unligated vessel that is bleeding or a trauma patient with a ruptured spleen, and (2) conditions leading to derangement of the hemostatic process. In this chapter, we focus on the latter category, which includes a broad spectrum of conditions, such as aspirin-induced platelet dysfunction, von Willebrand disease (vWD), disseminated intravascular coagulation (DIC), and even hemophilia.

Coagulopathies are varied in their causes, treatments, and prognoses. Our aim is not to downplay the usefulness of the specialized hematologic tests required for identification of rare congenital or acquired clotting abnormalities but to outline effective management approaches to the coagulopathies surgeons see most frequently. The vast majority of these coagulopathies can be diagnosed by means of a brief patient and family history, a review of medications, physical examination, and commonly used laboratory studies—in particular, activated partial thromboplastin time (aPTT), prothrombin time (PT, commonly expressed as an international normalized ratio [INR]), complete blood count (CBC), and D-dimer assay.

Exclusion of Technical Causes of Bleeding

It is critical for the surgeon to recognize that the most common causes of postoperative bleeding are technical: an unligated vessel or an unrecognized injury is much more likely to be the cause of a falling hematocrit than either a drug effect or an endogenous hemostatic defect. Furthermore, if an unligated vessel is treated as though it were an endogenous hemostatic defect (i.e., with transfusions), the outcome is likely to be disastrous. For these reasons, in all cases of ongoing bleeding, the first consideration must always be to exclude a surgically correctable cause.

Ongoing bleeding may be surprisingly difficult to diagnose. Healthy young patients can usually maintain a normal blood pressure until their blood loss exceeds 40% of their blood volume (roughly 2 L). If the bleeding is from a laceration to an extremity, it will be obvious; however, if the bleeding is occurring internally (e.g., from a ruptured spleen or an intraluminal GI source), there may be few physiologic signs [see 8:3 Shock]. For the purposes of the ensuing discussion, we assume that bleeding is known to have occurred or to be occurring.

Even when a technical cause of bleeding has seemingly been excluded, the possibility often must be reconsidered periodically throughout assessment. Patients who are either unresuscitated or underresuscitated undergo vasospasm that results in decreased bleeding.¹ As resuscitation proceeds, the catecholamine-induced vasospasm subsides and the bleeding may recur. For this reason, repeated reassessment of the possibility of a technical cause of bleeding is appropriate. Only when the surgeon is confident that a missed injury or unligated vessel is not the cause of the bleeding should other potential causes be investigated.

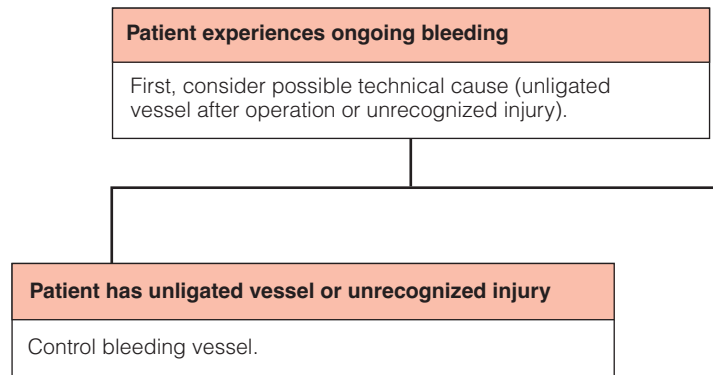

Initial Assessment of Potential Coagulopathy

The first step in assessment of a patient with a potential coagulopathy is to draw a blood sample. The blood should be drawn into a tube containing ethylenediaminetetraacetic acid (EDTA) for a CBC and into a citrated tube for coagulation analysis (at most centers, these tubes have purple and blue tops, respectively).

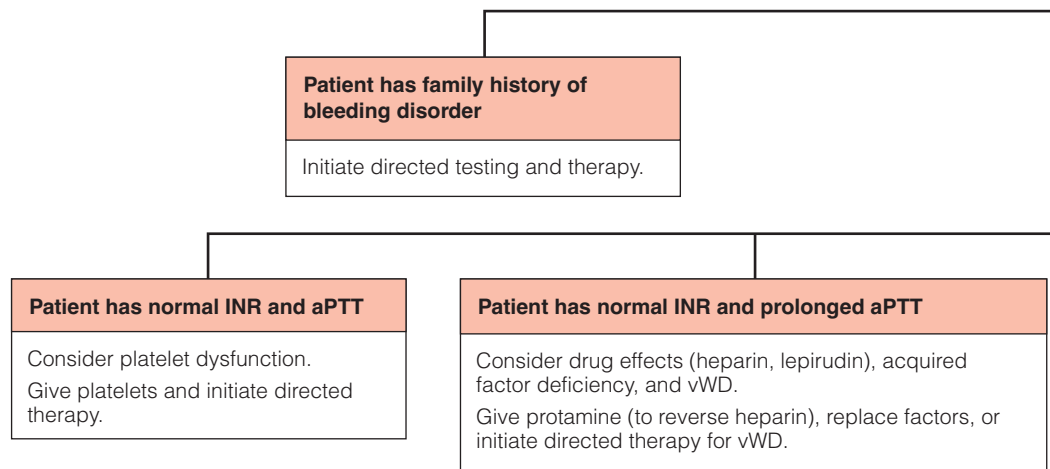

At the same time, the patient's temperature should be noted. Because coagulation is a chemical reaction, it slows with decreasing temperature.² Thus, a patient with a temperature lower than 35° C (95° F) clots more slowly and less efficiently than one with a temperature of 37° C (98.6° F).³ The resulting coagulopathy abnormality is what is known as a hypothermic coagulopathy. Upon receipt of the drawn specimen, the laboratory warms the sample to 37° C to run the coagulation assays (aPTT and INR). In a patient with a purely hypothermic coagulopathy, this step results in normal coagulation parameters. Hypothermic patients should be actively rewarmed.⁴ Typically, such patients cease to bleed after rewarming, and no further treatment is required. If the patient is normothermic and exhibits normal coagulation values but bleeding continues, attention should again be focused on the possibility of an unligated bleeding vessel or an uncontrolled occult bleeding source (e.g., the GI tract).

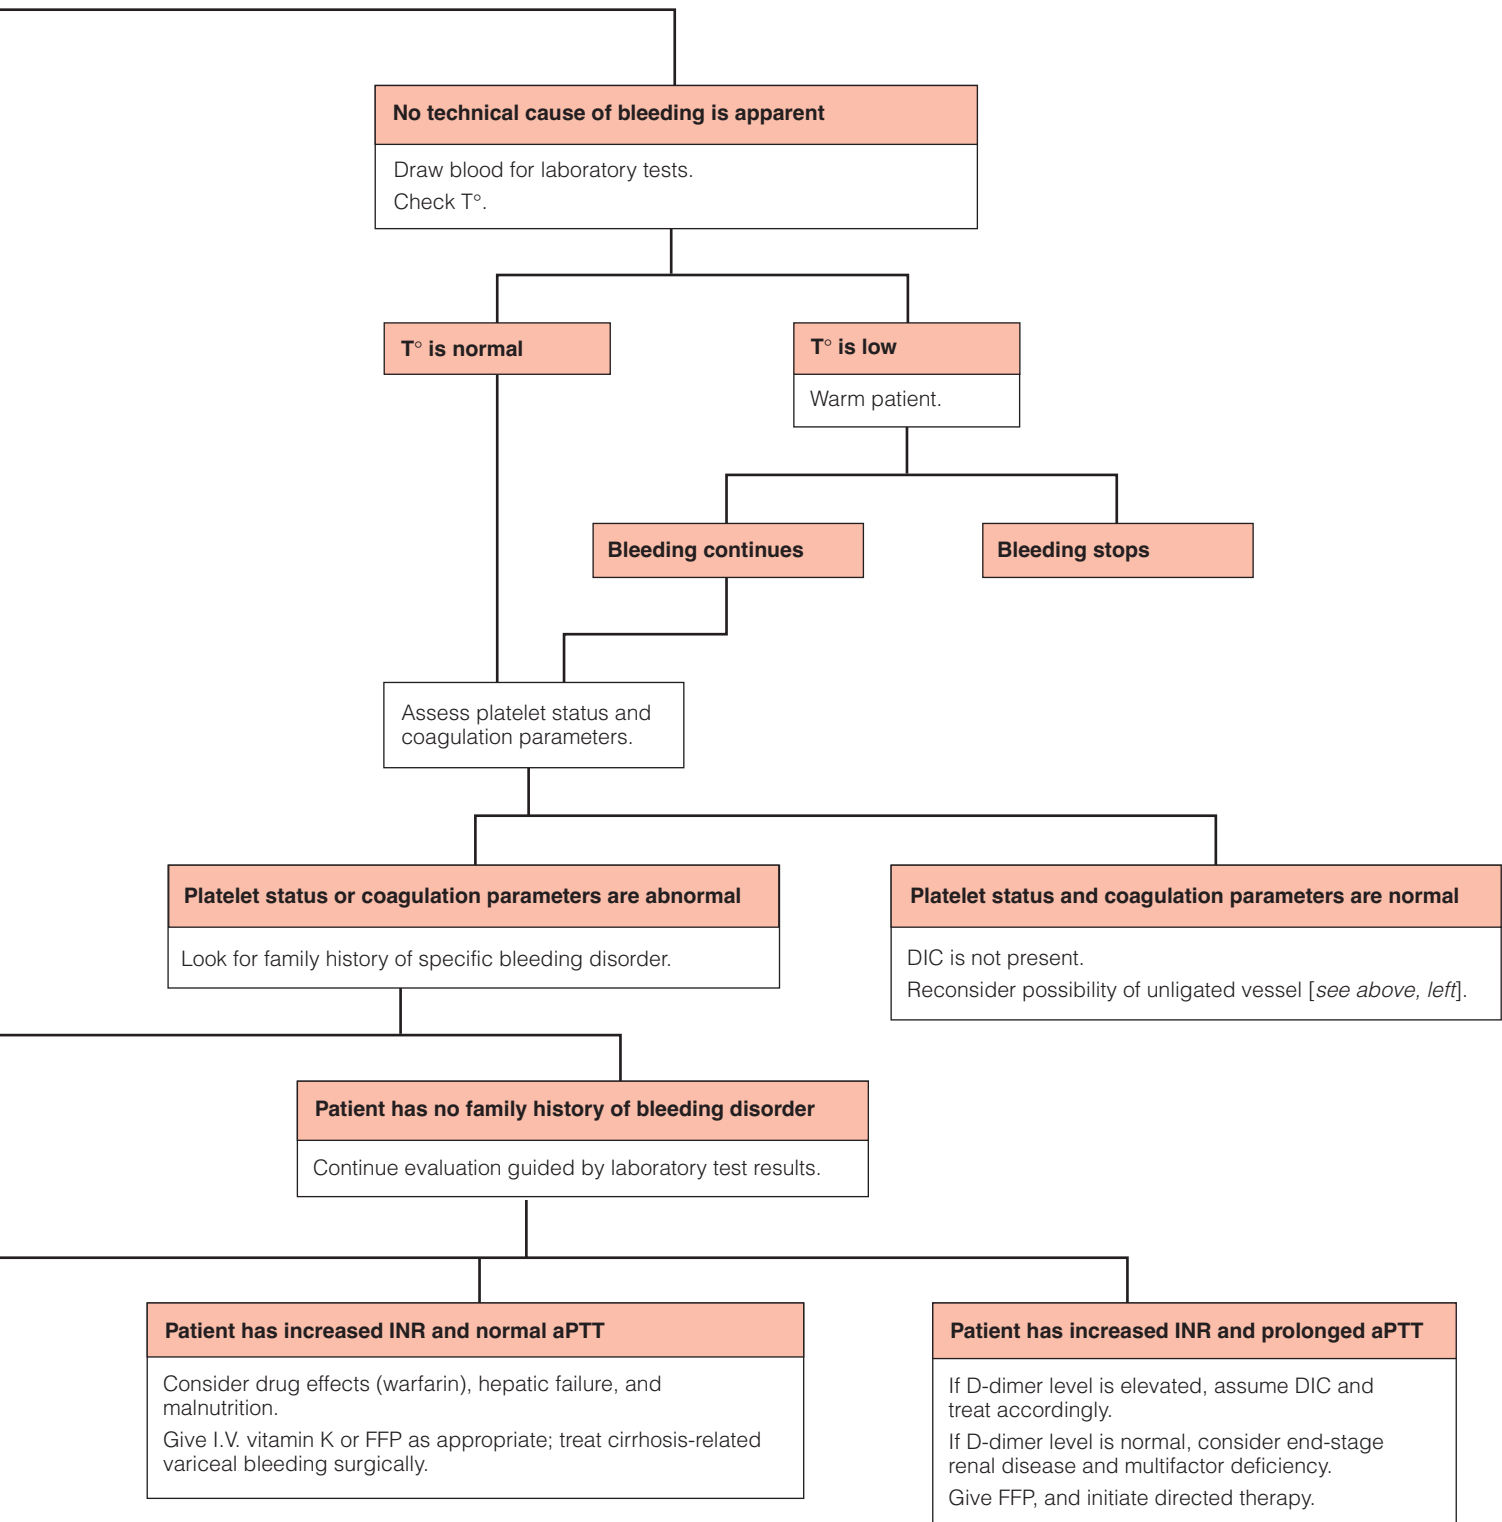

Ongoing bleeding in conjunction with abnormal coagulation parameters may have any of several underlying causes. In this setting, one of the most useful pieces of information to obtain is a personal and family history. A patient who has had dental extractions without major problems or who had a normal adolescence without any history of bleeding dyscrasias is very unlikely to have a congenital or hereditary bleeding disorder.⁵ If there is a personal or family history of a specific bleeding disorder, appropriate steps should be taken to diagnose and treat the disorder [see Discussion, Bleeding Disorders, below].

Approach to the Patient with Ongoing Bleeding

Measurement of Coagulation Parameters

NORMAL INR, NORMAL aPTT

Patients with a normal INR and aPTT who exhibit ongoing bleeding may have impaired platelet activity. Inadequate platelet activity is frequently manifested as persistent oozing from wound edges or as low-volume bleeding. Such bleeding is rarely the cause of exsanguinating hemorrhage, though it may be life-threatening on occasion, depending on its location (e.g., inside the cranium or the pericardium). Inadequate platelet activity may be attributable either to an insufficient number of platelets or to platelet dysfunction. In the absence of a major surgical insult or concomitant coagulopathy, a platelet count of 20,000/mm³ or higher is usually adequate for normal coagulation.^{6,7} There is some disagreement regarding the absolute level to which the platelet count must fall before platelet transfusion is justified in the absence of active bleeding. Patients undergoing procedures in which even capillary oozing is potentially life-threatening (e.g., craniotomy) should be maintained at a higher platelet count (i.e., > 20,000/mm³). Patients without ongoing bleeding who are not specifically at increased risk for major complications from low-volume bleeding may be safely watched with platelet counts lower than 20,000/mm³.

Oozing in a patient who has an adequate platelet count and normal coagulation parameters may be a signal of platelet dysfunction. The now-routine administration of aspirin to reduce the risk of myocardial infarction and stroke has led to a rise in the incidence of aspirin-induced platelet dysfunction. Aspirin causes irreversible platelet dysfunction through the cyclooxygenase pathway; the effect of aspirin can thus be expected to last for approximately 10 days. The platelet dysfunction caused by other nonsteroidal anti-inflammatory drugs (e.g., ibuprofen) is reversible and consequently does not last as long as that caused by aspirin. Newer platelet-blocking agents have been found to be effective in improving outcome after coronary angioplasty.⁸ These drugs function predominantly by blocking the platelet surface receptor glycoprotein (GP) IIb-IIIa, which binds platelets to fibrinogen.

In patients with platelet dysfunction caused by an inhibitor of platelet function, such as an elevated blood urea nitrogen (BUN) level or aspirin, 1-desamino-8-D-arginine vasopressin (DDAVP) is capable of significantly reversing the platelet dysfunction.⁹

Less common causes of bleeding in patients with a normal INR and a normal aPTT include factor XIII deficiency, hypofibrinogenemia or dysfibrinogenemia, and derangements in the fibrinolytic pathway [*see Discussion, Mechanics of Hemostasis, below*].

NORMAL INR, PROLONGED aPTT

Patients with a normal INR and an abnormal aPTT are likely to have a drug-induced coagulation defect. The agent most commonly responsible is unfractionated heparin. Reversal of the heparin effect, if desired, can be accomplished by administering protamine sulfate. Protamine should be given with caution, however, because it has been reported to induce a hypercoagulable state¹⁰ (though many of the thrombotic complications

may simply be related to reversal of a needed anticoagulant state). Protamine should also be used with caution in diabetic patients. These persons sometimes become sensitized to impurities in protamine through their exposure to similar impurities in protamine-containing insulin formulations, and this sensitization may result in an anaphylactic reaction.¹¹

It should be remembered that the aPTT does not accurately measure the anticoagulant activity of low-molecular-weight heparins (LMWHs). Because such heparins exert the greater proportion of their anticoagulant effect by potentiating antithrombin to inactivate factor Xa rather than factor IIa, an assay that measures anti-Xa activity is needed to measure the anticoagulant effect. This effect, however, unlike that of unfractionated heparin, is not effectively reversed by protamine.

It should also be noted that the anti-Xa laboratory assay does not truly measure the degree of anticoagulation *in vivo*; rather, it measures only the LMWH concentration in plasma. Because heparins (including LMWHs) function almost exclusively by catalyzing the activity of antithrombin, the therapeutic effect of heparin is critically dependent on adequate antithrombin levels; acquired antithrombin deficiency (as occurs with trauma and other critical illnesses) is the most common reason for LMWH to have an inadequate effect. The anti-Xa laboratory assay does not account for *in vivo* antithrombin levels, because it involves the addition of antithrombin itself to the plasma sample as a reagent. Consequently, the results of this assay cannot be taken as a reliable guide to the patient's coagulation status. In effect, all the assay actually does is give the physician some idea of the concentration of circulating LMWH, which is dependent on the dosing, renal clearance, and the time since LMWH was last administered.

An additional crucial point is that the administration of fresh frozen plasma (FFP) will not correct the anticoagulant effect of either unfractionated heparin or LMWHs. In fact, given that plasma contains antithrombin and that both unfractionated heparin and LMWHs act by potentiating antithrombin, administration of FFP could actually enhance the heparins' anticoagulant effect.

A variety of direct thrombin inhibitors (e.g., bivalirudin [Hirulog], lepirudin, argatroban, and ximelagatran) are currently available in Europe, Asia, and North America.¹² Many of them cause prolongation of the aPTT. One disadvantage shared by most of the direct thrombin inhibitors is that the effects are not reversible; if thrombin inhibition is no longer desired, FFP must be given to correct the aPTT. Because the inhibitor that is circulating but not bound at the time of FFP administration will bind the prothrombin in the FFP, the amount of FFP required to correct the aPTT may be greater than would be needed with a simple factor deficiency.

Von Willebrand disease is frequently, though not always, associated with a slight prolongation of the aPTT. Its clinical expression is variable. Confirmation of the diagnosis can be obtained by testing for circulating factor levels. Platelet function analysis will also show abnormal function. Correction is accomplished by administering directed therapy (von Willebrand factor [vWF]) [*see Discussion, Bleeding Disorders, below*], DDAVP, or cryoprecipitate.

Hemophilia may either cause spontaneous bleeding or lead to prolonged bleeding after a surgical or traumatic insult. As noted, hemophilia is rare in the absence of a personal or family history of the disorder. The most common forms of hemophilia involve deficiencies of factors VIII, IX, and XI (hemophilia A, hemophilia B, and hemophilia C, respectively). In contrast to depletion of natural anticoagulants such as antithrombin and protein C [*see 6:6 Venous Thromboembolism*], depletion of procoagulant factors rarely gives rise to significant manifestations until it is relatively severe. Typically, no laboratory abnormalities result from depletion of

Table 1 Preparations Used in Directed Therapy for Hemophilia

procoagulant factors until factor activity levels fall below 40% of normal, and clinical abnormalities are frequently absent even when factor activity levels fall to only 10% of normal. This tolerance for subcritical degrees of depletion is a reflection of the built-in redundancies in the procoagulant pathways.

If hemophilia is suspected, specific factor analysis is indicated. Appropriate therapy involves administering the deficient factor or factors [see Table 1]. Hemophiliac patients who have undergone extensive transfusion therapy may pose a particular challenge: massive transfusions frequently lead to the development of antibodies that make subsequent transfusion or even directed therapy impossible. Accordingly, several alternatives to transfusion or directed factor therapy (e.g., recombinant activated factor VII [rVIIa]) have been developed for use in this population.

INCREASED INR, NORMAL aPTT

An increased INR in association with a normal aPTT is a more ominous finding in a patient with a coagulopathy. Any of a number of causes, all centering on factor deficiency, may be responsible.

Cirrhosis is arguably the most serious of the causes of an elevated INR. It is a major problem not so much because of the coagulopathy itself but because of the associated deficits in wound healing and immune function that result from the synthetic dysfunction and the loss of reticuloendothelial function. In all cases, factor replacement should be instituted with FFP. If the bleeding is a manifestation of the cirrhosis (as in variceal bleeding), emergency portal decompression should be accomplished before the coagulopathy worsens. Management of cirrhotic patients who have sustained injuries is particularly troublesome because such patients are at disproportionately high risk for subdural hematoma. The reason this risk is so high is that in addition to their pathologic autoanticoagulation, these patients often have some degree of cerebral atrophy as a result of one of the more frequent causes of cirrhosis—namely, alcoholism. As a result, the bridging intracranial veins are more vulnerable to tears and more likely to bleed. For patients with life-threatening intracranial bleeding and an elevated INR, off-label use of activated factor VII has become widespread. Although to date, no prospective randomized studies have demonstrated that this practice confers a survival advantage, the administration of activated factor VII, 20 to 40 µg/kg, does appear promising.¹³ Modest elevations of the INR in patients who are not actively bleeding, have not recently undergone operation, and are not specifically at increased risk for life-threatening hemorrhage may be observed without correction.

An elevated INR with a normal aPTT may also be a consequence of warfarin administration. Such a coagulopathy is the result of a pure factor deficiency, and its degree is proportional to the prolongation of the INR. Because warfarin acts by disrupting vitamin K metabolism, the coagulopathy may be corrected by giving vitamin K [see Table 2].¹⁴ If the patient is actively bleeding, vitamin K should still be given, but the primary corrective measure should be to administer FFP in an amount proportional to the patient's size and the relative increase in the INR. The INR should subsequently be rechecked to ensure that replacement therapy is adequate. Vitamin K replacement therapy has two main potential drawbacks: (1) if the patient is to be reanticoagulated with warfarin in the near future, dosing will be difficult because the patient will exhibit resistance to warfarin for a variable period; and (2) anaphylactic reactions have been reported when vitamin K is given I.V.

INCREASED INR, PROLONGED aPTT

Increases in both the INR and the aPTT may be the most problematic finding of all. When both assays show increases, the patient is likely to have multiple factor deficiencies; possible causes include DIC, severe hemodilution, and renal failure with severe nephrotic syndrome. However, when dramatic elevations of the aPTT and the INR are observed in a seemingly asymptomatic patient, the problem may lie not in the patient's condition but in the laboratory analysis. If the tube in which the blood sample was drawn for these tests was not adequately filled, the results of the coagulation assays may be inaccurate. In such cases, the blood sample should be redrawn and the tests repeated.

Hemodilution and nephrotic syndrome result in a coagulopathy that is attributable to decreased concentration of coagulation proteins. Dilutional coagulopathy may occur when a patient who is given a large volume of packed red blood cell (RBC) units is not also given coagulation factors.¹⁵ Because of the tremendous redundancy of the hemostatic process, pure dilutional coagulopathy is rare. It is considered an unlikely diagnosis until after one full blood volume has been replaced (as when a patient requires 10 units of packed RBCs to maintain a stable hematocrit). Nephrotic syndrome is associated with loss of protein (coagulation proteins as well as other body proteins) from the kidneys.

Both hemodilution and nephrotic syndrome should be distinguished from DIC (which is a consumptive rather than a dilutional process¹⁶), though on occasion this distinction is a difficult one to make. A blood sample should be sent for D-dimer assay. If the D-dimer level is low (< 1,000 ng/ml), DIC is unlikely; if it is very high (> 2,000 ng/ml) and there is no other clear explanation (e.g., a complex unstable pelvic fracture), the diagnosis of DIC rather than dilution should be made. Treatment of dilutional coagulopathy should be directed at replacement of lost factors. FFP should be given first, followed by cryoprecipitate, calcium, and platelets. Transfusion should be continued until the coagulation parameters are corrected and the bleeding stops.

DIC is a diffuse, disorganized activation of the clotting cascade within the vascular space. It may result either from intravascular presentation of an overwhelming clotting stimulus (e.g., massive crush injury, overwhelming infection, or transfusion reaction) or from presentation of a moderate clotting stimulus in the context of shock. Different degrees of severity have been described. In the mildest form of DIC, acceleration of the clotting cascade is seen,

Table 2 Management of the Patient with an Increased INR¹⁴

Indication	Recommended Treatment
INR above therapeutic range but < 5.0	If no bleeding is present or surgery is indicated, lower or hold next dose
INR > 5.0 but < 9.0 Patient has no significant bleeding	In the absence of additional risk factors for bleeding, withhold next 1–2 doses; alternatively, withhold next dose and give vitamin K, 1.0–2.5 mg (oral route is acceptable)
Rapid reduction of INR is required	Give vitamin K, 2.0–4.0 mg p.o.; expected reduction of INR should occur within 24 hr
INR > 9.0 Patient has no significant bleeding	Give vitamin K, 3.0–5.0 mg p.o.; expected reduction of INR should occur within 24 hr
Patient has serious bleeding or is overly anticoagulated (INR > 20.0)	Give vitamin K, 10 mg I.V., and FFP; further vitamin K supplementation may be required every 12 hr
Patient has life-threatening bleeding or is seriously overanticoagulated	Prothrombin complexes may be indicated, along with vitamin K, 10 mg I.V.

and microthrombi are formed in the vascular space but are cleared effectively. Thus, mild DIC may be little more than an acceleration of the clotting cascade that escapes recognition. In the moderate form of DIC, the microthrombi are ineffectively lysed and cause occlusion of the microcirculation. This process is clinically manifested in the lungs as the acute respiratory distress syndrome (ARDS), in the kidneys as renal failure, and in the liver as hepatic failure.

Neither mild DIC nor moderate DIC is what surgeons traditionally think of as DIC. Severe DIC arises when congestion of the microvasculature with thrombi occurs, resulting in large-scale activation of the fibrinolytic system to restore circulation. This fibrinolytic activity results in breakdown of clot at previously hemostatic sites of microscopic injury (e.g., endothelial damage) and macroscopic injury (e.g., I.V. catheter sites, fractures, or surgical wounds). Bleeding and reexposure to tissue factor stimulate activation of factor VII with increased coagulation activity; thus, microthrombi are formed, and the vicious circle continues. The ultimate manifestation of severe DIC is bleeding from (1) fibrinolysis and (2) depletion (consumption) of coagulation factors.

Several scoring systems have been devised to assess the severity of DIC. In the absence of any specific treatment for this condition, these scoring systems are currently most useful for distinguishing DIC from other causes of coagulopathy (e.g., hypothermia, dilution, and drug effects) [see Table 3].¹⁷

DIC is a diagnosis of exclusion, largely because none of the various treatment strategies tried to date have been particularly suc-

Table 3 Coagulopathy (DIC) Score

Score	INR (sec)	aPTT (sec)	Platelets (1,000/mm ³)	Fibrinogen (mg/dl)	D-dimer (ng/ml)
0	< 1.2	< 34	> 150	> 200	< 1,000
1	> 1.2	> 34	< 150	< 200	< 2,000
2	> 1.4	> 39	< 100	< 150	< 4,000
3	> 1.6	> 54	< 60	< 100	> 4,000

aPTT—activated partial thromboplastin time DIC—disseminated intravascular coagulopathy INR—international normalized ratio

cessful. Heparin has been given in large doses in an attempt to break the cycle by stopping the clotting, thus allowing clotting factor levels to return to normal. Antifibrinolytic agents (e.g., ϵ -aminocaproic acid) have also been tried in an attempt to reduce fibrinolytic activity and thus slow the bleeding that stimulates subsequent clot formation. Antithrombotics (e.g., antithrombin and protein C) have been used as well; improvements have been noted in laboratory measures of DIC but not in survival. At present, interest is focused on activated factor VII, though as yet, the available data are insufficient to validate its use.

Currently, the most appropriate way of treating a patient with severe DIC is to follow a multifaceted approach. First, the clotting stimulus, if still present, should be removed: dead or devitalized tissue should be debrided, abscesses drained, and suspect transfusions discontinued. Second, hypothermia, of any degree of severity, should be corrected. Third, both blood loss (as measured by the hematocrit) and clotting factor deficits (as measured by the INR) should be aggressively corrected (with blood and plasma, respectively). This supportive approach is only modestly successful. For certain groups of patients in whom DIC develops (e.g., those who have sustained head injuries), mortality approaches 100%. This alarmingly high death rate is probably related more to the underlying pathology than to the hematologic derangement.

An increased INR with a prolonged aPTT may also be caused by various isolated factor deficiencies of the common pathway. Congenital deficiencies of factors X, V, and prothrombin are very rare. Acquired factor V deficiencies have been observed in patients with autoimmune disorders. Acquired hypoprothrombinemia has been documented in a small percentage of patients with lupus anticoagulants who exhibit abnormal bleeding. Factor X deficiencies have been noted in patients with amyloidosis.

Stabilized warfarin therapy will increase both the INR and the aPTT. Several current rodenticides (e.g., brodifacoum) exert the same effect on these parameters that warfarin does; however, because they have a considerably longer half-life than warfarin, the reversal of the anticoagulation effect with vitamin K or FFP may be correspondingly longer.¹⁸ Animal venoms may also increase the INR and the aPTT.

Management of Anemia and Indications for Transfusion

Anemia is common among hospitalized surgical patients. In two large prospective cohort studies, the average hemoglobin level in surgical ICU patients was 11.0 g/dl,¹⁹ and 55% of surgical ICU patients received transfusions.²⁰ Anemia results from at least three factors: (1) blood loss related to the primary condition or to the operation, (2) serial blood draws (totaling, on average, approximately 40 ml/day in the ICU),¹⁹ and (3) diminished erythropoiesis related to the primary illness.

Treatment of anemia has changed substantially since the early 1990s. Blood cell transfusions have been shown to have significant immunosuppressive potential, and transmission of fatal diseases through the blood supply has been extensively documented. Although the blood-banking community has systematically reduced the risk of transmission of infection by restricting the eligible donor pool and routinely testing blood products for serologic and nucleic acid evidence of pathogens,²¹ comparatively little progress has been made in defining and controlling the immunomodulatory effects of transfusion [see Discussion, Mechanism and Significance of Transfusion-Related Immunomodulation, *below*]. Moreover, at least one large trial, the Transfusion Requirements in Critical Care (TRICC) study, found that using a restrictive RBC

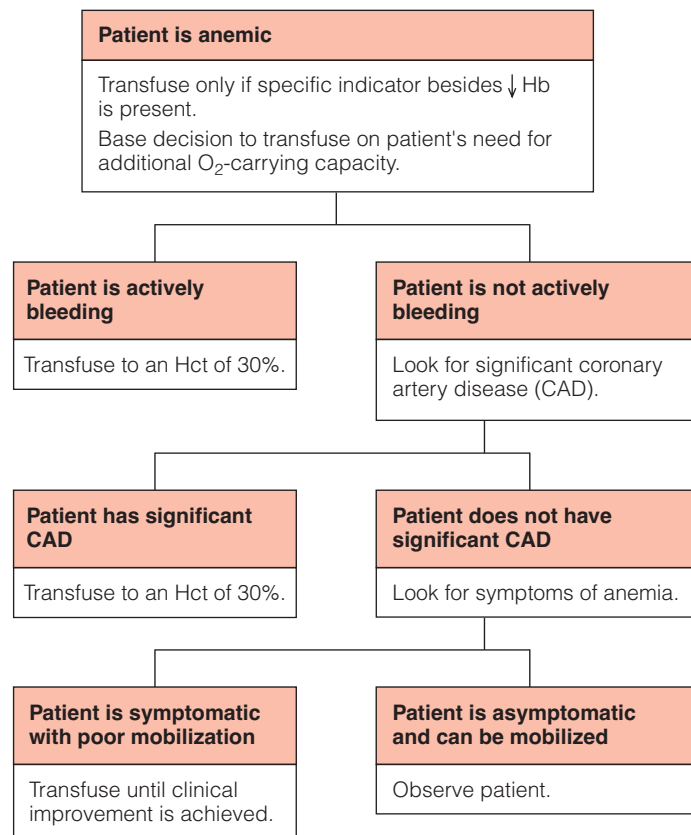

Figure 1 Algorithm depicts decision-making process for transfusion in anemic patients.

transfusion protocol (aimed at maintaining a hemoglobin concentration of 7.0 to 9.0 g/dl) in place of a more traditional protocol (aimed at maintaining a hemoglobin concentration of 10.0 to 12.0 g/dl) did not harm critically ill patients and even appeared to improve survival for younger or less severely ill patients.²² These findings have encouraged a paradigm shift with respect to RBC transfusion: whereas the traditional view was that anemia by itself was a sufficient indication for transfusion, the current consensus is that the threshold for transfusion should be determined by taking into account additional clinical factors besides the hemoglobin concentration.²³

The decision whether to transfuse should be based on the patient's current and predicted need for additional oxygen-carrying capacity [see *Figure 1*]. A major component of this decision is to determine as promptly as possible whether significant hypovolemia or active bleeding is present. In a hypovolemic or actively bleeding patient, liberal transfusion is indicated as a means of increasing intravascular volume and preventing the development of profound deficits in oxygen-carrying capacity. Coagulation factors must also be replaced as necessary [see Measurement of Coagulation Parameters, Increased INR, Prolonged aPTT, *above*]. In a hemodynamically stable patient without evidence of active hemorrhage, it is appropriate to take a more restrictive approach to transfusion, one that is tailored to the symptoms observed and to the specific anticipated risks. Thus, there is no specific hemoglobin concentration or hematocrit (i.e., transfusion trigger) at which all patients should receive transfusions.

There are two groups of patients for whom a more aggressive RBC transfusion policy should be considered. Patients who are at

high risk for active bleeding and patients who have acute coronary artery ischemic syndromes may benefit from a more liberal transfusion protocol than that applied to the general patient population.

HIGH RISK FOR ACTIVE BLEEDING

Patients who are at high risk for active bleeding (e.g., those with a massive liver injury or recurrent GI hemorrhage) should receive transfusions up to a level at which, should bleeding occur or recur, enough reserve oxygen-carrying capacity would be available to allow diagnosis and correction of the hemorrhage without significant compromise of oxygen delivery. In acute cases of major injury, we advocate an initial target hematocrit of 30%; however, this is not a fixed value but a rule-of-thumb figure that may be increased or decreased as appropriate, depending on the individual patient's reserves and the individual surgical team's ability to diagnose and correct the underlying problem.

ACUTE CORONARY ARTERY ISCHEMIC SYNDROMES

Currently, there is no consensus on what the most appropriate transfusion strategy is for patients with acute coronary artery ischemic syndromes, such as active myocardial infarction and unstable angina. The results of observational studies have been mixed,^{24,25} and no clinical trial has yet addressed this specific subgroup of patients. Some distinction should be drawn between patients who have acute coronary artery ischemic syndromes and those who merely have a history of coronary artery or other atherosclerotic disease. Although the TRICC trial apparently did not enroll many patients with severe cardiovascular morbidity,²² it included enough patients with cardiovascular disease to allow a sizable subgroup analysis.²⁶ This post hoc analysis suggested that in patients with cardiovascular disease as a primary diagnosis or an important comorbid condition, survival was essentially the same regardless of whether a liberal transfusion protocol or a restrictive one was followed. In patients with confirmed ischemic heart disease, however, a nonsignificant decrease in survival was noted, generating some concern that adverse cardiovascular events (e.g., myocardial infarction and stroke) might increase in frequency at lower hematocrits. Consequently, a target hematocrit of 30% is generally considered acceptable for patients with acute coronary artery ischemic syndromes or significant coronary artery disease.

NEUROLOGIC CONDITIONS

Some have argued that just as the heart may be sensitive to decreases in oxygen-carrying capacity, the injured central nervous system may be vulnerable to further damage from anemia because anemia may limit the delivery of oxygen to damaged tissue. According to this view, patients with traumatic brain injury, stroke, or spinal cord injury may be vulnerable to anemia-related damage; however, as yet, the clinical evidence is insufficient either to support or to refute this notion.

SYMPTOMATIC ANEMIA

An additional consideration in the decision to transfuse blood is the oxygen-carrying capacity that is necessary to prevent patient fatigue or discomfort. Typical symptoms of anemia include light-headedness, tachycardia, and tachypnea either during activity or at rest. Clearly, some degree of tachycardia is to be expected in any patient who has undergone a major operation or sustained a serious injury. The key judgment to make in deciding whether to treat symptomatic anemia with transfusion is whether the anemia is truly compromising the patient's health or recovery. It is not always easy, however, to determine whether the patient will actually benefit from transfusion. For example, a lib-

eral transfusion approach does not seem to lead to earlier liberation from mechanical ventilation.²⁷ Moreover, although some studies support the notion that transfusion speeds wound healing,²⁸ others suggest that transfusion may also increase the incidence of infection and impaired wound healing.²⁹ A major randomized trial, the Functional Outcomes in Cardiovascular Patients Undergoing Surgical hip fracture repair (FOCUS) study, is currently being conducted to address the issue of functional recovery. Its primary aim is to determine whether liberal transfusion improves walking ability among anemic patients with a history of cardiovascular disease who undergo operative repair of a hip fracture.³⁰

OBSERVATION OF ANEMIA

It is now standard practice to observe patients with low hemoglobin concentrations that in the past would have triggered transfusion. For most acutely anemic patients, the data currently available support this approach down to a hemoglobin concentration of 6 to 7 g/dl; however, below 6 g/dl, the data suggest that the benefits of transfusion outweigh the risks.

For all patients, if the hemoglobin level drops low enough, cellular metabolism cannot be sustained and death becomes a certainty. Followers of certain religious faiths have frequently declined blood transfusion even when death is the probable or certain consequence. Such situations have challenged the medical community to find techniques for supporting life at extremely low hemoglobin concentrations, and they have helped to define the limits beyond which a restrictive transfusion protocol may be fatal. Reviews of patients who have refused transfusion suggest that a hemoglobin below 5 g/dl results in substantial increases in mortality, especially in elderly persons and patients with cardiovascular disease.³¹

When RBC transfusion is not possible (whether because the patient declines transfusion or because compatible blood is unavailable), there are a number of temporizing measures that can be used to support life. First, steps should be taken to minimize additional iatrogenic blood loss. Laboratory tests should be restricted to those that are most likely to benefit the patient, and they should be conducted with the smallest amount of blood possible (e.g., the volume contained in pediatric specimen tubes). Non-emergency operations that are likely to involve appreciable blood loss should be postponed if possible. Second, any impediments to native erythropoiesis should be removed: iron should be supple-

Table 4 Blood Substitutes⁹⁹

Product (Manufacturer)	Source
PHP (Apex Bioscience)	Pyridoxylated human hemoglobin conjugated to polyoxyethylene
PEG-hemoglobin (Enzon)	Bovine hemoglobin conjugated to polyethylene glycol
PolyHeme (Northfield Laboratories)	Glutaraldehyde-polymerized pyridoxylated human hemoglobin
Hemopure (Biopure)	Glutaraldehyde-polymerized bovine hemoglobin
Hemolink (Hemosol)	Oxidized raffinose-cross-linked human hemoglobin from expired stored blood
Oxygent (Alliance Pharmaceutical)	Emulsified perflubron

mented orally if possible, and the administration of recombinant erythropoietin should be considered. Third, in extreme cases, consideration should be given to decreasing oxygen demand. Oxygen demand is directly proportional to metabolic activity; that is, as metabolic rate increases, so too does oxygen demand. Once the patient is immobile, respiration becomes a significant contributor to metabolic requirements. Mechanical ventilation reduces the work of breathing and with it the oxygen requirements of the respiratory muscles. Respiratory efforts can be fully eliminated with neuromuscular blocking agents, which will reduce oxygen demand in essentially all skeletal muscle, and the metabolic rate can be further reduced by inducing hypothermia.

A completely different approach to the issue of the unacceptability or unavailability of RBC transfusion involves the use of RBC substitutes to augment oxygen-carrying capacity. Various dif-

ferent substitutes are currently under investigation [see Table 4].³² None have been approved for routine use by the United States Food and Drug Administration, but several have demonstrated promise in clinical trials. Without modification, the hemoglobin molecule is nephrotoxic. Accordingly, virtually all of the products now being studied depend on techniques for making an acellular hemoglobin molecule nontoxic for I.V. administration.

Acellular blood substitutes clearly possess a number of advantages, including greatly increased shelf life, reduced risk of viral transmission, availability that is not limited by donor supply, reduced or eliminated risk of incompatibility reactions, and potentially greater acceptance among patients who decline blood transfusions.³³ To what extent this approach is suited to the treatment of anemia in surgical patients should be clarified when the results of the trials now under way are published.

Discussion

Mechanics of Hemostasis

Hemostasis is the term for the process by which cellular and plasma components interact in response to vessel injury in order to maintain vascular integrity and promote wound healing. The initial response to vascular injury (primary hemostasis) involves the recruitment and activation of platelets, which then adhere to the site of injury. Subsequently, plasma proteins, in concert with cellular components, begin to generate thrombin, which causes further activation of platelets and converts fibrinogen to fibrin monomers that polymerize into a fibrin clot. The final step is the release of plasminogen activators that induce clot lysis and tissue repair.

The cellular components of hemostasis include endothelium, white blood cells (WBCs), RBCs, and platelets. The plasma components include a number of procoagulant and regulatory proteins that, once activated, can accelerate or downregulate thrombin formation or clot lysis to facilitate wound healing. In normal individuals, these hemostatic components are in a regulatory balance; thus, any abnormality involving one or more of these components can result in a pathologic state, whether of uncontrolled clot formation (thrombosis) or of excessive bleeding (hemorrhage). These pathologies can result from either hereditary defects of protein synthesis or acquired deficiencies attributable to metabolic causes.

CELLULAR COMPONENTS

Endothelium

The endothelium has both procoagulant and anticoagulant properties. When vascular injury occurs, the endothelium serves as a nidus for recruitment of platelets, adhesion of platelets to the endothelial surface, platelet aggregation, migration of platelets across the endothelial surface, generation of fibrin, and expression of adhesion molecule receptors (E-selectin and P-selectin). Exposure of collagen fibrils and release of vWF from the Weibel-Palade bodies cause platelets to adhere to the cellular surface of the endothelium. The presence of interleukin-1 β (IL-1 β), tissue necrosis factor (TNF), interferon gamma (IFN- γ), and thrombin promotes expression of tissue factor (TF) on the endothelium.^{34,35} TF activates factors X and VII, and these activated factors generate additional thrombin, which increases both fibrin formation and platelet aggregation.

The endothelium also acts in numerous ways to downregulate coagulation.³⁶ Heparan sulfate and thrombomodulin are both

down-regulators of thrombin formation. In the presence of thrombin, the endothelium responds by (1) releasing thrombomodulin, which forms a complex with thrombin to activate protein C; (2) producing endothelium-derived relaxing factor (i.e., nitric oxide³⁷) and prostacyclin, which have vasodilating and platelet aggregation-inhibiting effects, respectively; and (3) releasing tissue plasminogen activator (t-PA) or urokinase-type plasminogen activator (u-PA), either of which converts the zymogen plasminogen to an active form (i.e., plasmin) that degrades fibrin and fibrinogen.^{34,38} Heparan sulfate, on the endothelium wall, forms a complex with plasma antithrombin to neutralize thrombin. The endothelium is also the source of tissue factor pathway inhibitor (TFPI), which downregulates TF-VIIa-Xa complexes.

Erythrocytes and Leukocytes

The nonplatelet cellular components of blood play indirect roles in hemostasis. RBCs contain thromboplastins that are potent stimulators of various procoagulant proteins. In addition, the concentration of RBCs within the bloodstream (expressed as the hematocrit) assists in primary hemostasis by physically forcing the platelets toward the endothelial surfaces. When the RBC count is low enough, the absence of this force results in inadequate endothelium-platelet interaction and a bleeding diathesis.

Leukocytes have several functions in the hemostatic process. The interaction between the adhesion molecules expressed on both leukocytes and endothelium results in cytokine production, initiation of inflammatory responses, and degradation of extracellular matrix to facilitate tissue healing. In the presence of thrombin, monocytes express TF, which is an integral procoagulant for thrombin generation. Neutrophils and activated monocytes bind to stimulated platelets and endothelial cells that express P-selectin. Adhesion and rolling of neutrophils, mediated by fibrinogen and selectins on the endothelium, appear to help restore vessel integrity but may also lead to inflammatory responses.^{39,40} Lymphocytes also adhere to endothelium via adhesion molecule receptors and appear to be responsible for cytokine production and inflammatory responses.

Platelets

The roles platelets play in hemostasis and subsequent fibrin formation rest on providing a phospholipid surface for localizing procoagulant activation. Activation of platelets by agonists such as

adenosine triphosphate (ATP), adenosine diphosphate (ADP), epinephrine, thromboxane A₂, collagen, and thrombin causes platelets to undergo morphologic changes and degranulation. Degranulation of platelets results in the release of procoagulants that promote further platelet adhesion and aggregation (e.g., thrombospondin, vWF, fibrinogen, ADP, ATP, and serotonin), and surface expression of P-selectin, which induces cellular adhesion. Platelet degranulation also results in the release of β -thromboglobulin, platelet factor 4 (which has antiheparin properties), various growth factors, coagulation procoagulants, and calcium as well as the formation of platelet microparticles. Plasminogen activator inhibitor-1 (PAI-1) released from degranulated platelets neutralizes the fibrinolytic pathway by forming a complex with t-PA.

Upon exposure to vascular injury, platelets adhere to the exposed endothelium via binding of vWF to the GPIIb-IX-V complex.⁴¹ Conformational changes in the GPIIb-IIIa complex on the activated platelet surface enhance fibrinogen binding, which results in platelet-to-platelet interaction (i.e., complex morphologic changes and aggregation). The phospholipid surface of the platelet membranes anchors activated IXa-VIIIa and Xa-Va complexes, thereby localizing thrombin generation.⁴²

PLASMA COMPONENTS

Procoagulants

Traditional diagrams of the coagulation cascade depict two distinct pathways for thrombin generation: the intrinsic pathway and the extrinsic pathway. The premise for the distinction between the two is that the intrinsic pathway requires no extravascular source for initiation, whereas the extrinsic pathway requires an extravascular component (i.e., TF). This traditional depiction is useful in interpreting coagulation tests, but it is not an accurate reflection of the hemostatic process in vivo. Accordingly, our focus is not on this standard view but rather on the roles contact factors (within the intrinsic cascade) and TF play in coagulation. As noted, circulating plasma vWF is necessary for normal adhesion of platelets to the endothelium. Plasma vWF also serves as the carrier protein for factor VIII, preventing its neutralization by the protein C regulatory pathway.

Even in patients in whom laboratory tests strongly suggest a severe clotting abnormality (i.e., the aPTT is markedly prolonged), contact factors do not play a significant role in the generation of thrombin. However, contact factor activation does appear to play secondary roles that are essential to normal hemostasis and tissue repair. Factor XII, prekallikrein, and high-molecular-weight kininogen are bound to the endothelium to activate the bradykinin (BK) pathway. The BK pathway exerts profibrinolytic effects by stimulating endothelial release of plasminogen activators. It also stimulates endothelial production of nitric oxide and prostacyclin, which play vital regulatory roles in vasodilation and regulation of platelet activation.⁴³

The key initiator of plasma procoagulant formation is the expression of TF on cell surfaces.^{35,44} TF activates factor VII and binds with it to form the TF-VIIa complex, which activates factors X and IX. Factor Xa also enhances its own production by activating factor IX, which in turn activates factor X to form factor Xa. Factor Xa also produces minimal amounts of thrombin by cleaving the prothrombin molecule. The thrombin generated from this process cleaves the coagulation cofactors V and VIII to enhance production of the factor complexes IX-VIIIa (intrinsic tenase) and Xa-Va (prothrombinase), which catalyze conversion of prothrombin to thrombin [see Figure 2].⁴⁵

Thrombin has numerous functions, including prothrombotic and regulatory functions. Its procoagulant properties include cleaving fibrinogen, activating the coagulation cofactors V and

VIII, inducing platelet aggregation, inducing expression of TF on cell surfaces, and activating factor XIII. In cleaving fibrinogen, thrombin causes the release of fibrinopeptides A and B (fibrin monomer). The fibrin monomer undergoes conformational changes that expose the α and β chains of the molecule, which then polymerize with other fibrin monomers to form a fibrin mesh. Activated factor XIII cross-links the polymerized fibrin (between the α chains and the γ chains) to stabilize the fibrin clot and delay fibrinolysis.

Fibrin(ogen)olysis

Plasminogen is the primary fibrinolytic zymogen that circulates in plasma. In the presence of t-PA or u-PA (released from the endothelium), plasminogen is converted to the active form, plasmin. Plasmin cleaves fibrin (or fibrinogen) between the molecule's D and E domains, causing the formation of X, Y, D, and E fragments. The secondary function of the fibrinolytic pathway is the activation by u-PA of matrix metalloproteinases that degrade the extracellular matrix.⁴⁶

Regulatory Factors

In persons with normal coagulation status, downregulation of hemostasis occurs simultaneously with the production of procoagulants (e.g., activated plasma factors, stimulated endothelium, and stimulated platelets). In addition to their procoagulant activity, both thrombin and contact factors stimulate downregulation of the coagulation process. Thrombin forms a complex with endothelium-bound thrombomodulin to activate protein C, which inhibits factors Va and VIIIa. The thrombin-thrombomodulin complex also regulates the fibrinolytic pathway by activating a circulating plasma protein known as thrombin-activatable fibrinolysis inhibitor (TAFI), which appears to suppress conversion of plasminogen to plasmin.⁴⁷ Contact factors are known to be required for normal surface-dependent fibrinolysis, and there is some evidence that contact factor deficiencies can lead to thromboembolism. Another plasma protein responsible for regulation of fibrinolysis is α_2 -antiplasmin, which binds to circulating and bound plasmin to limit breakdown of fibrin.

Circulating downregulating proteins include antithrombin (a serine protease inhibitor of activated factors—especially factors IXa, Xa, and XIa—and thrombin⁴⁵), proteins C and S (regulators of factors VIIIa and Va⁴⁸), C1 inhibitor (a regulator of factor XIa), TFPI (a regulator of the TF-VIIa-Xa complex⁴⁹), and α_2 -macroglobulin (a thrombin inhibitor—the primary thrombin inhibitor in neonates⁵⁰). Limitation of platelet activation occurs secondarily as a result of decreased levels of circulating agonists and endothelial release of prostacyclin [see Figure 2].

Bleeding Disorders

INHERITED COAGULOPATHIES

Numerous congenital abnormalities of the coagulation system have been identified. In particular, various abnormalities involving plasma proteins (e.g., hemophilia and vWD), platelet receptors (e.g., Glanzmann thrombasthenia and Bernard-Soulier syndrome), and endothelium (e.g., telangiectasia) have been described in detail. For the sake of brevity, we will refer to abnormal protein synthesis resulting in a dysfunctional coagulation protein as a defect and to abnormal protein synthesis resulting in decreased protein production as a deficiency.

Most of the coagulation defects associated with endothelium are closely related to thrombosis or atherosclerosis. Defects or

antihistamines, and phenytoin).⁶⁶⁻⁷⁰ Direct anti-platelet receptor drugs (e.g., abciximab and eptifibatid) block the GPIIb-IIIa complex, thereby preventing platelet aggregation.⁷¹ Thrombocytopenia can be primary or secondary to a number of clinical conditions. Primary bone disorders (e.g., myelodysplastic or myelophthisic syndromes) and spontaneous bleeding may arise when platelet counts fall below 10,000/mm³.

Thrombocytopenia can be associated with immune causes (e.g., immune thrombocytopenic purpura or thrombotic thrombocytopenic purpura) or can occur secondary to administration of drugs (e.g., heparin). Acquired platelet dysfunction (e.g., acquired vWD) that is not related to dietary or pharmacologic causes has been observed in patients with immune disorders or cancer.

Acquired plasma factor deficiencies are common as well. Patients with severe renal disease typically exhibit platelet dysfunction (from excessive amounts of uremic metabolites), factor deficiencies associated with impaired synthesis or protein loss (as with increased urinary excretion), or thrombocytopenia (from diminished thrombopoietin production).^{72,73} Patients with severe hepatic disease commonly have impairment of coagulation factor synthesis, increases in circulating levels of paraproteins, and splenic sequestration of platelets.

Hemodilution from massive RBC transfusions can occur if more than 10 packed RBC units are given within a short period without plasma supplementation. Immunologic reactions to ABO/Rh mismatches can induce immune-mediated hypercoagulation. Acquired multifactorial deficiencies associated with extracorporeal circuits (e.g., cardiopulmonary bypass, hemodialysis, and continuous venovenous dialysis) can arise as a consequence of hemodilution from circuit priming fluid or activation of procoagulants after exposure to thrombogenic surfaces.⁷⁴⁻⁷⁶ Thrombocytopenia can result from platelet destruction and activation caused by circuit membrane exposure, or it can be secondary to the presence of heparin antibody.

Animal venoms can be either procoagulant or prothrombotic. The majority of the poisonous snakes in the United States (rattlesnakes in particular) have venom that works by activating prothrombin, but cross-breeding has produced a number of new venoms with different hemostatic consequences. The clinical presentation of coagulopathies associated with snakebites generally mimics that of consumptive coagulopathies.⁷⁷

Drug-induced factor deficiencies are common, particularly as a result of anticoagulant therapy. The most commonly used anticoagulants are heparin and warfarin. Heparin does not cause a factor deficiency; rather, it accelerates production of antithrombin, which inhibits factor IXa, factor Xa, and thrombin, thereby prolonging clot formation. Warfarin reduces procoagulant potential by inhibiting vitamin K synthesis, thereby reducing carboxylation of factor VII, factor IX, factor X, prothrombin, and proteins C and S. Newer drugs that may also cause factor deficiencies include direct thrombin inhibitors (e.g., lepirudin and bivalirudin⁷⁸) and fibrinogen-degrading drugs (e.g., ancred⁷⁹).

Isolated acquired factor deficiencies are relatively rare. Clinically, they present in exactly the same way as inherited factor deficiencies, except that there is no history of earlier bleeding. In most cases, there is a secondary disease (e.g., lymphoma or an autoimmune disorder) that results in the development of antibody to a procoagulant (e.g., factor V, factor VIII, factor IX, vWF, prothrombin, or fibrinogen).⁸⁰⁻⁸²

Disseminated Intravascular Coagulation

DIC is a complex coagulation process that involves activation of the coagulation system with resultant activation of the fibrinolytic

pathway and deposition of fibrin; the eventual consequence is the multiple organ dysfunction syndrome (MODS).⁸³ The activation occurs at all levels (platelets, endothelium, and procoagulants), but it is not known whether this process is initiated by a local stimulus or a systemic one. It is crucial to emphasize that DIC is an acquired disorder that occurs secondary to an underlying clinical event (e.g., a complicated birth, severe gram-negative infection, shock, major head injury, polytrauma, severe burns, or cancer). As noted [*see Measurement of Coagulation Parameters, Increased INR, Prolonged aPTT, above*], there is some controversy regarding the best approach to therapy, but there is no doubt that treating the underlying cause of DIC is paramount to patient recovery.

DIC is not always clinically evident: low-grade DIC may lack clinical symptoms altogether and manifest itself only through laboratory abnormalities, even when thrombin generation and fibrin deposition are occurring. In an attempt to facilitate recognition of DIC, the disorder has been divided into three phases, distinguished on the basis of clinical and laboratory evidence. In phase I DIC, there are no clinical symptoms, and the routine screening tests (i.e., INR, aPTT, fibrinogen level, and platelet count) are within normal limits.⁸⁴ Secondary testing (i.e., measurement of antithrombin, prothrombin fragment, thrombin-antithrombin complex, and soluble fibrin levels) may reveal subtle changes indicative of thrombin generation. In phase II DIC, there are usually clinical signs of bleeding around wounds, suture sites, I.V. sites, or venous puncture sites, and decreased function is noted in specific organs (e.g., lung, liver, and kidneys). The INR is increased, the aPTT is prolonged, and the fibrinogen level and platelet count are decreased or decreasing. Other markers of thrombin generation and fibrinolysis (e.g., D-dimer level) show sizable elevations. In phase III DIC, MODS is observed, the INR and the aPTT are markedly increased, the fibrinogen level is markedly depressed, and the D-dimer level is dramatically increased. A peripheral blood smear would show large numbers of schistocytes, indicating RBC shearing resulting from fibrin deposition.

The activation of the coagulation system seen in DIC appears to be primarily caused by TF. The brain, the placenta, and solid tumors are all rich sources of TF. Gram-negative endotoxins also induce TF expression. The exposure of TF on cellular surfaces causes activation of factors VII and IX, which ultimately leads to thrombin generation. Circulating thrombin is rapidly cleared by antithrombin. Moreover, the coagulation pathway is downregulated by activated protein C and protein S. However, constant exposure of TF (as a result of underlying disorders) results in constant generation of thrombin, and these regulator proteins are rapidly consumed. TAFI and PAI also contribute to fibrin deposition by restricting fibrinolysis and subsequent fibrin degradation and clearance. Finally, it is likely that release of cytokines (e.g., IL-6, IL-10, and TNF) may play some role in causing the sequelae of DIC by modulating or activating the coagulation pathway.

Laboratory Assessment of Bleeding

Laboratory testing is an integral part of the diagnostic algorithm used in assessing the bleeding patient. It may not be prudent to wait for laboratory values before beginning treatment of acute bleeding, but it is imperative that blood samples for coagulation testing be drawn before therapy. The development of microprocessor technology has made it possible to perform diagnostic laboratory testing outside the confines of the clinical laboratory (so-called near-care testing). Whether near-care testing or clinical laboratory testing is employed, it is important to recognize that valuable as such testing is, it does not provide all of the needed diagnostic information.

In particular, the value of a careful patient history must not be underestimated. Previous bleeding events and a familial history of bleeding are both suggestive of a congenital coagulopathy. A thorough medication inventory is necessary to assess the possible impact of drugs on laboratory and clinical presentations. In the patient history query, it is advisable to ask explicitly about nonprescription drugs—using expressions such as “over-the-counter drugs,” “cold medicines,” and “Pepto-Bismol”—because unless specifically reminded, patients tend to equate the term medications with prescription drugs. If this is not done, many drugs that are capable of influencing hemostasis *in vivo* and *in vitro* (e.g., salicylates, cold and allergy medicines, and herbal supplements) may be missed. Mucosal and superficial bleeding is suggestive of platelet abnormalities, and deep bleeding is suggestive of factor deficiency.

It is important to be clear on the limitations of coagulation testing. At present, there are no laboratory or *ex vivo* methods capable of directly measuring the physiologic properties of the endothelium. Indirect assessments of endothelial damage can be obtained by measuring levels of several laboratory parameters (e.g., vWF, the soluble cytokines endothelin-1 and E-selectin, and thrombomodulin), but such measurements have no clinical utility in the assessment of a bleeding patient.

Another issue is that of bias resulting from technical factors. PT (i.e., INR) and aPTT testing involves adding activators, phospholipids, and calcium to plasma in a test tube (or the equivalent) and determining the time to clot formation. Time to clot formation is a relative value, in that it is compared with the time in a normal population. A perturbation within the coagulation cascade, an excess of calcium, or poor sampling techniques (e.g., inadequately filled coagulation tubes, excessive tourniquet time, and clotted or activated samples) can bias the results. Hemolysis from the drawing of blood can also bias results via the effects of thromboplastins released from RBC membranes to initiate the coagulation process. In addition, many coagulation factors are highly labile, and failure to process and run coagulation samples immediately can bias test results.

Finally, not all coagulation tests are functionally equivalent: different laboratory methods may yield differing results.⁸⁵ Coagulation reagents have been manufactured in such a way as to ensure that the coagulation screening tests are sensitive to factor VIII and IX deficiencies and the effects of anticoagulation with warfarin or heparin. Thus, a normal aPTT in a patient with an abnormal INR may not exclude the possibility of common pathway deficiencies (e.g., deficiencies of factors X, V, and II), and most current methods of determining the INR and the aPTT do not detect low fibrinogen levels. The approach we use assumes that the methods used to assess INR and aPTT can discriminate normal factor activity levels from abnormal levels (< 0.4 IU/ml).

The CBC (including platelet count and differential count), the INR, and the aPTT tests should be the primary laboratory tests for differentiating coagulopathies [see Figure 3].

Platelet count and platelet function should be considered as independent values [see Figure 4]. Patients with congenital thrombocytopathies often have normal platelet counts; therefore, assessment of platelet function is required as well. Historically, the bleeding time has been used to assess platelet function. This test is grossly inadequate, in that it may yield normal results in as many as 50% of patients with congenital thrombocytopathies.^{86,87} Numerous rapid tests of platelet function are currently available that can be used to screen for platelet defects; these tests should be considered in the diagnostic approach to the bleeding patient [see Table 5].⁸⁷⁻⁸⁹

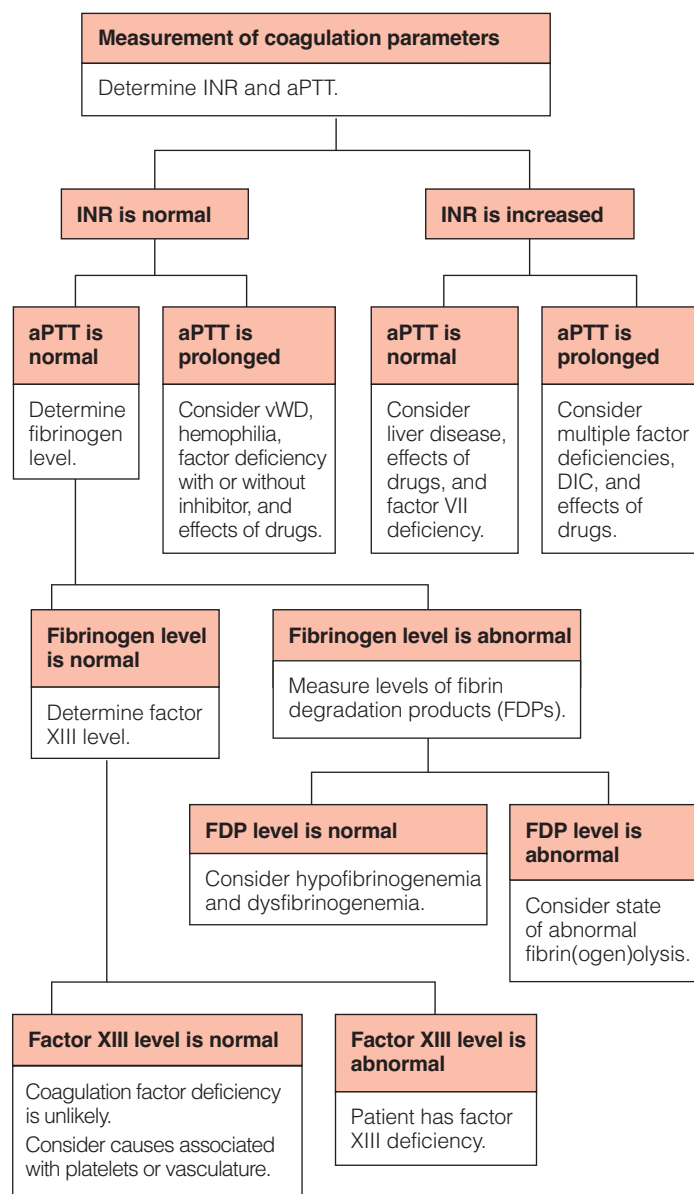

Figure 3 Algorithm depicts use of coagulation parameters in assessment of coagulopathies.

Novel and Experimental Therapies for Bleeding

Novel approaches to controlling bleeding have been developed for use in two specific patient groups: (1) patients with uncontrolled exsanguinating hemorrhage and (2) elderly patients on warfarin therapy who have a therapeutic INR and who present with intracranial bleeding.

As noted [see Measurement of Coagulation Parameters, Normal INR, Prolonged aPTT, *above*], recombinant factor VIIa is currently used for control of bleeding in hemophilia A patients with antibodies to factors VIII as well as in hemophilia B patients with antibodies to factor IX, and it has received FDA approval for this indication. The remarkable success of rVIIa in this setting led many investigators to consider the possibility that giving this agent to actively bleeding patients would enhance the normal clotting mechanism and provide nonsurgical control or reduction of traumatic bleeding. Accordingly, rVIIa has been advocated for early use in injured patients with uncontrolled hemorrhage.⁹⁰

One international randomized trial of rVIIa in severely injured trauma patients has been performed.⁹¹ The results of this trial suggested that there was a decreased requirement for blood transfusions and a trend toward decreased organ failure among blunt trauma patients who received rVIIa, but no reduction in mortality was demonstrated. It is to be hoped that the trauma surgery community will be able to organize a more robust trial that will be capable of formally determining whether the putative benefits of rVIIa are outweighed by the potential risks.⁹² In the absence of such a formal determination, surgeons will continue to encounter situations in which they must decide whether to use rVIIa despite its incompletely understood efficacy and safety profile in this setting. Accordingly, consensus recommendations have attempted to define appropriate usage in the light of insufficient evidence.⁹³

In elderly patients receiving therapeutic warfarin therapy, head injuries that would normally be inconsequential can result in life-threatening intracranial bleeding. Correction of the INR with either FFP or vitamin K may take so long that the patient becomes vegetative before the hemorrhage is controlled. Prothrombin complex concentrate appears to correct the INR more rapidly and effectively than FFP or vitamin K.⁹⁴ One randomized trial that included nonanticoagulated patients who had sustained a hemorrhagic stroke suggested that administration of rVIIa reduces hemorrhage volume and may improve survival as well.⁹⁵ With both prothrombin complex and rVIIa, additional trials will have to be done before routine use of these agents to correct elevated INRs in this patient population can be recommended.

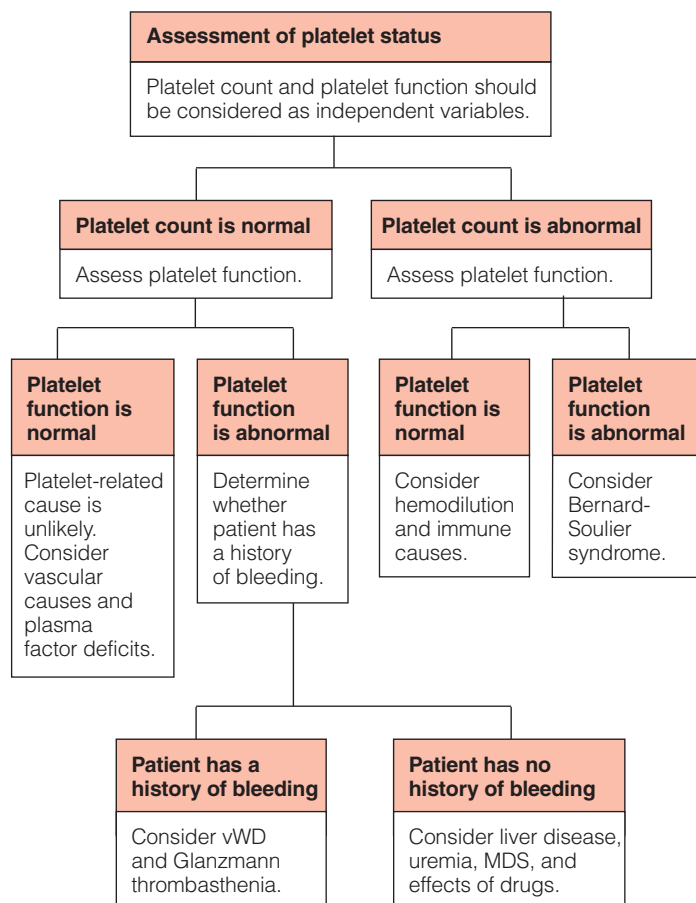

Figure 4 Algorithm depicts use of platelet count and platelet functional status in assessment of coagulopathies. (MDS—myeloid dysplastic syndrome)

Table 5 Tests of Platelet Function

Product (Manufacturer)	Method
PFA-100 (Dade Behring)	Measures time required to occlude aperture after exposure to platelet agonists at shear rates
hemoSTATUS (Medtronic)	Measures activated clotting time; platelet-activating factor is the platelet agonist
AggreStat (Centocor)	Measures changes in voltage (impedance) after addition of platelet agonist
Thromboelastograph (Haemoscope)	Measures changes in the viscoelastic properties of clotting blood induced by a rotating piston
Sonoclot Analyzer (Sienco)	Measures changes in the viscoelastic properties of clotting blood induced by a vibrating probe
Clot Signature Analyzer (Xylum)	Measures changes in platelet function at shear rates
Ultegra Analyzer (Accumetrics)	Used primarily for measuring the effect of platelet glycoprotein blockers (e.g., abciximab and eptifibatid); thrombin receptor activator peptide is the agonist

Another novel agent that has been assessed as a means of achieving hemostasis in military settings is QuikClot (Z-Medica, Wallingford, Connecticut), a granular substance containing the mineral zeolite. To date, however, the use of this contact agent has generally been restricted to the extremities, and the available data are not sufficient to determine its efficacy.

Mechanism and Significance of Transfusion-Related Immunomodulation

Although a unit of packed RBCs is an exceedingly complex biologic substance, blood is used frequently and somewhat casually, compared with many pharmaceutical agents that have undergone extensive regulatory review. A unit of allogeneic transfused blood contains antigenic RBCs, WBCs, and platelets; an array of antigenic or immunologically active substances in plasma (including both substances from donor plasma and substances that accumulate during storage); and, potentially, viral, bacterial, and parasitic pathogens. However, the specific transfusion-related factors that result in dysregulation of the innate or adaptive immune responses, as well as the clinical consequences of this immunomodulation, remain inadequately defined.

Interest in the immunosuppressive effect of blood transfusion stems from the observation by Opelz and associates in 1973 that recipients of cadaveric renal transplants experienced longer graft survival if they had undergone allogeneic blood transfusion before transplantation.⁹⁶ A subsequent randomized trial showed that even with concomitant use of cyclosporine-based immunosuppressive regimens, pretransplantation transfusion resulted in improved renal allograft survival at 5 years after operation.⁹⁷

A number of different strategies for mitigating this immunosuppressive effect have been considered, including the use of more restrictive criteria for transfusion and the administration of autologous blood products. Besides these two strategies, the approach that has attracted the most interest is to decrease the number of donor leukocytes in units of blood. In Europe, before the adoption of leukoreduction, buffy-coat reduction was employed to remove 70% to 80% of donor leukocytes. The concept was taken one step

further by the development of leukoreduction, which typically involves the use of prestorage filtration techniques to remove more than 99.9% of donor leukocytes. Although leukoreduction has been adopted by Canada and several European countries, the FDA has stopped short of mandating universal leukoreduction in the United States.

As an alternative to reducing the number of donor leukocytes, some have advocated controlling the storage time of blood products so that either fresher or older blood can be provided if desired. Fresh units of blood may contain fewer deformed erythrocytes that could impair the capillary microcirculation; older units of blood may contain fewer viable donor leukocytes, which may be the most harmful agents immunologically. Others have advocated restricting blood donations from previously pregnant women, who, by virtue of greater alloimmunization, may have more immunologically active leukocytes.

Since the initial report on the immunosuppressive effect of blood transfusion,⁹⁶ a plethora of observational studies and some

randomized trials have attempted to evaluate the role of blood transfusion in the recurrence of resected malignancies and postoperative infection. Most of the observational studies have compared the outcomes of transfused cohorts with those of nontransfused cohorts. The randomized trials, however, have mostly evaluated different kinds of blood transfusions against one another (e.g. autologous versus allogeneic and leukoreduced versus nonleukoreduced). The literature is extensive, but many methodologic issues have been identified that limit the validity of the studies.⁹⁸ Accordingly, the evidence appears to be insufficient to establish a causal connection between allogeneic blood transfusion and either increased cancer recurrence or postoperative infection. Nonetheless, the heterogeneity of the study results and the finding of the TRICC trial that a restrictive transfusion policy may improve survival in some patients continue to fuel debate over whether the avoidance or modification of allogeneic blood transfusion may improve patient outcomes.

5 POSTOPERATIVE PAIN

Henrik Kehlet, M.D., Ph.D., F.A.C.S. (Hon.)

Approach to the Patient with Postoperative Pain

Pain may usefully be classified into two varieties: acute and chronic. As a rule, postoperative pain is considered a form of acute pain, though it may become chronic if it is not effectively treated.

Postoperative pain consists of a constellation of unpleasant sensory, emotional, and mental experiences associated with autonomic, psychological, and behavioral responses precipitated by the surgical injury. Despite the considerable progress that has been made in medicine during the past few decades, the apparently simple problem of how to provide total or near total relief of postoperative pain remains largely unsolved. Pain management does not occupy an important place in academic surgery. However, government agencies have attempted to foster improved postoperative pain relief, and guidelines have been published.¹⁻³ In 2001, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) introduced standards for pain management,⁴ stating that patients have the right to appropriate evaluation and management and that pain must be assessed.

Postoperative pain relief has two practical aims. The first is provision of subjective comfort, which is desirable for humanitarian reasons. The second is inhibition of trauma-induced nociceptive impulses to blunt autonomic and somatic reflex responses to pain and to enhance subsequent restoration of function by allowing the patient to breathe, cough, and move more easily. Because these effects reduce pulmonary, cardiovascular, thromboembolic, and other complications, they may lead secondarily to improved postoperative outcome.

Inadequate Treatment of Pain

A common misconception is that pain, no matter how severe, can always be effectively relieved by opioid analgesics. It has repeatedly been demonstrated, however, that in a high proportion of postoperative patients, pain is inadequately treated.^{5,6} This discrepancy between what is possible and what is practiced can be

attributed to a variety of causes [see Table 1], which to some extent can be ameliorated by increased teaching efforts. In general, however, the scientific approach to postoperative pain relief has not been a great help to surgical patients in the general ward, where intensive surveillance facilities may not be available.

Guidelines for Postoperative Pain Treatment

The recommendations provided below are aimed at surgeons working on the general surgical ward; superior regimens have been constructed by specialized groups interested in postoperative pain research, but these regimens are not currently applicable to the general surgical population, unless an acute pain service is available. Consideration is given to the efficiency of each analgesic technique, its safety versus its side effects, and the cost-efficiency problems arising from the need for intensive surveillance. For several analgesic techniques, evidence-based recommendations are now available.⁷ For many others, however, there are not sufficient data in the literature to form a valid scientific database; accordingly, recommendations regarding their use are made on empirical grounds only.

In the past few years, efforts have been made to develop procedure-specific perioperative pain management guidelines. The impetus for these efforts has been the realization that the analgesic efficacy may be procedure dependent and that the choice of analgesia in a given case must also depend on the benefit-to-risk ratio, which varies among procedures. In addition, it is clear that some analgesic techniques will only be considered for certain specific operations (e.g., peripheral nerve blocks, cryoanalgesia, and intraperitoneal local anesthesia).⁸⁻¹⁰ At present, these procedure-specific guidelines are still largely in a developmental state and are available only for laparoscopic cholecystectomy, colon surgery, hysterectomy, and hip replacement.¹⁰⁻¹²

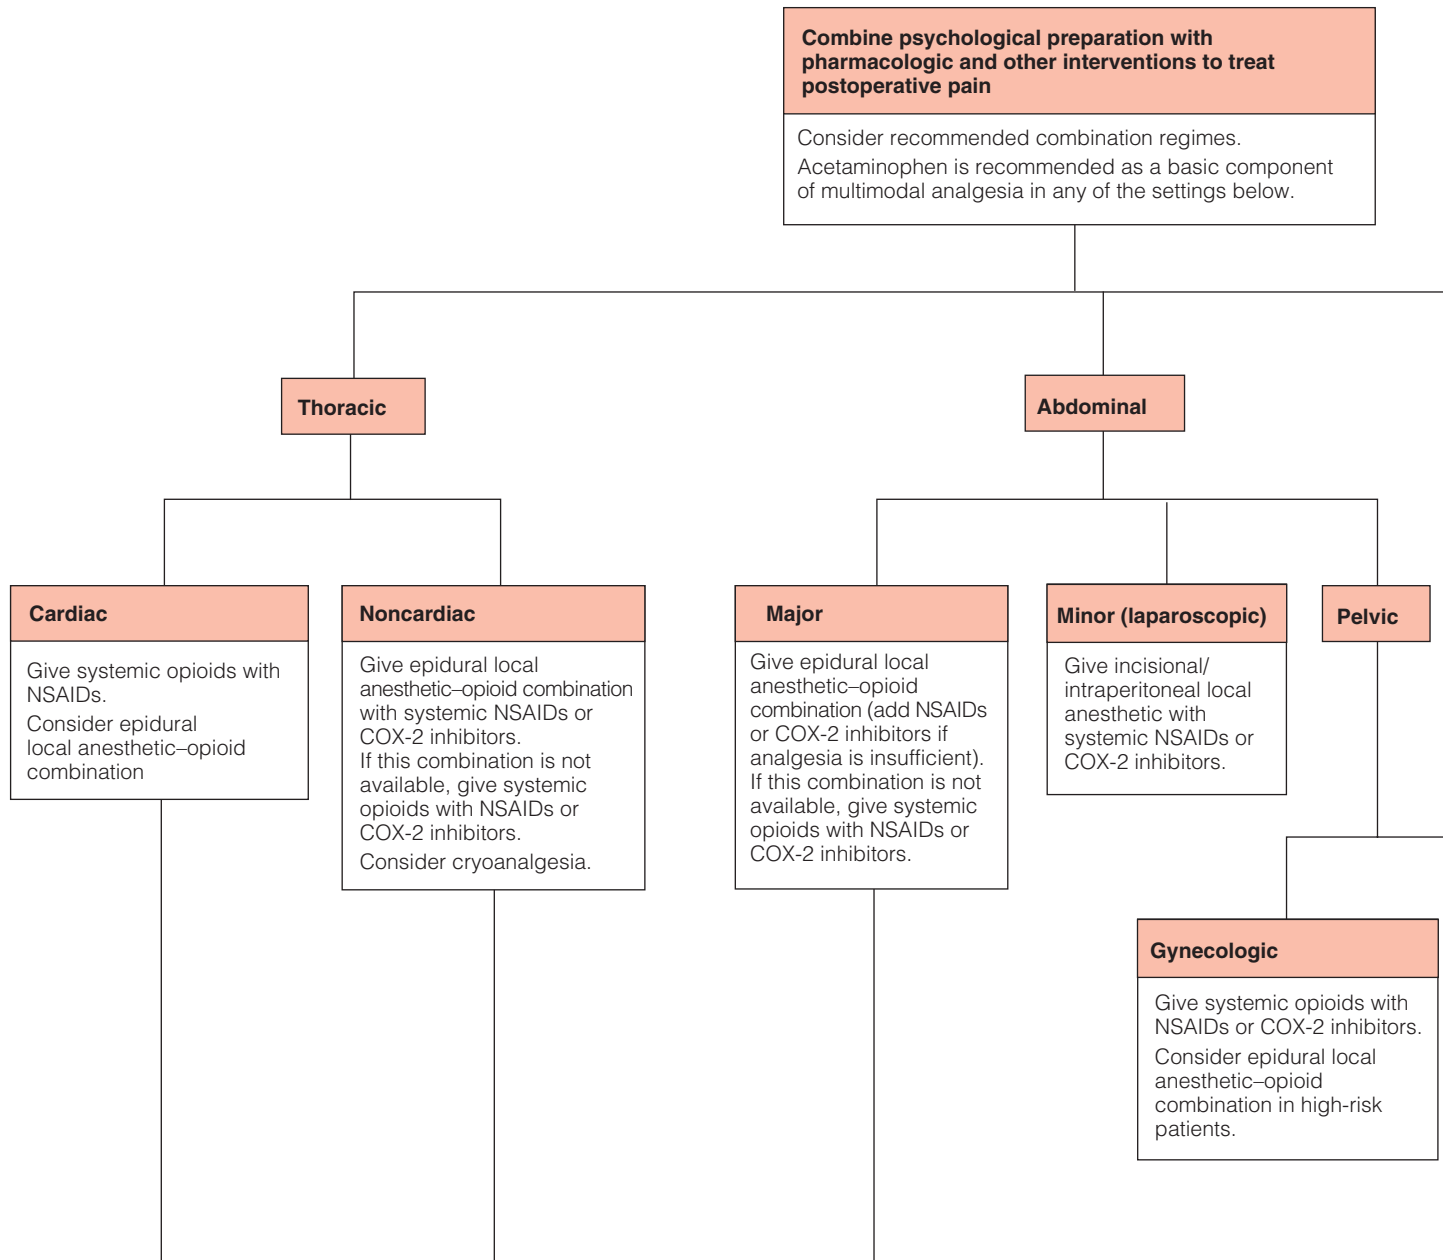

Table 1 Contributing Causes of Inadequate Pain Treatment

- Insufficient knowledge of drug pharmacology among surgeons and nurses
- Uniform (p.r.n.) prescriptions
- Lack of concern for optimal pain relief
- Failure to give prescribed analgesics
- Fear of side effects
- Fear of addiction

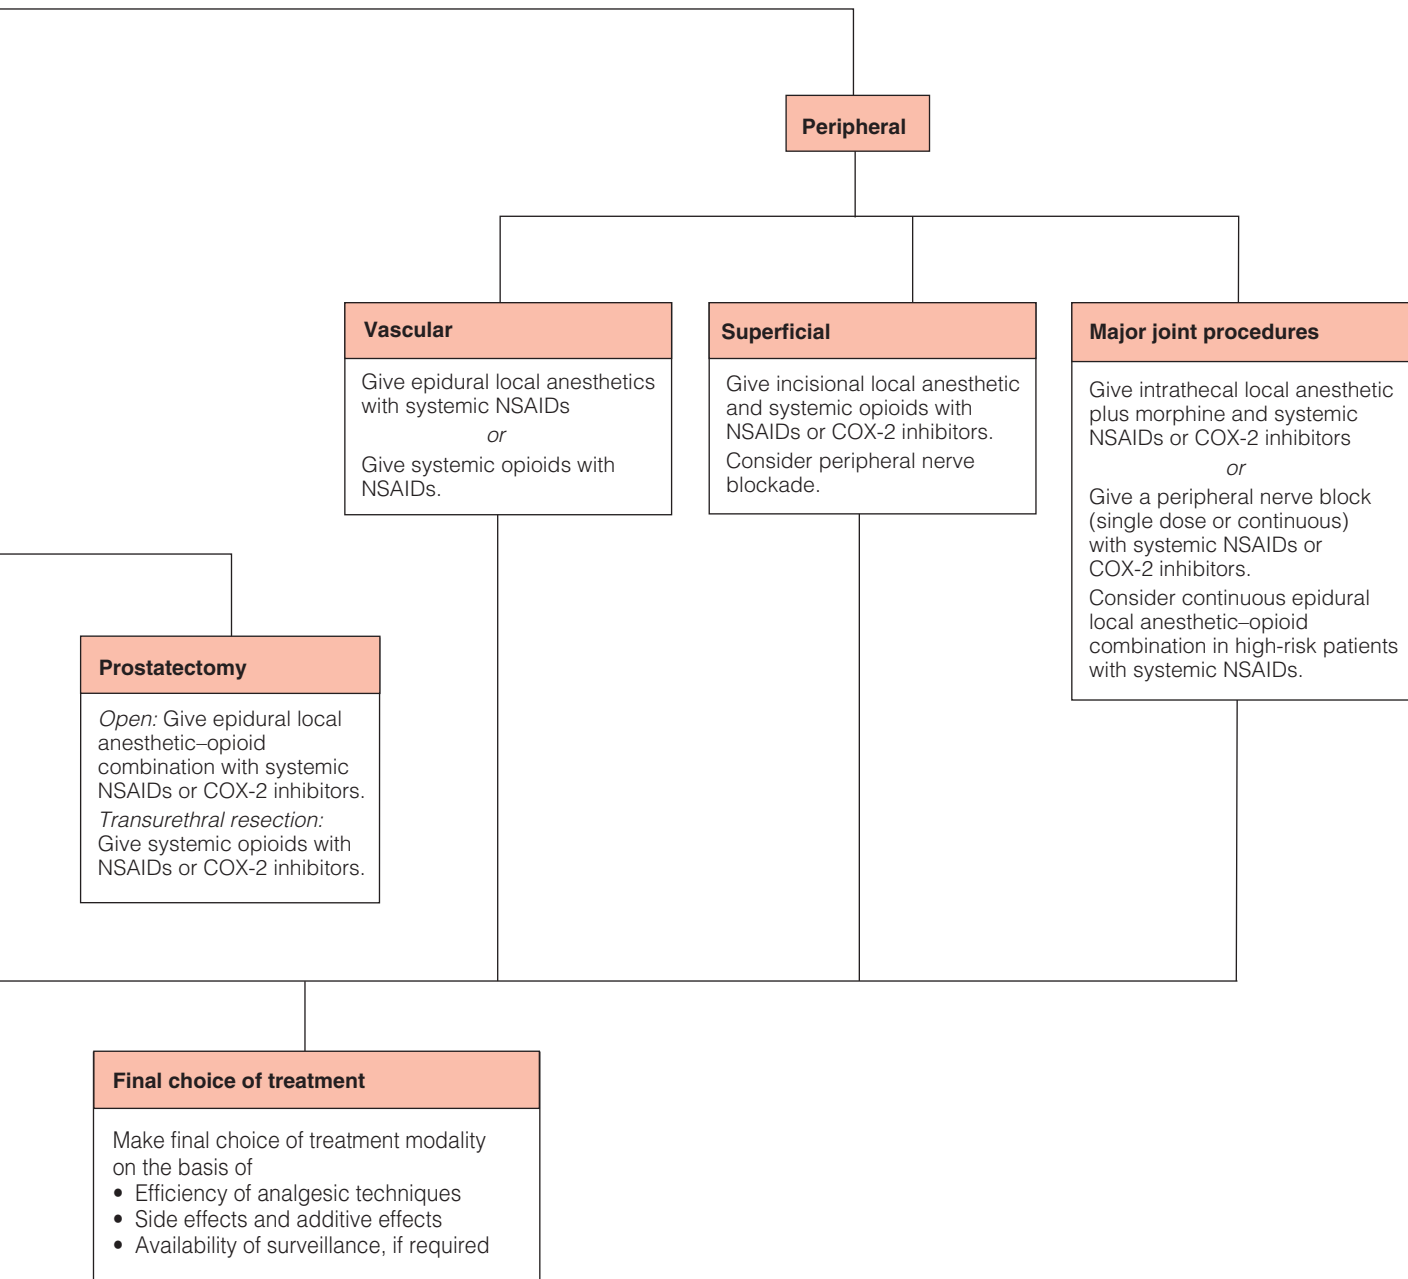

THORACIC PROCEDURES

Pain after thoracotomy is severe, and pain therapy should therefore include a combination regimen, preferably comprising epidural local anesthetics and opioids plus systemic non-steroidal anti-inflammatory drugs (NSAIDs) or cyclooxygenase-2 (COX-2) inhibitors (depending on risk factors). If the epidural regimen is not available, NSAIDs and systemic opioids should be

Approach to the Patient with Postoperative Pain

given to obtain the documented synergistic-additive effect. Cryoanalgesia is useful because it is moderately effective, easy to perform, free of significant side effects, and relatively inexpensive. Paravertebral blocks are also effective but necessitate continuous infusion. Acetaminophen is recommended as a basic analgesic for multimodal analgesia.

Pain after cardiac operation with sternotomy is less severe, and systemic opioids plus NSAIDs are recommended. The combined regimen of epidural local anesthetics and opioids is recommended when more effective pain relief is necessary, and it may reduce cardiopulmonary morbidity.¹³

ABDOMINAL PROCEDURES

Pain after major and upper abdominal operations is severe, and a combined regimen of epidural local anesthetics and opioids is recommended because it has proved to be very effective and to have few and acceptable side effects.^{11,12,14} Furthermore, the epidural regimen will reduce postoperative pulmonary complications and ileus, as compared with treatment with systemic opioids. Systemic NSAIDs or COX-2 inhibitors are added when needed. Acetaminophen is recommended as a basic analgesic for multimodal analgesia.

After gynecologic operations,¹² systemic opioids plus NSAIDs or COX-2 inhibitors are recommended except in patients in whom more effective pain relief is desirable. In such patients, the combined regimen of epidural local anesthetics and opioids is preferable. Acetaminophen is recommended as a basic analgesic for multimodal analgesia.

Pain following prostatectomy is usually not severe and may be treated with systemic opioids combined with NSAIDs or COX-2 inhibitors and acetaminophen. However, blood loss and thromboembolic complications are reduced when epidural local anesthetics are administered. This method is therefore recommended intraoperatively and continued in selected high-risk patients for pain relief after open prostatectomy and transurethral resection. In low-risk patients, systemic opioids with NSAIDs or COX-2 inhibitors and acetaminophen alleviate postoperative pain.

PERIPHERAL PROCEDURES

After vascular procedures, postoperative pain control is probably best achieved with epidural local anesthetic–opioid mixtures, combined with systemic NSAIDs or COX-2 inhibitors. Acetaminophen is recommended as a basic analgesic for multimodal analgesia. This regimen will be effective, and the increase in peripheral blood flow that is documented to occur with epidural local anesthetics may lower the risk of graft thrombosis.

Pain relief after major joint procedures (e.g., hip and knee operations)¹² may involve an epidural regimen in high-risk patients because such regimens have been shown to reduce thromboembolic complications and intraoperative blood loss and to facilitate rehabilitation. The severe pain noted after knee replacement is probably best treated with epidural local anesthetics combined with opioids. Otherwise, for routine management, a single intrathecal dose of a local anesthetic–low-dose

morphine combination will provide effective analgesia for the first 8 to 16 hours, after which NSAIDs or COX-2 inhibitors may be added. The use of peripheral nerve blocks is gaining more popularity and may be continued postoperatively.^{15,16} Acetaminophen is provided as a basic analgesic for multimodal analgesia. After arthroscopic joint procedures, instillation of a local anesthetic and an opioid analgesic (e.g., morphine) provides effective early postoperative pain relief.

During superficial procedures, systemic opioids combined with NSAIDs or COX-2 inhibitors should suffice. Acetaminophen is provided as a basic analgesic for multimodal analgesia.

Treatment Modalities

PSYCHOLOGICAL INTERVENTIONS

Individuals differ considerably in how they respond to noxious stimuli; much of this variance is accounted

for by psychological factors. Cognitive, behavioral, or social interventions should be used in combination with pharmacologic therapies to prevent or control acute pain, with the goal of such interventions being to guide the patient toward partial or complete self-control of pain.^{17,18} Sophisticated psychological techniques, such as biofeedback and hypnosis therapy, are not applicable to a busy surgical unit, but simple psychological techniques are a valuable part of good medical practice.

Psychological preparation in patients with postoperative pain has been demonstrated to shorten hospital stay and reduce postoperative narcotic use [see Table 2].¹⁹ Psychological techniques should be combined with pharmacologic or other interventions, but care must be taken to ensure that the pharmacologic treatment does not compromise the mental function necessary for the success of the planned psychological intervention.

SYSTEMIC OPIOIDS

The terminology associated with the pharmacology of the opioids is confusing, to say the least. Opiate is an appropriate term for any alkaloid derived from the juice of the plant (i.e., from opium). The proper term for the class of agents, whether exogenous, endogenous, natural, or synthetic, is opioid.

Table 2 Psychological Preparation of Surgical Patients

Procedural information	Give a careful and relevant description of what will take place
Sensory information	Describe the sensations that will be experienced either during or after the operation
Pain treatment information	Outline the plan for administering sedative and analgesic medication, and encourage patients to communicate concerns and discomforts
Instructional information	Teach patients postoperative exercises, such as leg exercises, and show them how to turn in bed or move so that pain is minimal
Reassurance	Reassure those who are mentally, emotionally, or physically unable to cooperate that they are not expected to take an active role in coping with pain and will still receive sufficient analgesic treatment

Table 3 Opioid Receptor Types and Physiologic Actions

Receptor Type	Prototypical Ligand		Physiologic Actions
	Endogenous	Exogenous	
Mu ₁	β-Endorphin	Morphine	Supraspinal analgesia
Mu ₂	β-Endorphin	Morphine	Respiratory depression
Delta	Enkephalin	—	Spinal analgesia
Kappa	Dynorphin	Ketocyclazocine	Spinal analgesia, sedation, ?visceral analgesia
Epsilon	β-Endorphin	—	?Hormone
Sigma	—	N-Allylnormetazocine	Psychotomimetic effect, dysphoria

Mechanisms of Action

Opioids produce analgesia and other physiologic effects by binding to specific receptors in the peripheral and central nervous system [see Table 3]. These receptors normally bind a number of endogenous substances called opioid peptides. These receptor-binding interactions mediate a wide array of physiologic effects.²⁰ Five types of opioid receptors and their subtypes have been discovered: mu, delta, kappa, epsilon, and sigma receptors. Most commonly used opioids bind to mu receptors. The mu₁ receptor is responsible for the production of opioid-induced analgesia, whereas the mu₂ receptor appears to be related to the respiratory depression, cardiovascular effects, and inhibition of GI motility commonly seen with opioids. In studies from 2001 and 2004, investigators were able to obtain a reduction in the GI side effects of morphine with a specific peripherally acting mu antagonist without interfering with analgesia.^{21,22}

The demonstration of the existence of peripheral opioid receptors has given rise to studies investigating the effect of administering small opioid doses at the surgical site. Unfortunately, incisional opioid administration has no significant beneficial effect²³; however, intra-articular administration does yield a modest benefit.²⁴

The relation between receptor binding and the intensity of the resultant physiologic effect is known as the intrinsic activity of an opioid. Most of the commonly used opioid analgesics are agonists. An agonist produces a maximal biologic response by binding to its receptor. Other opioids, such as naloxone, are termed antagonists because they compete with agonists for opioid receptor binding sites. Still other opioids are partial agonists because they produce a submaximal response after binding to the receptor. (An excellent example of a submaximal response produced by partial agonists is buprenorphine's action at the mu receptor.)

Drugs such as nalbuphine, butorphanol, and pentazocine are known as agonist-antagonists or mixed agonist-antagonists.²⁰ These opioids simultaneously act at different receptor sites: their action is agonistic at one receptor and antagonistic at another [see Table 4]. The agonist-antagonists have certain pharmacologic properties that are distinct from those of the more common mu agonists: (1) they exhibit a ceiling effect and cause only submaximal analgesia as compared with mu agonists, and (2) administration of an agonist-antagonist with a complete agonist may cause a reduction in the effect of the complete agonist.²⁰

Agents

Morphine Morphine is the opioid with which the most clinical experience has been gained. Sufficient pharmacokinetic and

pharmacodynamic data are available. Use of this agent is recommended; it may be given orally, intravenously, or intramuscularly [see Table 5].

Meperidine Detailed and sufficient pharmacokinetic and pharmacodynamic data on meperidine are available. It is less suitable than morphine as an analgesic because its active metabolite, normeperidine, can accumulate, even in patients with normal renal clearance, and this accumulation can result in CNS excitation and seizures.²⁰ Other agents should be used before meperidine is considered. Like morphine, meperidine can be given orally, intravenously, or intramuscularly.

Side Effects

By depressing or stimulating the CNS, opioids cause a number of physiologic effects in addition to analgesia. The depressant effects of opioids include analgesia, sedation, and altered respiration and mood; the excitatory effects include nausea, vomiting, and miosis.

All mu agonists produce a dose-dependent decrease in the responsiveness of brain-stem respiratory centers to increased carbon dioxide tension (PCO₂). This change is clinically manifested as an increase in resting PCO₂ and a shift in the CO₂ response curve. Agonist-antagonist opioids have a limited effect on the brain stem and appear to elicit a ceiling effect on increases in PCO₂.

Opioids also have effects on the GI tract. Nausea and vomiting are caused by stimulation of the chemoreceptor trigger zone of the medulla. Opioids enhance sphincteric tone and reduce peristaltic contraction. Delayed gastric emptying is caused by decreased motility, increased antral tone, and increased tone in the first part of the duodenum. Delay in passage of intestinal contents because of decreased peristalsis and increased sphincteric tone leads to greater absorption of water, increased viscosity, and desiccation of bowel contents, which cause constipation and contribute to postoperative ileus. Opioids also increase biliary tract pressure. Finally, opioids may inhibit urinary bladder function, thereby increasing the risk of urinary retention.

Several long-acting, slow-release oral opioids are currently available, but their role (in particular, their safety) in the setting of moderate to severe postoperative pain remains to be established. In addition, modern principles of treatment increasingly emphasize the use of opioid-sparing analgesic approaches to enhance recovery (see below).

EPIDURAL AND SUBARACHNOID OPIOIDS

Opioids were first used in the epidural and subarachnoid space

Table 4 Intrinsic Activity of Opioids

Opioid	Receptor Type			
	Mu	Kappa	Delta	Sigma
<i>Agonists</i>				
Morphine	Agonist	—	—	—

in 1979. Since that time, they have become the mainstay of postoperative management for severe pain. Epidural opioids may be administered in a single bolus or via continuous infusions. They are usually combined with local anesthetics in a continuous epidural infusion to enhance analgesia.¹⁴

Mechanisms of Action

Opioids injected into the epidural or subarachnoid space cause segmental (i.e., selective, spinally mediated) analgesia by binding to opioid receptors in the dorsal horn of the spinal cord.²⁵ The lipid solubility of an opioid, described by its partition coefficient, predicts its behavior when introduced into the epidural or subarachnoid space. Opioids with low lipid solubility (i.e., hydrophilic opioids) have a slow onset of action and a long duration of action. Opioids with high lipid solubility (i.e., lipophilic opioids) have a quick onset of action but a short duration of action. Thus, the lipid

solubility of an opioid determines its access to the dorsal horn via (1) diffusion through the arachnoid granulations and (2) diffusion into spinal radicular artery blood flow.

Subarachnoid opioids should be used when the required duration of analgesia after surgery is relatively short. When protracted analgesia is required, epidural administration is preferred; repeated injections may be given through epidural catheters, or continuous infusions may be used. Smaller doses of subarachnoid opioids are generally required to produce analgesia. Ordinarily, no more than 0.1 to 0.25 mg of morphine should be used. These doses, which are about 10% to 20% of the size of comparably effective epidural doses, provide reliable pain relief with few side effects.²⁶ Fentanyl has also been extensively used in the subarachnoid space in a dose range of 6.25 to 50 µg. Pain relief after administration of subarachnoid fentanyl is as potent but not as prolonged as analgesia after administration of morphine.

Table 5 Suggested Regimens for Systemic Morphine Administration

Intermittent Administration (Suggested Initial Dose)*				
	p.o.	I.M.	I.V.	Duration (hr)
Morphine	30–50 mg	10 mg	5–10 mg	3–4
Continuous I.V. Infusion†				
Morphine	≈ 3 mg/hr (loading dose: 5–10 mg)			

*Number of doses to be given is calculated with the following formula:

$$\frac{24 \text{ hr}}{\text{actual duration of single effective dose (hr)}}$$

Single doses should be given at calculated fixed intervals approximately 30 min before expected recurrence of pain. Single dose should be readjusted daily. Elderly patients may be more susceptible to opioids.

†Dose should be adjusted according to effect and side effects.

Regimens for Acute Pain Relief

It is generally agreed that at least 2 mg of epidural morphine is needed to achieve a significant analgesic response, but the criteria used to assess this response have varied greatly in reported studies, and no firm conclusion can be derived from them.^{25,27} Epidural opioids are less efficient in the earliest stages of the acute pain state than on subsequent days; moreover, they appear to be more successful at alleviating pain after procedures in the lower half of the body than at alleviating upper abdominal and thoracic pain. In general, 2 to 4 mg of morphine administered epidurally is sufficient after minor procedures, whereas about 4 mg is needed after vascular and gynecologic procedures and after major upper abdominal and thoracic procedures.^{20,25,27} On postoperative day 1, however, such a regimen, even when repeated as many as three times, relieves pain completely in fewer than 50% of patients; on subsequent days, the success rate is substantially higher. The efficiency of this approach is lowest after major procedures.

There is evidence to suggest that continuous epidural administration of low-dosage morphine (0.1 to 0.3 mg/hr) or fentanyl (10 to 20 µg/hr) may lower the risk of late respiratory depression and may be more efficient than intermittent administration of higher dosages of morphine.²⁷ The continuous low-dosage approach is therefore recommended.

Side Effects

The chief side effects associated with epidural and subarachnoid opioids are respiratory depression, nausea and vomiting, pruritus, and urinary retention.²⁵⁻²⁷ The poor lipid solubility of morphine is responsible for its protracted duration of action but also allows morphine to undergo cephalad migration in the cerebrospinal fluid. This migration can cause delayed respiratory depression, with a peak incidence 3 to 10 hours after an injection. The high lipid solubility of lipophilic opioids such as fentanyl allows them to be absorbed into lipids close to the site of administration. Consequently, the lipophilic opioids do not migrate rostrally in the CSF and cannot cause delayed respiratory depression. Of course, the high lipid solubility of lipophilic opioids allows them to be absorbed into blood vessels, which may cause early respiratory depression, as is commonly seen with systemic administration of opioids.

Naloxone reverses the depressive respiratory effects of spinal opioids. In an apneic patient, 0.4 mg I.V. will usually restore ventilation. If a patient has a depressed respiratory rate but is still breathing, small aliquots of naloxone (0.2 to 0.4 mg) can be given until the respiratory rate returns to normal.

Nausea and vomiting are caused by transport of opioids to the vomiting center and the chemoreceptor trigger zone in the medulla via CSF flow or the systemic circulation. Nausea can usually be treated with antiemetics or, if severe, with naloxone (in 0.2 mg increments, repeated if necessary).

Pruritus is probably the most common side effect of the spinal opioids. Histamine is released by certain opioids, but this mechanism probably plays a negligible role in the genesis of itching. Treatment of pruritus is similar to that of nausea.

The mechanism of spinal opioid-induced urinary retention involves inhibition of volume-induced bladder contractions and blockade of the vesical reflex. Naloxone administration is the treatment of choice, though bladder catheterization is sometimes required.

EPIDURAL LOCAL ANESTHETICS AND OTHER REGIONAL BLOCKS

Local anesthetics have become increasingly popular because of the growing familiarity with both epidural catheterization and

regional nerve blockade. In addition, there is a great deal of experimental evidence that documents the benefits of blocking noxious impulses.²⁸ Local anesthetic neural blockade is unique among available analgesic techniques in that it may offer sufficient afferent neural blockade, resulting in relief of pain; avoidance of sedation, respiratory depression, and nausea; and, finally, efferent sympathetic blockade, resulting in increased blood flow to the region of neural blockade.²⁸ Despite the considerable scientific data documenting these beneficial effects, the place of epidural local anesthesia as a method of pain relief remains somewhat controversial in comparison with that of other analgesic techniques. Its side effects (e.g., hypotension, urinary retention, and motor blockade) and the need for trained staff for surveillance argue against its use; however, these side effects can be reduced by using combination regimens (see below).²⁷

Mechanism of Action

Local anesthetic neural blockade is a nondepolarizing block that reduces the permeability of cell membranes to sodium ions.²⁹ Whether different local anesthetics have different effects on different nerve fibers is debatable.

Choice of Drug

For optimal management of postoperative pain, the anesthetic agent should provide excellent analgesia of rapid onset and long duration without inducing motor blockade. The various local anesthetic agents all meet one or more of these criteria; however, the ones that come closest to meeting all of the criteria are bupivacaine, ropivacaine, and levobupivacaine. This should not preclude the use of other agents, because their efficacy has also been demonstrated. Ropivacaine and levobupivacaine may have a better safety profile, but the improvement may be relevant only when high intraoperative doses are given.²⁹

Continuous Epidural Analgesia

No regimen has been found that provides complete analgesia in all patients all of the time, and it is unlikely that one ever will be

Table 6 Regimen for Pain Relief with Continuous Epidural Bupivacaine during Initial 24 Postoperative Hours

Type of Operation	Interspace for Catheter Insertion	Concentration (%)	Volume (ml/hr)
Thoracic procedures	T4–6	0.250–0.125	5–10
Upper laparotomy	T7–8	0.250–0.125	4–12
Gynecologic laparotomy	T10–12	0.250–0.125	4–10
Hip procedures	L2	0.125–0.0625	4–8
Vascular procedures	T10–12	0.250–0.125	4–10

Note: indications for postoperative epidural bupivacaine may be strengthened if this method is also indicated for intraoperative analgesia. Dosage requirements may vary and should be assessed 3 hr after the start of treatment, every 6 hr thereafter on the first day, and then every 12 hr (more often if pain occurs). The duration of treatment is 1–4 days, depending on the intensity of the pain. The concentration of bupivacaine employed should be the lowest possible and should be decreased with time postoperatively. Some patients, especially those who have undergone major upper abdominal operation, require 0.5% bupivacaine initially.

Table 7 Procedures for Maintenance of Epidural Anesthesia for Longer Than 24 Hours

1. Administer appropriate drug in appropriate dosage at selected infusion rate as determined by physician.
2. Nurse evaluates vital signs and intake and output as required for a postoperative patient.
3. Nurse checks infusion pump hourly to ensure that it is functioning properly, that infusion rate is proper, and that alarm is on.
4. Nurse also assesses
 - Bladder—for distention, if patient is not catheterized
 - Lower extremities—for status of motor function
 - CNS—for signs of toxicity or respiratory depression
 - Relief of pain (drug dosage may require modification)
 - Skin integrity on back (breakdown may occur if motor function is not present)
 - Tubing and dressing (disconnection of tubing or dislodgment of catheter may occur)
5. Every 48 hr, the catheter dressing should be removed, the catheter entrance site cleaned, and topical antibiotic applied (much as in care of a central venous catheter).

found. As a rule, the block should be limited to the area in which pain is felt. Care should be taken to avoid motor blockade and to spare autonomic function to the urinary bladder, as well as to formulate a regimen that requires only minimal attention from staff members and carries no significant toxicity. Given these requirements, continuous infusion [see Table 6] is more effective and reliable than intermittent injection.²⁷ Whether low hourly volume and high concentration approaches are preferable to high hourly volume and low concentration approaches remains to be determined.²⁷ The weaker solutions may produce less motor blockade while continuing to block smaller C and A-delta pain fibers and are recommended in lumbar epidural analgesia as a means of reducing the risk of orthostatic hypotension and lower-extremity motor blockade.²⁷

Specific indications for continuous epidural analgesia that are supported by data from controlled morbidity studies include (1) pain relief and reduction of deep vein thrombosis, pulmonary embolism, and hypoxemia after total hip replacement and prostatectomy; (2) pain relief, facilitation of coughing, and reduction of chest infections after thoracic, abdominal, and orthopedic procedures; (3) pain relief, control of hypertension, and enhancement of graft flow after major vascular operations; and (4) pain relief and reduction of paralytic ileus after abdominal procedures.^{30,31}

Side Effects

The main side effects of epidural local anesthesia are hypotension caused by sympathetic blockade, vagal overactivity, and decreased cardiac function (during a high thoracic block). Under no circumstances should epidural local anesthetics be used before a preexisting hypovolemic condition is treated. Hypotension may be treated with ephedrine, 10 to 15 mg I.V., and fluids, with the patient tilted in a head-down position. Atropine, 0.5 to 1.0 mg I.V., may be effective during vagal overactivity.

Urinary retention occurs in 20% to 100% of patients. Fortunately, urinary catheterization for only 24 to 48 hours in the course of a high-dose regimen probably has no important side effects, and many patients for whom epidural analgesia is indicated need an indwelling catheter for other reasons in any case. The incidence of urinary retention is probably below 10% when

epidural local anesthetics are used in weak solutions.³² Motor blockade may delay mobilization; however, its incidence can be reduced by using the weakest concentration of local anesthetic that is compatible with adequate sensory blockade. Cerebral and epidural analgesia should not be employed in patients already receiving anticoagulant therapy, but it may be started with catheter insertion before vascular or other procedures in which controlled heparin therapy is used. Epidural analgesia has been used in patients receiving thromboembolic prophylaxis with low-dose heparin and low-molecular-weight heparin without significant risk,²⁷ provided that current guidelines are followed.^{33,34} It should be emphasized that the heparin doses commonly employed in the United States are higher than those recommended in Europe; the higher doses may pose a risk when heparin prophylaxis is combined with epidural analgesia.^{33,34} The complications associated with the epidural catheter are minimal when proper nursing protocols are followed [see Table 7].²⁷ The decision to employ epidural local anesthetics in such patients should be made only after the risks^{33,34} are carefully compared with the documented advantages of such anesthetics.^{27,31} It is important that the level of insertion into the epidural space correspond with the level of incision.

Other Nerve Blocks

The popularity of single-dose intercostal block and intrapleural regional analgesia has decreased in comparison with that of continuous epidural treatment. Intermittent or continuous administration of local anesthetics through a catheter inserted into the paravertebral space seems to be a promising approach to providing analgesia after thoracic and abdominal procedures,³⁵ but further data are needed. Intravenous and intraperitoneal administration of local anesthetics cannot be recommended for postoperative analgesia, because they are not efficacious,³⁶ except in laparoscopic cholecystectomy.^{12,37} Intra-incisional administration of bupivacaine, which has negligible side effects and demands little or no surveillance, is recommended for patients undergoing relatively minor procedures.³⁸

Several studies have now reported that continuous administration of local anesthetics into the wound improves postoperative analgesia in a variety of procedures³⁸⁻⁴⁴; however, there is still a need for more procedure-specific data before general recommendations can be made. Continuous peripheral nerve blocks are growing in popularity, and the analgesic treatment may be continued after discharge.^{15,16,45} Before general recommendations for continuous peripheral blockade can be formulated, however, further safety data are required.

More detailed information on special blocks can be found in the anesthesiology literature. In general, despite its disadvantages, neural blockade with local anesthetics is recommended for relief of

Table 8 Recommended Dosages of NSAIDs or COX-2 Inhibitors for Relief of Postoperative Pain

NSAID	Dosage
Acetylsalicylic acid	500–1,000 mg q. 4–6 hr
Acetaminophen	500–1,000 mg q. 4–6 hr
Indomethacin	50–100 mg q. 6–8 hr
Ibuprofen	200–400 mg q. 4–6 hr
Ketorolac	30 mg q. 4–6 hr
Celecoxib	200–400 mg q. 12 hr
Rofecoxib	12–25 mg q. 12 hr

moderate to severe postoperative pain because of the advantageous physiologic effects it exerts and the reduction in postoperative morbidity it brings about.

CONVENTIONAL NSAIDS AND COX-2 INHIBITORS

NSAIDs are minor analgesics that, because of their anti-inflammatory effect, may be suitable for management of postoperative pain associated with a significant degree of inflammation (e.g., bone or soft tissue damage).⁴⁶ They may, however, have central analgesic effects as well and thus may have analgesic efficacy after all kinds of operations. Conventional NSAIDs inhibit both COX-1 and COX-2. Selective COX-2 inhibitors, which do not inhibit COX-1, have the potential to achieve analgesic efficacy comparable to that of conventional NSAIDs but with fewer side effects [see Table 8].⁴⁷⁻⁴⁹

Only a few of the NSAIDs may be given parenterally. The data now available on the use of NSAIDs for postoperative pain are insufficient to allow definitive recommendation of any agent or agents over the others, and selection therefore may depend on convenience of delivery, duration, and cost.⁴⁶ It is clear, however, that these agents may play a valuable role as adjuvants to other analgesics; accordingly, they have been recommended as basic analgesics for all operations in low-risk patients. All of the NSAIDs have potentially serious side effects: GI and surgical site hemorrhage, renal failure, impaired bone healing and asthma. The endoscopically verified superficial ulcer formation seen within 7 to 10 days after the initiation of NSAID therapy is not seen with selective COX-2 inhibitor treatment in volunteers. The clinical relevance of these findings for perioperative treatment remains to be established, however, given that acute severe GI side effects (bleeding, perforation) are extremely rare in elective cases.

Because prostaglandins are important for regulation of water and mineral homeostasis by the kidneys in the dehydrated patient, perioperative treatment with NSAIDs, which inhibit prostaglandin synthesis, may lead to postoperative renal failure. So far, specific COX-2 inhibitors have not been demonstrated to be less nephrotoxic than conventional NSAIDs.⁴⁸⁻⁵¹ Although little systematic evaluation has been done, extensive clinical experience with NSAIDs suggests that the renal risk is not substantial.⁵¹ Nonetheless, conventional NSAIDs and COX-2 inhibitors should be used with caution in patients who have preexisting renal dysfunction.

Although conventional NSAIDs prolong bleeding time and inhibit platelet aggregation, there generally does not seem to be a clinically significant risk of increased bleeding. However, in some procedures for which strict hemostasis is critical (e.g., tonsillectomy, cosmetic surgery, and eye surgery), these drugs have been shown to increase the risk of bleeding complications and should therefore be replaced with COX-2 inhibitors, which do not inhibit platelet aggregation.^{52,53} The observation that prostaglandins are involved in bone and wound healing has given rise to concern about potential side effects in surgical patients. Although there is experimental evidence that both conventional NSAIDs and COX-2 inhibitors can impair bone healing,⁵⁴⁻⁵⁷ the clinical data available at present are insufficient to document wound or bone healing failure with these drugs. This is a particularly important issue for future study, in that many orthopedic surgeons remain reluctant to use NSAIDs.

Currently, there is widespread concern about the increased risk of cardiovascular complications associated with long-term treatment with selective COX-2 inhibitors. Generally, such side effects have appeared after 1 to 2 years of treatment. In the past few years, however, two studies of patients undergoing coronary artery bypass grafting (CABG) found that the risk of cardiovascular complications was increased significantly (two- to threefold) in

this setting,^{58,59} and the investigators concluded that these drugs were therefore contraindicated in CABG patients. The larger question is whether these drugs should also be contraindicated for perioperative use, or at least used with caution, in high-risk cardiovascular patients who are undergoing procedures other than CABG. At present, the data are insufficient to allow any conclusions, but in my view, until more information is available, it may be prudent to avoid perioperative use of COX-2 inhibitors in all high-risk cardiovascular patients (i.e., those with uncontrolled hypertension, previous myocardial infarction, heart failure, or previous cerebral vascular disorders). In other patients, however, perioperative administration of selective COX-2 inhibitors may be justified if the advantageous effects appear to outweigh the potential (low) risk of complications.

Finally, the already quite low risk of NSAID-induced asthma may be further reduced by the use of selective COX-2 inhibitors.^{48,49}

Peripheral (i.e., surgical site) administration of NSAIDs may have a slight additional analgesic effect in comparison with systemic administration,⁶⁰ but further data on safety are required.

Acetaminophen also possesses anti-inflammatory capability, both peripherally and centrally. Its analgesic effect is somewhat (about 20% to 30%) weaker than those of conventional NSAIDs and COX-2 inhibitors; however, it lacks the side effects typical of these agents.⁶¹⁻⁶³ Combining acetaminophen with NSAIDs may improve analgesia, especially in smaller and moderate-sized oper-

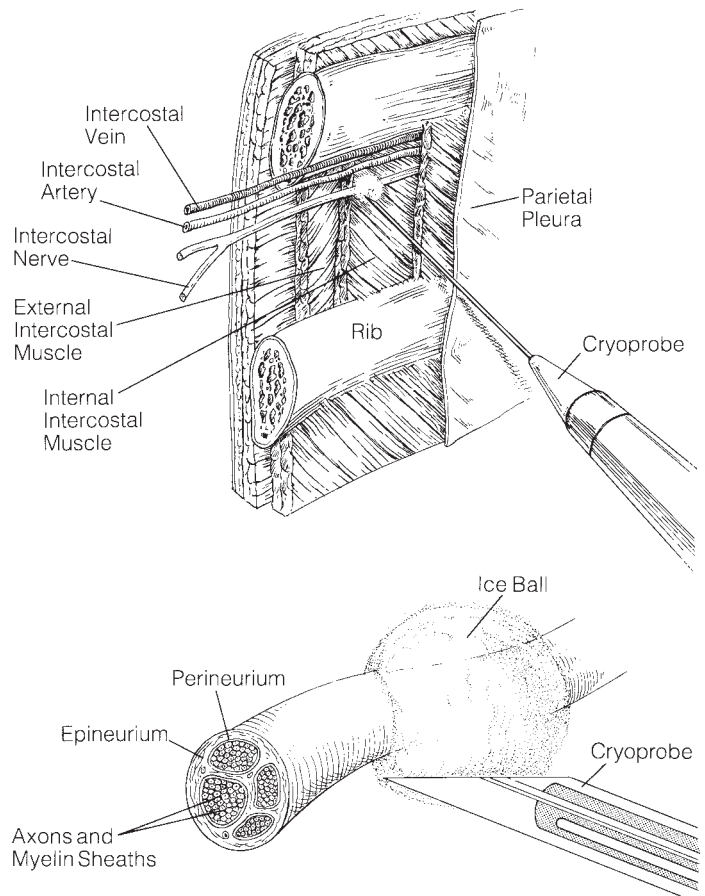

Figure 1 Illustrated is the procedure for performing cryoanalgesia in a thoracotomy. The intercostal nerve in the thoracotomy space is isolated, together with the two intercostal nerves above the space and the two below it, and the cryoprobe is applied to the nerves for 45 seconds. The probe is then defrosted and reapplied to the nerves for 45 seconds. The analgesia obtained lasts about 30 days.

ations⁶¹⁻⁶²; accordingly, this agent is recommended as a basic component of multimodal analgesia in all operations.

Despite the gaps in our current understanding of the workings and differential effects of NSAIDs and COX-2 inhibitors, what is known is sufficiently encouraging to suggest that they should be recommended for baseline analgesic treatment after most operative procedures, with the exceptions already mentioned (see above). This recommendation is based not only on their analgesic efficacy but also on their opioid-sparing effect, which may enhance recovery (see below).

Glucocorticoids are powerful anti-inflammatory agents and have proven analgesic value in less extensive procedures,⁶⁴ especially dental, laparoscopic, and arthroscopic operations. In addition, they have profound antiemetic effects. Concerns about possible side effects in the setting of perioperative administration have not been borne out by the results of randomized studies.⁶⁴

OTHER ANALGESICS

Tramadol is a weak analgesic that has several relatively minor side effects (e.g., dizziness, nausea, and vomiting).⁶⁵ It can be combined with acetaminophen to yield analgesic activity comparable to that of NSAIDs.⁶⁶

Several systematic reviews have suggested that some analgesic and perioperative opioid-sparing effects can be achieved by adding an *N*-methyl-D-aspartate receptor antagonist (e.g., ketamine),⁶⁷⁻⁶⁹ gabapentin, or pregabalin⁷⁰ [see Combination Regimens, *below*].

CRYOANALGESIA

Cryoanalgesia is the application of low temperatures (−20° to −29° C) to peripheral nerves with the goal of producing axonal degeneration and thus analgesia [see *Figure 1*]. Axonal regeneration takes place at a rate of 1 to 3 mm/day, which means that analgesia after intercostal blocks lasts about 30 days. Cryoanalgesia has no cardiac, respiratory, or cerebral side effects, and local side effects (e.g., neuroma formation) are extremely rare. In this context, it should be emphasized that postthoracotomy patients are at substantial risk (~30%) for chronic neuropathic pain without the use of cryoanalgesia⁷¹; however, this technique can be used only on sensory nerves or on nerves supplying muscles of no clinical importance.

At present, no information is available on the use of cryoanalgesia in operative procedures other than herniotomy and thoracotomy.⁷² Cryoanalgesia is not efficacious after herniotomy.⁷³ The data on postthoracotomy cryoanalgesia, however, suggest improved pain alleviation and a concomitant reduction in the need for narcotics, which, in conjunction with the simplicity and low cost of the modality and the absence of side effects, present a strong argument for more extensive use of cryoanalgesia.

TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION

Transcutaneous electrical nerve stimulation (TENS) is the application of a mild electrical current through the skin surface to a specific area, such as a surgical wound, to achieve pain relief; the exact mechanism whereby it achieves this effect is yet to be explained. Many TENS devices are available for clinical use, but the specific values and the proper uses of the various stimulation frequencies, waveforms, and current intensities have not been determined. Unfortunately, the effect of TENS on acute pain is too small to warrant a recommendation for routine use.⁷⁴

PATIENT-CONTROLLED ANALGESIA

Patient-controlled administration of opioids has experienced a dramatic increase in use. This increase may be attributed to (1) awareness of the inadequacy of traditional I.M. opioid regimens, (2) the development of effective and safe biotechnology, and (3)

Table 9 Prescription Guidelines for Intravenous Patient-Controlled Analgesia

Drug (Concentration)	Demand Dose	Lockout Interval (min)
Morphine (1 mg/ml)	0.5–3.0 mg	5–12
Meperidine (10 mg/ml)	5–30 mg	5–12
Fentanyl (10 µg/ml)	10–20 µg	5–10
Hydromorphone (0.2 mg/ml)	0.1–0.5 mg	5–10
Oxymorphone (0.25 mg/ml)	0.2–0.4 mg	8–10
Methadone (1 mg/ml)	0.5–2.5 mg	8–20
Nalbuphine (1 mg/ml)	1–5 mg	5–10

the widespread patient satisfaction with patient-controlled analgesia (PCA).^{75,76} It must be emphasized, however, that the effect of PCA on movement-associated pain is limited in comparison with that of epidural local anesthesia.¹⁴

Mechanisms of Action

Traditional I.M. dosing of opioids does not result in consistent blood levels,^{75,76} because opioids are absorbed at a variable rate from the vascular bed of muscle. Moreover, administration of traditional I.M. regimens results in opioid concentrations that exceed the concentrations required to produce analgesia only about 30% of the time during any 4-hour dosing interval. PCA avoids these pitfalls by allowing repeated dosing on demand. PCA yields more constant and consistent plasma opioid levels and therefore provides better analgesia.^{75,76}

Modes of Administration and Dosing Parameters

There are several modes by which opioids can be administered under patient control. Intermittent delivery of a fixed dose is known as demand dosing. Background infusions have been used to supplement patient-administered doses, but this practice increases the risk of respiratory depression and should therefore be avoided.^{75,76}

There are several basic prescription parameters for PCA: loading dose, demand dose, lockout interval, and 4-hour limits [see *Table 9*].^{75,76} When PCA is used for postoperative care, it is usually initiated in the recovery room. The patient is made comfortable by administering as much opioid as is needed (i.e., a loading dose). When the patient is sufficiently recovered from the anesthetic, he or she may begin to use the infuser.

Side Effects

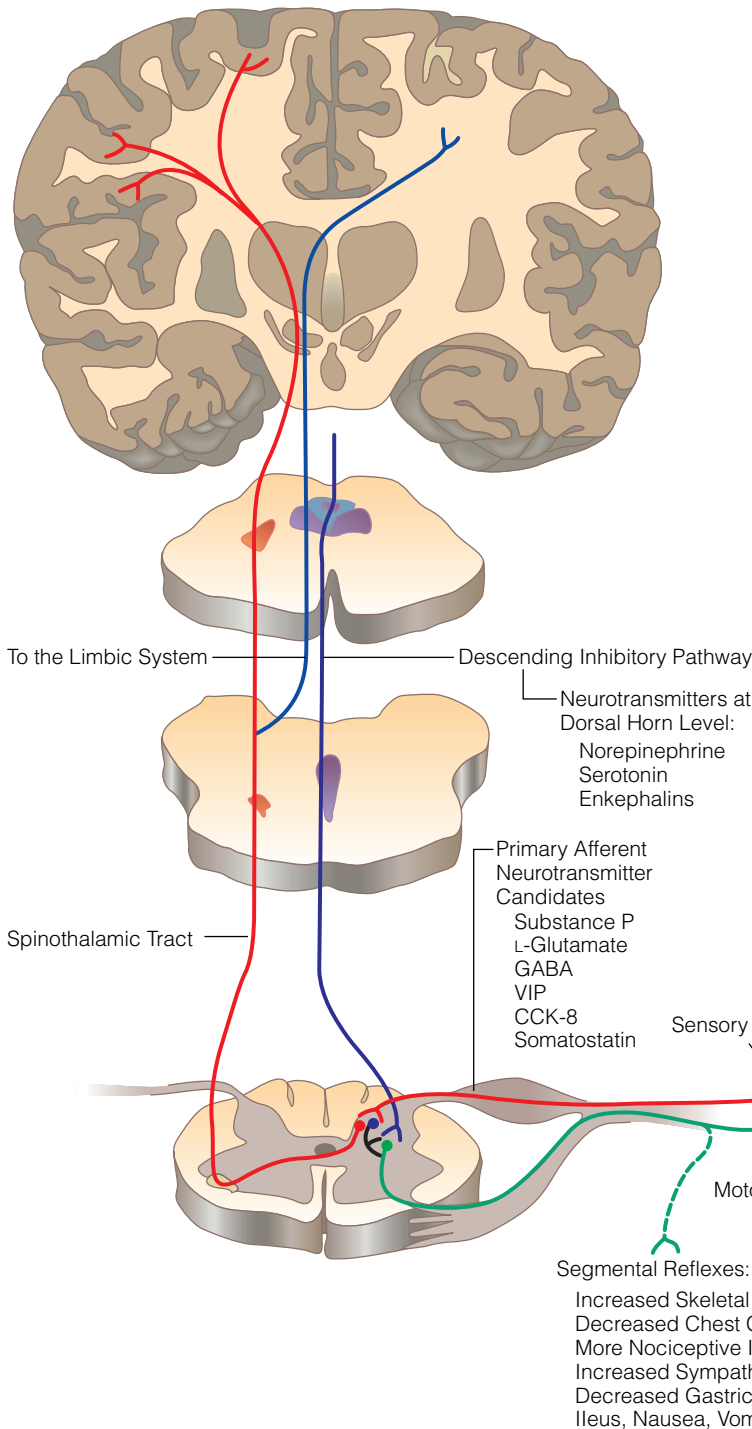

Minor side effects associated with PCA include nausea, vomiting, sweating, and pruritus. Clinically significant respiratory depression with PCA is rare. There is no evidence to suggest that PCA is associated with a higher incidence of side effects than are other routes of systemic opioid administration.^{75,76} Side effects are the result of the pharmacologic properties of opioids, not the method of administration.^{75,76}

COMBINATION REGIMENS

Because no single pain treatment modality is optimal, combination regimens (e.g., balanced analgesia or multimodal treatment)

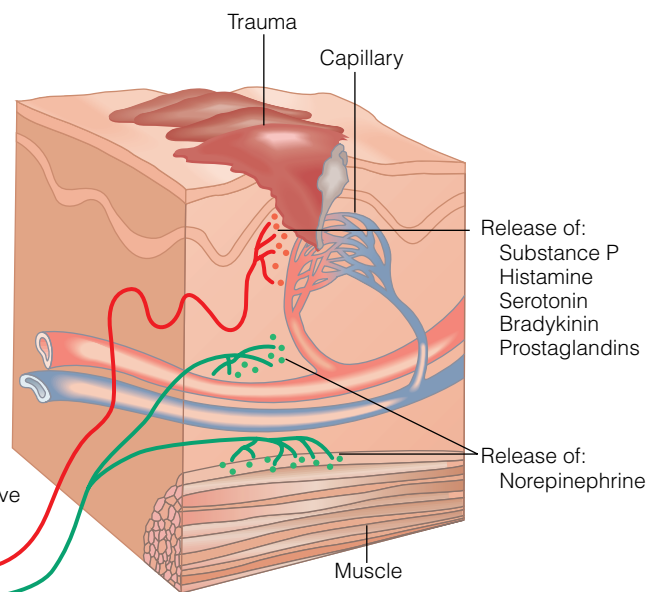

offer major advantages over single-modality regimens, whether by maintaining or improving analgesia, by reducing side effects, or by doing both.^{77,78} Combinations of epidural local anesthetics and morphine,^{14,27} of NSAIDs and opioids,^{46,77,78} of NSAIDs and acetaminophen,^{61,62} of acetaminophen and opioids,⁶³ of acetaminophen and tramadol,⁶⁶ and of a selective COX-2 inhibitor and gabapentin⁷⁹ have been reported to have additive effects. At present, information on other combinations (involving ketamine, clonidine, glucocorticoids, and other agents) is too sparse to allow firm recommendations; however, multimodal analgesia is undoubtedly promising, and multidrug combinations should certainly be explored further.

Perception of Pain

The potential of combination regimens is especially intriguing with respect to the concept of perioperative opioid-sparing analgesia. The use of one or several nonopioid analgesics in such regimens may enhance recovery, in that the concomitant reduction in the opioid dosage will lead to decreased nausea, vomiting, and sedation.⁸⁰⁻⁸⁴ Both the adverse events associated with postoperative opioid analgesia and the relatively high costs of such analgesia argue for an opioid-sparing approach.^{85,86} Another argument that has been advanced is that the introduction of the JCAHO pain initiative may precipitate increased use of opioids (and thereby an increased risk of side effects), though it is not certain that this will be the case.^{87,88}

Figure 2 Shown are the major neural pathways involved in nociception. Nociceptive input is transmitted from the periphery to the dorsal horn via A-delta and C fibers (for somatic pain) or via afferent sympathetic pathways (for visceral pain). It is then modulated by control systems in the dorsal horn and sent via the spinothalamic tracts and spinoreticular systems to the hypothalamus, to the brain stem and reticular formation, and eventually to the cerebral cortex. Ascending transmission of nociceptive input is also modulated by descending inhibitory pathways originating in the brain and terminating in the dorsal horn. Nociception may be enhanced by reflex responses that affect the environment of the nociceptors, such as smooth muscle spasm.

Discussion

Physiologic Mechanisms of Acute Pain

The basic mechanisms of acute pain are (1) afferent transmission of nociceptive stimuli through the peripheral nervous system after tissue damage, (2) modulation of these injury signals by control systems in the dorsal horn, and (3) modulation of the ascending transmission of pain stimuli by a descending control system originating in the brain [see *Figure 2*].⁸⁹⁻⁹²

PERIPHERAL PAIN RECEPTORS AND NEURAL TRANSMISSION TO SPINAL CORD

Peripheral pain receptors (nociceptors) can be identified by function but cannot be distinguished anatomically. The responsiveness of peripheral pain receptors may be enhanced by endogenous analgesic substances (e.g., prostaglandins, serotonin, bradykinin, nerve growth factor, and histamine), as well as by increased efferent sympathetic activity.⁸⁹ Antidromic release of substance P may amplify the inflammatory response and thereby increase pain transmission. The peripheral mechanisms of visceral pain still are not well understood⁹⁰—for example, no one has yet explained why cutting or burning may provoke pain in the skin but not provoke pain in visceral organs. Peripheral opioid receptors have been demonstrated to appear in inflammation on the peripheral nerve terminals, and clinical studies have demonstrated that there are analgesic effects from peripheral opioid administration during arthroscopic knee surgery.⁹³

Somatic nociceptive input is transmitted to the CNS through A-delta and C fibers, which are small in diameter and either unmyelinated or thinly myelinated. Visceral pain is transmitted through afferent sympathetic pathways; the evidence that afferent parasympathetic pathways play a role in visceral nociception is inconclusive.⁹⁰

DORSAL HORN CONTROL SYSTEMS AND MODULATION OF INCOMING SIGNALS

All incoming nociceptive traffic synapses in the gray matter of the dorsal horn (Rexed's laminae I to IV). Several substances may be involved in primary afferent transmission of nociceptive stimuli in the dorsal horn: substance P, enkephalins, somatostatin, neurotensin, γ -aminobutyric acid (GABA), glutamic acid, angiotensin II, vasoactive intestinal polypeptide (VIP), and cholecystokinin octapeptide (CCK-8).⁹¹ From the dorsal horn, nociceptive information is transmitted through the spinothalamic tracts to the hypothalamus, through spinoreticular systems to the brain stem and reticular formation, and finally to the cerebral cortex.

DESCENDING PAIN CONTROL SYSTEM

A descending control system for sensory input originates in the brain stem and reticular formation and in certain higher brain areas. The main neurotransmitters in this system are norepinephrine, serotonin, and enkephalins. Epidural-intrathecal administration of alpha-adrenergic agonists (e.g., clonidine) may therefore provide pain relief.⁹¹

SPINAL REFLEXES

Nociception may be enhanced by spinal reflexes that affect the environment of the nociceptive nerve endings. Thus, tissue damage may provoke an afferent reflex that causes muscle spasm in the vicinity of the injury, thereby increasing nociception. Similarly, sympathetic reflexes may cause decreased microcirculation in

injury tissue, thereby generating smooth muscle spasm, which amplifies the sensation.

POSTINJURY CHANGES IN PERIPHERAL AND CENTRAL NERVOUS SYSTEMS

After an injury, the afferent nociceptive pathways undergo physiologic, anatomic, and chemical changes.^{91,92} These changes include increased sensitivity on the part of peripheral nociceptors, as well as the growth of sprouts from damaged nerve fibers that become sensitive to mechanical and alpha-adrenergic stimuli and eventually begin to fire spontaneously. Moreover, excitability may be increased in the spinal cord, which leads to expansion of receptive fields in dorsal horn cells. Such changes may lower pain thresholds, may increase afferent barrage in the late postinjury state, and, if normal regression does not occur during convalescence, may contribute to a chronic pain state.⁹¹

Neural stimuli have generally been considered to be the main factor responsible for initiation of spinal neuroplasticity; however, it now appears that such neuroplasticity may also be mediated by cytokines released as a consequence of COX-2 induction.⁹² Improved understanding of the mechanisms of pain may serve as a rational basis for future drug development and may help direct therapy away from symptom control and toward mechanism-specific treatment.⁹⁴

In experimental studies, acute pain behavior or hyperexcitability of dorsal horn neurons may be eliminated or reduced if the afferent barrage is prevented from reaching the CNS. Preinjury neural blockade with local anesthetics or opioids can suppress excitability of the CNS; this is called preemptive analgesia. Because similar antinociceptive procedures were less effective in experimental studies when applied after injury, timing of analgesia seems to be important in the treatment of postoperative pain; however, a critical analysis of controlled clinical studies that compared the efficacy of analgesic regimens administered preoperatively with the efficacy of the same regimens administered postoperatively concluded that preemptive analgesia does not always provide a clinically significant increase in pain relief.^{95,96} Nonetheless, it is important that pain treatment be initiated early to ensure that patients do not wake up with high-intensity pain. As long as the afferent input from the surgical wound continues, continuous treatment with multimodal or balanced analgesia may be the most effective method of treating postoperative pain.^{95,97}

Effects of Pain Relief

METABOLIC RESPONSE TO OPERATION

It still is not generally appreciated that acute pain in the postoperative period or after hospitalization for accidental injury not only serves no useful function but also may actually exert harmful physiologic and psychological effects. Therefore, except in the initial stage in acutely injured hypovolemic patients for whom increased sympathetic activity may provide cardiovascular support, the pain-induced reflex responses that may adversely affect respiratory function, increase cardiac demands, decrease intestinal motility, and initiate skeletal muscle spasm (thereby impairing mobilization) should be counteracted by all available means.

The traditional view of the physiologic role of the stress response to surgical injury is that it is a homeostatic defense mechanism that helps the body heal tissue and adapt to injury. However, the neces-

sity for the stress response in modern anesthesiology and surgery has been questioned.²⁸ Thus, concern about the detrimental effects of operative procedures (e.g., myocardial infarction, pulmonary complications, and thromboembolism) that cannot be attributed solely to imperfections in surgical technique has led to the hypothesis that the unsupported continuous injury response may instead be a maladaptive response that erodes body mass and physiologic reserve.^{28,98} Because neural stimuli play an important role in releasing the stress response to surgical injury, pain relief may modify this response, but this modulation is dependent on the mechanism of action of the pain treatment modality employed.²⁸

Alleviation of pain through antagonism of peripheral pain mediators (i.e., through use of NSAIDs) has no important modifying effect on the response to operation.^{22,30} The effects of blockade of afferent and efferent transmission of pain stimuli by means of regional anesthesia have been studied in detail.^{22,31} Spinal or epidural analgesia with local anesthetics prevents the greater part of the classic endocrine metabolic response to operative procedures in the lower region of the body (e.g., gynecologic and urologic procedures and orthopedic procedures in the lower limbs) and improves protein economy; however, this effect is considerably weaker in major abdominal and thoracic procedures, probably because of insufficient afferent neural blockade. The modifying effect of epidural analgesia on the stress response is most pronounced if the neural blockade takes effect before the surgical insult. The optimal duration of neural blockade for attenuating the hypermetabolic response has not been established, but it should include at least the initial 24 to 48 hours.^{22,31}

Alleviation of postoperative pain through administration of epidural-intrathecal opioids has a smaller modifying effect on the surgical stress response, in comparison with the degree of pain relief it provides^{22,31}; furthermore, it does not provide efferent sympathetic blockade. Systemic administration of opioids, either according to a fixed administration regimen or according to a demand-based regimen, has no important modifying effect on the stress response.²² The effects of pain relief by acetaminophen, tramadol, cryoanalgesia, or TENS on the stress response have not been established but probably are of no clinical significance. Further studies aimed at defining the effects of multimodal analgesia on the surgical stress response are required.

POSTOPERATIVE MORBIDITY

The effects of nociceptive blockade and pain relief on postoperative morbidity remain to be defined, except with respect to intraoperative spinal or epidural local anesthetics in lower-body procedures, about which the following four conclusions can be made.^{22,99} First, intraoperative blood loss is reduced by about 30%. Second, thromboembolic and pulmonary complications are reduced by about 30% to 40%. Third, when epidural local anesthetics are continuously administered (with or without small doses of opioids) to patients undergoing abdominal or thoracic procedures, pulmonary infectious complications appear to be reduced by about 40%.³⁰ Fourth, the duration of postoperative ileus is reduced^{14,31}; this effect may be of major significance, in that reduction of ileus allows earlier oral nutrition,³¹ which has been demonstrated to improve outcome.

The impact of continuous epidural analgesia on postoperative outcome after major operations remains the subject of some debate. Three large randomized trials from 2001 and 2002 found no positive effects except for improved pulmonary outcome.¹⁰⁰⁻¹⁰² One explanation for these negative findings may be the use of a predominantly opioid-based epidural analgesic regimen, which would hinder the normal physiologic responses supporting recovery to a

greater extent than a local anesthetic regimen would.²² Another explanation may be inadequate study design in some cases: most studies to date have focused on the effects of a single factor (i.e., epidural analgesia) on overall postoperative morbidity, which is probably too simplistic an approach, given that overall postoperative outcome is known to be determined by multiple factors.^{103,104} Besides postoperative pain relief, reinforced psychological preparation of the patient, reduction of stress by performing neural blockade or opting for minimal invasive procedures, and enforcement of early oral postoperative feeding and mobilization may all play a significant role in determining outcome.^{103,104} Prevention of intraoperative hypothermia, avoidance of fluid overloading, and avoidance of hypoxemia may be important as well.^{103,104}

Therefore, although adequate pain relief is obviously a prerequisite for good outcome, the best results are likely to be achieved by combining analgesia with all the aforementioned factors in a multimodal rehabilitation effort.^{103,104} Observations from patients undergoing a variety of surgical procedures suggest that such a multimodal approach may lead to significant reductions in hospital stay, morbidity, and convalescence.^{103,104} Admittedly, these preliminary observations require confirmation by randomized or multicenter trials. The role of the acute pain service¹⁰⁵ and the effect of establishing a postoperative rehabilitation unit should be assessed as well.

TOLERANCE, PHYSICAL DEPENDENCE, AND ADDICTION

Continued exposure of an opioid receptor to high concentrations of opioid will cause tolerance. Tolerance is the progressive decline in an opioid's potency with continuous use, so that higher and higher concentrations of the drug are required to cause the same analgesic effect. Physical dependence refers to the production of an abstinence syndrome when an opioid is withdrawn. It is defined by the World Health Organization as follows¹⁰⁶:

A state, psychic or sometimes also physical, resulting from interactions between a living organism and a drug, characterized by behavioural and other responses that always include a compulsion to take the drug on a continuous or periodic basis in order to experience its psychic effects, and sometimes to avoid discomfort from its absence.

This definition is very close to the popular conception of addiction. It is important, however, to distinguish addiction (implying compulsive behavior and psychological dependence) from tolerance (a pharmacologic property) and from physical dependence (a characteristic physiologic effect of a group of drugs). Physical dependence does not imply addiction. Moreover, tolerance can occur without physical dependence; the converse does not appear to be true.

The possibility that the medical administration of opioids could result in a patient's becoming addicted has generated much debate about the use of opioids. In a prospective study of 12,000 hospitalized patients receiving at least one strong opioid for a protracted period, there were only four reasonably well documented cases of subsequent addiction, and in none of these was there a history of previous substance abuse.¹⁰⁷ Thus, the iatrogenic production of opioid addiction may be very rare.

CONCLUSION

The choice of therapeutic intervention for acute postoperative pain is determined largely by the nature of the patient's problem, the resources available, the efficacy of the various treatment techniques, the risks attendant on the procedures under consideration, and the cost to the patient.¹⁰⁸ Whereas trauma has been the subject of intensive research, the mechanisms of the pain associated

with trauma and surgical injury and the optimal methods of relieving such pain have received comparatively little attention from surgeons. It is to be hoped that our growing understanding of basic pain mechanisms and appropriate therapy, combined with the promising data supporting the idea that adequate inhibition of surgically induced nociceptive stimuli may reduce postoperative

morbidity, will stimulate more surgeons to turn their attention to this area. Effective control of postoperative pain, combined with a high degree of surgical expertise and the judicious use of other perioperative therapeutic interventions within the context of multimodal postoperative rehabilitation, is certain to improve surgical outcome.

6 POSTOPERATIVE MANAGEMENT OF THE HOSPITALIZED PATIENT

Deborah L. Marquardt, M.D., Roger P. Tatum, M.D., F.A.C.S., and Dana C. Lynge, M.D., F.A.C.S

At the beginning of the modern era of surgery, operative procedures commonly took place in an operating theater, performed by plainclothes surgeons in aprons for audiences of students and other onlookers. Afterward, patients were typically cared for at home or in a hospital ward, with scarcely any monitoring and little to help them toward recovery besides their own strength and physiologic reserve. In the current era, surgery is a high-tech, rapid-paced field, with new knowledge and technological advances seemingly appearing around every corner. Many of these new discoveries have allowed surgeons to work more efficiently and safely, and as a result, a number of operations have now become same-day procedures. In addition, some very complex operations that were once thought to be impossible or to be associated with unacceptably high morbidity and mortality have now become feasible, thanks to advances in surgical technique, anesthesia, postoperative management, and critical care. The focus of our discussion is on the postoperative considerations that have become essential for successful recovery from surgery.

Each patient is unique, and each patient's case deserves thoughtful attention; no two patients can be managed in exactly the same way. Nevertheless, there are certain basic categories of postoperative care that apply to essentially all patients who undergo surgical procedures. Many of these categories are discussed in greater detail elsewhere in *ACS Surgery*. Our objective in this chapter is to provide a complete yet concise overview of each pertinent topic.

Disposition

The term disposition refers to the location and level of care and monitoring to which the patient is directed after the completion of the operative procedure. Although disposition is not often discussed as a topic in its own right, it is an essential consideration that takes into account many important factors. It may be classified into four general categories, as follows:

1. Home or same-day surgery via the recovery room.
2. The intensive care unit, with or without a stay in the recovery room.
3. The surgical floor via the recovery room.
4. The telemetry ward via the recovery room.

The disposition category that is appropriate for a given patient is determined by considering the following four factors:

1. The patient's preoperative clinical status (including both the condition being treated and any comorbid conditions), as indicated by the history, the physical examination, and the input of other medical practitioners.
2. The operative procedure to be performed.
3. The course and duration of the operative procedure.
4. The patient's clinical status at the completion of the procedure, as managed with the help of anesthesia colleagues.

The initial phase of disposition planning begins preoperatively. After a full history has been obtained and a complete physical

examination carried out, the procedure to be performed is decided on. This decision then initiates a discussion of the complexity and potential complications associated with the procedure, as well as of the concerns and special needs related to any comorbid conditions that may be present. If, as is often the case, the surgeon requires some assistance with planning the operation around the patient's other health problems, input from appropriate medical and surgical colleagues can be extremely helpful. Key factors to take into consideration include the potential complications related to the procedure and the urgency of their treatment; the level of monitoring the patient will require with respect to vital signs, neurologic examination, and telemetry; and the degree of care that will be necessary with respect to treatments, use of drains, and wound care. There are relatively few published references describing specific criteria for the various disposition categories; however, most hospitals and surgery centers will have developed their own policies specifying a standard of care to be provided for each category.

SAME-DAY SURGERY

Same-day surgery is appropriate for patients who (1) have few or no comorbid medical conditions and (2) are undergoing a procedure that involves short-duration anesthesia or local anesthesia plus sedation and that carries a low likelihood of urgent complications. Operations commonly performed on a same-day basis include inguinal or umbilical hernia repair, simple laparoscopic cholecystectomy, breast biopsy, and small subcutaneous procedures.

The growth in the performance of minor and same-day procedures has led to the development of various types of short-stay units or wards. The level of care provided by a short-stay ward is generally equivalent to that provided by a regular nursing ward; however, the anticipated duration of care is substantially shorter, typically ranging from several hours to a maximum of 48 hours. Short-stay wards also undergo some modifications to facilitate the use of streamlined teaching protocols designed to prepare patients for home care. Many hospitals now have short-stay units, as do some independent surgery centers.

SURGICAL FLOOR

The vast majority of patients receive the postoperative care they require on the surgical floor (or regular nursing ward). Assessment of vital signs, control of pain, care of wounds, management of tubes and drains, and monitoring of intake and output are addressed every 2 to 8 hours (depending on the variable). Assignment of the patient to the regular nursing ward presupposes that he or she is hemodynamically stable and does not need continuous monitoring.

The telemetry ward is a variant of the regular nursing ward. The care provided in the telemetry ward is generally equivalent to that provided on other floor wards, except that patients undergo continuous cardiac monitoring. Patients commonly assigned to the telemetry ward after operation include (1) those with a known medical history of arrhythmias that may necessitate intervention, (2) those with intraoperative arrhythmias or other electrocardio-

graphic (ECG) changes who are not believed to require ICU monitoring but who do need this form of cardiac follow-up, and (3) those making the transition from the ICU to a regular ward who are hemodynamically stable but who require ongoing follow-up of a cardiac issue.

INTENSIVE CARE UNIT

When early postoperative complications may necessitate urgent intervention and close observation is therefore essential, patients should be admitted to the ICU for postoperative care. Postoperative ICU admission may also be appropriate for patients who are clinically unstable after the procedure; these patients often require ongoing resuscitation, intravenous administration of vasoactive agents, ventilatory support, or continuous telemetry monitoring for dysrhythmias. In addition, admission to the ICU should be considered for patients in whom the complexity of drain management, wound care, or even pain control may necessitate frequent postoperative monitoring that is not available on a regular nursing ward. At present, there is no single set of accepted guidelines directing ICU admission. There are, however, published sources that can provide some guidance. For example, a 2003 article supplied recommendations for the various services to be provided by differing levels of ICUs.¹ Published recommendations of this sort may be adopted or modified by individual hospitals and surgery centers as necessary.

Care Orders

Nurses and other ancillary personnel provide the bulk of the care received by patients after a surgical procedure; accordingly, it is essential that they receive clear and ample instructions to guide their work. Such instructions generally take the form of specific postoperative orders directed to each ancillary service. Services for which such orders may be appropriate include nursing, respiratory therapy, physical therapy (PT), occupational therapy (OT), and diet and nutrition. In what follows, we briefly outline some of the common tasks that require orders to be directed toward these services.

NASOGASTRIC TUBES

Nasogastric (NG) tubes are commonly placed after gastrointestinal operations, most frequently for drainage of gastric secretions when an ileus is anticipated or offloading of the upper GI tract when a fresh anastomosis is located close by. Although NG tubes have often been placed routinely after abdominal surgery, the current literature cites a number of reasons why routine use is inadvisable and selective use is preferable. For example, significantly earlier return of bowel function, a trend toward less pulmonary complications, and enhanced patient comfort and decreased nausea are reported when NG tubes are not routinely placed or when they are removed within 24 hours after operation.²

When postoperative placement of an NG tube is considered appropriate, an order from a physician is required, along with direction regarding the method of drainage. Sometimes, NG tubes are placed to low continuous suction; more often, however, they are placed to low intermittent suction to eliminate the chance of continuous suction against a visceral wall and to promote generalized drainage. If large volumes of secretions are not expected, continuous gravity may be used instead of suction. A key concern with NG tubes is maintenance of the patency of both the main port and the sump port. Should either port become blocked, the tube will be rendered ineffective. This concern should be discussed with the nursing staff. At times, it may be necessary to

issue specific orders to ensure that this concern is appropriately addressed. As a rule, surgical nurses are well acquainted with tube maintenance; however, if thick secretions are expected, orders for routine flushing may be indicated. When the tube is no longer indicated, its removal may be ordered.

URINARY CATHETERS

Urinary catheters can serve a large variety of purposes. In the setting of bladder or genitourinary surgery, they are often employed to decompress the system so that it will heal more readily. After general surgical procedures—and many other surgical procedures as well—they are used to provide accurate measurements of volume output and thus, indirectly, to give some indication of the patient's overall volume and resuscitation status. Furthermore, after many procedures, patients initially find it extremely difficult or impossible to mobilize for urination, and a urinary catheter may be quite helpful during this time.

Their utility and importance notwithstanding, urinary catheters are associated with the development of nosocomial urinary tract infections (UTIs). As many as 40% of all hospital infections are UTIs, and 80% to 90% of these UTIs are associated with urinary catheters [*see Complications, below*]. Accordingly, when catheterization is no longer deemed necessary, prompt removal is indicated. As a rule, orders specifically pertaining to urinary catheter care are few, typically including gravity drainage, flushing to maintain patency (if warranted), and removal when appropriate. At times, irrigation is employed after urologic procedures or for the management of certain infectious agents.

OXYGEN THERAPY

Supplemental administration of oxygen is often necessary after a surgical procedure. Common indicators of a need for postoperative oxygen supplementation include shallow breathing and pain, atelectasis, operative manipulation in the chest cavity, and postoperative impairment of breathing mechanics. Because supplemental oxygen is considered a medication, a physician's order is required before it can be administered. In many cases, oxygen supplementation is ordered on an as-needed basis with the aim of enabling the patient to meet specific peripheral oxygen saturation criteria. In other cases, it is ordered routinely in the setting of known preoperative patient oxygen use.

An important factor to keep in mind is that oxygen supplementation protocols may vary from one nursing unit to another. Different units may place different limitations on the amount of supplemental oxygen permitted, depending on their specific monitoring and safety guidelines. Another important factor is that patients with known obstructive pulmonary disease and carbon dioxide retention are at increased risk for respiratory depression with hyperoxygenation; accordingly, particular care should be exercised in ordering supplemental oxygen for these patients.

DRAINS

Drains and tubes are placed in a wide variety of locations for a number of different purposes—in particular, drainage of purulent materials, serum, or blood from body cavities. Several types are commonly used, including soft gravity drains (e.g., Penrose), closed suction drains (e.g., Hemovac, Jackson-Pratt, and Blake), and sump drains, which draw air into one lumen and extract fluid via a companion lumen. Traditionally, surgeons have often made the decision to place a drain on the basis of their surgical training and practice habits rather than of any firm evidence that drainage is warranted. Multiple randomized clinical trials have now demonstrated that routine use of drains after elective operations—

including appendectomies and colorectal, hepatic, thyroid, and parathyroid procedures—does not prevent anastomotic and other complications (though it does reduce seroma formation). Consequently, it is recommended that drains, like NG tubes, be employed selectively.³⁻⁵ Once a drain is in place, specific orders must be issued for its maintenance. These include use of gravity or suction (and the means by which suction is to be provided if ordered), management and measurement of output, stripping, and care around the drain exit site.

Biliary tract drains include T tubes, cholecystostomy tubes, percutaneous drains of the biliary tree, and nasobiliary drains. Daily site maintenance, flushing, and output recording are performed by the nursing staff. Most biliary tract drains are removed by the practitioner or other trained midlevel staff members.

T tubes are generally placed after operative exploration or repair of the common bile duct (CBD). The long phalanges are left within the CBD, and the long portion of the tube is brought out to the skin for drainage. The tube is left in place until the CBD is properly healing and there is evidence of adequate distal drainage (signaled by a decrease in external drainage of bile). Before the T tube is removed, a cholangiogram is recommended to document distal patency and rule out retained gallstones or leakage.⁶

Cholecystostomy tubes are placed percutaneously—typically under ultrasonographic guidance and with local anesthesia—to decompress the gallbladder. Generally, they are used either (1) when cholecystectomy cannot be performed, because concomitant medical problems make anesthesia or the stress of operation intolerable, or (2) when the presence of severe inflammation leads the surgeon to conclude that dissection poses too high an operative risk. Particularly in the latter setting, delayed elective cholecystectomy may be appropriate; if so, the cholecystostomy tube may be removed at the time of the operation.

Nasobiliary tubes are placed endoscopically in the course of biliary endoscopy. They are used to decompress the CBD in some settings. They usually are placed to gravity and otherwise are managed in much the same way as NG tubes.⁷

WOUND CARE

The topic of wound care is a broad one. Here, we focus on initial postoperative dressing care, traditional wet-to-dry dressings, and use of a vacuum-assisted closure device (e.g., VAC Abdominal Dressing System; Kinetic Concepts, Inc., San Antonio, Texas). These and other components of wound care are discussed in more detail elsewhere [*see 1:7 Acute Wound Care and 3:3 Open Wound Requiring Reconstruction*].

Initial wound management after an operative procedure generally entails placement of a sterile dressing to cover the incision. The traditional recommendation has been to keep this dressing in place and dry for the first 48 hours after operation; because epithelialization is known to take place within approximately this period, the assumption is that this measure will reduce the risk of wound infection. Although most surgeons still follow this practice, especially in general surgical cases, supporting data from randomized clinical studies are lacking. In addition, several small studies that evaluated early showering with closed surgical incisions found no increases in the rate of infection or dehiscence.^{8,9} It should be kept in mind, however, that these small studies looked primarily at soft tissue and other minor skin incisions that did not involve fascia. Thus, even though the traditional approach to initial dressing management is not strongly supported, the data currently available are insufficient to indicate that it should be changed.

Wet-to-dry dressings are used in a variety of settings. In a surgical context, they are most often applied to a wound that cannot be

closed primarily as a consequence of contamination or inability to approximate the skin edges. Wet-to-dry dressings provide a moist environment that promotes granulation and wound closure by secondary intention. Moreover, their removal and replacement causes debridement of excess exudate or unhealthy superficial tissue. Postoperative orders should specify the frequency of dressing changes, as well as the solution used to provide dampness. For most clean open incisions, twice-daily dressing changes using normal saline solution represent the most common approach. If there is excess wound exudate to be debrided, dressing changes may be performed more frequently. If there is particular concern about wound contamination or superficial colonization of organisms, substitution of dilute Dakin solution for normal saline may be considered.

A new era of wound management arrived in the late 1990s with the introduction of negative-pressure wound therapy (NPWT). In NPWT, a vacuum-assisted wound closure device places the wound under subatmospheric pressure conditions, thereby encouraging blood flow, decreasing local wound edema and excess fluid (and consequently lowering bacterial counts and encouraging wound granulation), and increasing wound contraction.^{10,11} Since the first published animal studies, NPWT has been successfully employed for a multitude of wound types, including complex traumatic and surgical wounds, skin graft sites, and decubitus wounds. Before vacuum-assisted closure is used, however, it is necessary to consider whether and to what extent the wound is contaminated, the proximity of the wound to viscera or vascular structures, and the potential ability of the patient to tolerate dressing changes. Wounds that are grossly contaminated or contain significant amounts of nonviable tissue probably are not well suited to an occlusive dressing system of this type, given that frequent evaluation and possibly debridement may be needed to prevent ongoing tissue infection and death. Furthermore, the suction effect of the standard vacuum sponge may cause serious erosion of internal viscera or exposed major blood vessels. Some silicone-impregnated nonadherent sponges are available that may be suitable in this setting, but caution should be exercised in using them. Finally, because of the adherence of the sponge and the occlusive adhesive dressing, some patients may be unable to tolerate dressing changes without sedation or anesthesia.

Nutrition

The patient's nutritional status has a significant effect on postoperative morbidity and even mortality. After most operative procedures that do not involve the alimentary tract or the abdomen and do not affect swallowing and airway protection, the usual practice is to initiate the return to full patient-controlled oral nutrition as soon as the patient is fully awake. In these surgical settings, therefore, it is rarely necessary to discuss postoperative nutrition approaches to any great extent.

After procedures that do involve the alimentary tract or the abdomen, however, the situation is different. The traditional practice has been to institute a nihil per os (NPO) policy, with or without nasogastric drainage, after all abdominal or alimentary tract procedures until the return of bowel function, as evidenced by flatus or bowel movement, is confirmed. The routine application of this practice has been challenged, however, especially over the past 15 years. Data from prospective studies of high statistical power are lacking, but many smaller studies evaluating early return to enteral nutrition after alimentary tract procedures have yielded evidence tending to favor more routine use of enteral intake within 48 hours after such procedures.

Issues related to postoperative nutritional support are discussed further and in greater detail elsewhere [*see 8:23 Nutritional Support*].

NPO STATUS

In the setting of elective colorectal surgery, it is well-accepted practice to initiate a return to patient-controlled enteral-oral feeding within 24 to 48 hours after operation; this practice yields no increase in the incidence of postoperative complications (e.g., anastomotic leakage, wound and intra-abdominal infection, and pneumonia) or the length of hospital stay and, according to some reports, may even decrease them.¹² In the setting of upper GI surgery (specifically, gastric resection, total gastrectomy, and esophagectomy), the situation is less clear-cut. Traditional concerns—in particular, the need to avoid distention stress on gastric or gastrojejunal anastomoses after gastric resection, the more tenuous nature of a esophagojejunostomy after total gastrectomy, and the delayed gastric conduit emptying, aspiration risk, and anastomotic stress seen after esophagectomy or resection—have led to the current practice of instituting nasogastric drainage and placing the patient on NPO status postoperatively until evidence of the return of bowel function is apparent, as well as, in some cases, investigating the anastomosis for possible leakage by means of contrast fluoroscopy. There are no clinical trial data to support this approach. In fact, many surgeons routinely remove the NG tube within 24 hours after gastric resection and early feeding without incurring increased complications. However, there are also no clinical trial data indicating that the current approach is potentially ineffective or harmful. Consequently, traditional management methods after upper GI procedures still are often endorsed in the literature.^{13,14}

ENTERAL NUTRITION

Enteral nutrition may be delivered via several routes. Most patients who have undergone an operation are able to take in an adequate amount of calories orally. When they are unable to do so, whether because of altered mental status, impaired pulmonary function, or some other condition, the use of enteral feeding tubes may be indicated. In the acute setting, nasogastric and nasojejunal feeding tubes are the types most commonly employed to deliver enteral solutions into the GI tract. Either type is appropriate for this purpose; the two types are equivalent overall as regards their ability to provide adequate nutrition, and there are no significant differences in outcome or complications. In cases where prolonged inability to take in adequate calories orally is expected, the use of an indwelling feeding tube, such as a gastrostomy or jejunostomy tube, may be indicated. These tubes must be placed either at the time of operation or subsequently via surgical or percutaneous means, and there is some potential for complications. The specific indications for the use of such tubes are patient derived; they are not routinely associated with the performance of specific procedures.

TOTAL PARENTERAL NUTRITION

Total parenteral nutrition (TPN) is a surrogate form of nutrition in which dextrose, amino acids, and lipids are delivered via a central venous catheter. It is a reliable method, in that it delivers nutrients and calories regardless of whether the patient's gut is functioning or not. Nevertheless, multiple studies over the past 20 years have shown that when the patient has a functioning intestinal tract, enteral feeding is clearly preferable to TPN. Although the specific mechanisms are not fully understood, enteral nutrition is known to foster gut mucosal integrity, to support overall immune function, and to be associated with lower

complication rates and shorter hospital stays. In contrast, TPN is known to be associated with altered immune function, an increased rate of infectious complications, and, in some studies, a higher incidence of anastomotic complications after GI surgery. Moreover, there are as yet no data to indicate that acute utilization of TPN during short periods of starvation benefits patients who are adequately nourished preoperatively. TPN may, however, be lifesaving in patients who are malnourished and who do not have functioning GI tracts (e.g., those with short gut syndrome, severe gut dysmotility or malabsorption, mesenteric vascular insufficiency, bowel obstruction, high-output enteric fistulas, or bowel ischemia).¹⁵

CALORIC GOALS

Once a route of nutritional support has been decided on, overall goals for caloric and protein intake may be established on the basis of the patient's ideal body weight (IBW) and expected postoperative metabolic state. One approach is to rely on a general estimate; a commonly used formula is 25 kcal/kg IBW. Another approach is to calculate a basal energy requirement by using the Harris-Benedict equation. This calculation is separate from the calculation of protein needs. A daily protein intake goal may be calculated on the basis of the patient's estimated level of physical stress. A well-nourished unstressed person requires a protein intake of approximately 1.0 g/kg IBW/day. A seriously ill patient under ongoing severe physical stress, however, may require 2.0 g/kg IBW/day; in some settings (e.g., extensive burns), a protein intake as high as 3.0 g/kg IBW/day may be recommended. Once the patient's needs specific needs have been calculated, the amount and type of nutrient solution to be provided enterally or via TPN is determined. If the patient is on a full oral diet, a calorie count or recording of the percentage of items eaten at each meal or snack may be made by the nursing staff and used to estimate the patient's intake, with nutritional supplementation provided as needed.¹⁶

Patients who require assistance with nutritional intake should be monitored to determine whether the interventions being carried out are having the desired effect. The most common method of monitoring patients' nutritional status with nutritional supplementation is to measure the serum albumin and prealbumin (transferrin) concentrations. Albumin has a half life of approximately 14 to 20 days and thus serves as a marker of longer-term nutritional status. A value lower than 2.2 g/dl is generally considered to represent severe malnutrition, but even somewhat higher values (< 3.0 g/dl) have been associated with poorer outcomes after elective surgery. Although the serum albumin concentration is a commonly used marker, it is not always a reliable one. Because of albumin's relatively long half-life, the serum concentration does not reflect the patient's more recent nutritional status. In addition, the measured concentration can change quickly in response to the infusion of exogenous albumin or to the development of dehydration, sepsis, and liver disease despite adequate nutrition. Prealbumin is a separate serum protein that has a half-life of approximately 24 to 48 hours and thus can serve as a marker of current and more recent nutritional status. Like the albumin concentration, the prealbumin concentration can be affected by liver and renal disease. Overall, however, it is more immediately reliable in following the effects of nutritional intervention.

Fluid Management

Intravenous fluids may be classified into two main categories: resuscitation and maintenance. Supplemental fluids constitute a third category.

RESUSCITATION FLUIDS

Resuscitation fluids maintain tissue perfusion in the setting of hypovolemia by restoring lost volume to the intravascular space. They may be further classified into two subcategories: crystalloids and colloids.

Crystalloids

Crystalloid solutions are water-based solutions to which electrolytes (and, sometimes, organic molecules such as dextrose) have been added. The crystalloid solutions used for resuscitation are generally isotonic to blood plasma and include such common examples as 0.9% sodium chloride, lactated Ringer solution, and Plasma-Lyte (Baxter Healthcare, Round Lake, Illinois). The choice to use one solution over another is usually inconsequential, but there are a few notable exceptions. For example, in the setting of renal dysfunction, there is a risk of hyperkalemia when potassium-containing solutions such as lactated Ringer solution and Plasma-Lyte are used. As another example, the administration of large volumes of 0.9% sodium chloride, which has a pH of 5.0 and a chloride content of 154 mmol/L, can lead to hyperchloremic metabolic acidosis. Regardless of which crystalloid solution is used, large volumes may have to be infused to achieve a significant increase in the circulating intravascular volume. Only one third to one quarter (250 to 330 mL) of the fluid administered stays in the intravascular space; the rest migrates by osmosis into the interstitial tissues, producing edema and potential impairment of tissue perfusion (the latter is a theoretical consequence whose existence has not yet been directly demonstrated).¹⁷

Colloids

Colloid solutions are composed of microscopic particles dispersed in a second substance in such a way that they are suspended and do not separate out by normal filtration. Colloids are derived from three main forms of semisynthetic molecules: gelatins, dextrans, and hydroxyethyl starches. All of the commonly used synthetic colloids are dissolved in crystalloid solution. Nonsynthetic colloids also exist, including human albumin solutions, fresh frozen plasma, plasma-protein fraction, and immunoglobulin solutions. Compared with crystalloid solutions, colloid solutions increase the circulating intravascular volume to a much greater degree per unit of volume infused. In this respect, the various colloids may be thought of as a single group; however, in practice, they are most often given selectively on the basis of secondary characteristics other than their volume-increasing action, such as effect on hemostasis, risk of allergic reaction, and cost.

Crystalloids versus Colloids

The debate over whether crystalloids or colloids are superior for resuscitation has been going on for at least 30 years. Although multiple randomized, controlled trials have compared the two types of solutions in a variety of settings, including sepsis, trauma, burns, and surgery, the evidence accumulated to date has not established that one is clearly better than the other in terms of overall outcome. Supporters of crystalloid resuscitation cite the risk of altered hemostasis, the increased likelihood of drug interactions and allergic reactions, the potential for volume overload, and the relatively high cost as factors arguing against the use of colloids. Supporters of colloid resuscitation cite the large volume of crystalloid needed to produce significant volume effects, the subsequent tissue edema, and for the potential for impaired tissue perfusion and oxygenation as factors arguing against the use of crystalloids. Current recommendations favor crystalloid for resus-

citation, with colloid an acceptable substitute when its secondary effects are desired in specific situations.^{17,18}

MAINTENANCE FLUIDS

Maintenance fluids provide required daily amounts of free water and electrolytes (e.g., sodium, potassium, and chloride) in order to balanced expected daily losses and maintain homeostasis. A basic rule of thumb used by many practitioners to calculate the infusion rate for maintenance I.V. fluids is the so-called 4, 2, 1 rule:

- 4 ml/kg/hr for the first 10 kg of body weight;
- 2 ml/kg/hr for the next 10 kg of body weight; and
- 1 ml/kg/hr for every 1 kg of body weight above 20 kg.

Generally accepted maintenance requirements include 30 to 35 ml/kg/day for free water, 1.5 mEq/kg/day for chloride, 1 mEq/kg/day for sodium, and 1 mEq/kg/day for potassium. In the setting of starvation or poor oral intake, dextrose 5% is often added to maintenance fluids to inhibit muscle breakdown. In regular practice, however, these specific values are not commonly used: more often, a rough estimate is made of expected daily fluid requirements, and solutions are ordered in accordance with this estimate. Although this practice is unlikely to cause noticeable harm in the majority of postoperative patients, there are situations where inaccurate calculations can lead to dehydration and volume overload. Three studies from the early 2000s evaluated patients undergoing elective colorectal surgery with the aim of determining whether providing higher volumes of fluid perioperatively had an impact on outcome.¹⁹⁻²¹ In all three, the data supported the use of smaller fluid volumes perioperatively, which was shown to result in earlier return of gut function after operation, shorter hospital stays, and overall decreases in cardiopulmonary and tissue-healing complications.

SUPPLEMENTAL FLUIDS

Supplemental fluids are given to replace any ongoing fluid loss beyond what is expected to occur via insensible loss and excretion in urine and stool. They are most commonly required by patients with prolonged NG tube output, enterocutaneous fistulas, diarrhea, high-output ileostomies, or large open wounds associated with excessive insensible fluid loss. In each case, the amount of fluid lost daily should be calculated, and replacement fluid should be given in a quantity determined by this measurement (either as a whole or in part) and by the patient's overall intravascular volume status. The particular solution to be used depends on the characteristics of the fluid loss. The components and volume of the fluids produced in the GI tract are different at different sites [see Table 1].

Pain Control

The topic of postoperative pain control covers a broad spectrum of possible interventions that serve a wide range of purposes. The most obvious purpose is simply to relieve the suffering and stress associated with postoperative pain. Another is to improve the patient's overall postoperative status. Bringing the patient closer to the baseline sensory state by reducing pain allows him or her to engage in activities that promote healing and prevent complications, including mobilization to help prevent deep vein thrombosis (DVT) and deep breathing and coughing to help prevent pneumonia. Common methods of pain relief include intravenous infusion of narcotics, epidural analgesia using local anesthetics with or without narcotics, oral administration of narcotics, and the use of

Table 1 Electrolyte Content and Rate of Production of Fluids Secreted in the Gastrointestinal Tract

Source of Secretion	Electrolyte Concentration (mEq/L)					Rate of Production (ml/day)
	Na ⁺	K ⁺	Cl ⁻	HCO ₃ ⁻	H ⁺	
Salivary glands	50	20	40	30		100–1,000
Stomach						
Basal	100	10	140		30	1,000
Stimulated	30	10	140		100	4,000
Bile	140	5	100	60		500–1,000
Pancreas	140	5	75	100		1,000
Duodenum	140	5	80			100–2,000
Ileum	140	5	70	50		100–2,000
Colon	60	70	15	30		

nonnarcotic oral medications such as nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen (see below). These and other issues related to postoperative pain control are discussed in greater detail elsewhere [*see 1:5 Postoperative Pain*].

I.V. NARCOTIC ANALGESIA

Intravenous narcotics may be administered either by the medical staff or, if patient-controlled analgesia (PCA) is feasible, by the patient. In most cases, with the exception of brief hospital stays (< 48 hours) and ICU settings where the patient may not be alert enough to manage a patient-controlled system, PCA is now generally considered preferable to as-needed nurse-administered I.V. narcotic analgesia. Numerous studies and reviews have shown that PCA is safe and is no more likely to cause side effects (e.g., oversedation, overdose, itching, and nausea) than nurse-administered I.V. narcotic analgesia is. In addition, the use of PCA improves patients' subjective perceptions of the efficacy of pain relief and the timeliness of drug administration.²²

EPIDURAL ANALGESIA

Epidural analgesia usually makes use of a local anesthetic (e.g., bupivacaine), with or without the addition of a narcotic (e.g., fentanyl). The anesthetic solution is instilled into the epidural space, bathing the nerve roots in a given region and thereby providing pain relief. Until the past decade or so, epidural analgesia was considered a more dangerous method of pain relief and was not routinely employed outside the ICU. With time and further observation has come the recognition that epidural analgesia is safe and effective for postoperative pain control in a routine floor setting if managed by the proper supporting team of physicians.

There has been some debate regarding whether epidural analgesia leads to earlier return of bowel function after GI surgery or reduces the incidence of pulmonary complications; at present, this debate remains unresolved. There is clear evidence, however, that patients subjectively experience less pain with epidural analgesia, both at rest and in the course of activities such as mobilization and coughing. Moreover, in patients who have sustained traumatic rib fractures, early use of epidural analgesia in place of I.V. narcotic analgesia has been shown to reduce the incidence of associated pneumonia and shorten the time for which mechanical ventilation is required.²³ Epidural analgesia does have certain drawbacks, including an increased incidence of orthostatic episodes and a need for more frequent adjustments of the medication dosage. Nevertheless, it can be highly effective and can be a reasonable option when judged appropriate by the anesthesiologist and agreed to by the patient.^{24,25}

ORAL ADMINISTRATION OF NARCOTICS

Oral administration of narcotics is one of the oldest methods of providing postoperative pain relief. Numerous different narcotic agents are now available for use in this setting. When deciding which narcotic to prescribe, however, physicians typically do not select freely from the entire available range; rather, they tend to choose from a small subset of agents that they know well and are comfortable with. A key point to keep in mind is that in some formulations, narcotics are combined with other compounds (e.g., acetaminophen or aspirin), and these added medications can have side effects of their own if taken in excessively high doses. Such formulations may require more careful titration than narcotics alone would. Another key point is that many narcotics are available in both short-acting and long-acting versions. In patients who are experiencing substantial postoperative pain, a combination of long-acting agents and short-acting agents may yield more sustained and predictable pain relief than either type alone would.

Finally, for patients who have a history of chronic pain conditions and who regularly used pain medications preoperatively, the assistance of an acute pain service management team may be invaluable in treating pain postoperatively.

NSAIDS AND ACETAMINOPHEN

NSAIDs are available both by prescription and over the counter. They not only provide effective analgesia for pain from minor procedures but also may be a powerful adjunct to narcotics in more acute hospital settings. Their major disadvantages, which in some contexts are substantial enough to limit their use, include their propensity to cause gastric irritation and ulceration; their antiplatelet effects, which increase the tendency toward bleeding; and their potential nephrotoxic effects in some formulations. When employed in settings where these disadvantages are not considered to pose a high risk, NSAIDs can be a useful addition to narcotics, both by providing further pain relief and by reducing the required narcotic doses (and thus the incidence of narcotic-related side effects).

Like the NSAIDs, acetaminophen provides minor pain relief and is an antipyretic, but unlike the NSAIDs, it has no anti-inflammatory effect. Acetaminophen also is often added to narcotic regimens or formulations to reduce the need for narcotics. Its greatest potential side effect is hepatic toxicity with excessive use. Accordingly, the dosage should be less than 2 g/day in patients with normal hepatic function and even lower in those with impaired hepatic function. It is particularly important to keep these dose limits in mind when narcotic-acetaminophen combinations are prescribed on an as-needed basis; in this situation, safe dosage limits may well be exceeded if sufficient care is not taken.

Glycemic Control

Over the last decade, blood glucose control in the postoperative period has become a topic of great interest. Many studies, beginning with that of Van den Bergh and associates in 2001,²⁶ have found that strict glucose control reduces morbidity and mortality in critically ill surgical ICU patients. Although most of the data currently available are derived from ICU patients rather than from the surgical population as a whole, the principle of tight glycemic control has been generalized to apply to most postoperative patients.

The target glucose range has been the subject of debate, with most institutions using a range of 80 to 140 mg/dl. The ability to achieve this target range and the means of achieving it vary according to the level of nursing care that is provided. Options include continuous I.V. insulin infusion and combinations of subcutaneous injections that utilize various long- and short-acting insulin formulations. Episodes of hypoglycemia are an ever-present risk with tight glucose control; accordingly, the use of standard dosage regimens and careful monitoring are recommended to reduce the risk of such episodes.

The debate over the specifics of glycemic control notwithstanding, it is generally well accepted that this issue should be addressed in all patients who have undergone major operative procedures, regardless of whether they carry a preoperative diagnosis of diabetes mellitus.^{26,27}

Postoperative Complications

There are numerous complications that may arise in the postoperative period. Many of these are specific to particular operative procedures and hence are best discussed in connection with those procedures. Many others, however, may develop after virtually any operation and thus warrant a general discussion in this chapter (see below). Prompt discovery and treatment of these latter complications relies heavily on a sufficiently high index of suspicion.

POSTOPERATIVE FEVER

Postoperative temperature elevations are quite common, occurring in nearly one third of patients after surgery. Only a relatively small number of these are actually caused by infection. Fevers that are caused by infections (e.g., pneumonias, wound infections, or urinary tract infections) tend to reach higher temperatures (> 38.5°C), usually are associated with moderate elevation of the white blood cell (WBC) count 3 or more days after operation, and typically extend over consecutive days. Noninfectious causes of postoperative fevers include components of the inflammatory response to surgical intervention, reabsorption of hematomas, and (possibly) atelectasis.²⁸

Beyond checking the WBC count, a shotgun approach to the workup of postoperative fever probably is not warranted. A focused approach based on well-directed questioning and a careful physical examination is more likely to obtain the highest diagnostic yield. Coughing, sputum production, and respiratory effort should be noted, and the lungs should be auscultated for rales. All incisions should be inspected for erythema and drainage, and current and recent I.V. sites should be checked for evidence of cellulitis. If a central line has been placed, particularly if it has been in place for several days, the possibility of a line infection should be considered. Patients who have undergone prolonged nasogastric intubation may have sinusitis, which is most readily diagnosed through computed tomography of the sinuses. Further workup for fever may include, as indicated, chest x-ray, sputum cultures, urinalysis, blood cultures, or CT of the abdomen (after procedures

involving laparotomy—especially bowel resections—where intra-abdominal abscess is a possible complication).

PNEUMONIA

Respiratory infections in the postoperative period are generally considered nosocomial pneumonias and, as such, are potentially serious complications [see 8:16 *Nosocomial Infection*]. The estimated incidence of postoperative pneumonia varies significantly, with many estimates tending to run high. A 2001 study of more than 160,000 patients undergoing major noncardiac surgery provided what may be a reasonable overall figure, finding the incidence of postoperative pneumonia to be approximately 1.5%.²⁹ In the 2,466 patients with pneumonia, the 30-day mortality was 21%. Thoracic procedures, upper abdominal procedures, abdominal aortic aneurysm repair, peripheral vascular procedures, and neurosurgical procedures were all identified as placing patients at significantly increased risk for pneumonia. Patient-specific risk factors included age greater than 60 years, recent alcohol use, dependent functional status, long-term steroid use, and a 10% weight loss in the 6 months preceding the operation.²⁹

The diagnosis of postoperative pneumonia is based on the usual combination of index of suspicion, findings from the history and physical examination (e.g., fever, shortness of breath, hypoxia, productive cough, and rales on lung auscultation), imaging, and laboratory evaluation [see 8:17 *Postoperative and Ventilator-Associated Pneumonia*]. Appropriate workup, directed by the clinical findings, typically starts with chest x-rays (preferably in both posteroanterior and lateral views, if possible) and sputum cultures, sometimes accompanied by CT scanning of the chest and, possibly, bronchoscopy with bronchoalveolar lavage (which may be useful in directing antibiotic therapy when sputum cultures are nondiagnostic). Empirical broad-spectrum antibiotic therapy is typically initiated before the causative organism is identified; this practice has been shown to reduce mortality. Piperacillin-tazobactam, which is effective against *Pseudomonas aeruginosa*, is commonly used for this purpose; however, when Gram's staining of the sputum identifies gram-positive cocci, vancomycin or linezolid may be used initially instead.³⁰ Once the causative organism is identified, specific antibiotic therapy directed at that organism is indicated, as in treatment of other infectious processes. Drainage of parapneumonic effusions may also be necessary, and this measure may be helpful in diagnosing or preventing the development of empyema.

SURGICAL SITE INFECTION

Surgical site infection (SSI) is one of the most common postoperative complications and may occur after virtually any type of procedure [see 1:2 *Prevention of Postoperative Infection*]. Rates of infection vary widely (from less than 1% to approximately 20%), depending on the procedure performed, the classification of the operative wound (clean, clean-contaminated, contaminated, or dirty), and a host of patient-related and situation-specific factors. The majority of SSIs, regardless of site, are caused by skin-based flora, most commonly gram-positive cocci (e.g., staphylococci). Gram-negative infections are also commonly seen after GI procedures, and anaerobes may be present after pharyngoesophageal procedures.³¹ With SSI, as with other postoperative infectious complications, prompt recognition of the signs and symptoms is the key to successful management. Hence, regular examination of the wound, particularly in the setting of postoperative fever, is critical. Erythema and induration (indicative of cellulitis) are obvious signs of SSI, as is active drainage of pus from the wound. A more subtle sign is pain that is greater than

expected, especially when the pain seems to be increasing several days after operation.

In most cases, it is necessary to open and drain the wound (which is easily done at the bedside or in the clinic in most cases) and allow it to heal via secondary intention. Generally, wet-to-dry dressing changes with saline are employed; however, larger wounds may benefit from NPWT [see Care Orders, Wound Care, *above*]. Success with NPWT has been widely reported, and this technique has been used to treat such difficult wounds as exposed vascular grafts and sternotomy infections.^{32,33} The use of antibiotics depends on the presence and degree of cellulitis. The initial choice of an agent should be guided by the likelihood that particular organisms will be present, which is estimated on the basis of the site of the operation and the type of procedure being performed. Whenever possible, any purulent material in the SSI should be cultured; this step may permit more targeted antimicrobial therapy.

DEEP VEIN THROMBOSIS AND PULMONARY EMBOLISM

In the absence of appropriate prophylaxis, the incidence of DVT may be as high as 30% in abdominal and thoracic surgery patients, and that of fatal pulmonary embolism (PE) may be as high as 0.9%. Thus, prophylaxis against thromboembolism is clearly of high importance in the postoperative care of many patients [see 6:6 *Venous Thromboembolism*]. Major risk factors for DVT and PE in this setting include the operation itself, physical immobility, advanced age, the presence of a malignancy, obesity, and a history of smoking.³⁴

DVT should be suspected postoperatively whenever a patient complains of lower-extremity pain or one leg is noticeably more swollen than the other. The gold standard for diagnosis remains a venous duplex examination, which has a sensitivity of 97% for detecting DVT of the femoral and popliteal veins.³⁵ In most cases, treatment involves starting a heparin infusion (typically without a loading bolus in the postoperative setting), targeting a partial thromboplastin time (PTT) that is double to triple the normal PTT (i.e., approximately 60 to 80 seconds), and then switching to warfarin therapy when the patient is stable and able to tolerate oral medications.

PE should be suspected whenever a postoperative patient experiences a decrease in oxygen saturation or shortness of breath; this decrease may be accompanied by chest pain, tachycardia, and diaphoresis, all of which may also be seen in the setting of myocardial infarction (MI). When PE is suspected, it may be appropriate to start heparin therapy even before the diagnosis has been confirmed, depending on the degree of suspicion and the relative risk anticoagulation may pose to the patient. Currently, the principal means of diagnosing acute PE is spiral CT. This modality has relatively wide availability, can be performed fairly rapidly, and has a sensitivity of 53% to 100% and a specificity of 81% to 100%. In addition, it is readily usable in most critically ill patients, including those undergoing mechanical ventilation (though the amount of I.V. contrast material it requires may limit its use in patients with renal insufficiency). Greater diagnostic yield may be obtained by combining spiral CT with a lower-extremity venous duplex examination.³⁶ For most patients with postoperative PE, anticoagulation is administered in the form of heparin. Low-molecular-weight heparins (LMWHs) are also generally safe and effective; however, because their effect cannot be turned off in the same way as that of I.V. unfractionated heparin, they may be less useful in the period after operation.³⁷ In patients with massive PE, surgical embolectomy or suction-catheter embolectomy may be considered, as conditions warrant. Thrombolytic therapy is generally contraindicated in the postoperative setting.

CARDIAC COMPLICATIONS

Cardiac dysrhythmias may occur after a wide variety of surgical procedures; as one might imagine, they are most common after cardiac operations. Predisposing factors and possible causes are numerous and various, including underlying cardiac disease, perioperative systemic stress, electrolyte and acid-base imbalances, hypoxemia, and hypercarbia. Thus, controlling such conditions to the extent possible both preoperatively and postoperatively is an important part of preventing and managing postoperative cardiac dysrhythmias. Treatment generally involves first achieving hemodynamic stability and then converting the rhythm back to sinus if possible.

Supraventricular tachycardias (SVTs) are the dysrhythmias most commonly seen in the postoperative period, occurring after approximately 4% of noncardiac major operations. Atrial fibrillation and atrial flutter account for the majority of SVTs.³⁸ Ventricular rate control may be achieved pharmacologically by infusing diltiazem. Digoxin has long been used for this purpose, but it is less effective in acute settings than diltiazem is. Amiodarone, which is used to treat ventricular dysrhythmias [see 8:2 *Acute Cardiac Dysrhythmia*], may also be used to restore sinus rhythm postoperatively in some cases, especially after cardiac procedures.³⁹ When pharmacologic rate control is not possible, particularly in hypotensive patients, cardioversion is indicated.

Approximately one third of patients who undergo noncardiac surgery in the United States have some degree of coronary artery disease and thus are at increased risk for perioperative MI. The incidence of coronary artery disease is even higher in certain subpopulations, such as patients who undergo major vascular procedures.^{40,41} In the perioperative setting, however, the pathophysiology of coronary ischemia is different from that in nonsurgical settings, where plaque rupture is the most common cause of MI. Approximately 50% of all MIs occurring in surgical patients are caused by increased myocardial oxygen demand in the face of inadequate supply resulting from factors such as fluid shifts, physiologic stress, hypotension, and the effects of anesthesia. The majority of cardiac ischemic events occur in the first 4 days of the postoperative period.⁴¹

Perioperative beta blockade for patients at risk for MI is now routine. Multiple trials and meta-analyses have demonstrated that this practice yields significant risk reductions in terms of both cardiac morbidity and mortality^{42,43} and that these risk reductions are achieved regardless of the type of surgery being performed. Although there has been some variation in the protocols used by these trials and the results reported, there is general agreement that beta blockade should be initiated preoperatively, delivered at the time of surgery, and continued postoperatively for up to 1 week.⁴²

Diagnosis of postoperative MI is complicated by the fact that as many as 95% of patients who experience this complication may not present with classic symptoms (e.g., chest pain). Identification of MI may be further hindered by the ECG changes brought on by the stress of the perioperative period (including dysrhythmias). Ultimately, the most useful signal of an ischemic cardiac event in the postoperative period is a rise in the levels of cardiac enzymes, particularly troponin-I. Accordingly, cardiac enzyme activity should be assessed whenever there is a high index of suspicion for MI or a patient is considered to be at significant perioperative risk for MI.⁴⁰

Treatment of postoperative MI focuses on correcting any factors contributing to or exacerbating the situation that led to the event (e.g., hypovolemia or hypotension). Typically, although antiplatelet agents (e.g., aspirin) are sometimes given, thrombolytic therapy is avoided because of concerns about postoperative bleeding. Acute percutaneous coronary intervention is also associ-

ated with an increased risk of bleeding, but it has nonetheless been used successfully in the perioperative setting and is recommended by some physicians.⁴⁴ Beta blockade is often advocated as a means of treating postoperative MI, though it is probably more effective when used both preoperatively and perioperatively as a means of preventing MI.⁴⁰

Discharge

Planning for discharge from the hospital is clearly an essential part of perioperative care. In the best of circumstances, discharge planning starts before admission for elective surgery and is discussed with the patient and family as part of preoperative patient education. Starting the process early enables the provider to estimate the patient's probable needs at the end of acute hospitalization and thus to make preliminary arrangements as needed. For example, if it appears likely that the patient will have to stay in a skilled nursing or extended care facility or will require prolonged physical therapy and rehabilitation, these matters can be addressed to the mutual satisfaction of both patient and physician in advance of hospital discharge. In this way, delays in discharge and unnecessary days of acute hospitalization can be avoided, at least in some instances.

Criteria for discharge or transfer from acute hospital care vary widely, depending on the procedure, the provider, and the patient; rarely are they codified. For example, in a 2005 survey of 16 surgeons performing open colorectal resections within one hospital, only two factors—absence of complications and reported postoperative bowel movement—were considered criteria for early discharge by most (but not all) of the surgeons.⁴⁵ There was wide disagreement on all other criteria, including postoperative mobility and the ability to tolerate a general diet. Given such variation in discharge criteria for even one category of procedure, it is clear that a discussion of specific criteria for each type of surgery is well beyond the scope of this chapter. It is worth pointing out, however, that the various discharge criteria now in use, despite their differences, have a common basis—namely, the idea that at discharge, the patient should ideally be able to manage basic self-care activities (e.g., feeding, wound care, and mobility) without advanced assistance and that the likelihood of readmission should be minimized to the extent possible. Identification, investigation, and control of factors such as nausea, pain, fever, deconditioning, and fatigue are important in determining whether a patient is at risk for a return to the hospital in the postoperative period.⁴⁶

Over the past two decades, critical pathways, which are organized plans that outline the sequence of patient care and discharge, have been increasingly used in managing postoperative care after a variety of procedures from all disciplines. They have been shown to reduce hospital stays and maintain safety in patients undergoing common procedures (e.g., colectomy), patients undergoing complex procedures (e.g., esophagectomy),⁴⁷ and patients with high comorbidity.⁴⁸ Individual pathways are typically specific to a hospital or health care system; thus, the discharge criteria are those agreed on by the providers involved in the care of eligible patients at that particular institution. Critical pathways can be helpful not only by standardizing care and improving the relative appropriateness of postoperative discharge but also, in many cases, by decreasing the overall length of postoperative hospitalization.⁴⁶ In a 2003 study of 27 postoperative critical pathways used at the Johns Hopkins Hospital, the authors found that seven (27%) of the pathways were associated with significant (5% to 45%) decreases in length of stay.⁴⁹

Regardless of whether critical pathways are implemented, if discharge planning is not addressed preoperatively, addressing it as early as possible in the postoperative period is extremely valuable not only for ensuring an appropriate length of stay but also for maintaining the satisfaction and comfort of both patient and family. Specific issues should be addressed at this point as needed, including the home resources and support available to the patient, wound care, ostomy care, management of feeding tubes and drains, I.V. antibiotic therapy, and physical rehabilitation. Thus, as soon as it appears that a patient is on track either for discharge home or for transfer to a rehabilitation or skilled nursing facility, a discussion with the appropriate social work or discharge planning personnel should be scheduled. Physical therapy and occupational therapy (PT/OT) evaluations early in the postoperative course can also be of great assistance in determining a patient's needs upon discharge, and such evaluations are essential for any patient who may need a stay in an inpatient rehabilitation facility. Typically, it requires at least 1 day to set up services such as home health care and outpatient physical therapy, and it may take this long or longer to obtain a bed at an appropriate rehabilitation or skilled nursing facility. Consequently, the earlier these plans are made, the better. For many surgical patients, formal discharge planning and PT/OT evaluations are not actually necessary. Brief discussions with the patient, the family, or the nursing staff caring for the patient will assist in determining which surgical patients are most likely to benefit from this approach.

7 ACUTE WOUND CARE

Stephen R. Sullivan, M.D., Loren H. Engrav, M.D., F.A.C.S., and Matthew B. Klein, M.D.

Approach to Acute Wound Management

Acute wounds are the result of local trauma and may be associated with severe life-threatening injuries. The approach to a patient with an acute wound begins with assessment of the ABCs (Airway, Breathing, and Circulation). Management of

any life-threatening injuries present is addressed first; only after more urgent problems have been ruled out or corrected is management of the wound itself addressed. A complete history is obtained and a thorough physical examination performed, with special attention paid to both local and systemic wound environment factors that may affect healing. Information about the cause of injury is sought. In the case of a hand injury, the patient's hand dominance and occupation are determined. All patients with acute wounds should be assessed for malnutrition, diabetes, peripheral vascular disease, neuropathy, obesity, immune deficiency, autoimmune disorders, connective tissue diseases, coagulopathy, hepatic dysfunction, malignancy, smoking practices, medication use that could interfere with healing, and allergies. The local wound environment should be evaluated to determine the extent and complexity of injury, the tissues involved, the presence or absence of contamination by microorganisms or foreign bodies, and the degree of any damage related to previous irradiation or injury to surrounding tissues.

Gloves and a shielded mask are worn to protect the practitioner from exposure to body fluids. Gloves must be powder free, as well as latex free (to prevent allergic reactions to latex).¹ The wound is carefully examined, with particular attention paid to size, location, bleeding, arterial or venous insufficiency, tissue temperature, tissue viability, and foreign bodies. The possibility of damage to vessels, nerves, ducts, cartilage, muscles, or bones in proximity to the injury is assessed. X-rays and a careful motor and sensory examination may be required to rule out such coexisting injuries. While these tests are being performed, moist gauze should be applied to wounds. For thorough assessment of injuries, it may be necessary to probe ducts (e.g., the parotid duct or the lacrimal duct).

At this point, decisions must be made about acute wound care. The goal of acute wound management is a closed, healing wound that will result in the best functional and aesthetic outcome. In what follows, we address the key considerations in management of the acute wound, including anesthesia, choice of repair site (i.e., operating room or emergency department), debridement, irrigation, hemostasis, closure materials, timing and methods of closure, appropriate closure methods for specific wound types, dressings, adjunctive treatment (e.g., tetanus and rabies prophylaxis, antibiotics, and nutritional supplementation), postoperative wound care, and potential disturbances of wound healing. Finally, we briefly review the physiology of wound healing.

Wound Preparation

ANESTHESIA

Adequate general or local anesthesia, preceded by careful motor and sensory examination, must be instituted before examination and treatment of the wound can begin. General anesthesia in the OR is employed if the patient is unable to tolerate local anesthesia; adequate pain control cannot be achieved with a local block; the wound requires significant debridement, exploration, or repair; bleeding is difficult to control; or the local anesthetic dose required for adequate pain control exceeds the maximum dose that can be safely delivered. Local anesthesia is usually sufficient for debridement and closure of most small traumatic wounds. Often, the local anesthetic may be injected directly into wounded tissue. However, direct wound injection may be less reliable in inflamed or infected tissue or may distort important anatomic landmarks used to align wound edges. In these situations, regional nerve blocks directed at specific sensory nerves outside the injured field may be employed instead.

The main injectable anesthetics can be broadly divided into amides and esters [see Table 1]. (An easy way of remembering which category an agent belongs to is to recall that the amides all have two *I*s in their generic name, whereas the esters have only one.) Lidocaine, an amide, is the most commonly used local anesthetic. Its advantages include its rapid onset of action (< 2 minutes), its extended duration of action (60 to 120 minutes), its relative safety in comparison with more potent anesthetics (e.g., bupivacaine), and its availability in multiple forms (e.g., liquid, jelly, and ointment) and concentrations (e.g., 0.5%, 1.0%, and 2.0%). In addition, lidocaine rarely causes allergic reactions, whereas ester anesthetics (e.g., tetracaine) are metabolized to para-aminobenzoic acid, to which some persons are allergic. Cocaine, an ester, is an excellent local anesthetic for wounds in

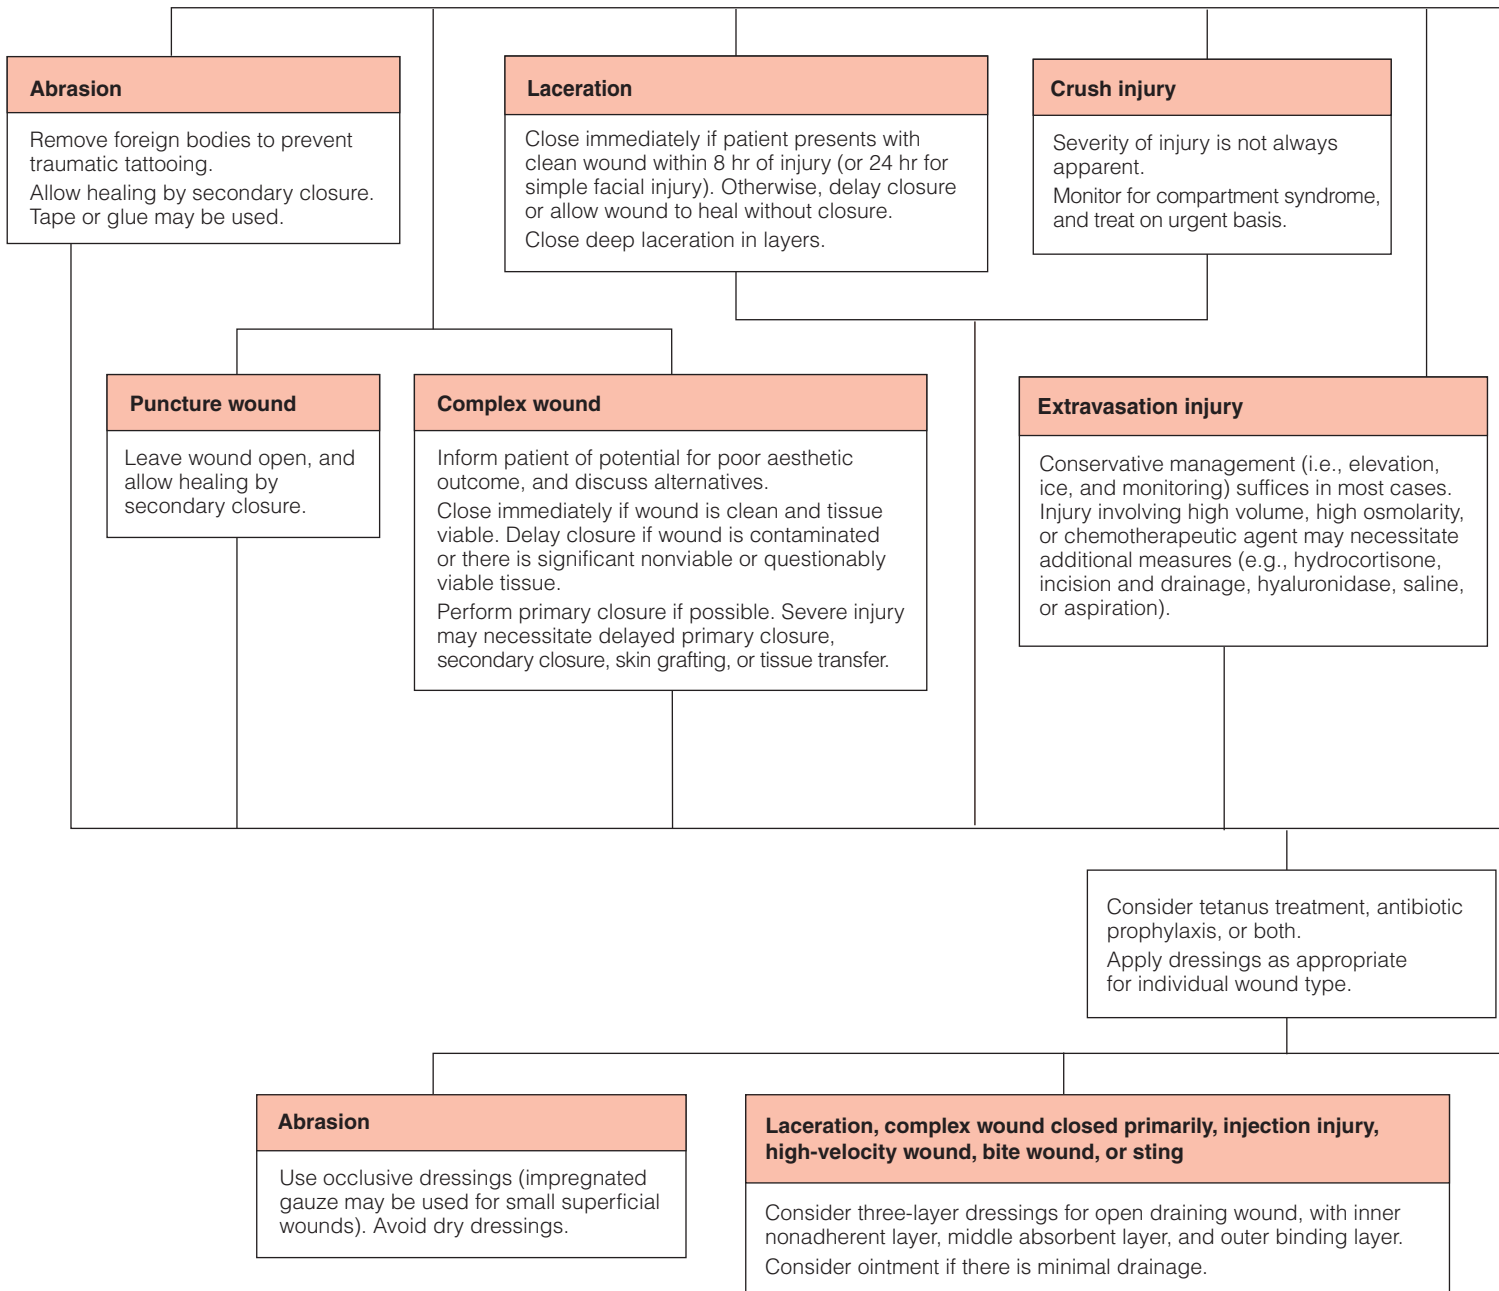

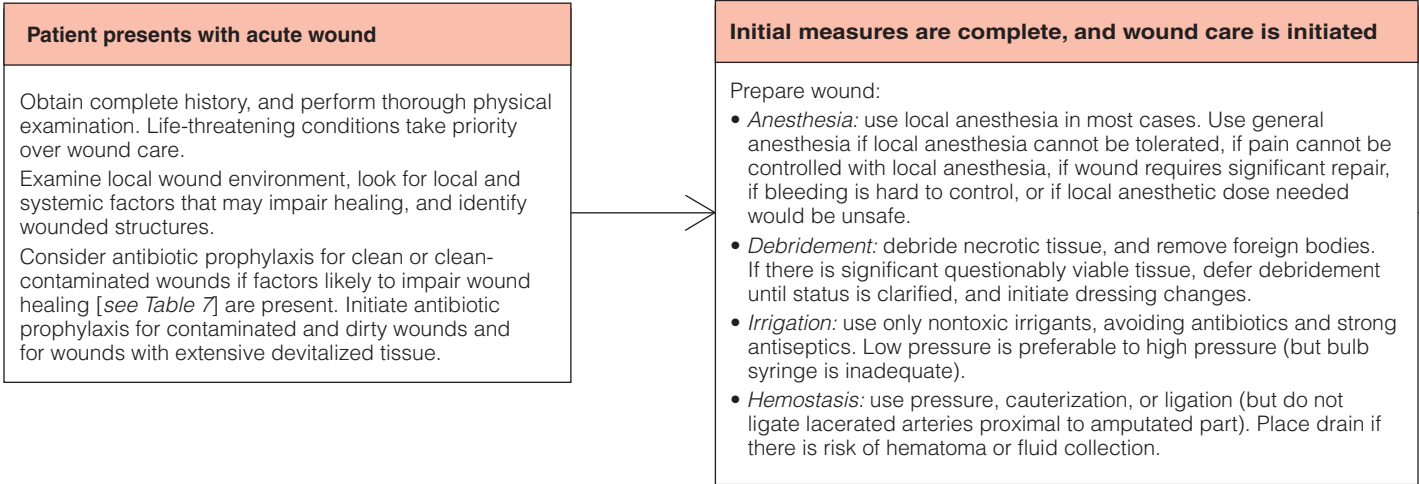

Table 1 Common Injectable Anesthetics³

Amides	Esters
Lidocaine (Xylocaine)	Procaine (Novocain)
Bupivacaine (Marcaine)	Chloroprocaine (Nesacaine)
Mepivacaine (Carbocaine)	Tetracaine (Pontocaine)
Prilocaine (Citanest)	Benzocaine (multiple brands)
Etidocaine (Duranest)	Propoxycaine (Ravocaine)
Phenocaine	Cocaine
Dibucaine (Nupercainal)	
Ropivacaine (Naropin)	
Levobupivacaine (Chirocaine)	

Approach to Acute Wound Management

Wound is ready for closure

Select closure materials: sutures, tapes, staples, or adhesives.
 Determine timing and methods of closure:

- *Immediate primary closure*: clean wound without contraindications to closure
- *Delayed primary closure*: contaminated wound, wound with questionably viable tissue, or patient who cannot tolerate immediate closure
- *Secondary closure (allowing wound to heal by itself)*: wound with contamination or contraindication to closure, patient who cannot tolerate closure, or wound for which closure is not needed for aesthetic result
- *Skin grafting*: large superficial wound
- *Tissue transfer*: large wound with exposed vital structure

Formulate specific closure approach suitable for individual wound type.

Injection injury

Wound appearance is often deceptively benign. Examine wound area carefully and obtain appropriate radiographs.
 Treat aggressively with incision, wide exposure, debridement, and removal of foreign bodies.
 Allow healing by secondary closure.

Bite wound

Take into account risks of rabies, bacterial and other viral infections, and envenomation.
 Treat with exploration, irrigation, and debridement.
 Close immediately if wound is clean and tissue viable. Delay closure if wound is contaminated or there is significant nonviable or questionably viable tissue.
 Perform primary closure if possible. Severe injury may necessitate secondary closure, skin grafting, or tissue transfer.
 Consider rabies treatment, rabies prophylaxis, or both.

High-velocity wound

Wound appearance is often deceptively benign; foreign bodies are frequently present. Examine wound area carefully and obtain appropriate radiographs.
 Debride wound extensively and identify all injured tissue.
 Avoid immediate primary closure. Perform delayed primary closure or allow healing by secondary closure.

Sting

Take into account risk of envenomation. Symptoms may be local or systemic. Treatment is usually directed toward local symptoms. For systemic reactions, epinephrine, diphenhydramine, and supportive airway and BP care may be required.

Complex wound left open or closed after delay

Generally, use wet-to-dry dressings; use wet-to-wet dressings if wound bed contains tendons, arteries, nerves, or bone. Avoid compression dressings.
 Consider NPWT for large open wound.

Extravasation injury or crush injury

Avoid compression dressings.

mucous membrane (e.g., those in the nose or the throat). It is unique among local anesthetics in that it causes vasoconstriction, which helps reduce hemorrhage. Typically, cocaine is applied topically by soaking gauze or pledgets in a solution.

Vasoconstriction can also be produced by adding epinephrine to a local anesthetic, usually in a dilution of 1:100,000 or 1:200,000 (5 to 10 µg/ml). Through vasoconstriction, epinephrine prolongs the anesthetic agent's duration of action, allows a larger dose to be safely administered, and aids in hemostasis.² Traditionally, local anesthetics with epinephrine have not been used in finger and toe wounds, because of the theoretical risk of ischemia and tissue loss; however, these adverse effects have not yet been reported clinically or documented by any prospective studies.³

Local anesthetics can cause systemic toxicity when injected intravascularly or given in excessive doses. Manifestations of systemic toxicity begin with central nervous system effects (e.g., vertigo, tinnitus, sedation, and seizures) and may progress to cardiovascular effects (e.g., hypotension, cardiac conduction abnormalities, and cardiovascular collapse). Treatment for systemic toxicity is supportive, with oxygen, airway support, and cardiovascular bypass (if necessary) provided until the anesthetic has been metabolized by the liver. The maximum safe dose of lidocaine is 3 to 5 mg/kg without epinephrine and 7 mg/kg with epinephrine. Doses as high as 55 mg/kg have been used without toxicity for tumescent anesthesia in patients undergoing liposuction⁴; however, in this scenario, some of the anesthetic is aspirated by the liposuction, which means that the effective dose is lower. The lidocaine doses used for local wound injection should be substantially smaller than those used in liposuction. The maximum safe dose of cocaine is 2 to 3 mg/kg. To prevent local anesthesia from causing systemic toxicity, the recommended safe doses of the anesthetics should not be exceeded, and aspiration should be performed before injection into the wound to ensure that the agent will not be injected intravascularly.

The pain associated with injection of the local anesthetic can be minimized by using a small-caliber needle (27 to 30 gauge), warming the anesthetic, injecting the agent slowly, using a subcutaneous rather than an intradermal injection technique,⁵ providing counterirritation, buffering the anesthetic with sodium bicarbonate to reduce acidity (in a 1:10 ratio of sodium bicarbonate to local anesthetic),⁶ and applying a topical local anesthetic before injection. Topical local anesthetics (e.g., TAC [tetracaine, adrenaline (epinephrine), and cocaine] and EMLA [a eutectic mixture of lidocaine and prilocaine]) are as effective as injectable anesthetics when applied to an open wound.⁷ EMLA requires approximately 60 minutes to induce sufficient anesthesia for open wounds; TAC requires approximately 30 minutes.⁸ EMLA is more effective than TAC for open wounds of the extremity. Benzocaine 20% (in gel, liquid, or spray form) can also be used for topical anesthesia and is frequently employed before endoscopic procedures. It is poorly absorbed through intact skin but well absorbed through mucous membranes and open wounds. A 0.5- to 1-second spray is usually recommended, though even with a standardized spray duration, the delivered dose can vary considerably.⁹ A 2-second spray results in a statistically, though not clinically, significant increase in methemoglobin levels.¹⁰ Methemoglobinemia is a rare but life-threatening complication of benzocaine spray use. If symptoms of methemoglobinemia develop (e.g., cyanosis or elevated methemoglobin levels on cooximetry), prompt treatment with intravenous methylene blue, 1 to 2 mg/kg, is indicated.⁹

DEBRIDEMENT

Normal healing can proceed only if tissues are viable, if the wound contains no foreign bodies, and if tissues are free of exces-

sive bacterial contamination. To reduce the risk of infection in an acute wound, necrotic tissue and foreign bodies must be removed.¹¹ The wound and the surrounding local tissue must be exposed so that necrotic tissue can be identified and debrided. Hair may be trimmed with scissors or an electric clipper or retracted with an ointment or gel to facilitate exposure, debridement, and wound closure. Close shaving with a razor should be avoided, however, because it potentiates wound infections.¹² Clipping of eyebrows should also be avoided, both because the eyebrows may not grow back and because the hair is necessary for proper alignment.

Some wounds contain a significant amount of questionably viable tissue. If there is enough questionably viable tissue to preclude acute debridement, dressing changes may be initiated. When all tissue has been declared to be either viable or necrotic and when the necrotic tissue has been debrided surgically or by means of dressing changes, the wound can be closed.

Most foreign bodies are easily removed from wounds either by hand or via surgical debridement. Abrasion injuries or gunpowder explosions can cause small foreign body fragments to be embedded in and beneath the skin. These small foreign bodies are often difficult to extract but should be removed as soon after the injury as possible. Irrigation usually suffices for removal of loose foreign bodies, but surgical debridement with a small drill, a sharp instrument, or a brush may be required for removal of more firmly embedded foreign material. If the interval between injury and treatment exceeds 1 to 2 days, the wounds will begin to epithelialize and the embedded material will be trapped in the skin, resulting in traumatic tattooing.

IRRIGATION

After debridement of necrotic tissue and foreign bodies, the next step is irrigation of the wound. This may be accomplished by means of several different methods, including bulb syringe irrigation, gravity flow irrigation, and pulsatile lavage. These methods can be further divided into high-pressure (35 to 70 psi) and low-pressure (1 to 15 psi) delivery systems. High-pressure pulsatile lavage reduces bacterial concentrations in the wound more efficiently than low-pressure and bulb syringe irrigation do,¹³ but it also causes considerable disruption to soft tissue structure¹⁴ and results in deeper penetration and greater retention of bacteria in soft tissue than low-pressure lavage does.¹⁵ In general, low-pressure systems should be employed for acute wound irrigation, though merely running saline over a wound is of little value. To obtain continuous irrigation with pressures as low as 5 to 8 psi, one group recommended using a saline bag in a pressure cuff inflated to 400 mm Hg and connected to I.V. tubing with a 19-gauge angiocatheter.¹⁶

Only nontoxic solutions (e.g., 0.9% sterile saline, lactated Ringer solution, sterile water, and tap water) should be used for wound irrigation.¹⁷ Irrigation with an antibiotic solution appears to offer no advantages over irrigation with a nonsterile soap solution, and the antibiotic solution may increase the risk of wound-healing problems.¹⁸ Strong antiseptics (e.g., povidone-iodine, chlorhexidine, alcohol, sodium hypochlorite, and hydrogen peroxide) should not be placed directly into the wound, because they are toxic to the tissues and impede healing. The surrounding skin should be prepared with an antibacterial solution, and a sterile field created to limit contamination.

HEMOSTASIS

In most wounds, hemorrhage can be readily controlled with pressure, cauterization, or ligation of vessels. Lacerated arteries

proximal to amputated parts such as fingers or ears, however, should not be ligated, because an intact vessel is necessary for microsurgical replantation. Packing, wrapping, and elevating can help control hemorrhage temporarily. If necessary (though the need should be rare), a tourniquet may be applied to an injured extremity. Hemostasis prevents hematoma formation, which increases the risk of infection and wound inflammation. If there appears to be a potential risk of hematoma or fluid collection, drains should be placed. Although drains may help prevent accumulation of blood or serum in the wound, they are not a replacement for meticulous hemostasis. Drains facilitate approximation of tissues, particularly under flaps; however, they also tend to potentiate bacterial infections and should therefore be removed from the wound as soon as possible.¹⁹

As a rule, drains can be safely removed when drainage reaches levels of 25 to 50 ml/day. If a hematoma or seroma forms, the subsequent course of action depends on the size of the fluid collection. Small hematomas and seromas usually are reabsorbed and thus can be treated conservatively. Larger hematomas and seromas provide a significant barrier to healing, and treatment may require reopening the wound and placing drains. Intermittent sterile aspirations, followed by application of a compressive dressing, may be indicated for seromas. If this approach fails to eliminate the seroma, a drain may be reintroduced.

Wound Closure

MATERIALS

Once the appropriate preparatory measures have been taken (see above), the wound is ready to be closed. The first step is to choose the material to be used for wound closure. The materials currently available for this purpose include sutures, staples, tapes, and glues. Selection of the appropriate material is based on the type and location of the wound, the potential for infection, the patient's ability to tolerate closure, and the degree of mechanical stress imposed by closure. The selected material must provide wound edge approximation until the tensile strength of the wound has increased to the point where it can withstand the stress present.

The majority of wounds are closed with sutures. A suture is a foreign body by definition, and as such, it may generate an inflammatory response, interfere with wound healing, and increase the risk of infection. Accordingly, the number and diameter of sutures used to close a wound should be kept to the minimum necessary for coaptation of the edges.

Sutures are categorized on the basis of material used, tensile strength, configuration, absorbability, and time to degradation [see Table 2]. Suture material may be either natural or synthetic; natural fibers (e.g., catgut and silk) cause more intense inflammatory reactions than synthetic materials (e.g., polypropylene) do.²⁰ The tensile strength of suture material is defined as the amount of weight required to break a suture divided by the suture's cross-sectional area. It is typically expressed in an integer-hyphen-zero form, whereby larger integers correspond to smaller suture diameters (e.g., 3-0 sutures have a greater diameter and more tensile strength than 5-0 sutures do).²¹ Closure of acute wounds rarely requires sutures larger than 4-0. In terms of configuration, suture material may be composed either of a single filament or of multiple filaments. Multifilament suture material may be twisted or braided, and the interstices created by braiding may harbor organisms and

increase the risk of infection. Monofilament sutures hold knots less well than multifilament sutures, requiring five knots for security; multifilament sutures are easier to handle and require only three knots. With all sutures, the knots must be square to be secure and must be only tight enough to coapt the wound edges. To minimize foreign body bulk, buried suture knot ends should be cut right on the knot. In terms of absorbability, either absorbable or nonabsorbable sutures may be appropriate, depending on the situation. Absorbable sutures are generally used for buried sutures to approximate deep tissues (e.g., dermis, muscle, or fascia). Absorption of synthetic suture material occurs by hydrolysis and causes less tissue reaction than absorption of natural suture material, which occurs by proteolysis. Nonabsorbable sutures (e.g., those made of silk, nylon, polyester, or polybutester) are most commonly used for wounds in the skin, from where they will eventually be removed, or for wounds in deeper structures that require prolonged support (e.g., abdominal wall fascia, tendons, nerves, and blood vessels).

Staple closure is less expensive and significantly faster than suture closure, and it offers a slightly, though not significantly, better cosmetic outcome when used to close scalp wounds.^{22,23} Contaminated wounds closed with staples have a lower incidence of infection than those closed with sutures.²⁴ In addition, staple closure eliminates the risk that a health care provider will experience a needle stick, which is a particularly important consideration in caring for a trauma patient with an unknown medical history.

The tapes used for wound closure either are rubber-based or employ an acrylate adhesive. Rubber-based tapes (e.g., athletic tape) are a potential irritant to skin, degrade with exposure to heat, light, and air, and are occlusive, thereby preventing transepidermal water loss. Tapes that include acrylate adhesives (e.g., Micropore and Steri-Strip), however, are hypoallergenic, have a long shelf life, and are porous, thereby allowing water to evaporate.²⁵ Linear wounds in areas with little tension are easily approximated with tape alone, whereas wounds in areas where the skin is more taut (e.g., the extremities) generally require that tape skin closure be supplemented by dermal sutures. The use of tape alone is desirable when feasible, in that it spares the patient the discomfort associated with suture removal, prevents suture puncture scars, and avoids the emotional upset that may attend suture closure of small facial wounds on children.²⁵ Tape closure has some significant advantages: it immobilizes wound edges, permits early suture removal, is easy to perform and comfortable for the patient, leaves no marks on the skin, and yields a lower infection rate in contaminated wounds than suture closure does.²⁶ It also has a few disadvantages: patients may inadvertently remove the tapes, and wound edge approximation is less precise with tapes alone than with sutures. In addition, tape will not adhere to mobile areas under tension (e.g., the plantar aspects of the feet) or to moist areas (e.g., mucous membranes and groin creases), and wound edema can lead to blistering at the tape margins and to inversion of taped wound edges.

The use of tissue adhesives (e.g., octylcyanoacrylate) is a fast, strong, and flexible method of approximating wound edges. Compared with sutures, staples, and tapes, adhesives provide a faster closure and are essentially equivalent in terms of cosmetic outcome, infection rate, and dehiscence rate.²⁷ Adhesives can be used on most parts of the body and have been employed to close wounds ranging from 0.5 to 50 cm in length. Their advantages include reduced cost, ease of application, and the absence of any need for needles or suture removal; their major disadvantage is lack of strength.²⁸ They must not be applied to tissues within wounds but, rather, should be applied to intact skin at wound edges, where they serve to hold injured surfaces together. In addi-

Table 2 Types and Characteristics of Suture Material Used for Wound Closure

Suture Type	Material	Comment	Configuration	Method of Absorption	Tensile Strength at 2 Wk	Time to Degradation
Absorbable	Plain catgut (bovine intestinal serosa)	Natural; high tissue reactivity	Monofilament	Proteolysis	0%	10–14 days
	Chromic catgut (bovine intestinal serosa treated with chromic acid)	Natural; stronger, less reactive, and longer-lasting than plain catgut	Monofilament	Proteolysis	0%	21 days
	Fast-absorbing catgut	Natural	Monofilament	Proteolysis	0%	7–10 days
	Polyglytone 6211 (Caprosyn)	Synthetic	Monofilament	Hydrolysis	10%	56 days
	Glycomer 631 (Biosyn)	Synthetic	Monofilament	Hydrolysis	75%	90–110 days
	Polyglycolic acid (Dexon)	Synthetic	Monofilament/ multifilament	Hydrolysis	20%	90–120 days
	Polyglactic acid (Vicryl)	Synthetic	Multifilament	Hydrolysis	20%	60–90 days
	Polyglyconate (Maxon)	Synthetic	Monofilament	Hydrolysis	81%	180–210 days
	Polyglycolide (Polysorb)	Synthetic	Multifilament	Hydrolysis	80%	56–70 days
	Polydioxanone (PDS)	Synthetic	Monofilament	Hydrolysis	74%	180 days
	Polyglecaprone 25 (Monocryl)	Synthetic	Monofilament	Hydrolysis	25%	90–120 days
	Polyglactin 910 (Vicryl RAPIDE)	Synthetic	Multifilament	Hydrolysis	0%	7–14 days
Nonabsorbable	Polybutester (Novafil)	Synthetic; low tissue reactivity; elastic; good knot security	Monofilament	—	High	—
	Nylon (Monosof, Dermalon, Ethilon)	Synthetic; low tissue reactivity; memory effect necessitates more knots	Monofilament	—	High	—
	Nylon (Nurolon)	Synthetic; low tissue reactivity	Multifilament	—	High	—
	Nylon (Surgilon)	Synthetic; silicon coated; low tissue reactivity	Multifilament	—	High	—
	Polypropylene (Prolene, Surgilene, Surgipro)	Synthetic; low tissue reactivity; slippery	Monofilament	—	High	—
	Polyethylene (Dermalene)	Synthetic	Monofilament	—	High	—
	Stainless steel	Lowest tissue reactivity of all sutures; poor handling; creates artifact on CT scan; moves with MRI	Monofilament/ multifilament	—	Highest	—
	Cotton	Natural	Multifilament	—	—	—
	Silk (Sofsilik)	Natural; high tissue reactivity; good knot security	Multifilament	—	Poor	—
	Polyester (Dacron, Mersilene, Surgidac)	Synthetic; uncoated; high friction; low tissue reactivity; poor knot security	Multifilament	—	High	—
	Polyester (Ticron)	Synthetic; silicon coated; low tissue reactivity; good knot security	Multifilament	—	High	—
	Polyester (Ethibond)	Synthetic; polybutylate coated; low tissue reactivity; good knot security	Multifilament	—	High	—
Polyester (Ethiflex, Tevdek)	Synthetic; Teflon coated; low tissue reactivity; good knot security	Multifilament	—	High	—	

tion, they should not be used for wounds in mucous membranes, contaminated wounds, deep wounds, or wounds under tension. Adhesives are particularly useful for superficial wounds or wounds in which the deep dermis has been closed with sutures.

TIMING AND METHODS

Appropriate materials having been selected, the next issue to address is the timing of wound closure. The choices are (1) to close the wound at the time of initial presentation, (2) to delay closure until after a period of healing or wound care, and (3) to allow the wound to heal on its own. The best choice in a given situation depends whether the patient is stable and able to undergo wound repair, whether hemorrhage is under control, whether necrotic material has been adequately debrided and foreign bodies removed, whether and to what degree bacterial contamination is present, and what the expected aesthetic outcome of immediate closure might be in comparison with that of delayed closure or secondary healing.

The timing of wound closure determines the method that will be employed. The closure methods available include (1) primary closure by direct approximation; (2) delayed primary closure, in which the wound is closed after a healing period; (3) secondary closure, in which the wound is allowed to heal on its own; (4) skin grafting; and (5) the use of local or distant flaps. The ideal wound closure method would support the wound until it has nearly reached full strength (i.e., about 6 weeks), would not induce inflammation, would not induce ischemia, would not penetrate the epidermis and predispose to additional scars, and would not interfere with the healing process. Unfortunately, no existing method accomplishes all of these goals in all cases; some sort of compromise is virtually always necessary. In the acute wound setting, the simplest method that will achieve a good closure is preferred.

Primary closure provides optimal wound healing when two perpendicular, well-vascularized wound edges are approximated without tension. Closure should proceed from deep to superficial. The initial step is to identify landmarks and line up tissues, using skin hooks or fine forceps to keep from causing wound edge trauma. Although wound closure is usually a straightforward process, situations occasionally arise in which special caution is necessary. For instance, when a wound crosses tissues with different characteristics (e.g., at the vermilion border of the lip, the eyebrow, or the hairline of the scalp), particular care must be taken to align the damaged structures accurately. In the repair of soft tissue, it is critical to handle tissue gently with atraumatic surgical technique, to place sutures precisely, and to minimize tension and contamination.

The next step is tissue-specific repair, which may require the consultation of an experienced surgeon. Bone fractures are reduced and repaired with plates, rods, or external fixation devices. Muscle lacerations should be repaired because muscle is capable of a significant degree of regeneration. A completely lacerated muscle that is properly repaired recovers approximately 50% of its ability to produce tension and 80% of its ability to shorten, whereas a partially lacerated muscle that is properly repaired recovers approximately 60% of its ability to produce tension and 100% of its ability to shorten.²⁹ Tendon lacerations should be meticulously approximated to allow gliding and restore tensile strength. Either 4-0 multifilament polyester or monofilament polypropylene is a reasonable choice for muscle and tendon repair.³⁰ Early active mobilization promotes the restoration of tensile strength in muscles and tendons. Penetrating nerve trauma is treated with tension-free coaptation at the time of wound closure by primary repair or repair with a nerve graft or nerve tube. Epineurial coaptation is typically achieved by placing 8-0 to 10-0 monofilament

nylon sutures under loupe or microscope magnification. For ischemic or amputated tissues (e.g., an ear, a digit, or a limb), vessel repair is performed with 8-0 to 10-0 monofilament nylon sutures under magnification.

In subcutaneous fat, suture placement should be avoided whenever possible; if sutures in this location are absolutely necessary, they should be placed at the fat-fascia junction or the fat-dermis junction, not in fat alone. Fat cannot hold sutures by itself, and because it has a poor blood supply, suturing may lead to fat necrosis. The deeper fascial layers that contribute to the structural integrity of areas such as the abdomen, the chest, and the galea should be closed as a separate layer to prevent hernias, structural deformities, and hematomas.

At the skin level, the deep dermis is responsible for the strength of the acute wound closure. Deep dermal repair is performed with 4-0 absorbable suture material (e.g., polyglactin 910) and a cutting needle. The sutures are buried and placed 5 to 8 mm apart, with care taken to evert the skin edges. Buried dermal sutures are often used in conjunction with tapes (e.g., Steri-Strips), fine epidermal sutures, or adhesives to facilitate precise alignment. Skin edges should be coapted and everted with 4-0 to 6-0 nylon or polypropylene sutures placed in the superficial dermis and the epidermis. The distance between the sutures and the distance between the wound edge and the suture insertion point should be equal to the thickness of the skin (epidermis and dermis combined).

Several different skin suturing methods may be used, depending on the nature of the wound. Simple interrupted sutures are useful for irregular wounds. Vertical mattress sutures are good for either thick (e.g., scalp) or thin (e.g., eyelid) skin. Horizontal mattress sutures can lead to ischemia and thus must be applied loosely; they may look untidy early after repair, but they generally achieve good wound-edge eversion and long-term healing. Half-buried horizontal and vertical mattress sutures are used for flap edges to minimize ischemia. A continuous intradermal or subcuticular suture is easy to remove and relatively inconspicuous visually. A simple continuous suture should be used only for linear wounds; it is quick to place but tends to invert the wound edges. Flap tips should be sutured with a three-point method to prevent strangulation [see Figure 1]. For children, suture removal can be both emotionally and physically traumatic; accordingly, when suturing is employed for skin closure in a pediatric patient, the use of fast-absorbing suture material (e.g., plain catgut) or a pullout continuous subcuticular suturing method should be considered.

Primary direct approximation of wounds is not always indicated. In cases where obvious bacterial contamination is present, there is a substantial amount of questionably necrotic tissue, or the patient is unstable and unfit to undergo primary repair at the time of presentation, delayed primary closure is performed. Delayed primary closure involves direct approximation of wound edges after a period (usually 4 to 5 days) of wound hygiene. This closure method markedly diminishes the incidence of wound infection in patients with contaminated wounds.

Secondary closure, in which the wound is left open and allowed to heal on its own, is also sometimes chosen. Secondary closure depends on contraction of the surrounding tissue and epithelialization from the wound margins. When this approach is followed, caution and close observation are essential because the process of tissue contraction can sometimes lead to contracture, a pathologic scar deformity. Secondary closure can, however, yield acceptable results with specific wound types and at specific anatomic sites. With puncture wounds, for example, secondary closure is preferred because it diminishes the likelihood of infection. For both abrasions and puncture wounds, the functional and aesthetic

Figure 1 Shown is the method for inserting three-point sutures, along with three different applications of this method.

results of secondary closure are generally as good as or better than those obtained by primary or delayed primary closure. For wounds on anatomically concave surfaces (e.g., the medial canthal region, the nasolabial region, or the perineum), secondary wound healing generally yields excellent results.³¹ Secondary closure should also be considered for severely contaminated wounds, infected wounds, wounds with significant amounts of devitalized tissue, wounds with foreign bodies, lacerations older than 24 hours, wounds in patients who are in shock, and high-velocity wounds.³²

Occasionally, an acute wound is so large that neither primary nor secondary closure will suffice. Such wounds must be covered with skin grafts or transferred tissue (i.e., flaps) [see 3:3 *Open Wound Requiring Reconstruction* and 3:7 *Surface Reconstruction Procedures*]. Local or distant flaps must be considered for wounds that involve exposed bone denuded of periosteum, cartilage denuded of perichondrium, tendon denuded of paratenon, or nerve denuded of perineurium.

CLOSURE OF SPECIFIC TYPES OF WOUNDS

Wounds may be divided into 10 main types: abrasions, puncture wounds, lacerations, complex wounds, crush injuries, extravasation injuries, injection injuries, high-velocity wounds, bite wounds, and stings. In addition, the American College of Surgeons (ACS) has divided wounds into four major categories: clean, clean-contaminated, contaminated, and dirty [see *Table 3*]. The likelihood of infection after any surgical procedure is correlated with the ACS wound category: class I and II wounds have infection rates lower than 11%, whereas wounds in class IV have infection rates as high as 40%.³³

Abrasions

Abrasions are superficial wounds caused by scraping. They involve only the epidermis and a portion of the dermis and frequently heal secondarily within 1 to 2 weeks. If an abrasion is to be closed primarily, tape or glue may be used for epidermal approximation to prevent suture mark scars (which could be worse than the actual wound scar). In some patients who have experienced abrasion injuries (e.g., motorcycle accidents in which victims slide along asphalt) or blast injuries (e.g., firework explosions), small foreign body fragments become embedded in and beneath the skin, often

proving quite difficult to remove. Complete debridement of these embedded foreign bodies within 24 to 48 hours of injury is crucial in preventing so-called traumatic tattooing. In the early postinjury period, surgical debridement with a small drill, a sharp instrument, or a scrub brush may suffice for removal of the foreign material causing the traumatic tattoo; later, dermabrasion will be necessary.^{34,35} Once the wound is adequately debrided, semioclusive dressings should be applied to optimize epithelialization.

Puncture Wounds

Puncture wounds should be examined for foreign bodies, which must be removed when found. They are typically left open, treated with wound care, and allowed to heal by secondary intention. With puncture wounds, secondary closure reduces the risk of infection and generally yields excellent aesthetic results.

Lacerations

The type of wound most commonly encountered by surgeons is a superficial or deep acute traumatic or surgical wound that is suitable for primary closure by direct approximation of the wound edges. In this setting, the goal is to provide the best possible chance for uncomplicated healing. If the wound is to be closed, primary closure at the time of evaluation is preferred if it is feasible. As a rule, closure should be completed within 6 to 8 hours of the injury, though simple noncontaminated wounds of the face can be safely closed as long as 24 hours after the injury. Primary closure is generally desirable in that it eliminates the need for extensive wound care, allows the wound to heal more quickly, and minimizes patient discomfort. However, lacerations containing foreign bodies or necrotic tissue that cannot be removed by irrigation or debridement and lacerations with excessive bacterial contamination should not be closed primarily, nor should wounds in which hemostasis is incomplete. Hematomas,³⁶ necrotic tissue,³⁷ and foreign bodies³⁸ all promote bacterial growth and place a mechanical barrier between healing tissues.

Complex Wounds

The term complex wounds includes stellate wounds and those caused by degloving, avulsion, and mutilation. The goals of treatment include achieving closure within 6 to 8 hours of the injury, providing treatment in a manner consistent with the patient's general health, keeping bacterial counts at a low level, protecting tissues from desiccation, applying only nonnoxious agents, and supplying adequate permanent coverage. In addition, it is important to discuss with the patient the particular treatment difficulties posed by these wounds. Often, a patient with a complex wound must be treated in the OR under general anesthesia because the injury is extensive or because there is a need for exploration of tissues, removal of foreign bodies, and debridement of nonviable tissue.

Stellate wounds can be approximated with careful placement of interrupted and three-point sutures. Severely injured tissue may have to be removed as an ellipse, with the resulting defect closed.

Degloving refers to circumferential elevation of skin and fat from muscle; the skin flap created by this process rarely survives. In the acute setting, questionably viable flaps of tissue may be evaluated by administering fluorescein, up to 15 mg/kg I.V., and observing the flap for fluorescence under an ultraviolet lamp after 10 to 15 minutes have elapsed.³⁹ Viable flap tissue fluoresces green. Tissue that is determined to be devascularized, on the basis of either physical examination or fluorescein testing, should be debrided. If the viability of a tissue segment is in doubt, the segment may be sewn back into its anatomic location and allowed to define itself as viable or nonviable over time.

Large open wounds resulting from avulsion can be either left to heal by secondary intention or treated with delayed skin grafting.³²

Mutilating wounds caused by machinery (e.g., farm equipment) are often contaminated by a mixture of gram-positive and gram-negative organisms, though not always excessively so.⁴⁰ When such a wound is grossly contaminated, antibiotic therapy (preferably with an agent or combination of agents that offers broad-spectrum coverage) is indicated. Contaminated wounds closed with either tape or staples have a lower incidence of infection than those closed with sutures.^{24,26}

Crush Injuries

A notable feature of crush injury is that the severity of the wound is not always readily apparent. In many cases, no external laceration can be seen, even though deep tissue damage may be extensive.

Ultrasonography or magnetic resonance imaging may help identify a hematoma that is amenable to evacuation.³² Deep tissue injury can lead to compartment syndrome and subsequent extremity loss. Early diagnosis is the key to successful treatment. Generally, the diagnosis can be made on the basis of physical signs and symptoms, including increasing pain that is out of proportion to the stimulus, altered sensation, pain on passive stretching of the affected muscle compartment, muscle weakness, and palpable tenseness of the compartment.⁴¹

If compartment syndrome is suspected, the intracompartmental pressure should be measured.⁴² If the intracompartmental pressure exceeds 30 mm Hg or if the so-called delta pressure (i.e., the diastolic blood pressure minus the intracompartmental pres-

Table 3 Classification and Infection Rates of Operative Wounds

Classification	Infection Rate (%)	Wound Characteristics
Clean (class I)	1.5–5.1	Atraumatic, uninfected; no entry of GU, GI, or respiratory tract
Clean-contaminated (class II)	7.7–10.8	Minor breaks in sterile technique; entry of GU, GI, or respiratory tract without significant spillage
Contaminated (class III)	15.2–16.3	Traumatic wounds; gross spillage from GI tract; entry into infected tissue, bone, urine, or bile
Dirty (class IV)	28.0–40.0	Drainage of abscess; debridement of soft tissue infection

sure) is less than or equal to 30 mm Hg, compartment syndrome is considered to be present. If clinical symptoms develop or the delta pressure is below 30 mm Hg, appropriate therapeutic measures should be taken, including restoration of normal blood pressure in the hypotensive patient, removal of all constrictive dressings, and maintenance of the limb at heart level.¹ If the delta pressure remains below 30 mm Hg, clinical symptoms and signs persist despite conservative measures, or both, fasciotomies should be performed within 6 hours.⁴¹ Hyperbaric oxygen therapy may also be beneficial in cases of crush injury with compartment syndrome in an extremity.⁴³ Compartment syndrome with muscle damage can also lead to rhabdomyolysis and renal failure. If an elevated serum creatine kinase concentration is reported, intravascular volume is stabilized, and urine flow is confirmed, a forced mannitol-alkaline diuresis should be initiated as prophylaxis against hyperkalemia and acute renal failure.⁴⁴

Extravasation Injuries

In some patients with arterial or venous catheters in place, a vessel may become occluded or a catheter dislodged from the intravascular space, leading to extravasation injury, whereby solutions or medicines are delivered into the interstitial space. The majority of acute extravasation injuries are quickly diagnosed and heal without complications, and in most cases, conservative management (i.e., elevation of the limb, application of ice packs, and careful monitoring) is adequate.⁴⁵ However, extravasation injuries involving high fluid volumes, high-osmolar contrast agents, or chemotherapeutic drugs can have more serious effects, resulting in skin ulceration and extensive soft tissue necrosis. Treatment of these injuries is not standardized; it may include conservative management, hydrocortisone cream, incision and drainage, hyaluronidase injection, saline injection, and aspiration by means of liposuction.^{45–47}

Injection Injuries

Wounds caused by injection of foreign materials (e.g., paint, oil, grease, or dirty water) can be severe. Injection injuries usually result from the use of high-pressure spray guns (600 to 12,000 psi) and

often occur on the nondominant hand.^{48,49} On initial examination, the injury may appear deceptively benign, with only a punctate entry wound visible; however, foreign material is often widely distributed in the deeper soft tissues. Radiographs are obtained to identify any fractures present and, in some cases, to determine the extent to which the injected material is distributed. Injection wounds must be treated aggressively with incision, wide exposure, debridement, and removal of foreign bodies to prevent extensive tissue loss and functional impairment. The functional outcome is determined by the time elapsed between injury and treatment and by the type of material injected. Oil-based paint is more damaging to tissues than water-based paint, oil, grease, water, or air.^{50,51}

High-Velocity Wounds

High-velocity wounds from explosions or gunshots cause extensive tissue damage as a consequence of the release of kinetic energy. Small entry wounds are common, but the seemingly benign appearance of such a wound often belies the actual severity of injury: the exit wound and interspace may contain large areas of ischemic and damaged tissue that affect critical structures (e.g., bone and blood vessels). Clothing and dirt may also be transmitted into the deep spaces. Radiographs may identify radiopaque foreign bodies (e.g., metal objects or pieces of leaded glass).⁵² Treatment of wounds created by high-velocity missiles involves extensive debridement and identification of injured tissue. Wounds should be left open to heal by secondary or delayed primary closure.³²

Bite Wounds

Treatment of bite wounds involves thorough exploration, irrigation, and debridement. X-rays must be obtained and wounds explored to evaluate the patient for fractures or open joint injuries. If a joint capsule has been violated, the joint must be thoroughly cleaned. Because of the infection risk, wounds may be allowed to heal by secondary or delayed primary closure; primary closure is also possible if thorough debridement is performed.³² Rabies prophylaxis treatment should be considered for patients who have been bitten by wild animals [see Adjunctive Wound Treatment, Rabies Prophylaxis, below].

Humans and nonvenomous animals Most human bite wounds are clenched fist wounds sustained by young men.⁵³ Human bite wounds are considered infected from the moment of infliction and must be treated with antibiotics.^{54,55} The antibiotic regimen should be selected on the basis of the bacterial species believed to be present. Common isolates from bite wounds includes *Streptococcus anginosus*, *Staphylococcus aureus*, *Eikenella corrodens*, *Fusobacterium nucleatum*, *Prevotella melaninogenica*, and *Candida* species.⁵³ To cover these species, a broad-spectrum antibiotic or combination of antibiotics (e.g., amoxicillin-clavulanate or moxifloxacin) should be administered.⁵³

Nonhuman primates can cause viral infection, most commonly with cercopithecine herpesvirus type 1. If left untreated, such infection can lead to meningoencephalitis, which carries a 70% mortality. Accordingly, acyclovir prophylaxis is recommended.⁵⁶

Wounds caused by cat bites or scratches are at high (80%) risk for infection, usually attributable to *Pasteurella multocida*. The aer-

obic and anaerobic organisms commonly found in cat-bite wounds are similar to those found in dog-bite wounds, and antibiotic prophylaxis with amoxicillin-clavulanate is appropriate.⁵⁷ Acute regional lymphadenitis after a cat scratch is known as cat-scratch disease and is caused by *Bartonella henselae*⁵⁸; it is treated by administering azithromycin.⁵⁹

Dog-bite wounds are at lower (16%) risk for infection than human-bite or cat-bite wounds and tend to be less severely contaminated with bacteria. The aerobic species commonly isolated from such wounds include *Pasteurella (P. canis)*, *Streptococcus*, *Staphylococcus*, *Moraxella*, and *Neisseria*; common anaerobic isolates include *Fusobacterium*, *Bacteroides*, *Porphyromonas*, and *Prevotella*.⁵⁷ Prophylactic treatment with a combination of a β -lactam antibiotic with a β -lactamase inhibitor (e.g., amoxicillin-clavulanate) is appropriate.^{57,60}

Venomous animals *Snake bites.* Four types of poisonous snakes are native to the United States: the coral snakes (*Micrurus* and *Micruroides* species), from the family Elapidae, and three species of pit vipers, from the family Viperidae (rattlesnakes [*Crotalus* species], copperheads [*Agkistrodon tortorrix*], and cottonmouths or water moccasins [*Agkistrodon piscivorus*]).⁶¹⁻⁶³ Pit vipers can be identified by the pit between the eye and the nostril on each side of the head, the vertical elliptical pupils, the triangle-shaped head, the single row of subcaudal plates distal to the anal plate, and the two hollow fangs protruding from the maxillae that produce the characteristic fang marks.⁶⁴ Coral snakes have rounder heads and eyes and lack fangs; they are identified by their characteristic color pattern, consisting of red, yellow, and black vertical bands.

Patients bitten by any of the pit vipers must be examined for massive swelling and pain, which, in conjunction with fang marks, suggest envenomation. Local pain and swelling typically develops within 30 minutes of the bite, though in some cases, these manifestations may take up to 4 hours to appear. Erythema, petechiae, bullae, and vesicles are sometimes seen. Severe envenomation may induce systemic reactions, including disseminated intravascular coagulation (DIC), bleeding, hypotension, shock, acute respiratory distress syndrome (ARDS), and renal failure. Patients bitten by coral snakes, on the other hand, show no obvious local signs when envenomation has occurred. Consequently, the physician must look for systemic signs, such as paresthesias, increased salivation, fasciculations of the tongue, dysphagia, difficulty in speaking, visual disturbances, respiratory distress, convulsions, and shock. These symptoms may not develop until several hours after the bite.

If signs or symptoms suggestive of envenomation are found, appropriate laboratory tests (hematocrit, fibrinogen level, coagulation studies, platelet count, urinalysis, and serum chemistries) should be ordered. Laboratory tests should be repeated every 8 to 24 hours for the first 1 to 3 days to determine whether envenomation is progressing. Severe envenomation can cause decreased fibrinogen levels, coagulopathy, bleeding, and myoglobinuria.

Treatment of venomous snake bites includes immobilization and elevation. If envenomation is suspected or confirmed, antivenin should be administered intravenously and as early as possible. Antivenins commonly used in the United States include Antivenin (Crotalidae) Polyvalent (ACP) (Wyeth Pharmaceuticals, Collegeville, Pennsylvania) and Crotalidae Polyvalent Immune Fab (Ovine) (CroFab; Protherics Inc., Nashville, Tennessee).⁶⁵ Fab antivenom (FabAV) is less allergenic and more potent than ACP and thus has largely supplanted it in the United States.^{65,66} Patients are treated with a loading dose of four to six vials of FabAV, followed by three two-vial maintenance doses at 6, 12, and 18 hours to prevent recurrence of symptoms. If symptoms

progress despite antivenin treatment, an additional four to six vials of FabAV are given twice more; if symptoms continue to progress, consideration should be given to using ACP. ACP remains the most effective antivenin for patients with coral snake bites and those who do not respond to FabAV. Before ACP is administered, the patient must be tested for sensitivity. The major complication of antivenin therapy is serum sickness. This complication occurs in approximately 50% to 75% of patients treated with ACP but in only 16% of those treated with FabAV.^{65,67}

Compartment syndrome is a rare but severe complication of a snake bite. Fasciotomy is sometimes required to relieve extremity compartment syndrome, but it is not necessary for prophylactic purposes. Tourniquets, incision and suction, cryotherapy, and electric shock treatment are of little value for snake bites and may increase complication rates. There is no clear evidence to support antibiotic prophylaxis in this setting.⁶⁴

Spider bites. The bites of most spiders found in the United States cause little to no wound or local reaction; however, there are three types that are capable of injecting venom with skin-penetrating bites. Brown recluse spiders (*Loxosceles reclusa*) can be identified by a violin-shaped dorsal mark. They are nocturnal, live in dark and dry places, and are found in the central and southern United States. The venom is a phospholipase enzyme that acts as a dermal toxin and almost always causes a local reaction.⁶⁸ Local signs and symptoms may be limited to minor irritation, though they may also progress to extreme tenderness, erythema, and edema. The onset of local signs and symptoms may be delayed for as long as 8 hours after a bite, and tissue necrosis may then develop over the following days to weeks. Systemic reactions may include mild hemolysis, mild coagulopathy, and DIC, though severe intravascular hemolytic syndrome and death have also been reported.^{68,69} Oral administration of dapsone (50 to 100 mg/day) to minimize tissue necrosis has been advocated by some⁷⁰; however, this treatment is of uncertain efficacy, and no prospective data currently support its use. Moreover, dapsone can cause a serious unwanted side effect, hemolytic anemia.⁶⁹ If systemic symptoms develop, systemic corticosteroid therapy and supportive measures are indicated. Brown recluse antivenin is not available in the United States.

Black widow spiders (*Latrodectus mactans*) can be identified by a red-hourglass ventral mark.⁶³ They live in dark, dry, and protected areas and are distributed widely throughout the continental United States. The venom is a neurotoxin that produces immediate and severe local pain. Local signs and symptoms include two fang marks, erythema, swelling, and piloerection.⁶⁸ Systemic reactions with neurologic signs may develop within 10 minutes and may include muscle pain and cramps starting in the vicinity of the bite, abdominal pain, vomiting, tremors, increased salivation, paresthesias, hyperreflexia, and, with severe envenomation, shock. Systemic symptoms may last for days to weeks. High-risk persons (e.g., those who are younger than 16 years, the elderly, pregnant women, hypertensive patients, or persons who continue to show symptoms despite treatment) may experience paralysis, hemolysis, renal failure, or coma. Treatment includes 10% calcium gluconate I.V. for relief of muscle spasm, methocarbamol or diazepam for muscle relaxation, and a single dose of antivenin. Antivenin causes serum sickness in as many as 9% of patients; consequently, its use is controversial except in cases where the patient is at high risk.⁷¹

Hobo spiders (*Tegenaria agrestis*) can be identified by their long hairy legs and a cephalothorax that is marked by two stripes and butterfly markings dorsally and two stripes ventrally. Found

throughout the northwestern United States, they live in low places and build funnel-shaped webs in dark spaces. Hobo spiders have been reported to inflict painful bites that lead to wound ulceration, dermonecrosis, and a persistent headache, though the accuracy of such reports has been debated.^{69,72,73} A slow-healing ulcer that leaves a central crater has been described. Treatment consists of local wound care.

Stings

Scorpions Stings from most of scorpion species found in the United States cause only limited local reactions that can be managed conservatively; however, stings from *Centruroides sculpturatus*, which is found in California and many

southern states, may be more severe. *Centruroides* has a sting that causes envenomation with a neurotoxin. Erythema, edema, and ecchymosis at the site of the sting are evidence that envenomation did not take place. Instead, envenomation is indicated by an immediate and intense burning pain at the wound site.⁷⁴ The initial local pain may then be followed by systemic symptoms such as muscle spasm, excess salivation, fever, tachycardia, slurred speech, blurry vision, convulsions, or death.⁶⁸ Treatment consists of icing and elevation of the wounded area, followed by administration of barbiturates for control of neuromuscular activity and institution of supportive therapy with antihistamines, corticosteroids, and analgesics.⁷⁴

Centipedes Centipedes are slender, multisegmented, and multilegged arthropods that range in size from 1 to 30 cm and in color from bright yellow to brownish black. The first pair of legs are modified into sharp stinging structures that are connected to venom glands. Centipedes prefer dark, damp environments and may be found throughout the southern United States. Local symptoms associated with centipede stings include pain, erythema, edema, lymphangitis, lymphadenitis, weakness, and paresthesia. Skin necrosis may occur at the envenomation site. Systemic symptoms may include anxiety, fever, dizziness, palpitations, and nausea.⁷⁵ Treatment consists of symptomatic pain control, infiltration of local anesthetics, administration of antihistamines, and local wound care.⁷⁵

Hymenoptera The order Hymenoptera includes wasps, bees, and ants. Wasps, which are found across the United States, live in small colonies and may attack in groups when provoked. Honeybees (*Apis mellifera*) and bumblebees (*Bombus* species), also found across the United States, are generally docile and rarely sting unless provoked. Africanized honeybees (*Apis mellifera scutellata*, also referred to as killer bees), found primarily in the southwestern states, are far more aggressive than other bees. Fire ants (*Solenopsis invicta* and *Solenopsis richteri*) are wingless, ground-dwelling arthropods that are found in many southern states and that attack in an aggressive swarm.

Although Hymenoptera stingers are small, they can evoke severe local and systemic reactions. The local response to a Hymenoptera sting is a painful, erythematous, and edematous papule that develops within seconds and typically subsides in 4 to 6 hours. Some stingers are barbed and must be removed with a scraping, rather than pinching, motion to prevent the injection of more venom. Systemic reactions occur in about 5% of the population and may lead to anaphylaxis with syncope, bronchospasm, hypo-

tension, and arrhythmias. Wounds and local reactions are treated with ice, elevation, and analgesics. Systemic reactions are treated with subcutaneous epinephrine, diphenhydramine, and supportive airway and blood pressure care.⁶⁸ Persons with a history of systemic reactions to insect stings should carry epinephrine kits.

DRESSINGS FOR SPECIFIC TYPES OF WOUNDS

Generally, the functions of a wound dressing include protection, antiseptics, pressure, immobilization, debridement, provision of a physiologic environment, absorption, packing, support, information, comfort, and aesthetic appearance. More specifically, the functions of a dressing should be tailored to the wound type, and the purpose of the dressing must be carefully considered before application.

With sutured wounds, dressings are required only until drainage from the wound ceases. With nondraining wounds, dressings may be removed after 48 hours, by which time epithelial cells will have sealed the superficial layers of the wound. An alternative method of treating minimally draining incisional wounds is to apply an antibacterial ointment [see Adjunctive Wound Treatment, Topical Antimicrobials, *below*]. Such ointments are occlusive and maintain a sterile, moist environment for the 48 hours required for epithelialization. In anatomic areas that are difficult to dress (e.g., the scalp), it may be reasonable to forgo a dressing and simply apply ointments or allow a scab to form on the wound surface. Operative incisional wounds are also sometimes covered with an occlusive dressing to optimize epithelialization [see Abrasions, *above*]. Some of these dressings are transparent, allowing observation of the wound. The disadvantage of occlusive dressings is their limited absorptive capacity, which allows drainage from the wound to collect underneath.

Complex Wounds

Abrasions
Abrasions heal by epithelialization, which is accelerated by the warm, moist environment created by an occlusive dressing.^{76,77} Such an environment not only promotes epithelialization but also enhances healing, both because of the moisture itself and because of the low oxygen tension that promotes the inflammatory phase.⁷⁸ A variety of dressings are suitable for treatment of abrasions, including biologic dressings, hydrogels, hydrocolloids, and semipermeable films. These dressings need not be changed as long as they remain adherent. Small, superficial wounds also heal readily when dressed with impregnated gauze dressings (e.g., Xeroform and Scarlet Red [Kendall, Mansfield, Massachusetts]), which allow exudates to pass through while maintaining a moist wound bed.⁷⁸ These less adherent dressings must be changed more regularly.⁷⁹

Dry dressings (e.g., gauze) should be avoided with abrasions because they facilitate scab formation. Scabs slow epithelialization, in that advancing cells must enzymatically debride the scab-wound interface in order to migrate.⁸⁰ Wounds covered with a scab also tend to cause more discomfort than wounds covered with occlusive dressings.

For complex wounds containing questionably necrotic tissue, foreign bodies, or other debris that cannot be removed sharply, wet-to-dry dressings are effective, simple, and inexpensive. A single layer of coarse wet gauze is applied to a wound, allowed to dry over a period of 6 hours, and removed. Necrotic tissue, granulation tissue, debris, and wound exudate become incorporated within the gauze and are removed with the dressing. The disadvantages of wet-to-dry dressings are pain and damage to or removal of some viable tissue. If the wound bed contains tendons, arteries, nerves, or bone, wet-to-wet dressings should be used to prevent desiccation of these critical structures.

Wet-to-wet dressings, which are not allowed to dry, cause less tissue damage than wet-to-dry dressings but do not produce as much debridement. Most wet-to-wet dressings are kept moist with saline. Wounds with significant bacterial contamination may be treated with dressings that contain antibacterial agents (e.g., mafenide, silver sulfadiazine, silver nitrate, or iodine).

Biologic and semipermeable films also maintain a moist wound bed, but they are difficult to use on deep or irregular wounds and wounds with a great deal of drainage. Consequently, wet-to-wet dressings with agents such as silver sulfadiazine are often used for these types of wounds. Enzymatic agents can debride wounds effectively and are a reasonable alternative to wet-to-dry or wet-to-wet dressings for wounds that contain necrotic tissue.⁸²

Lacerations

For sutured deep wounds, the specific purposes of a dressing are to prevent bacterial contamination, to protect the wound, to manage drainage, and to facilitate epithelialization. Dressings used on such wounds usually consist of three basic layers. The inner (contact) layer is chosen to minimize adherence of the dressing to the wound and to facilitate drainage through itself to the overlying layers. Common choices for this layer include fine-mesh gauze, petrolatum gauze, Xeroform or Xeroflo (Kendall, Mansfield, Massachusetts) gauze, and Adaptic (Johnson & Johnson, New Brunswick, New Jersey). These substances should be applied only as a single layer; in multiple layers, they become occlusive. The middle layer is chosen for absorbency and ability to conform to shape of the wound area. It is usually composed of fluffs, Kerlix (Kendall, Mansfield, Massachusetts), or wide-mesh gauze, all of which facilitate capillary action and drainage.⁸¹ The middle layer must not be allowed to become soaked, because if it is, exudate will collect on the wound surface, and maceration and bacterial contamination may occur. The outer (binding) layer serves to secure the dressing. Common choices for this layer include Kling (Johnson & Johnson, New Brunswick, New Jersey), ACE bandages (BD Medical, Franklin Lakes, New Jersey), and Coban (3M, St. Paul, Minnesota).

Table 4 Recommendations for Tetanus Immunization^{89,90}

Tetanus Immunization History	Tt*	TIG
Unknown	Yes	Yes
> 10 yr since last booster	Yes	Yes
≥ 5 and ≤ 10 yr since last booster	Yes	No
< 5 yr since last booster	No	No

Note: Tetanus toxoid (Tt) and tetanus immune globulin (TIG) should be administered with separate syringes at different anatomic sites. Tetanus and diphtheria toxoids are contraindicated for the wounded patient if there is a history of a neurologic or severe hypersensitivity reaction after a previous dose. Local side effects alone do not preclude continued use. If a systemic reaction is suspected of representing allergic hypersensitivity, immunization should be postponed until appropriate skin testing is performed. If a contraindication to a Tt-containing preparation exists, TIG alone should be used.

*For patients younger than 7 years, diphtheria-tetanus-pertussis vaccine (DTP) (or tetanus and diphtheria toxoids, if pertussis vaccine is contraindicated) is preferable to Tt alone. For patients 7 years of age or older, Tt alone may be given.

Some wounds are difficult to dress and require special consideration. For wounds with flaps or questionably viable tissue, compression dressings should not be used, because they may cause ischemia. Wounds that cross joints are best dressed with plaster splints for temporary immobilization; semipermeable films are flexible and may also be used in this setting. Wounds with high levels of exudates may be dressed with hydrocolloids, hydrogels, or alginates.⁷⁸ For large or irregular wounds, negative-pressure wound therapy (NPWT) with the VAC system (Kinetic Concepts Inc., San Antonio, Texas) is recommended; VAC dressings conform well and remain adherent. Additionally, NPWT uses subatmospheric pressure to remove excess wound fluid, stimulates the formation of granulation tissue, improves peripheral blood flow and tissue oxygenation, and reduces the size of the wound.^{83,84} Use of the VAC system is contraindicated in wounds with exposed blood vessels or bowel.

Adjunctive Wound Treatment

PROPHYLACTIC SYSTEMIC ANTIBIOTICS

For most wounds, antibiotic prophylaxis is not indicated. When it is called for, the agent or agents to be used should be selected on the basis of the bacterial species believed to be present. The anatomic location of a wound may also suggest whether oral flora, fecal flora, or some less aggressive bacterial contaminant is likely to be present. Gram staining can provide an early clue to the nature of the contamination. Ultimately, the choice of a prophylactic antibiotic regimen is based on the clinician's best judgment regarding which agent or combination of agents will cover the pathogens likely to be present in the wound on the basis of the information available.

As a rule, clean and clean-contaminated wounds are adequately treated with irrigation and debridement. There are, however, some local factors (e.g., impaired circulation and radiation injury) and systemic factors (e.g., diabetes, AIDS, uremia, and cancer) that increase the risk of wound infection; in the presence of any of these factors, prophylactic antibiotics should be considered. In addition, prophylactic antibiotics should be given to patients with extensive injuries to the central area of the face (to prevent spread of infection through the venous system to the meninges), patients with valvular disease (to prevent endocarditis), and patients with prostheses (to reduce the risk of bacterial seeding of the prosthesis). Lymphedematous extremities are especially prone to cellulitis, and antibiotics are indicated whenever such extremities are wounded.

Contaminated and dirty wounds are associated with a higher risk of infection and are therefore more likely to necessitate antibiotic prophylaxis. Human bite wounds, mammalian bite wounds, and wounds contaminated with dirt, bodily fluids, or feces are all prone to infection and must be treated with antibiotics.^{54,55} Prophylactic administration of a combination of a β -lactam antibiotic with a β -lactamase inhibitor (e.g., amoxicillin-clavulanate) is appropriate.^{57,60} Antibiotic prophylaxis is also indicated for mutilating wounds with extensive amounts of devitalized tissue. Such wounds are often contaminated by a mixture of gram-positive organisms and gram-negative organisms.⁴⁰ When antibiotics are indicated for these injuries, broad-spectrum coverage is appropriate.

TOPICAL ANTIMICROBIALS

Topical antimicrobials (e.g., antibiotic ointments, iodine preparations, and silver agents) are commonly used to prevent wound infection. Application of mupirocin ointment to a clean surgical

wound before an occlusive dressing does not reduce the infection rate and may promote antibiotic resistance.⁸⁵ For uncomplicated traumatic wounds, however, application of bacitracin and neomycin ointment results in a significantly lower infection rate than application of petrolatum.⁸⁶ Neomycin-containing ointments reduce bacterial counts in partial-thickness wounds in animals, but many other over-the-counter antibiotic ointments are not effective at reducing bacterial counts in wounds.⁸⁷

Wounds contaminated by bacteria can be treated with dressings that contain antibacterial agents such as mafenide, silver nitrate, silver sulfadiazine, or iodine. Mafenide penetrates eschar well, but it can cause pain and has the potential to induce metabolic acidosis through inhibition of carbonic anhydrase. Silver has microbicidal effects on common wound contaminants and may also be effective against methicillin-resistant *S. aureus* (MRSA).⁸⁴ Silver nitrate does not cause pain, but it can cause hypochloremia, and it stains fingernails and toenails black. Silver sulfadiazine is frequently used because of its broad antibacterial spectrum, its relatively low side effect profile (transient leukopenia is occasionally seen), and its ability to maintain a moist wound environment (thereby speeding healing and epithelialization).⁸⁸

TETANUS PROPHYLAXIS

Tetanus is a nervous system disorder that is caused by *Clostridium tetani* and is characterized by muscle spasm. In the past, wounds were classified as either tetanus-prone or non-tetanus-prone on the basis of their severity. It is now clear, however, that wound severity is not directly correlated with tetanus susceptibility; tetanus has been associated with a wide variety of injury types over a broad spectrum of wound severity.⁸⁹ Accordingly, all wounds, regardless of cause or severity, must be considered tetanus prone, and the patient's tetanus immunization status must always be considered. Tetanus wound prophylaxis should be provided as appropriate [see Table 4].^{89,90}

RABIES PROPHYLAXIS

Rabies is an acute progressive encephalitis that is caused by viruses from the family Rhabdoviridae. The rabies virus can be transmitted by any mammal, but viral reservoirs are found only in carnivores and bats. In North America, raccoons, skunks, bats, and foxes are the animals most commonly responsible for transmission.⁹¹ Bite wounds in which the animal's saliva penetrates the dermis are the most common cause of exposure.

Postexposure treatment consists of wound care, infiltration of rabies immune globulin into the wound, and administration of vaccine.^{91,92} Wound care involves washing with soap and water, as well as the use of iodine- or alcohol-based virucidal agents.⁹³ Guidelines for postexposure prophylaxis have been established [see Table 5]. The vaccination regimen is determined by the patient's previous vaccination status [see Table 6].

Postoperative Wound Care

Closed wounds should be kept clean and dry for 24 to 48 hours after repair. Epithelialization begins within hours after wound approximation and forms a barrier to contamination. Gentle cleansing with running water will help remove bacteria and crusting. The patients should not place tension on the wound or engage in strenuous activity until the wound has regained sufficient tensile strength. In the first 6 weeks after repair, the wound's tensile strength increases rapidly; after this period, tensile strength increases more slowly, eventually reaching a maximum of 75% to 80% of normal skin strength [see Figure 2].

Table 5 Recommendations for Postexposure Rabies Prophylaxis⁹¹⁻⁹³

Animal Type	Animal Disposition and Evaluation	Prophylaxis
Dogs, cats, ferrets	If animal is healthy and available, it is confined for 10 days of observation	Start vaccination if animal exhibits rabies symptoms*
	If animal is rabid or suspected of being rabid, no observation is indicated	Provide immediate vaccination
	If animal's rabies status is unknown, consultation is indicated	Consult public health official
Bats, skunks, raccoons, foxes, bobcats, coyotes, mongooses, and most carnivores	Animal is regarded as rabid unless brain laboratory tests are negative	Provide immediate vaccination unless brain laboratory tests are negative
Livestock, small rodents (e.g., squirrels, chipmunks, rats, hamsters, gerbils, guinea pigs, and mice), large rodents (e.g., woodchucks and beavers), rabbits, hares, and other mammals	Each case is considered individually; rabies reported in large rodents in some areas	Consult public health officials; almost never require antirabies treatment

*If the isolated animal shows symptoms of rabies, postexposure prophylaxis is started immediately, and the animal is euthanized for laboratory testing. Vaccination prophylaxis is stopped if laboratory tests are negative for rabies.

Wounds at risk for infection should be assessed by a medical provider within 48 hours of care. In addition, the patient should be taught to look for signs of infection (e.g., erythema, edema, pain, purulent drainage, and fever).

The timing of suture or staple removal is determined by balancing the requirements for optimal cosmesis against the need for wound support. On one hand, it is clear that for optimal cosmesis, sutures should be removed early, before inflammation and epithelialization of suture tracts. An epithelialized tract will develop around a suture or staple that remains in the skin for longer than 7 to 10 days; once the suture or staple is removed, the tract will be replaced by scar.⁹⁴ On the other hand, it takes a number of weeks for the wound to gain significant tensile strength, and early removal of wound support can lead to dehiscence of wounds that are under substantial tension. Early suture removal is warranted for some wounds. For example, sutures in aesthetically sensitive areas (e.g., the face) may be removed on day 4 or 5, and sutures in areas under minimal tension (e.g., in wounds parallel to skin tension lines) may be removed on day 7. Sutures in wounds subject to greater stress (e.g., wounds in the lower extremities or the

trunk) should remain in place longer, as should sutures in wounds sustained by patients who have a condition that hinders healing (e.g., malnutrition). In such cases, suture-mark scars are considered acceptable. The appropriate method of removing a suture is first to cut it, then to pull on the knot parallel to or toward, rather than away from, the wound.

After suture removal, numerous methods are employed to minimize unsightly scar formation. The cosmetic outcome of a scar is largely determined by the nature and severity of the wound, which are outside the surgeon's control. The greatest impact a surgeon can have on cosmetic outcome is derived from providing meticulous care when the acute wound is initially encountered. Postoperative wound care measures employed to optimize cosmetic outcome include massage, the use of silicone bandages or pressure garments, and the application of lotions. These interventions appear to help, but prospective trials are needed to confirm their efficacy and establish treatment guidelines. The healing wound is fragile, and topical application of ointments to achieve an improved scar appearance may actually achieve the opposite result. For example, vitamin E, which is commonly applied to healing wounds, can induce contact dermatitis and cause scars to look worse.⁹⁵

Table 6 Recommendations for Postexposure Rabies Vaccination⁹¹⁻⁹³

Vaccine	Dosage	
	No Previous Vaccination	Previous Vaccination
Human rabies immune globulin (HRIG)	Full dose of 20 IU/kg infiltrated around wound(s) at initial presentation; use separate syringe and anatomic site from vaccine	Not administered
Human diploid cell vaccine (HDCV), rabies vaccine adsorbed (RVA), or purified chick embryo cell vaccine (PCECV)	1.0 ml IM on days 0, 3, 7, 14, and 28*	1.0 ml IM on days 0 and 3*

*Vaccine administration site for adults is the deltoid; for children, the anterolateral thigh may be used. To prevent sciatic nerve injury and reduce adipose depot delivery, the gluteus is never used.

Factors That May Hinder Wound Healing

Despite a surgeon's best efforts, healing does not always occur in an undisturbed fashion: sometimes, a closed wound dehisces. If the dehiscence is sudden, the wound is clean, and only skin and superficial tissues are involved, then the wound should be reclosed, and the cause of the dehiscence should be corrected if possible. If the dehiscence is slow and the wound is contaminated or infected, then the wound should be allowed to heal secondarily, with dressing changes and scar revision to be performed at a later date.

There are a number of local and systemic factors [see Table 7] that can interfere with wound healing (see below). Accordingly, it is essential for clinicians to be aware of and knowledgeable about these factors and, whenever possible, to take appropriate measures to improve the chances for optimal healing. The use of nutrients and growth factors to stimulate wound healing may be considered; this measure is currently the subject of extensive research.

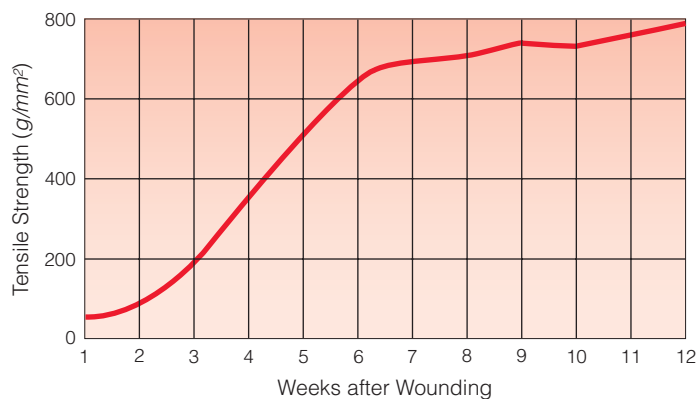

Figure 2 The tensile strength of skin wounds increases rapidly for approximately 6 weeks after wounding; it then continues to increase slowly for 6 to 12 months after wounding, though it never reaches the tensile strength of unwounded tissue. Collagen is remodeled and replaced with highly cross-linked collagen along tissue stress lines. The process of collagen replacement and scar remodeling continues for years.

LOCAL FACTORS

Tension

Tension—whether from inherent skin tension, poor surgical technique, movement of joints, or inadequate wound support—may lead to separation of wound edges. It should be minimized by undermining the wound edges during closure to allow easy coaptation. Tissue ellipses from complex wound edges should be kept as narrow as possible and should be created along relaxed skin tension lines. Adequate support of the wound after suture removal is critical; many surgeons keep tapes (e.g., Steri-Strips) over a wound for 3 weeks, until the strength of the wound equals that of the deep sutures and tapes. Wounds over joints should be splinted to reduce tension.

Foreign Body

All foreign bodies that contaminate a wound should be removed at the time of initial debridement and before wound closure. Retained foreign bodies may cause failed healing, infection, or traumatic tattooing. Iatrogenic foreign bodies may also interfere with wound healing and promote infection. Suture material is a foreign body; thus, the number and size of sutures placed in a wound should be kept to the minimum necessary for coaptation of the wound edges.

Infection

All traumatic wounds are contaminated and should therefore be irrigated to remove organisms. Infection occurs when bacteria are too numerous ($>10^5$ organisms/g tissue) or virulent for local tissue defenses to be able to control them.⁹⁶ As noted [see *Adjunctive Wound Care, Prophylactic Antibiotics, above*], local factors (e.g., impaired circulation and radiation injury) increase the risk of infection, as do various systemic diseases (e.g., diabetes, AIDS, uremia, and cancer). Wound cultures should be obtained, and broad-spectrum antibiotic therapy should be started when infection is diagnosed. The antibiotic regimen is adjusted on the basis of culture results and sensitivities.

Ischemia

Ischemic wound tissue readily becomes infected and therefore must be debrided. Tissue with dermal edges that do not bleed or

that show no perfusion on fluorescein testing is ischemic. Questionably viable tissue should be monitored closely and debrided when declared nonviable.

Hematoma and Seroma

Hematomas and seromas increase the risk of infection and the likelihood of wound dehiscence. To prevent their formation, hemostasis at the time of wound closure must be meticulous, and bleeding diatheses must be corrected. Because the rubbing of wound edges against one another is associated with the formation of hematomas and seromas, wound edge movement should be minimized and immobilization employed as necessary. Wounds at significant risk for hematoma or seroma formation should be closed over a drain.

Large hematomas or seromas that are recognized early, before infection develops, should be evacuated, and the wound should be reclosed. Small hematomas or seromas can usually be treated conservatively until they are reabsorbed, but close observation is required. If a hematoma or seroma is not recognized until late, when infection has already set in, the wound should be opened, drained, and allowed to heal secondarily; scar revision may be carried out at a later point.

Trauma

Tissue injury is obviously associated with external trauma, but it can also be iatrogenic. Rough handling of tissue edges with forceps produces minute crush injuries, which promote wound infection. It is preferable to handle wound edges with hooks, using gentle surgical technique.

Edema

Edema results from the accumulation of fluid in the interstitial space. It may occur as an acute process, in which tissue injury leads to histamine release, leaky capillaries, and inflammation, or as a chronic process, in which venous insufficiency, lymphatic insufficiency, and a low plasma oncotic pressure may cause fluid to collect in the interstitium. In both cases, edema raises tissue pressure and inhibits perfusion and healing. The proteinaceous and fibrin-rich fluid also forms clot and fibrous tissue, which hinder the supply of oxygen and inflammatory cells.⁹⁷ Clearance of wound edema is necessary for healing and may be successfully accomplished by means of compression therapy⁹⁸ or NPWT with a VAC device.⁸³

Table 7 Local and Systemic Factors That Impair Wound Healing

Local Factors	Systemic Factors
Tension	Inherited connective tissue disorders
Foreign body	Hypothermia
Infection	Oxygen
Ischemia	Tobacco smoking
Hematoma and seroma	Malnutrition
Edema	Jaundice
Irradiation	Age
	Diabetes mellitus
	Uremia
	Steroids
	Chemotherapeutic agents
	Other drugs

Irradiation

Irradiation damages the skin and can cause wounds to heal slowly. It also induces chronic skin changes: previously irradiated tissues demonstrate delayed healing when wounded.⁹⁹ Irradiated tissue is characterized by a thickened and fibrotic dermis, a thin epidermis, pigment changes, telangiectasia, decreased hair, and increased dryness (as a consequence of damage to sebaceous and sweat glands). The microvasculature of the skin is obliterated, leading to tissue ischemia and impaired healing. Keratinocytes, which are necessary for wound epithelialization, exhibit impaired mitotic ability and slow progressive desquamation (as a consequence of their superficial location and high replication rate).⁹⁷ Collagen bundles become edematous and fibrotic. Fibroblasts, which are necessary for collagen synthesis, also show diminished migration and proliferation.¹⁰⁰

Because irradiated skin is irreversibly damaged, tissue transfer may be required for repair of wounds in areas subjected to radiation. Vitamin A supplementation can lessen the adverse effects of irradiation on wound healing.¹⁰¹

SYSTEMIC FACTORS

Inherited Connective Tissue Disorders

Several inherited connective tissue disorders are known to interfere with normal wound healing. Ehlers-Danlos syndrome exists as multiple types that exhibit certain differences, but in general, the syndrome leads to deficient collagen cross-linking, which results in lax and fragile skin, lax joints, and impaired wound healing. For example, an Ehlers-Danlos patient who undergoes an elective hernia repair or facelift may have a poor outcome as a consequence of deficient collagen formation and poor wound healing.^{102,103} Osteogenesis imperfecta is a procollagen formation disorder that is clinically manifested by brittle bones, increased laxity of ligaments and skin, bone deformities, and impaired wound healing.¹⁰⁴ Marfan syndrome is an autosomal dominant disorder characterized by deficient synthesis of fibrillin, which is a key component in elastin formation. Patients with this syndrome have long extremities and hyperextendable joints; those who are seriously affected have lax ligaments, dissecting aneurysms, dislocated eye lenses, pectus excavatum, and scoliosis. Surgical repair of aneurysms and hernias is usually successful in this population, though healing difficulties may be encountered.¹⁰³ Cutis laxa is a disease in which an elastase inhibitor deficiency gives rise to defective elastic tissue. Patients with this disease have thick, coarse, and drooping skin, along with hernias, aneurysms, heart disease, and emphysema. Unlike patients with the other heritable diseases mentioned, cutis laxa patients often show no impairment of wound healing.¹⁰⁵

Hypothermia

Hypothermia may develop as a consequence of administration of anesthetic drugs, exposure to cold, or redistribution of body heat; it leads to peripheral vasoconstriction and impaired wound oxygen delivery.¹⁰⁶ Wound tensile strength increases more slowly when healing occurs in a cold environment. Prevention or correction of hypothermia reduces the wound infection rate and increases collagen deposition in patients undergoing abdominal surgery.¹⁰⁷ Preoperative systemic and local warming also reduces the wound infection rate in patients undergoing elective operations.¹⁰⁸ A warm body temperature must be maintained in all wounded patients to reduce subcutaneous vasoconstriction and maximize wound healing potential.

Oxygen

Tissue oxygenation is necessary for aerobic metabolism, fibroblast proliferation, collagen synthesis, and the antimicrobial oxidative burst of inflammatory cells. Transcutaneous oxygen tension is directly correlated with wound healing.¹⁰⁹ Wound tissue oxygenation is determined by blood perfusion, hemoglobin dissociation, local oxygen consumption, fraction of inspired oxygen ($F_{I}O_2$), oxygen-carrying capacity (as measured by hemoglobin content), arterial oxygen tension (P_aO_2), circulating blood volume, cardiac function, arterial inflow, and venous drainage.^{106,110} Each of these variables should be addressed in promoting wound healing.

Supplemental administration of oxygen (inspired or hyperbaric) has beneficial effects on wound healing. The incidence of infection in surgical wounds can be reduced by improving the $F_{I}O_2$ with supplemental oxygen.¹¹¹ In a study of patients undergoing colon surgery, for example, the wound infection rate was 50% lower when an $F_{I}O_2$ of 0.8 was maintained intraoperatively and for 2 hours postoperatively than when an $F_{I}O_2$ of 0.3 was maintained.¹¹² Hyperbaric oxygen therapy (i.e., the delivery of oxygen in an environment of increased ambient pressure) has been used for treatment of many types of wounds in which tissue hypoxia may impair healing.⁴³ It increases tissue oxygen concentrations tenfold while also causing vasoconstriction, which results in decreased posttraumatic edema and decreased compartment pressures.¹¹³ The elevated pressure and hyperoxia induced by hyperbaric oxygen therapy may promote wound healing; for patients with an acute wound, this modality may be a useful adjunct in treating limb-threatening injury, crush injury, and compartment syndrome.⁴³

Circulating volume can be improved by administering crystalloids or blood. However, anemia alone is not associated with impaired wound healing unless it is severe enough to limit circulating blood volume.¹¹⁴ The vasculature may be compromised either systemically (e.g., by diabetes mellitus or peripheral vascular disease) or locally (e.g., by trauma or scar). Vascular bypasses may be necessary to improve tissue oxygenation in patients with poor arterial inflow.⁹⁷

Tobacco Smoking

Tobacco smoking reduces tissue oxygen concentrations, impairs wound healing, and contributes to wound infection and dehiscence.^{115,116} The effects of smoking are attributable to vasoconstriction (caused by nicotine), displacement of oxygen binding (resulting from the high affinity of carbon monoxide for hemoglobin), increased platelet aggregation,¹¹⁷ impairment of the inflammatory cell oxidative burst,¹¹⁸ endothelial damage, and the development of atherosclerosis.^{115,116,119} All acutely injured patients should stop smoking, and ideally, all noninjured patients scheduled to undergo surgery should stop smoking at least 3 weeks before an elective surgical wound is made.^{118,120} Like smoked tobacco, transcutaneous nicotine patches alter the inflammatory cell oxidative burst and cause vasoconstriction; accordingly, they too should not be used when a wound is present.¹¹⁸

Malnutrition

On average, hospitalized patients show a 20% increase in energy expenditure, and this increase calls for appropriate nutritional compensation.⁹⁷ Good nutritional balance and adequate caloric intake (including sufficient amounts of protein, carbohydrates, fatty acids, vitamins, and other nutrients) are necessary for normal wound healing.¹²¹

All patients who have sustained wounds should undergo nutritional assessment,¹²² which typically includes measuring serum

levels of albumin, protein, prealbumin, transferrin, and insulinlike growth factor-1 (IGF-1).⁹⁷ The serum albumin level is one of the best predictors of operative mortality and morbidity.¹²³ A value lower than 2.5 g/dl is considered severely depressed, and a value lower than 3.4 g/dl is associated with higher perioperative mortality.^{124,125} Protein provides an essential supply of the amino acids used in collagen synthesis, and hypoproteinemia results in impaired healing; consequently, it is not surprising that protein replacement and supplementation can improve wound healing.^{126,127} In particular, supplementation specifically with the amino acids arginine, glutamine, and taurine (which are essential for anabolic processes and collagen synthesis) is known to enhance wound healing.¹²⁸⁻¹³⁰ Glutamine is the most abundant free amino acid in the body, and under catabolic conditions, it is released from muscle unless provided as a supplement.

Vitamins C, A, K, and D are essential for normal healing. Vitamin C (ascorbic acid) hydroxylates the amino acids lysine and proline during collagen synthesis and cross-linking. A deficiency of this vitamin causes scurvy, marked by failed healing of new wounds and dehiscence of old wounds. Vitamin C supplementation (100 to 1,000 g/day) can improve wound healing.^{97,130} Vitamin A (retinoic acid) is essential for normal epithelialization, proteoglycan synthesis, and normal immune function.¹³¹⁻¹³³ Retinoids and topical tretinoin may help foster acute wound healing by accelerating epithelialization of full- and partial-thickness wounds, activating fibroblasts, increasing type III collagen synthesis, and decreasing metalloprotease activation.^{134,135} Oral retinoid treatment significantly increases the decreased hydroxyproline content, tumor growth factor- β (TGF- β) level, and IGF-1 concentration associated with corticosteroids.¹³⁴ In addition, all aspects of corticosteroid-impaired healing—other than wound contraction—can be reversed by providing supplemental oral vitamin A at a recommended dosage of 25,000 IU/day.¹³⁶ The retinoic acid derivative isotretinoin (13-*cis*-retinoic acid), however, impairs wound epithelialization and delays wound healing.¹³⁷ Vitamin K is a cofactor in the synthesis of coagulation factors II, VII, IX, and X, as well as thrombin. Consequently, vitamin K is necessary for clot formation and hemostasis, the first step in acute wound healing. Vitamin D is required for normal calcium metabolism and therefore plays a necessary role in bone healing.

Dietary minerals (e.g., zinc and iron) are also essential for normal healing. Zinc is a necessary cofactor for DNA and RNA synthesis. A deficiency of this mineral can lead to inhibition cell proliferation, deficient granulation tissue formation,¹³⁸ and delayed wound healing.¹³⁹ Zinc replacement and supplementation can improve wound healing.¹³⁰ However, daily intake should not exceed 40 mg of elemental zinc, because excess zinc can immobilize macrophages, bind copper, and depress wound healing.¹⁴⁰ Iron is also a cofactor for DNA synthesis, as well as for hydroxylation of proline and lysine in collagen synthesis.⁹⁷ However, iron deficiency anemia does not appear to affect wound strength.¹⁴¹

Jaundice

The effect of jaundice on wound healing is controversial. Jaundiced patients appear to have a higher rate of postoperative wound healing complications,¹⁴² as well as a lower level of collagen synthesis.¹⁴³ However, obstructive jaundice does not affect healing of blister wounds in humans.¹⁴³ Jaundiced animals show a significant delay in collagen accumulation within the wound, but no significant reduction in the mechanical strength of the wound.¹⁴⁴ Biliary drainage may be considered in jaundiced patients with

wounds; this measure will improve collagen synthesis, though it may not have any appreciable effect on the healing rate.¹⁴³

Age

Aging has a deleterious effect on the capacity for wound healing.¹⁴⁵ Increasing age is associated with an altered inflammatory response, impaired macrophage phagocytosis, and delayed healing.¹⁴⁶ Nevertheless, even though the wound healing phases begin later in elderly persons, proceed more slowly, and often do not reach the same level that they would in younger persons, elderly patients are still able to heal most wounds with ease.¹⁴⁷

Diabetes Mellitus

Diabetes mellitus is associated with poor wound healing and an increased risk of infection. Diabetic neuropathy leads to sensory loss (typically in the extremities) and diminished ability to detect or prevent injury and wounding. Once present, wounds in diabetic patients heal slowly. The etiology of this healing impairment is multifactorial. Diabetes is associated with impaired granulocyte function and chemotaxis, depressed phagocytic function, altered humoral and cellular immunity, peripheral neuropathy, peripheral vascular disease, and various immunologic disturbances, any of which may hinder wound healing.¹⁴⁸⁻¹⁵¹ In addition, it is associated with a microangiopathy that can limit perfusion and delivery of oxygen, nutrients, and inflammatory cells to the healing wound.¹⁵² Diabetes-induced impairment of healing, as well as the attendant morbidity and mortality, may be reduced by tightly controlling blood sugar levels with insulin.¹⁵³ Diabetic patients must also closely monitor themselves for wounds and provide meticulous care for any wounds present.

Uremia

Uremia and chronic renal failure are associated with weakened host defenses, an increased risk of infection, and impaired wound healing.¹⁵⁴ Studies using uremic animal models show delayed healing of intestinal anastomoses and abdominal wounds.¹⁵⁵ Uremic serum also interferes with the proliferation of fibroblasts in culture.^{103,155} Treatment of this wound healing impairment includes dialysis.

Uremic patients with wounds may experience bleeding complications. In this situation, appropriate evaluation includes determining the prothrombin time (PT), the activated partial thromboplastin time (aPTT), the platelet count, and the hematocrit. Treatment includes dialysis without heparin; administration of desmopressin (0.3 μ g/kg), cryoprecipitate, conjugated estrogens (0.6 mg/kg/day I.V. for 5 days),¹⁵⁶ and erythropoietin; and transfusion of red blood cells to raise the hematocrit above 30%.^{157,158}

Uremic patients with hyperparathyroidism may also exhibit the uremic gangrene syndrome (calciophylaxis), which involves the spontaneous and progressive development of skin and soft tissue wounds, usually on the lower extremities. Patients with this syndrome typically are dialysis dependent and have secondary or tertiary hyperparathyroidism. Wound biopsies demonstrate fat necrosis, tissue calcification, and microarterial calcification.¹⁵⁹ Treatment includes local wound care, correction of serum phosphate levels with oral phosphate binders,¹⁶⁰ correction of calcium levels with dialysis, and subtotal parathyroidectomy.¹⁵⁹

Drugs

Steroids Corticosteroids are anti-inflammatory agents that inhibit all aspects of healing, including inflammation, macrophage migration, fibroblast proliferation, protein and collagen synthesis,

development of breaking strength, wound contraction, and epithelialization.^{103,136,161} In the setting of an acute wound that fails to heal, corticosteroid doses may be reduced, vitamin A administered topically or systemically, and anabolic steroids given to restore steroid-retarded inflammation.^{103,136}

Unlike corticosteroids, anabolic steroids accelerate normal collagen deposition and wound healing. Oxandrolone is an oral anabolic steroid and testosterone analogue that is employed clinically to treat muscle wasting, foster wound healing, and mitigate the catabolism associated with severe burn injury. Supplementation with this agent leads to significant improvements in the wound healing rate.¹⁶² In burn patients treated with oral oxandrolone, hospital length of stay is significantly reduced, and the number of necessary operative procedures is decreased.¹⁶³ In ventilator-dependent surgical patients receiving oxandrolone, however, the course of mechanical ventilation is longer than in those not treated with oxandrolone. It has been suggested that the very ability of oxandrolone to enhance wound healing may increase collagen deposition and fibrosis in the later stages of ARDS and thereby prolong recovery.¹⁶⁴ Acute elevation of liver enzyme levels has been seen in some patients treated with oxandrolone; accordingly, hepatic transaminase concentrations should be intermittently monitored in all patients treated with this agent.¹⁶³

Chemotherapeutic agents Both wound healing and tumor growth depend on metabolically active and rapidly dividing cells. Consequently, chemotherapeutic anticancer drugs that hinder tumor growth can also impair wound healing. These agents (which include adrenocorticosteroids, alkylating agents, antiestrogens, antimetabolites, antitumor antibodies, estrogen, progestogens, nitroureas, plant alkaloids, and random synthetics) attenuate the inflammatory phase of wound healing, decrease fibrin deposition,

reduce the synthesis of collagen by fibroblasts, and delay wound contraction.⁹⁷ Some cytotoxic drugs (e.g., methotrexate and doxorubicin) substantially attenuate the early phases of wound repair and reduce wound tear strength.¹⁶⁵ The magnitude of these effects is influenced by the timing of the chemotherapeutic agent's delivery in relation to the time when the wound is sustained. Preoperative delivery has a greater adverse effect on healing; for example, doxorubicin impairs wound healing to a greater extent if given before operation than if treatment is delayed until 2 weeks after operation.¹⁶⁶ Chemotherapy also results in myelosuppression and neutropenia that can decrease resistance to infection, allowing small wounds to progress to myonecrosis and necrotizing soft tissue infections.¹⁶⁷ In all acutely wounded patients who have recently been treated with, are currently taking, or will soon begin to take chemotherapeutic agents, the wounds must be closely observed for poor healing and complications.

Other drugs Many other commonly used drugs affect wound healing and thus should be avoided in the setting of an acute wound. Nicotine, cocaine, ergotamine, and epinephrine all cause vasoconstriction and tissue hypoxia. Nonsteroidal anti-inflammatory drugs (e.g., ibuprofen and ketorolac) inhibit cyclooxygenase production and reduce wound tensile strength. Colchicine decreases fibroblast proliferation and degrades newly formed extracellular matrix. Antiplatelet agents (e.g., aspirin) inhibit platelet aggregation and arachidonic acid-mediated inflammation. Heparin and warfarin impair hemostasis by virtue of their effects on fibrin formation.^{84,168,169} As noted [see Malnutrition, *above*], isotretinoin inhibits wound epithelialization and delays wound healing.¹³⁷ Vitamin E (α -tocopherol) impairs collagen formation, inflammation, and wound healing¹⁷⁰; topical application of this agent can cause contact dermatitis and worsen the cosmetic appearance of scars.⁹⁵

Discussion

Physiology of Wound Healing

Wound healing is not a single event but a continuum of processes that begin at the moment of injury and continue for months. These processes take place in much the same way throughout the various tissues of the body and, for the purposes of description, may be broadly divided into three phases: (1) inflammation, (2) migration and proliferation, and (3) maturation [see *Figure 3*]. Humans, unlike (for instance) salamanders, lack the ability to regenerate specialized structures; instead, they heal by forming a scar that lacks the complex and important skin structures seen in unwounded skin [see *Figure 4*].

INFLAMMATORY PHASE

The inflammatory phase of wound healing begins with hemostasis, followed by the arrival first of neutrophils and then of macrophages. This response is most prominent during the first 24 hours after a wound is sustained. Signs of inflammation (i.e., erythema, edema, heat, and pain) are apparent, generated primarily by changes in the venules on the distal side of the capillary bed. In clean wounds, signs of inflammation dissipate relatively quickly, and few if any inflammatory cells are seen after 5 to 7 days. In contaminated wounds, inflammation may persist for a prolonged period.

Because wounds bleed when blood vessels are injured, hemostasis is essential. In the first 5 to 10 minutes after wounding, vasoconstriction contributes to hemostasis, and the skin blanches as a result. Vasoconstriction is mediated by catecholamines (e.g., epi-

nephrine and norepinephrine) and prostaglandins (e.g., prostaglandin $F_{2\alpha}$ [$PGF_{2\alpha}$] and thromboxane A_2 [TXA_2]). As vessels contract, platelets aggregate and adhere to the blood vessel collagen exposed by the injury. Aggregating platelets release alpha-granule proteins, resulting in further platelet aggregation and triggering cytokine release. The cytokines involved in cutaneous wound healing include epidermal growth factors, fibroblast growth factors, transforming growth factor- β , platelet-derived growth factor, vascular endothelial growth factor (VEGF), tumor necrosis factor- α (TNF- α), interleukin-1 (IL-1), IGF-1, granulocyte colony-stimulating factor, and granulocyte-macrophage colony-stimulating factor.¹⁷¹ Some of these cytokines have direct effects early in the healing process; others are bound locally and play critical roles in later healing phases. The use of specific cytokines to reverse healing deficits or promote wound healing appears to be a promising clinical tool and is currently the subject of ongoing basic scientific and clinical research.¹⁷²

The coagulation cascade also contributes to hemostasis. The extrinsic pathway is essential to hemostasis and is stimulated by the release of tissue factor from injured tissue; the intrinsic cascade is not essential and is triggered by exposure to factor XII. Both coagulation pathways lead to the generation of fibrin, which acts with platelets to form a clot in the injured area [see *1:4 Bleeding and Transfusion*]. Fibrin both contributes to hemostasis and is the primary component of the provisional matrix [see *Migratory and Proliferative Phase, Provisional Matrix Formation, below*].

Figure 3 Depicted are the phases of wound healing. In the inflammatory phase (top, left), platelets adhere to collagen exposed by damage to blood vessels to form a plug. The intrinsic and extrinsic pathways of the coagulation cascade generate fibrin, which combines with platelets to form a clot in the injured area. Initial local vasoconstriction is followed by vasodilatation mediated by histamine, prostaglandins, serotonin, and kinins. Neutrophils are the predominant inflammatory cells (a polymorphonucleocyte is shown here). In the migratory and proliferative phase (top, right; bottom, left), fibrin and fibronectin are the primary components of the provisional extracellular matrix. Macrophages, fibroblasts, and other mesenchymal cells migrate into the wound area. Gradually, macrophages replace neutrophils as the predominant inflammatory cells. Angiogenic factors induce the development of new blood vessels as capillaries. Epithelial cells advance across the wound bed. Wound tensile strength increases as collagen produced by fibroblasts replaces fibrin. Myofibroblasts induce wound contraction. In the maturational phase (bottom, right), scar remodeling occurs. The overall level of collagen in the wound plateaus; old collagen is broken down as new collagen is produced. The number of cross-links between collagen molecules increases, and the new collagen fibers are aligned so as to yield an increase in wound tensile strength.

Vasoconstriction and hemostasis are followed by vasodilatation, which is associated with the characteristic signs of erythema, edema, heat, and pain. Vasodilatation is mediated by prostaglandins (e.g., PGE₂ and PGI₂ [prostacyclin]), histamine, serotonin, and kinins.^{173,174} As the blood vessels dilate, the endothelial cells separate from one another, thereby increasing vascular permeability. Inflammatory cells initially roll along the endothelial cell lining, subsequently undergo integrin-mediated adhesion, and finally transmigrate into the extravascular space.¹⁷⁵

For the first 48 to 72 hours after wounding, neutrophils are the predominant inflammatory cells in the wound. About 48 to 96 hours after wounding, however, monocytes migrate from nearby tissue and blood and transform into macrophages, and eventually, macrophages become the predominant inflammatory cells in the wound. Both neutrophils and macrophages engulf damaged

tissue and bacteria and digest them. After neutrophils phagocytose damaged material, they cease to function and often release lysosomal contents, which can contribute to tissue damage and a prolonged inflammatory response. Macrophages, however, are essential to wound healing and do not cease to function after phagocytosing bacteria or damaged material.¹⁷⁶ In the wound environment, macrophages also secrete collagenase, elastase, and matrix metalloproteinases (MMPs) that break down damaged tissue. Macrophages also produce cytokines that mediate wound-healing processes, as well as IL-1 (which can lead to a systemic response, including fever) and TNF- α .¹⁷¹

MIGRATORY AND PROLIFERATIVE PHASE

The migratory and proliferative phase is marked by the attraction of epidermal cells, fibroblasts, and endothelial cells to the

Figure 4 Shown are the key anatomic components of the skin.

wound. Cells migrate along the scaffolding of fibrin and fibronectin. This process involves the upregulation of integrin receptor sites on the cell membranes, which allows the cells to bind at different sites in the matrix and pull themselves through the scaffolding. Migration through the provisional matrix is facilitated by proteolytic enzymes. Cytokines and growth factors then stimulate the proliferation of these cells.^{171,176}

Epithelialization

Within approximately 24 hours of injury, epidermal cells from the wound margin and skin appendages begin to migrate into the wound bed. These migrating epidermal cells dissect the wound, separating desiccated eschar from viable tissue.⁸⁰ At 24 to 48 hours after wounding, epidermal cells at the wound margin begin to proliferate, producing more migrating cells.¹⁷¹ As epidermal migration is initiated, the desmosomes that link epidermal cells together and the hemidesmosomes that link the epidermal cells to the basement membrane disappear.¹⁷⁷ Migrating epidermal cells express integrin receptors that allow interaction with extracellular matrix proteins, laminin, collagen, and fibrin clot.¹⁷⁸ When epidermal cells migrating from two areas meet, contact inhibition prevents further migration. The cells making up the epidermal monolayer then differentiate, divide, and form a multilayer epidermis.

Provisional Matrix Formation

Formation of the provisional matrix and granulation tissue begins approximately 3 to 4 days after wounding. Fibroblasts synthesize an extracellular matrix of fibrin, fibronectin, and proteoglycans that supports epidermal and endothelial cell migration and proliferation.^{178,179} Proteoglycans (e.g., dermatan sulfate, heparin, heparan sulfate, keratan sulfate, and hyaluronic acid) consist of a protein core that is linked to one or more glycosaminoglycans; they anchor proteins and facilitate the alignment of collagen into fibrils.

Fibrin becomes coated with vitronectin and fibronectin, which are glycoproteins that facilitate the adhesion of migrating fibro-

blasts and other cells to the provisional extracellular matrix.¹⁸⁰ By influencing cellular attachment, fibronectin helps modulate cell migration into the wound.¹⁸¹ In addition, the fibrin-fibronectin lattice binds various cytokines that are released at the time of injury and serves as a reservoir for these factors in the later stages of healing.¹⁸²

Fibroblasts then replace the provisional extracellular matrix with a collagen matrix, and the wound gains strength. The rate of collagen synthesis increases greatly after the initial 3 to 5 days and continues at an increased rate for 21 days before gradually declining.¹⁸³ Of the many types of collagen, the ones that are of primary importance in the skin are types I and III. Approximately 80% to 90% of the collagen in the skin is type I collagen; the remaining 10% to 20% is type III. The percentage of type III collagen is higher in embryonic skin and in skin that is in the early stages of wound healing.

Collagen molecules are synthesized by fibroblasts. Lysine and proline residues within the collagen molecule become hydroxylated after being incorporated into polypeptide chains. This process requires specific enzymes, as well as various cofactors (i.e., oxygen, vitamin C, α -ketoglutarate, and ferrous iron). The result is procollagen, which is released into the extracellular space. Individual collagen molecules then align and associate with one another to form fibrils. Covalent cross-links form between various combinations of the hydroxylated residues (lysine and hydroxylysine) in aligned collagen fibrils, with the strongest links occurring between hydroxylysine and hydroxylysine. These cross-links are essential to the tensile strength of the wound. Cofactor deficiencies (e.g., vitamin C deficiency in scurvy) and the use of corticosteroids can lead to the synthesis of weak, underhydroxylated collagen that is incapable of generating strong cross-links.

Angiogenesis

The growth of new blood vessels, which is necessary to support the wound tissue, begins 2 to 3 days after wounding. This process of angiogenesis may be stimulated by the hypoxic and acidic

wound microenvironment, as well as by cytokines (e.g., VEGF) derived from epidermal cells and macrophages.^{171,184} Endothelial cells from surrounding vessels express fibronectin receptors and grow into the provisional matrix. These migrating endothelial cells create paths in the matrix for developing capillaries by releasing plasminogen activator, procollagenase, heparanase, and MMPs, which break down fibrin and basement membranes.^{171,185} The budding capillaries join and initiate blood flow. As the wounded area becomes better vascularized, the capillaries consolidate to form larger blood vessels or undergo apoptosis.¹⁸⁶

MATURATIONAL PHASE

Wound Contraction

Myofibroblasts are specialized fibroblasts containing alpha-smooth muscle actin microfilaments that contribute to wound contraction.^{187,188} The wound edges are pulled together by the contractile forces supplied by the myofibroblast. Wound contraction generally begins in the 4- to 5-day period after wounding and continues for 12 to 15 days or until the wound edges meet. The rate at which contraction occurs varies with the laxity of the tissue and is

highest at anatomic sites with redundant tissue. Excessive contraction can lead to contracture, a pathologic scarring that impairs the function and appearance of the scar.

Scar Remodeling

Collagen remodeling begins approximately 3 weeks after wounding. Collagen synthesis is downregulated, the rates at which collagen is synthesized and broken down reach equilibrium, and the wound becomes less cellular as apoptosis occurs. During this process, the extracellular matrix, including collagen, is continually remodeled and synthesized in a more organized fashion along stress lines.¹⁸³ Collagen breakdown is mediated by MMPs.¹⁸⁹ The number of cross-links between collagen fibers increases,¹⁸³ and the realigned, highly cross-linked collagen is much stronger than the collagen produced during the earlier phases of healing. The tensile strength of the wound increases rapidly for 6 weeks after injury; accordingly, during this period, heavy lifting and any other activity that applies stress across the wound should be avoided. After the initial 6 weeks, tensile strength increases more slowly for a further 6 to 12 months, though it never reaches the tensile strength of unwounded tissue [see *Figure 2*].

1 HEAD AND NECK DIAGNOSTIC PROCEDURES

Adam S. Jacobson, M.D., Mark L. Urken, M.D., F.A.C.S., and Marita S. Teng, M.D.

Head and neck surgery deals with a wide range of pathologic conditions affecting the upper aerodigestive tract and the endocrine organs of the head and neck. As in other areas of the body, the causes of these conditions can be inflammatory, infectious, congenital, neoplastic, or traumatic. This chapter discusses the diagnostic approach to head and neck disorders, with particular attention to cancer.

Anatomic Considerations

The head and neck can be conceptualized by dividing it into the following segments: (1) nasal cavity and paranasal sinuses, (2) oral cavity, (3) pharynx, (4) larynx, (5) salivary glands, and (6) thyroid [see Figure 1].

NASAL CAVITY AND PARANASAL SINUSES

The nasal vault and paranasal sinuses are a complex labyrinth of interconnected cavities. These cavities are lined with mucous membranes and are normally well aerated. The nasal vault itself is divided into two equal halves by the nasal septum. There are three paired turbinates in the nasal cavity, which further subdivide the nasal vault from cephalad to caudal, creating the superior, middle, and inferior meatuses.

The ethmoid sinus is the most complicated of the paranasal sinuses; it is also known as the ethmoid labyrinth [see Figure 2]. The maxillary sinus lies within the body of the maxilla and is the largest of the paranasal sinuses. The frontal sinus lies within the frontal bone and is divided into two asymmetrical halves by an intersinus septum. The sphenoid sinus lies posterior to the nasal cavity and superior to the nasopharynx. It too is an asymmetrical structure that is divided by an intersinus septum. The sphenoid sinus remains the most dangerous sinus to manipulate surgically because of the surrounding vital structures (i.e., the carotid artery, the optic nerve, the trigeminal nerve, and the vidian nerve).

Tumors within the nasal vault or the paranasal sinuses present as nasal airway obstruction, epistaxis, pain, and nasal discharge. They can originate in any of the paranasal sinuses or the nasal cavity proper and often remain silent or are mistakenly treated as an infectious or inflammatory condition, with a consequent delay in the diagnosis.

ORAL CAVITY

Anatomically, the oral cavity extends from the vermilion border to the junction of the hard and soft palates and the circumvallate papillae. It includes the lips, the buccal mucosa, the upper and lower alveolar ridges, the retromolar trigones, the oral tongue (anterior to circumvallate papillae), the hard palate, and the floor of the mouth.

PHARYNX

The pharynx is a tubular structure extending from the base of the skull to the esophageal inlet. Superiorly, it opens into the nasal and oral cavities; inferiorly, it opens into the larynx and the

esophagus. The pharynx is subdivided into the nasopharynx, the oropharynx, and the hypopharynx.

Nasopharynx

The nasopharynx extends from the posterior choanae to the inferior surface of the soft palate. Malignancies of the nasopharynx can present as nasal obstruction, epistaxis, tinnitus, headache, diminished hearing, and facial pain.

Oropharynx

The oropharynx extends from the junction of the hard and soft palates and the circumvallate papillae to the valleculae. It includes the soft palate and uvula, the base of the tongue, the pharyngoepiglottic and glossoepiglottic folds, the palatine arch (which includes the tonsils and the tonsillar fossae and pillars), the valleculae, and the lateral and posterior oropharyngeal walls. Carcinomas of the oropharynx can present as pain, sore throat, dysphagia, and referred otalgia.

Hypopharynx

The hypopharynx extends from the superior border of the hyoid bone to the inferior border of the cricoid cartilage. It includes the pyriform sinuses, the hypopharyngeal walls, and the post-cricoid region (i.e., the area of the pharyngoesophageal junction). Malignancies of the hypopharynx can present as odynophagia, dysphagia, hoarseness, referred otalgia, and excessive salivation.

LARYNX

The larynx is subdivided into the supraglottis, the glottis, and the subglottis [see Figure 3]. It consists of a framework of cartilages that are held together by extrinsic and intrinsic musculature and lined with a mucous membrane that is topographically arranged into two characteristic folds (the false and true vocal cords). Neoplasms of the larynx can present as hoarseness, dyspnea, stridor, hemoptysis, odynophagia, dysphagia, and otalgia.

Supraglottis

The supraglottis extends from the tip of the epiglottis to the junction between respiratory and squamous epithelium on the floor of the ventricle (the space between the false and true cords). Carcinomas of the supraglottis can present as sore throat, odynophagia, dysphagia, and otalgia.

Glottis

The space between the free margin of the true vocal cords is the glottis. This structure is bounded by the anterior commissure, the true vocal cords, and the posterior commissure. The most common symptom of carcinoma of the glottis is hoarseness.

Subglottis

The subglottis extends from the junction of squamous and respiratory epithelium on the undersurface of the true vocal cords (approximately 5 to 10 mm below the true vocal cords) to the inferior edge of the cricoid cartilage. The most common symptom of carcinoma of the subglottis is hoarseness.

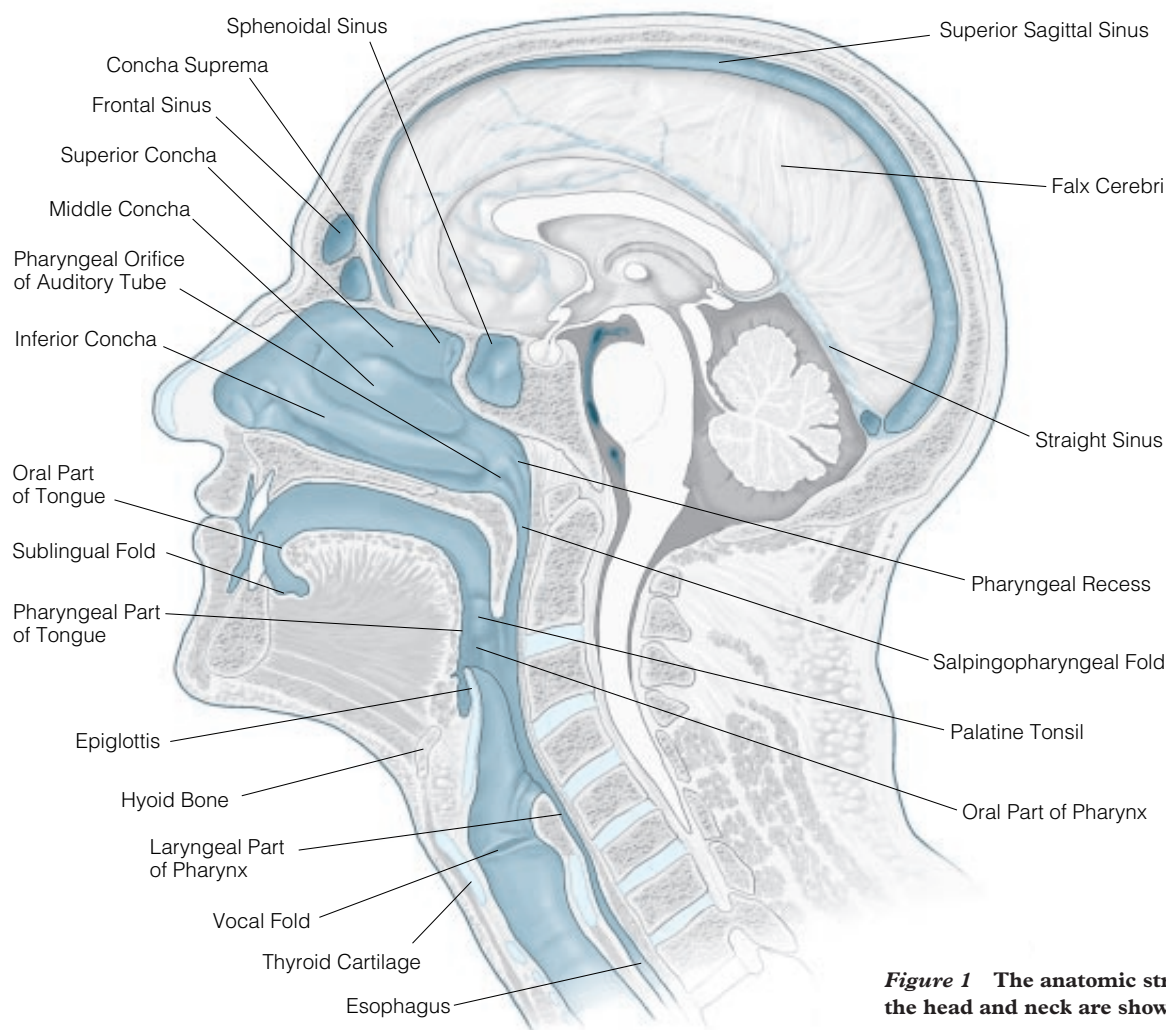

Figure 1 The anatomic structures of the head and neck are shown.

SALIVARY GLANDS

Salivary glands are subdivided into major and minor salivary glands. The major salivary glands consist of the parotid glands, the submandibular glands, and the sublingual glands. The minor salivary glands are dispersed throughout the submucosa of the upper aerodigestive tract. Classically, benign neoplasms present as painless, slow-growing masses. A sudden increase in size is usually the result of infection, cystic degeneration, hemorrhage into the mass, or malignant transformation. Malignant neoplasms also usually present as a painless swelling or mass. However, certain features are strongly suspicious for a malignancy, such as overlying skin involvement, fixation of the mass to the underlying structures, pain, facial nerve paralysis, ipsilateral weakness or numbness of the tongue, and cervical lymphadenopathy.

THYROID

The thyroid gland performs a vital role in regulating metabolic function. It is susceptible to benign conditions (e.g., nodule, goiter, and cyst), inflammatory disease (e.g., thyroiditis), and malignancies. Additionally, congenital anomalies of the thyroid, such as a thyroglossal duct cyst, can present later in life. Thyroid lesions can present as pain, hoarseness, dyspnea, or dysphagia.

On the posterior aspect of the thyroid gland reside the four parathyroid glands. These glands play a vital role in maintaining calcium balance. Parathyroid adenomas and, rarely, carcinomas can develop.

Clinical Evaluation

The diagnostic approach to the upper aerodigestive tract begins with a thorough history, starting with a detailed evaluation of the chief complaint. Once the chief complaint has been defined (e.g., neck mass, hoarseness, hemoptysis, or nasal obstruction), it must be further characterized. The physician must determine how long the problem has been present and whether the patient has any associated symptoms (e.g., pain, paresthesias, discharge, change in voice, dyspnea, hemoptysis). In addition, it is important to ask about recent infection (e.g., of the ear, mouth, teeth, or lungs) and previous medical treatment. Once a complete history of the chief complaint has been obtained, the physician should elicit a more comprehensive general medical history from the patient, including pertinent past medical history, past surgical history, medications, allergies, social history (tobacco, ethanol, I.V. drug use), and family history.

After completion of the history, the next step is to perform a comprehensive physical examination. This begins with a thorough inspection of the entire surface of the head and neck, with a focus on gross lesions, areas that are topographically abnormal, and old scars from previous injuries or procedures. The examination should proceed in an orderly fashion from superior to inferior. Next, the inspection focuses on the mucosal surfaces of the upper aerodigestive tract.

Although an accurate history and careful physical examination of the head, neck, and mucosal surfaces are the most important steps in evaluating a lesion in this part of the body, this clinical evaluation

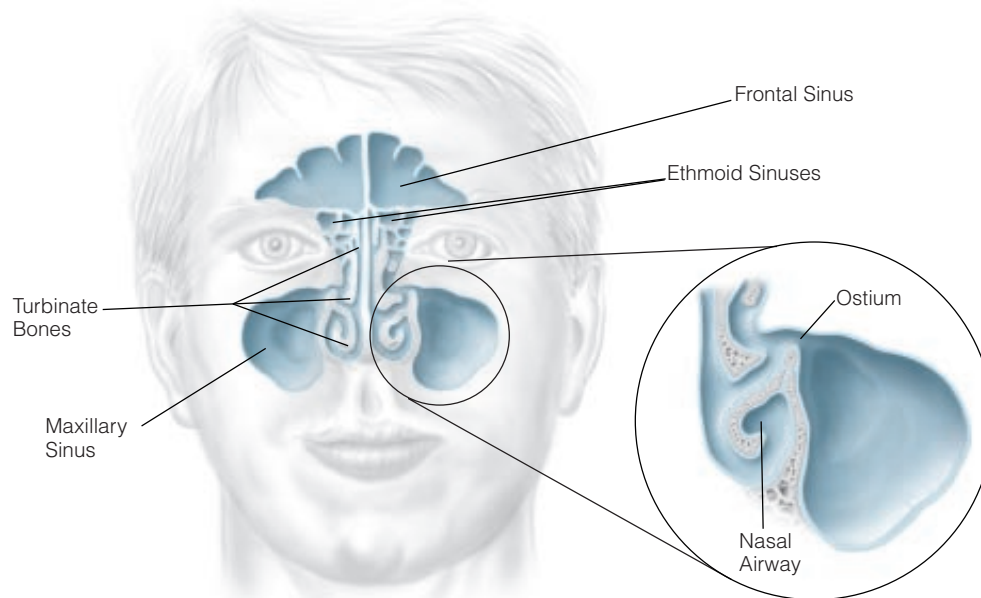

Figure 2 The paranasal sinuses are shown.

usually provides only a working diagnosis. The head and neck surgeon must then proceed in a stepwise fashion to further clarify the diagnosis and, in the case of neoplasm, to perform an accurate staging.

Radiographic techniques allow the head and neck surgeon to visualize the mass and determine its characteristics (i.e., to differentiate between solid and cystic lesions), as well as determine its anatomic associations. Ultrasonography, magnetic resonance imaging, and computed tomography each provides a unique view of the pathology in question and thereby helps narrow the differential diagnosis. Acquisition of a tissue specimen for cytologic or histologic analysis, or both, is the next step. Fine-needle aspiration (FNA) is often utilized at this stage in the workup, provided that the location of the mass lends itself to a safe procedure. If the lesion is located deep in the neck near vital structures, image-guided FNA can be attempted before resorting to an open biopsy. If the lesion is on a mucosal surface of the upper aerodigestive tract, an endoscopic biopsy is performed. Often, a panendoscopic procedure is performed at this point to accurately map the lesion, obtain a tissue specimen, and, in patients with cancer, assess the rest of the upper aerodigestive tract for a synchronous primary tumor.

After a histologic diagnosis has been made and correlated with the imaging information, the patient and physician can have a comprehensive discussion of the pathology, the stage of the disease, and the selection of therapy.

Nasal Diagnostic Procedures

ANTERIOR RHINOSCOPY

Using a variety of different light sources that provide both illumination and coaxial vision, the head and neck surgeon can view the nasal vault through a nasal speculum [see Figure 4]. This technique is performed both before and after nasal decongestion, with particular attention to mucosal color, edema, and discharge and the effect of vasoconstriction. Limited visualization of the nasal septum, the turbinates, and the vault is also possible with this technique.

RIGID NASAL ENDOSCOPY

The rigid nasal endoscope comes with a variety of lens angles (0°,

60°, and 90°), which allow for visualization of structures that are inaccessible by simple anterior rhinoscopy. Rigid nasal endoscopy is especially useful for visualizing deeper structures and structures that are not in a straight axis from the nasal aperture.

Indirect Laryngoscopy

Indirect laryngoscopy has been used since the 1800s for visualizing the pharynx and larynx. In this technique, the head light source illuminates the mirror, which in turn illuminates the laryngopharynx [see Figure 5]. The patient is seated in the sniffing position and protrudes the tongue while a warmed laryngeal mirror is introduced firmly against the soft palate in the midline to elevate the uvula out of the field (gently, so as not to elicit the gag reflex). The image seen on the mirror can be used to assess vocal cord mobility, as well as to inspect for a mass or foreign body of the larynx or pharynx. This technique can be performed rapidly and is inexpensive.

Endoscopic Procedures

Endoscopic evaluation of the upper aerodigestive tract is crucial in establishing a definitive diagnosis. The equipment used consists of both rigid and flexible laryngoscopes, bronchoscopes, and esophagoscopes. Many of these techniques can be performed in the office setting, providing the surgeon with an array of methods for gaining the information necessary for a working diagnosis and, in some cases, for performing a therapeutic intervention. Operative endoscopy is performed to obtain a definitive diagnosis, to stage tumors, and to rule out synchronous lesions. There is no substitute for thorough examination and biopsy of a lesion with the patient under general anesthesia. Regardless of the endoscopic method used, an adequate biopsy specimen must be obtained for a histologic diagnosis.

FLEXIBLE RHINOLARYNGOSCOPY

Flexible rhinolaryngoscopy is currently one of the most commonly used techniques for visualizing the nasal cavity, the sinuses, the pharynx, and the larynx. The technique utilizes a small-caliber flexible endoscope and can be performed in an office setting [see Figure 6]. Before the procedure, the patient's nasal cavity

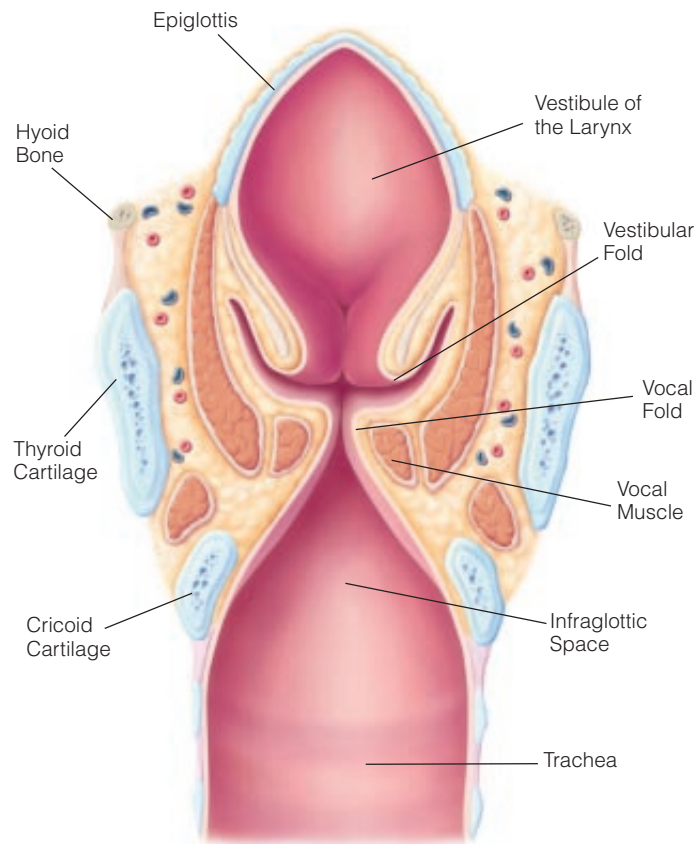

Figure 3 Cross-sectional anatomy of the larynx is shown.

is decongested and anesthetized for maximum visualization and minimal discomfort. In the procedure, the examiner threads the end of the scope into the nasal aperture along the floor of the nasal cavity. As the scope is advanced, the examiner can visualize the nasal cavity proper for any evidence of lesions or masses. Once the scope approaches the nasopharynx, it is directed inferiorly and advanced slowly, allowing direct visualization of the entire pharynx and larynx.

DIRECT LARYNGOSCOPY

Direct laryngoscopy has the advantage of permitting both diagnostic and therapeutic intervention [see Figure 7]. It is performed with the patient under general anesthesia and intubated. The procedure allows for direct visualization of the pharynx and the larynx and permits the surgeon to perform biopsies and remove small lesions. At the same time, the surgeon has the opportunity to palpate the structures of the oral cavity, the oropharynx, and the hypopharynx, which cannot be properly palpated in an awake patient.

The laryngoscope can also be suspended from a table-mounted Mayo stand (for hands-free use), and a microscope can be maneuvered into focal distance to allow magnified visualization of the glottis and subglottis. During a microscopic direct laryngoscopy, small lesions or topographic abnormalities can be better characterized and removed if desired. Some examples of lesions that can be diagnosed by direct laryngoscopy are vocal cord polyps, leukoplakia, intubation granulomas, contact ulcers, webs, nodules, hematomas, and papillomatosis. Additionally, small malignant lesions of the vocal cords can be examined and ablated or extirpated by using a CO₂ laser under direct microlaryngoscopic guidance.

ESOPHAGOSCOPY

Esophagoscopy plays an important role in the evaluation of patients with dysphagia, odynophagia, caustic ingestion, trauma, ingested foreign bodies, suspected anomalies, and upper aerodigestive tract malignancies. This procedure may be performed with either a flexible or a rigid scope.

Flexible Esophagoscopy

The primary application for flexible esophagoscopy is diagnosis. The procedure is particularly useful in elderly patients with limited spinal mobility and in patients with short, thick necks.

The flexible esophagoscope is used with local anesthesia and sedation in a monitored setting. To facilitate control of secretions and the passage of the instrument, the patient is placed in a flexed position and lying on one side. Using insufflation, the surgeon visualizes and enters the cricopharynx and carries out a safe and detailed visual study of the esophagus. If a malignancy is suspected, either a brush specimen is sent for cytology or a cup forceps is used to acquire a specimen for histologic analysis.

Rigid Esophagoscopy

Rigid esophagoscopy can be used to treat a variety of problems, including foreign bodies, hemorrhage (e.g., from esophageal varices), and endobronchial tumors. Rigid esophagoscopes [see Figure 8] are used with the patient under general anesthesia. The patient is placed in the supine position with the neck extended. The esophagoscope is then passed along the right side of the tongue, with the endoscopist using the left hand to cradle the instrument. The right hand is used for stabilization of the proximal end of the scope, suctioning, and insertion of instruments through the lumen of the esophagoscope. The lip of the esophagoscope is positioned anteriorly for manipulation of the epiglottis and visualization of the pyriform sinus and the arytenoids. The scope is then passed along the pyriform sinus into the cricopharynx (i.e., the superior esophageal valve). The left thumb is then used to advance the instrument down the esophagus. If no major lesions are noted on insertion of the esophagoscope, a careful inspection of the mucosa should be made during withdrawal of the instrument.

Figure 4 Shown is an assortment of nasal specula.

Figure 5 Shown is a laryngeal mirror. Such an instrument is used for indirect laryngoscopy.

BRONCHOSCOPY

Bronchoscopy provides clinically useful information by direct inspection of the tracheobronchial tree. Like esophagoscopes, bronchoscopes come in both flexible and rigid forms. The flexible bronchoscope is used primarily for diagnosis. The value of the rigid bronchoscope lies in its therapeutic applications, which include foreign-body removal, removal of bulky tumors, introduction of radioactive materials, and placement of stents.

Flexible Bronchoscopy

The flexible fiberoptic bronchoscope is usually used with local anesthesia and sedation in a monitored setting (e.g., an operating suite). After local anesthesia and decongestion of the nasal vault with topical tetracaine and 1% phenylephrine, the flexible scope is gently passed along the nasal floor into the nasopharynx, where the tip of the scope is angled inferiorly to permit visualization of the pharynx. The instrument is then advanced slowly into the glottis (between the true vocal folds) and into the tracheobronchial tree. After a visual inspection of the airway has been completed, a specimen can be retrieved by means of brush biopsy, bronchoalveolar lavage, or a biopsy forceps.

Rigid Bronchoscopy

Rigid bronchoscopy [see Figure 9] is performed with the patient under general anesthesia. The patient is placed in the supine position with the neck hyperextended. The bronchoscope is then passed along the right side of the tongue, with the endoscopist using the left hand to cradle the instrument. The instrument is initially held almost vertically until it reaches the posterior pharyngeal wall, at which point it is slowly guided into a more horizontal position. While advancing the scope, the endoscopist cradles the instrument with the fingers of the left hand, providing guidance and protecting the patient's lips and teeth. Once the tip of the epiglottis is

Figure 6 A small-caliber flexible laryngoscope is used for rhinolaryngoscopy.

visualized, the instrument is threaded anteriorly to allow visualization of the glottis. The bronchoscope is then passed between the vocal cords and into the trachea. At this point, ventilation may be resumed either by positive pressure or by jet ventilation techniques (ventilating bronchoscopes have a side port for attachment of the tubing from the ventilator). The patient's head is manipulated with the endoscopist's right hand so as to direct the tip of the bronchoscope and permit bilateral exploration of the major airways.

PANENDOSCOPY

The term panendoscopy refers to the combination of direct laryngoscopy (with or without microscopic assistance), esophagoscopy, and bronchoscopy. Together, these three procedures provide a complete examination of the entire upper aerodigestive tract. In cancer patients, this combination of procedures allows the examiner to create a detailed map of the tumor, as well as to rule out synchronous primary tumors.

Biopsy Procedures

FINE-NEEDLE ASPIRATION

FNA is often used to make an initial tissue diagnosis of a neck mass. The advantages of this technique include high sensitivity and specificity; however, 5% to 17% of FNAs are nondiagnostic. Another advantage of FNA is speed: If a cytologist or a pathologist is available, diagnosis can often be made within minutes of the biopsy.

FNA is performed with a 10 ml syringe with an attached 21- to 25-gauge needle. Larger needles are more likely to result in tumor seeding. The patient is positioned to allow for optimal palpation of the mass. The skin overlying the mass is prepared with a sterile alcohol prep sponge. Local anesthesia is not necessary. The mass is grasped and held in a fixed and stable position. The needle is introduced just under the skin surface. As the needle is advanced, the plunger of the syringe is pulled back, to create suction. Once the mass is entered, multiple passes are made without exiting the skin surface; this maneuver is critical in maximizing specimen yield. After the final pass is completed, the suction on the syringe is released and the needle withdrawn from the skin. If a cyst is encountered, it should be completely evacuated and the fluid sent for cytologic analysis.

A drop of aspirated fluid is placed on a glass slide. A smear is made by laying another glass slide on top of the drop of fluid and pulling the slides apart to spread the fluid. Fixative spray is then applied. Alternatively, wet smears are placed in 95% ethyl alcohol and treated with the Papanicolaou technique and stains.

FNA has several advantages over excisional biopsy. An FNA requires only an office visit, with minimal loss of time from work for the patient. In contrast, excisional biopsy is commonly performed in an operating room, so the patient must undergo preoperative testing. Patients with a significant medical history may require formal medical clearance. An excisional biopsy exposes the patient to the risks of anesthesia, postoperative wound infection, and tumor seeding.

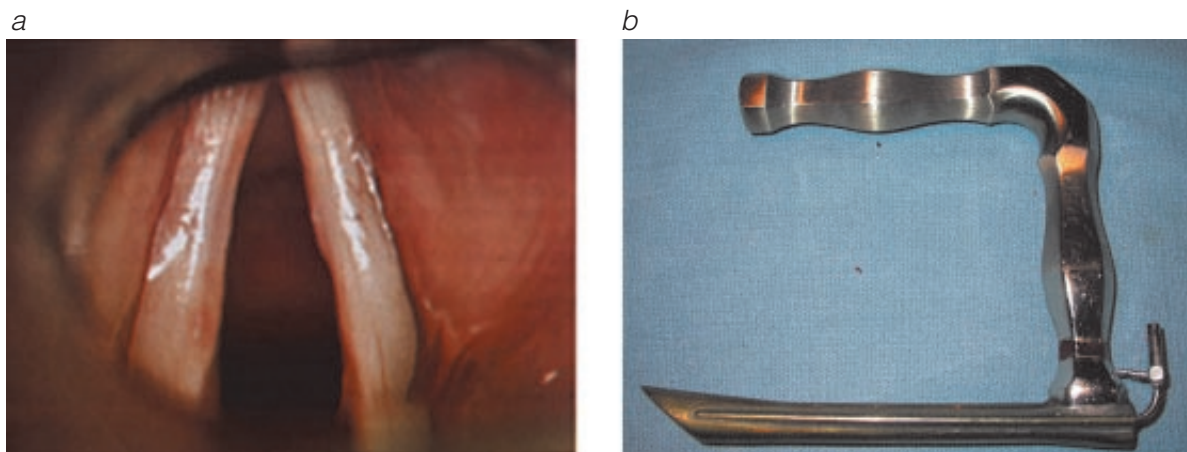

Figure 7 Shown are (a) normal vocal folds directly visualized via (b) a rigid laryngoscope.

ULTRASOUND-GUIDED FNA

Ultrasonographic guidance of FNA enables the surgeon to obtain a cytologic specimen of deeper or nonpalpable masses that are not amenable to standard FNA. Real-time imaging of the needle's passage allows the surgeon to plot a more accurate trajectory and avoid underlying vital structures. Furthermore, it provides an image of the mass, allowing its characterization as solid, cystic, or heterogeneous. With cystic or complex masses, it is imperative to place the tip of the needle into the wall to increase specimen yield.

CT-GUIDED FNA

CT-guided FNA is most commonly employed to diagnose poorly accessible or deep-seated lesions of the head and neck. Like ultrasound-guided FNA, CT-guided FNA provides visualization of the needle as it is passed through the tissue and into the underlying structures, thus allowing a more accurate needle trajectory and avoidance of underlying vital structures. Additionally, visual guidance of the needle greatly increases the likelihood of obtaining a specimen from the mass rather than the surrounding tissues.

Imaging Procedures

Because many of the deep structures of the head and neck are inaccessible to either direct evaluation by palpation or indirect evaluation via endoscopy, further information must be obtained by radiography. Imaging procedures such as CT, MRI, ultrasound, and positron emission tomography (PET) scanning permit the diagnosis and analysis of pathologic conditions affecting these deep structures, including the temporal bone, skull base, paranasal sinuses, soft tissues of the neck, and larynx.

ULTRASONOGRAPHY

Ultrasonography is a safe and inexpensive method of gaining high-resolution real-time images of the structures of the head and

neck. Palpable masses in the neck [see 2:3 *Neck Mass*] can be assessed for changes in size, for association with other local structures, and for character (i.e., solid, cystic, or complex). Applications of ultrasonography include assessment of masses such as thyroglossal duct cysts, branchial cleft cysts, cystic hygromas, salivary gland tumors, abscesses, carotid body tumors, vascular tumors, and thyroid masses. Additionally, ultrasonography combined with FNA and cytologic evaluation can provide both a detailed visual description and an accurate cytologic evaluation of masses in the neck [see *Ultrasound-Guided FNA, above*].

COMPUTED TOMOGRAPHY

A CT scan with intravenous contrast is often the first-line imaging technique used to evaluate a mass of the neck and to assess for pathologic adenopathy. CT has proved to be an effective method for primary staging of tumors and lymph nodes. Additionally, it has been shown to be effective in studying capsular penetration and extranodal extension. It is clearly superior to MRI in evaluating bone cortex erosion, given that MRI cannot assess bone cortex status at all. CT scans are also widely used for post-treatment surveillance in cancer patients.

MAGNETIC RESONANCE IMAGING

MRI avoids exposing the patient to radiation and provides the investigator with superior definition of soft tissue. For example, MRI can differentiate mucous membrane from tumor, as well as detect neoplastic invasion of bone marrow. In patients with nasal cavity tumors, MRI can distinguish between neoplastic, inflammatory, and obstructive processes. MRI is also valuable in assessing the superior extent of metastatic cervical lymphadenopathy (i.e., intracranial extension). A disadvantage of MRI is its limited ability to show bone detail; it therefore cannot detect invasion of bone cortex by a neoplasm. Furthermore, an MRI scan is significantly more expensive than a CT scan.

Figure 8 Shown is a rigid endoscope.

Figure 9 (a) Rigid bronchoscopes incorporate stainless-steel tubes of varying length and diameter. The beveled distal end of this Hopkins bronchoscope facilitates mobilization of the epiglottis during intubation; the side ports permit ventilation and use of suction catheters. (b) Illumination is provided by fiberoptic rods that are inserted into the bronchoscope.

POSITRON EMISSION TOMOGRAPHY

PET scanning is a functional imaging technique that measures tissue metabolic activity through the use of radioisotopically tagged cellular building blocks, such as glucose precursors. A range of physiologic tracers has been developed for PET imaging, with the glucose analogue 2-deoxy-2-[(18)F]fluoro-D-glucose (FDG) the most commonly used. FDG has a half-life of 110 minutes. Once given to the patient, FDG is taken up by glucose transporters and is phosphorylated by hexokinase to become FDG-6-phosphate (FDG-6-P). Further metabolism of FDG-6-P is blocked by the presence of an extra hydroxyl moiety, which allows FDG-6-P to accumulate in the cell and serve as a marker for glucose metabolism and utilization.

Because neoplastic cells have higher rates of glycolysis, localized areas of increased cellular activity on PET scans may represent neoplastic tissue. In this respect, PET is very different from CT and MRI, which depict tissue structure rather than tissue metabolic activity.

Because FDG is nonspecifically accumulated in glycolytically active cells, it demarcates areas of inflammation as well as neoplastic tissue, which can lead to a false positive scan. Muscular activity during the scan can also lead to areas of increased uptake in nonneoplastic tissue. Furthermore, healing bone, foreign body granulomas, and paranasal sinus inflammation can produce false positive results.

False negative scans occur when tumor deposits are very small (i.e., 3 to 4 mm or less in diameter). Thus, micrometastases are not reliably detected using an FDG-PET image. Furthermore, a false negative scan can occur if the PET scan is performed too soon after radiation therapy.

The role of PET imaging in head and neck oncology is rapidly expanding. Currently, the majority of PET imaging used in head and neck oncology is FDG based. FDG-PET is actively being used to look for unknown primary lesions and second primaries, to stage disease before therapy, to detect residual or recurrent disease after surgery or radiation therapy, to assess the response to organ preservation therapy, and to detect distant metastases. Because false positive and false negative PET scans do occur, accurate interpretation of PET scans requires a thorough understanding of the potential confounding factors.

PET/CT

PET/CT is essentially an FDG-PET scan that has been coregistered with a simultaneous CT scan to allow the radiologist to precisely correlate the area of increased cellular activity with the anatomic structure. This technique removes some of the guesswork involved with interpreting an area of increased activity on a simple PET scan and provides the physician with a morphologic correlate for the area of increased uptake.

2 ORAL CAVITY LESIONS

David P. Goldstein, M.D., Henry T. Hoffman, M.D., F.A.C.S., John W. Hellstein, D.D.S., and Gerry F. Funk, M.D., F.A.C.S.

Approach to Oral Cavity Lesions

The oral cavity is a complex structure that plays a role in many important functions, including mastication, swallowing, speech, and respiration. It extends from the vermilion border of the lips to the oropharynx and is separated from the oropharynx by the anterior tonsillar pillars, the junction of the hard and soft palates, and the junction between the base of the tongue and the oral tongue at the circumvallate papillae.

In most cases, lesions of the oral cavity reflect locally confined processes, but on occasion, they are manifestations of systemic disease. The cause of an oral cavity lesion can usually be identified by the history and the physical examination; however, it is most often determined definitively by either a response to a therapeutic trial or a biopsy. A systematic classification of oral cavity lesions facilitates the development of a differential diagnosis. One approach to classification is based on the appearance of the lesion (e.g., white, red, pigmented, ulcerative, vesiculobullous, raised, or cystic). Another approach is first to categorize the lesion as either neoplastic or nonneoplastic and then to further divide the nonneoplastic lesions into various subcategories (e.g., infectious, inflammatory, vascular, traumatic, and tumorlike) [see Table 1]. In the following discussion, we adopt the second approach.

Clinical Evaluation

HISTORY

The onset, duration, and growth rate of the oral lesion should be determined. Inflammatory lesions usually have an acute onset and are self-limited, and they may be recurrent. Neoplasms tend to exhibit progressive enlargement; a rapid growth rate is suggestive of malignancy. It is often possible to identify specific events (e.g., upper respiratory tract infection, oral trauma, or medications) that precipitated the lesions. Both malignancies and inflammatory conditions may be associated with various nonspecific symptoms, including pain and dysphagia. Symptoms suggestive of malignancy include trismus, bleeding, a change in denture fit or occlusion, facial sensory changes, and referred otalgia. Fever, night sweats, and weight loss may occur in various settings but are particularly associated with lymphomas and systemic inflammatory conditions. Some oral lesions are identified without presenting signs or symptoms as incidental findings noted during a general dental or medical examination.¹

A review of systems may uncover signs (e.g., rashes or arthritis) that suggest a possible autoimmune disorder. The medical history should always address previous or current connective tissue diseases, malignancies, radiation therapy, chemotherapy, and HIV infection. It is especially important to elicit a medication history because many classes of medications cause drug eruptions

that involve the oral mucosa: for instance, well over 100 medications are associated with lichenoid drug reaction, and even more are associated with xerostomia. Use of alcohol or tobacco is a notable risk factor for the development of oral cavity carcinoma, as is a previous head and neck carcinoma. The quantity of alcohol or tobacco consumed should be determined because a dose-response relationship exists between the level of use and the risk of cancer. Other risk factors for oral cavity carcinoma include sun exposure (lip cancer), human papillomavirus infection, and nutritional deficiencies. Radiation exposure is a risk factor for soft tissue sarcoma, lymphoma, and minor salivary gland tumors, and HIV infection is a risk factor for Kaposi sarcoma.

PHYSICAL EXAMINATION

The head and neck should be examined in an organized and systematic manner. Illumination with a headlight or a reflecting mirror facilitates oral examination by freeing the examiner's hands for use in retracting the cheeks and the tongue.

The mucosa of the oral cavity is evaluated at each of the oral subsites [see Figure 1]. Any trismus should be noted, as should the general health of the teeth and the gingiva. Percussion of carious teeth with pulpitis often elicits pain, though this is not always the case if caries is shallow or pulpal necrosis is present. Palpation of the tongue, the floor of the mouth, and the oral vestibule is an essential component of oral examination. Palpation of the submandibular and submental regions is best performed bimanually.

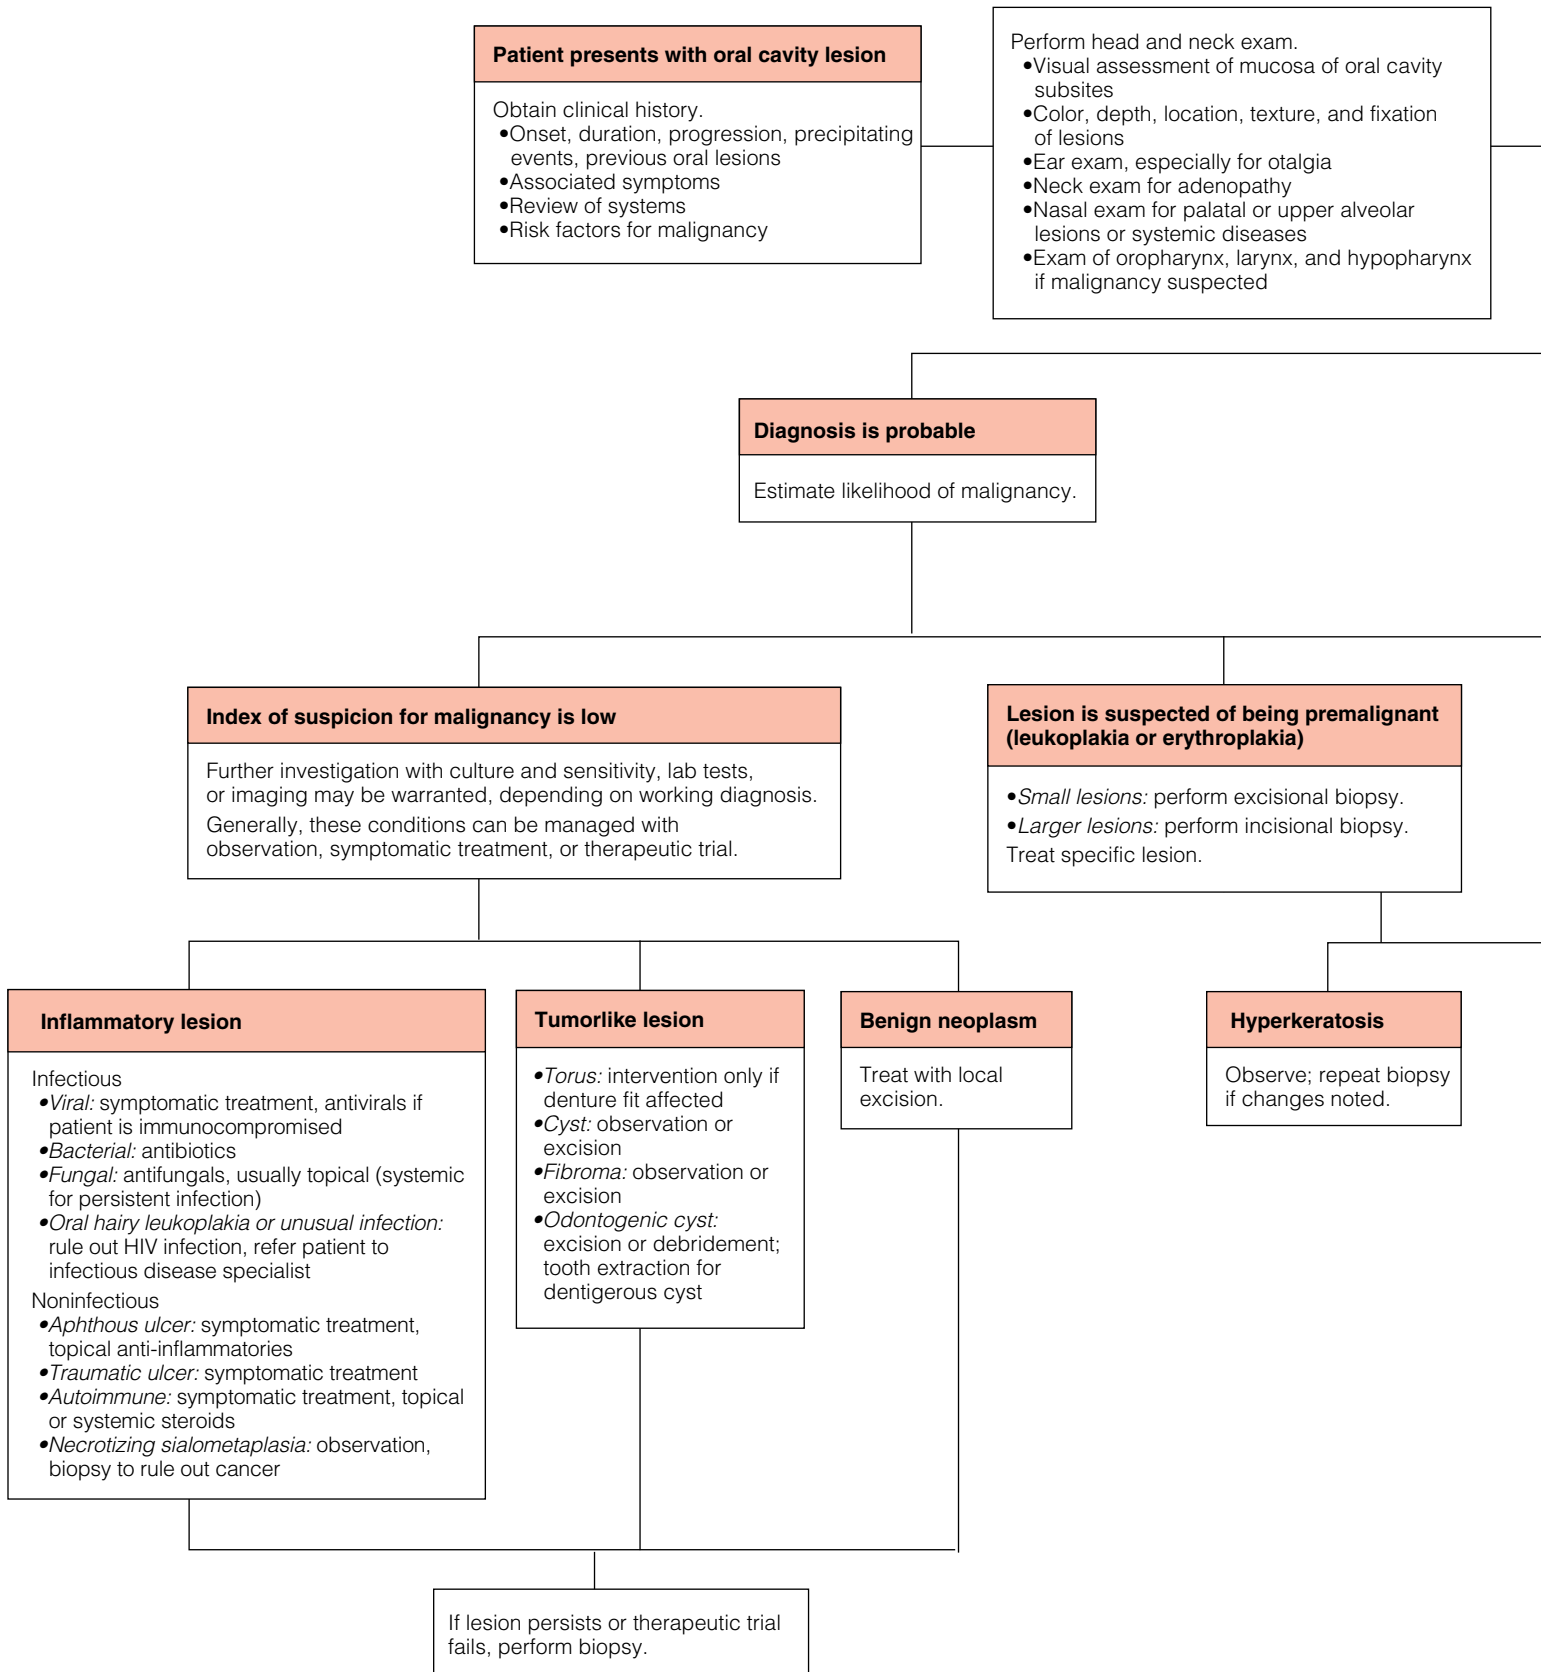

Oral lesions should be characterized in terms of color, depth, location, texture, fixation, and other applicable attributes. When cancer is present, tenderness, induration, and fixation are common. Invasion of surrounding structures (e.g., the mandible, the parotid duct, or the teeth) by a malignant lesion should be noted. Physical examination is not a definitive means of detecting mandibular invasion, because tumor fixation can be secondary to other factors and cortical invasion can occur with minimal fixation.² In addition, lesions in some areas of the oral cavity (e.g., the hard palate and the attached gingiva) almost always appear to be fixed.

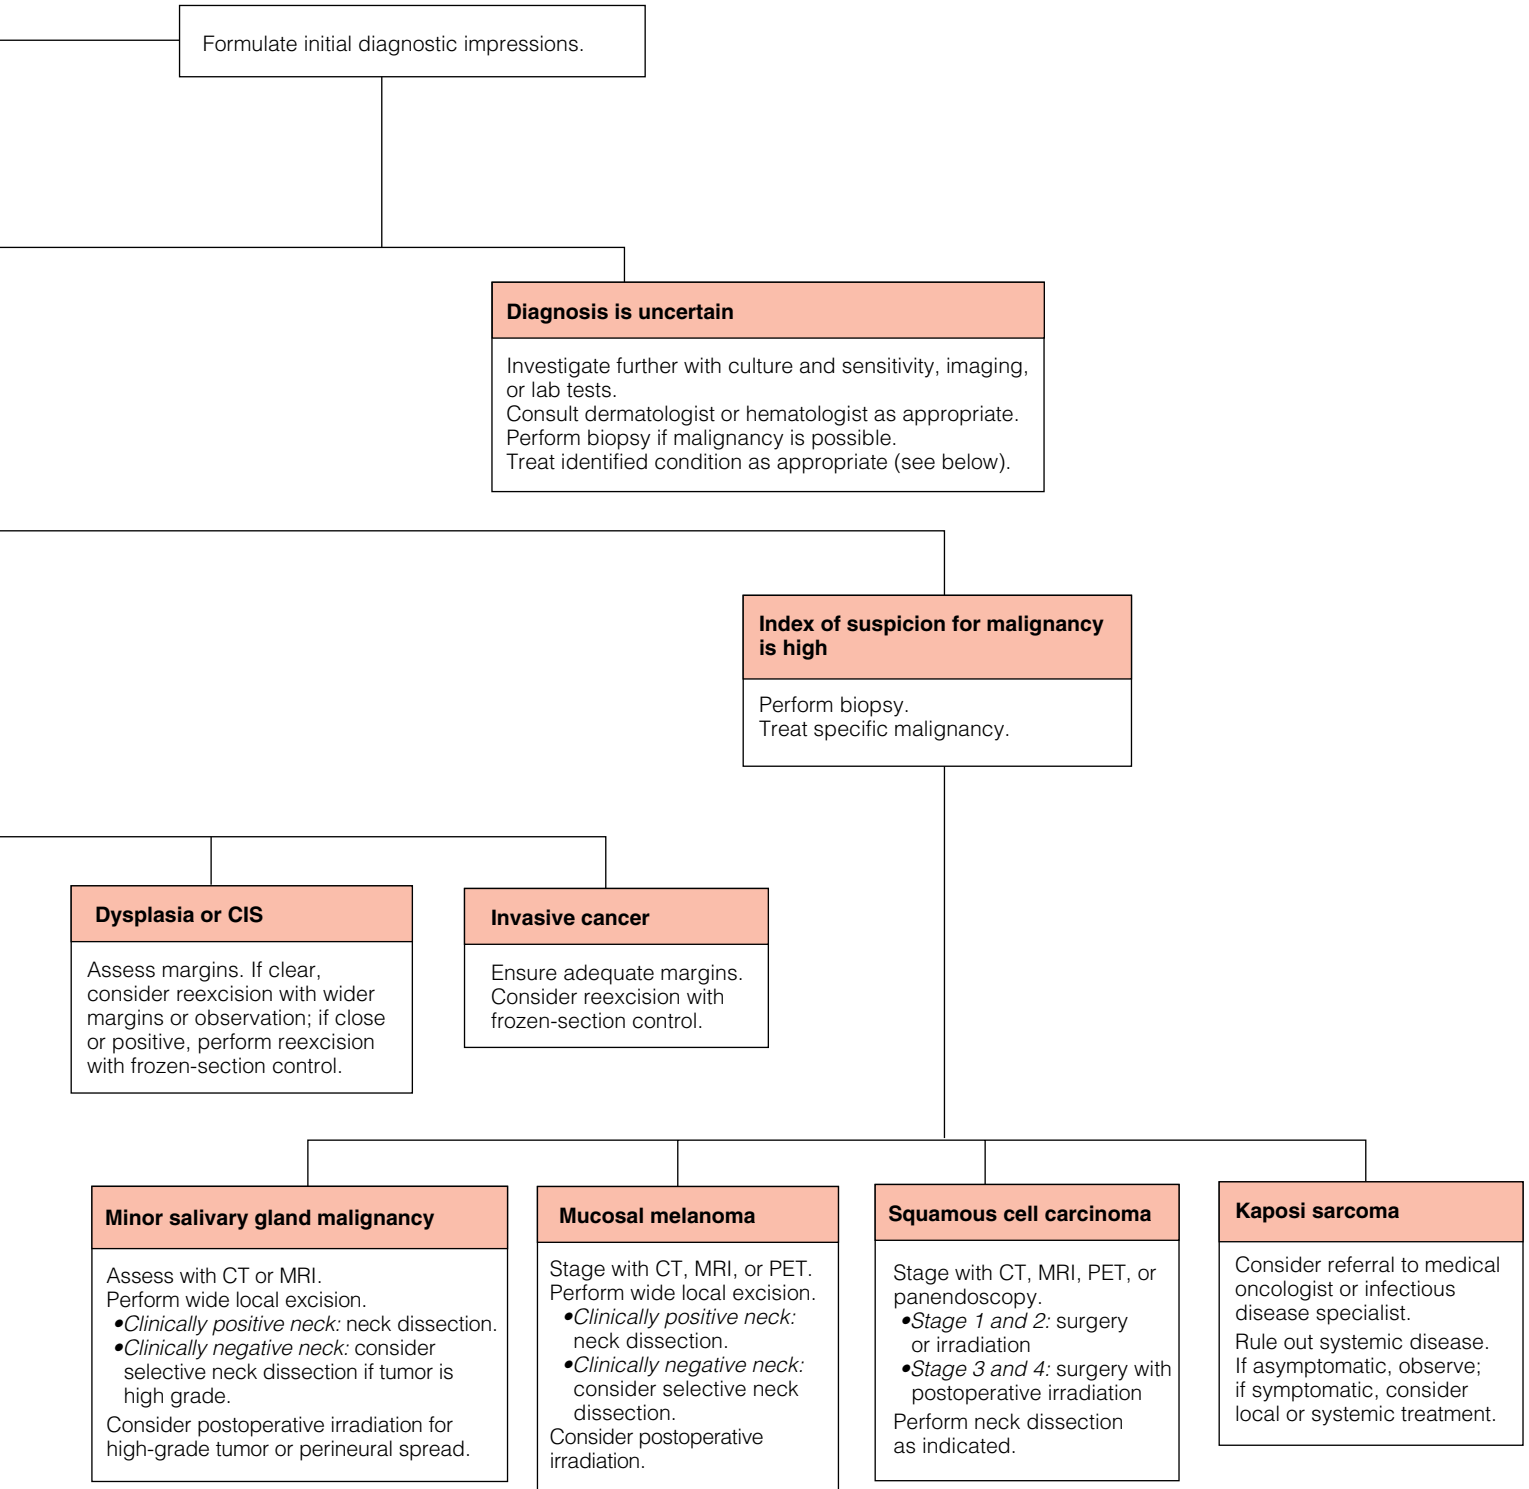

A history of otalgia warrants otoscopic examination. Otalgia in the absence of any identifiable pathologic condition of the ear often represents referred pain from a malignancy of the upper aerodigestive tract. The presence of otalgia in a middle-aged person should always trigger a search for an underlying cause. The nasal cavity should be examined with a speculum to rule out tumor extension in lesions of the hard palate, and transnasal fiberoptic pharyngoscopy and laryngoscopy should be done if a malignant neoplasm is a possibility or if a systemic condition is suspected that may also affect the nasal or pharyngeal mucosa.

Examination of the neck may reveal enlarged lymph nodes. Lymphadenopathy in an adult should be considered to represent metastatic cancer until proved otherwise. A benign ulcer in the oral cavity may cause a reactive adenopathy as a consequence of

Approach to Oral Cavity Lesions

the associated inflammation, but in the setting of cervical lymphadenopathy, the initial diagnostic assumptions should emphasize the strong possibility of a primary oral cancer with metastases to the neck. Asymmetrical enlargement of the parotid or submandibular glands may result either from obstruction of the ducts by an oral cavity mass or from enlargement of nodes intimately associated with the glands. Symmetrical enlargement suggests a systemic process (e.g., Sjögren syndrome or HIV infection). The

Figure 1 Depicted are the major anatomic subsites of the oral cavity.

cranial nerves should be examined, with particular attention focused on the trigeminal, facial, and hypoglossal nerves.

Investigative Studies

The history and physical examination should narrow down the differential diagnosis and lead to a working diagnosis. If a benign local process (e.g., aphthous stomatitis, traumatic ulcer, or viral infection) is suspected, no further investigation, other than reevaluation, may be needed. If the lesion persists or progresses, further investigation is warranted.

LABORATORY TESTS

Laboratory studies are usually not beneficial in the initial workup of oral cavity lesions. If a connective tissue disease is suspected, serologic tests [see Table 2] and referral to a rheumatologist or another appropriate specialist may be considered.

IMAGING

The value of advanced imaging with computed tomography, magnetic resonance imaging, or both in the management of oral cavity lesions has not been firmly established. Accordingly, judgment must be exercised. There is evidence to suggest that early oral cavity malignancies can be managed without either CT or MRI. Nevertheless, many clinicians obtain these studies in all

cases of malignancy and in most cases of suspected malignancy. CT and MRI can help assess the size and location of the lesion and determine the degree to which surrounding structures are involved. In patients with oral cavity carcinoma, imaging facilitates the staging of tumors and the planning of treatment. In patients with cervical metastases, physical examination augmented by MRI and CT has a better diagnostic yield than physical examination alone. Bone-window CT scans are particularly helpful for assessing invasion of the mandible, the maxilla, the cervical spine, and the base of the skull. CT scans are highly sensitive and specific for detecting mandibular invasion.^{2,3} MRI provides better soft tissue delineation than CT, with fewer dental artifacts, and therefore is particularly valuable for assessing malignancies of the tongue, the floor of the mouth, and the salivary glands. Loss of the usual marrow enhancement on T₁-weighted MRI images suggests bone invasion, though this is not a specific finding. Chest x-ray, CT, or both may be employed to search for lung metastases or a second primary tumor.

Positron emission tomography (PET) is playing an increasingly important role in the workup of patients with head and neck carcinoma or mucosal melanoma. PET is useful for confirming the presence of a malignancy, as well as for assessing cervical and distant metastases⁴⁻⁶; it is particularly valuable for detecting recurrent or persistent disease.⁷ Drawbacks include frequent false positive results with active inflammation, high cost, and limited availability. In addition, the quality of the PET images obtained and the level of technical experience available vary considerably among institutions. Although broad guidelines have been developed for certifying physicians in the use of PET, the specific expertise needed for optimal imaging of the complexities of the head and neck is not easily acquired.

BIOPSY

For oral cavity lesions that are suggestive of malignancy or are probably of neoplastic origin, biopsy is usually required. A brief observation period to allow reevaluation, with biopsy withheld, may be warranted if a response to therapy or spontaneous resolution is possible. The potential morbidity associated with a biopsy done in a previously irradiated region should be considered in deciding whether biopsy is advisable. Specimens are usually sent to the pathologist in 10% buffered formalin, but there are notable exceptions. If a lymphoma is suspected, specimens should be sent without formalin for genetic testing and flow cytometry. If an autoimmune disease is suspected, special tests requiring immunofluorescence are indicated, and specimens should be sent either fresh or in Michel solution. In addition, if fungal, mycobacterial,

bacterial, or viral infection is suspected, a small portion of a specimen may be sent separately for culture. If there is an associated neck mass [see 2:3 Neck Mass], fine-needle aspiration (FNA) may be performed to rule out metastatic disease. In general, FNA is not useful for biopsy of oral lesions: incisional biopsy is often technically easier and provides more tissue.

EXAMINATION UNDER ANESTHESIA AND PANENDOSCOPY

In patients with oral carcinoma, examination under anesthesia (EUA) and panendoscopy may be performed either before or during operation to assess the extent of the primary tumor and identify any synchronous tumors. Both EUA and panendoscopy are commonly performed in the operating room with the patient under general anesthesia. Panendoscopy involves endoscopic examination of the larynx, the oropharynx, the hypopharynx, the esophagus, and, occasionally, the nasopharynx. As a rule, assessment of the tumor and neck is more accurately performed when the patient is relaxed under a general anesthetic. With improved imaging techniques and the wider availability of office endoscopes, the role of panendoscopy is decreasing.

Diagnosis and Management of Specific Oral Cavity Lesions

INFLAMMATORY LESIONS

Infectious

Viral stomatitis may be caused by a number of different viruses, including herpes simplex virus (type 1 or type 2), varicella-zoster virus, and coxsackievirus [see Figures 2a and 2b].⁸ It is most common in children and immunocompromised patients. The lesions of viral stomatitis are generally vesicular, occur in the oral cavity and the oropharynx, and erupt over the course of several days to form painful ulcers. Eruption may be preceded by local symptoms (e.g., burning, itching, or tingling) or systemic symptoms (e.g., fever, rash, malaise, or lymphadenopathy). The diagnosis is usually established by the history and the physical examination and may be confirmed by means of biopsy or viral culture.

Treatment of viral stomatitis primarily involves managing symptoms with oral rinses, topical anesthetics, hydration, and antipyretics. Systemic antiviral medications may shorten the course of herpetic stomatitis and are indicated in immunocompromised patients.⁹

Candidiasis is a common fungal infection of the oral cavity [see Figures 2c and 2d]. *Candida albicans* is the species most commonly responsible; however, other *Candida* species can cause this condition as well, with *C. glabrata* emerging as a growing problem in immunocompromised hosts. Factors predisposing to oral candidal infection include immunosuppression, use of broad-spectrum antibiotics, diabetes, prolonged use of local or systemic steroids, and xerostomia.¹⁰ Oral candidiasis presents in several different forms [see Table 3], of which pseudomembranous candidiasis (thrush) is the most common. This form is characterized by white, curdlike plaques on the oral mucosa that may be wiped off (with difficulty) to leave an erythematous, painful base (the Auspitz sign). Widespread oral and pharyngeal involvement is common. The diagnosis is based on the clinical appearance of the lesion and on evaluation of scrapings with the potassium hydroxide (KOH) test. Culture is generally not useful, because *Candida* is a common commensal oral organism.¹¹

Ideally, initial management of oral candidiasis is aimed at

Table 2 Serologic Tests for Diagnosing Connective Tissue Disease

Connective Tissue Disease	Serologic Tests
SLE	CBC, antinuclear antibody, anti-double-stranded DNA antibody, anti-Smith antibody
Sjögren syndrome	Antinuclear antibody, rheumatoid factor, anti-Ro (SS-A), and anti-La (SS-B) antibodies
Wegener granulomatosis	cANCA, serum creatinine level, urine microscopy
Sarcoidosis	Serum calcium and ACE levels

ACE—angiotensin-converting enzyme cANCA—cytoplasmic antineutrophil cytoplasmic antibodies CBC—complete blood count SLE—systemic lupus erythematosus

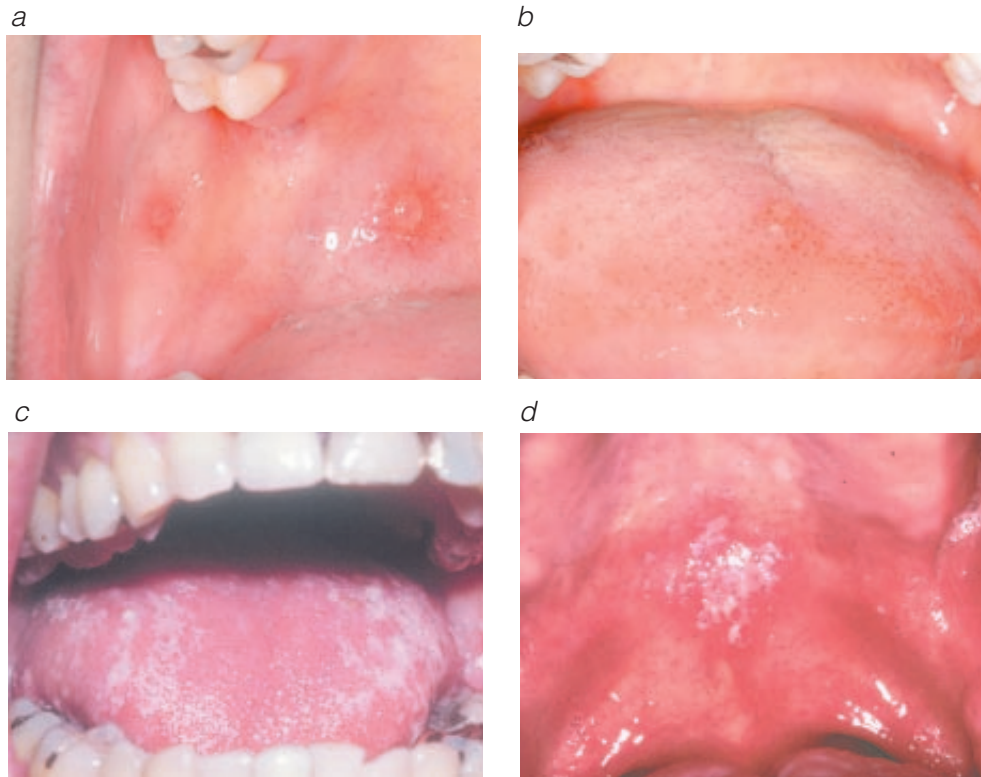

Figure 2 Shown are infectious lesions of the oral cavity: (a) primary herpes stomatitis of the buccal mucosa and soft palate; (b) primary herpes stomatitis of the tongue (in the same patient as in frame a); (c) oral candidiasis (pseudomembranous form); and (d) oral candidiasis (erythematous form).

reversing the underlying condition, though this is not always possible. Treatment typically involves either topically administered antifungal agents or, if infection is severe or topical therapy fails, systemically administered antifungals. Patients who are immunocompromised or have xerostomia may benefit from long-term prophylaxis.

Noninfectious

Recurrent aphthous stomatitis Aphthous stomatitis is a common idiopathic ulcerative condition of the oral cavity [see Figures 3a and 3b]. The ulcers are typically painful and may occur anywhere in the oral cavity and the oropharynx but are rarely found on the hard palate, the dorsal tongue, and the attached gingiva.⁹ Affected patients often have a history of lesions, beginning before adolescence. There are three different clinical presentations of recurrent aphthous stomatitis, of which minor aphthous

ulcers are the most common [see Table 4].⁹ The diagnosis is made on the basis of the history and the physical examination; biopsy is reserved for lesions that do not heal or that grow in size.

Numerous therapies have been tried for recurrent aphthous stomatitis, most with only minimal success. The majority of aphthous ulcers heal within 10 to 14 days and require no treatment; however, patients with severe symptoms may require medical intervention. Temporary pain relief can be obtained with topical anesthetic agents (e.g., viscous lidocaine). Tetracycline oral suspension and antiseptic mouthwashes have also been used, with varying success.⁹ Topical steroids are the mainstay of therapy and may shorten the duration of the ulcers if applied during the early phase.¹¹ These agents may be applied either in a solution (e.g., dexamethasone oral suspension, 0.5 mg/5 ml) or in an ointment (e.g., fluocinolone or clobetasol). Ointments work much better in the oral cavity than creams or gels do. Systemic steroids are indicated when the number of ulcers is large or when the outbreak has persisted for a long time.

Table 3 Clinical Presentation of Oral Candidiasis

Type of Oral Candidiasis	Presentation
Pseudomembranous	White, curdlike plaques on oral mucosa that when wiped off (with difficulty) leave erythematous, painful base
Hyperplastic	Thick white plaques on oral mucosa that cannot be rubbed off
Erythematous	Red, atrophic areas on palate or dorsum of tongue
Angular cheilitis	Cracking and fissuring at oral commissures

Necrotizing sialometaplasia Necrotizing sialometaplasia is a rare benign inflammatory lesion of the minor salivary glands that resembles carcinoma clinically and histologically and is readily mistaken for it [see Figure 3c].¹² This condition most commonly develops in white males in the form of a deep, sudden ulcer of the hard palate. The presumed cause is ischemia of the minor salivary glands resulting from infection, trauma, surgery, irradiation, or irritation caused by ill-fitting dentures.⁹ Biopsy is usually necessary to rule out squamous cell carcinoma or a minor salivary gland malignancy. Review of the tissue by a pathologist well versed in head and neck pathology is essential. Characteristic histologic findings include coagulation necrosis of the salivary gland acini,

Figure 3 Shown are noninfectious inflammatory lesions of the oral cavity: (a) minor aphthous ulcer of the lower lip; (b) minor aphthous ulcer of the upper lip; (c) necrotizing sialometaplasia of the hard palate; (d) resolution of necrotizing sialometaplasia without treatment (in the same patient as in frame c); (e) pyogenic granuloma of the upper alveolus; (f) reticular lichen planus involving the buccal mucosa; (g) lichen planus of the lateral tongue; (h) pemphigus vulgaris of the oral cavity, with an erythematous base after rupture of bullae (involving the left lateral tongue, the buccal mucosa, and the lip); and (i) traumatic ulcer of the tongue secondary to dental trauma.

ductal squamous metaplasia, preservation of the lobular architecture, and a nonmalignant appearance of squamous nests.^{12,13}

Lesions resolve without treatment within 6 to 10 weeks [see Figure 3d].

Pyogenic granuloma A pyogenic granuloma is an aggregation of proliferating endothelial tissue [see Figure 3e] that occurs in response to chronic persistent irritation (e.g., from a calculus or a foreign body) or trauma.¹⁰ The lesion appears as a raised, soft, sessile or pedunculated mass with a smooth, red surface that bleeds easily and can grow rapidly.¹⁴ Surface ulceration may occur, but the ulcers are not invasive. The gingiva is the most common location, but any of the oral tissues may be involved.

Conservative excision with management of the underlying irri-

tant is the recommended treatment. The classic presentation is in a pregnant woman, and hormonal influences may have an additional influence on recurrence.

Lichen planus Lichen planus is a common immune-mediated inflammatory mucocutaneous disease [see Figures 3f and 3g].¹⁵ Clinically, idiopathic lichen planus is indistinguishable from lichenoid drug reaction. The reticular form of lichen planus is the most common one and presents as interlacing white keratotic striae on the buccal mucosa, the lateral tongue, and the palate.¹⁵ Lichen planus is usually bilateral, symmetrical, and asymptomatic.¹⁶ The symptomatic phases may wax and wane, with erythematous and ulcerative changes being the primary signs. Cutaneous lesions occur less frequently and appear as small, violaceous, pru-

ritic papules. The diagnosis is generally made on the basis of the history and the physical examination; biopsy is not always necessary.

For asymptomatic lesions, no treatment is required other than observation.¹⁷ For painful lesions, which are more common with the erosive form of the disease, either topical or systemic steroids are appropriate.¹⁷ There is some controversy regarding the risk of malignant transformation; however, long-term follow-up is still recommended.^{16,18} The main risk posed by lichen planus may be the masking effect that the white striae cause, which can prevent the clinician from observing the early leukoplakic and erythroplakic changes associated with epithelial dysplasia.

Ulcer from autoimmune disease Oral ulcers may be the first manifestation of a systemic illness. The most common oral manifestation of systemic lupus erythematosus (SLE) is the appearance of painful oral ulcers in women of childbearing age. Patients with Behçet disease present with the characteristic triad of painful oral ulcers, genital ulcers, and associated iritis or uveitis. Patients with Crohn disease or Wegener granulomatosis frequently manifest oral ulceration during the course of the illness. These disorders should be managed in conjunction with a rheumatologist.

Mucous membrane pemphigoid and pemphigus vulgaris are chronic vesiculobullous autoimmune diseases that frequently affect the oral mucosa [see Figure 3h]. In mucous membrane pemphigoid, the antibodies are directed at the mucosal basement membrane, resulting in subepithelial bullae.¹⁶ These bullae rupture after 1 to 2 days to form painful ulcers, which may heal over a period of 1 to 2 weeks but often do not display a predictable periodicity. Oral pain is often the chief complaint, but there may be undetected ocular involvement that can lead to entropion and blindness.

Pemphigus vulgaris is a more severe disease than mucous membrane pemphigoid. In this condition, the antibodies are directed at intraepithelial adhesion molecules, leading to the formation of intraepithelial bullae.⁹ The blisters are painful and easily ruptured and tend to occur throughout the oral cavity and the pharynx.¹⁹ The Nikolsky sign (i.e., vesicle formation or sloughing when a lateral shearing force is applied to uninvolved oral mucosa or skin) is present in both pemphigus and pemphigoid. In most cases, biopsy with pathologic evaluation (including immunofluorescence studies) is

helpful in establishing the diagnosis. Circulating antibodies may be present in either condition but are more common in pemphigus. Serologic tests may suffice to establish the diagnosis, without any need for biopsy. Management involves administration of immunosuppressive agents, often in conjunction with a dermatologist.

Traumatic ulcer Trauma (e.g., from tooth abrasion, tooth brushing, poor denture fit, or burns) is a common cause of oral mucosal ulceration [see Figure 3i]. The ulcers usually are painful but typically are self-limited and resolve without treatment. Topical anesthetic agents may be beneficial if pain is severe enough to limit oral intake.

Tumorlike Lesions

TORUS MANDIBULARIS AND TORUS PALATINUS

Palatal and mandibular tori are benign focal overgrowths of cortical bone [see Figures 4a and 4b].¹⁰ They appear as slow-growing, asymptomatic, firm, submucosal bony masses developing on the lingual surface of the mandible or the midline of the hard palate.¹⁴ When these lesions occur on the labial or buccal aspect of the mandible and the maxilla, they are termed exostosis.²⁰ Torus mandibularis tends to occur bilaterally, whereas torus palatinus arises as a singular, often lobulated mass in the midline of the hard palate. Surgical management is required only if the tori are interfering with denture fit.

MUCOCELE AND MUCOUS RETENTION CYST

A mucocele is a pseudocyst that develops when injury to a minor salivary gland duct causes extravasation of mucous, surrounding inflammation, and formation of a pseudocapsule [see Figures 4c and 4d].¹⁴ Mucoceles are soft, compressible, bluish or translucent masses that may fluctuate in size. They are most commonly seen on the lower lip but also may develop on the buccal mucosa, anterior ventral tongue, and floor of the mouth. Only very rarely do they involve the upper lip; masses in the upper lip, even if they are fluctuant, should be assumed to be neoplastic, developmental, or infectious. Treatment involves excision of the mucocele and its associated minor salivary gland.

A ranula (from a diminutive form of the Latin word for frog) is a mucocele that develops in the floor of the mouth as a consequence of obstruction of the sublingual duct,¹⁶ secondary either to trauma or to sublingual gland sialoliths. If the ranula extends through the mylohyoid muscle into the neck, it is referred to as a plunging ranula. A plunging ranula may present as a submental or submandibular neck mass. Imaging helps delineate the extent of the mass and may confirm the presence of a sialolith. The recommended treatment is excision of the ranula with removal of the sublingual gland and often the adjacent submandibular gland. Marsupialization is an option but is associated with a relatively high recurrence rate.²¹

A mucous retention cyst (salivary duct cyst) is usually the result of partial obstruction of a salivary gland duct accompanied by mucous accumulation and ductal dilatation [see Figure 4e].²¹ It is a soft, compressible mass that may occur at any location in the oral cavity where minor salivary glands are present. Treatment involves surgical excision with removal of the associated minor salivary gland.

FIBROMA

A fibroma is a hyperplastic response to inflammation or trauma [see Figures 4f and 4g].²² It is a pedunculated soft or firm mass

Table 4 Clinical Presentation of Aphthous Stomatitis

Type of Aphthous Ulcer	Presentation	Time to Resolution
Minor	Multiple painful, well-demarcated ulcers, < 1.0 cm in diameter, are noted, with yellow fibrinoid base and surrounding erythema; typically involve mobile mucosa, with tongue, palate, and anterior tonsillar pillar the most common sites	7–10 days, without scarring
Major (Sutton disease)	Ulcers, often multiple, may range in size from a few millimeters to 3 cm and may penetrate deeply with elevated margins; typically involve mobile mucosa, with tongue, palate, and anterior tonsillar pillar the most common sites	4–6 wk, with scarring
Herpetiform	Small (1–3 mm) ulcers occur in "crops" but are still limited to movable mucosal surfaces; gingival involvement, if present, is caused by extension from nonkeratinizing crevicular epithelium	1–2 wk

Figure 4 Shown are tumorlike lesions of the oral cavity: (a) torus mandibularis, with bilateral bony protuberances on the lingual surface of the mandible; (b) mandibular exostosis, with a unilateral bony protuberance on the labial-buccal surface of the mandible; (c) mucocele of the lip (note the bluish hue of the cystic lesion; cf. frame e); (d) mucocele of the floor of the mouth associated with the sublingual gland (ranula); (e) mucous retention cyst of the lower lip (presenting much like mucocele, but appearing more transparent); (f) fibroma of the hard palate resulting from denture trauma; (g) fibroma of the lower lip; and (h) dentigerous cyst (a unilocular radiolucency surrounding the crown of an unerupted tooth, with no bone destruction).

with a smooth mucosal surface that may be located anywhere in the mouth. Such lesions are managed with either observation or local excision.

ODONTOGENIC CYST

A dentigerous cyst is an epithelium-lined cyst that, by definition, is associated with the crown of an unerupted tooth [see *Figure 4h*]. Such cysts cause painless expansion of the mandible or the maxilla. Treatment involves enucleation of the cyst and its lining and extraction of the associated tooth.²³

An odontogenic keratocyst is a squamous epithelium-lined cyst that produces keratin. Bone resorption occurs secondary to

pressure resorption and to inflammation caused by retained keratin. Management involves either excision or debridement and creation of a well-ventilated and easily maintained cavity.²⁴

Neoplastic Lesions

BENIGN

Squamous Papilloma

Squamous papilloma is one of the most common benign neoplasms of the oral cavity [see *Figures 5a and 5b*].¹³ It usually presents as a solitary, slow-growing, asymptomatic lesion, typically

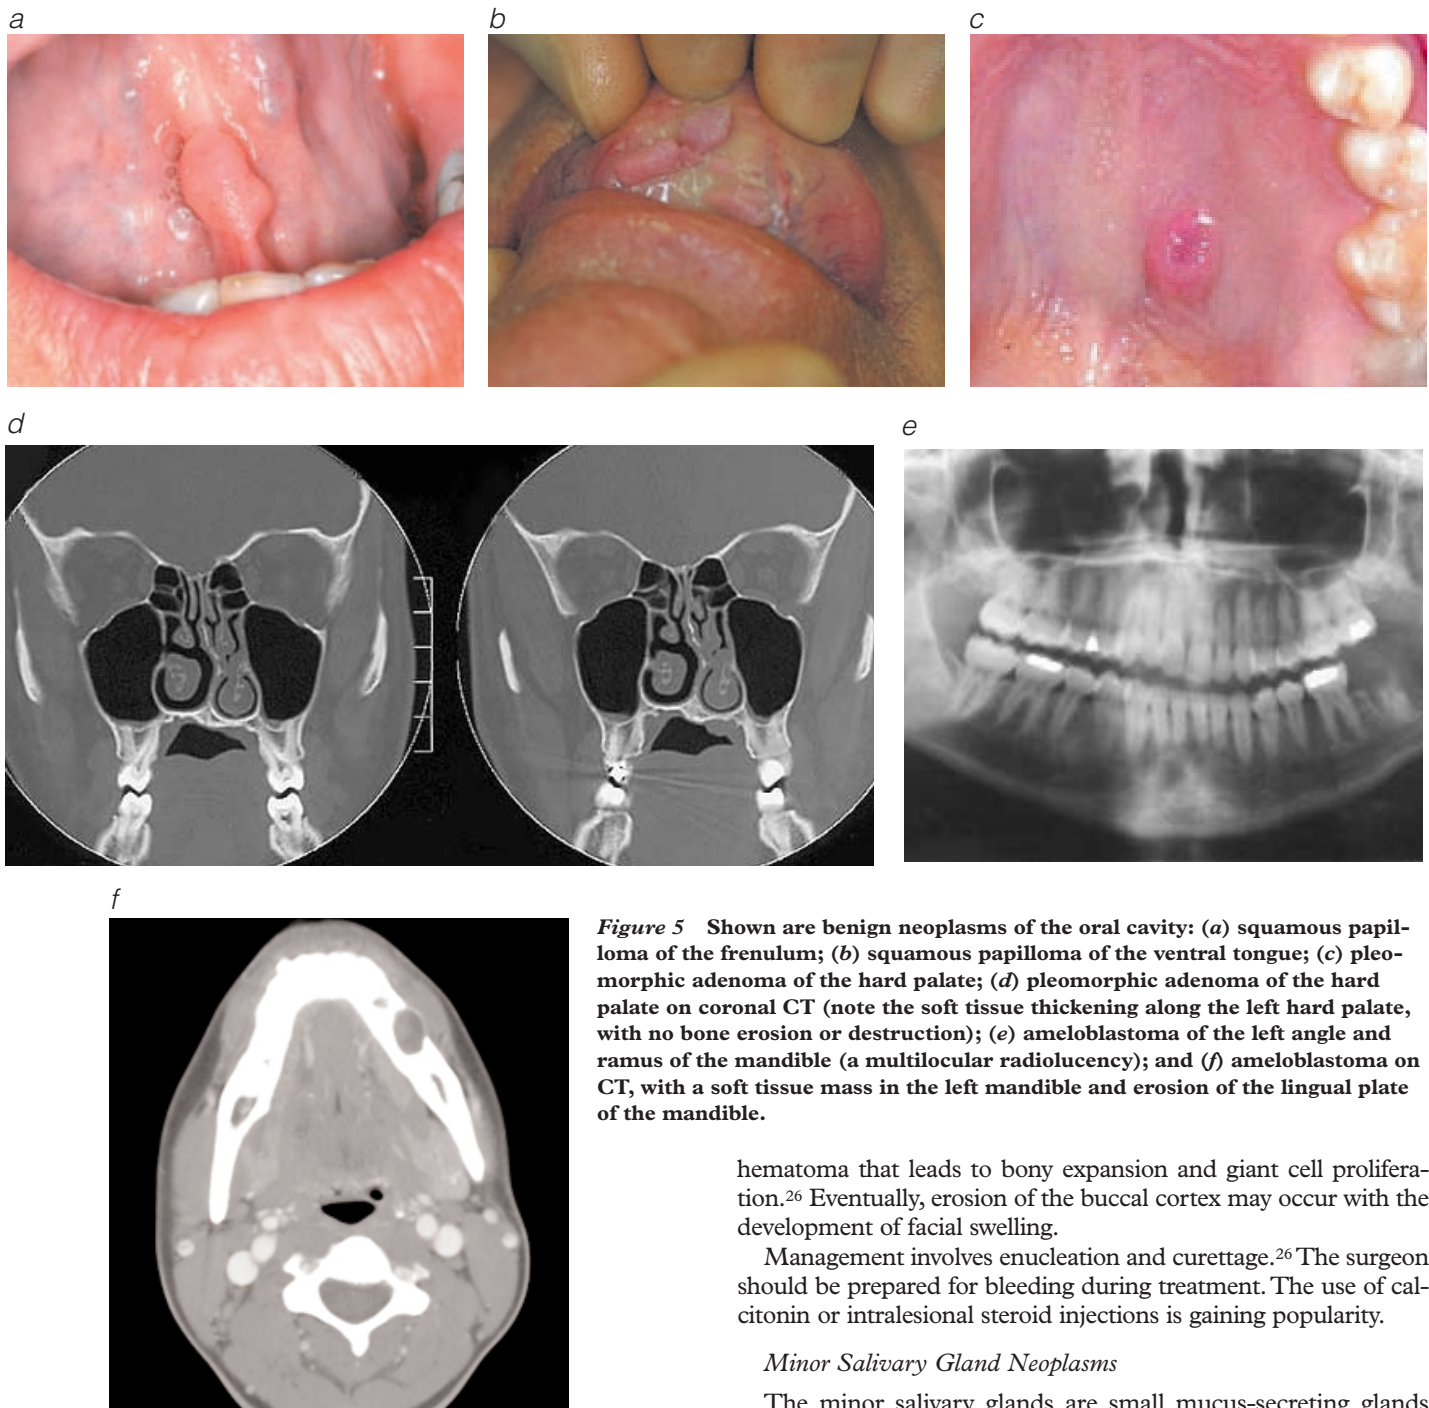

Figure 5 Shown are benign neoplasms of the oral cavity: (a) squamous papilloma of the frenulum; (b) squamous papilloma of the ventral tongue; (c) pleomorphic adenoma of the hard palate; (d) pleomorphic adenoma of the hard palate on coronal CT (note the soft tissue thickening along the left hard palate, with no bone erosion or destruction); (e) ameloblastoma of the left angle and ramus of the mandible (a multilocular radiolucency); and (f) ameloblastoma on CT, with a soft tissue mass in the left mandible and erosion of the lingual plate of the mandible.

less than 1 cm in diameter. It is well circumscribed and pedunculated and has a warty appearance.¹⁶ The palate and tongue are the sites most frequently affected¹³; occasionally, multiple sites are involved. The presumed cause is a viral infection, most likely human papillomavirus.²⁵

Papillomas are managed with complete excision, including the base of the stalk.

Giant Cell Lesions

Central giant cell granulomas, brown tumors of hyperparathyroidism, aneurysmal bone cysts, and lesions associated with genetic diseases (e.g., cherubism) may all be seen in the jaws. Of particular note is the aneurysmal bone cyst that may occur at sites of trauma, which, in theory, is the consequence of an organizing

hematoma that leads to bony expansion and giant cell proliferation.²⁶ Eventually, erosion of the buccal cortex may occur with the development of facial swelling.

Management involves enucleation and curettage.²⁶ The surgeon should be prepared for bleeding during treatment. The use of calcitonin or intralesional steroid injections is gaining popularity.

Minor Salivary Gland Neoplasms

The minor salivary glands are small mucus-secreting glands that are distributed throughout the upper aerodigestive tract, with the largest proportion concentrated in the oral cavity. Minor salivary gland neoplasms are uncommon, but when they do occur, they are most likely to develop in the oral cavity. Within the oral cavity, the hard palate and the soft palate are the most common sites of minor salivary gland neoplasms; however, tumors involving the tongue, the lips, the buccal mucosa, and the gingivae have been described. Approximately 30% of minor salivary gland neoplasms are benign. Of these benign lesions, the most common is pleomorphic adenoma, which presents as a painless, slow-growing submucosal mass [see Figures 5c and 5d].^{13,27}

Pleomorphic adenoma is managed with complete surgical excision to clear margins. This tumor exhibits small pseudopodlike extensions that may persist and cause recurrence if enucleation around an apparent capsule is attempted.

Granular Cell Tumor

A granular cell tumor is a benign neoplasm that is thought to arise from Schwann cells.¹³ It usually presents as a small, asymptomatic, solitary submucosal mass. The lateral border and the dorsal surface of the tongue are the sites where this tumor is most frequently found in the oral cavity.²⁸ Pathologic examination may reveal pseudoepitheliomatous hyperplasia, which is similar in appearance to well-differentiated squamous cell carcinoma.²⁹ This similarity has led to reports of misdiagnosis on histopathologic evaluation. Accordingly, given the known rarity of squamous cell carcinoma of the dorsal surface of the anterior two thirds of the tongue, it may be prudent to obtain a second histopathologic opinion whenever a diagnosis of squamous cell carcinoma is rendered in this location. Treatment consists of conservative excision.²⁸

Ameloblastoma

Ameloblastoma is a neoplasm that arises from odontogenic (dental) epithelium, most frequently in the third and fourth decades of life [see Figures 5e and 5f].²² It often presents as a painless swelling with bony enlargement. Approximately 80% of ameloblastomas involve the mandible and 20% the maxilla³⁰; the mandibular ramus is the most common site.³⁰ Ameloblastomas are usually benign but are often locally aggressive and infiltrative. Malignant ameloblastomas are rare but are notable for being associated with pain, rapid growth, and metastases.¹¹

On CT and panoramic jaw films, ameloblastomas typically appear as multilocular radiolucent lesions with a honeycomb appearance and scalloped borders.³¹ These tumors are often associated with an unerupted third molar tooth and, with the exception of the desmoplastic variant, rarely appear radiopaque. They may also appear unilocular on radiographic imaging.³² Histologic examination shows proliferating odontogenic epithelium with palisading peripheral cells that display reverse polarization of the nuclei.¹³

Appropriate management of ameloblastomas involves resection to clear margins. For mandibular ameloblastomas, either a marginal or a segmental mandibulectomy is done, depending on the relation of the lesion to the inferior cortical border. Curettage is associated with a high recurrence rate.³³ The prognosis for maxillary multicystic ameloblastoma is relatively poor because of the higher recurrence rate and the greater frequency of invasion of local adjacent structures (e.g., the skull base).³⁴

Most types of mesenchymal neoplasms may be found also in the oral region. Benign mesenchymal neoplasms known to occur in the oral cavity include (but are not limited to) hemangiomas, lipomas, schwannomas, neuromas, and neurofibromas. These are relatively rare lesions but should nonetheless be included in the differential diagnosis of intraoral masses. The diagnosis is usually made on the basis of histopathologic examination of biopsy specimens. Benign bone tumors, though uncommon, are not unknown. Chondromas, hemangiomas, ossifying fibromas, and osteomas may all present as intraoral masses with bony expansion and normal overlying mucosa.

PREMALIGNANT

Leukoplakia

Leukoplakia is defined by the World Health Organization as a whitish patch or plaque that cannot be characterized clinically or pathologically as any other disease and that is not associated with any physical or chemical causative agent

(except tobacco).³⁵ It is often considered a potentially premalignant lesion. Leukoplakic lesions vary in size, shape, and consistency; there is usually no relationship between morphologic appearance and histologic diagnosis. Histologic examination may reveal hyperkeratosis, dysplasia, carcinoma in situ (CIS), or invasive squamous cell carcinoma, or other pathologic processes.¹⁶ Dysplasia occurs in as many as 30% of leukoplakic lesions.⁸ Whereas a small percentage of lesions show invasive squamous cell carcinoma on pathologic examination,¹⁴ 60% of oral mucosa carcinomas present as white, keratotic lesions.¹⁶

All leukoplakic lesions should undergo biopsy. For small areas of leukoplakia, excisional biopsy is usually appropriate. For larger lesions, incisional biopsy is generally preferable: it is important to obtain an adequate-size biopsy specimen, in that varying degrees of hyperplasia and dysplasia may occur within the same specimen. Hyperkeratotic lesions may be followed on a long-term basis, with rebiopsy performed if there are any changes in size or appearance. Lesions characterized by dysplasia and CIS should be completely excised to clear margins when possible.

Erythroplakia

Erythroplakia is defined as a red or erythematous patch of the oral mucosa. It is associated with significantly higher rates of dysplasia, CIS, and invasive carcinoma than leukoplakia is.⁸ Erythroplakia is managed in much the same fashion as leukoplakia, with biopsy performed to rule out a malignant or premalignant lesion. Complete surgical excision is indicated if either a malignancy or a premalignancy is confirmed, and frequent follow-up is necessary.

MALIGNANT

Minor Salivary Gland Malignancies

The majority (60% to 70%) of minor salivary gland neoplasms are malignant, with adenoid cystic carcinoma, mucoepidermoid carcinoma, and adenocarcinoma [see Figure 6a] being the most commonly encountered cancers.^{27,36} As with benign minor salivary gland neoplasms, the hard and soft palates are the most common sites.³⁶

A minor salivary gland malignancy usually appears as a painless, slow-growing intraoral mass.³⁷ Nodal involvement at presentation is uncommon.²⁷ Treatment usually involves surgical excision; adequate margins should be obtained with frozen-section control. Because these malignancies—particularly adenoid cystic carcinoma and polymorphous low-grade adenocarcinoma—have a propensity for perineural spread, frozen-section analysis of the nerves within the field of resection is usually obtained at the time of operation. If perineural spread occurs, postoperative irradiation is usually indicated, and distant metastases are likely to develop despite surgery and locoregional radiotherapy. As a result, it is usually best to limit the extent of the operation if major morbidity is anticipated from a radical resection.

Neck dissection is warranted in the treatment of minor salivary gland malignancies only if there is clinical or radiographic evidence of cervical metastases. Postoperative irradiation is indicated for most patients with high-grade malignancies, positive or close surgical margins, cervical metastases, or pathologic evidence of perineural spread or bone invasion.³⁷ Studies suggest that postoperative radiotherapy allows improved local control and may lead to longer disease-free survival.^{38,39}

Local recurrence and distant metastases are common, often

Figure 6 Shown are malignant lesions of the oral cavity: (a) polymorphous low-grade adenocarcinoma of the hard palate (raised, erythematous lesion); (b) extensive squamous cell carcinoma of the tongue, the alveolar ridge, and the floor of the mouth; (c) squamous cell carcinoma of the right floor of the mouth, with mandibular invasion on CT scan; (d) squamous cell carcinoma of the lip (ulcerative lesion); (e) squamous cell carcinoma of the floor of the mouth (exophytic lesion); (f) squamous cell carcinoma of the hard palate; and (g) squamous cell carcinoma of the retro-molar trigone.

developing many years later; regional recurrence is uncommon.³⁶ The survival rate for adenoid cystic carcinoma is relatively high (approximately 80%) at 5 years but decreases dramatically over the subsequent 10 to 15 years.^{36,40} Various factors predictive of poor survival have been identified [see Table 5].⁴⁰

Mucosal Melanoma

After the sinonasal region, the oral cavity is the site at which mucosal melanoma most often occurs in the head and neck.⁴¹ Within the oral cavity, mucosal melanoma is most frequently found involving the upper alveolus and the hard palate.⁴² It is most common in men, usually developing in the sixth decade of life.⁴² No specific risk factors or premalignant lesions have been identified. There may, however, be an increased risk among certain subsets of East Asian patients.

Oral mucosal melanoma typically appears as a flat or nodular pigmented lesion, frequently associated with ulceration. Amelanotic melanoma is, fortunately, rare.⁴³ Patients usually seek medical attention at an advanced stage of the disease, when pain develops or when they notice a change in the fit of their dentures. Early asymptomatic lesions are usually identified incidentally by either a physician or a dentist. Approximately 25% of patients

have nodal metastases at presentation.⁴² Tumors thicker than 5 mm are associated with an increased likelihood of nodal metastases at presentation.⁴⁴

No formal staging system has been developed for mucosal melanoma. The diagnosis is made by means of biopsy and immunohistochemical staining (e.g., for HMB-45 antigen, Melan-A, or S-100 protein). Any suspicious pigmented lesion in the oral cavity should undergo biopsy to rule out melanoma. Amalgam tattoos are common in the oral cavity and can often be diagnosed on the basis of

Table 5 Poor Prognostic Factors for Minor Salivary Gland Malignancies

Advanced disease at time of diagnosis
Positive nodes
High-risk histologic type (i.e., high-grade malignancies such as high-grade mucoepidermoid carcinoma, adenocarcinoma, carcinoma ex pleomorphic adenoma, and adenoid cystic carcinoma)
Positive margins
Male sex

Table 6 Poor Prognostic Factors for Mucosal Melanoma

- Amelanotic melanoma
- Advanced stage at presentation
- Tumor thickness > 5 mm
- Presence of vascular invasion
- Distant metastases

the presence of metallic fragments on dental radiographs.

Mucosal melanoma is managed primarily with surgical resection. The role of radiation therapy in this setting remains controversial.⁴¹ Some clinicians recommend postoperative radiotherapy for all cases of mucosal melanoma; others recommend it only for patients with close or positive margins. The role of lymph node mapping [see 3:6 *Lymphatic Mapping and Sentinel Node Biopsy*] has not been defined for mucosal melanoma. Because of the high incidence of nodes at presentation and the high regional recurrence rates reported in some studies, consideration should be given to treating the neck prophylactically by extending the postoperative radiation fields to cover this region.^{41,42}

The poor prognosis of mucosal melanoma with conventional treatment employing surgery and irradiation is a strong argument for referring patients to a medical oncologist for potential enrollment in postoperative systemic therapy trials. The survival rate for oral mucosal melanomas at 5 years ranges from 15% to 45%,^{42,43,45} with most patients dying of distant disease. Nodal involvement further reduces survival.⁴³ Melanoma of the gingiva has a slightly better prognosis than melanoma of the palate.⁴³ Several factors predictive of poor survival have been identified [see Table 6].⁴² The relation between lesion depth and prognosis is not as clearly defined for oral mucosal melanoma as it is for cutaneous melanoma.

Squamous Cell Carcinoma

The incidence of squamous cell carcinoma increases with age, with the median age at diagnosis falling in the seventh decade of life,^{46,47} and is higher in men than in women. This cancer may be found at any of a number of oral cavity subsites [see Figures 6b through 6g]. Lip carcinoma is the most common oral cavity cancer; 80% to 90% of these lesions occur on the lower lip.¹³ After the lip, the most common sites for oral cavity carcinoma are the tongue and the floor of the mouth. When the primary lesion is on the tongue, the lateral border is the most common location, followed by the anterior tongue and the dorsum.⁸ Approximately 75% of

Table 7 Growth Patterns of Squamous Cell Carcinoma of Oral Cavity⁶⁵

Growth Pattern	Characteristics
Ulceroinfiltrative	Most common pattern; appears as ulcerated lesion that penetrates deep into underlying structures with surrounding induration
Exophytic	Common on lip and buccal mucosa; appears as papillary mass that may ulcerate when large
Endophytic	Uncommon; extends deep into soft tissue, with only small surface area involved
Superficial	Flat, superficial appearance; may be either a white patch or a red/velvety patch

Table 8 American Joint Committee on Cancer TNM Classification of Head and Neck Cancer

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ
	T1	Tumor 2 cm or less in greatest dimension
	T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension
	T3	Tumor more than 4 cm in greatest dimension
Regional lymph nodes (N)	T4a	Tumor invades adjacent structures, extending through cortical bone into deep (extrinsic) muscles of tongue, maxillary sinus, or facial skin
	T4b	Tumor invades masticator space, pterygoid plates, or skull base or encases internal carotid artery
	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastases
Distant metastases (M)	N1	Metastases in a single ipsilateral lymph node ≤ 3 cm in greatest dimension
	N2a	Metastases in a single ipsilateral lymph node > 3 cm but ≤ 6 cm in greatest dimension
	N2b	Metastases in multiple ipsilateral lymph nodes, none > 6 cm in greatest dimension
	N2c	Metastases in bilateral or contralateral lymph nodes, none > 6 cm in greatest dimension
	N3	Metastases in lymph node > 6 cm in greatest dimension
Distant metastases (M)	MX	Distant metastases cannot be assessed
	M0	No distant metastases
	M1	Distant metastases

cases of oral cavity squamous cell carcinoma arise from a specific 10% of the mucosal surface of the mouth,¹¹ an area extending from the anterior floor of the mouth along the gingivobuccal sulcus and the lateral border to the retromolar trigone and the anterior tonsillar pillar.¹¹ Verrucous carcinoma is a subtype of squamous cell carcinoma and occurs most frequently on the buccal mucosa, appearing as a papillary mass with keratinization.

Between 80% and 90% of patients with oral cavity carcinoma have a history of either tobacco use (cigarette smoking or tobacco chewing) or excessive alcohol intake.⁴⁸ A synergistic effect is created when alcohol and tobacco are frequently used together.⁴⁸ In Asia, the practice of reverse smoking is associated with a high incidence of palatal carcinoma; betel nut chewing is associated with a high incidence of buccal carcinoma.

Small lesions tend to be asymptomatic. Larger lesions are often associated with pain, bleeding, poor denture fit, facial weakness or sensory changes, dysphagia, odynophagia, and trismus. Oral intake may worsen the pain, leading to malnutrition and dehydration.

Squamous cell carcinoma of the oral cavity has four different possible growth patterns: ulceroinfiltrative, exophytic, endophytic, and superficial [see Table 7].⁴⁹ Lip and buccal carcinomas tend to appear as exophytic masses. Ulceration is less common early in the course of cancers arising at these sites, but it may develop as the lesion enlarges. Cancers of the floor of the mouth may be associated with invasion of the tongue and the mandible. Decreased tongue mobility as a result of fixation is an indicator of an advanced tumor.^{8,50} Mandibular invasion occurs frequently in carcinomas of the floor of the mouth, the retromolar trigone, and the alveolar ridge as a consequence of the tight adherence of the mucosa to the periosteum in these regions.² The risk of mandibular invasion increases with higher tumor stages. The majority

Table 9 American Joint Committee on Cancer Staging System for Head and Neck Cancer

Stage	T	N	M
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3 T1, T2, T3	N0 N1	M0 M0
Stage IVA	T4a T1, T2, T3, T4a	N0, N1 N2	M0 M0
Stage IVB	Any T T4b	N3 Any N	M0 M0
Stage IVC	Any T	Any N	M1

(70%–80%) of alveolar ridge carcinomas occur on the lower alveolus, often in areas of leukoplakia.⁵¹

Oral cavity carcinoma is generally classified according to the staging system developed by the American Joint Committee on Cancer [see Tables 8 and 9].⁵² Staging is based on clinical examination and diagnostic imaging. The diagnosis is made on the basis of biopsy and immunohistochemical staining (e.g., for cytokeratin and epithelial membrane antigen).

Squamous cell carcinoma of the oral cavity is usually managed with surgery, radiation therapy, or a combination of the two; chemotherapy is used primarily for palliation of incurable disease. For localized disease without bone invasion, the cure rate for radiation therapy is comparable to that of surgery.⁴⁸ Advanced tumors of the oral cavity are best managed with both surgery and irradiation. Traditionally, in North America, oral cavity cancer is treated primarily with surgery, and postoperative radiotherapy is added if the disease is advanced or if there are pathologic features indicative of a high risk of recurrence (i.e., positive margins on microscopy; extensive perineural or intravascular invasion; two or more positive nodes or positive nodes at multiple levels; or nodal capsular extension). North American practice is reflected in the guidelines developed by the American Head and Neck Society (www.headandneckcancer.org/clinicalresources/docs/oralcavity.php).

Postoperative radiation, if indicated, should be started 4 to 6 weeks after surgery. The total radiation dose depends on the clinical and pathologic findings; the usual range is between 50 and 70 Gy, administered over 5 to 8 weeks. Brachytherapy can be used as an adjunct when close or positive margins are noted. Advances in

Table 10 Incidence of Nodal Metastases* at Presentation in Oral Cavity Subsites

Oral Cavity Subsite	Incidence of Metastases
Lip	10%
Tongue	30%–40%
Floor of mouth	50%
Alveoli	28%–32%
Buccal mucosa	40%–52%

*Clinically detectable or occult.

Table 11 Five-Year Carcinoma Survival Rates for Oral Cavity Subsites

Oral Cavity Subsite	Survival Rate
Lip	80%; > 90% for early-stage disease
Tongue	30%–35% (advanced-stage disease); > 80% (early-stage disease)
Floor of mouth	85% for stages I and II (T1 lesions > 95%); 20%–52% for stages III and IV
Alveoli	50%–60%
Retromolar trigone	75% for T1 and T2 lesions; approximately 20%–50% for T3 and T4 lesions
Buccal mucosa	49%–68%
Palate	85% for T1 lesions; 30% for T4 lesions

treatment planning and conformal radiotherapy have led to improved dosimetry with external beam radiotherapy, which has limited the perceived value of brachytherapy in our practice.

The decision regarding which treatment is presented to a patient as the first option is often determined by factors other than the extent of the tumor. Patient factors to be considered include desires and wishes, age, medical comorbidities, and performance status. Disease factors to be considered include tumor grade and stage; extent of invasion; primary site; the presence and degree of nodal or distant metastasis; and previous treatment. It is often helpful to discuss each case at a multidisciplinary treatment planning conference in order to develop a ranked list of options.

Squamous cell carcinoma of the oral cavity tends to spread to regional lymph nodes in a relatively predictable fashion. The primary levels of metastatic spread from oral cavity carcinoma includes level I through III nodes and, less frequently, level IV nodes^{53–55}; metastases to level V are infrequent.^{53,55} The likelihood that cervical node metastases will develop varies depending on the location of the primary tumor in the oral cavity and on the stage of the tumor. Cervical metastases from carcinomas of the lip or the hard palate usually occur only in advanced disease⁸; however, cervical metastases from carcinomas of any of the other oral cavity subsites are common at presentation [see Table 10].^{8,11,48,50,51,53,56,57} Larger tumors carry a higher risk of cervical metastasis.

The clinically positive neck is usually managed with either a radical or a modified radical neck dissection, depending on the extent of the disease. Some studies have found that for N1 and some N2a patients, a comparable control rate can be achieved with a selective neck dissection encompassing levels I through IV, with postoperative radiation therapy added when indicated.^{58,59}

The clinically negative neck can occasionally be managed with observation alone, with treatment initiated only when nodal metastases develop. Alternatively, the nodal basins at risk can be managed prophylactically by means of either surgery or radiation therapy (involving levels I through III and, possibly, IV). The rationale for prophylactic neck management is that treatment initiated while metastases are still occult is thought to be more effective than treatment initiated after the disease has progressed to the point where it is clinically detectable. For this reason, many clinicians advocate prophylactic neck dissection for patients with oral cavity carcinomas who are at moderate

Figure 7 Shown is coccidioidomycosis of the tongue in an HIV-positive patient.

(15%–20%) risk for occult metastases at presentation. The selective neck dissection not only addresses any occult metastatic nodes but also functions as a staging procedure that helps in determining the prognosis and assessing the need for postoperative radiotherapy.^{60,61} In general, elective neck management is recommended for T2 and higher-stage carcinomas of the tongue, the floor of the mouth, the buccal mucosa, the alveolus, and the retromolar trigone, as well as for advanced (T3 or T4) carcinomas of the lip and the hard palate.^{8,11,48,57,62,63} Most surgeons now emphasize the depth of invasion of the primary tumor as a critical determinant of the risk of occult nodal metastases. It has been suggested that elective treatment of the neck with surgery or radiation therapy should be considered on the basis of the depth of tumor invasion rather than the surface diameter of the lesion. The tumor depth that is held to warrant investigation varies among published studies, ranging from 2 to 5 mm.^{64–66} Bilateral neck dissection may be indicated for midline oral cavity cancers.

Radiation may be delivered to an oral cavity carcinoma via either external beam radiotherapy or brachytherapy, with the former being more commonly employed. Primary radiation therapy is indicated for patients with stage I and selected stage II oral cavity carcinomas, patients who refuse surgery or in whom surgery is contraindicated, and patients with incurable lesions who require palliative treatment. The total radiation dose for primary treatment ranges from 65 to 75 Gy. Radiation therapy is less effective against large or deeply invasive tumors, especially those that are invading bone, and therefore generally is not used alone for curative management of T3 and T4 lesions. For advanced-stage tumors of the oral cavity, surgery with postoperative radiotherapy is performed to decrease recurrence rates.

The prognosis depends on the location of the tumor in the oral cavity. Overall, if all of the oral cavity subsites are considered

together, the presence of cervical metastases decreases survival by approximately 50%. Varying 5-year survival rates have been reported for the different subsites of the oral cavity [see Table 11].^{8,11,48,50,51,56,67}

Oral Cavity Manifestations of HIV Infection

Infectious and neoplastic oral cavity lesions are often the first manifestation of HIV infection or the first indication of the progression to AIDS.

INFECTIONS

The same organisms that affect the general population cause most of the oral infections seen in the HIV population; however, oral infections in HIV patients tend to be recurrent, comparatively severe, and relatively resistant to treatment.⁶⁸ Oral hairy leukoplakia, caused by Epstein-Barr virus, is a common oral infection seen almost exclusively in the HIV population. It presents as an asymptomatic, corrugated, whitish, nonremovable, slightly raised patch on the lateral borders of the tongue. The finding of such a lesion on clinical examination of an HIV patient is suggestive of the diagnosis, but confirmation of the diagnosis requires biopsy. Treatment usually is not necessary. High-dose acyclovir may be given if the patient requests treatment.

Several rare infections of the oral cavity are being seen with increasing frequency in the HIV population, including tuberculosis, syphilis, *Rochalimaea henselae* infection (bacillary angiomatosis), *Borrelia vincentii* infection (acute necrotizing ulcerative gingivitis), cryptococcosis, histoplasmosis, coccidioidomycosis [see Figure 7], and human papillomavirus infection.

NEOPLASMS

The two most common intraoral neoplasms in the HIV population are Kaposi sarcoma and non-Hodgkin lymphoma. Kaposi sarcoma occurs most commonly in patients with HIV, though it is not exclusive to this population. It frequently involves the oral cavity, showing a predilection for the attached mucosa of the palate or the gingiva.⁶⁸ The characteristic lesions are blue, brown, purple, or red exophytic masses that may be either confined to the oral mucosa or systemic. They are usually asymptomatic but may become painful or obstructive with growth or ulceration. Treatment is aimed at palliation of symptoms and may involve sclerotherapy, intralesional chemotherapy, laser ablation, cryotherapy, surgical excision, or radiation therapy.⁶⁹ Systemic chemotherapy may be provided if the disease is systemic.

The risk of non-Hodgkin lymphoma is much higher in the HIV population than in the general population.⁶⁹ It should be suspected in any HIV patient who presents with an intraoral mass or an ulcerated lesion. Non-Hodgkin lymphoma appears as painful lesions that show a predilection for the palate, the retromolar trigone, and the tongue. Associated symptoms include facial paresthesias, loose dentition, fever, night sweats, and weight loss. Local disease is managed with radiation, systemic disease with chemotherapy.

3 NECK MASS

Barry J. Roseman, M.D., and Orlo H. Clark, M.D., F.A.C.S.

Assessment of a Neck Mass

Clinical Evaluation

HISTORY

The evaluation of any neck mass begins with a careful history. The history should be taken with the differential diagnosis in mind [see Table 1] because directed questions can narrow down the diagnostic possibilities and focus subsequent investigations. For example, in younger patients, one would tend to look for congenital lesions, whereas in older adults, the first concern would always be neoplasia.

The duration and growth rate of the mass should be determined: malignant lesions are far more likely to exhibit rapid growth than benign ones, which may grow and shrink. Next, the location of the mass in the neck should be determined. This is particularly important for differentiating congenital masses from neoplastic or inflammatory ones because each type usually occurs consistently in particular locations. In addition, the location of a neoplasm has both diagnostic and prognostic significance. The possibility that the mass reflects an infectious or inflammatory process should also be assessed. One should check for evidence of infection or inflammation (e.g., fever, pain, or tenderness); a recent history of tuberculosis, sarcoidosis, or fungal infection; the presence of dental problems; and a history of trauma to the head and neck. Masses that appear inflamed or infected are far more likely to be benign.

Finally, factors suggestive of cancer should be sought: a previous malignancy elsewhere in the head and neck (e.g., a history of skin cancer, melanoma, thyroid cancer, or head and neck cancer); night sweats (suggestive of lymphoma); excessive exposure to the sun (a risk factor for skin cancer); smoking or excessive alcohol consumption (risk factors for squamous cell carcinoma of the head and neck); nasal obstruction or bleeding, otalgia, odynophagia, dysphagia, or hoarseness (suggestive of a malignancy in the upper aerodigestive tract); or exposure to low-dose therapeutic radiation (a risk factor for thyroid cancer).

PHYSICAL EXAMINATION

Examination of the head and neck is challenging in that much of the area to be examined is not easily visualized. Patience and practice are necessary to master the special instruments and techniques of examination. A head and neck examination is usually performed with the patient sitting in front of the physician. Constant repositioning of the head is necessary to obtain adequate visualization of the various areas. Gloves must be worn during the examination, particularly if the mucous

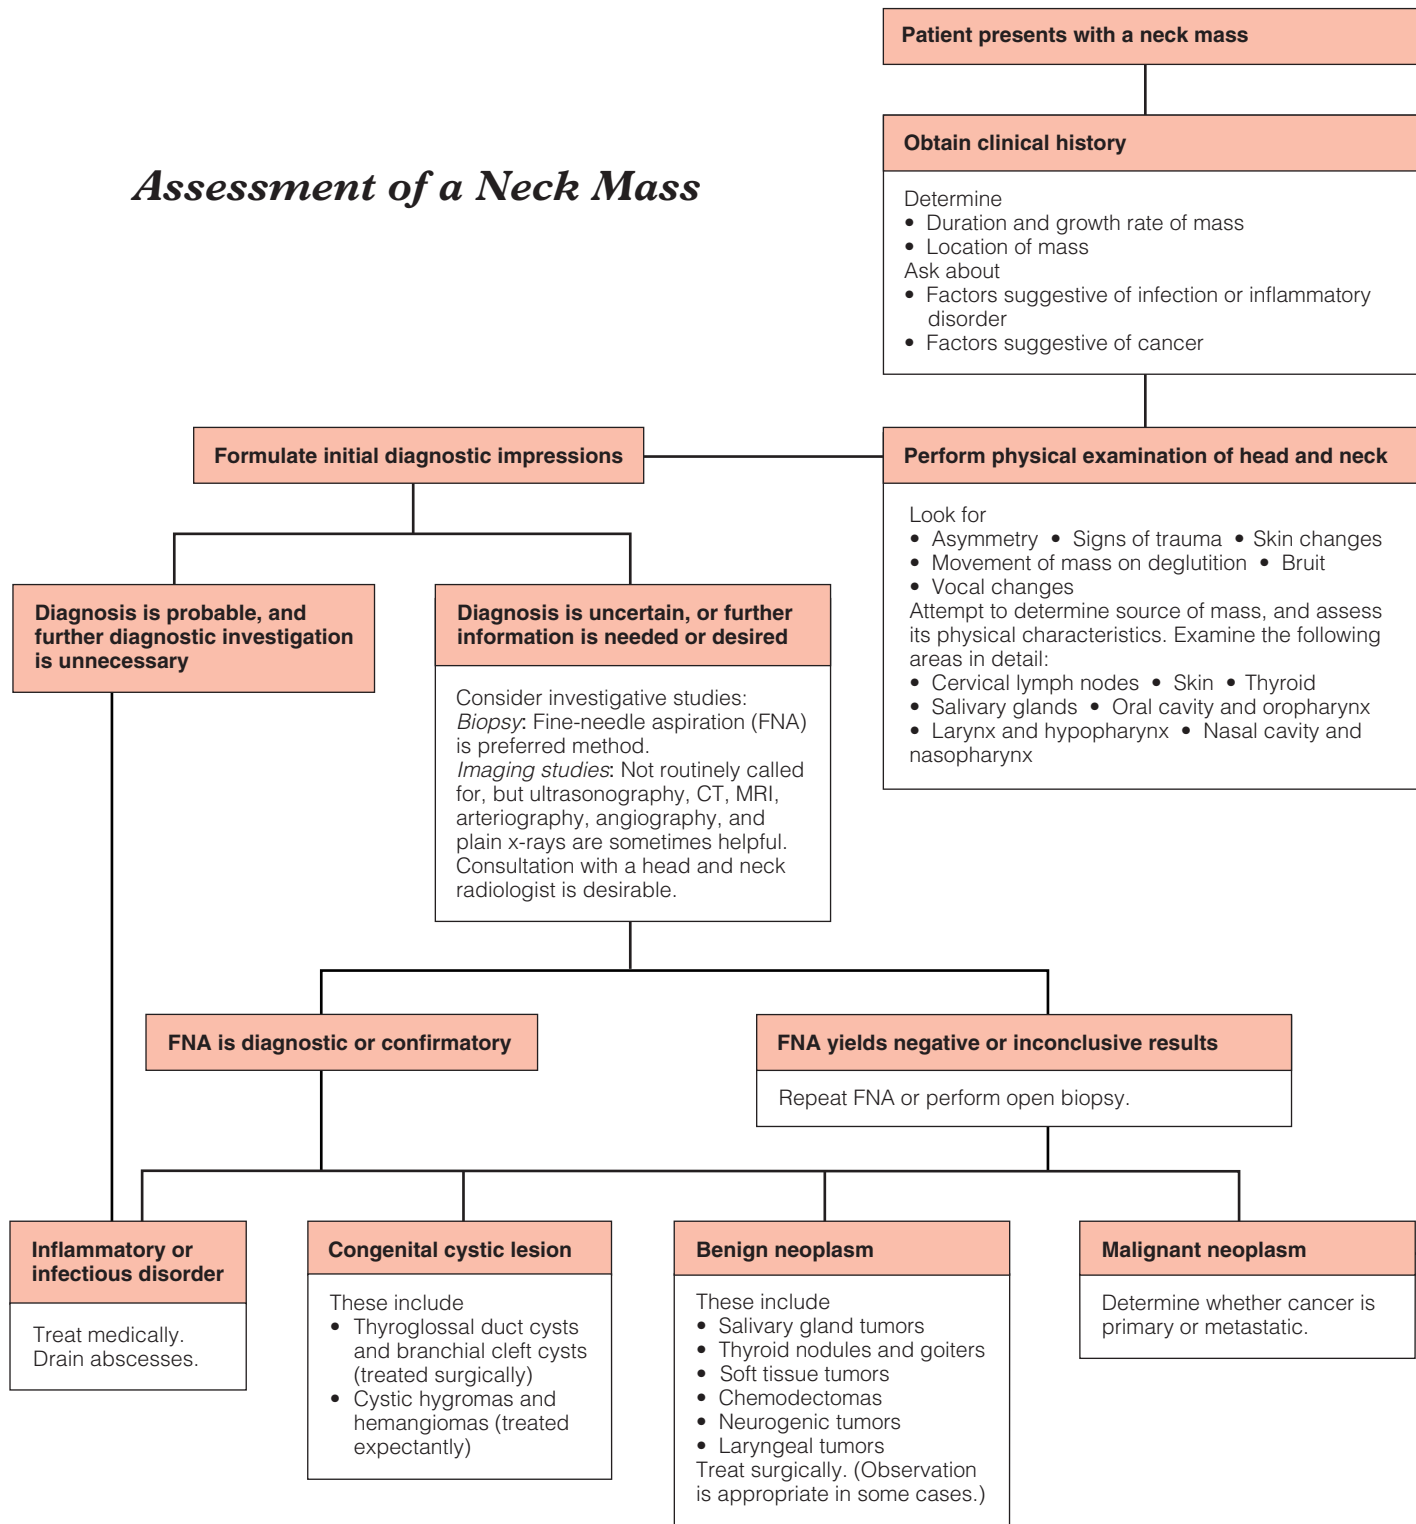

membranes are to be examined. Good illumination is essential. The time-honored but cumbersome head mirror has been largely supplanted by the headlight (usually a high-intensity halogen lamp). Fiberoptic endoscopy with a flexible laryngoscope and a nasopharyngoscope has become a common component of the physical examination for evaluating the larynx, the nasopharynx,

Assessment of a Neck Mass

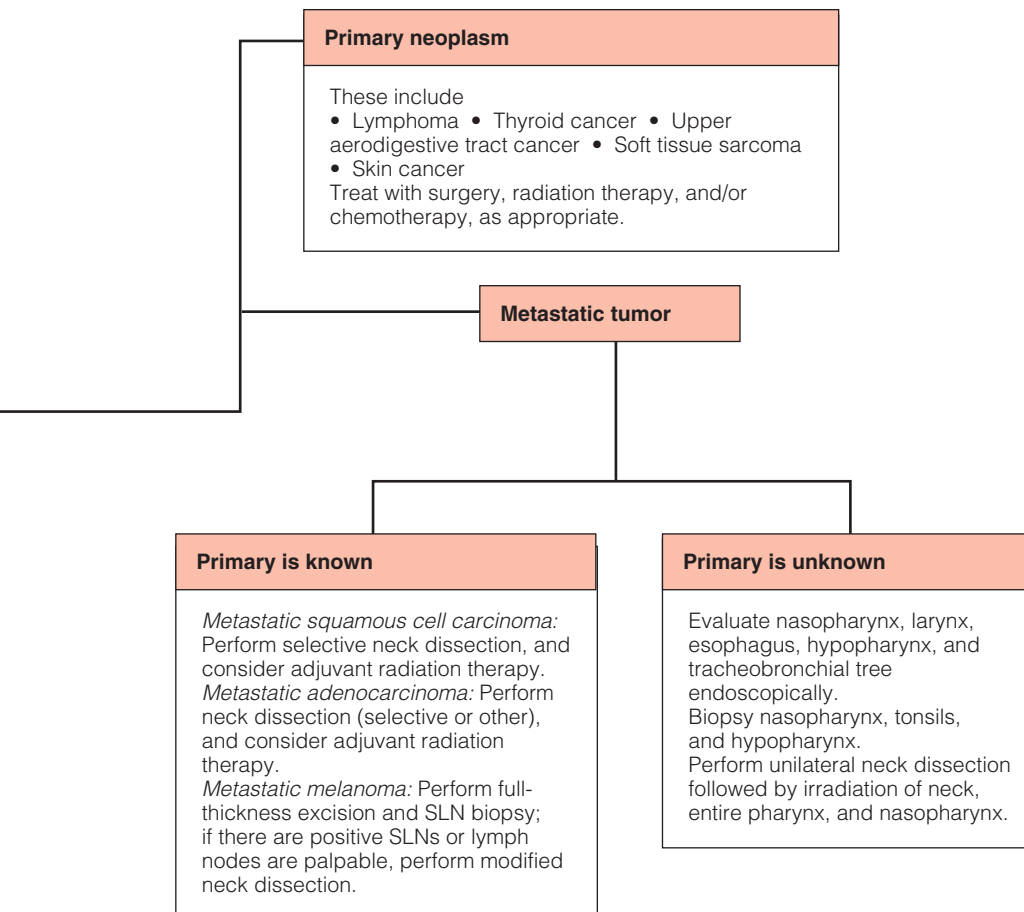

Table 2 Classification of Cervical Lymph Nodes

Level	Nodes
I	Submental nodes Submandibular nodes
II	Upper internal jugular chain nodes
III	Middle internal jugular chain nodes
IV	Lower internal jugular chain nodes
V	Spinal accessory nodes Transverse cervical nodes
VI	Tracheoesophageal groove nodes

and the paranasal sinuses, especially when these areas cannot be adequately visualized with more standard techniques.

The examination should begin with inspection for asymmetry, signs of trauma, and skin changes. One should ask the patient to swallow to see if the mass moves with deglutition. Palpation should be done both from the front and from behind. Auscultation is performed to detect audible bruits. One should also ask about the patient's voice, changes in which may suggest either a laryngeal tumor or recurrent nerve dysfunction from locally invasive thyroid cancer.

During the physical examination, one should be thinking about the following questions: What structure is the neck mass arising from? Is it a lymph node? Is the mass arising from a normally occurring structure, such as the thyroid gland, a salivary gland, a nerve, a blood vessel, or a muscle? Or is it arising from an abnormal structure, such as a laryngocele, a branchial cleft cyst, or a cystic hygroma? Is the mass soft, fluctuant, easily mobile, well-encapsulated, and smooth? Or is it firm, poorly mobile, and fixed to surrounding structures? Does it pulsate? Is there a bruit? Does it appear to be superficial, or is it deeper in the neck? Is it attached to the skin? Is it tender?

The following areas of the head and neck are examined in some detail.

Cervical Lymph Nodes

Enlarged lymph nodes are by far the most common neck masses encountered. The cervical lymphatic system consists of interconnected groups or chains of nodes that parallel the major neurovascular structures in the head and neck. The skin and mucosal surfaces of the head and neck all have specific and predictable nodes associated with them. The classification of cervical lymph nodes has been standardized to comprise six levels [see Table 2 and Figure 1]. Accurate determination of lymph node level on physical examination and in surgical specimens not only helps establish a common language among clinicians but also permits comparison of data among different institutions.

The location, size, and consistency of lymph nodes furnish valuable clues to the nature of the primary disease. Other physical characteristics of the adenopathy should be noted as well, including the number of lymph nodes affected, their mobility, their degree of fixation, and their relation to surrounding anatomic structures. One can often establish a tentative diagnosis on the basis of these findings alone. For example, soft or tender nodes are more likely to derive from an inflammatory or infectious condition, whereas hard, fixed, painless nodes are more likely to rep-

resent metastatic cancer. Multiple regions of enlarged lymph nodes are usually a sign of systemic disease (e.g., lymphoma, tuberculosis, or infectious mononucleosis), whereas solitary nodes are more often due to malignancy. Firm, rubbery nodes are typical of lymphoma. Low cervical nodes are more likely to contain metastases from the thyroid or a primary source other than the head and neck, whereas upper cervical nodes are more likely to contain metastases from the head and neck.

The submental and submandibular nodes (level I) are palpated bimanually. Metastases to level I are commonly from the lips, the oral cavity, or the facial skin. The three levels of internal jugular chain nodes (levels II, III, and IV) are best examined by gently rolling the sternocleidomastoid muscle between the thumb and the index finger. Level II and level III lymph nodes are common sites for lymph node metastases from primary cancers of the oropharynx, the larynx, and the hypopharynx. Metastases in level IV lymph nodes can arise from cancers of the upper aerodigestive tract, cancers of the thyroid gland, or cancers arising below the clavicle (Virchow's node). Nodal metastases in the posterior triangle (level V) can arise from nasopharyngeal and thyroid cancers as well as from squamous cell carcinoma or melanoma of the posterior scalp and the pinna of the ear. The tracheoesophageal groove nodes (level VI) or control nodes are then palpated.

Skin

Careful examination of the scalp, the ears, the face, the oral cavity, and the neck will identify potentially malignant skin lesions, which may give rise to lymph node metastases.

Thyroid Gland

The thyroid gland is first observed as the patient swallows; it is then palpated and its size and consistency assessed to determine whether it is smooth, diffusely enlarged, or nodular and whether one nodule or several are present. If it is unclear whether the mass is truly thyroid, one can clarify the point by asking the patient to swallow and watching to see whether the mass moves. Signs of superior mediastinal syndrome (e.g., cervical venous engorgement and facial edema) suggest retrosternal extension of a thyroid goiter. Elevation of the arms above the head often causes such signs in a patient with a substernal goiter (a positive Pemberton sign). The larynx and trachea are examined, with special attention to the cricothyroid membrane, over which Delphian nodes can be palpated. These nodes can be a harbinger of thyroid or laryngeal cancer.

Major Salivary Glands

Examination of the paired parotid and submandibular glands involves not only palpation of the neck but also an intraoral examination to inspect the duct openings. The submandibular glands are best assessed by bimanual palpation, with one finger in the mouth and one in the neck. They are normally lower and more prominent in older patients. The parotid glands are often palpable in the neck, though the deep lobe cannot always be assessed. A mass in the region of the tail of the parotid must be distinguished from enlarged level II jugular nodes. The oropharynx is inspected for distortion of the lateral walls. The parotid (Stensen's) duct may be found opening into the buccal mucosa, opposite the second upper molar.

Oral Cavity and Oropharynx

The lips should be inspected and palpated. Dentures should be removed before the mouth is examined. The buccal mucosa, the teeth, and the gingiva are then inspected. The patient should be

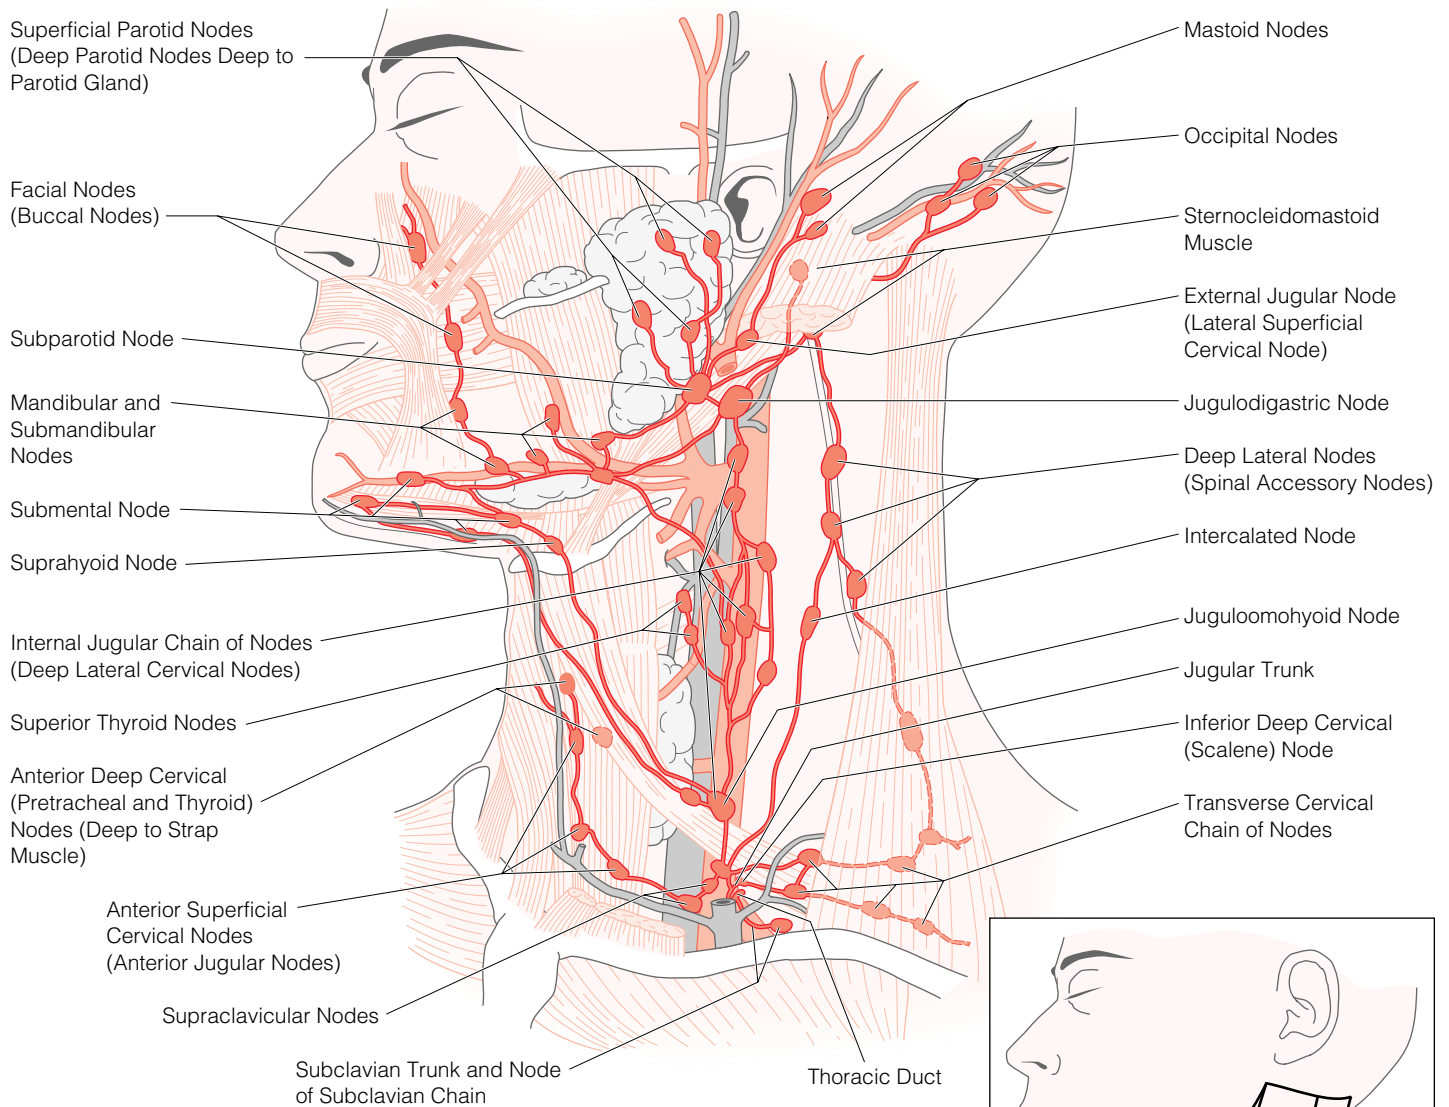

Figure 1 Cervical lymph nodes can be classified into six levels (inset) on the basis of their location in the neck.¹

asked to elevate the tongue so that the floor of the mouth can be examined and bimanual inspection performed. The tongue should be inspected both in its normal position in the mouth and during protrusion.

Most of the oropharyngeal contents are easily visualized if the tongue is depressed. Only the anterior two thirds of the tongue is clearly visible on examination, however. The base of the tongue is best visualized by using a mirror. In most persons, the tongue base can be palpated, at the cost of some discomfort to the patient. The ventral surface of the tongue must also be care-

fully inspected and palpated.

The hard palate is examined by gently tilting the patient's head backward, and the soft palate is inspected by gently depressing the tongue with a tongue blade. The movement of the palate is assessed by having the patient say "ahh."

The tonsils are then examined. They are usually symmetrical but may vary substantially in size. For example, in young patients, hyperplastic tonsils may almost fill the oropharynx, but in adult patients, this is an uncommon finding. Finally, the posterior pharyngeal wall is inspected.

Larynx and Hypopharynx

The larynx and the hypopharynx are best examined by indirect or direct laryngoscopy. A mirror is warmed, and the patient's tongue is gently held forward to increase the space between the oropharyngeal structures. The mirror is carefully introduced into the oropharynx without touching the base of the tongue. The oropharynx, the larynx, and the hypopharynx can be visualized by changing the angle of the mirror.

The lingual and laryngeal surfaces of the epiglottis are examined. Often, the patient must be asked to phonate to bring the endolarynx into view. The aryepiglottic folds and the false and true vocal cords should be identified. The mobility of the true vocal cords is then assessed: their resting position is carefully noted, and their movement during inspiration is recorded. Normally, the vocal cords abduct during breathing and move to the median position during phonation. The larynx is elevated when the patient attempts to say "eeeeee"; this allows one to observe vocal cord movement and to better visualize the piriform sinuses, the postcricoid hypopharynx, the laryngeal surface of the epiglottis, and the anterior commissure of the glottic larynx. Passage of a fiberoptic laryngoscope through the nose yields a clear view of the hypopharynx and the larynx. This procedure is well tolerated by almost all patients, particularly if a topical anesthetic is gently sprayed into the nose and swallowed, thereby anesthetizing both the nose and the pharynx.

Nasal Cavity and Nasopharynx

The nasopharynx is examined by depressing the tongue and inserting a small mirror behind the soft palate. The patient is instructed to open the mouth widely and breathe through it to elevate the soft palate. With the patient relaxed, a warmed nasopharyngeal mirror is carefully placed in the oropharynx behind the soft palate without touching the mucosa.

The nasal septum, the choanae, the turbinates, and the eustachian tube orifices are systematically assessed. The dorsum of the soft palate, the posterior nasopharyngeal wall, and the vault of the nasopharynx should also be assessed. The exterior of the nose should be carefully examined, and the septum should be inspected with a nasal speculum. Polyps or other neoplasms can be mistaken for turbinates.

Careful evaluation of the cranial nerves is essential, as is examination of the eyes (including assessment of ocular movement and visual activity), the external ear, and the tympanic membrane.

Additional Areas

The remainder of the physical examination is also important, particularly as regards the identification of a possible source of metastases to the neck. Other sets of lymph nodes—especially axillary and inguinal nodes—are examined for enlargement or tenderness. Women should undergo complete pelvic and rectal examinations. Men should undergo rectal, testicular, and prostate examinations; tumors from these organs may metastasize to the neck, albeit rarely.

Initial Diagnostic Impressions

Having obtained a comprehensive history and performed a physical examination, one is likely to have a better idea of whether the neck mass is inflammatory, benign, or malignant. In

some patients, the findings are clear enough to strongly suggest a specific disease entity. For example, a rapidly developing mass that is soft and tender to palpation is most likely a reactive lymph node from an acute bacterial or viral illness. A slow-growing facial mass associated with facial nerve deficits is probably a malignant parotid tumor. A thyroid nodule with an adjacent abnormal lymph node in a young patient probably represents thyroid cancer. In an elderly patient with a substantial history of smoking and alcohol use, a neck mass may well be a metastasis from squamous cell carcinoma in the aerodigestive tract.

The initial diagnostic impressions and the degree of certainty attached to them determine the next steps in the workup and management of a neck mass; options include empirical therapy, ultrasonographic scanning, computed tomography, fine-needle aspiration (FNA), and observation alone. For example, in a patient with suspected bacterial lymphadenitis from an oral source, empirical antibiotic therapy with close follow-up is a reasonable approach. In a patient with a suspected parotid tumor, the best first test is a CT scan: the tumor probably must be removed, which means that one will have to ascertain the relation of the mass to adjacent structures. In a patient with suspected metastatic cancer, FNA is a sensible choice: it will confirm the presence of malignancy and may suggest a source of the primary cancer.

Investigative Studies

Neck masses of suspected infectious or inflammatory origin can be observed for short periods. Most neck masses in adults, however, are abnormal, and they are often manifestations of serious underlying conditions. In most cases, therefore, further diagnostic evaluation should be rigorously pursued.

BIOPSY

Whether or not the history and the physical examination strongly suggest a specific diagnosis, the information obtained by sampling tissue from the neck mass is often highly useful. In many cases, biopsy establishes the diagnosis or, at least, reduces the diagnostic possibilities. At present, the preferred method of obtaining biopsy material from a neck mass is FNA, which is generally well tolerated and can usually be performed without local anesthesia. Although FNA is, on the whole, both safe and accurate, it is an invasive diagnostic procedure and carries a small but definable risk of potential problems (e.g., bleeding and sampling error). Accordingly, FNA should be done only when the results are likely to influence treatment.

FNA reliably distinguishes cystic from solid lesions and can often diagnose malignancy. It has in fact become the standard for making treatment decisions in patients with thyroid nodules and for confirming the clinical suspicion of a cystic lesion. FNA is also useful in patients with a known distant malignancy in whom confirmation of metastases is needed for staging and for planning therapy, as well as in patients with a primary tumor of the head and neck who are not candidates for operation but in whom a tissue diagnosis is necessary for appropriate nonsurgical therapy to be initiated. In addition, FNA is helpful in dealing with overly anxious patients in whom the clinical index of suspicion for a neoplasm is low and the head and neck examination is negative: negative biopsy results tend to reassure these patients and allow the surgeon time to follow the mass more confidently. (Of course,

negative FNA results should not be considered the end point of any search and do not rule out cancer.)

Several studies have shown FNA to be approximately 90% accurate in establishing a definitive diagnosis. Lateral cystic neck masses that collapse on aspiration usually represent hygromas, branchial cleft cysts, or cystic degeneration of a metastatic papillary thyroid cancer. Fluid from these masses is sent for cytologic examination. If a palpable mass remains after cyst aspiration, a biopsy of the solid component should be done; the morphology of the cells will be better preserved.

If an extensive physical examination has been completed and the FNA is not diagnostic, one may have to perform an open biopsy to obtain a specimen for histologic sections and microbiologic studies. It is estimated that open biopsy eventually proves necessary in about 10% of patients with a malignant mass. In an open biopsy, it is important to orient skin incisions within the boundaries of a neck dissection; the incisions can then, if necessary, be extended for definitive therapy or reexcised if reoperation subsequently proves necessary. Crossing incisions should never be situated over vessels.

A case in which lymphoma and metastatic squamous cell carcinoma are diagnostic possibilities constitutes a special situation. FNA alone is often incapable of determining the precise histologic subtype for lymphoma, but it is usually capable of distinguishing a lymphoproliferative disease from metastatic squamous cell carcinoma. This is a crucial distinction, in that the two neoplasms are treated in drastically different ways.

If a lymphoma is suspected, FNA is typically followed by open biopsy, frozen-section confirmation, and submission of fresh tissue to the pathologist. The intact node is placed in normal saline and sent directly to the pathologist for analysis of cellular content and nodal architecture and identification of lymphocyte markers. If, however, metastatic squamous cell carcinoma is suspected, FNA usually suffices for establishing the diagnosis and formulating a treatment plan, which often includes chemotherapy and radiation initially. In this setting, performing an open biopsy can lead to significant wound healing complications; there is no need to incur this risk when FNA is all that is necessary to initiate treatment.

IMAGING

Diagnostic imaging should be used selectively in the evaluation of a neck mass; imaging studies should be performed only if the results are likely to affect subsequent therapy. Such studies often supply useful information about the location and characteristics of the mass and its relation to adjacent structures. Diagnostic imaging is particularly useful when a biopsy has been performed and a malignant tumor identified. In such cases, these studies can help establish the extent of local disease and the presence or absence of metastases.

Ultrasonography of the neck reliably differentiates solid masses from cystic ones and is especially useful in assessing congenital and developmental cysts. It is a valuable noninvasive technique for vascular lesions and clearly delineates thyroid and parathyroid abnormalities. CT is also useful for differentiating cysts from solid neck lesions and for determining whether a mass is within or outside a gland or nodal chain. In addition, CT scanning can delineate small tongue-base or tonsillar tumors that have a minimal mucosal component. MRI provides much the same information as CT. T₂-weighted gadolinium-enhanced scans are particularly useful for delineating the invasion of soft tissue by tumor: endocrine tumors are often enhanced on such scans. PET scanning is useful in the staging of many cancers, as well as in search-

ing for the primary site in metastatic disease from an unknown source.

Arteriography is useful mainly for evaluating vascular lesions and tumors fixed to the carotid artery. Angiography is helpful for evaluating the vascularity of a mass, its specific blood supply, or the status of the carotid artery, but it provides very little information about the physical characteristics of the mass. Plain radiographs of the neck are rarely helpful in differentiating neck masses, but a chest x-ray can often confirm a diagnosis (e.g., in patients with lymphoma, sarcoidosis, or metastatic lung cancer). A chest x-ray is also important in any patient with a new diagnosis of cancer to determine if pulmonary metastases are present. It is also an essential component of preoperative evaluation for any patient older than 40 years.

It is important to communicate with the radiologist: an experienced head and neck radiologist may be able to offer the surgeon valuable guidance in choosing the best diagnostic test in a specific clinical scenario. Furthermore, providing the radiologist with a detailed clinical history facilitates interpretation of the images.

Management of Specific Disorders

INFLAMMATORY AND INFECTIOUS DISORDERS

Acute infection of the neck (cervical adenitis) is most often the result of dental infection, tonsillitis, pharyngitis, viral upper respiratory tract infection, or skin infection. Lymph node enlargement is a frequent finding that may reflect any of a number of infectious disorders. The most common cause of this symptom is an acute infection of the mouth or pharynx. In this situation, the enlarged lymph nodes are usually just posterior and inferior to the angle of the mandible. Signs of acute infection (e.g., fever, malaise, and a sore mouth or throat) are usually present. A constitutional reaction, tenderness of the cervical mass, and the presence of an obvious infectious source confirm the diagnosis. Treatment should be directed toward the primary disease and should include a monospot test for infectious mononucleosis.

Neck masses may also derive from subcutaneous abscesses, infected sebaceous or inclusion cysts, or multiloculated carbuncles (most often occurring in the back of the neck in a patient with diabetes mellitus). The physical characteristics of abscesses make recognition of these problems relatively straightforward.

On occasion, primary head and neck bacterial infections can lead to infection of the fascial spaces of the neck. A high index of suspicion is required in this situation: such infections are sometimes difficult to diagnose. Aggressive treatment with antibiotics and drainage of closed spaces is indicated to prevent overwhelming fasciitis.

Various chronic infections (e.g., tuberculosis, fungal lymphadenitis, syphilis, cat-scratch fever, and AIDS) may also involve cervical lymph nodes. Certain chronic inflammatory disorders (e.g., sarcoidosis) may present with cervical lymphadenopathy as well. Because of the chronic lymph node involvement, these conditions are easily confused with neoplasms, especially lymphomas. Biopsy is occasionally necessary; however, skin tests and serologic studies are often more useful for establishing a diagnosis. Treatment of these conditions is primarily medical; surgery is reserved for complications.

CONGENITAL CYSTIC LESIONS

Thyroglossal Duct Cysts

Thyroglossal duct cysts are remnants of the tract along which the thyroid gland descended into the neck from the foramen cecum [see Figure 2].

They account for about 70% of all congenital abnormalities of the neck. Thyroglossal duct cysts may be found in patients of any age but are most common in the first decade of life. They may take the form of a lone cyst, a cyst with a sinus tract, or a solid core of thyroid tissue. They may be so small as to be barely perceptible, as large as a grapefruit, or anything in between. Thyroglossal duct cysts are almost always found in the midline, at or below the level of the hyoid bone; however, they may be situated anywhere from the base of the tongue to the suprasternal notch. They occasionally present slightly lateral to the midline and are sometimes associated with an external fistula to the skin of the anterior neck. They are often ballotable and can usually be moved slightly from side to side but not up or down; however, they do move up and down when patients swallow or protrude the tongue.

Thyroglossal duct cysts must be differentiated from dermoid cysts, lymphadenomegaly in the anterior jugular chain, and cutaneous lesions (e.g., lipomas and sebaceous cysts). Operative treatment is almost always required, not only because of cosmetic considerations but also because of the high incidence of recurrent infection, including abscess formation. About 1% of thyroglossal duct cysts contain cancer; papillary cancer is the neoplasm most commonly encountered, followed by squamous cell carcinoma. About 25% of patients with papillary thyroid cancer in thyroglossal duct cysts have papillary thyroid cancer in other parts of the thyroid gland as well. About 10% have nodal metastases, which in some cases are bilateral.

Branchial Cleft Cysts

Branchial cleft cysts are vestigial remnants of the fetal branchial apparatus from which all neck structures are derived. Early in embryonic development, there are five branchial arches and four grooves (or clefts) between them. The internal tract or opening of a branchial cleft cyst is situated at the embryologic derivative of the corresponding pharyngeal groove, such as the tonsil (second arch) or the piriform sinus (third and fourth arches). The second arch is the most common area of origin for such cysts. The position of the cyst tract is also determined by the embryologic relation of its arch to the derivatives of the arches on either side of it.

The majority of branchial cleft cysts (those that develop from the second, third, and fourth arches) tend to present as a bulge along the anterior border of the sternocleidomastoid muscle, with or without a sinus tract. Branchial cleft cysts may become symptomatic at any age, but most are diagnosed in the first two decades of life. They often present as a smooth, painless, slowly enlarging mass in the lateral neck. Frequently, there is a history of fluctuating size and intermittent tenderness. The diagnosis is more obvious when there is an external fistulous tract and there is a history of intermittent discharge. Infection of the cyst may be the reason for the first symptoms.

Treatment consists of complete surgical removal of the cyst and the sinus tract. Any infection or inflammation should be treated and allowed to resolve before the cyst and the tract are removed.

Cystic Hygromas (Lymphangiomas)

A cystic hygroma is a lymphangioma that arises from vestigial lymph channels in the neck. Almost always, this condition is first noted by the second year of life; on rare occasions, it is first diagnosed in adulthood. A cystic hygroma may present as a relatively simple thin-walled cyst in the floor of the mouth or may involve all the tissues from the floor of the mouth to the mediastinum. About 80% of the time, there is only a painless cyst in the posterior cervical triangle or in the supraclavicular area. A cystic hygroma can also occur, however, at the root of the neck, in the angle of the jaw (where it may involve the parotid gland), and in the midline (where it may involve the tongue, the floor of the mouth, or the larynx).

The typical clinical picture is of a diffuse, soft, doughy, irregular mass that is readily transilluminated. Cystic hygromas look and feel somewhat like lipomas but have less well defined margins. Aspiration of cystic hygromas yields straw-colored fluid. They may be confused with angiomas (which are compressible), pneumatoceles from the apex of the lung, or aneurysms. They can be distinguished from vascular lesions by means of arteriography. On occasion, a cystic hygroma grows suddenly as a result of an upper respiratory tract infection, infection of the hygroma itself, or hemorrhage into the tissues. If the mass becomes large enough, it can compress the trachea or hinder swallowing.

In the absence of pressure symptoms (i.e., obstruction of the airway or interference with swallowing) or gross deformity, cystic hygromas may be treated expectantly. They tend to regress spontaneously; if they do not, complete surgical excision is indicated. Excision can be difficult because of the numerous satellite extensions that often surround the main mass and because of the association of the tumor with vital structures such as the cranial nerves. Recurrences are common; staged resections for complete excision are often necessary.

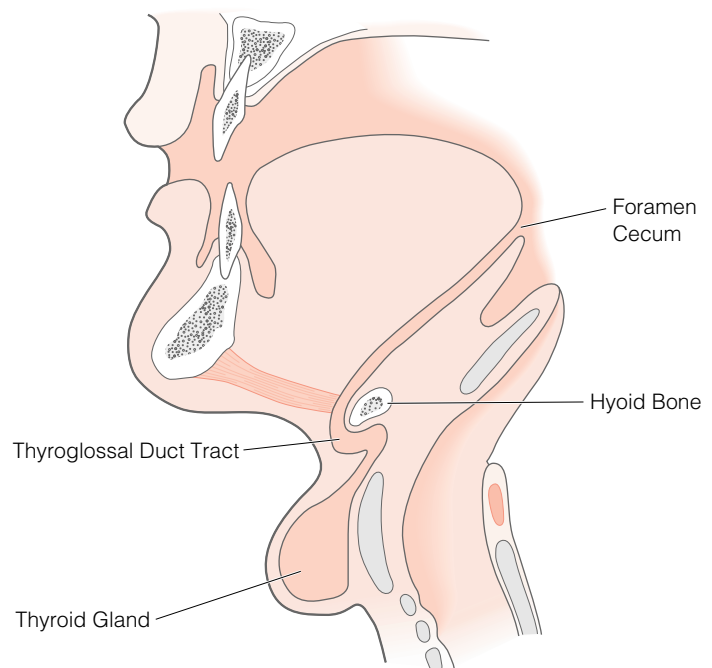

Figure 2 Shown is the course of the thyroglossal duct tract from its origin in the area of the foramen cecum to the pyramidal lobe of the thyroid gland.² In the operative treatment of a thyroglossal duct cyst, the central portion of the hyoid bone must be removed to ensure complete removal of the tract and to prevent recurrence.

Vascular Malformation (Hemangiomas)

Hemangiomas are usually considered congenital because they either are present at birth or appear within the first year of life. A number of characteristic findings—bluish-purple coloration, increased warmth, compressibility followed by refilling, bruit, and thrill—distinguish them from other head and neck masses. Angiography is diagnostic but is rarely indicated.

Given that most of these congenital lesions resolve spontaneously, the treatment approach of choice is observation alone unless there is rapid growth, thrombocytopenia, or involvement of vital structures.

BENIGN NEOPLASMS

Salivary Gland Tumors

The possibility of a salivary gland neoplasm must be considered whenever an enlarging solid mass lies in front of and below the ear, at the angle of the mandible, or in the submandibular triangle. Benign salivary gland lesions are often asymptomatic; malignant ones are often associated with seventh cranial nerve symptoms or skin fixation. Diagnostic radiographic studies (CT or MRI) indicate whether the mass is salivary in origin but do not help classify it histologically. The diagnostic test of preference is open biopsy in the form of complete submandibular gland removal or superficial parotidectomy.

With any mass in or around the ear, one should be prepared to remove the superficial lobes of the parotid, the deep lobes, or both and to perform a careful facial nerve dissection. Any less complete approach reduces the chances of a cure: there is a high risk of implantation and seeding of malignant tumors. Benign mixed tumors make up two thirds of all salivary tumors; these must also be completely removed because recurrence is common after incomplete resection.

Benign Thyroid Nodules and Nodular Goiters

Thyroid disease is a relatively common cause of neck masses: in the United States, about 4% of women and 2% of men have a palpable thyroid nodule. Patients should be questioned about local symptoms (pain, dysphagia, pressure, hoarseness, or a change in the voice), about the duration of the nodule, and about systemic symptoms (from hyperthyroidism, hypothyroidism, or any other illness). Although most nodules are benign, malignancy is a significant concern. Nodules in children, young men, older persons, pregnant women, or persons with a history of radiation exposure or a family history of thyroid cancer are more likely to be malignant. Nodules that are truly solitary, feel firm or hard on examination, are growing rapidly, or are nonfunctional on scans are more likely to be malignant.

If physical examination suggests a discrete thyroid nodule, FNA should be done to ascertain whether malignancy is present within the nodule. If malignancy is confirmed or suspected, surgery is indicated. If the nodule is histologically benign or disappears with aspiration, thyroid suppression and observation are often sufficient. FNA often yields unrepresentative results in patients with a history of radiation exposure, in whom there is approximately a 40% chance that one of the nodules present contains cancer.

Surgery for thyroid nodules involves excisional biopsy consisting of at least total lobectomy [see 2:7 *Thyroid and Parathyroid Procedures*]; enucleation is almost never indicated. The surgical ap-

proach of choice for most patients with Graves disease or multinodular goiter is subtotal or total thyroidectomy or total lobectomy on one side and subtotal lobectomy on the other (Dunhill's operation). Treatment of thyroid cancer is discussed elsewhere [see Primary Malignant Neoplasms, Thyroid Cancer, *below*].

Soft Tissue Tumors (Lipomas, Sebaceous Cysts)

Superficial intracutaneous or subcutaneous masses may be sebaceous (or epidermal inclusion) cysts or lipomas. Final diagnosis and treatment usually involves simple surgical excision, often done as an office procedure with local anesthesia.

Chemodectomas (Carotid Body Tumors)

Carotid body tumors belong to a group of tumors known as chemodectomas (or, alternatively, as glomus tumors or nonchromaffin paragangliomas), which derive from the chemoreceptive tissue of the head and neck. In the head and neck, chemodectomas most often arise from the tympanic bodies in the middle ear, the glomus jugulare at the skull base, the vagal body near the skull base along the inferior ganglion of the vagus, and the carotid body at the carotid bifurcation. They are occasionally familial and sometimes occur bilaterally.

A carotid body tumor presents as a firm, round, slowly growing mass at the carotid bifurcation. Occasionally, a bruit is present. The tumor cannot be separated from the carotid artery by palpation and can usually be moved laterally and medially but not in a cephalocaudal plane. The differential diagnosis includes a carotid aneurysm, a branchial cleft cyst, a neurogenic tumor, and nodal metastases fixed to the carotid sheath. The diagnosis is made by means of CT scanning or arteriography, which demonstrate a characteristic highly vascular mass at the carotid bifurcation. Neurofibromas tend to displace, encircle, or compress a portion of the carotid artery system, events that are readily demonstrated by carotid angiography.

Biopsy should be avoided. Chemodectomas are sometimes malignant and should therefore be removed in most cases to prevent subsequent growth and pressure symptoms. Fortunately, even malignant chemodectomas are usually low grade; long-term results after removal are excellent on the whole. Vascular surgical experience is desirable, in that bleeding may occur and clamping of the carotid artery may result in a stroke. Expectant treatment may be indicated in older or debilitated individuals. Radiotherapy may be appropriate for patients with unresectable tumors.

Neurogenic Tumors (Neurofibromas, Neurilemmomas)

The large number of nerves in the head and neck renders the area susceptible to neurogenic tumors. The most common of such tumors, neurilemmomas (schwannomas) and neurofibromas, arise from the neurilemma and usually present as painless, slowly growing masses in the lateral neck. Neurilemmomas can be differentiated from neurofibromas only by means of histologic examination.

Given the potential these tumors possess for malignant degeneration and slow but progressive growth, surgical resection is indicated. This may include resection of the involved nerves, particularly with neurofibromas, which tend to be more invasive and less encapsulated than neurilemmomas.

Laryngeal Tumors

In rare cases, a chondroma may arise from the thyroid cartilage or the cricoid cartilage. It is firmly fixed to the cartilage and may present as a mass in the neck or as the cause of a progressively compromised airway. Surgical excision is indicated.

PRIMARY MALIGNANT
NEOPLASMS

Lymphomas

Cervical adenopathy is one of the most common presenting symptoms in patients with Hodgkin and non-Hodgkin lymphoma. The nodes tend to be softer, smoother, more elastic, and more mobile than nodes containing metastatic carcinoma would be. Rapid growth is not unusual, particularly in non-Hodgkin lymphoma. Involvement of extranodal sites, particularly Waldeyer's tonsillar ring, is often seen in patients with non-Hodgkin lymphoma; enlargement of these sites may provide a clue to the diagnosis. The diagnosis is usually suggested by FNA, then confirmed via excisional biopsy of an intact lymph node. The precise histologic subtype cannot be determined by FNA alone. Open biopsy must ultimately be done and fresh tissue must be submitted for analysis by histology, immunochemistry, and electron microscopy.

Lymphoma is treated by means of radiation therapy, chemotherapy, or both, depending on the disease's pathologic type and clinical stage.

Thyroid Cancer

The approach to suspected thyroid cancer differs in some respects from the approach to benign thyroid disease. The operation of choice for papillary thyroid cancer that is occult (< 1 cm in diameter) and confined to the thyroid gland and for follicular thyroid cancer that is minimally invasive (i.e., exhibiting only capsular invasion) is thyroid lobectomy; the prognosis is excellent. The procedure of choice for papillary, follicular, Hürthle cell, and medullary thyroid cancer is total or near-total thyroidectomy (when it can be done safely) [see 2:7 *Thyroid and Parathyroid Procedures*]. Patients who present with thyroid nodules and have a history of radiation exposure or a family history of thyroid cancer should also undergo total or near-total thyroidectomy because about 40% of them will have at least one focus of papillary thyroid cancer. Total thyroidectomy decreases recurrence and permits the use of iodine-131 (¹³¹I) to scan for and treat residual disease; it also makes serum thyroglobulin and calcitonin assays more sensitive for diagnosing recurrent or persistent differentiated thyroid tumors of follicular or parafollicular cell origin.

Patients with medullary thyroid cancer should undergo meticulous elective (prophylactic) or therapeutic bilateral central neck dissection. All patients with medullary thyroid cancer should be screened for *ret* proto-oncogene mutations on chromosome 10, as well as for pheochromocytoma. Therapeutic modified neck dissection is indicated for all patients with thyroid cancer and palpable nodes laterally. Prophylactic modified neck dissection is indicated for patients with medullary thyroid cancer and either primary tumors larger than 1.5 cm or evidence of central neck node involvement.

Patients with anaplastic thyroid cancer are probably best treated with a combination of chemotherapy and radiation therapy, in conjunction with the removal of as much of the neoplasm as can safely be excised. Most patients with thyroid lymphoma should receive chemotherapy, radiation therapy, or both.

Upper Aerodigestive Tract Cancer

Deciding on the optimal therapeutic approach to tumors of the aerodigestive tract (i.e., surgery, radiation therapy, or some combination of the two) generally requires expertise beyond that of most general surgeons. Therefore, cancers involving the nose, the

paranasal sinuses, the nasopharynx, the floor of the mouth, the tongue, the palate, the tonsils, the piriform sinus, the hypopharynx, or the larynx are best managed by an experienced head and neck oncologic surgeon in conjunction with a radiation therapist and a medical oncologist.

Soft Tissue Sarcomas

Malignant sarcomas are not common in the head and neck. The sarcomas most frequently encountered include the rhabdomyosarcoma seen in children, fibrosarcoma, liposarcoma, osteogenic sarcoma (which usually arises in young adults), and chondrosarcoma. The most common head and neck sarcoma, however, is malignant fibrous histiocytoma (MFH). MFH is seen most frequently in the elderly and extremely rarely in children, but it can arise at any age. It is often difficult to differentiate pathologically from other entities (e.g., fibrosarcoma). MFH can occur in the soft tissues of the neck or involve the bone of the maxilla or the mandible. The preferred treatment is wide surgical resection; adjuvant radiation therapy and chemotherapy are being studied in clinical trials.

Rhabdomyosarcoma, usually of the embryonic form, is the most common form of sarcoma in children. It generally occurs near the orbit, the nasopharynx, or the paranasal sinuses. The diagnosis is confirmed by biopsy. A thorough search for distal metastases is made before treatment—consisting of a combination of surgical resection, radiation therapy, and chemotherapy—is begun.

Skin Cancer

Basal cell carcinomas are the most common of the skin malignancies [see 3:4 *Skin Lesions*]. These lesions arise in areas that have been extensively exposed to sunlight (e.g., the nose, the forehead, the cheeks, and the ears). Treatment consists of local resection with adequate clear margins. Metastases are rare, and the prognosis is excellent. Inadequately excised and neglected basal cell carcinomas may ultimately spread to regional lymph nodes and can cause extensive local destruction of soft tissue and bone. For example, basal cell carcinoma of the medial canthus may invade the orbit, the ethmoid sinus, and even the brain. Periauricular basal cell carcinoma can spread across the cartilage of the ear canal or into the parotid gland.

Squamous cell carcinoma also arises in areas associated with extensive sunlight exposure; the lower lip and the pinna are the most common sites. Unlike basal cell carcinoma, however, squamous cell carcinoma tends to metastasize regionally and distally. This tumor must also be excised with an adequate margin.

Melanoma is primarily classified on the basis of depth of invasion (as quantified by Clark level or Breslow thickness), location, and histologic subtype, although the prognosis is closely related to the thickness of the tumor [see *Metastatic Tumors, Metastatic Melanomas, below*]. In addition to the typical pigmented, irregularly shaped skin lesions [see 3:4 *Skin Lesions*], malignant melanoma may also arise on the mucous membranes of the nose or the throat, on the hard palate, or on the buccal mucosa. The treatment of choice is wide surgical resection. Radiation therapy, chemotherapy, and immunotherapy may also be considered.

METASTATIC TUMORS

Any surgeon who is managing patients with head and neck cancers must have a thorough understanding of neck dissections and should have sufficient training and experience to perform these operations in the appropriate clinical circumstances.

Classification of Neck Dissections

There are two classification systems for neck dissections. The first is based on the indications and goals of surgery. An *elective* (or *prophylactic*) neck dissection is done when the neck is clinically negative (that is, when no abnormal lymph nodes are palpable or visible on radiographic imaging). A *therapeutic* neck dissection is done to remove all palpable and occult disease in patients with suspicious lymph nodes discovered via physical examination or CT scanning.

The second system is based on the extent and type of dissection. *Comprehensive* neck dissections include the classic radical neck dissection, as well as the modified radical (or functional) neck dissection [see Figure 3]. In a radical neck dissection, the sternocleidomastoid muscle, the internal and external jugular veins, the spinal accessory nerve, and the submaxillary gland are removed, along with all lymph node-bearing tissues. The modified radical or functional neck dissection is a modification of the radical neck dissection in which the lymphatic tissue from these areas is removed but the functional structures are preserved. *Selective* neck dissections involve the removal of specific levels of lymph nodes [see Figure 1]. The rationale for selective dissections is that several head and neck cancers consistently metastasize to specific localized lymph node regions. The following are examples of selective neck dissections: suprahyoid neck dissection (levels I and II); supraomohyoid neck dissection (levels I, II, and III); lateral neck dissection (levels II, III, and IV); and posterolateral neck dissection (levels II, III, IV, and V).

Metastatic Squamous Cell Carcinomas

The basic principle in the management of metastatic squamous cell carcinoma is to treat all regional lymph node groups at highest risk for metastases by means of surgery or radiation therapy, depending on the clinical circumstances. Selective lymph node dissection can be performed along with wide excision of the primary tumor at the time of initial operation. For example, carcinomas of the oral cavity are treated with supraomohyoid neck dissection, and carcinomas of the oropharynx, the hypopharynx, and

the larynx are treated with lateral neck dissection. If extranodal extension or the presence of multiple levels of positive nodes is confirmed by the pathologic findings, the patient should receive adjuvant bilateral neck radiation for 4 to 6 weeks after operation.

Metastatic Adenocarcinomas

Adenocarcinoma in a cervical node most frequently represents a metastasis from the thyroid gland, the salivary glands, or the GI tract. The primary tumor must therefore be sought through endoscopic and radiologic study of the bronchopulmonary tract, the GI tract, the genitourinary tract, the salivary glands, and the thyroid gland. Other possible primary malignancies to be considered include breast and pelvic tumors in women and prostate cancer in men.

If the primary site is controlled and the patient is potentially curable or if the primary site is not found and the neck disease is the only established site of malignancy, neck dissection is the appropriate treatment. Postoperative adjuvant radiation may also be considered. If the patient has thyroid cancer and palpable nodes, lateral neck dissection and ipsilateral central neck dissection are recommended.

Overall survival is low—about 20% at 2 years and 9% at 5 years—except for patients with papillary or follicular thyroid cancer, who have a good prognosis. Two factors associated with a better prognosis are unilateral neck involvement and limitation of disease to lymph nodes above the cricoid cartilage.

Metastatic Melanomas

If the patient has a thin melanoma (Breslow thickness < 1 mm; Clark level I, II, or III), full-thickness excision with 1 cm margins should be done. Intermediate-thickness melanomas (Breslow thickness 1 to 4 mm; Clark level IV) have a definable risk of lymph-node spread and thus are staged with lymphatic mapping and sentinel lymph node (SLN) biopsy [see 3:6 *Lymphatic Mapping and Sentinel Lymph Node Biopsy*] in addition to wide excision with at least 1.5 to 2 cm margins. All patients with intermediate-thickness melanomas and positive SLNs and all melanoma patients with palpable lymph nodes should undergo modified neck dissection for adequate local disease control. Because these tumors may metastasize to nodes in the parotid region, superficial parotidectomy is often included in the neck dissection, particularly in the case of melanoma located on the upper face or the anterior scalp. Consultation with a medical oncologist is indicated for all patients with intermediate-thickness or thick (Breslow thickness > 4 mm; Clark level V) melanomas; immunotherapy or chemotherapy may be considered. Radiation therapy is often considered in patients with extensive local or nodal disease.

Metastases from an Unknown Primary Malignancy

Management of patients with an unknown primary malignancy is challenging for the surgeon. It is helpful to know that when cervical lymph nodes are found to contain metastatic squamous cell carcinoma, the primary tumor is in the head and neck about 90% of the time. Typically, such patients are found to have squamous cell carcinoma on the basis of FNA of an abnormal cervical lymph node; this finding calls for an exhaustive review of systems as well as a detailed physical examination of the head and neck.

If no primary tumor is identified, the patient should undergo endoscopic evaluation of the nasopharynx, the hypopharynx, the

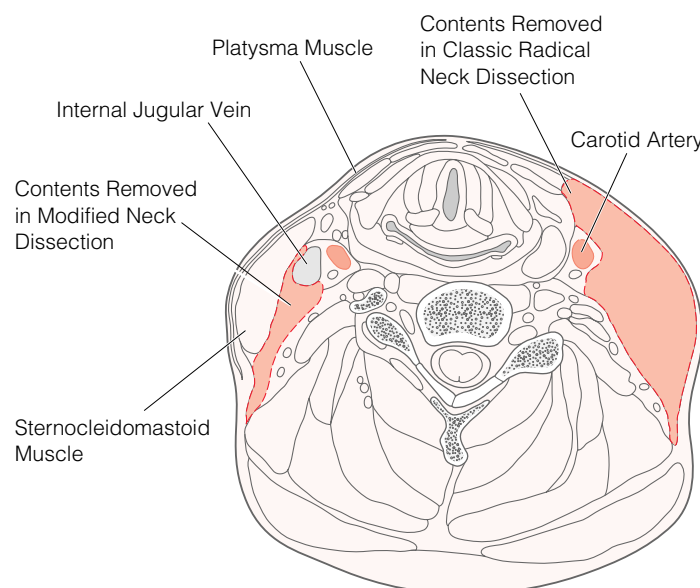

Figure 3 Cross section of the neck shows the structures removed in a classic radical neck dissection (right) and in a modified radical neck dissection (left).³

esophagus, the larynx, and the tracheobronchial tree under general anesthesia. Biopsies of the nasopharynx, the tonsils, and the hypopharynx often identify the site of origin (though there is some debate on this point). If the biopsies do not reveal a primary source of cancer, the preferred treatment is unilateral neck dissection, followed by radiation therapy directed toward the neck, the entire pharynx, and the nasopharynx. In 15% to 20% of cases, the primary cancer is ultimately detected. Overall 5-year survival in such cases ranges from 25% to 50%.

If a malignant melanoma is found in a cervical lymph node but no primary tumor is evident, the patient should be asked about previous skin lesions, and a thorough repeat head and neck examination should be done, with particular attention to the scalp, the

nose, the oral cavities, and the sinuses. An ophthalmologic examination is also required. If physical examination and radiographic studies find no evidence of metastases, modified neck dissection should be performed on the involved side.

Metastatic adenocarcinoma in a cervical lymph node with no known primary tumor is discussed elsewhere [see *Metastatic Adenocarcinomas, above*]. The most common primary sites in the head and neck are the salivary glands and the thyroid gland. The possibility of an isolated metastasis from the breast, the GI tract, or the genitourinary tract must also be rigorously investigated. If no primary site is identified, the patient should be considered for protocol-based chemotherapy and radiation therapy, directed according to what the primary site is most likely to be in that patient.

4 ORAL CAVITY PROCEDURES

Carol R. Bradford, M.D., F.A.C.S., and Mark E. Prince, M.D., F.R.C.S.(C)

Preoperative Evaluation

Oral cavity procedures are commonly performed to treat malignancies. Tumors should be assessed preoperatively to allow accurate staging of the disease and to facilitate planning of definitive treatment. In most cases, an examination under anesthesia with endoscopy and biopsy is required to stage the primary tumor and to look for synchronous second primary tumors. Except in the case of very superficial lesions, computed tomography plays an important role in preoperative planning. In selected cases, plain radiographs (e.g., Panorex views) may be useful in evaluating the mandible. When the lesion is located in the tongue, magnetic resonance imaging may provide additional information about the extent of the primary tumor.

Wide surgical margins are necessary for adequate treatment of primary squamous cell carcinoma of the head and neck. A margin of 1 to 2 cm should be achieved whenever possible, ideally with frozen-section control. Current evidence clearly indicates that overall patient outcome improves when clear margins are obtained.

Nodal metastases are common with oral cavity tumors. Accordingly, patients should be assessed for cervical adenopathy both clinically and radiographically. A chest x-ray should be obtained in all cases. CT or MRI can provide valuable information regarding the nodal status of the neck. In patients with advanced disease, a more extensive search for distant metastases should be conducted, including a CT scan of the chest. In some circumstances, combining CT with positron emission tomography (PET) may be useful.

Operative Planning

Surgical management of the neck is an evolving field. In general, if the risk of occult metastasis is greater than 20% to 25%, a selective neck dissection [see 2:6 Neck Dissection] is recommended, particularly if postoperative radiation therapy is not planned. Whenever there is clinical evidence of nodal disease, treatment of the neck must be included in operative planning.

The oral cavity is a major component of a number of important functions, including speech and swallowing. Reconstruction of the anticipated surgical defect must be carefully planned to achieve the best results. Several basic considerations must be kept in mind. Tongue mobility and sensation must be maintained to the extent possible. Maintenance of mandibular continuity (especially in the anterior segment of the mandible) is vital for ensuring postoperative oral competence. Separation of the nasal cavity from the oral cavity is critical for the oral phase of swallowing and speech. Maintenance of the gingivobuccal and gingivolabial sulcus is important for oral function and the fitting of dentures.

As a rule, oral cavity defects should be closed primarily whenever possible. Primary closure has the advantage of using sensate tissue similar in form to the tissue that was excised. With experience and careful judgment, the surgeon can usually determine when a defect is too large for primary closure or when primary closure is likely to cause distortion and tethering of adjacent tis-

sues and result in a significant functional disturbance. In such cases, a flap reconstruction must be considered. In select cases, pedicled flaps may be appropriate. Often, particularly with larger or more complicated defects, free flaps provide the best reconstructive result. Free tissue reconstruction has the advantage of allowing the surgeon to reconstruct the defect with the exact tissue components that were excised, including bone and skin. In addition, free flaps can be reinnervated to achieve a sensate reconstruction.

If the planned surgical procedure involves resection of part of the maxilla or the mandible, appropriate dental consultation should be obtained. If a postoperative splint, obturator, or dental prosthesis is to be placed, it is critical that dental impressions be obtained before operation. Thyroid function should be tested in all patients who have a history of radiation therapy to the neck to confirm that they are euthyroid.

In cooperative patients, small primary lesions of the oral cavity can sometimes be excised with local anesthesia; however, general anesthesia with adequate relaxation is required in the majority of cases. The route of intubation must be carefully considered for each patient. When the planned resection is extensive and when significant postoperative edema is anticipated, a tracheostomy should be performed. Patients with bulky lesions should undergo tracheostomy under local anesthesia before general anesthesia is induced. When a tracheostomy is not planned, nasotracheal intubation is often desirable.

When the excision is limited to the oral cavity, perioperative antibiotics are generally unnecessary. When a graft, a flap, or packing is employed, however, perioperative I.V. administration of antibiotics is advisable. In all cases in which the neck is entered, perioperative antibiotics are recommended. The oral cavity can be prepared preoperatively with chlorhexidine and a toothbrush.

A nasogastric feeding tube should be inserted whenever it is believed that the patient may have a problem maintaining oral nutrition postoperatively. Patients who undergo primary closure or split-thickness skin grafting or whose surgical wound is allowed to heal by secondary intention may be allowed clear liquids in 24 to 48 hours and a pureed diet by postoperative day 3; they can often tolerate a soft diet within 1 week. Patients who undergo flap reconstruction will have to be fed via a nasogastric tube until they have healed to the point where they can resume oral intake.

Patients should be advised to maintain oral hygiene postoperatively by means of frequent irrigation and rinses with either normal saline or half-strength hydrogen peroxide. Teeth may be gently cleaned with a soft toothbrush until healing has occurred.

Anterior Glossectomy

OPERATIVE PLANNING

Either orotracheal or nasotracheal intubation may be appropriate, depending on the surgical approach and the extent of the

planned resection. A tracheostomy should be performed whenever significant postoperative swelling or airway compromise is anticipated.

The depth of the excision and the size of the anticipated defect determine the optimal reconstructive approach. Defects that connect to the neck, unless they are small and can easily be closed primarily, usually necessitate creation of a flap for optimal reconstruction. When the excision extends down to the underlying musculature but there is no connection to the neck, a skin graft may be used. If a postoperative dental splint is planned to hold a skin graft in place, a dental consultation must be obtained before operation.

The patient should be supine in a 20° reverse Trendelenburg position. Turning the table 180° may facilitate access and positioning for the surgeon.

OPERATIVE TECHNIQUE

Step 1: Surgical Approach

Small anterior lesions up to 2 cm in diameter may be approached transorally, as may certain carefully selected larger lesions. Exposure of the tongue is usually achieved with the help of an appropriately sized bite block; alternatively, a specialized retractor (e.g., a Molt retractor) may be used. Retraction of the tongue is facilitated by the use of a piercing towel clip or a heavy silk suture placed through the tip of the tongue.

Access to posterior lesions and most larger lesions is obtained by performing a mandibulotomy through a lip-splitting incision [see Figure 1]. A stair-step incision is made in the lip and extended downward straight through the mentum, and a Z-plasty is done at the mental crease. Alternatively, the incision may be carried around the mental subunit.

The mandibular periosteum is elevated and a plate contoured to the mandible before the mandible is divided; this measure ensures exact realignment of the cut ends of the mandible. When possible, the mandibulotomy should be made anterior to the mental foramen to preserve sensation throughout the distribution of the mental nerve. Repair of the mandibulotomy is greatly facilitated by making a stair-step or chevron-type mandibulotomy [see Figure 2]. A paralingual mucosal incision is made to allow retraction of the mandible and exposure of the posterior oral cavity.

As an alternative, a visor flap may be created [see Figure 3]. Such a flap allows the surgeon to avoid making a lip-splitting incision and provides adequate exposure of small lesions of the anterior oral cavity; however, it is inadequate for exposure of lesions posterior to the middle third of the tongue or in the area of the retromolar trigone. Furthermore, creation of a visor flap results in anesthesia of the lower lip because of the necessity of dividing both mental nerves.

To create a visor flap, an incision is made from mastoid to mastoid along a skin crease in the neck, with care taken to remain below the marginal mandibular nerves. The skin flap is elevated in the subplatysmal plane to the level of the mandible. The marginal mandibular nerves are preserved. The flap is elevated from the lateral surface of the mandible, and the two mental nerves are divided. An incision is made in the oral cavity mucosa along the gingivolabial sulcus and continued so that it connects to the skin incision. The flap is then retracted superiorly to expose the anterior mandible and the oral cavity.

Step 2: Resection

The excision should include a generous mucosal margin around the visible lesion. A significant amount of the tongue musculature surrounding the lesion should be resected as well.

Figure 1 Anterior glossectomy. A lip-splitting incision is made that extends downward straight through the mentum.

Palpation of the lesion is critical for obtaining adequate deep surgical margins.

Resection may be performed with a monopolar electrocautery, with the cutting current used to incise the mucosa and the coagulation current used to cut the muscle. Alternatively, resection may be performed with a scalpel and a scissors. Hemostasis is achieved with a monopolar or bipolar electrocautery. Larger vessels are ligated with chromic catgut or Vicryl ties.

Lesions of the lateral tongue should be wedge-excised in a transverse (rather than horizontal) fashion to facilitate closure and enhance postoperative function. With larger lesions, for which either flap reconstruction or healing by secondary intention is typically indicated, the shape of the defect is contoured so as to obtain wide margins around the lesion, and the flap is designed to fill the contoured defect.

Step 3: Reconstruction

After negative margins are confirmed by frozen section examination, repair of the surgical defect is initiated. Careful preoperative assessment of the anticipated defect lays the groundwork for optimal reconstruction. Many defects can be either repaired primarily or allowed to heal by secondary intention. Free tissue transfer is an excellent reconstructive option in many cases, allowing the maintenance of tongue mobility and the separation of the tongue from the mandible and making sensate reconstruction possible.

In many patients with wedge-excised lateral tongue lesions, primary closure of the defect yields good results. The deep muscle is carefully reapproximated with long-lasting absorbable sutures. The mucosa is also closed with absorbable sutures. Care should be taken not to strangulate tissues by making the sutures too tight. When complete primary closure is not possible or desirable, the tongue may be allowed to granulate and heal by secondary intention. Split-thickness skin grafts, though useful for relining the floor of the mouth, generally do not take well on the tongue.

For large defects of the tongue and those involving the floor of the mouth, flap reconstruction is appropriate. Defects that connect to the neck, unless they are small and can be closed primarily, should also be closed with a flap. Free tissue transfer is frequently the optimal reconstructive approach. Free fasciocuta-

Figure 2 Anterior glossectomy. A stair-step mandibulotomy is made.

neous flaps from the radial forearm, the anterior lateral thigh, or the lateral arm are well suited to reconstruction in this area. Pedicled flaps (e.g., myocutaneous flaps from the pectoral muscle) are also used in this setting, but they are bulkier and harder to contour to the defects.

If a mandibulotomy was made, it is repaired with the previously contoured plate. The lip-splitting incision is closed in three layers (mucosa, muscle, and skin). Great care must be taken to ensure accurate realignment of the vermilion border and the orbicularis oris muscle.

Alternative Procedure: Laser Vaporization

Very superficial and premalignant lesions of the tongue may be vaporized by using a CO₂ laser. The desired depth of tissue destruction for leukoplakia is approximately 1 to 2 mm.

TROUBLESHOOTING

Larger excisions may lead to airway edema. Whenever this possibility is a concern, a tracheostomy should be performed. A single intraoperative dose of steroids may reduce postoperative tongue edema without adversely affecting wound healing. Using a stair-step incision for the lip-splitting incision facilitates accurate reapproximation of the vermilion border. Excessive tongue movement may result in dehiscence of the closure. Voice rest for 3 to 5 days after operation may be beneficial.

POSTOPERATIVE CARE

Patients who undergo primary closure of the tongue may begin a fluid diet on the day after operation; they should remain on a liquid diet for 7 to 10 days. Patients who undergo skin grafting may also begin a liquid diet on postoperative day 1. If a flap was used to close the defect or if there is some question whether the patient will be capable of adequate oral intake, a nasogastric feeding tube should be inserted and maintained until the suture lines heal.

Bolster dressings may be removed and skin grafts inspected

after 7 to 10 days. Patients with skin grafts should stay on a soft diet for 2 weeks. If a tracheotomy was performed, the patient may be decannulated when postoperative edema has settled.

Meticulous and frequent oral hygiene is essential. Mouth rinses and irrigation with normal saline or half-strength hydrogen peroxide should be done at least four times a day and after every meal. Teeth may be gently cleaned with a soft toothbrush.

COMPLICATIONS

The main complications of anterior glossectomy are as follows:

1. Injury to the lingual nerve, which causes numbness and loss of the sense of taste in the ipsilateral tongue.
2. Injury to the submandibular and sublingual gland ducts, which causes obstruction of the glands, pain and swelling, and possibly ranula formation.
3. Injury to the hypoglossal nerve, portions of which are resected with the lesion. Injury to the main trunk of this nerve leads to paralysis and atrophy of the remaining ipsilateral tongue.
4. Tethering and scarring of the tongue, which can lead to difficulties with speech and swallowing. This problem can usually be avoided by careful preoperative planning of reconstruction.

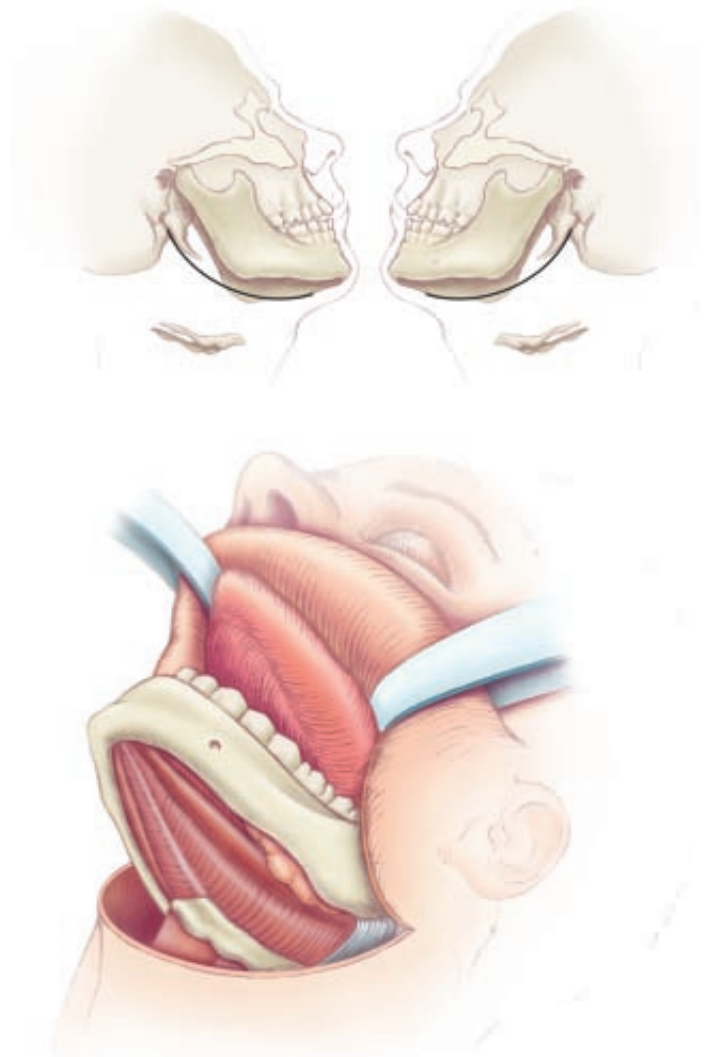

Figure 3 Anterior glossectomy. As an alternative to a lip-splitting incision with mandibulotomy, a visor flap may be employed for exposure.

Excision of Floor-of-Mouth Lesions

OPERATIVE PLANNING

Planning for excision of a lesion from the floor of the mouth is essentially the same as that for anterior glossectomy [see Anterior Glossectomy, Operative Planning, *above*]. If either or both of Wharton's ducts are to be transected without excision of the submandibular glands, consideration must be given to the management of these glands.

OPERATIVE TECHNIQUE

Step 1: Surgical Approach

The surgical approach is the same as that described for glossectomy [see Anterior Glossectomy, Operative Technique, Step 1, *above*].

Step 2: Resection

The area to be excised, including adequate margins, is marked. The lesion is then excised with a monopolar electrocautery; as in a glossectomy, the cutting current is used to cut the mucosa, the coagulation current to cut the deeper tissues. Palpation is important for obtaining adequate deep surgical margins.

If the excision cuts across Wharton's duct, the duct should be identified and transected obliquely so as to create a wider opening. The transected stump is held with a 4-0 chromic catgut suture. Once the resection is complete, the duct is transposed posteriorly to the cut edge of the mucosa of the floor of the mouth and sutured in place with two or three 4-0 chromic sutures. During subsequent reconstruction, care should be taken not to obstruct the orifice of the duct.

Step 3: Reconstruction

After clean surgical margins have been verified by frozen section examination, repair of the surgical defect is initiated. Small superficial defects of the floor of the mouth may be allowed to heal by secondary intention.

For small defects that do not connect to the neck, reconstruction with a 0.014 to 0.016 in.-thick split-thickness skin graft is appropriate. The graft is cut to size and sutured in place with 4-0 chromic sutures. Several perforations should be made in the graft to allow the egress of blood and serum. A Xeroform gauze bolster is fashioned to fit over the skin graft and sutured in place with 2-0 silk tie-over bolster stitches; alternatively, it may be held in place by a prefabricated dental prosthesis.

For larger defects, particularly those involving the tongue, a flap reconstruction typically yields the best functional results. In select cases, a platysma flap may be used for reconstruction of defects in the floor of the mouth. Other regional flaps tend to be bulky and difficult to shape to the contours of the defect. Free tissue transfer frequently provides the most suitable reconstructive tissue characteristics and the most favorable postoperative results. A free fasciocutaneous radial forearm flap is usually the optimal choice for reconstruction of floor-of-mouth defects when a flap is required.

TROUBLESHOOTING

Special care should be taken to identify the lingual nerve and artery so that these structures are not inadvertently divided. Meticulous hemostasis should be obtained in all cases. Any skin grafts used should be adequately sized and should not "tent up." Generally, skin grafting and bolsters do not work well on mobile structures. Quilting grafts to the underlying tissues with multiple absorbable sutures can eliminate the need for a bolster and result in acceptable graft take.

POSTOPERATIVE CARE

Postoperative care of patients undergoing excision of floor-of-mouth lesions is virtually identical to that of patients undergoing anterior glossectomy [see Anterior Glossectomy, Postoperative Care, *above*].

COMPLICATIONS

Excision of floor-of-mouth lesions is associated with the same complications as anterior glossectomy [see Anterior Glossectomy, Complications, *above*].

Excision of Superficial or Plunging Ranulas

OPERATIVE PLANNING

Planning for excision of a superficial or plunging ranula resembles that for glossectomy. A Ring-Adair-Elwyn (RAE) tube is inserted orally and taped to the contralateral cheek. Cervical exploration is usually unnecessary, because the cervical component of the ranula resolves after removal of the ipsilateral sublingual gland. In select cases, especially those involving disease recurrence after a previous attempt at excision, a transcervical approach should be considered.

OPERATIVE TECHNIQUE

Step 1: Surgical Approach

Ranulas are resected via the transoral approach. A bite block or a Molt retractor is used to gain exposure.

Step 2: Resection

A local anesthetic preparation with epinephrine is infiltrated into the area of the mucosal incisions. A small superficial ranula may be marsupialized and packed with gauze. The ranula is widely unroofed and the contents removed with suction. The margins of the cyst are sutured to the mucosa with 4-0 chromic sutures, and the cavity is packed with iodoform strip gauze. The gauze may be removed in 5 to 7 days.

A plunging ranula is treated with complete surgical excision of the cyst and the sublingual gland [see *Figure 4*]. A mucosal incision is made directly over the cyst. Careful dissection is carried out around the cyst and the associated gland. Hemostasis is achieved with a bipolar electrocautery, with care taken not to injure the adjacent lingual nerve. The submandibular gland duct is cannulated with a lacrimal probe to help guard against inadvertent injury to this structure. The incision is closed with 4-0 chromic suture.

TROUBLESHOOTING

Efforts should be made to identify the lingual nerve and artery so as to prevent inadvertent division of these structures. Meticulous hemostasis should be obtained in all cases. If the submandibular gland duct is injured, it should be transected and the cut end sutured to the adjacent floor-of-mouth mucosa (sialodochoplasty).

COMPLICATIONS

The three main complications of the procedure for excising a ranula are among those that are also associated with anterior glossectomy and excision of floor-of-mouth lesions: injury to the lingual nerve, injury to the submandibular gland duct, and injury to the hypoglossal nerve [see Anterior Glossectomy, Complications, *above*].

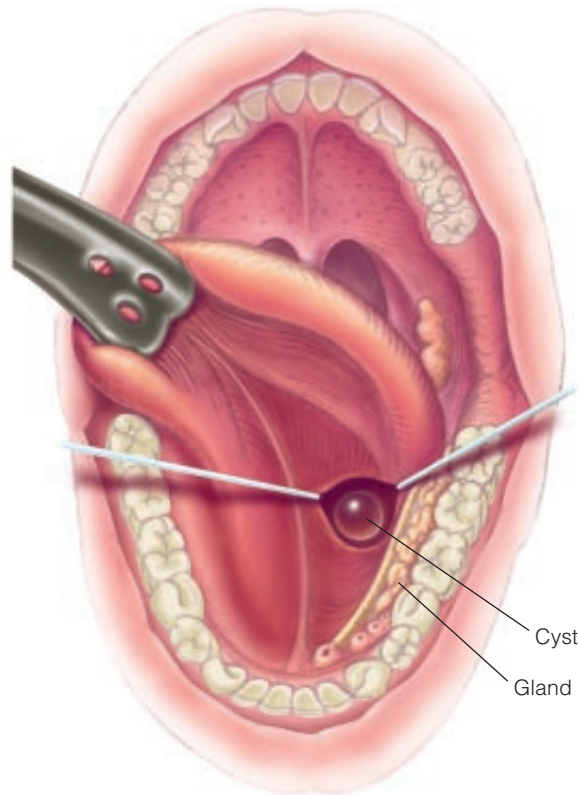

Figure 4 Excision of plunging ranula. A mucosal incision is made over the cyst, dissection is done around the cyst and the associated sublingual gland, and cyst and gland are completely excised.

Removal of Submandibular Gland Duct Stones

OPERATIVE PLANNING

When a submandibular gland duct stone is readily palpable in the floor of the mouth, a transoral approach is appropriate. When the stone is within the hilum of the gland, however, it generally cannot be removed transorally and often must be treated by excising the submandibular gland.

OPERATIVE TECHNIQUE

Step 1: Surgical Approach

The procedure is easily accomplished with local anesthesia in a cooperative patient. The patient is seated upright in the examining chair, and a topical anesthetic is applied to the oral cavity.

Step 2: Resection

A local anesthetic preparation with epinephrine is infiltrated into the floor of the mouth and around the duct in which the stone is palpated. A 2-0 silk suture may be placed around the duct behind the stone to prevent it from migrating back into the hilum of the gland.

A lacrimal probe is inserted into the duct and advanced to the stone in a retrograde manner. A mucosal incision is then made directly over the stone and extended downward to the duct, with the stone and the lacrimal probe serving as guides. The duct is incised and the stone delivered. As a rule, repair of the duct is not required.

TROUBLESHOOTING

Careful dissection directly onto the duct and stone usually serves to prevent inadvertent injury to the lingual nerve.

COMPLICATIONS

The main complications of the procedure are as follows:

1. Injury to the lingual nerve, resulting in numbness and loss of the sense of taste to the ipsilateral tongue.
2. Stricture of the submandibular gland duct. This is an unusual complication that can be corrected by transecting the duct posterior to the stricture and suturing it to the mucosa of the floor of the mouth.

Resection of Hard Palate

OPERATIVE PLANNING

Careful evaluation is required to determine whether resection of part of the hard palate will suffice or whether a more extensive dissection (e.g., maxillectomy) will be required. If it is anticipated that a dental prosthesis will be required, a dental consultation should be obtained before operation. When the lesion to be resected is superficial or only a limited amount of the bony hard palate must be resected, the procedure may be performed via the transoral approach.

OPERATIVE TECHNIQUE

Step 1: Surgical Approach

The patient is supine, with the bed turned 180° to facilitate the surgeons' access to the operative site. An oral RAE tube is inserted and taped in the midline. The lesion is approached transorally, and a Dingman or Crowe-Davis retractor is used to obtain exposure.

Step 2: Resection

An incision is made around the periphery of the lesion in such a way as to maintain adequate margins; a monopolar electrocautery with a needle tip is ideal for this purpose. The periosteum is elevated away from the underlying bone, and the lesion is removed [see Figure 5].

When bone must be resected, the periosteum is elevated away from the incision site. A high-speed oscillating saw or an osteotome is used to make the cuts in the bone, after which the specimen is rocked free and removed.

Step 3: Reconstruction

After surgical margins have been verified by frozen-section review, repair of the surgical defect is initiated. Small mucosal defects may be allowed to heal by secondary intention. Small through-and-through resections may be closed by placing relaxing incisions laterally and advancing the mucosa to permit primary closure. Larger defects may be closed with palatal mucosal flaps. Many through-and-through defects can be closed quite satisfactorily with a dental obturator.

POSTOPERATIVE CARE

The patient should be maintained on a soft diet postoperatively. Meticulous oral hygiene is important. Oral rinses and flushes with normal saline or half-strength hydrogen peroxide should be performed at least four times daily and after meals.

Figure 5 Resection of hard palate. An incision is made around the lesion, with adequate margins maintained, the periosteum is lifted off the bone, and the lesion is removed.

COMPLICATIONS

The most significant potential complication of hard palate resection is oral antral or oronasal fistula; careful tissue reconstruction and the use of an obturator can prevent this complication.

Maxillectomy

OPERATIVE PLANNING

General anesthesia with muscle relaxation is essential for all types of maxillectomy. Either orotracheal or nasotracheal intubation may be appropriate, depending on the surgical approach. Skin incisions should be marked before the endotracheal tube is taped in place to avoid distortion of facial structures and skin lines. The patient should be supine in a 20° reverse Trendelenburg position. The eyes should be protected carefully (e.g., with a corneal shield or a temporary nylon tarsorrhaphy suture).

Radiographic evaluation plays a vital role in planning the surgical approach and determining the extent of resection required [see Figure 6]. Lesions of the infrastructure of the maxilla can be excised by means of partial maxillectomy via the transoral route. More extensive lesions usually must be accessed via facial incisions in conjunction with the transoral approach.

In all cases, a dental consultation should be obtained preoperatively so that a dental impression can be taken and an obturator fashioned for intraoperative use. Antibiotics should be given preoperatively and continued until nasal packing is removed.

OPERATIVE TECHNIQUE

Step 1: Surgical Approach

In addition to the transoral approach, maxillectomy usually requires exposure of the anterior face of the maxilla. There are several options for achieving such exposure, including a Weber-Ferguson incision and midface degloving. Midface degloving has the advantage of eliminating the need for visible facial incisions, but it yields limited exposure in the ethmoid region. The choice of surgical approach is determined by the extent of the planned resection and by the preferences of the patient and the surgeon.

In the Weber-Ferguson approach, the first step is to mark the path of the incision, which begins in the midline of the upper lip; extends through the philtrum; curves around the nasal vestibule and the ala; continues upward along the lateral nasal wall, just medial to the junction of the nasal sidewall and the cheek; and ends near the medial canthus. For added exposure in the ethmoid region, a Lynch extension, in which the incision is continued superiorly up to the medial eyebrow, may be performed. Alternatively, the Weber-Ferguson incision may be continued laterally in the subciliary crease along the inferior eyelid to the lateral canthus of the eye; this extension yields added exposure of the posterolateral aspect of the maxilla.

The skin incisions should initially be made with a scalpel and then continued with an electrocautery. The upper lip is divided through its full thickness, and the incision is continued in the gingivolabial sulcus laterally until the posterolateral aspect of the sinus is exposed. When possible, the infraorbital nerve is identified and preserved. The soft tissues are elevated from the anterior wall of the maxillary sinus; if access to the pterygomaxillary fissure is desired, elevation should be continued up to the zygoma.

In a midface degloving, the skin of the lower face and nose is mobilized and retracted superiorly. A standard transfixion incision is made, transecting the membranous septum. Intercartilaginous incisions are then made bilaterally and connected to the transfixion incision. The incision is then continued laterally along the cephalic border of the lower lateral cartilage and across the floor of the nose. To prevent stenosis, a small Z-plasty [see 3:7 *Surface Reconstruction Procedures*] or triangle is incised medially just before the transfixion incision is joined. The soft tissues are elevated over the nasal dorsum and the nasal tip with Joseph scissors. An incision is made in the gingivolabial sulcus with the monopolar cautery, and this incision is connected to the floor-of-nose incisions by means of gentle dissection. The soft tissues are then elevated from the anterior maxilla as far as the infraorbital rims and laterally as far as the zygoma.

Step 2: Resection

A Molt retractor is placed on the side opposite the side of the planned excision and opened as wide as possible to expose the hard palate and the alveolus.

The infraorbital rim should be preserved if it is possible to do so safely. Often, a thin strip of the rim can be preserved even when the rest of the bone must be resected. If the orbital floor must be resected but the orbital contents can be preserved, the periorbita can be dissected away from the bone of the orbital floor and preserved. If the orbital contents are involved, an orbital exenteration must be performed in conjunction with the maxillectomy.

The cut along the infraorbital rim and superior anterior maxillary wall is made with a high-speed oscillating saw with a fine blade. The level at which this superior cut is made is determined by the extent of the resection. Lesions that are confined to the alveolus or the palate and do not invade the maxilla typically can

be removed by excising the infrastructure of the maxilla. The line of transection is continued through the nasal process of the maxilla medially and downward through the piriform aperture. Laterally, the cut extends to the zygomatic process of the maxilla and around the posterolateral aspect of the sinus.

If the pterygoid plates are to be preserved, they are cut free by placing a curved osteotome along the posterior wall of the sinus and sharply dividing the plates from the sinus wall. If the pterygoid plates, part of the pterygoid musculature, or both are to be resected, the soft tissue attachments are cut sharply with curved Mayo scissors once the entire maxillary specimen has been mobilized.

The line of transection in the maxillary alveolus can run between two teeth if a suitable gap is evident. In the majority of cases, however, it is advisable to extract a tooth and make the cut through the extraction site. A power saw is used, and the cut is connected to the transection line through the nasal process of the maxilla and the piriform aperture. The hard palate mucosa is then incised lateral to the proposed cut in the hard palate bone to preserve a flap of mucosa that can be used to cover the raw cut bony edge of the palate. This incision is made with a needle-tip electrocautery and carried down to the bone of the hard palate. It should extend from the maxillary tuberosity posteriorly to the cut bone in the maxillary alveolus anteriorly, with care taken to obtain adequate mucosal margins. The mucosa is elevated for a short distance over the hard palate bone to create a short muco-

sal flap that is wrapped over the cut bony edge of the palate. The mucosal cut is connected around the maxillary tuberosity to the gingivolabial sulcus incision that was made earlier.

The hard palate is then cut with a power saw. Once all the bone cuts are complete, an osteotome may be used to connect them if necessary. The remaining soft tissue attachments are divided along the posterior hard palate with curved Mayo scissors. The surgical defect is packed to control bleeding. Bleeding from the internal maxillary artery is controlled by ligatures or ligating clips.

Step 3: Reconstruction

All sharp spicules of bone are debrided. The flap of hard palate mucosa is brought up over the cut bony edge of the palate and held in place with several Vicryl sutures. The anterior and posterior cut edges of the soft palate are reapproximated with absorbable sutures.

A split-thickness skin graft, 0.014 to 0.016 in. thick, is harvested and used to line the raw undersurface of the cheek flap. The skin graft is sutured to the mucosal edge of the cheek flap with 3-0 chromic sutures. Superiorly, the graft is not sutured but draped into position and retained by a layer of Xeroform packing and strip gauze coated with antibiotic ointment. Gentle pressure is applied to the packing so that it conforms to the defect. The previously fabricated dental obturator is placed to support the packing and to close the oral cavity from the nasal cavity. In a dentulous patient, the obturator may be wired to the remaining

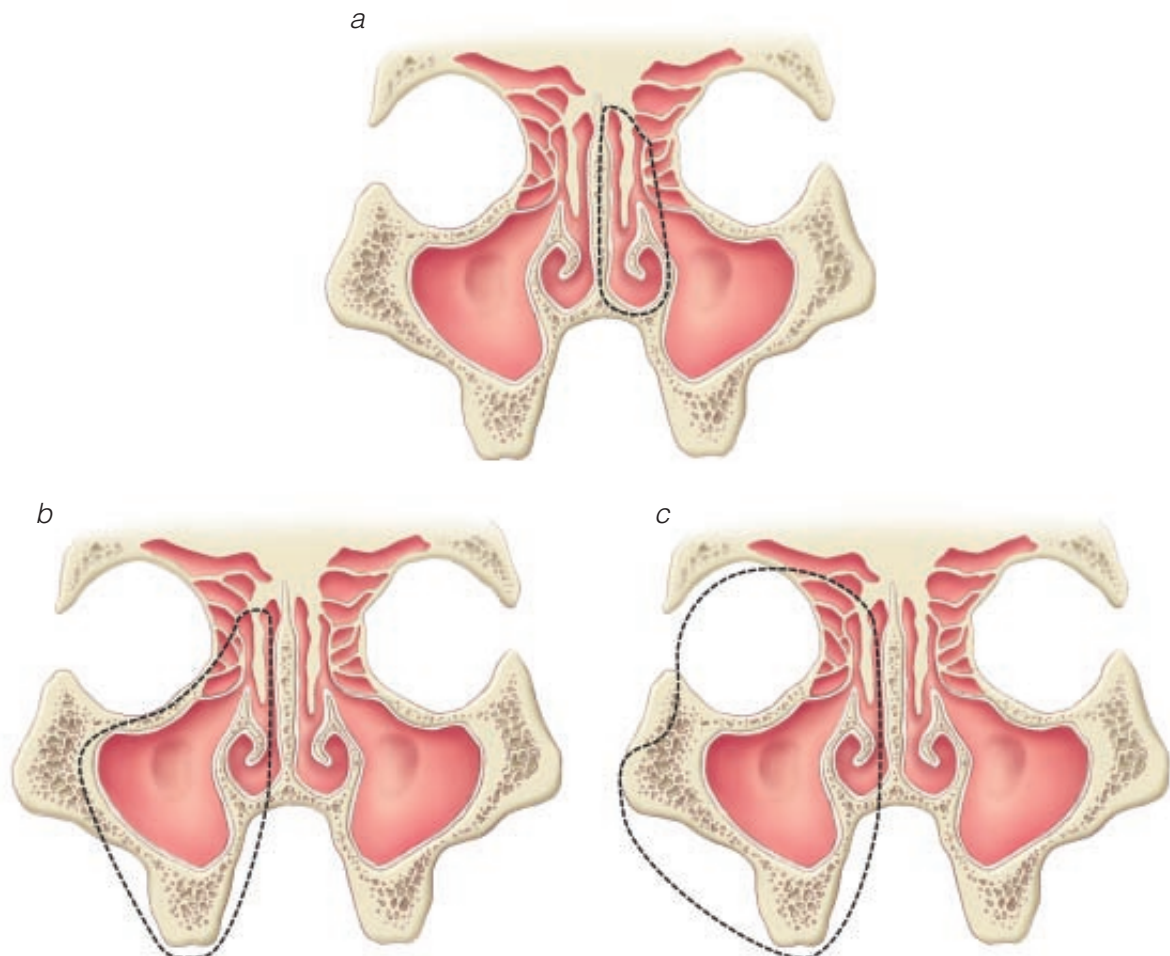

Figure 6 Maxillectomy. Radiographic assessment helps determine the required extent of resection. Depicted are (a) medial maxillectomy, (b) subtotal maxillectomy without orbital exenteration, and (c) total maxillectomy with orbital exenteration.

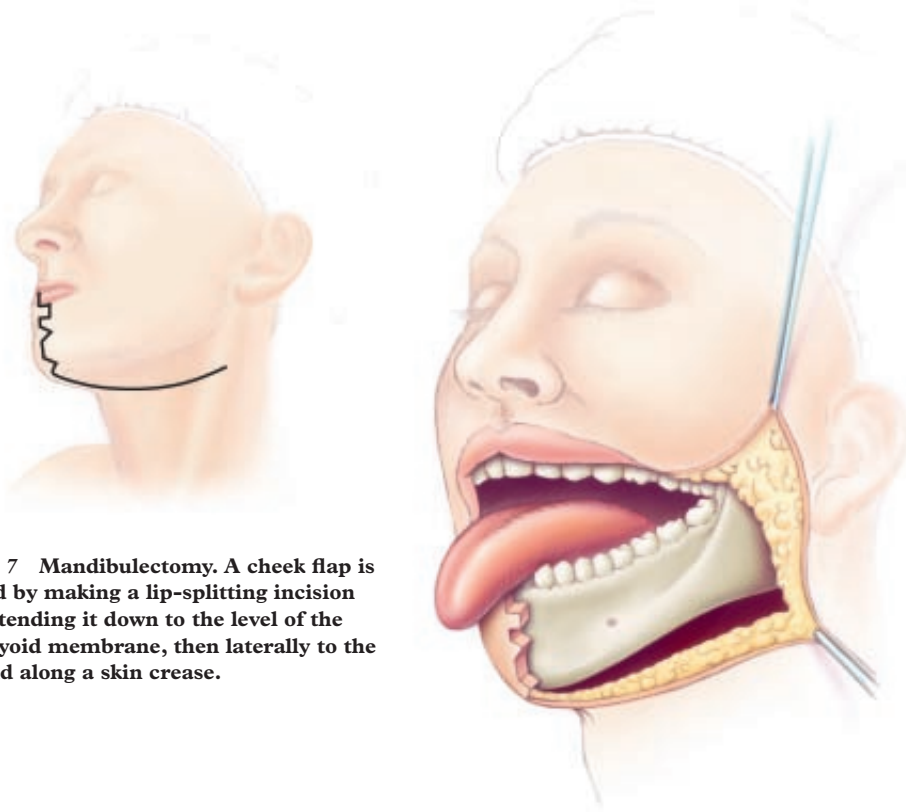

Figure 7 Mandibulectomy. A cheek flap is created by making a lip-splitting incision and extending it down to the level of the thyrohyoid membrane, then laterally to the mastoid along a skin crease.

teeth; in an edentulous patient, it may be temporarily fixed in place with two screws placed in the remaining hard palate.

The skin incisions are closed in two layers, with interrupted absorbable sutures used for the deep layers and nonabsorbable monofilament sutures for the skin. If a lip-splitting incision was made, care must be taken to ensure exact reapproximation of the orbicularis oris and the vermilion border.

If the infraorbital rim was resected, it should be reconstructed to yield good aesthetic results. A split calvarial bone graft may be used for this purpose when there is adequate soft tissue coverage for the bone grafts available. When soft tissue coverage is inadequate or the orbital floor must be reconstructed, an osteocutaneous radial forearm or scapular flap may be employed with excellent results.

Alternative Procedure: Peroral Partial Maxillectomy

The oral cavity is exposed with cheek retractors. An incision is made in the gingivobuccal sulcus and the mucosa of the hard palate, with care taken to maintain adequate margins; a monopolar electrocautery, set to use the cutting current, is suitable for this purpose. Incisions are made circumferentially through all the soft tissues up to the anterior wall of the maxilla and the hard palate. The infraorbital nerve should be preserved if it is not involved with the disease process.

The cut in the hard palate mucosa should be made lateral to the planned cuts in the hard palate bone to create a mucosal flap, which will be used to cover the cut bony edge of the hard palate. If necessary, teeth may be extracted to allow the surgeon to make bone cuts through tooth sockets while preserving adjacent teeth. The bone is cut with a high-speed power saw, and an osteotome is used to divide any remaining bony attachments and deliver the specimen. If the mucosa remaining in the maxillary antrum is not diseased, it need not be removed.

A split-thickness skin graft, 0.014 to 0.016 in. thick, is harvested from the anterolateral thigh and used to reline the raw buccal

mucosa area. The graft is sutured to the cut edge of the buccal mucosa with 4-0 chromic catgut. Xeroform and strip gauze coated with antibiotic ointment are gently packed into the defect to secure the skin graft. The previously fabricated dental obturator is wired to the remaining teeth to hold the packing in place.

TROUBLESHOOTING

If a lip-splitting incision is planned, lip contraction can be reduced and vermilion border realignment improved by employing a stair-step lip incision and a Z-plasty. A single intraoperative steroid dose reduces facial edema without compromising wound healing. Retention of the obturator is aided by the band of scar tissue that forms at the junction of the mucosa and the skin graft. Covering the cut edge of the hard palate bone with mucosa eliminates pain caused by pressure from the obturator on thinly covered bone.

If more than a small area of the floor of the orbit is resected, it should be repaired to prevent enophthalmos. Epiphoria is uncommon; when it occurs, it is related to scarring of the nasolacrimal duct. Identifying the duct and transecting it obliquely should reduce the incidence of this complication.

POSTOPERATIVE CARE

A nasogastric tube is placed at the end of the procedure. Many patients are able to begin a liquid diet and advance to a soft diet within a few days after operation. A soft diet should be continued for at least 2 weeks. Oral rinses and flushes with normal saline or half-strength hydrogen peroxide should be performed at least four times daily and after meals.

The obturator and the packing may be removed from the cavity in 7 to 10 days. The obturator should be replaced to maintain oral competence. The prosthodontist makes a final obturator once healing is complete and the cavity has stabilized. Facial incisions are cleaned twice daily and coated with antibiotic ointment. Facial sutures are removed 5 to 7 days after operation.

COMPLICATIONS

The main complications of maxillectomy are as follows:

1. Enophthalmos and hypophthalmos, which create a cosmetic deformity.
2. Infraorbital nerve injury, which results in anesthesia or paresis of the ipsilateral cheek and upper lip. On occasion, the infraorbital nerve may have to be sacrificed as part of the planned resection.
3. Epiphoria, caused by scarring of the nasolacrimal duct.
4. Difficult retention of the dental prosthesis, which can usually be prevented by careful preoperative evaluation and appropriate choice of reconstructive method. In select cases, free tissue reconstruction without a dental prosthesis may be optimal.

Mandibulectomy

OPERATIVE PLANNING

General anesthesia with muscle relaxation is essential for all types of mandibulectomy. Either orotracheal or nasotracheal intubation is appropriate, depending on the surgical approach and the extent of the planned resection. A tracheostomy should be performed whenever significant postoperative swelling or airway compromise is anticipated. Skin incisions should be marked before the endotracheal tube is taped in place.

Preoperative radiographic evaluation is essential for planning the surgical approach and determining the extent of the proposed resection. For lesions without radiographic or clinical evidence of bone invasion, a marginal mandibulectomy is often appropriate. This procedure may also be performed to obtain adequate surgical margins for lesions that are in close proximity to the mandible. When the lesion is small, it is occasionally possible to perform marginal mandibulectomy via the transoral route. For more extensive lesions and those that show evidence of bone invasion, a segmental mandibulectomy is required.

The patient should be supine in a 20° reverse Trendelenburg position. Perioperative antibiotics should be administered.

OPERATIVE TECHNIQUE

Step 1: Exposure

Wide exposure for access to primary tumors of the oral cavity and the mandible may be achieved by means of either a lower-cheek flap or a visor flap. The former is often preferable, in that it allows resection of the primary and ipsilateral lymph nodes.

To create a lower-cheek flap, a lip-splitting incision is made through the full thickness of the lower lip and carried down through the chin tissues to the periosteum of the anterior mandible [see Figure 7]. This incision may be made straight through the mental subunit with a Z-plasty placed at the mental crease; alternatively, it may be made around the mental subunit. The incision is continued vertically to approximately the level of the thyrohyoid membrane, then extended laterally to the mastoid along a skin crease. The transverse component of the incision should be made at least two fingerbreadths below the mandible to prevent injury to the marginal mandibular nerve. The cheek flap is fully developed by incising the oral mucosa along the gingivolabial sulcus while maintaining adequate surgical margins around the lesion. The periosteum of the mandible is then elevated and the cheek flap retracted to expose the mandible.

A visor flap [see Figure 3] has the advantage of not requiring a lip-splitting incision, and it provides adequate exposure for lesions of the anterior oral cavity. However, it is inadequate for exposing lesions posterior to the middle third of the tongue or in the area of

the retromolar trigone, and it may lead to anesthesia of the lower lip as a consequence of the need to divide both mental nerves. Technical aspects of visor flap creation are summarized elsewhere [see Anterior Glossectomy, Operative Technique, Step 1, above].

Step 2: Resection

If a plate is to be used in the reconstruction of the mandible, a template and a reconstruction plate are shaped and conformed to the mandible before resection. The segment of mandible to be resected is marked. The plate is applied to the buccal cortex of the mandible, and screw holes are predrilled in the mandible for gauging of depth. The plate is then set aside until needed for reconstruction.

Mucosal incisions are made around the lesion with the electrocautery, with care taken to maintain adequate surgical margins. The mandibular segment to be removed is cut with a high-speed sagittal saw. The lingual nerve and the hypoglossal nerve are preserved if possible. Muscle attachments to the resected mandibular segment are sharply divided, allowing the surgical specimen to be delivered [see Figure 8].

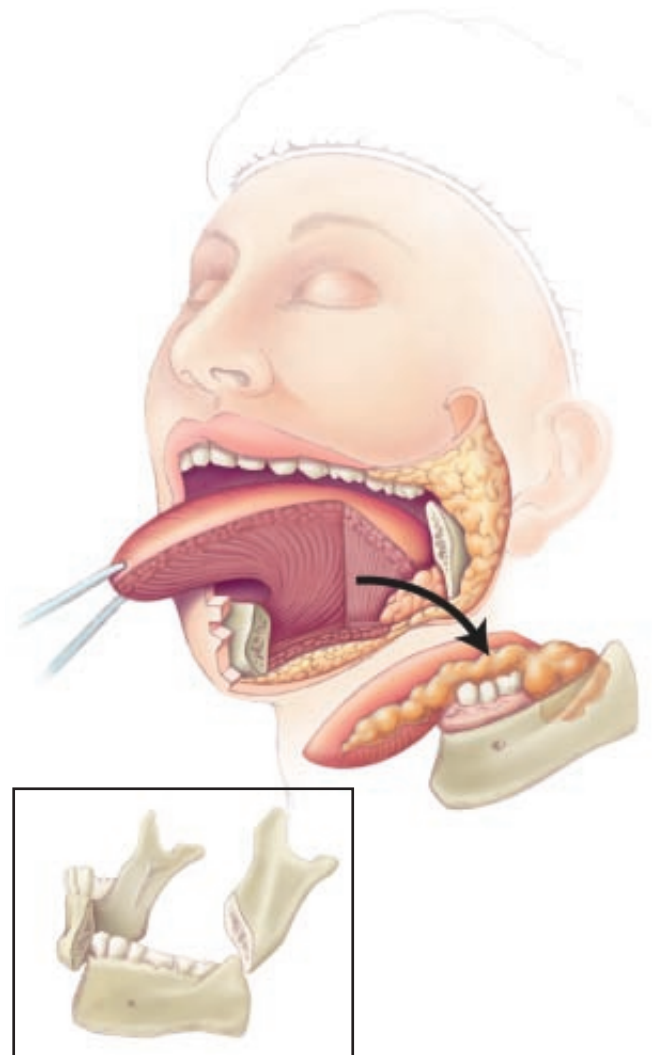

Figure 8 Mandibulectomy. The segment to be removed is cut with a high-speed saw, with care taken to preserve the lingual and hypoglossal nerves if possible, and the muscle attachments to the segment are sharply divided to free the surgical specimen.

In some cases, only a marginal mandibulectomy of the lingual or alveolar cortex of the mandible is necessary. The bone is cut with a high-speed saw in such a way that the cuts are rounded off and lack sharp angles, which are prone to fracturing. Once the bone cuts are made, an osteotome may be used to free the specimen.

Step 3: Reconstruction

When a marginal mandibulectomy has been performed, a plate is sometimes needed to support the mandible. This is especially likely to be the case for a patient with a thin edentulous mandible, in which the remaining bone cannot withstand the forces of mastication.

When the anterior mandible has been resected, it must be reconstructed with vascularized bone. Any of several free flaps may be employed, depending on the tissue requirements for the planned reconstruction. Free tissue flaps from the fibula, the scapula, or the iliac crest can provide bone that is suitable for mandibular reconstruction, as well as soft tissue that is suitable for reconstruction of accompanying mucosal and cutaneous defects.

After lateral mandibular resections, good results can be achieved by using mandibular reconstruction plates with suitable soft tissue reconstruction. There is a significant risk of plate failure, however, especially in dentulous patients. In many cases, replacing the resected portion of the mandible with vascularized bone—especially if the defect is longer than a few centimeters—yields better long-term results than using a reconstruction plate alone.

POSTOPERATIVE CARE

A nasogastric tube is placed at the end of the surgical procedure;

most patients will need to be fed through this tube until their incisions are healed. A soft diet should be continued for 6 weeks. Oral rinses and flushes with normal saline or half-strength hydrogen peroxide should be performed at least four times a day and after meals.

Facial incisions are cleaned twice a day and coated with antibiotic ointment. Facial sutures are removed 5 to 7 days after operation.

TROUBLESHOOTING

Contouring the reconstruction plate to the mandible before resecting the mandibular segment will prevent malocclusion and enhance cosmetic results. Preserving the lingual nerve and the hypoglossal nerve, when possible, will improve postoperative swallowing and speech. The marginal mandibular nerve should be identified and protected as well. If a lip-splitting incision is used, performing a stair-step lip incision and a Z-plasty reduces lip contraction and improves vermilion border realignment.

COMPLICATIONS

The main complications of mandibulectomy are as follows:

1. Malocclusion, caused by inaccurate repair of the resected mandibular segment.
2. Plate failure or fracture, which can be reduced by reconstructing bony defects larger than 1 to 2 cm with revascularized bone.
3. Oral incompetence, caused by inadequate reconstruction of anterior mandibular defects.

5 PAROTIDECTOMY

Leonard R. Henry, M.D., and John A. Ridge, M.D., Ph.D., F.A.C.S.

Anatomic Considerations

The parotid (“near the ear”) gland, the largest of the salivary glands, occupies the space immediately anterior to the ear, overlying the angle of the mandible. It drains into the oral cavity via Stensen’s duct, which enters the oral vestibule opposite the upper molars. The gland is invested by a strong fascia and is bounded superiorly by the zygomatic arch, anteriorly by the masseter, posteriorly by the external auditory canal and the mastoid process, and inferiorly by the sternocleidomastoid muscle. The masseter muscle, the styloid muscles, the posterior belly of the digastric muscle, and a portion of the sternocleidomastoid muscle lie deep to the parotid. Terminal branches of the external carotid artery, the facial vein, and the facial nerve are found within the gland. Parasympathetic innervation to the parotid is via the otic ganglion, which gives fibers to the auriculotemporal branch of the trigeminal nerve. Sympathetic innervation to the gland originates in the sympathetic ganglia and reaches the auriculotemporal nerve by way of the plexus around the middle meningeal artery.¹

The facial nerve trunk exits the stylomastoid foramen and courses toward the parotid. Once inside the gland, it commonly bifurcates into superior (temporal-frontal) and inferior (cervico-marginal) divisions before giving rise to its terminal branches. The nerve branching within the parotid can be quite complex, but the common patterns are well known and their relative frequencies well established.^{2,3} The portion of the parotid gland lateral to the facial nerve (about 80% of the gland) is designated as the superficial lobe; the portion medial to the facial nerve (the remaining 20%) is designated as the deep lobe. Deep-lobe tumors often present clinically as retromandibular or parapharyngeal masses, with displacement of the tonsil or soft palate appreciated in the throat.

Operative Planning

Obtaining informed consent for parotidectomy entails discussing both the features and the potential complications of the procedure. It is appropriate to address the possibility of facial nerve injury, but in doing so, the surgeon should not neglect other, far more common sequelae, such as cosmetic deformity, earlobe numbness, and Frey syndrome. Even conditions that are expected beforehand may prove distressing or debilitating for the patient. The risk of complications such as nerve injury is greater in cases involving reoperation or resection of malignant or deep-lobe tumors. The overwhelming majority of parotid tumors, however, are benign and lateral to the facial nerve. Accordingly, in what follows, we focus primarily on superficial parotidectomy, referring to variants of the procedure where relevant.

Excellent lighting, correctly applied traction and countertraction, adequate exposure, and clear definition of the surgical anatomy are essential in parotid surgery. The use of magnifying loupes and headlights is recommended. General anesthesia without muscle relaxation should be employed.

The patient is placed in the supine position, with the head elevated and turned away from the side undergoing operation and with the neck slightly extended. The table is positioned to allow the first assistant to stand directly above the patient’s head, while

the surgeon faces the operative field. A small cottonoid sponge is placed in the external auditory canal, where it remains for the duration of the procedure to prevent otitis externa from blood clots in the external auditory canal. The skin is painted with an antiseptic agent. A single perioperative dose of an antibiotic is administered.

The patient is draped in a fashion that permits the operating team to see all of the muscle groups innervated by the facial nerve. To this end, we employ a head drape that incorporates the endotracheal tube and hose. This drape secures the airway, keeps the tube from interfering with the surgeon, and permits rotation of the head without tension on the endotracheal tube. The skin of the upper chest and neck is widely painted and draped with a split sheet to allow additional exposure in the unlikely event that a neck dissection or a tracheostomy becomes necessary. The nose, the lips, and the eyes are covered with a sterile transparent drape that allows observation of movement during the procedure and permits access to the oral cavity (if desired) [see Figure 1].

Operative Technique

STEP 1: INCISION AND SKIN FLAPS

The incision is planned so as to permit excellent exposure with good cosmetic results. It begins immediately anterior to the ear, continues downward past the tragus, curves back under the ear (staying close to the earlobe), and finally turns downward to descend along the sternocleidomastoid muscle [see Figure 1]. Either all or part of this incision may be used, depending on circumstances. The incision is marked before draping. Skin creases typically help conceal the resulting scar.

Skin flaps are then created to expose the parotid gland. A tacking suture is placed within the dermis of the earlobe so that it can be retracted posteriorly. Skin hooks are used to apply vertical traction. The anterior flap is created superficial to the parotid fascia to afford access to the appropriate dissection plane. Vertically oriented blunt dissection minimizes the risk of injury to the distal branches of the facial nerve [see Figure 2]. The face is observed for muscle motion. The flap is raised until the anterior border of the gland is identified. The facial nerve branches are rarely encountered during flap elevation until they emerge from the parenchyma of the parotid. If muscle movement occurs, the flap has been more than adequately developed. The anterior flap is retracted with a suture through the dermis.

The posterior-inferior skin flap is then elevated in a similar manner. Careful dissection is performed to define the relationship of the parotid tail to the anterior border of the sternocleidomastoid. During this portion of the procedure, the great auricular nerve is identified coursing cephalad and superficial to the sternocleidomastoid muscle. Uninvolved branches of this nerve should be preserved if possible to prevent postoperative numbness of the earlobe.^{4,5} The parotid tail is dissected away from the sternocleidomastoid muscle. Vertical traction is applied to the gland surface with clamps to facilitate exposure.

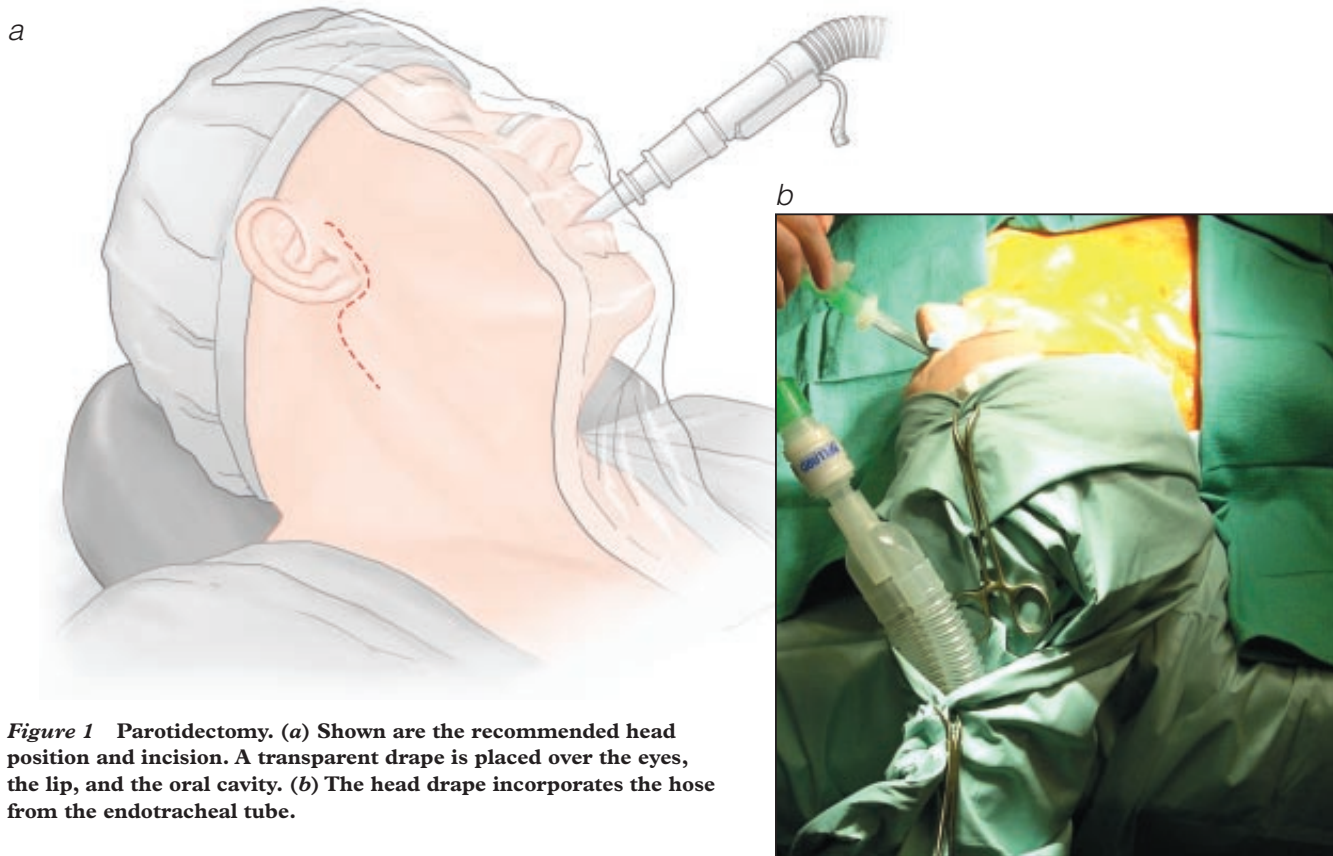

Figure 1 Parotidectomy. (a) Shown are the recommended head position and incision. A transparent drape is placed over the eyes, the lip, and the oral cavity. (b) The head drape incorporates the hose from the endotracheal tube.

Troubleshooting

A favorable skin crease, if available, may be used for the incision to improve the postoperative cosmetic result; however, it is important to keep the incision a few millimeters from the earlobe itself. A wound at the junction of the earlobe with the facial skin will distort the earlobe and create a visible contour change. An incision behind the tragus may lead to similar problems.

STEP 2: IDENTIFICATION OF FACIAL NERVE

Once the flaps have been developed and retracted, the next step is to identify the facial nerve. Usually, the nerve may be identified either at its main trunk (the antegrade approach) or at one of the distal branches, with subsequent dissection back toward the main trunk (the retrograde approach). For a lateral parotidectomy, our preference is to identify the main trunk first (unless it is thoroughly obscured by tumor or scar).

Antegrade Approach

The dissection plane is immediately anterior to the cartilage of the external auditory canal. The gland is mobilized anteriorly by means of blunt dissection. To reduce the risk of a traction injury, tissue is spread in a direction that is perpendicular to the incision and thus parallel to the direction of the main trunk of the nerve [see Figure 3]. The nerve trunk can usually be located underlying a point about halfway between the tip of the mastoid process and the ear canal. In addition, there are several anatomic landmarks that facilitate identification of the nerve, including the tragal pointer, the posterior belly of the digastric muscle, and the tympanomastoid suture. Of these, the tympanomastoid suture is closest to the main trunk of the facial nerve.⁶ The clinical utility of this landmark is limited, however, because the tympanomastoid suture is not easily appreciated in every case. In addition, deep-lobe

tumors may displace the nerve from its normal location. For appropriate and safe exposure of the nerve trunk, it is necessary to mobilize several centimeters of the parotid, thereby creating a trough rather than a deep hole. Small arteries run superficial and parallel to the facial nerve; these must be divided. Use of the electrocautery this close to the nerve is potentially hazardous. Bleeding is typically minor but nonetheless must be controlled.

Retrograde Approach

As noted, when the main trunk cannot be exposed, the most common alternative method of identifying the facial nerve is to find a peripheral branch and then dissect proximally toward the main trunk. Which branch is sought may depend on factors such as the surgeon's level of comfort with the relevant anatomy and known consistency or inconsistency of the nerve branch's location. Often, in this setting, tumor bulk is the deciding factor.

The anatomic relationships between the nerve branches and various landmarks can be exploited for more efficient identification. For example, the marginal mandibular branch of the facial nerve characteristically lies below the horizontal ramus of the mandible.⁷ Often, the facial vein can be traced toward the parotid or the submandibular gland; the nerve branch can then be found coursing perpendicular and superficial to the vein. The buccal branch of the facial nerve has a typical location in the so-called buccal pocket—the area inferior to the zygoma and deep to the superficial musculoaponeurotic layer, which contains the buccal fat pad and Stensen's duct in addition to the buccal branch.⁷ The zygomatic branch of the facial nerve lies roughly 3 cm anterior to the tragus, and the temporal-frontal branch lies at the midpoint between the outer canthus of the eye and the junction of the ear's helix with the preauricular skin.⁷ Nerve branches to the eye should be dissected with particular care: even transient

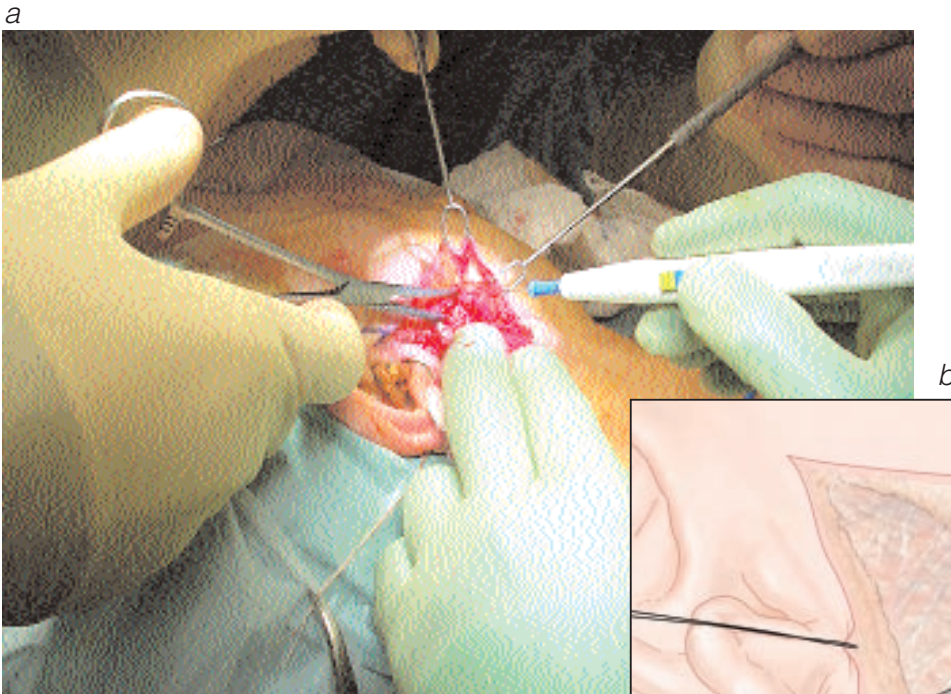

Figure 2 Parotidectomy. (a) Shown is the creation of the anterior skin flap superficial to the parotid gland. (b) Vertically oriented blunt dissection minimizes the risk of injury to facial nerve branches as they exit the gland.

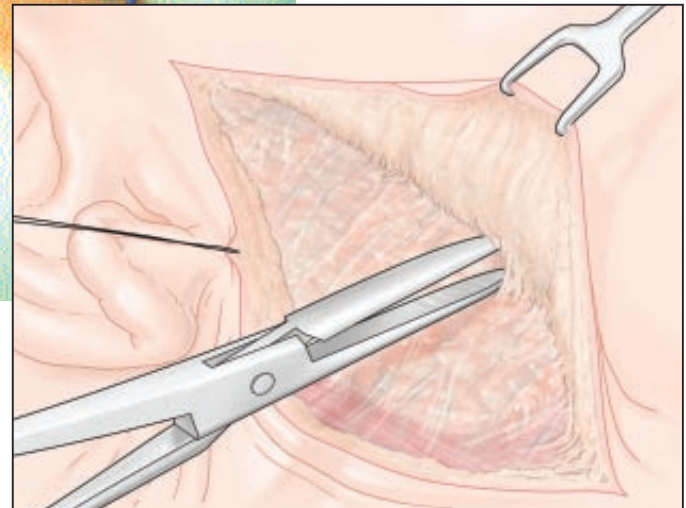

Figure 3 Parotidectomy. Depicted is identification of the facial nerve at its trunk. A wide trough is created anterior to the external auditory canal and deepened by spreading a blunt curved instrument in a direction perpendicular to the incision and parallel to the nerve trunk. Anatomic landmarks assist in identification of the nerve.

weakness of these branches may have a significant impact on morbidity.

Troubleshooting

Special efforts should be made to ensure that the cartilage of the ear canal is not injured during exposure of the facial nerve trunk. Any injury to this cartilage must be repaired, or else an intense whistling will be heard from the closed suction drain after operation.

The anxiety associated with isolation of the nerve trunk may be alleviated somewhat by keeping in mind that the nerve typically lies deeper than one might expect. In a study of 46 cadaver dissections, the facial nerve was found to lie at a median depth of 22.4 mm from the skin at the stylomastoid foramen (range, 16 to 27 mm). The diameter of the nerve trunk was found to range from 1.1 to 3.4 mm.⁸ In our experience, the facial nerve trunk is slightly larger than the nearby deep vessels.

Some surgeons advocate the use of a nerve stimulator to aid in identifying the facial nerve trunk or its branches; however, we have substantial reservations about whether this measure should be employed on a regular basis [see Complications, Facial Nerve Injury, below]. Knowledge of the anatomy and sound surgical technique are the keys to a safe parotidectomy; it may be hazardous to rely too much on practices that may diminish them.

STEP 3: PARENCHYMAL DISSECTION

Once identified, the plane of the facial nerve remains uniform throughout the gland (unless the nerve is displaced by a tumor) and serves to guide the parenchymal dissection. We divide the substance of the parotid gland sharply, using ligatures as appro-

Figure 4 Parotidectomy. Dissection of the gland parenchyma is carried out over the branches of the facial nerve to minimize the risk of nerve injury. Each division of the substance of the gland should reveal more of the facial nerve.

appropriate when bleeding is encountered. Usually, there is no significant hemorrhage: loss of more than 30 ml of blood is rare.

The parenchymal dissection proceeds directly over the facial nerve. We favor using fine curved clamps for this portion of the procedure. To prevent trauma to the nerve, care must be taken to resist the tendency to rest the blades of the clamp on the nerve during dissection. Each division of the gland should reveal more of the facial nerve [see Figure 4]. When this is the case, the surgeon can continue the parenchymal dissection with confidence that the nerve will not be injured. As a rule, if a parenchymal division does not immediately show more of the facial nerve, it is in an improper plane.

We do not regularly resect the entire lateral lobe of the parotid unless the tumor is large and such resection is required on oncologic grounds. The goal in resecting the substance of the parotid gland is to obtain sound margins while preserving the remainder of the gland. This so-called partial superficial parotidectomy has been shown to reduce the incidence of Frey syndrome without increasing the rate of recurrence of pleomorphic adenoma.⁹ The plane of dissection is developed along facial nerve branches until the lateral margins have been secured. This is the portion of the procedure during which the risk of nerve injury is highest. Once the lateral margins have been secured, the parenchymal dissection can proceed from deep to superficial for the excision of the tumor. The vertical portion of the dissection seldom poses a threat to the integrity of the facial nerve, but care must be taken to maintain appropriate margins. If division of Stensen's duct is required, the distal remnant may be either left open¹⁰ or ligated.

Caution is appropriate in the resection of deep-lobe tumors. Tumors medial to the facial nerve may displace this structure laterally. Thus, after establishing the plane of the facial nerve, the surgeon must remain careful when dissecting near the tumor to keep from injuring the nerve. Once the substance of the gland obscuring the tumor has been removed, the nerve branches in the

area of the tumor are retracted to allow exposure of the deep portion of the gland and facilitate resection. Traction injury to the nerve may still result in transient facial weakness.

Troubleshooting

Complete superficial parotidectomy with full dissection of all facial nerve branches is seldom necessary, though in some cases, it is mandated by tumor size or histologic findings. Removal of the entire superficial lobe with the intention of gaining a larger lateral margin is rarely useful, because the closest margin is usually where the tumor is nearest the facial nerve. Even temporary paresis of the temporal-frontal branch of the facial nerve may have devastating consequences, and dissection near this branch is usually unnecessary in treating a benign tumor in the parotid tail. Any close margins remaining after nerve-preserving cancer treatment can be addressed by means of postoperative radiation therapy, usually with excellent results.¹¹

The question of whether to sacrifice the facial nerve almost invariably arises in the setting of malignancy. In our view, this measure is seldom necessary. Benign tumors tend to displace the nerve, not invade it. Sacrifice of the nerve probably does not enhance survival.^{12,13} Although the issue remains the subject of debate, it is our practice, like that of others,¹⁴ to sacrifice only those branches intimately involved with tumor. Repair, if feasible, should be performed [see Complications, Facial Nerve Injury, below].

STEP 4: DRAINAGE AND CLOSURE

Before closure, absolute hemostasis is confirmed; the Valsalva maneuver is approximated by transiently increasing airway pressure to 30 cm H₂O. We may then assess the integrity of the facial nerve with a nerve stimulator. A 5 mm closed suction drain is placed through a stab incision posterior to the inferior aspect of the ear in a hair-bearing area. The tip of the drain is loosely tacked to the sternocleidomastoid muscle, with care taken to avoid direct contact with the facial nerve. The wound is closed with the drain placed on continuous suction. The skin is closed with interrupted 5-0 nylon sutures. Bacitracin is applied to the wound. No additional dressing is necessary or desirable [see Figure 5].

Troubleshooting

The use of interrupted skin sutures instead of a continuous suture allows the surgeon to perform directed suture removal to drain the rare postoperative hematoma or fluid collection instead of reopening the entire wound.

Postoperative Care

The patient is evaluated for facial nerve function in the recovery room, with particular attention paid to whether the patient is able to close the eyelid. The patient resumes eating when nausea (if any) abates. Pain is generally well controlled by means of oral agents. At discharge, the patient should be warned to protect the numb earlobe against cold injury. The closed suction drain is kept in place for 5 to 7 days (until the first postoperative visit) to minimize the risk of salivary fistula.

Complications

FACIAL NERVE INJURY

Studies have found that transient paralysis of all or part of the facial nerve occurs in 17% to 100% of patients undergoing parot-

idectomy,¹⁵⁻¹⁸ depending on the extent of the resection and the location of the tumor. Fortunately, permanent paralysis is uncommon, occurring in fewer than 5% of cases.^{17,19}

Nerve monitoring has been advocated to reduce the incidence of facial nerve injury. To date, however, no randomized trial has demonstrated that intraoperative facial nerve monitoring or nerve stimulators yield any significant reduction in the incidence of facial nerve paralysis. Indeed, indiscriminate use of nerve monitoring and nerve stimulators may imbue the surgeon with a false sense of security and cause him or her to pay insufficient attention to the appearance of nerve tissue. Transient nerve dysfunction may follow inappropriate (or even appropriate and unavoidable) trauma to or traction and pressure on nerve trunks. Nerve monitoring does not prevent such problems; moreover, it adds to the cost of the procedure and increases operating time.²⁰ Some, in fact, have suggested that nerve stimulators may actually increase transient dysfunction. Accordingly, our use of nerve stimulators is selective.

The management of facial nerve injury depends on when the injury is discovered and on how sure the surgeon is of the anatomic integrity of the nerve. If the injury is discovered intraoperatively, it should be repaired if possible. Primary repair—performed with interrupted fine permanent monofilament sutures under magnification²¹—is preferred if sufficient nerve is available for a tension-free anastomosis. If both transected nerve ends are identified but tension-free repair is not feasible, interposition nerve grafts may be used. Sensory nerves harvested from the neck (e.g., the great auricular nerve) are often employed for this purpose. If the nerve is injured (or deliberately sacrificed) in conjunction with treatment of malignancy, use of nerve grafts from distant sites may be indicated.²¹

If unexpected facial nerve dysfunction is identified in the postanesthesia care unit and if the surgeon is unsure of the anatomic integrity of the nerve (ideally, a rare occurrence), the patient should be returned to the operating room for wound

exploration so that either the continuity of the nerve can be confirmed or the injury to the nerve can be identified and repaired if possible. When the surgeon is certain that the nerve is intact, facial nerve dysfunction can be managed without reoperation, in anticipation of recovery²¹; however, this may take many months.

Management of enduring facial nerve paralysis (from any cause) is beyond the scope of our discussion and constitutes a surgical subspecialty in itself.²¹

GUSTATORY SWEATING (FREY SYNDROME)

Gustatory sweating, or Frey syndrome, occurs in most patients after parotidectomy; it has been seen after submandibular gland resection as well. The symptom complex includes sweating, skin warmth, and flushing after chewing food and is caused by cross-innervation of the parasympathetic and sympathetic fibers supplying the parotid gland and the overlying skin. The reported incidence of Frey syndrome varies greatly, apparently depending on the sensitivity of the test used to elicit it. When Minor's starch iodine test is employed, the incidence of Frey syndrome may reach 95% at 1 year after operation.²² Fortunately, the majority of patients exhibit only subclinical findings, and only a small fraction complain of debilitating symptoms.²² Most symptomatic patients are adequately treated with topical antiperspirants; eventually, however, they tend to become noncompliant with such measures, preferring simply to dab the face with a napkin while eating.²² Despite the relatively low incidence of clinically significant Frey syndrome, there is an extensive literature addressing prevention and treatment of this condition.^{9,19,23-30}

SIALOCELE (SALIVARY FISTULA)

Sialocele, or salivary fistula, has been reported to occur after 1% to 15% of parotidectomies.^{9,31} Although this condition is generally minor and self-limited, it may nonetheless be embarrassing for the patient. We believe that the incidence of sialocele can be reduced by maintaining closed suction drainage for 5 to 7 days (to

Figure 5 Parotidectomy. Shown is drainage and closure after parotidectomy. (a) A closed suction drain is placed in the operative bed and loosely tacked to the sternocleidomastoid muscle. (b) Interrupted monofilament sutures are used for the skin. Bacitracin is applied. No additional dressings are used.

facilitate adhesion of the skin flaps to the underlying parotid parenchyma). Postparotidectomy salivary fistula is usually attributable to gland disruption rather than to duct transection and therefore tends to resolve without difficulty.³² Compression dressings are generally effective.³¹ Anticholinergic agents have been used in this setting as well.³³⁻³⁶ Low-dose radiation,³⁷ completion parotidectomy, and tympanic neurectomy³⁸ have all been employed in refractory cases.

COSMETIC CHANGES

Parotidectomy creates a hollow anterior and inferior to the ear, which may extend behind the mandible and may reach a significant size in patients with large or recurrent tumors. This cosmetic change is a necessary feature of the procedure, not a complication; nonetheless, it should be discussed with the patient before operation. Many augmentation methods, using a wide variety of techniques, have been devised for improving postoperative appearance

(as well as alleviating Frey syndrome).^{24-28,39,40} All of these methods have limitations or drawbacks that have kept them from being widely applied and accepted.

Outcome Evaluation

With proper surgical technique, superficial or partial superficial parotidectomy can be performed safely and within a reasonable operating time. Blood transfusions should be required only in very rare cases. Given adequate exposure, good knowledge of the relevant anatomy, limited trauma to the nerve, and appropriate use of closed suction drains (see above), complications should be uncommon. Although patients may tolerate parotidectomy on an outpatient basis, we prefer to keep them in the hospital overnight. Patients should be able to leave the hospital with minimal pain, comfortable with their drain care, by the morning of postoperative day 1.

Preoperative Evaluation

In the majority of cases, cancer in the neck is a metastasis from a primary lesion in the upper aerodigestive tract, though metastases from skin, thyroid, and salivary gland neoplasms are also encountered. Lymphomas often present as cervical lymphadenopathy.

When a patient presents with a suspicious lesion in the neck, a careful history and physical examination should be performed, along with a thorough evaluation of the aerodigestive tract aimed at locating the source of possible metastatic disease. Fine-needle aspiration (FNA) of the neck mass should then be done to determine whether the mass is malignant. FNA can often differentiate between epithelial and lymphoid malignancies, and this differentiation will guide subsequent workup. The reported sensitivity of FNA ranges from 92% to 98%; the reported specificity, from 94% to 100%.^{1,2}

If FNA reveals the presence of atypical lymphoid cells, an excisional lymph node biopsy should be performed to supply the pathologist with a large enough sample to allow full typing of the tissue. An excisional biopsy may also be performed if the FNA is negative or indeterminate, the surgeon suspects a malignancy, and the rest of the physical examination yields negative results. Routine excisional biopsy of neck masses for diagnostic purposes is not recommended, however, because it may result in tumor spillage into the wound and complicate subsequent definitive resection.

Once the presence of an epithelial malignancy is established, the primary site of the lesion must be determined if it is not apparent on initial physical examination. Imaging studies (e.g., computed tomography and magnetic resonance imaging) may be helpful in locating the source of a cervical metastasis. Positron emission tomography (PET) detects lesions with increased metabolic activity but has the limitation of being unable to detect lesions smaller than 1 cm in diameter. Primary lesions greater than 1 cm in diameter usually are easily identified on physical examination and other imaging studies; thus, PET scans are of limited value in this setting. In any patient with metastatic cervical adenopathy thought to originate in the upper aerodigestive tract, panendoscopy and biopsy with general anesthesia are mandatory for locating and characterizing the primary source of the tumor and ruling out the presence of synchronous lesions. The most common occult primary sites are the base of the tongue, the tonsils, and the nasopharynx. In 5% to 10% of patients who present with a metastatic node, the primary lesion is never found despite extensive workup.

INCIDENCE AND IMPACT OF NECK METASTASES

Cutaneous Squamous Cell Carcinoma

The incidence of cervical metastases is governed by many factors. Cervical metastases from cutaneous squamous cell carcinomas are rare, occurring in 2% to 10% of cases. However, certain lesions—those that are greater than 2 cm in diameter; are recur-

rent; are deeper than 6 mm; involve the ear, the temple, or the classic H zone; occur in an immunocompromised patient; or are poorly differentiated—have a significant occult metastatic rate, ranging from 20% to 60%. The presence of cervical metastases reduces 5-year survival to about 32%,³ which suggests that early intervention for high-risk cutaneous lesions, involving regional lymphadenectomy, sentinel lymph node (SLN) biopsy, or irradiation of at-risk lymph node basins, may be warranted.

Salivary Gland Neoplasms

With salivary gland neoplasms [see 2:2 *Oral Cavity Lesions*], the incidence of cervical metastases is related to the histopathology as well as the size of the tumor. The most aggressive salivary gland lesions are squamous cell carcinoma, carcinoma ex pleomorphic adenoma, adenocarcinoma, and salivary ductal carcinoma. Patients with these lesions often have cervical metastases at presentation that warrant a therapeutic neck dissection [see Table 1]. How best to manage occult cervical salivary gland metastatic disease is controversial. The occult metastatic rate for aggressive lesions ranges from 25% to 45%. For such lesions, a selective neck dissection is typically incorporated into the surgical approach.⁴

Metastatic Well-Differentiated Thyroid Cancer

Cervical lymph node metastases are present in 10% to 15% of patients with well-differentiated thyroid carcinoma. The impact of nodal metastases on local recurrence and survival has not been established. Other factors (e.g., age, sex, tumor extent, and distant metastases) appear to have a greater effect on prognosis. Nevertheless, in the presence of clinically apparent nodal disease, a formal neck dissection is advised: so-called cherry-picking operations or limited lymph node excisions result in higher rates of recurrence.⁵

Squamous Cell Carcinoma of the Upper Aerodigestive Tract

With upper aerodigestive tract squamous cell carcinomas, the incidence of cervical metastases is related to the site of the primary lesion, the size of the tumor, the degree of differentiation, the depth of invasion, and a number of other factors. A significant proportion of head and neck cancer patients who harbor clinically silent primary tumors of the base of the tongue, the tonsils, or the nasopharynx initially present with cervical adenopathy [see Table 1]. These sites lack anatomic barriers that limit tumor spread and are supplied by rich lymphatic networks that facilitate metastasis. In contrast, patients with glottic and lip cancers are more likely to present early, without clinical adenopathy.

The presence of cervical metastases negatively affects prognosis and has been associated with increased recurrence rates and reduced disease-free and overall survival. The presence of clinical adenopathy decreases survival by 50%. Metastatic tumors that rupture the lymph node capsule—a process known as extracapsular spread (ECS)—are biologically more aggressive. Patients

Table 1 Incidence of Cervical Metastases in Selected Head and Neck Cancers

Tumor	Incidence of Cervical Adenopathy
Cutaneous squamous cell carcinoma	2%–10%
Salivary gland malignancies	
Mucoepidermoid carcinoma (high-grade)	30%–70%
Adenoid cystic carcinoma	8%
Malignant mixed tumor	25%
Squamous cell carcinoma	46%
Salivary duct carcinoma	50%
Acinic cell carcinoma	40%
Metastatic well-differentiated thyroid cancer	10%–15%
Squamous cell carcinoma of upper aerodigestive tract	
Alveolar ridge	30%
Hard palate	10%
Oral tongue	30%
Anterior pillar/retromolar trigone	45%
Floor of mouth	30%
Soft palate	44%
Tonsillar fossa	76%
Tongue base	78%
Bilateral	20%

who have palpable cervical lymphadenopathy with ECS manifest a 50% decrease in survival compared with those who have palpable cervical lymphadenopathy without ECS.⁶ In addition, about 50% of clinically negative, pathologically positive neck specimens exhibit ECS. Clinically negative, pathologically positive, and ECS-positive specimens are associated with a high risk of regional recurrence and distant metastases.^{7–9} The presence of ECS in lymph node metastases may in fact be the single most important prognostic factor in patients with head and neck cancer. Identification of this patient subset may be the most important benefit of elective neck dissection, in that it allows these patients to be offered adjuvant therapy. Nonrandomized studies have found that both disease-specific and overall survival are significantly improved when these high-risk patients are treated with adjuvant postoperative chemoradiation.¹⁰ However, randomized clinical trials are needed to confirm the clinical benefits of adjuvant chemoradiation in this setting.

Whereas anatomic and pathologic factors (e.g., ECS) have long been known to predict tumor behavior, it is only comparatively recently that the impact of comorbidity has been well characterized. When patients are stratified by tumor stage, those with comorbidities fare worse. In fact, the impact of comorbidity on overall survival is greater than that of tumor stage or treatment type.^{10,11} In addition, comorbidity is associated with both increased frequency and increased severity of surgical complications. These factors may be important in treatment selection and patient counseling. To date, comorbidity has not been incorporated into clinical staging of head and neck cancer patients.

STAGING OF NECK CANCER

Staging of the neck for metastatic squamous cell carcinomas of the head and neck is based on the TNM classification formulated by the American Joint Committee on Cancer (AJCC) [see 2:2 *Oral Cavity Lesions*]. The N classification applies to cervical metastases from all upper aerodigestive tract mucosal sites except

the nasopharynx; it also applies to metastases from major salivary gland and sinonasal malignancies but not to metastases from cutaneous or thyroid malignancies, which use an alternate staging system.

The purpose of staging is to characterize the tumor burden of an individual patient. Accordingly, an effective staging system should incorporate factors known to have prognostic and therapeutic significance, thereby facilitating planning of therapy and appropriate patient counseling. In addition, it should attempt to standardize reporting so that meaningful cross-institutional comparisons can be obtained. A staging system ideally should also be simple to apply while still incorporating biologically important factors that permit accurate patient stratification in prospective clinical trials. Precise characterization and differentiation of tumors facilitate identification of those patients who are most likely to benefit from treatment.

The TNM staging system does not include a number of factors that are known to have an impact on prognosis, such as the presence or absence of ECS and the pattern of lymphatic spread. Nonanatomic factors (e.g., comorbidity, immune status, and nutritional status) have a strong impact on survival as well but are also not incorporated in the current staging system. In general, TNM staging has been found inadequate for use in clinical trials.¹²

The limitations of clinical staging of the neck are well described. The addition of imaging to clinical examination improves diagnostic sensitivity but not specificity. Imaging is particularly useful after chemoradiation because of the difficulty of clinical examination in this setting. Pathologic review of neck specimens remains the gold standard for anatomic staging. The addition of ultrasound-guided FNA of neck nodes yields enhanced diagnostic accuracy in cases where the neck is clinically negative but the radiologic findings are positive. This approach is employed to select patients for neck dissection in a number of centers, particularly in Europe; whether it provides more accurate staging than alternative methods, such as SLN biopsy, remains to be determined. Results from the First International Conference on Sentinel Node Biopsy in Mucosal Head and Neck Cancer revealed that SLN biopsy of the clinically negative neck has a sensitivity comparable to that of a staging neck dissection.¹³ In general, imaging modalities appear to be neither sufficiently sensitive nor sufficiently specific in the evaluation of the clinically negative neck. Uptake of 2-deoxy-3 [¹⁸F] fluoro-D-glucose, as measured by PET scans, is undetectable in small foci of cancer in the clinically negative neck.¹⁴

Proper staging is important for stratification of patients into risk categories on the basis of tumor biology, so that high-risk patients may be appropriately selected for clinical trials or offered adjuvant therapy and other patients may be spared unnecessary treatment. Until accurate methods of assessing the clinically negative neck are developed, selective neck dissection will be performed to treat the neck when the occult metastatic rate is expected to be higher than 20%.

INDICATIONS FOR NECK DISSECTION

The classic indication for neck dissection is for treatment of metastatic carcinoma in the neck, most frequently deriving from a mucosal site in the upper aerodigestive tract. Over time, the indications for neck dissection have changed. With wider use of chemoradiation therapy for head and neck cancer, treatment of metastatic disease in the neck has become increasingly nonsurgical. Currently, neck dissections are considered either therapeutic (performed to treat palpable disease in the neck) or elective (per-

Figure 1 Cervical lymph nodes are divided into six levels on the basis of their location in the neck.

formed when the expected incidence of occult metastases from a lesion exceeds 20%). Technically, neck dissections are classified as comprehensive dissections, which incorporate five levels of the neck, or selective dissections, in which only selected lymph node levels are removed according to predicted drainage patterns from specific primary sites. There is also a third technical classification, extended neck dissections, which can be combined with selective or comprehensive neck dissections for removal of additional nodal basins [see Operative Planning, Choice of Procedure, below]. Six lymph node drainage basins in the neck are recognized [see Figure 1].

CONTRAINDICATIONS TO NECK DISSECTION

The only absolute contraindication to neck dissection is surgical unresectability. The determination of unresectability is made by the operating surgeon either preoperatively, on the basis of imaging studies, or in the operating room. Typically, the presence of Horner syndrome, paralysis of the vagus nerve or the phrenic nerve, or invasion of the brachial plexus or the prevertebral muscles indicates that the tumor is unresectable. The involvement of the carotid artery may be predicted on the basis of imaging studies. Encasement of the carotid artery by tumor suggests direct invasion of the vessel; however, studies correlating imaging characteristics and pathologic invasion of the carotid have shown that tumors surrounding 180° or more of the carotid's circumference have a higher incidence of carotid invasion than tumors surrounding less than 180° (75% versus 50%). In the absence of direct invasion of the vessel wall, tumor may be peeled off by means of subadventitial surgical dissection. Tumors surrounding 270° of the vessel have an 83% incidence of carotid invasion, necessitating sacrifice of the artery.¹⁵ However, sacrifice of the carotid artery, with or without reconstruction with a vein graft, has been associated with significant morbidity and confers no survival benefit.¹⁶

Operative Planning

CHOICE OF PROCEDURE

Comprehensive Dissection: Radical and Modified Radical Neck Dissection

The radical neck dissection was first described in 1906 by George Crile, who based his approach on the Halstedian principle of en bloc resection. The procedure was subsequently standardized by Hayes Martin at Memorial Hospital in New York in the 1930s and 1940s. In this latter version of the procedure, lymphatic structures from the strap muscles anteriorly, the trapezius posteriorly, the mandible superiorly, and the clavicle inferiorly are removed. Nonlymphatic structures in this space are also sacrificed, including the spinal accessory nerve, the sternocleidomastoid muscle, the internal and external jugular veins, the submandibular gland, and sensory nerve roots. The routine sacrifice of the spinal accessory nerve, the internal jugular vein, and the sternocleidomastoid muscle contributes to the significant morbidity associated with radical neck dissection.

Since the 1970s, the necessity of en bloc resection for oncologic cure has been reexamined. Structures once routinely sacrificed are now routinely preserved unless they are grossly involved with cancer. The various functional, or modified, radical neck dissections are classified according to which structures are preserved. Type I dissections preserve the spinal accessory nerve; type II, the spinal accessory nerve and the internal jugular vein; type III, both of these structures along with the sternocleidomastoid muscle. Modified radical neck dissections have proved to be as effective in controlling metastatic disease to the neck as the classic radical neck dissection.¹⁷

Selective Neck Dissection

In a selective neck dissection, at-risk lymph node drainage basins are selectively removed on the basis of the location of the primary tumor in a patient with no clinical evidence of cervical lymphadenopathy. Cancers in the oral cavity, for example, typically metastasize to levels I through III and, occasionally, IV; laryngeal cancers typically metastasize to levels II through IV. The rationale for selective neck dissection is based on retrospective pathologic reviews of radical neck dissection specimens from patients without palpable lymphadenopathy. These reviews revealed that lymph node micrometastases were confined to specific neck levels for a given aerodigestive tract site.¹⁸

The advantages of selective neck dissection over radical and modified radical neck dissection are both cosmetic and functional. A selective neck dissection involves less manipulation (and thus less risk of devascularization) of the spinal accessory nerve, thereby decreasing the incidence of postoperative shoulder dysfunction. Preservation of the sternocleidomastoid muscle alleviates the cosmetic deformity seen with a radical neck dissection and provides some protection for the carotid artery.

Preservation of the internal jugular vein decreases venous congestion of the head and neck and is necessary if the contralateral internal jugular vein is sacrificed. With primary lesions located in the midline in the base of the tongue, the supraglottic larynx, or the medial wall of the piriform sinus, bilateral regional metastases are common, and bilateral neck dissections are therefore indicated. Sacrifice of both internal jugular veins is associated with significant morbidity, including increased intracranial pressure, syndrome of inappropriate antidiuretic hormone secretion, airway edema, and death. Bilateral internal jugular sacrifice is managed by staging the neck dissections or by carrying out vascular repair.

In the presence of multiple pathologically positive lymph nodes or evidence of ECS, adjuvant therapy is indicated.¹⁹ Accordingly, selective neck dissection may be viewed as a diagnostic as well as a therapeutic procedure. To date, however, no randomized clinical trials have demonstrated that selective neck dissection with adjuvant treatment as needed is better than so-called watchful waiting with regard to prolonging survival in patients who present without evidence of cervical metastatic disease. Therefore, it is not yet possible to justify the added cost and morbidity of elective neck dissection in patients without evidence of metastatic disease. SLN mapping may facilitate pathologic staging in this setting and spare low-risk patients from unnecessary interventions; however, its sensitivity and specificity for this purpose are still under investigation.

The growing focus on preservation of function and limitation of morbidity has led some surgeons to promote the use of selective neck dissection to treat node-positive neck tumors. Although retrospective studies have suggested that a selective neck dissection may be adequate in carefully selected node-positive patients,²⁰ the effectiveness of this approach is still unproven, and its application remains subject to individual surgical judgment.

Extended Neck Dissection

Extended neck dissections can be combined with selective or comprehensive neck dissections to remove additional nodal basins, such as the suboccipital and retroauricular nodes. These groups of nodes, which are located in the upper posterior neck, are the first-echelon nodal basins for posterior scalp skin cancers. The retroauricular nodes lie just posterior to the mastoid process, and the suboccipital nodes lie near the insertion of the trapezius muscle into the inferior nuchal line. Cancers of the anterior scalp, the temple, and the preauricular skin drain to parotid lymph nodes; these lymph nodes are removed in conjunction with a parotidectomy [see 2:5 *Parotidectomy*]. Retropharyngeal nodes may be removed in the treatment of selected cancers originating in the posterior pharynx, the soft palate, or the nasopharynx. A mediastinal lymph node dissection may be combined with a neck dissection in the treatment of metastatic thyroid carcinomas.

NECK DISSECTION AFTER CHEMORADIATION

The indications for neck dissection have been significantly affected by the increasing use of organ preservation protocols for the treatment of head and neck cancer. Nasopharyngeal carcinomas, which are uniquely radiosensitive, are generally treated with irradiation, with or without chemotherapy; neck dissection is reserved for patients who experience an incomplete response and for patients with bulky cervical lesions. Similarly, patients with early nodal disease (N0 or N1) treated according to organ preservation protocols may undergo nonsurgical therapy. For patients who have advanced neck disease (N2 or N3) or who respond incompletely to therapy, a planned posttreatment neck dissection is recommended because surgical salvage of so-called neck failures is rarely successful.²¹ As a rule, the planned neck dissection should be done within 6 weeks of the completion of chemoradiation therapy: if it is delayed past the 6-week point, progressive soft tissue fibrosis may develop, resulting in difficult surgical dissection, increased postoperative morbidity, and, potentially, tumor progression.

A 2003 study highlighted the need for planned neck dissection after definitive chemoradiation for N2 or N3 nodal disease.²² In this study, 76 patients presenting with N2 or N3 disease under-

went a planned neck dissection. Tumor cells were present in the neck specimens of 25% of patients with complete and 39% of patients with incomplete clinical responses. No patients with complete pathologic responses experienced regional recurrence, whereas 20% of patients with pathologically positive neck dissection specimens experienced nonsalvageable regional recurrences. In addition, planned neck dissection led to reduced rates of regional recurrence in patients treated with chemoradiation. The authors suggested that all patients presenting with N2 or N3 cervical lymphadenopathy should undergo planned neck dissection, regardless of clinical response to chemoradiation therapy.

The required extent of planned neck dissection after chemoradiation is still under investigation. Neck dissection after chemoradiation carries significant morbidity in the form of severe soft tissue fibrosis and increased spinal accessory nerve injury. Pathologic review of comprehensive neck specimens after chemoradiation reveals that in patients with oropharyngeal cancer, levels I and V are rarely involved in the absence of radiographic abnormalities,²³ which suggests that a planned selective dissection involving levels II through IV may be sufficient for cases of oropharyngeal cancer treated with chemoradiation. This more limited approach undoubtedly causes less morbidity, but additional data are required to assess its oncologic efficacy.

Typically, management of the neck is determined in part by management of the primary tumor. Early neck dissection for bulky nodal disease before nonsurgical treatment of the primary lesion is a controversial practice. Bulky cervical adenopathy is unlikely to exhibit a complete pathologic response to nonsurgical treatment. A patient who requires dental extractions before radiation therapy may undergo a neck dissection at the same time, proceeding to radiation therapy 7 to 10 days after operation. Early neck dissection decreases the tumor burden, thereby allowing lower adjunctive doses of radiation to be delivered to the neck. Thus, it is possible that early neck dissection for bulky resectable cervical adenopathy can reduce the expected morbidity of planned postchemoradiation neck dissection. There is limited evidence in the literature that such an approach is feasible in certain circumstances²⁴; however, it is recommended that significant delays in initiating treatment to the primary site be avoided because such delays may ultimately have a negative impact on survival.

RECONSTRUCTION AND RECURRENCE AFTER NECK DISSECTION

The use of microvascular free tissue transfer to reconstruct surgical defects in the head has allowed surgeons to resect large tumors with large margins while simultaneously achieving improved functional results. Preservation of vascular—and, occasionally, neural—structures during neck dissection may facilitate the reconstructive process. Typically, several vessels, including an artery and one or two veins, are required for inflow and outflow into a free flap. The facial artery, the retro-mandibular vein, and the external jugular vein, which are preserved during level I and level II dissection, are the vessels that are most frequently used for flap revascularization. If these vessels are unavailable as a consequence of high-volume neck disease, the superior thyroid artery and the transverse artery, with companion veins, are suitable substitutes. To date, there is no evidence in the literature that preservation of vascular structures in the neck predisposes patients to regional recurrence. Caution must, however, be exercised in the setting of pathologic lymphadenopathy.

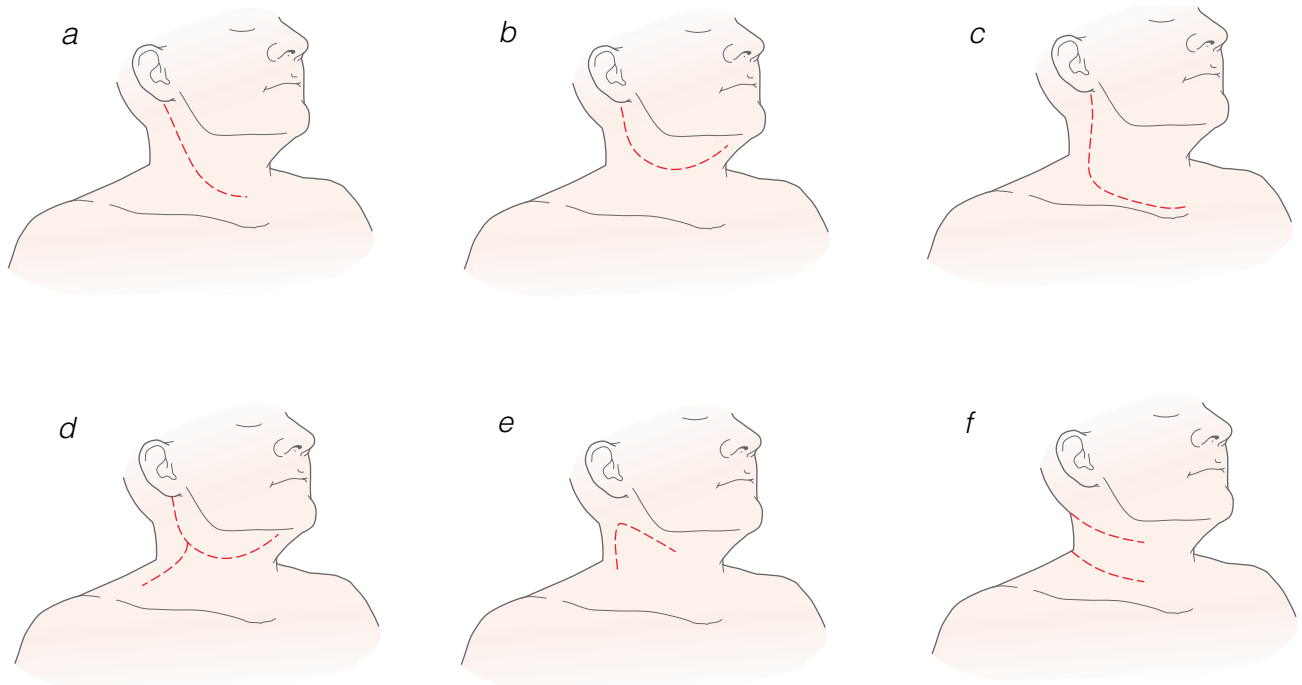

Figure 2 Illustrated are incisions used for neck dissections. Incision design is a critical element of operative planning. Incisions are chosen with the aims of optimizing exposure of relevant neck levels and minimizing morbidity. The incisions depicted in (a) and (b) are useful for selective neck dissections. For the more extensive exposure required in a radical or modified radical neck dissection, a deeper half-apron style incision (c) may be used, or a vertical limb may be dropped from a mastoid-submental incision (d); the latter incision is less reliable and may break down, exposing vital structures such as the carotid. The incision depicted in (e) is also useful for selective neck dissections. The Macfee incision (f) provides limited exposure and results in persistent lymphedema in the bipediced skin flap.

Operative Technique

RADICAL NECK DISSECTION

Step 1: Incision and Flap Elevation

When a radical or modified radical neck dissection is indicated, appropriate neck incisions must be designed so as to facilitate exposure while preserving blood flow to the skin flaps [see Figure 2]. The incision provides access to the relevant levels of the neck, affects cosmesis, and determines the extent of lymphedema and postoperative fibrosis (“woody” neck), especially in previously irradiated areas. If a biopsy was previously performed, the tract should be excised and incorporated into the new incision. When a total laryngectomy is done, the stoma is fashioned separately from the neck incision; in the event of a pharyngocutaneous fistula, the salivary flow will be diverted away from the stoma.

Once the incision is made, subplatysmal flaps are raised. If there is extensive lymphadenopathy or extension of tumor into the soft tissues of the neck, skin flaps may be raised in a supraplatysmal plane to ensure negative surgical margins. Such flaps, however, are not as reliably vascularized as subplatysmal flaps. Clinical judgment must be exercised in these situations. The flaps are raised to the mandible superiorly, the clavicle inferiorly, the omohyoid muscle and the submental region anteriorly, and the trapezius posteriorly. Typically, radical neck dissections are performed in patients with clinically positive lymphadenopathy, and adequate exposure of levels I through V is required. If a vertical limb is used, it must not be centered over the carotid artery, because of the risk of potentially catastrophic dehiscence. Deep utility-type incisions yield more limited exposure of level I but provide reliable vascular inflow to skin flaps.

Step 2: Dissection of Anterior Compartment

Embedded within the fascia overlying the submandibular gland is the marginal mandibular branch of the facial nerve, which must be elevated and retracted to prevent lower-lip weakness. The submental fat pad is then grasped, retracted posteriorly and laterally, and mobilized away from the floor of the submental triangle. The omohyoid muscle is identified inferior to the digastric tendon and skeletonized to its intersection with the sternocleidomastoid muscle posteriorly. The omohyoid muscle forms the anteroinferior limit of the dissection.

Fat and lymphatic structures are dissected away from the digastric muscle and the mylohyoid muscle. The hypoglossal and lingual nerves lie just deep to the mylohyoid muscle and are protected by it [see Figure 3]. In this region, the distal end of the facial artery can be identified and preserved as needed for reconstructive purposes. Once the posterior edge of the mylohyoid muscle is visualized, an Army-Navy retractor is inserted beneath the muscle to expose the submandibular duct, the lingual nerve with its attachment to the submandibular gland, and the hypoglossal nerve. The submandibular duct and the submandibular ganglion, with its contributions to the gland, are ligated, and the submandibular gland is retracted out of the submandibular triangle.

The posterior belly of the digastric muscle is then identified inferior to the submandibular gland and skeletonized to the sternocleidomastoid muscle posteriorly, where it inserts on the mastoid tip. The specimen must be mobilized off structures just inferior to the digastric muscle. To prevent inadvertent injury, it is essential to understand the relationships among these structures [see Figure 3]. The hypoglossal nerve emerges from beneath the mylohyoid muscle and passes into the neck under the digastric

Figure 3 Depicted are the key anatomic relationships in levels I and II that must be kept in mind in performing a neck dissection. View is of the right neck.

muscle. It then loops around the external carotid artery at the origin of the occipital artery and ascends to the skull base between the external carotid artery and the internal jugular vein. Often, the hypoglossal nerve is surrounded by a plexus of small veins, branching off the common facial vein. Bleeding in this region places the hypoglossal nerve at risk. The jugular vein, located just posterior to the external carotid artery and the hypoglossal nerve, may be isolated and doubly suture-ligated at this point. Frequently, the spinal accessory nerve is identified just lateral and posterior to the internal jugular vein, proceeding posteriorly into the sternocleidomastoid muscle.

In a radical neck dissection, the sternocleidomastoid muscle and the spinal accessory nerve are transected at this point and elevated off the splenius capitis and the levator scapulae to the trapezius posteriorly. The anterior edge of the trapezius is skeletonized from the occiput to the clavicle. The accessory nerve is again transected where it penetrates the trapezius.

Step 3: Control of Internal Jugular Vein Inferiorly; Ligation of Lymphatic Pedicle

The sternal and clavicular heads of the sternocleidomastoid muscle are transected and elevated to expose the anterior belly of the omohyoid muscle. The soft tissue overlying the posterior belly of the omohyoid muscle is dissected, clamped, and ligated as necessary. The omohyoid muscle is then transected, and the jugular vein, the carotid artery, and the vagus nerve are exposed. The jugular vein is isolated and doubly suture-ligated. Care is taken not to transect the adjacent vagus nerve and carotid artery. The lymphatic tissues in the base of the neck adjacent to the internal jugular vein are clamped and suture-ligated 1 cm superior to the clavicle. If a chyle leak is encountered, a figure-eight stitch is

placed along the lymphatic pedicle until there is no evidence of clear or turbid fluid on the Valsalva maneuver. Care is taken to avoid inadvertent injury to the vagus nerve or the phrenic nerve, which course through this region.

Step 4: Mobilization of Supraclavicular Fat Pad (“Bloody Gulch”)

The fascia overlying the supraclavicular fat pad is incised, and the supraclavicular fat pad is bluntly retracted superiorly so as to free the tissues from the supraclavicular fossa. If transverse cervical vessels are encountered, they are clamped and ligated as necessary. Fascia is left on the deep muscles of the neck, which also envelop the brachial plexus and the phrenic nerve.

Step 5: Dissection and Removal of Specimen

Attention is then turned to the posterior aspect of the neck. Fat and lymphatic tissues are retracted anteriorly with Allis clamps, and the specimen is dissected off the deep muscles of the neck with a blade. Again, a layer of fascia is left on the deep cervical musculature: stripping fascia off the deep cervical musculature results in denervation of these muscles, which adds to the morbidity associated with accessory nerve sacrifice. Once the specimen is mobilized beyond the phrenic nerve, the cervical nerves (C1–C4) may be divided. The specimen is peeled off the carotid artery and removed.

Step 6: Closure

The neck incision is closed in layers over suction drains.

MODIFIED RADICAL NECK DISSECTION

The incision is made and flaps elevated as in a radical neck dis-

section. Care must be exercised in elevating the posterior skin flap. Typically, the platysma is deficient in this area, and often, no natural plane exists. Dissection deep in the posterior triangle may result in inadvertent injury to the spinal accessory nerve, which travels inferiorly and posteriorly across the posterior triangle in a relatively superficial plane to innervate the trapezius.

A type I modified radical neck dissection begins with dissections of levels I and II, as described for a radical neck dissection (see above). The spinal accessory nerve is identified just superficial or posterior to the internal jugular vein and preserved; the distal spinal accessory nerve is then identified in the posterior triangle. Typically, the spinal accessory nerve can be identified 1 cm superior to the cervical plexus along the posterior border of the sternocleidomastoid muscle. Provided that the patient is not fully paralyzed, the surgeon can distinguish this nerve from adjacent sensory branches by using a nerve stimulator.

Once the spinal accessory nerve is identified, it is dissected and mobilized distally to the point at which it penetrates the trapezius. Proximally, the nerve is dissected through the sternocleidomastoid muscle, which is transected over the nerve. The branch to the sternocleidomastoid muscle is divided with Metz scissors, and the nerve is fully mobilized from the trapezius posteroinferiorly to the posterior belly of the digastric muscle anterosuperiorly, then gently retracted out of the way.

The rest of the neck dissection proceeds as described for a radical neck dissection. If the tumor does not involve the internal jugular vein, it may also be preserved; this constitutes a type II modified radical neck dissection. If the spinal accessory nerve, the internal jugular vein, and the sternocleidomastoid muscle are all preserved, the procedure is a type III modified radical neck dissection. In a type III dissection, the sternocleidomastoid muscle is fully mobilized and retracted with two broad Penrose drains, and the contents of the neck are exposed. The spinal accessory nerve is preserved throughout its entire course, including the branch to the sternocleidomastoid muscle. The remainder of the neck dissection proceeds as previously described (see above).

SELECTIVE NECK DISSECTION

Levels I to IV

In a selective neck dissection, the posterior triangle is not removed; thus, there is no need to elevate skin flaps posterior to the sternocleidomastoid muscle. Limited elevation of skin flaps is beneficial, particularly for patients who have previously undergone chemoradiation therapy, in whom extensive flap elevation may contribute to significant persistent lymphedema after operation. Subplatysmal skin flaps are raised sufficiently to expose the neck levels to be dissected, with the central compartment left undisturbed. If level I dissection is planned, the fascia overlying the submandibular gland is raised and retracted so as to preserve the marginal nerve. The submental fat pad is grasped and mobilized away from the floor of the submental triangle (composed of the anterior belly of the digastric muscle and the mylohyoid muscle). Inferiorly, the lymphatic tissues are mobilized off the posterior aspect of the omohyoid muscle, which forms the anteroinferior limit of the neck dissection.

Once the digastric tendon and the posterior edge of the mylohyoid muscle are visualized, the mylohyoid is retracted with an Army-Navy retractor so that the submandibular duct, the lingual nerve with its attachment to the submandibular gland, and the hypoglossal nerve are visualized. The submandibular duct and ganglion are ligated, and the submandibular gland is retracted out of the submandibular triangle.

At this point, the facial artery is encountered and suture-ligat-

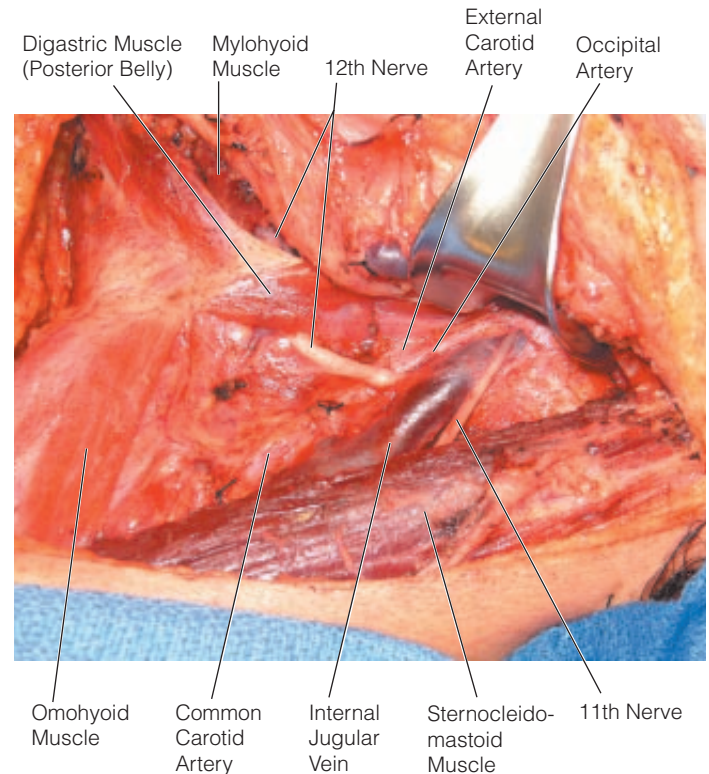

Figure 4 Selective neck dissection. The posterior belly of the digastric muscle is identified inferior to the submandibular gland. This muscle protects several critical structures just deep to it (the hypoglossal nerve, the carotid artery, the internal jugular vein, and the spinal accessory nerve). View is of a left neck dissection.

ed. Because the artery curves around the submandibular gland, the facial artery, if not preserved, must be ligated twice (proximally and distally). If the neck dissection is part of a large extirpative procedure involving free-flap reconstruction, the facial artery is preserved for use in microvascular anastomosis.

The posterior belly of the digastric muscle is then identified inferior to the submandibular gland. This muscle has been referred to as one of several “resident’s friends” in the neck because it serves to protect several critical structures that lie just deep to it, including the hypoglossal nerve, the external carotid artery, the internal jugular vein, and the spinal accessory nerve [see Figure 4]. The posterior belly of the digastric muscle is skeletonized to the sternocleidomastoid muscle, where it inserts on the mastoid tip. The specimen is then mobilized away from structures just inferior to the digastric muscle. The hypoglossal nerve emerges from beneath the mylohyoid muscle and passes into the neck just below the digastric muscle, looping around the external carotid artery at the origin of the occipital artery and ascending to the skull base between the external carotid artery and the internal jugular vein. Bleeding from small branches of the common facial vein that envelop the hypoglossal nerve place this structure at risk for injury. The spinal accessory nerve is often visualized just superficial or posterior to the internal jugular vein, extending posteriorly to innervate the sternocleidomastoid muscle.

Next, the fascia overlying the sternocleidomastoid muscle is grasped and unrolled medially throughout its length, starting at the anterior edge of the muscle. The fascia is removed until the spinal accessory nerve is identified at the point where it penetrates the muscle. This nerve is dissected and mobilized superiorly through fat and lymphatic tissues to the digastric muscle. Care must be taken not to inadvertently injure the internal jugular

vein, which lies in close proximity to the nerve superiorly. Tissue posterior to the accessory nerve is grasped and freed from the deep muscles of the neck, the digastric muscle superiorly, and the sternocleidomastoid muscle posteriorly. The tissue included in so-called level IIB is passed beneath the spinal accessory nerve and incorporated into the main specimen.

The sternocleidomastoid muscle is retracted, and the fascia posterior to the internal jugular vein is incised. Dissection is carried down to the deep cervical musculature and cervical nerves, which form the floor of the dissection. The specimen is retracted anteriorly. A layer of fascia is left on the deep cervical musculature and the cervical nerves to preserve innervation of the deep muscles of the neck and protect the phrenic nerve as it courses over the anterior scalene muscle.

The specimen is peeled off the internal jugular vein and removed. Dissection too far posteriorly behind the vein may result in injury to the vagus nerve or the sympathetic trunk and predisposes to postoperative thrombosis of the vein. Ligation of internal jugular vein branches should be done without affecting the caliber of the vein or giving the vessel a “sausage link” appearance, which would create turbulent flow patterns predisposing to thrombosis. Overall, gentle dissection around all vessels, with care taken to avoid pulling-related trauma, minimizes the risk of endothelial injury. Dissection behind the internal jugular vein may result in injury to the vagus nerve or the sympathetic trunk.

A level IV dissection may be facilitated by retracting the omohyoid muscle inferiorly or by dividing it for additional exposure. The tissue inferior to the omohyoid is mobilized and delivered with the main specimen. The lymphatic pedicle is clamped and ligated. Care is taken to look for leakage of chyle, particularly when a level IV dissection is performed on the left.

Levels II to IV

When level I is spared, a smaller incision suffices for exposure. Subplatysmal flaps are raised superiorly to the level of the submandibular gland. The inferior flap is raised, exposing the anterior edge of the sternocleidomastoid muscle. Dissection proceeds just inferior to the submandibular gland until the posterior belly of the digastric muscle is identified. The digastric muscle is skeletonized posteriorly to the sternocleidomastoid muscle and anteriorly to the omohyoid muscle, which forms the anterior limit of the dissection. The rest of the neck dissection proceeds as described for a selective neck dissection involving levels I through IV.

Complications

INTRAOPERATIVE

Most intraoperative complications may be prevented by means of careful surgical technique, coupled with a thorough understanding of head and neck anatomy. Injury to the internal jugular vein may occur either proximally or distally. Uncontrolled proximal bleeding endangers adjacent critical structures, such as the carotid artery and the hypoglossal nerve. The bleeding may be initially controlled with pressure, followed by a methodical search for the bleeding source. Internal jugular vein lacerations can often be repaired with 5-0 nylon sutures; if a laceration cannot be repaired, the vein must be ligated. Occasionally, a laceration extends up to the skull base, and the vessel cannot be controlled with clamping and ligation. In these cases, it is acceptable to pack the jugular foramen for hemostasis.

It is important to gain distal control of the internal jugular vein before repair to prevent air embolism. Harbingers of air embolism

include the presence of a sucking sound in the neck, a mill-wheel murmur over the precordium, ECG changes, and hypotension. Predisposing factors include elevation of the head of the bed and spontaneous breathing, which increase negative intrathoracic pressure and thus promote entry of air into the venous system. Injury to the internal jugular vein is more difficult to control when it occurs distally in the neck or chest at the junction with the subclavian vein. For this reason, ligation of the internal jugular vein in radical and modified radical neck dissections is typically performed 1 cm superior to the clavicle.

Opalescent or clear fluid in the inferior neck suggests the presence of a chyle fistula. Chyle fistulas generally can be prevented by clamping and ligating the lymphatic pedicle at the base of the neck. Those fistulas that occur are repaired at the time of the neck dissection. There is no benefit in isolating individual lymphatic vessels, because these structures are fragile, do not hold stitches, and are prone to tearing. A figure-eight stitch is placed along the lymphatic pedicle until there is no evidence of clear or turbid fluid on the Valsalva maneuver. Care must be taken not to inadvertently injure the vagus nerve or the phrenic nerve during repair of a chyle leak.

POSTOPERATIVE

The best treatment of postoperative complications such as hematoma and chyle leak is prevention. Hematomas, once present, are best managed by promptly returning the patient to the OR for evacuation. Management of postoperative leakage of chyle depends on the volume of the leak. Low-volume leaks may be managed with packing, wound care, and nutritional supplementation with medium-chain triglycerides.

Wound complications (e.g., infection, flap necrosis, and carotid artery exposure or rupture) share certain interrelated causative factors. Poor nutritional status, advanced tumor stage at presentation, hypothyroidism, and preoperative radiation therapy have all been associated with wound complications. After chemoradiation therapy, the use of smaller incisions and more limited dissection of soft tissues may lower the incidence of postoperative wound problems, including persistent lymphedema and soft tissue fibrosis. Conversely, poor planning of skin incisions may increase the likelihood of wound complications such as wound breakdown, skin flap loss, and exposure of vital structures. Wound complications predispose to carotid artery rupture, the most catastrophic complication of neck dissection.

In some cases, severe edema after planned neck dissections in patients previously treated with chemoradiation may cause respiratory decompensation that necessitates tracheotomy. Postoperative internal jugular vein thrombosis is not uncommon despite preservation at the time of surgery,²⁵ and it may exacerbate edema. Impaired venous outflow predisposes to increased intracranial pressure.²⁶ This may be a greater concern in patients who require bilateral neck dissections. If a radical neck dissection is performed on one side, the internal jugular vein must be preserved on the other, or else the neck dissections must be staged. These problems are further exacerbated when the patient has undergone chemoradiation therapy before operation.

Most neck dissections result in some degree of temporary shoulder dysfunction. Patients in whom nerve-sparing procedures are performed can expect function to return within 3 weeks to 1 year, depending on the procedure performed. Shoulder dysfunction and pain are exacerbated when nerves supplying the deep muscles of the neck are also sacrificed. All patients benefit from physical therapy, which preserves full range of motion in the shoulder while function returns.

7 THYROID AND PARATHYROID PROCEDURES

Gregg H. Fossart, M.D., F.A.C.S., and Orlo H. Clark, M.D., F.A.C.S.

Thyroidectomy

OPERATIVE PLANNING

If the patient has had any hoarseness or has undergone a neck operation before, indirect or direct (ideally, fiberoptic) laryngoscopy is essential to determine whether the vocal cords are functioning normally. All patients scheduled for thyroidectomy should be euthyroid at the time of operation; in all other respects, they should be prepared as they would be for any procedure calling for general anesthesia.

Optimum exposure of the thyroid is obtained by placing a sandbag between the scapula and a foam ring under the occiput; in this way, the neck is extended, and the thyroid can assume a more anterior position. The head must be well supported to prevent postoperative posterior neck pain. The patient is placed in a 20° reverse Trendelenburg position. The skin is prepared with 1% iodine or chlorhexidine.

OPERATIVE TECHNIQUE

General Troubleshooting

Thyroid and parathyroid operations should be performed in a blood-free field so that vital structures can be identified. Operating telescopes (magnification: $\times 2.5$ or $\times 3.5$) are also recommended because they make it easier to identify the normal parathyroid glands and the recurrent laryngeal nerve. If bleeding occurs, pressure should be applied. The vessel should be clamped only if (1) it can be precisely identified or (2) the recurrent laryngeal nerve has been identified and is not in close proximity to the vessel.

As a rule, dissection should always be done first on the side where the suspected tumor is; if there is a problem with the dissection on this side, a less than total thyroidectomy can be performed on the contralateral side to prevent complications. There is, however, one exception to this rule: if the tumor is very extensive, the surgeon will sometimes find it easier to do the dissection on the “easy” side first to facilitate orientation with respect to the trachea and the esophagus.

Step 1: Incision and Mobilization of Skin Layers

A Kocher transverse incision paralleling the normal skin lines of the neck is made 1 cm caudad to the cricoid cartilage [see Figure 1]. As a rule, the incision should be about 4 to 6 cm long and should extend from the anterior border of one sternocleidomastoid muscle to the anterior border of the other and through the platysma. Five straight Kelly clamps are placed on the dermis to facilitate dissection, which proceeds first cephalad in a

subplatysmal plane anterior to the anterior jugular veins and posterior to the platysma to the level of the thyroid cartilage notch and then caudad to the suprasternal notch. Skin towels and a self-retaining retractor are then applied.

Troubleshooting Placing the incision 1 cm below the cricoid locates it precisely over the isthmus of the thyroid gland. The course of the incision should conform to the normal skin lines or creases. The length of the incision should be modified as necessary for good exposure. Patients with short, thick necks, low-lying thyroid glands, or large thyroid tumors require longer incisions than those with long, thin necks and small tumors. Patients whose necks do not extend also require longer incisions for adequate exposure. A sterile marking pen should be used to mark the midline of the neck, the level at which the incision should be made (i.e., 1 cm below the cricoid), and the lateral margins of the incision (which should be at equal distances from the midline so that the incision will be symmetrical). A scalpel should never be used to mark the neck: doing so will leave an unsightly scar in some patients. To mark the incision site itself, a 2-0 silk tie should be pressed against the neck [see Figure 1].

The upper flap is dissected first by placing five straight Kelly clamps on the dermis and retracting anteriorly and superiorly. Lateral traction with a vein retractor or an Army-Navy retractor

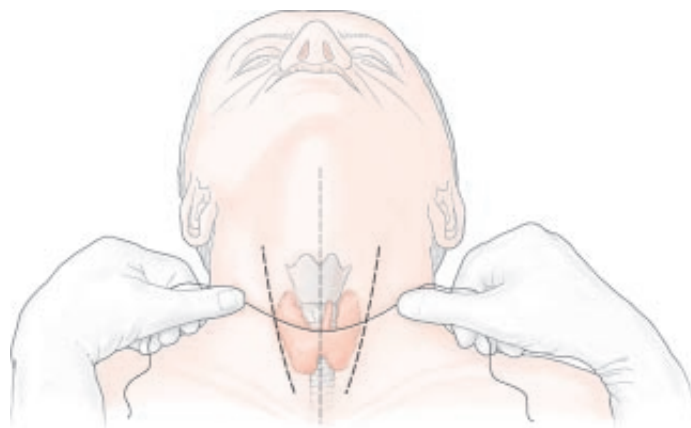

Figure 1 The initial incision in a thyroidectomy is made 1 cm below the cricoid cartilage and follows normal skin lines. A sterile marking pen is used to mark the midline of the neck, the level of the incision, and the lateral borders of the incision. A 2-0 silk tie is pressed against the neck to mark the incision site itself.²

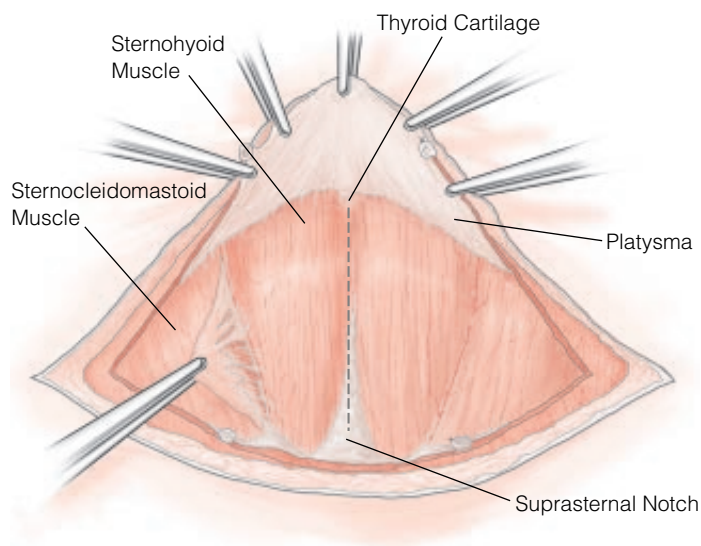

Figure 2 To expose the thyroid, a midline incision is made through the superficial layer of deep cervical fascia between the strap muscles. The incision is begun at the suprasternal notch and extended to the thyroid cartilage.³

helps identify the semilunar plane for dissection. This blood-free plane is deep to the platysma and superficial to the anterior jugular veins. Cephalad dissection can be done quickly with the electrocautery or a scalpel, and lateral dissection can be done bluntly. The same principles are applied to dissection of the lower flap. In thin patients, the surgeon must be careful not to dissect through the skin from within, especially at the level of the thyroid cartilage.

Step 2: Midline Dissection and Mobilization of Strap Muscles

The thyroid gland is exposed via a midline incision through the superficial layer of deep cervical fascia between the strap muscles. Because the strap muscles are farthest apart just above the suprasternal notch, the incision is begun at the notch and extended to the thyroid cartilage [see Figure 2].

On the side where the thyroid nodule or the suspected parathyroid adenoma is located, the more superficial sternohyoid muscle is separated from the underlying sternothyroid muscle by blunt dissection, which is extended laterally until the ansa cervicalis becomes visible on the lateral edge of the sternothyroid muscle and on the medial side of the internal jugular vein. The sternothyroid muscle is then dissected free from the thyroid and the prethyroidal fascia by blunt or sharp dissection until the middle thyroid vein or veins are encountered laterally.

A 2-0 silk suture is placed deeply through the thyroid lobe for retraction to facilitate exposure. This stitch should never be placed through the thyroid nodule: doing so could cause seeding of thyroid cancer cells. The thyroid is retracted anteriorly and medially and the carotid sheath laterally; this retraction places tension on the middle thyroid veins and helps expose the area posterolateral to the thyroid, where the parathyroid glands and the recurrent laryngeal nerves are situated. The middle thyroid veins are divided to give better exposure behind the superior portion of the thyroid lobe [see Figure 3].

Troubleshooting As a rule, it is not necessary to divide the strap muscles; however, if they are adherent to the underlying thyroid tumor, the portion of the muscle that is adhering to the

tumor should be sacrificed and allowed to remain attached to the thyroid. Separation of the sternohyoid muscle from the sternothyroid muscle provides better exposure of the operative field. The middle thyroid veins should be cleaned of adjacent tissues to prevent any injury to the recurrent laryngeal nerve when these veins are ligated and divided. It is always safest to mobilize tissues parallel to the recurrent laryngeal nerve.

Step 3: Division of Isthmus

When a thyroid lobectomy is to be performed, the isthmus of the thyroid gland is usually divided with Dandy or Colodny clamps at an early point in dissection to facilitate the subsequent mobilization of the thyroid gland. The thyroid tissue that is to remain is oversewn with a 2-0 silk ligature. To minimize the chance of invasion into the trachea or to avoid a visible mass in patients with compensatory thyroid hypertrophy, thyroid tissues should not be left anterior to the trachea.

Troubleshooting With larger glands, we divide the isthmus first. This step facilitates the lateral dissection by making the gland more mobile.

Step 4: Mobilization of Thyroid Gland and Identification of Upper Parathyroid Glands

Once the isthmus has been divided, dissection is continued superiorly, laterally, and posteriorly with a small peanut sponge on a clamp. The superior thyroid artery and veins are identified by retracting the thyroid inferiorly and medially. The tissues lateral to the upper lobe of the thyroid and medial to the carotid sheath can be mobilized caudally to the cricothyroid muscle; the recurrent laryngeal nerve enters the cricothyroid muscle at the level of the cricoid cartilage, first passing through Berry's ligament [see Figure 4]. The superior pole vessels are individually identified, skeletonized, double- or triple-clamped, ligated, and divided low on the thyroid gland [see Figure 5]. To prevent injury to the external laryngeal nerve, the vessels are divided and ligated on the thyroid surface, the thyroid is retracted laterally and caudally, and dissection is carried out on the medial edge of the thyroid gland and lateral to the cricothyroid muscle. As alternatives to

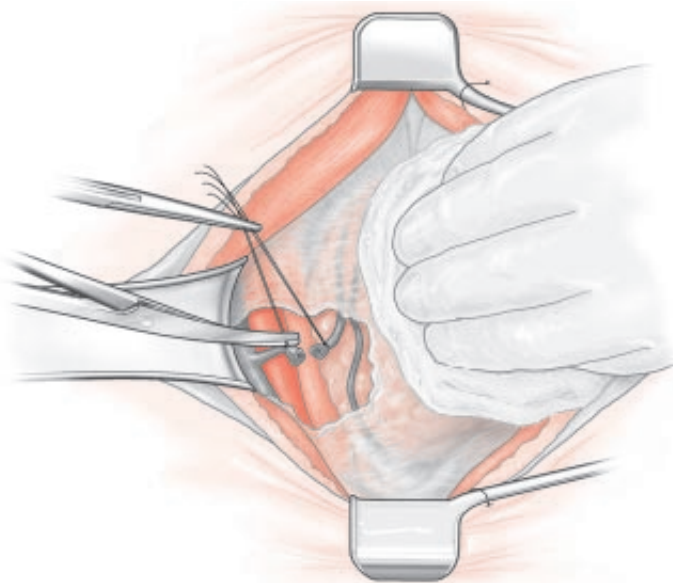

Figure 3 The middle thyroid veins are divided to give better exposure behind the superior portion of the thyroid lobe.²

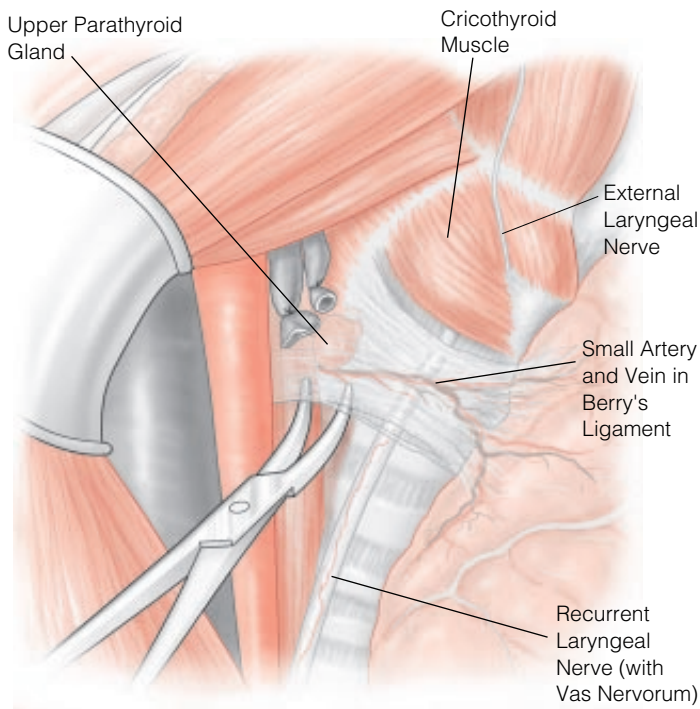

Figure 4 The recurrent laryngeal nerve enters the cricothyroid muscle at the level of the cricoid cartilage, first passing through Berry's ligament.²

sutures, devices such as the Harmonic Scalpel (Ethicon Endo-Surgery, Inc.), the Ligasure Precise (Valleylab), and the Hem-o-lok clip (Weck Closure Systems) may be used to control vessels.

The tissues posterior and lateral to the superior pole that have not already been mobilized can now be easily swept by blunt dissection away from the thyroid gland medially and anteriorly and away from the carotid sheath laterally. The upper parathyroid gland is often identified at this time at the level of the cricoid cartilage.

Troubleshooting It is essential to keep from injuring the external laryngeal nerve. This nerve is the motor branch of the superior laryngeal nerve and is responsible for tensing the vocal cords; it is also known as the high note nerve or the Amelita Galli-Curci nerve. In about 80% of patients, the external laryngeal nerve runs on the surface of the cricothyroid muscle; in about 10%, it runs with the superior pole vessels; and in the remaining 10%, it runs within the cricothyroid muscle. Given that this nerve is usually about the size of a single strand of a spider web, one should generally try to avoid it rather than to identify it. Injury to the external laryngeal nerve occurs in as many as 10% of patients undergoing thyroidectomy. The best ways of preventing such injury are (1) to provide gentle traction on the thyroid gland in a caudal and lateral direction and (2) to ligate the superior pole vessels directly on the capsule of the upper pole individually and low on the thyroid gland rather than to cross-clamp the entire superior pole pedicle.

The internal laryngeal nerve is the sensory branch of the superior laryngeal nerve; it provides sensory innervation to the posterior pharynx. Injury to this nerve can result in aspiration. Because the internal laryngeal nerve typically is cephalad to the area of dissection during thyroidectomy and runs cephalad to the lateral portion of the thyroid cartilage, it usually is at risk only when the surgeon dissects cephalad to the thyroid carti-

lage. Such dissection is necessary only when laryngeal mobilization is performed to relieve tension on the tracheal anastomosis after tracheal resection.

Step 5: Identification of Recurrent Laryngeal Nerves and Lower Parathyroid Glands

When the thyroid lobe is further mobilized, the lower parathyroid gland is usually seen; this gland is almost always located anterior to the recurrent laryngeal nerve and is usually located inferior to where the inferior thyroid artery crosses the recurrent laryngeal nerve [see Figure 6]. The carotid sheath is retracted laterally, and the thyroid gland is retracted anteriorly and medially. This retraction puts tension on the inferior thyroid artery and consequently on the recurrent laryngeal nerve, thereby facilitating the identification of the nerve. The recurrent laryngeal nerve is situated more medially on the left (running in the tracheoesophageal groove) and more obliquely on the right. Dissection should proceed cephalad along the lateral edge of the thyroid. Fatty and lymphatic tissues immediately adjacent to the thyroid gland are swept from it with a peanut sponge on a clamp, and small vessels are ligated. No tissue should be transected until one is sure that it is not the recurrent laryngeal nerve.

Troubleshooting The upper parathyroid glands are usually situated on each side of the thyroid gland at the level where the recurrent laryngeal nerve enters the cricothyroid muscle [see Figure 6]. Because the recurrent laryngeal nerve enters the cricothyroid muscle at the level of the cricoid cartilage, the area cephalad to the cricoid cartilage is relatively safe.

The right and left recurrent laryngeal nerves must be preserved during every thyroid operation. Although both nerves enter at the posterior medial position of the larynx in the cricothyroid muscle, their courses vary considerably. The right recurrent laryngeal nerve takes a more oblique course than the left recurrent laryngeal nerve and may pass either anterior or

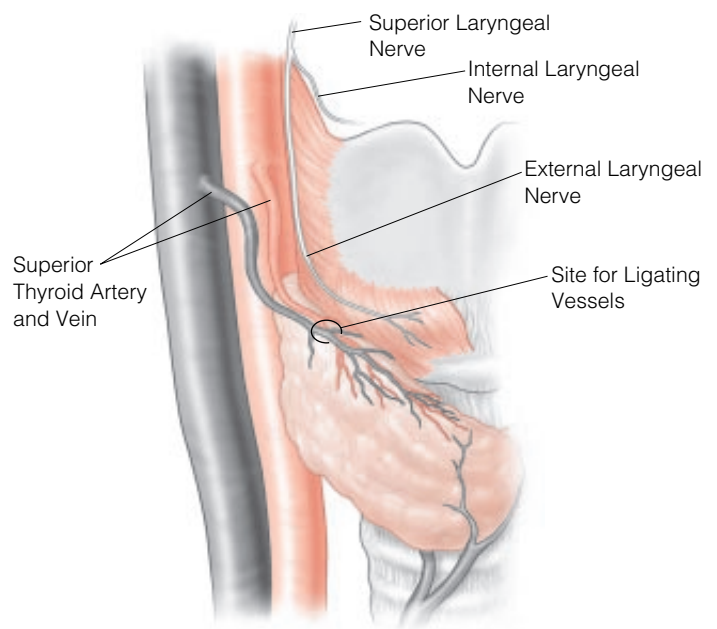

Figure 5 The superior pole vessels should be individually identified and ligated low and laterally on the thyroid gland to minimize the chances of injury to the external laryngeal nerve.²

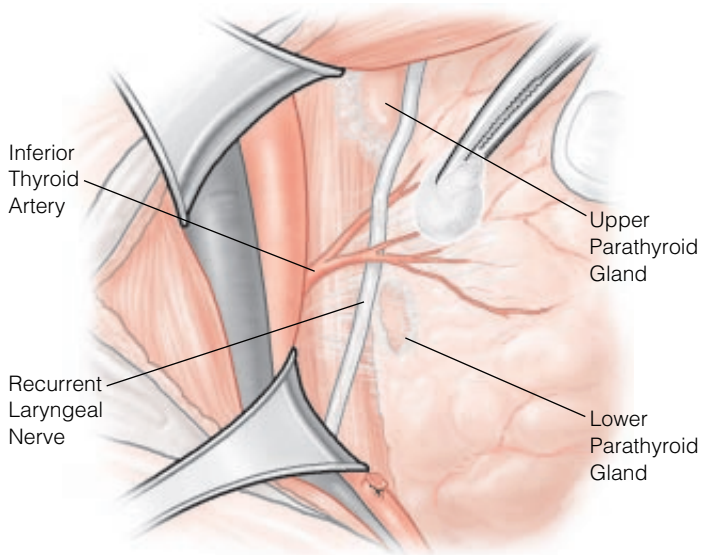

Figure 6 The upper parathyroid glands are usually situated on either side of the thyroid at the level where the recurrent laryngeal nerve enters the cricothyroid muscle. The lower parathyroid glands are usually anterior to the recurrent laryngeal nerve and inferior to where the inferior thyroid artery crosses this nerve.²

posterior to the inferior thyroid artery. In about 0.5% of persons, the right recurrent laryngeal nerve is in fact nonrecurrent and may enter the thyroid from a superior or lateral direction.¹ On rare occasions, both a recurrent and a nonrecurrent laryngeal nerve may be present on the right. The left recurrent laryngeal nerve almost always runs in the tracheoesophageal groove because of its deeper origin within the thorax as it loops around the ductus arteriosus. Either recurrent laryngeal nerve may branch before entering the larynx; the left nerve is more likely to do this. Such branching is important to recognize because all of the motor fibers of the recurrent laryngeal nerve are usually in the most medial branch.

In identifying the recurrent laryngeal nerves, it is helpful to remember that they are supplied by a small vascular plexus and that a tiny vessel runs parallel to and directly on each nerve [see Figures 4 and 6]. In young persons, the artery usually is readily distinguished from the recurrent laryngeal nerve; however, in older persons with arteriosclerosis, the white-appearing artery may be mistaken for a nerve, and thus the nerve may be injured as a result of the misidentification. Lateral traction on the carotid sheath and medial and anterior traction on the thyroid gland place tension on the inferior thyroid artery; this maneuver often helps identify the recurrent laryngeal nerve where it courses lateral to the midportion of the thyroid gland. One should, however, be careful not to devascularize the inferior parathyroid glands by dividing the lateral vascular attachments: to remove the thyroid lobe, it is best to divide the vessels directly on the thyroid capsule to preserve the blood supply to the parathyroid glands. It is usually safest to identify the recurrent laryngeal nerve low in the neck and then to follow it to where it enters the cricothyroid muscle through Berry's ligament. The recurrent laryngeal nerves can usually be palpated through the surrounding tissue in the neck; they feel like a taut ligature of approximately 2-0 gauge.

Parathyroid glands should be swept from the thyroid gland on as broad a vascular pedicle as possible to prevent devascu-

larization. When it is unclear whether a parathyroid gland can be saved on its own vascular pedicle, one should biopsy the gland to confirm that it is parathyroid and then autotransplant it in multiple 1 × 1 mm pieces into separate pockets in the sternocleidomastoid muscle. At times, it is preferable to clip the blood vessels running from the thyroid to the parathyroid glands rather than to clamp and tie them. Clipping not only marks the parathyroid gland (which is useful if another operation subsequently becomes necessary) but also enables the gland to remain with minimal manipulation and with its remaining blood supply preserved.

In patients who have extensive thyroid tumors or who require reoperation, extensive scarring is often present. For some of these patients, it is preferable to identify the recurrent laryngeal nerve from a medial approach by dividing the isthmus with Colodny clamps and ligating and dividing the superior thyroid vessels. By carefully dissecting the thyroid away from the trachea, one can identify the recurrent laryngeal nerve at the point where its position is most consistent (i.e., at its entrance into the larynx immediately posterior to the cricothyroid muscle).

The most difficult part of dissection in a thyroidectomy is the part that involves Berry's ligament, which is situated at the posterior portion of the thyroid gland just caudal to the cricoid cartilage [see Figure 4]. A small branch of the inferior thyroid artery traverses the ligament, as do one or more veins from the thyroid gland. If bleeding occurs during this part of the dissection, it should be controlled by applying pressure with a gauze pad. Nothing should be clamped in this area until the recurrent laryngeal nerve is identified. In some patients (about 15%), the peduncle of Zuckerkandl, a small protuberance of thyroid tissue on the right, tends to obscure the recurrent laryngeal nerve at the level of Berry's ligament.

Step 6: Mobilization of Pyramidal Lobe

The pyramidal lobe is found in about 80% of patients. It extends in a cephalad direction, often through the notch in the thyroid cartilage to the hyoid bone. One or more lymph nodes are frequently found just cephalad to the isthmus of the thyroid gland over the cricothyroid membrane (so-called Delphian nodes) [see Figure 7]. The pyramidal lobe is mobilized by retracting it caudally and by dissecting immediately adjacent to it in a cephalad direction. Small vessels are coagulated or ligated.

Step 7: Thyroid Resection

Once the parathyroid glands have been carefully swept or dissected from the thyroid gland and the recurrent nerve has been identified, the thyroid lobe can be quickly resected. For total thyroidectomy, the same operation is done again on the other side.

Troubleshooting The thyroid lobe or gland should be carefully examined after removal. If a parathyroid gland is identified, a biopsy of it should be performed to confirm that it is parathyroid and then autotransplanted. In a thyroid procedure, every parathyroid gland should be treated as if it is the last one, and at least one parathyroid gland should be definitely identified. As a rule, biopsies should not be performed on normal parathyroid glands during a thyroid procedure.

Step 8: Closure

The sternothyroid muscles are approximated with 4-0 absorbable sutures, and a small opening is left in the midline at the suprasternal notch to make any bleeding that occurs more evident and to allow the blood to exit. The sternohyoid muscles are

reapproximated in a similar fashion, as is the platysma. The skin is then closed with butterfly clips, which are hemostatic and inexpensive and permit precise alignment of the skin edges. In children, the skin is usually closed with a subcuticular stitch or a tissue adhesive (e.g., Indermil; Tyco Healthcare), or both, instead. A sterile pressure dressing is applied.

Special Concerns

Invasion of the trachea or the esophagus On rare occasions, thyroid or parathyroid cancers may invade the trachea or the esophagus. As much as 5 cm of the trachea can be resected safely, without impairment of the patient's voice. If the invasion is not extensive and is confined to the anterior portion of the trachea, a small section of the trachea that contains the tumor should be excised, and a tracheostomy may be placed at the site of resection. If the invasion is more extensive or occurs in the lateral or posterior portion of the trachea, a segment of the trachea measuring several centimeters long is resected, and the remaining segments are reanastomosed. To prevent tension on the anastomosis, the trachea should be mobilized before resection, the recurrent laryngeal nerves should be preserved and mobilized from the trachea, and the mylohyoid fascia and muscles should be divided above the thyroid cartilage to drop the cartilage. Care must be taken not to injure the internal laryngeal nerves during this dissection, given that these nerves course from lateral to medial just above the lateral aspects of the thyroid cartilage. After resection, the trachea is reapproximated with 3-0 Maxon sutures. One or two Penrose drains should be left near the resection site to allow air to exit. The drains are removed after several days, when there is no more evidence of air leakage.

If the esophagus is invaded by tumor, the muscular wall of the esophagus can be resected along with the tumor, with the inner esophageal layer left in place.

Neck dissection for nodal metastases Lymph nodes in the central neck (medial to the carotid sheath) are frequently involved in patients with papillary, medullary, and Hürthle cell cancer. These nodes should be removed without injury to the parathyroid glands or the recurrent laryngeal nerves. In most patients, it is relatively easy to remove all tissue between the carotid sheath and the trachea. In some patients with extensive lymphadenopathy, it is necessary to remove the parathyroids, perform biopsies on them to confirm that they are in fact parathyroid, and autotransplant them into the sternocleidomastoid muscle.

When lymph nodes are palpable in the lateral neck, a modified neck dissection is performed through a lateral extension of the Kocher collar incision to the anterior margin of the trapezius muscle (a MacFee incision). The jugular vein, the spinal accessory nerve, the phrenic nerve, the vagus nerve, the cervical sympathetic nerves, and the sternocleidomastoid muscle are preserved unless they are directly adherent to or invaded by tumor.

In patients with medullary thyroid cancer, a meticulous and thorough central neck dissection is necessary. When a primary medullary tumor is larger than 1 cm or the central neck nodes are obviously involved, these patients will also benefit from a lateral modified radical neck dissection (with the structures just mentioned preserved). During the dissection, all fibrofatty lymph node tissues should be removed from the level of the clavicle to the level of the hyoid bone. The deep dissection plane is devel-

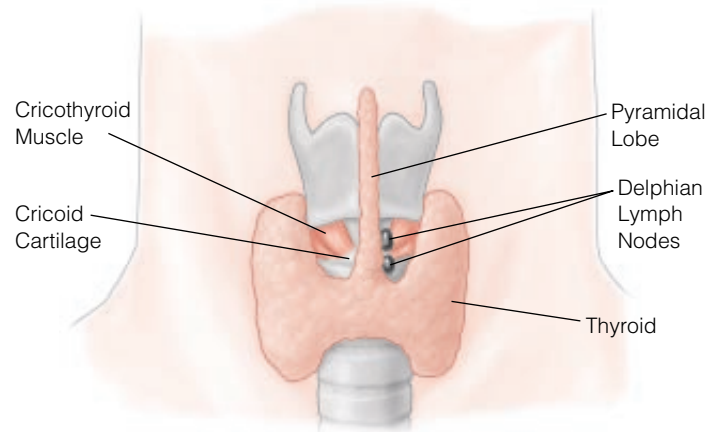

Figure 7 Delphian lymph nodes may be found just cephalad to the isthmus over the cricothyroid membrane.

oped anterior to the scalenus anticus muscle, the brachial plexus, and the scalenus medius muscle. The phrenic nerve runs obliquely on the scalenus anticus muscle. The cervical sensory nerves can usually be preserved unless there is extensive tumor involvement.

Median sternotomy A median sternotomy is rarely necessary for removal of the thyroid gland because the blood supply to the thyroid gland, the thymus, and the lower parathyroid glands derives primarily from the inferior thyroid arteries in the neck. Metastatic lymph nodes frequently extend inferiorly in the tracheoesophageal groove into the superior mediastinum; these nodes can almost always be removed through a cervical incision without any need for a sternotomy. On rare occasions, metastatic nodes spread to the aortic pulmonary window and can be identified preoperatively on CT or MRI. If a median sternotomy proves necessary, the sternum should be divided to the level of the third intercostal space and then laterally on one side at the space between the third rib and the fourth. Median sternotomy provides excellent exposure of the upper anterior mediastinum and the lower neck.

POSTOPERATIVE CARE

The duration of a thyroid operation is 1 to 3 hours, depending on the size and invasiveness of the tumor, its vascularity, and the location of the parathyroid glands. Postoperatively, the patient is kept in a low Fowler position with the head and shoulders elevated 10° to 20° for 6 to 12 hours to maintain negative pressure in the veins. The patient typically resumes eating within 3 to 4 hours, and an antiemetic is ordered as needed (many patients experience postoperative nausea and emesis).

The serum calcium level is measured approximately 5 to 8 hours after operation in patients who have undergone bilateral procedures; no tests are required in those who have undergone unilateral procedures. On the first morning after the thyroidectomy, the serum calcium and serum phosphate levels are measured. If the patient is still hospitalized on postoperative day 2, these tests are repeated on the second morning as well. Oral calcium supplements are given if the serum calcium is below 7.5 mg/dl or if the patient experiences perioral numbness or tingling. A low serum phosphate level (< 2.5 mg/dl) usually is a sign of so-called bone hunger and suggests that there is little

reason to be concerned about permanent hypoparathyroidism, whereas a high level (> 4.5 mg/dl) should prompt concern about permanent hypoparathyroidism.

The surgical clips are removed on postoperative day 1, and tissue adhesive or Steri-Strips are applied to prevent tension on the healing wound. (If Steri-Strips are used, they are removed on day 10.) Patients usually are discharged on the first day, are given a prescription for thyroid hormone (L-thyroxine, 0.1 to 0.2 mg/day orally) if the procedure was more extensive than a thyroid lobectomy, and are told to take calcium tablets for any tingling or muscle cramps. Patients with papillary, follicular, or Hürthle cell cancer should receive enough L-thyroxine to keep their serum levels of thyroid-stimulating hormone (TSH) below 0.1 mIU/ml. On postoperative day 10, the pathology is reviewed, and further management is discussed in the light of the pathologic findings. In patients with thyroid cancer, values for serum calcium, TSH, and thyroglobulin are obtained; in patients with coexisting hyperparathyroidism, values for serum calcium, phosphorus, and parathyroid hormone (PTH) are obtained.

COMPLICATIONS

The following are the most significant complications of thyroidectomy.

1. Injury to the recurrent laryngeal nerve. Bilateral injury to the recurrent laryngeal nerve may result in vocal cord paresis and stridor and may have to be treated with a tracheostomy.
2. Hypoparathyroidism. This complication may arise as the result of removal of, injury to, or devascularization of the parathyroid glands. As noted [*see Operative Technique, above*], we recommend leaving parathyroid glands on their own vascular pedicle; however, if one is concerned about possible devascularization of a parathyroid, biopsy should be performed on the gland to confirm its identity and then autotransplanted in 1×1 mm pieces into separate pockets in the sternocleidomastoid muscle.
3. Bleeding. Postoperative bleeding can be life threatening in that it can compromise the airway. Any postoperative respiratory distress can be thought of as attributable to a neck hematoma until proved otherwise. Most bleeding occurs within four hours of operation, and virtually all occurs within 24 hours.
4. Injury to the external laryngeal nerve [*see Operative Technique, above*].
5. Infection. This complication is quite rare after thyroidectomy. Any patient with acute pharyngitis should not undergo this procedure.
6. Seroma. Most seromas are small and resorb spontaneously; some must be aspirated.
7. Keloid. Keloid formation after thyroidectomy is most common in African-American patients and in patients with a history of keloids.
8. There are a number of miscellaneous complications that are somewhat less common.

OUTCOME EVALUATION

Most patients can return to work or full activity in 1 to 2 weeks. Patients with benign lesions who have undergone hemithyroidectomy may or may not require thyroid hormone; those with multinodular goiter, thyroiditis, or occult papillary cancer typically do, whereas those with follicular adenoma typically do not. Patients who have undergone total or near-total thyroidectomy will require thyroid hormone. Patients with papillary or

follicular cancer who have undergone total or near-total thyroidectomy appear to benefit from radioactive iodine scanning and therapy. (It is necessary to discontinue L-thyroxine for 6 to 8 weeks and L-triiodothyronine for 2 weeks before scanning.) Those considered to be at low risk (age < 45 years, tumor confined to the thyroid and not invasive, and tumor diameter < 4 cm) may receive radioactive iodine on an outpatient basis in a dose of approximately 30 mCi. Those who are considered to be at high risk should receive approximately 100 to 150 mCi. Long-term (20-year) mortality is about 4% in low-risk patients and about 40% in high-risk patients. Serum thyroglobulin levels should be determined before and after discontinuance of thyroid hormone; such levels are very sensitive indicators of persistent thyroid disease after total thyroidectomy.

Parathyroidectomy

OPERATIVE PLANNING

The preparation for parathyroidectomy is the same as that for thyroidectomy. Patients who have profound hypercalcemia (serum calcium ≥ 12.5 mg/dl) or mild to moderate renal failure should be vigorously hydrated and given furosemide before operation. On rare occasions, such patients require additional treatment—for example, administration of diphosphonates, mithramycin, or calcitonin. Any electrolyte abnormalities (e.g., hypokalemia) should be corrected.

We recommend either bilateral exploration or focused exploration with intraoperative PTH assay for most patients undergoing initial operations for primary sporadic hyperparathyroidism. The latter approach can be taken only when the abnormal gland has been identified by sestamibi scanning. For patients with familial primary hyperparathyroidism or secondary hyperparathyroidism, bilateral exploration is recommended because most of these patients have multiple abnormal parathyroid glands.

Preoperative localization studies (e.g., ultrasonography, MRI, sestamibi scanning, and CT scanning) are generally unnecessary: they provide useful information in about 75% of patients, but they are often not considered cost-effective, because an experienced surgeon can treat hyperparathyroidism successfully 95% to 98% of the time. Such studies are, however, essential when reoperation for persistent or recurrent hyperparathyroidism is indicated and when a focused approach with intraoperative PTH assay is to be used. We do not believe that using the gamma probe is any better than preoperative sestamibi scanning. All patients requiring reoperation should undergo direct or indirect laryngoscopy before operation for evaluation of vocal cord function.

OPERATIVE TECHNIQUE

Steps 1 through 4

Steps 1, 2, 3, and 4 of a parathyroidectomy are virtually identical to steps 1, 2, 4, and 5 of a thyroidectomy (see above), and essentially the same troubleshooting considerations apply.

Troubleshooting About 85% of people have four parathyroid glands, and in about 85% of these persons, the parathyroids are situated on the posterior lateral capsule of the thyroid. Normal parathyroid glands measure about $3 \times 3 \times 4$ mm and are light brown in color. The upper parathyroid glands are more posterior (i.e., dorsal) and more constant in position (at the level of the cricoid cartilage) than the lower parathyroid glands, which typi-

cally are more anteriorly placed (on the posterior-lateral surface of the thyroid gland). Both the upper and the lower parathyroid glands are supplied by small branches of the inferior and superior thyroid arteries in most patients. About 15% of parathyroid glands are situated within the thymus gland, and about 1% are intrathyroidal. Other abnormal sites for the parathyroid glands are (1) the carotid sheath, (2) the anterior and posterior mediastinum, and (3) anterior to the carotid bulb or along the pharynx (undescended parathyroids).

The upper parathyroid glands are usually lateral to the recurrent laryngeal nerve at the level of Berry's ligament; their position makes them generally easier to preserve during thyroidectomy and easier to find during both parathyroid and thyroid surgery. When the upper parathyroids are not found at this site, they often can be found in the tracheoesophageal groove or in the posterior mediastinum along the esophagus. The lower parathyroid glands are almost always situated anterior to the recurrent laryngeal nerves and caudal to where the recurrent laryngeal nerve crosses the inferior thyroid artery; they may be surrounded by lymph nodes. When the lower parathyroids are not found at this site, they usually can be found in the anterior mediastinum (typically in the thymus or the thymic fat).

Step 5: Parathyroid Resection

Abnormal parathyroid glands are removed. In about 80% of patients with primary hyperparathyroidism, one parathyroid gland is abnormal; in about 15%, all glands are abnormal (diffuse hyperplasia); and in about 5%, two or three glands are abnormal and one or two normal. Parathyroid cancer occurs in about 1% of patients with primary hyperparathyroidism. About 50% of patients with parathyroid cancer have a palpable tumor, and most exhibit profound hypercalcemia (serum calcium \geq 14.0 mg/dl).

Troubleshooting In some patients, parathyroid tumors and hyperplastic parathyroid glands are difficult to find. If this is the case, the first step is to explore the sites where parathyroids are usually located, near the posterolateral surface of the thyroid gland. (About 80% of parathyroid glands are situated within 1 cm of the point where the inferior thyroid artery crosses the recurrent laryngeal nerve.) When a lower gland is missing from the usual location, it is likely to be found in the thymus; this possibility can be confirmed by mobilizing the thymus from the

anterior-superior mediastinum. In all, about 15% of parathyroid glands are found within the thymus. If an upper parathyroid gland cannot be located, one should look not only far behind the thyroid gland superiorly but also in a paraesophageal position down into the posterior mediastinum. A thyroid lobectomy or thyroidotomy should be done on the side where fewer than two parathyroid glands have been located and no abnormal parathyroid tissue has been identified. The carotid sheath and the area posterior to the carotid, as well as the retrosophageal area, should also be explored. In rare cases, there may be an undescended parathyroid tumor anterior to the carotid bulb.

Although we do not recommend routine biopsy of more than one normal-appearing parathyroid gland, we do recommend biopsy (not removal) and marking of all normal parathyroid glands that have been identified when no abnormal parathyroid tissue can be found. When four normal parathyroid glands are found in the neck, the fifth (abnormal) parathyroid gland is usually in the mediastinum. The surgeon's responsibility is to make sure during parathyroidectomy that the elusive parathyroid adenoma is not in or removable through the cervical incision used for the initial operation and to minimize complications. The risk of permanent hypoparathyroidism or injury to the recurrent nerve should be less than 2%.

Step 6: Closure

Closure is essentially the same for parathyroidectomy as for thyroidectomy.

COMPLICATIONS

The complications of parathyroidectomy are similar to those of thyroidectomy but occur less often. Patients with a very high serum alkaline phosphatase level and osteitis fibrosa cystica are prone to profound hypocalcemia after parathyroidectomy. In such patients, both serum calcium and serum phosphorus levels are low. In contrast, patients with hypoparathyroidism exhibit low serum calcium levels but high serum phosphorus levels.

OUTCOME EVALUATION

Outcome considerations are essentially the same as for thyroidectomy. The patient should have a normal voice and be normocalcemic. The overall complication rate should be less than 2%.

8 PAROTID MASS

Ashok R. Shaha, M.D., F.A.C.S.

Approach to Evaluation of a Parotid Mass

There are three major salivary glands in the human body—the parotid gland, the submandibular gland, and the sublingual gland—of which the parotid gland is the largest. In addition, there are approximately 600 to 800 minor salivary glands distributed throughout the entire upper aerodigestive tract, starting from the lip and extending to the lower end of the esophagus and up to the pulmonary alveoli. Almost half of these minor salivary glands are on the hard palate. Accordingly, any mass on the hard palate should be considered a minor salivary gland tumor until proved otherwise.¹

The majority of salivary gland tumors originate in the parotid gland. Approximately 75% to 80% of parotid tumors are benign.^{2,3} In the evaluation and surgical treatment of parotid tumors, it is essential to maintain awareness of the possibility of temporary or permanent facial nerve injury [see Discussion, Principles of Facial Reanimation, *below*]. Because surgery necessarily entails some risk of an injury to this structure or its branches, as well as because most parotid masses do not give rise to significant symptoms, many patients with parotid tumors may find the prospect of surgical therapy difficult to accept.

Clinical Evaluation

HISTORY

Evaluation of a parotid mass begins with a good clinical history. The most important question is, how long has the mass been present? If local pain and swelling of recent onset (i.e., within the past few days) are reported, infection or obstruction is the likely cause. If the mass has been present for a longer period (i.e., weeks to months), a neoplasm is more likely. Unfortunately, the presentations of some nonneoplastic conditions resemble those of neoplasms, and distinguishing one type of condition from the other can be challenging. Thus, the history should continue with further questions focusing on local or systemic signs and symptoms, the presence of swelling or other masses in the salivary glands, and previous medical conditions (including skin cancer).

Classification

Major salivary gland masses can be classified as nonneoplastic, lymphoepithelial, or neoplastic.⁴

Nonneoplastic The causes of nonneoplastic masses include congenital, granulomatous, infectious or inflammatory, and non-inflammatory conditions. Some congenital lesions (e.g., hemangioma or vascular malformation) present as a vague swelling in the parotid region that has been present since childhood. One congenital lesion, a first branchial cleft cyst, presents as a mass inferior to the cartilaginous ear canal, with a cyst tract that can be either medial or lateral to the facial nerve and may even divide the trunk of the nerve. This cyst is most commonly noted in the second through fourth decades in life.

Granulomatous diseases are frequently manifested by an asymptomatic, gradual enlargement of a lymph node within the gland; often, they cannot be readily distinguished from neoplasms. In sarcoidosis, salivary gland involvement may cause duct obstruction, pain associated with the duct, xerostomia, or enlargement of the gland. The diagnosis is supported by chest x-rays that show bilateral hilar adenopathy and by elevated levels of angiotensin-converting enzyme (ACE).

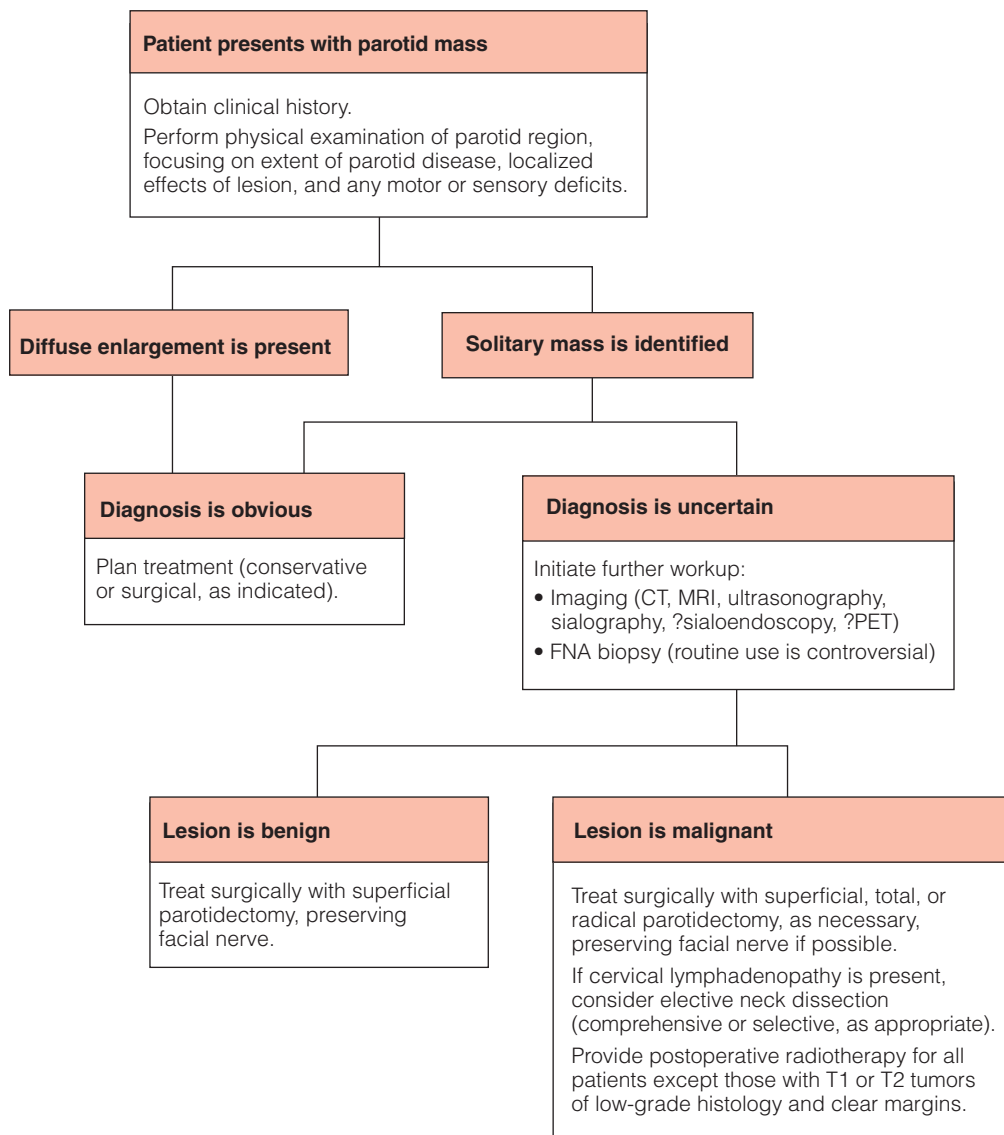

As noted (see above), infectious or inflammatory diseases involving the parotid, unlike neoplasms, tend to give rise to pain in their early stages. Most such inflammatory conditions begin with diffuse enlargement of one or more salivary glands. Although parotitis is generally unilateral, it may be bilateral if a systemic causative condition is involved, and other salivary glands may be affected as well. The pain reported may be related to the presence of a stone in the salivary duct or to diffuse obstructive parotitis. Chronic parotitis may lead to recurrent infection and inflammation. When recurrent swelling of the salivary gland does occur, it is directly related to eating and increased salivation.

Sialadenosis is a noninflammatory, nonneoplastic condition of unknown origin that is characterized by diffuse enlargement of the salivary gland, with no discrete mass or inflammation.

Lymphoepithelial Lymphoepithelial lesions may be divided into lymphocytic infiltrative diseases and lymphomas. In many cases, patients with lymphocytic infiltrative diseases (e.g., Mikulicz disease, sicca complex, and Sjögren syndrome) have had their conditions for long periods, and they may feel that they have always been chubby, when in fact they have had chronic enlargement of both parotid glands. In patients with Sjögren syndrome, malignant transformation to high-grade lymphoma is known to occur. Lymphoepithelial cysts are benign cystic lesions that may arise from lymph nodes or from lymphoid aggregates in the salivary gland. These lesions may be associated with HIV infection.

Approach to Evaluation of a Parotid Mass

Primary lymphoma of the salivary gland is uncommon, occurring in fewer than 5% of patients with parotid masses.⁵ Suggestive clinical features include (1) the development of a parotid mass in a patient with a known history of malignant lymphoma, (2) the occurrence of a parotid mass in a patient with an immune disorder (e.g., Sjögren syndrome, rheumatoid arthritis, or AIDS), (3) the presence of a parotid mass in a patient with a previous diagnosis of benign lymphoepithelial lesion, (4) the finding of multiple masses in one parotid gland or of masses in both parotid glands, and (5) the association of a parotid mass with multiple enlarged cervical lymph nodes unilaterally or bilaterally.⁶

Neoplastic Neoplastic masses may be present for years without causing any symptoms. Benign salivary tumors are more common in younger persons, whereas malignant parotid lesions are more common in the fifth and sixth decades of life.⁷ The classic presentation of a benign parotid tumor is that of an asymptomatic parotid mass that has been present for months to years. Benign neoplasms of the parotid include pleomorphic adenoma, basal cell adenoma, myoepithelioma, Warthin tumor, oncocytoma, and cystadenoma. The observation of rapid growth in a long-standing pleomorphic adenoma is suggestive of malignant transformation. In a 2005 study of 94 patients with pleomorphic adenoma, malignant transformation to carcinoma was documented in 8.5% of cases.⁸ Rapid tumor growth, metastasis to lymph nodes, deep fixation, and facial nerve weakness are all strongly suggestive of malignant disease and are indicators of a poor prognosis.⁹ Although pain is more often experienced by patients with benign conditions, it is also reported by some patients with infiltrative malignant tumors. In the latter patients, pain is another indicator of a poor prognosis.¹⁰

The presence of facial nerve palsy should raise the index of suspicion for malignancy. Occasionally, patients present with classic Bell palsy. This condition is usually of viral origin, and most patients recover over time. If Bell palsy persists, however, further investigation is required, including imaging studies to rule out any obvious parotid lesion. Facial palsy occurring in association with parotitis and anterior uveitis is known as Heerfordt syndrome and is often seen in patients with sarcoidosis.

PHYSICAL EXAMINATION

The physical examination should focus on the extent of the disease in the parotid, the neck, and the parapharynx; the localized effects of the tumor (including trismus); and the motor or sensory deficits resulting from neural invasion.

The mass is palpated to determine whether it is painless or painful; whether it is soft, firm, hard, or cystic; and whether it is mobile or fixed to deep tissue or skin. The skin of the scalp, the ear, and the face is examined for lesions. The neck is palpated for adenopathy. In the oral cavity, the ducts are examined for discharge or saliva after the glands are milked. The pharyngeal wall is examined for deviation, and the jaw is examined for trismus.

The parotid occupies a large area, starting from the zygoma and extending to the upper portion of the neck and behind the mandible to what is commonly called the tail of the parotid. Occasionally, the parotid tissue extends behind the earlobe, in which case it may be misdiagnosed preoperatively as a nonsalivary pathologic condition. Accessory parotid tissue is present along Stenson's duct in approximately 21% of persons.¹¹ Patients sometimes present with a tumor (most commonly, a benign mixed tumor) of this accessory tissue.¹² Attempts to excise such masses locally must be avoided, because of the high risk of injury to branches of the facial nerve.

The most common presentation of a parotid mass, whether benign or malignant, is an asymptomatic swelling in the preauricular or retromandibular region. Occasionally, patients present with metastases to the intraparotid or periparotid lymph nodes. There are approximately 17 to 20 lymph nodes in the substance of the parotid and along its tail, and there may be a smaller number of lymph nodes within the deep lobe of the gland. These lymph nodes may be directly affected by metastatic tumors originating from the anterior scalp or the temporal, periocular, or malar regions. Especially with elderly patients, it is extremely crucial to obtain a detailed history of any previously excised skin lesions, some of which may have been squamous cell carcinomas (SCCs) that metastasized to the periparotid nodes. Generally, such metastasis involves multiple superficial lymph nodes and presents as diffuse enlargement of the parotid parenchyma. With the massive involvement of the parotid gland, facial nerve palsy is not uncommon in this setting. The majority of metastases to the parotid gland derive from cutaneous SCC or melanoma; however, metastatic spread from the lung, the breast, and the kidney also is known to occur.¹³

The location of the parotid mass is a very important diagnostic factor. The classic presentation of a benign mixed tumor is as a marblelike lesion in the parotid gland—a firm, mobile mass that commonly originates in the superficial portion of the gland and generally is not fixed to the deeper structures or to the skin. Parotid tumors that originate in the deep lobe may present as a vague, diffuse swelling behind the angle of the mandible; more often, however, they present as a swelling of the parapharyngeal area accompanied by medial displacement of the tonsil or the soft palate.

Although physical examination of a parotid mass is a simple process in itself, it should be accompanied by a thorough evaluation of the head and neck that includes a detailed examination of the oral cavity and the oropharyngeal, nasopharyngeal, hypopharyngeal, and laryngopharyngeal areas. Occasionally, a tumor of the oropharynx presents as cervical lymphadenopathy or as metastatic disease in the tail of the parotid. In such cases, it may be difficult to determine whether the patient has a primary salivary gland tumor or a metastatic lesion. The presence of any suspicious pathologic condition in the oropharynx or the base of the tongue is an indication for appropriate endoscopy and biopsy of the suspected primary site.

Physical findings suggestive of malignancy include a large and fixed mass, facial nerve weakness, lymph node metastasis, and skin involvement; patients with advanced parotid malignancies may present with trismus. Whereas patients with benign parotid tumors rarely exhibit facial nerve weakness, approximately 12% to 15% of patients with parotid malignancies have facial nerve dysfunction at presentation.¹⁴ The most common causes of facial nerve weakness in this setting are adenoid cystic carcinoma, poorly differentiated carcinoma, and SCC. Primary SCC of the parotid is quite rare, and a diagnosis of SCC in the gland should lead one to suspect that a tumor has metastasized to the parotid lymph nodes. Before the diagnosis of primary SCC of the parotid is made, high-grade mucoepidermoid carcinoma and metastatic SCC must be excluded.

The presence of cervical lymph node metastasis may direct one's attention to the parotid mass, though only about 20% of persons with parotid malignancies actually have clinically apparent cervical lymph node metastases at the time of initial presentation.¹⁰ The parotid tumors most commonly associated with metastatic disease to the lymph nodes at presentation are high-

grade mucoepidermoid carcinoma, poorly differentiated carcinoma, and SCC. Lymph node metastases may also derive from high-grade adenocarcinomas or malignant mixed tumors.

Some patients are totally asymptomatic, with the only significant physical finding being a mass visible through the open mouth, which is suggestive of either a deep-lobe parotid tumor or a parapharyngeal tumor. The majority of parotid tumors develop within the superficial lobe of the parotid—not surprisingly, given that between 80% and 90% of the parotid tissue is superficial to the facial nerve. However, a significant minority of parotid masses—about 10%—are found within the deep lobe. Most deep-lobe parotid tumors are benign, in which case surgical treatment generally consists of a superficial parotidectomy with dissection and preservation of the facial nerve, followed by removal of the tumor. Occasionally, however, malignant deep-lobe parotid tumors do occur. Such tumors frequently involve the facial nerve, and surgical treatment may require sacrifice of the facial nerve in select circumstances. Most patients who have undergone surgical treatment of a malignant deep-lobe tumor will require postoperative radiation therapy.

Investigative Studies

The majority of parotid masses can easily be evaluated with a careful history and a thorough physical examination. Nevertheless, it sometimes happens that even after these measures have been carried out, there remains some clinical uncertainty regarding whether the pathologic process is of parotid or of nonsalivary origin. A number of nonsalivary tumors (e.g., neurofibromas, lipomas, lymphadenopathies, metastatic cutaneous lesions, and lymphomas) are known to present in the parotid region on occasion. These tumors may be difficult to evaluate clinically, and further diagnostic studies may therefore be required.

IMAGING

Generally, parotid masses are imaged with either computed tomography or magnetic resonance imaging.¹⁵ CT is superior to MRI for evaluation of the bony structures, whereas MRI may be more helpful in distinguishing between inflammatory conditions and salivary neoplasms. CT scanning is indicated in patients with diffuse enlargement of the parotid gland, tumor extension beyond the superficial lobe, facial nerve weakness, trismus, or deep-lobe parotid tumors that are difficult to evaluate clinically. If the parotid mass appears to be fixed to the deeper structures, it is appropriate to proceed with CT to evaluate the extent and parapharyngeal extension of the disease. MRI is indicated in patients with facial nerve paralysis. Occasionally, it may be necessary to perform both CT and MRI. Both imaging methods are helpful and accurate in distinguishing deep-lobe parotid tumors from other parapharyngeal masses. They are also useful for evaluating suspicious lymph nodes and the periphery of the mass (specifically with respect to determining whether the lesion is encapsulated or has irregular borders).

Ultrasonography can be useful for determining the location of the lesion and for guiding fine-needle aspiration (FNA) biopsy. In the past, technetium-99m scanning was commonly employed for the diagnosis of oncocytoma and Warthin tumor.¹⁶

Various other diagnostic studies are available for evaluation of parotid masses. At one time, sialography was commonly employed to assess patients with suspected salivary stones, as well as to eval-

uate the ductal arrangements in patients with chronic sialoadenitis. Currently, however, sialography is rarely used, both because there is a significant possibility of an infectious flare-up and because the study actually yields only minimal information. In the early 1980s, CT sialography became popular for a time; however, it was quite a complicated procedure, and clinicians eventually found that the information it yielded could easily be obtained from spiral (helical) CT. Occasionally, surface-coil MRI may be helpful for evaluating parotid masses deriving from subcutaneous processes. Sialoendoscopy has generated considerable interest, especially in Europe and Germany¹⁷; however, this sophisticated technology has not yet entered everyday practice. Although sialoendoscopy may be of some value in the assessment of salivary stone disease or chronic sialectasis, it is rarely performed in the United States at present, and its eventual role in the evaluation of parotid masses remains to be determined.

For a classic benign mixed tumor presenting in the form of a small nodule in the superficial lobe of the parotid gland, imaging is not required.

Currently, the role of positron emission tomography (PET) in the initial evaluation of a parotid mass remains undefined. This modality may, however, be of some value in the evaluation of suspected recurrent parotid cancers, lymph node metastases, or distant metastases.

FINE-NEEDLE ASPIRATION BIOPSY

Routine use of FNA biopsy in the evaluation of a parotid mass [see Table 1] continues to be controversial. One reason for the controversy is that cytologic evaluation is difficult. Another is that the extent of surgical treatment can easily be defined by means of the clinical assessment. The main argument against routine use of FNA biopsy is based on the standard approach to most parotid masses, which is a superficial parotidectomy that includes identification and preservation of the facial nerve. Nevertheless, FNA biopsy can be quite helpful, especially for the purposes of preoperative consultation with patients regarding the suspected pathologic process and the extent of surgical therapy. FNA biopsy has an overall accuracy that exceeds 90%,^{18,19} and it is considered a good investigational tool as long as it is used in the appropriate clinical context.

In the case of a classic benign mixed tumor, which presents as a mobile, confined, superficial nodule in the parotid gland, FNA biopsy is not required for further treatment. However, in cases where the clinical picture is not definitive and one cannot determine whether the pathologic process is of parotid origin or not, FNA biopsy is extremely important. Besides distinguishing between benign and malignant conditions, FNA biopsy can also distinguish between salivary and nonsalivary processes [see Table

Table 1 Uses of FNA Biopsy in Evaluation of Parotid Mass

- To identify suspected malignancy
- To diagnose metastatic carcinoma
- To identify suspected lymphoma
- To distinguish between salivary and nonsalivary lesions
- To facilitate conservative management of Warthin tumor or pleomorphic adenoma in a poor-risk patient
- To confirm preoperatively suspected malignancy in a patient with facial palsy
- To evaluate bilateral tumors

Table 2 Salivary and Nonsalivary Pathologic Processes Distinguished by FNA Biopsy

Salivary processes	Benign Mixed tumor Warthin tumor Malignant Primary salivary gland cancer Metastatic disease in salivary gland Cystic adenoma SCC Adenocarcinoma Melanoma
Nonsalivary processes	Lipoma Sebaceous cyst Lymph node pathology Benign melanoma Metastatic cancer Lymphoma

2].²⁰ A variety of different lymph node pathologies, benign parotid tumors, and even suspected malignant parotid tumors can be differentiated by means of FNA biopsy. Furthermore, lymphoepithelial lesions of the parotid, benign mixed tumors, and Warthin tumors are easily diagnosed with this procedure. FNA biopsy is particularly useful when a parotid mass is likely to be the result of metastasis.

Occasionally, in an elderly person whose overall physical condition is poor, a conservative approach can be taken when a Warthin tumor is diagnosed by means of FNA biopsy. Similarly, in a person with a long-standing benign mixed tumor, observation may be appropriate if the patient is not a candidate for surgical intervention and if FNA biopsy confirms that the lesion is benign.

FNA biopsy findings that suggest lymphoma may help one avoid unnecessary parotidectomy and risk to the facial nerve. Often, it is hard to achieve a definitive diagnosis of lymphoma by means of FNA biopsy alone. In such cases, core biopsy or open biopsy can be performed to establish the diagnosis. Core biopsy of a parotid mass is a difficult procedure (unless the mass is very large and very superficial), and it is generally contraindicated on the grounds that it may cause bleeding or facial nerve injury. Nevertheless, if core biopsy can be performed safely, it can be a good choice in cases where lymphoma is suspected on the basis of FNA biopsy.²¹ Open incisional biopsy can also be performed safely when done in conjunction with continuous monitoring of the facial nerve.²²

Benign lymphoepithelial lesions related to HIV disease are readily diagnosed by means of FNA biopsy, especially if they are multiply recurrent cystic lesions in the tail of the parotid or if they occur bilaterally. In general, HIV-related pathology is quite easy to diagnose with FNA; HIV-infected patients with benign lymphoepithelial lesions may be treated by providing appropriate management of the underlying illness.

The crucial points for clinicians with respect to FNA biopsy in the setting of a parotid mass are (1) that this investigative study will not make a definitive diagnosis of parotid malignancy and (2) that one therefore should not make decisions about how to manage the facial nerve solely on the basis of an FNA-suggested malignant diagnosis. Any decisions regarding the approach to the facial nerve should also be based on preoperative assessment of facial nerve function and intraoperative evaluation of the nerve in relation to the tumor.

Table 3 American Joint Committee on Cancer TNM Clinical Classification of Major Salivary Gland Tumors

Primary tumor (T)	TX: Primary tumor cannot be assessed T0: No evidence of primary tumor T1: Tumor ≤ 2 cm in greatest dimension without extraparenchymal extension T2: Tumor > 2 cm but ≤ 4 cm in greatest dimension without extraparenchymal extension T3: Tumor having extraparenchymal extension without seventh nerve involvement and/or > 4 cm but ≤ 6 cm in greatest dimension T4: Tumor invades base of skull, seventh nerve, and/or > 6 cm in greatest dimension
Regional lymph nodes (N)	NX: Regional lymph nodes cannot be assessed N0: No regional lymph node metastasis N1: Metastasis in a single ipsilateral lymph node, ≤ 3 cm in greatest dimension N2: Metastasis in a single ipsilateral lymph node, > 3 cm but ≤ 6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, none > 6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, none > 6 cm in greatest dimension N2a: Metastasis in a single ipsilateral lymph node > 3 cm but ≤ 6 cm in greatest dimension N2b: Metastasis in multiple ipsilateral lymph nodes, none > 6 cm in greatest dimension N2c: Metastasis in bilateral or contralateral lymph nodes, none > 6 cm in greatest dimension N3: Metastasis in a lymph node > 6 cm in greatest dimension
Distant metastasis (M)	MX: Distant metastasis cannot be assessed M0: No distant metastasis M1: Distant metastasis

Staging and Prognosis

For cancers of the parotid gland (as well as those of other major salivary glands), staging is accomplished by means of the familiar tumor-node-metastasis (TNM) system developed by the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (UICC) [see Tables 3 and 4].²³

The prognostic factors in the management of parotid gland tumors must be understood in relation to the stage the disease has reached, the need for postoperative radiation therapy, and the overall long-term outcome [see Table 5]. Such factors include age

Table 4 American Joint Committee on Cancer Staging System for Major Salivary Gland Tumors

Stage	T	N	M
Stage I	T1, T2	N0	M0
Stage II	T3	N0	M0
Stage III	T1, T2	N1	M0
Stage IV	T4 T3, T4 Any T Any T	N0 N1 N2, N3 Any N	M0 M0 M0 M1

Table 5 Prognostic Factors for Salivary Gland Tumors

Age at diagnosis	Facial nerve dysfunction
Pain at presentation	Perineural growth
T stage	Positive surgical margins
N stage	Soft tissue invasion
Skin invasion	Treatment type

at diagnosis, pain at presentation, TNM staging, skin invasion, facial nerve dysfunction, perineural growth of the primary tumor, positive surgical margins in the final pathology report, soft tissue invasion by the primary tumor, treatment type, and extranodal spread of the metastatic disease in the neck. To make definitive decisions regarding treatment, it is necessary to analyze these prognostic factors critically in individual patients. An example of such critical analysis is the prognostic index devised by the Dutch Head and Neck Cooperative Group for patients with parotid cancer.^{24,25} In this index, a weighted combination of the parameters of age, pain, tumor size, nodal stage, skin invasion, facial nerve dysfunction, perineural growth, and positive surgical margins is employed to compute a prognostic score. The score is then used to assign patients to one of four groups, each of which is associated with an expected recurrence-free percentage.

Management

Treatment of a parotid mass depends on the nature and extent of the lesion [see Table 6]. Malignant parotid masses are treated surgically according to established oncologic principles [see Surgical Therapy, below], with postoperative radiation therapy added as necessary [see Radiation Therapy, below]. Generally, benign parotid masses are managed surgically as well, with exploration of the parotid gland, evaluation of the neoplasm, and appropriate parotidectomy with identification and preservation of the facial nerve and its branches. In the case of a suspected benign mixed tumor, enucleation is contraindicated because of the possibility of tumor spillage, incomplete removal of the tumor, injury to the capsule and resultant seeding of the tumor into the parotid tissue, or inadvertent injury to the branches of the facial nerve. Enucleation of such a tumor is very likely to result in local recurrence, which invariably is much more difficult to manage than the original lesion was and poses a high risk of injury to the facial nerve.

SURGICAL THERAPY

Parotidectomy with or without Facial Nerve Reconstruction

The minimum surgical procedure for a parotid mass is superficial parotidectomy with identification and preservation of the facial nerve [see 2:5 Parotidectomy]. Subtotal parotidectomy may be required for larger tumors that involve the deep lobe of the parotid gland; however, true total parotidectomy with preservation of the facial nerve is almost impossible, because of the parotid gland tissues surrounding the nerve. If the tumor involves the facial nerve and is directly infiltrating into it, a diagnosis of malignancy should be explored, and only if the diagnosis is confirmed should the facial nerve be sacrificed. Preoperative facial nerve weakness generally indicates that the tumor is involving the nerve, in which case

due consideration should be given to the sacrifice and subsequent reconstruction of this structure.

Reconstruction of the facial nerve can be performed with a nerve graft from the greater auricular nerve, from the sural nerve in the leg, or from the ansa hypoglossi. In view of the technical complexity of nerve grafting, preoperative consultation with a plastic surgeon may be necessary. The functional results of nerve grafting vary considerably, depending on the age of the patient, the extent of the disease, and the identification of and appropriate anastomosis to the peripheral branches of the facial nerve. If postoperative radiation therapy is envisioned, its potential deleterious effects on nerve regeneration should be kept in mind.

If the tumor involves only an isolated branch of the facial nerve, one may opt for selective sacrifice of that branch, along with nerve grafting. If the tumor extends beyond the parotid gland and involves the infratemporal fossa, the ascending ramus of the mandible, or the mastoid process, a much more extensive surgical procedure (e.g., composite resection, lateral temporal bone resection, or radical parotidectomy with sacrifice of the entire facial nerve) becomes necessary. Such patients invariably require postoperative radiation therapy [see Radiation Therapy, below]. However, in the majority of patients who present with an isolated parotid mass and a functioning facial nerve, every attempt should be made to preserve the nerve.²⁶ It is rarely necessary to sacrifice a functioning facial nerve: the only indication for doing so is a situation in which the entire tumor cannot be resected without sacrifice of the main trunk or the branches of the facial nerve and there is concern about leaving any gross tumor behind.

Intraoperative Frozen-Section Examination

The role of intraoperative frozen-section examination in the evaluation of a parotid mass, like that of FNA biopsy, is the subject of considerable debate. Nevertheless, frozen-section examination has been found to be useful for distinguishing salivary processes from nonsalivary processes and benign disease from malignant disease. In 80% to 90% of cases, the findings from intraoperative frozen-section examination correlate with the final pathologic diagnosis.²⁷ This study is also helpful in making a definitive diagnosis of Warthin tumor. If frozen-section examination shows a benign mixed tumor and this finding agrees with one's clinical judgment, lateral superficial parotidectomy should be sufficient. If frozen-section examination shows high-grade mucoepidermoid carcinoma, selective neck dissection may be considered (mainly for staging purposes, to determine whether any of the deep jugular nodes are positive). If frozen-section examination provides a definitive diagnosis of malignancy, further decisions about the extent of parotidectomy and possible selective neck dissection can be made accordingly; if not, the procedure originally planned can be performed, with any further interventions (if required) dictated by the final pathologic diagnosis. Obviously, the decision whether to sacrifice the facial nerve must not be based solely on whether the frozen section shows a benign or a malignant process.

Table 6 Principles of Treatment of Parotid Tumors

Adequate local excision of tumor, based on extent of primary lesion
Preservation of facial nerve if possible
Elective neck dissection reserved for selected patients
Postoperative radiotherapy when indicated (in appropriate fields)
Prognosis determined primarily by stage and grade of tumor

Table 7 Indications for Postoperative Radiation Therapy for Parotid Cancer

- Aggressive, highly malignant tumor
- Invasion of adjacent tissues outside parotid capsule
- Regional lymph node metastases
- Deep-lobe cancer
- Gross residual tumor after resection
- Recurrent tumor after resection
- Invasion of facial nerve by tumor

Neck Dissection

Overall, about 20% of patients with malignant parotid tumors present with clinically detectable cervical lymphadenopathy (cN+).¹⁰ There is wide agreement that these patients require either a comprehensive or a modified neck dissection [see 2:6 Neck Dissection], depending on the extent of the disease, but there continues to be controversy regarding the management of patients with salivary malignancies who have no clinically detectable cervical lymphadenopathy (cN0). In one study, approximately 14% of the patients were in cN+ status; however, approximately 12% were in cN0 status but presented with pathologically positive nodes (pN+).²⁸ In view of the low frequency of occult metastasis in the group as a whole, the investigators generally did not recommend routine elective treatment of the neck. They did find that certain histologic grades were associated with a higher incidence of metastatic disease to the neck nodes: the incidence of occult metastasis was about 49% in patients with high-grade lesions, compared with 7% in those with intermediate-grade or low-grade lesions. In addition, the incidence of having occult metastatic disease was more than 20% in patients with tumors larger than 4 cm, compared with 4% in those with smaller tumors.

The incidence of lymph node metastasis is affected not only by the size and histologic grade of the tumor but also by the histologic type, the primary tumor stage, the presence of facial nerve palsy, the patient's age, the extraparotid extension of the disease, and the degree of perilymphatic invasion.²⁹ In a multivariate analysis, the variables that showed the highest correlation with the incidence of lymph node metastasis were the histologic type (i.e., adenocarcinoma, undifferentiated carcinoma, high-grade mucoepidermoid carcinoma, SCC, or salivary duct carcinoma) and the T stage.³⁰

Thus, elective neck dissection may be considered in patients with advanced-stage primary tumors, those whose tumors are of high histologic grades, and those whose tumors are of certain specific histologic types. A selective neck dissection may be performed to remove the lymph nodes of the submandibular triangle, level II, level III, and the upper part of level V for the purposes of staging.²⁹ However, a comprehensive neck dissection that encompasses levels I through V may be necessary in patients who present with clinically obvious cervical metastases.

Discussion

Implications of Histopathologic Classification of Parotid Gland Cancer

Although considerable controversy and debate continue to surround the histopathologic classification of malignant parotid tumors, most clinicians currently prefer either the classification system of the Armed Forces Institute of Pathology³⁵ or that of the

Figure 1 Depicted is the impact of postoperative radiation therapy (RT) on overall outcome for patients with stage I or II tumors and patients with stage III or IV tumors.

RADIATION THERAPY

Patients who present with advanced-stage (stage III or IV) disease, a large primary tumor, close margins, perineural spread, soft tissue extension, facial nerve dysfunction, or cervical lymph node metastasis invariably require postoperative radiation therapy [see Table 7].^{31,32} In general, this means that postoperative radiation therapy is indicated for all patients except those with T1 or T2 malignant tumors of low-grade histology and clear margins. Thus, the decision whether to employ such therapy depends largely on the intraoperative findings and the final pathology report. A 1990 analysis showed that postoperative radiation therapy had a major impact on overall outcome in patients with stage III or IV tumors but conferred no statistically significant benefit on patients with stage I or II tumors [see Figure 1].³³

Currently, there is substantial interest in the potential role of neutron therapy as a primary treatment modality for parotid malignancies, especially advanced inoperable parotid cancers and adenoid cystic carcinomas. A group from the University of Washington demonstrated that neutron therapy exerted a beneficial effect when used as the sole treatment of advanced parotid cancers.³⁴ Although these results are extremely promising, the patients treated with this modality clearly experienced an increased incidence of complications. Nevertheless, for patients with inoperable parotid cancer, neutron therapy may be the best option currently available.

World Health Organization.³⁶ The most common types of parotid tumor are mucoepidermoid carcinoma, adenoid cystic carcinoma, adenocarcinoma, malignant mixed tumor, acinic cell carcinoma, and primary SCC [see Figure 2].

As noted (see above), primary SCC of the parotid gland is quite rare, and most diagnoses of parotid SCC represent skin cancer

Figure 2 Shown are the approximate relative frequencies of the most common types of parotid gland tumors.

that has metastasized to the periparotid lymph nodes. Primary SCC has a high malignant potential, and radical surgical extirpation (with preservation of the facial nerve when possible), followed by planned postoperative radiotherapy, is the treatment of choice.³⁷

Mucoepidermoid carcinomas are best divided into low-grade, intermediate-grade, and high-grade tumors.³⁸ For high-grade tumors, selective node dissection may be appropriate, with due consideration given to postoperative radiation therapy. For the majority of low-grade tumors—provided that they are properly excised with appropriate superficial parotidectomy—postoperative radiation therapy is unnecessary, because the incidence of local recurrence is lower than 5%.

Adenoid cystic carcinoma is a unique salivary gland tumor with a classic Swiss-cheese appearance under the microscope. There is a very high incidence of perineural spread with skip metastasis along the facial nerve and its branches, and the incidence rises with higher T stages.³⁹ The incidence of local recurrence is also very high, and thus, postoperative radiation therapy should be provided to patients who are at high risk for relapse (i.e., those with close or positive margins and those with perineural invasion). Such therapy appears to reduce the incidence of local recurrence.⁴⁰ The incidence of cervical lymph node metastasis in patients with adenoid

cystic carcinoma is low; however, the incidence of distant metastasis (especially pulmonary metastasis) appears to be high.⁴¹ It is noteworthy that even when adenoid cystic carcinoma patients have pulmonary metastases, they tend to do remarkably well. Quite often, the metastatic disease in the lungs remains dormant for months or even years. At present, the role of chemotherapy in the management of adenoid cystic carcinoma and parotid tumors is supported only by anecdotal evidence and remains investigational.

Principles of Facial Reanimation

Every surgeon who performs parotid surgery, especially surgery for parotid cancer, should be familiar with the principles of facial reanimation. If the facial nerve dysfunction is recognized before the operation, appropriate arrangements may be made for plastic surgical consultation and facial nerve grafting. If the proximal stump of the facial nerve can be identified and the peripheral branches detected at the time of the operation, a nerve graft repair can be performed. The main donor nerves used in facial nerve grafting are the greater auricular nerve, the ansa hypoglossi, and the sural nerve. Of these, the greater auricular nerve is the preferred source for a graft: harvesting is relatively easy, the diameter matches that of the facial nerve, and the arborization of the distal branches allows for a greater number of facial nerve grafts.⁴² The use of loupes or a microscope helps in the placement of the 9-0 nylon stitches employed in facial nerve grafting.

Regeneration of the facial nerve may take 3 to 6 months. There is some controversy regarding whether postoperative radiation therapy has a beneficial effect on functional outcome after nerve grafting: some studies cite detrimental effects,⁴³ whereas others report adequate functional outcomes.^{42,44} In any case, if it is feasible to perform nerve grafting, every attempt should be made to do so. Currently, hypoglossal nerve transfer is rarely performed,⁴⁵ because various effective alternatives (e.g., fascia lata slings and Gore-Tex slings) are available. A consultation with a facial plastic surgeon may be quite helpful in the management of patients with total facial nerve palsy.

One of the most important considerations in addressing facial nerve paralysis is how to prevent exposure keratopathy and other ocular complications. Placement of a gold weight or a palpebral spring on the upper eyelid may be considered as a primary rehabilitative measure aimed at preventing corneal ulceration and opacification.⁴⁶ In the past, lateral tarsorrhaphy was commonly employed for this purpose, but currently, as a consequence of the superior results obtained with the gold weight and the palpebral spring, it is rarely performed. Other, simpler measures for preventing or minimizing ocular complications include the use of artificial tears and an eye patch during the day and the use of ointment with proper taping to keep the eyelid closed at night.

9 TRACHEOSTOMY

Ara A. Chalian, M.D., F.A.C.S.

Strictly speaking, the term tracheostomy refers to the surgical creation of an opening into the trachea, whereas the term tracheotomy refers to an incision of the trachea. However, many surgeons use these terms virtually interchangeably; in particular, they commonly refer to more temporary openings, in which cutaneous flaps are not sutured to the trachea, as tracheotomies. Other surgeons prefer to observe a more formal distinction between the two words. In this chapter, I use the term tracheostomy to refer to the process of creating an opening in the trachea, reserving the term tracheotomy for the actual tracheal incision.

Initially, tracheostomy was performed primarily as a life-saving intervention to secure and establish an airway in patients with life-threatening airway obstruction as a consequence of infection or neoplastic disease. Currently, it is most commonly done to facilitate prolonged ventilator-based respiration in patients with respiratory failure. Tracheostomy has become an integral part of complex head and neck tumor resections for cancer involving the larynx, the base of the tongue, the pharynx, and, in some cases, the base of the skull. In addition, it is performed to provide airway diversion in patients with laryngeal stenosis or bilateral vocal cord paralysis.

Preoperative Evaluation

Patients scheduled for elective tracheostomy undergo the standard preoperative assessments. Because the surrounding tissues are highly vascular, anticoagulants and aspirin should be discontinued before operation in nonemergency settings, as should antiplatelet medications. The cervical and tracheal anatomy should be assessed; in rare instances, an extra-long tracheotomy tube will be required. Any lesions, scars, or masses in the central thyrotracheal compartment of the neck should be noted. If there is a mass in the thyroid gland (especially in the isthmus), workup or simple resection should be considered. Previous operations on the thyroid, the larynx, the trachea, or the cervical spine can alter the anatomy and present additional difficulties to the surgeon. A low-lying larynx or cricoid resulting from kyphosis or another cause is particularly troublesome. In some patients, the cricoid is at the sternal notch or even lower.

In this last situation, if it is determined that a tracheostomy is absolutely necessary, the potential problems must be considered. Although it is logical to assume that the trachea can be pulled superiorly, it is important to remember that after the procedure, the position of this structure will tend to drift down toward the mediastinum, presenting the problem of an incorrectly positioned tracheostomy tube that may “kick out” from the anterior tracheal wall opening or press against a mucosal surface. Often, this tube will pivot against the anterior wall or the trachea cephalad to the opening, thereby potentially contributing to cartilage injury with subsequent malacia or stenosis.

If the trachea is inferiorly displaced to a substantial degree, resection of the manubrium should be considered. This measure very rarely proves necessary, however, and is mentioned only for the sake of completeness.

Operative Planning

COUNSELING AND INFORMED CONSENT

The patient, the family, or both should receive counseling on the risks and benefits of the procedure. Commonly discussed issues include pain, mortality, and the range of possible early and late complications [see Complications, *below*]. In my experience, many families are intimidated or upset by the consideration of tracheostomy. To address their concerns, I offer the option of removing the oral or nasal tube from the areas that most affect patient comfort and ability to interact with the family. When this is done, oral alimentation and mouth care become much more feasible, and the patient’s ability to speak (or at least mouth) words is often greatly improved. In patients with significant central nervous system injuries or other conditions that alter mental status, it may be advisable to secure the tracheotomy tube to the neck to maintain safety and prevent unintentional extubation.

SITE OF PROCEDURE

A tracheostomy may be performed in an intensive care unit, a shock trauma bay, or an operating room. Emergency tracheostomies are often performed in these areas, and thus, the surgical equipment is most often kept there. In elective situations, however, a tracheostomy may be performed virtually anywhere. The most commonly required equipment is portable. An electrocautery should be available, and good lighting (whether from overhead lights, headlights, or portable OR lights) is critical. OR personnel usually are more familiar with the procedure than ICU or trauma bay personnel; accordingly, many teams request a scrub nurse or a technician, then train team members in the alternative environments.

ANESTHESIA

The patient’s comfort can be optimized with conscious sedation or, possibly, with local anesthesia alone. Communication and cooperation with the anesthesiologist (including specific discussion of the role of sedation and analgesia) can be critical to a successful outcome and should therefore be key components of preparation for emergency tracheostomy. In a decompensating patient, the effect of suppression of the respiratory drive is potentially catastrophic.

Operative Technique

SURGICAL TRACHEOSTOMY

The patient is positioned with a shoulder roll and a foam pad (doughnut) under the head. If cervical spine precautions are in force, the posterior portion of the cervical collar should remain in place, and the head should be stabilized by a team member. The procedure may be more difficult to execute in this setting, but otherwise, the surgical technique is the same.

The position of the patient can also be optimized by extend-

ing the headrest of the surgical bed. This measure permits better palpation of landmarks if soft tissues are thick. For patients with cervical stenosis or symptoms related to cervical spine pathology, a larger incision or so-called neutral-position tracheostomy may be considered; such problems do not necessarily preclude the procedure.

Step 1: Incision of Skin

Before the incision is made, the patient should also be assessed for a high-riding innominate artery or medially placed carotid arteries. These anatomic variants are rare, but when they are present, additional care may have to be exercised.

The cutaneous incision may be made either vertically or horizontally. Either incision leaves a well-healed scar once the tracheostomy tube is removed. The level and location of the incision may vary, depending on individual surgeons' preferences. In general, a good placement is 1 cm below the cricoid or halfway between the cricoid and the sternal notch [see Figure 1]. The size of the incision is also, to an extent, a matter of individual preference. Given the current emphasis on minimizing scars, I strive to use the smallest possible safe incision. For transverse incisions, 2 to 2.5 cm is often adequate. In an emergency setting, a longer incision—often vertical—may facilitate exposure and help the surgeon avoid large subplatysmal anterior jugular veins. The skin incision may be accompanied by excision of some of the subcutaneous fat in the immediate area.

It should be kept in mind that these recommendations regarding the size of the incision are only suggestions, not hard-and-fast rules. Each case should be considered individually, and each incision should be designed so as to allow the safest exposure in a given patient.

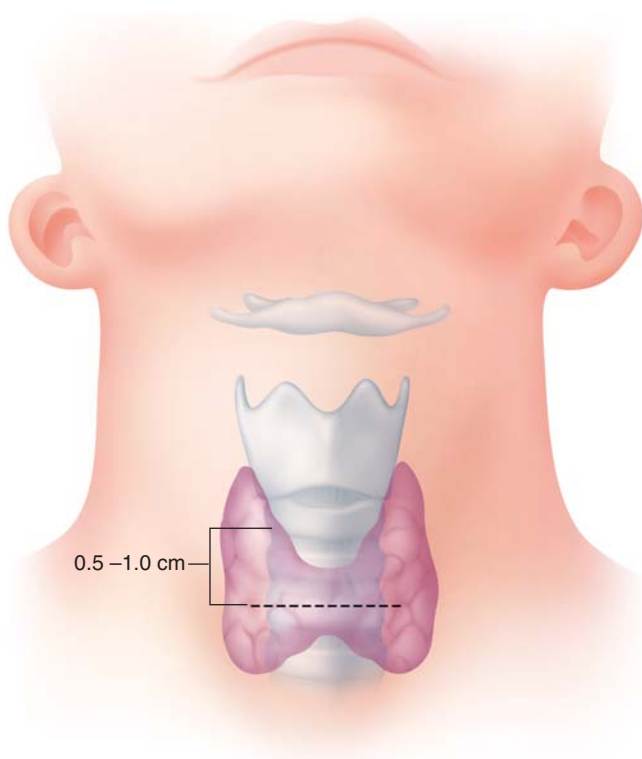

Figure 1 Surgical tracheostomy. A transverse cutaneous incision is made that is approximately 2 to 3 cm long (or as long as is necessary for adequate exposure). The extent of flap elevation may be 1 cm or less.

Figure 2 Surgical tracheostomy. Retractors are placed, the skin is retracted, and the strap muscles are visualized in the midline. The muscles are divided along the raphe, then retracted laterally.

Step 2: Retraction of Strap Muscles

The strap muscles are identified, and the midline raphe is divided. The muscles are then retracted laterally by the assistant with Senn or Army-Navy retractors [see Figure 2]. Undermining should be limited to minimize the potential creation of avenues for the passage of air, secretions, or instruments (including the tracheostomy tube). When there is a malignant neoplasm in the soft tissue or the thyroid compartment, anatomic landmarks may be difficult to identify. In such cases, dissection to the notch of the thyroid cartilage helps one identify the midline and work inferiorly [see Step 5, below].

Step 3: Dissection of Thyroid Gland

The thyroid isthmus lies in the field of the dissection [see Figure 3]. Its size and thickness may vary greatly. Typically, the isthmus is 5 to 10 mm in its vertical dimension. If the organ is within this size range, one can often mobilize it away from the trachea and retract it superiorly (or inferiorly), then place the tracheal incision in the second or third tracheal interspace [see Figure 4]. If the isthmus is large enough that it may block the tracheostomy site, one may divide it and ligate the edges. In the instance of an isthmus nodule, removal of the isthmus and the nodule is reasonable for diagnostic and therapeutic purposes. Although the recurrent nerves are in the surgical field, they typically are not at great risk for injury during tracheostomy; however, they may be subjected to trauma if dissection or even a retractor extends into the tracheoesophageal groove. The blood supply to the trachea is laterally based, which is another reason for avoiding significant lateral exposure of the trachea.

Step 4: Incision of Trachea

The tracheostomy should be performed with a knife. If one desires, the pretracheal tissues may be coagulated with a bipolar (or, cau-

Figure 3 Surgical tracheostomy. With the strap muscles retracted, the thyroid isthmus is visualized, and the inferior (or superior) edge of the isthmus is dissected down to the trachea. The isthmus is then retracted superiorly (or inferiorly) or divided to permit visualization of the trachea before the tracheal incision is made.

Figure 4 Surgical tracheostomy. A tracheostomy is made either between the second and third tracheal rings or between the third and fourth rings. A Bjork flap (inset) may be created by extending the ends of the tracheostomy downward through the next lower tracheal ring in an inverted U shape.

tiously, with a monopolar) electrocautery. The opening of the airway will bring volatile, flammable gases into the operative field; accordingly, the use of a monopolar electrocautery must be limited (or avoided if possible). The choice of a tracheal incision will not make a significant difference to the execution of the procedure.

Linear incision A linear incision is probably the simplest choice and the one that is least traumatic to the cartilage. Typically, it is made through either the interspace between the second and third tracheal rings or that between the third and fourth.

Tracheal window Instead of a simple incision, one may opt to remove the midportion of the third or fourth tracheal ring to create a window. The theoretical rationale for the tracheal window is that it minimizes trauma to the remaining cartilage resulting from passage of the tracheostomy tube.

Bjork flap A Bjork flap is an inferiorly based U-shaped flap that incorporates the ring below the tracheal incision. It is sewn to the skin at the inferior margin of the tracheostomy. The theoretical justification for the use of the Bjork flap is that it helps keep the tracheal incision close to the skin edge and facilitates tube replacement if the tube is accidentally dislodged or removed. The flap suture can be released after 3 to 5 days, once the tract has started to mature.

Stay sutures Many surgeons place lateral, inferior, or superior stay sutures (often, though not always, made of silk) in the trachea to help stabilize this structure during the procedure. For optimal stabilization of the exposure during subsequent manipulations or possible emergencies, they generally leave the sutures in situ until the first tracheostomy tube change. These sutures are taped to the patient's chest and should be labeled for easy identification in emergency situations. The use of stay sutures in tracheostomies is now a well-established (though not universal) practice, particularly in children and neonates.

Step 5 (optional): Division of Tumor to Facilitate Tube Placement

In the case of a neoplasm involving the thyroid, the tumor may have to be resected in the midline to allow placement of the tube. Often, the airway cannot be palpated. To identify the airway, the dissection should begin at the level of the thyroid cartilage—possibly, as high as the thyroid notch—and continue inferiorly until the cricoid and the trachea are identifiable. In these situations, the depth of the wound that must be created before the trachea is reached can be a problem. A standard tracheostomy tube may be too short for its intended use, in which case a custom tube will have to be ordered. With a custom tube, it is possible to specify both the distance from the tube faceplate to the turn entering the airway and the length of the segment going into the airway. If there is not enough time to order a custom tracheostomy tube, an endotracheal tube can be placed as a temporizing measure to provide an airway. To help set the length of the tube segment that will enter the airway, the endotracheal tube can be bivalved (i.e., split) along its proximal extent.

Step 6: Removal or Withdrawal of Endotracheal Tube and Placement of Tracheostomy Tube; Management of Anesthesia and Oxygenation

During the transition to tracheostomy tube ventilation, the endotracheal tube either is removed or is withdrawn and kept in position at the level of the vocal cords until the tracheostomy tube is secured. Preoxygenation is important to allow adequate apnea time for incision, withdrawal of the endotracheal tube, and place-

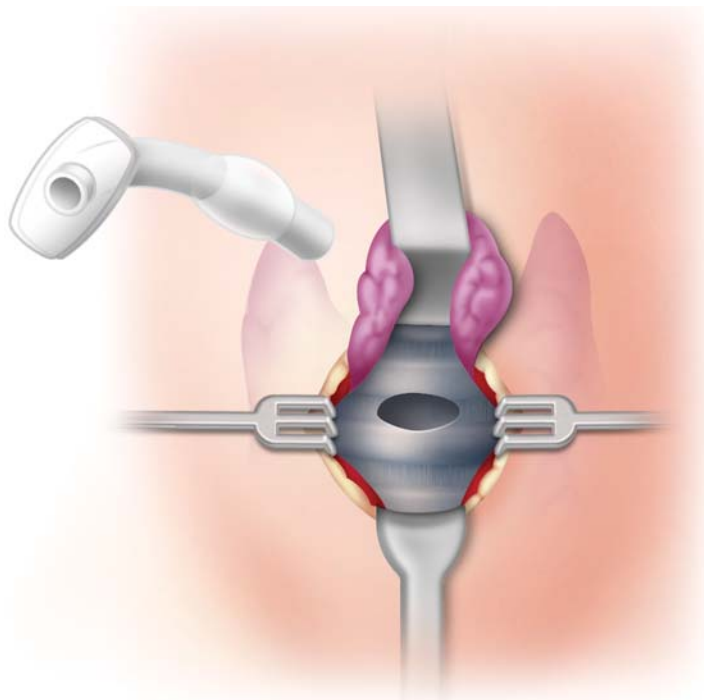

Figure 5 Surgical tracheostomy. The tracheostomy tube is inserted into the tracheal opening from the side, with the faceplate rotated 90° so that the tube's entry into the airway can be well visualized.

ment of the tracheostomy tube. To optimize oxygen tension, administration of nitrous oxide is often stopped before the airway is entered.

Some surgeons prepare and drape the endotracheal tube into the operative field, preferring to withdraw it themselves gradually as the changeover to the tracheostomy tube is occurring. Often, the anesthesiologist or another team member is assigned to manage the release and withdrawal of the endotracheal tube. I prefer to advance the endotracheal tube before the tracheal incision is made so that the cuff lies deep (distal) to the tracheostomy site. This measure delays the start of apnea and potentially minimizes its duration, permitting ventilation to continue even though the airway has been entered. Delivery of the volatile anesthetic, ventilation, and oxygenation can be performed actively during the first step of entry into the airway and preparation for tube changeover.

The size of the tracheostomy tube is chosen on the basis of the length and diameter required to achieve adequate respiration and correct positioning in a given patient. A No. 6 tube is appropriate for most adults. If frequent suction bronchoscopy is required, many intensivists will request a larger tube, such as a No. 8; the No. 8 tube allows passage of a standard suction bronchoscope and permits ventilation to continue.

The placement of the tracheostomy tube [see Figure 5] should be confirmed with auscultation or, in cases where capnography is unavailable, with visualization of chest movement; alternatively, in cases involving end-tidal CO₂ monitoring, it may be confirmed visually with the capnograph.

The fresh tracheostomy tube should be secured with sutures from the faceplate to the skin and with tracheostomy ties. (If the patient has had a microvascular flap and the tracheostomy tube was placed concurrently, the ties are not used, so as to ensure that the veins providing outflow are not compressed.) If the patient has a long-term need for a tracheostomy, the use of a soft foam collar band with hook-and-loop fasteners is recommended, once the first

tracheostomy tube change has been performed and the tract is considered safe. If a patient has excess skin folds in the neck, any collar is likely to irritate the skin, and the application of a semi-permeable membrane dressing, such as Tegaderm (3M, St. Paul, Minnesota), may be advisable to help prevent ulceration. Any local infection that develops should be appropriately treated. Some patients, nurses, and surgeons prefer to use a split gauze swatch placed around the tracheostomy and the tube to help manage the drainage from the site.

Care of the patient with a tracheostomy tube Humidified air or oxygen should be delivered via a tracheostomy tube collar; the humidification is necessary to prevent tracheal crusts. The inner cannula should be cleaned frequently to remove built-up mucus. The skin and area around the stoma may be cleaned with half-strength hydrogen peroxide and water. A spare inner cannula and a spare tracheostomy tube are often kept at the bedside. Flexible tracheal suction catheters and suction devices must be readily available. Because patients' ability to verbalize will be altered (temporarily, at least), they should be given easy access to the call button and be taught its use.

First tracheostomy tube change On my service, the first tracheostomy tube change in a patient who requires ventilatory support is performed approximately 1 week after operation. In a patient with a neoplasm who does not need a cuffed tube, the initial tube is exchanged for a cuffless tube at an earlier point if possible (i.e., if the anatomy is favorable).

I do not use fenestrated tracheostomy tubes. These tubes are more often associated with suprastomal granulation (resulting from irritation of the mucosa by the fenestrae) and with the development of crusting on the fenestrae. Moreover, fenestrated inner cannulae are often difficult to find.

PERCUTANEOUS TRACHEOSTOMY

In certain centers, percutaneous tracheostomy has largely supplanted open tracheostomy. The percutaneous approach involves using Seldinger-like techniques to enter the trachea transcutaneously with a catheter, then dilating the opening and placing a tracheostomy tube. A fiberoptic bronchoscope may be used to confirm entry into the airway and facilitate the procedure.

The suitability of this procedure for a given patient is determined primarily by the patient's stability or lack thereof, the anatomy of the neck, and the skills of the team. For example, a patient with a thick neck and unclear anatomic landmarks is not a suitable candidate, whereas a patient with a thin neck and good range of motion is an ideal candidate.

AWAKE TRACHEOSTOMY

Anesthetic Considerations

For an awake tracheostomy, the patient should be placed in a semi-Fowler position to give the anesthesiologist ready access to the airway, to optimize his or her own comfort, and, most important, to enhance primary and accessory respiratory muscle function. Every effort should be made to keep the patient comfortable and to minimize (or, if possible, eliminate) environmental stimuli, especially the work noise generated by the surgical team. Generally, sedatives are contraindicated, because they can diminish or even abolish respiratory drive and protective mechanisms.

Clear communication with the anesthesiologist must be ensured before the patient even enters the room; life-threatening emergencies may arise that necessitate close collaboration. The same is true

for the scrub and circulating nurses and technicians. Their instrument tray should contain the most essential equipment, along with an appropriate selection of tracheostomy tubes prepared for use.

Tracheal Stents and T Tubes

As tracheobronchial airway stenting becomes more common, tracheostomy tubes may be increasingly required for definitive or end-of-life care. The position of the airway stent must be known with some precision because the tracheostomy tube may have to interface exactly with the end of the stent. Alternatively, the stent may have to be incised to afford entry into the airway. If the stent is metal, incision may not be possible.

Complications

EARLY

Soft Tissue Placement (False Passage) of Tracheostomy Tube Adjacent to Trachea

If the tracheostomy tube is inadvertently misplaced in soft tissue during the procedure, the endotracheal tube should be advanced from its intermediate position in the larynx back into the airway. The patient should undergo ventilation, and when oxygenation and ventilation are adequate, the endotracheal tube should be withdrawn and the tracheostomy tube replaced. If the tracheostomy tube cannot be placed directly, a guide tube may be employed (via the Seldinger technique) to help guide the tube into the airway; alternatively, a flexible bronchoscope may be used for this purpose. If the tracheostomy tube cannot be properly or effectively placed, transoral intubation is the safest way of resecuring the airway.

Decannulation

If the tracheostomy tube becomes decannulated on an acute basis, the protocol for reestablishing the airway is to intubate the patient via standard transoral approaches. Although it is theoretically possible to replace the tracheostomy tube directly into the tracheostomy site, it is safer to take an endolaryngeal approach, which allows the tube to be replaced into the tracheostomy site with good lighting and retraction and with the patient stable.

Pneumomediastinum

Pneumomediastinum is a potential complication if the tube is placed in a false passage or if the patient requires ventilation with the trachea incised.

Pneumothorax

Pneumothorax is an uncommon complication of tracheostomy—so uncommon that most protocols do not require chest x-rays after routine tracheostomies.

Bleeding

Bleeding may occur after tracheostomy, usually related either to the vasculature in the field (in particular, the thyroid vessels) or to the gland itself. If the bleeding is minor, it can generally be treated by applying absorptive gauze or a collagen-type dressing to the site; if it is coming from vessels of significant size, exploration and ligation or cauterization may be required. In rare cases, early bleeding from a major vessel may become apparent through the tracheostomy site. When this occurs, it is managed with the techniques used to treat tracheoinnominate or tracheoesophageal fistula [see Late, Tracheoinnominate or Tracheoesophageal Fistula, below].

Infection

Impaired handling of tracheal secretions may facilitate the development of local site infection. Such infection can generally be treated with antibiotics and local wound care.

Crusting or Mucous Plug

Mucus and blood, individually or in combination, can create difficult management problems. Accordingly, a fresh tracheostomy should be carefully supported with humidified oxygen or air. Tracheal suction should be available, and the nurses caring for the patient should be comfortable with using it. The patient and the family should also learn how to employ tracheal suction. With some mucous plugs, suction bronchoscopes may be required for removal.

Negative Pressure Pulmonary Edema

This complication may develop when an awake tracheostomy is done in the setting of significant airway obstruction. The patient's negative inspiratory pressures and effort are initially high, then suddenly drop to normal after the trachea is incised. A frothy pulmonary edema will be apparent. The standard treatment is positive pressure ventilatory support, often including positive end-expiratory pressure (PEEP).

LATE

Granulation

Granulation tissue may develop at the suprastomal region as a consequence of irritation by the tracheostomy tube. Symptoms related to speech or airway function may be seen when the tracheostomy tube is capped or fitted with Passy-Muir valves, which allow inspiration via the tube and exhalation via the native airway. In some cases, granulation at the tip of the tracheostomy tube may lead to bleeding or airway symptoms (e.g., dyspnea). When these accumulations of granulation tissue give rise to symptoms, removal should be considered.

Tracheomalacia

Tracheomalacia, defined as the loss of cartilage structure in the trachea, can cause a dynamic collapse with partial or complete blockade of the trachea during inspiration. Fortunately, it is a rare complication; typically, it is manifested as inspiratory noise and, potentially, as dyspnea after decannulation. It may be related less to the placement or presence of the tracheostomy tube than to the loss of tracheal cartilage at the site of the endotracheal tube balloon as a result of previous intubation, infection, or even pressure (e.g., the pressure that can be generated by large thyroid goiters).

Stenosis

Tracheal stenosis may be seen at the site of the tracheostomy or at any site along the trachea where trauma caused by cuffs or tubes has occurred. Laryngeal stenosis, though rare, may develop after placement of the tracheostomy tube or after decannulation. Like tracheal stenosis, laryngeal stenosis is most often related to endolaryngeal or endotracheal intubation, infection, or neoplastic disease. In rare instances, stenosis can be a manifestation of conditions such as gastroesophageal reflux disease or sarcoidosis.

Tracheoinnominate or Tracheoesophageal Fistula

Moderate to heavy bleeding, though uncommon, sometimes develops. It may herald an erosion of the anterior tracheal wall into the innominate artery and may be fatal if this vessel ruptures. Such

bleeding is a result either of injury caused by the tip of the tracheostomy tube or of other types of injuries associated with endotracheal intubation. Diagnostic assessment should include partial or total withdrawal of the tube to allow flexible assessment of the anterior tracheal wall for erosions, clot, or cartilage breakdown and defects and to permit visualization of the mediastinal tissues.

Supportive management includes preparation for transfusion if the patient is anemic and formulation of a plan to manage the airway if hemorrhage is occurring. In the event of hemorrhage, the tracheostomy tube usually will have to be removed, and an endotracheal tube will have to be placed through the tracheostomy and advanced deeper so that the inflated cuff is distal to the bleeding site. To tamponade the bleeding, one should try to place the tip of a finger into the tracheostomy site and compress the trachea against the manubrium; this must be done with the tube in the airway as well. Alternatively, one may pass a rigid bronchoscope into the tracheostomy, provide ventilation through the scope, and then press the scope anteriorly against the manubrium to achieve hemostasis. For salvage in cases where the bleeding is immediately life-threatening, emergency operative intervention with the appropriate cardiovascular or vascular teams is required.

Tracheocutaneous Fistula

Tracheocutaneous fistula is not a common side effect of tracheostomy. If a cutaneous-lined tract persists, repair is indicated (see below). The key differential point to consider when a fistula persists is whether there is a stenosis in the endolaryngeal or endotracheal airway that is causing the condition.

Planned Decannulation Protocols

If there is any doubt about the patient's respiratory drive, level of consciousness, or airway protective mechanisms, the airway may be sequentially downsized. If there is no real doubt, flexible laryngoscopy and tracheoscopy may be done to confirm the presence of an intact airway. If the airway is adequate, the tracheostomy tube may be withdrawn and the wound managed with local cleaning and dry compressive dressings. The wound should heal by secondary intention. If a fistula forms, the cutaneous tract should be freshened or excised, after which the wound typically heals by secondary intention. Some surgeons prefer to close the wound in three layers, including the trachea. If this approach is followed, there is a potential for cervical emphysema or for dissection into the chest and pneumomediastinum.

Assessment and Management of Breast Complaints

Given that approximately one of every two women will consult a health care provider for a breast-related complaint during her lifetime,¹ all clinicians should have a fundamental understanding of the evaluation and management of breast disorders. Although most breast complaints do not result in a diagnosis of cancer, the heightened public awareness of breast cancer—currently, the most common malignancy affecting women in the United States²—can induce significant anxiety and a sense of urgency in women who present with symptoms suggestive of a breast disorder. Accordingly, any woman presenting with a breast complaint should receive a comprehensive evaluation.

Unfortunately, it is becoming more and more difficult for practitioners to stay current with the increasingly complex management of breast disease. Breast problems still are often written about in a manner that is more disease-focused than patient management-focused—an approach that we believe is of limited clinical utility. In this chapter, we outline the evaluation and management of the most common clinical presentations of breast disease, and we discuss specific breast disease problems in a manner clinically relevant to the practicing surgeon.

Most breast problems encountered by practicing surgeons fall into six general categories, which are associated with varying degrees of risk for breast cancer [see Table 1]. With some presentations, such as a dominant mass in a postmenopausal woman, the index of suspicion for malignancy is high and the workup should be prompt and relatively straightforward. With other breast presentations, such as a tender breast thickening in a premenopausal woman, benign disease is much more likely. It is important to recognize, however, that any of these presentations can be associated with a malignancy, and thus, all of them warrant a complete evaluation. In fact, it is the evaluation of the usually benign symptoms that places the greatest demands on the physician's clinical judgment. When such symptoms are the main presenting complaint of a breast cancer, their seemingly benign nature may be misleadingly reassuring and delay the diagnosis of malignancy. Missed or delayed diagnosis of breast cancer is currently a major cause of malpractice claims and plaintiff awards.³

Risk Factors for Breast Cancer

The fundamental task facing a physician seeing a patient with a breast complaint is to determine whether the abnormality is

benign or malignant. To this end, knowledge of the main risk factors for breast cancer is essential: prompt identification of the patients at highest risk for malignancy allows the physician to take an appropriately vigorous approach from the beginning of the diagnostic workup.

Various factors that place women at increased risk for breast carcinoma have been identified [see Table 2].⁴ These risk factors include increasing age; mutations in breast cancer risk genes (including *BRCA1* and *BRCA2*, *PTEN*, and *p53*) and other factors related to a family history of breast cancer⁵; hormonal and reproductive factors, including early menarche, late menopause, nulliparity, the absence of lactation,⁶ and the use of exogenous hormones^{4,7-12}; environmental factors, including diet and the lifestyle characteristic of developed Western nations¹³⁻¹⁵; certain pathologic findings within breast tissue, including previous breast cancer and various premalignant lesions¹⁶⁻¹⁸; and certain non-breast malignancies, including ovarian and endometrial carcinomas. There are also a number of molecular markers that can be correlated with prognosis, including estrogen receptor (ER) status and *HER-2/neu* gene amplification.¹⁹

Recognition of risk factors facilitates appropriate screening and clinical management of individual patients. It must be recognized, however, that in many women in whom breast cancer develops, known risk factors for breast carcinoma are entirely absent. The absence of these risk factors should not prevent full evaluation or biopsy of a suspicious breast lesion.

BREAST CANCER SCREENING

In the absence of a specific breast complaint, patients at risk for breast cancer may be identified through screening. The three main methods of breast cancer screening are breast self-examination (BSE), clinical breast examination (CBE), and screening

Table 1 Common Presenting Symptoms of Breast Disease

Symptom	Likelihood of Malignancy	Risk of Missed Malignancy
Palpable mass	↑ Highest ↓ Lowest	↓ Lowest ↑ Highest
Abnormal mammogram with normal breast examination		
Vague thickening or nodularity		
Nipple discharge		
Breast pain		
Breast infection		

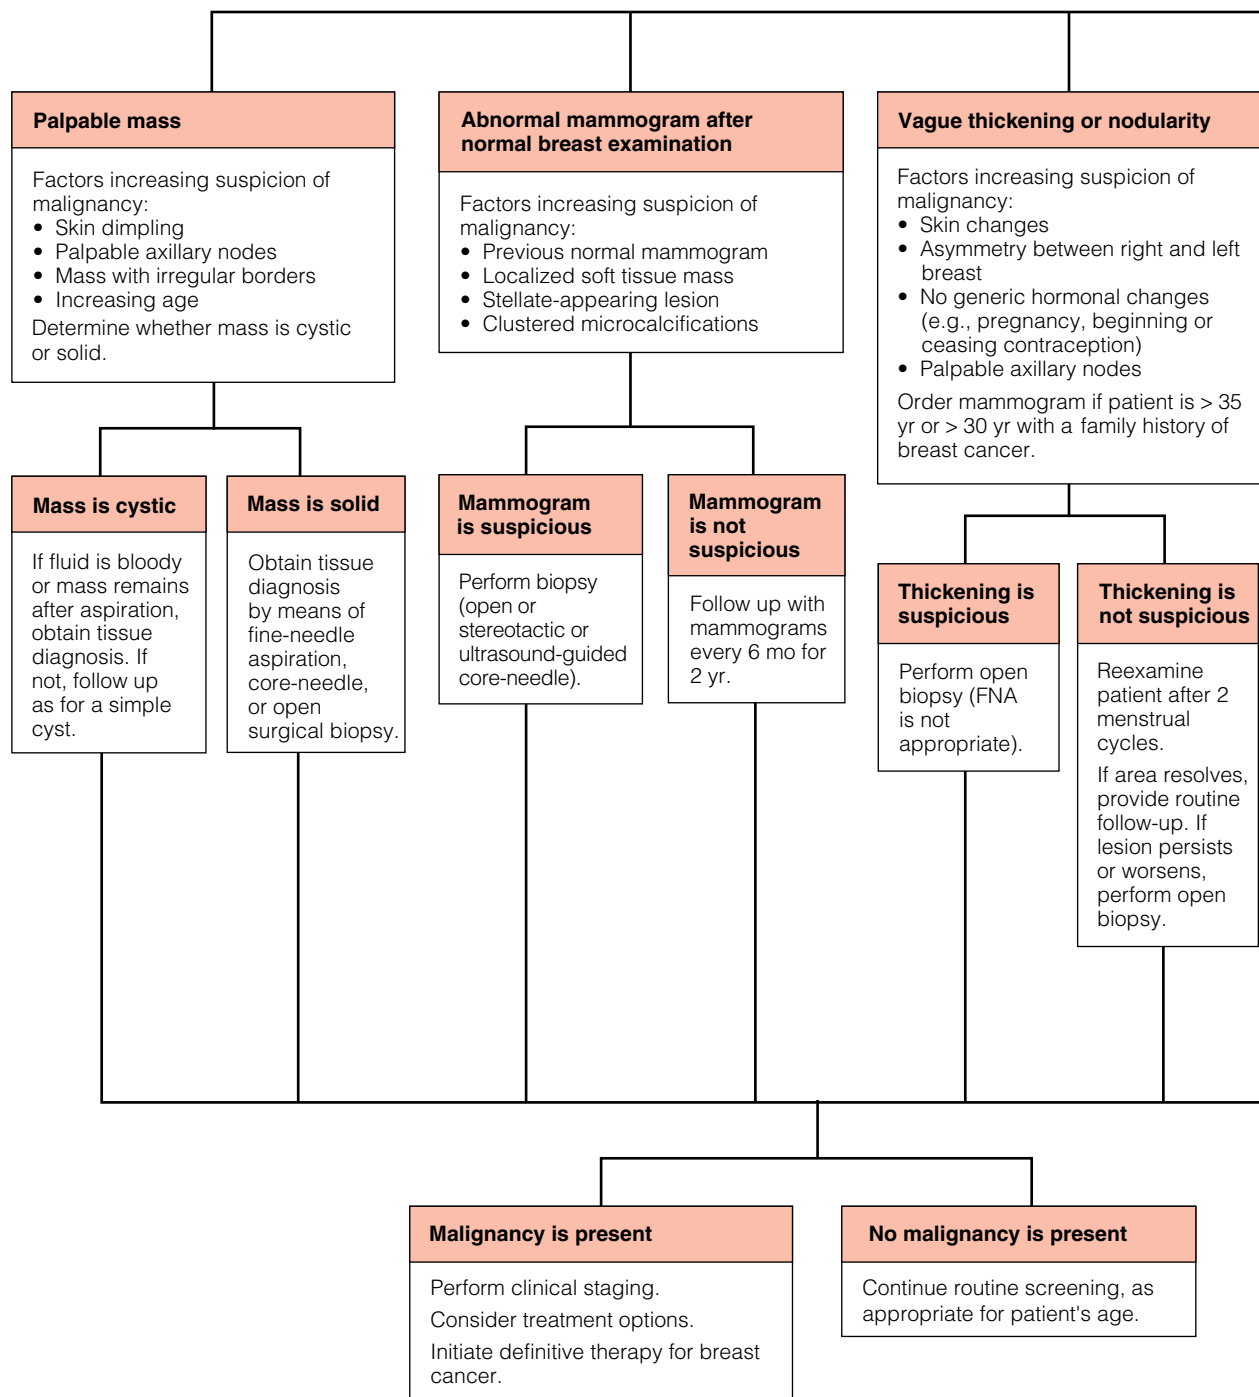

Assessment and Management of Breast Complaints

Patient presents with breast complaint

The most common presenting problems are

- Palpable mass
- Vague thickening or nodularity
- Normal physical examination with abnormal mammogram
- Nipple discharge
- Breast pain
- Breast infection or inflammation

Evaluate likelihood that lesion reflects cancer [see Table 1], and be aware of patient risk factors for cancer [see Table 2].

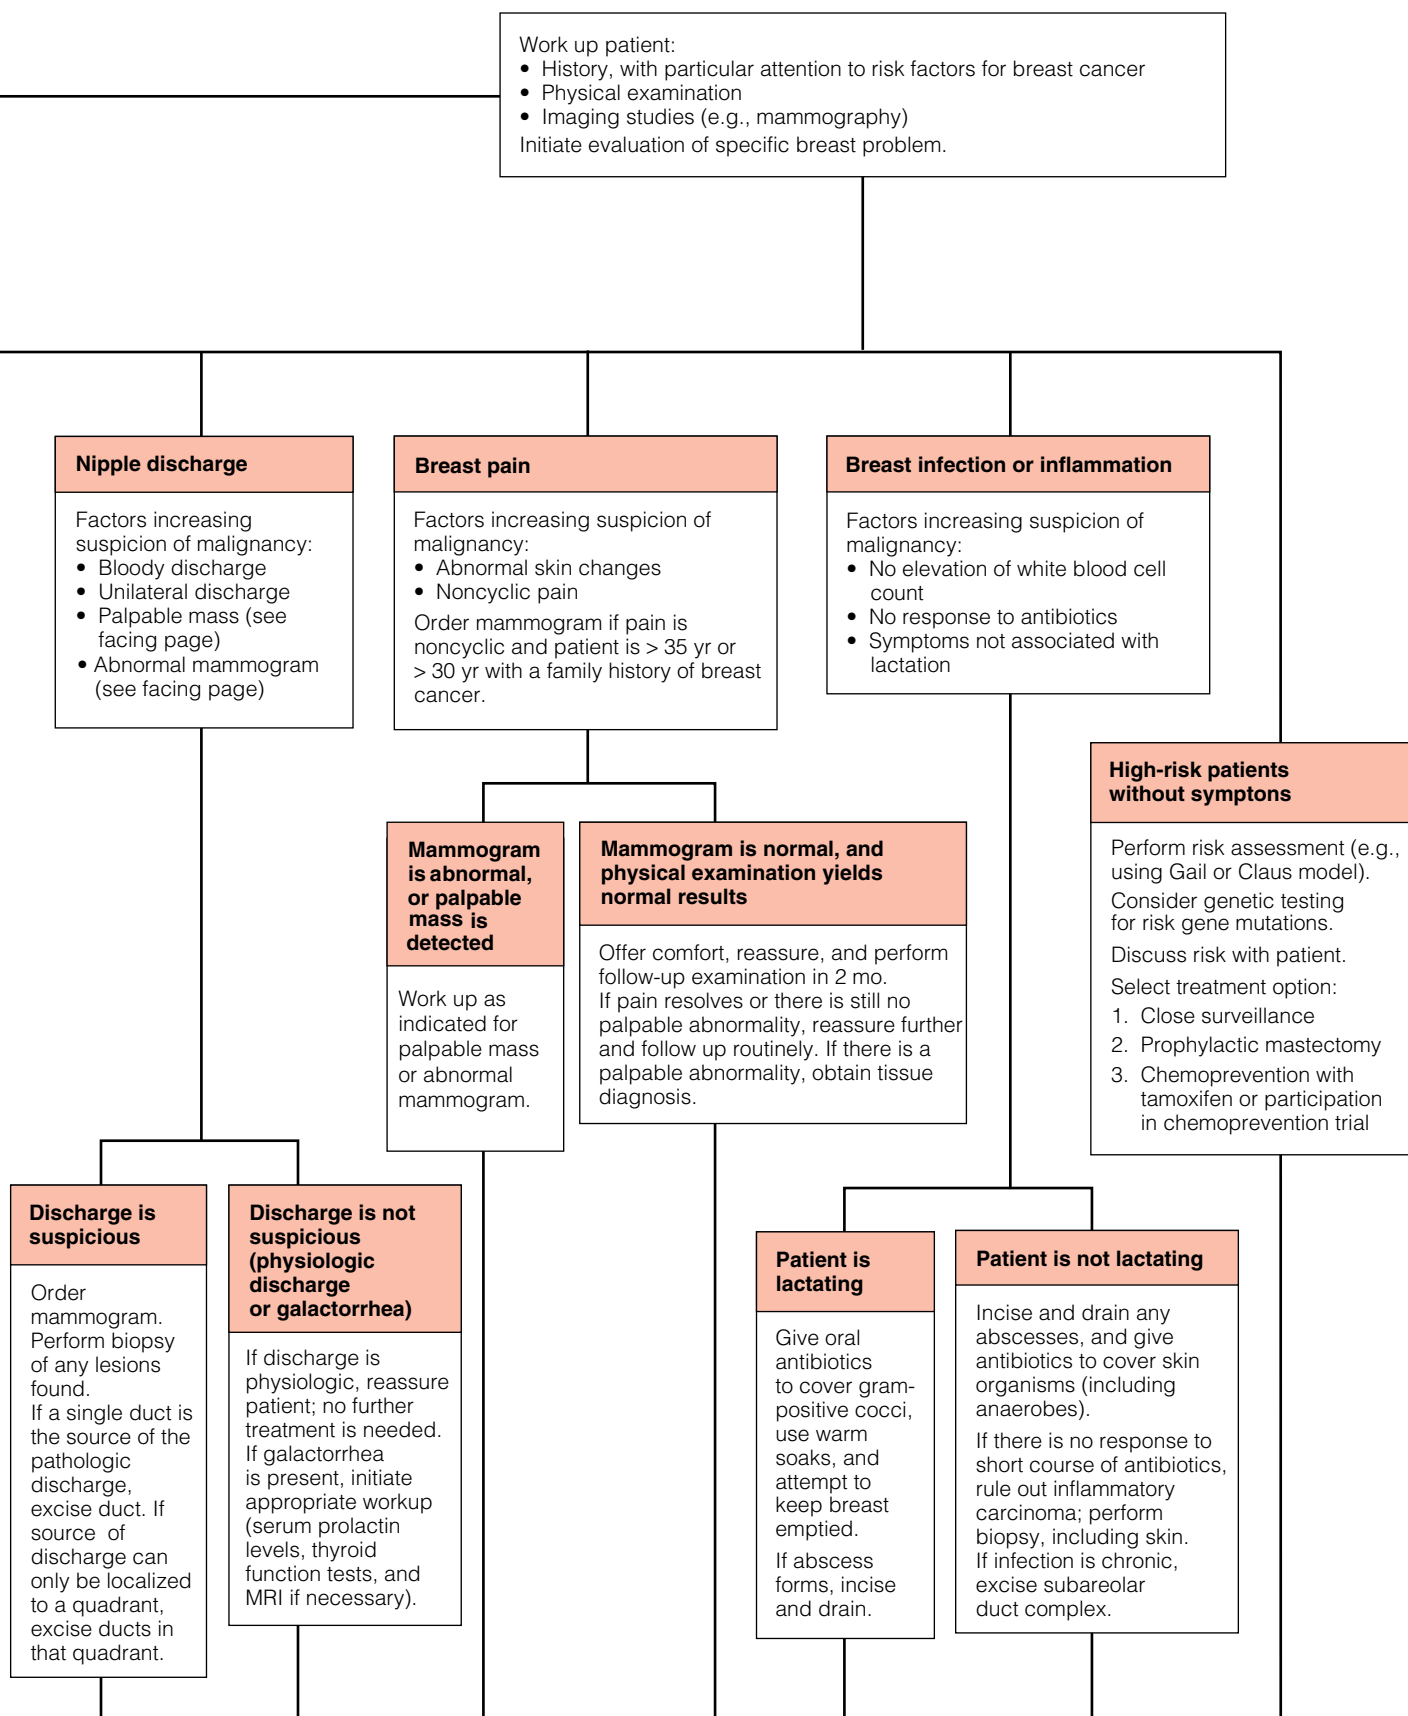

Table 2 Risk Factors for Breast Cancer

Increasing age
White race
Age at menarche \leq 11 years
Age at menopause \geq 55 years
Nulliparity
Age at first pregnancy \geq 30 years
Absence of history of lactation
? Prolonged use of oral contraceptives before first pregnancy
Use of postmenopausal estrogen replacement, especially if prolonged
Use of other hormones, fertility regimens, or diethylstilbestrol
Mutations in breast cancer risk genes, including <i>BRCA1</i> and <i>BRCA2</i> , <i>PTEN</i> , and <i>p53</i>
Family history of breast cancer: multiple affected relatives, early onset, bilaterality
Family history of ovarian cancer: multiple affected relatives, early onset
Pathologic findings that indicate increased risk (e.g., atypical hyperplasia, lobular carcinoma in situ, proliferative fibrocystic disease)
Previous breast cancer
Previous breast problems
Previous breast operations
Previous exposure to radiation

mammography.²⁰ American Cancer Society screening guidelines for women aged 40 years and older specify that mammography and CBE should be included as part of an annual health examination.²¹ In addition, health care providers should tell women about the benefits and limitations of BSE, stressing the importance of promptly reporting any new breast symptoms.

Breast Self-Examination

In BSE, the patient herself inspects and palpates the complete breast and the axilla. Given that women themselves detect many breast tumors, one might reasonably assume that BSE instruction would improve breast cancer detection. There is, however, no conclusive evidence that BSE is of significant value in this regard. Many self-detected tumors are in fact found incidentally, not during BSE. In addition, the best technique for BSE and the optimal frequency have not been established. The American Cancer Society recommends monthly self-examination as part of a breast cancer screening process that includes mammography and CBE.²¹

Clinical Breast Examination

In CBE, a qualified health care professional carries out a complete examination of the breast and axilla. As with BSE, there is little conclusive evidence indicating that annual or semiannual CBE increases breast cancer detection rates.²² Nevertheless, we believe that it is prudent for the clinician to include CBE as part of the physical examination performed on every female patient.

Screening Mammography

There has been considerable debate regarding the value of screening mammography. The studies done to date suffer from flaws in the conduct of the trials and in the methods used to analyze the data. This state of affairs has led not only to uncertainty among practitioners but also to confusion among patients. Nevertheless, screening mammography is recommended by several professional societies, including both the American Cancer Society and the National Cancer Institute (NCI). The NCI continues to

evaluate data from ongoing studies and to promote and fund research aimed at developing more effective screening tools and strategies. In a statement from January 31, 2002, the NCI made the following recommendations²³:

1. Women in their 40s should be screened every 1 to 2 years with mammography.
2. Women 50 years of age and older should be screened every 1 to 2 years.
3. Women who are at higher than average risk of breast cancer should seek expert medical advice about whether they should begin screening before 40 years of age and about the frequency of screening.

A woman should continue to undergo screening mammography as long as she is in reasonably good health and would be a candidate for treatment if cancer were detected. Thus, although no specific age has been established as a definitive cutoff point beyond which screening yields no benefit,²⁴ patients with comorbidities whose life expectancy is shorter than 5 years would not be expected to benefit from routine mammography.

The increased use of screening mammography has led to a dramatic rise in the number of nonpalpable breast lesions that call for tissue acquisition [see Investigative Studies, Biopsy, below]. Because primary care practitioners are the clinicians who order most screening mammograms, it is vital that they be capable of evaluating women who have abnormal results [see Management of Specific Breast Problems, Abnormal Mammogram, below].

Clinical Evaluation

HISTORY

The first step in the evaluation of any breast complaint is a complete history. Questions should be asked regarding how long the breast complaint has been present, whether any change has been observed, and whether there are any associated symptoms. In particular, any changes in the size or tenderness of any palpable abnormalities since their initial discovery should be recorded, with special attention paid to any changes that occurred during the menstrual cycle. Previous breast problems or breast operations should also be documented, and pathology reports from any such operations should be obtained. All imaging studies or medical evaluations that have already been performed should be reviewed.

Next, the clinician should identify any risk factors for breast cancer that may be present. A reproductive history should be obtained that notes age at menarche, age at menopause, parity, and age at first full-term pregnancy. A personal or family history of breast, ovarian, or endometrial cancer and the use of oral contraceptives, fertility hormones, or postmenopausal estrogen are significant risk factors.

Approximately 10% of all breast cancers are hereditary, accounting for roughly 20,000 cases of breast cancer yearly in the United States.²⁵ Hereditary breast cancer is characterized by early age at onset, bilaterality, vertical transmission through both the maternal and the paternal line, and familial association with tumors of other organs, particularly the ovary and the prostate gland. Therefore, an accurate and complete family history is essential for quantifying a woman's genetic predisposition to breast cancer. Questions about breast cancer in family members should go back several generations and should extend to third-degree rela-

tives, with age at diagnosis recorded if available. Similarly, any family history of ovarian or other cancers (particularly those that developed when the relative was young) should be recorded, along with age at diagnosis. Any personal history of cancer should be recorded, with particular attention paid to breast, ovarian, and endometrial cancers. Previous exposure to radiation, especially in the area of the chest wall, should be noted. Admittedly, it is not always possible to obtain complete and precise family history data, whether because of time constraints or because of family issues such as premature deaths, small family size, and distant or broken families.

It is difficult for practicing surgeons to stay current with the explosive growth of knowledge related to the genetics of breast cancer. Researchers have identified two genes—*BRCA1* and *BRCA2*—that are associated with an inherited predisposition to breast and ovarian cancers. Specific founder mutations in *BRCA1* and *BRCA2* are found within certain ethnic groups (e.g., Ashkenazi Jews).²⁶ Tests are commercially available that detect mutations in these genes. Whether to pursue genetic testing and how to interpret the results are complex issues. Accordingly, clinicians should consider consulting a professional genetics counselor if the option is available.

Finally, as with any surgical patient, an overview of the general medical history should be obtained that includes current medications, allergies, tobacco and alcohol use, previous surgical procedures, medical problems, and a brief social history.

PHYSICAL EXAMINATION

A thorough physical examination is an essential second step in the evaluation of any patient with a breast complaint. First, the breast should be inspected for any asymmetry, skin or nipple retraction, erythema, or *peau d'orange* (orange-peel appearance). Skin dimpling can be accentuated by having the patient sit with her hands pushing against her hips to contract the pectoral muscles. Each breast should then be carefully palpated from the clavicle to below the inframammary fold and from the sternum to the posterior axillary line, with careful attention to the subareolar area. This is done with the patient both supine and sitting. If an abnormal area is identified, its location, size, consistency, contour, tenderness, and mobility should be described; a diagram of the lesion is extremely useful for future reference. Although certain physical findings (e.g., skin changes, irregular borders, firmness, irregular margins, and immobility) are associated with a greater likelihood of cancer, the absence of these findings does not exclude the diagnosis of cancer.

Next, the nipples and the areolae are inspected for skin breakdown and squeezed gently to check for discharge. The number and position of any ducts from which discharge is obtained should be recorded, and the color of the discharge (milky, green, yellow, clear, brown, or bloody) and its consistency (watery, sticky, or thick) should be noted. Discharge on one side calls for a careful search for discharge on the other side because unilateral, single-duct discharge is much more suspicious than bilateral, multiple-duct discharge. Any discharge obtained should be tested for occult blood. Cytologic study of nipple discharge generally is not indicated: it adds expense and rarely contributes significantly to the decision whether biopsy is needed.

Finally, the axillary, supraclavicular, and infraclavicular areas are palpated bilaterally for suspicious adenopathy. If enlarged nodes are discovered, their size, mobility, and number should be recorded. Any matting of nodes or fixation of nodes to the chest walls should also be recorded. Tenderness of enlarged nodes may suggest a reactive process and should therefore be recorded as well.

Investigative Studies

IMAGING

Mammography

Diagnostic mammography is the first imaging study employed to evaluate breast abnormalities. Diagnostic, as opposed to screening, mammography is performed when a breast abnormality is already present; it is a more comprehensive examination and consists of multiple specialized images (e.g., magnification views or spot compression views). Diagnostic mammography includes a mammogram of the contralateral breast to rule out synchronous, nonpalpable lesions whenever a woman older than 35 years presents with a palpable breast mass or other specific symptoms. Approximately 4% to 5% of breast cancers occur in women younger than 40 years, and about 25% occur in women younger than 50 years.

Mammography fails to detect 10% to 15% of all palpable malignant lesions, and its sensitivity is particularly decreased in women with lobular carcinoma or radiographically dense breast tissue. Therefore, a negative mammogram should not influence the decision to perform a biopsy of a clinically palpable lesion. The purpose of mammography is to look for synchronous lesions or nonpalpable calcifications surrounding the palpable abnormality, not to determine whether to perform a biopsy of the palpable lesion.

Ultrasonography

The main value of ultrasonography is in distinguishing cystic from solid lesions. If the lesion is palpable, this distinction is best made by direct needle aspiration, which is both diagnostic and therapeutic; if the lesion is not palpable, ultrasonography can determine whether the lesion is cystic and thus potentially eliminate the need for additional workup or treatment. Ultrasonography has not proved useful for screening: it fails to detect calcifications, misses a large number of malignancies, and identifies a great deal of normal breast texture as potential nodules. It is useful, however, for directing fine-needle or core-needle biopsy of the lesions that it does visualize: it permits real-time manipulation of the needle and direct confirmation of the position of the needle within the lesion. In the operating room, ultrasonography can assist in localizing and excising nonpalpable breast lesions and achieving negative lumpectomy margins.²⁷ It has also been used to guide the performance of investigational tumor-ablating techniques [see 3:5 *Breast Procedures*].

Magnetic Resonance Imaging

Magnetic resonance imaging after injection of gadolinium contrast enhances many malignant lesions in relation to normal breast parenchyma. Although some benign lesions (e.g., fibroadenomas) are also enhanced by gadolinium, the contrast agent appears to enhance malignant lesions more rapidly and often to a greater extent.

The sensitivity and specificity of MRI in distinguishing benign from malignant lesions are still being assessed. The main approved use of MRI in breast disease is for identification of leaks in silicone breast implants, because MRI can detect the ruptured silicone membrane within the silicone gel. MRI is also useful in identifying occult primary tumors in women who have palpable axillary nodes but no palpable or mammographically identified primary breast lesion. MRI appears to be effective for assessing the extent of vaguely defined tumors, identifying unsuspected multifocal disease, and helping identify patients who are not eligible for breast-

conserving surgery. In addition, it appears that MRI can distinguish between a locally recurrent tumor and surgical scarring or radiation-induced change after lumpectomy and radiation, though the technology may not provide reliable readings until 18 months or more after surgery or the completion of radiation therapy. The utility of MRI for screening of young high-risk women with mammographically dense breast tissue is being explored.²⁸

Nuclear medicine studies, such as sestamibi scintimammography and positron emission tomography (PET), remain primarily investigational tools. At present, there is no proven role for thermography or xerography in the evaluation of breast problems.

BIOPSY

In the past, the preferred biopsy method for nonpalpable mammographically detected lesions was needle-localized surgical biopsy. This procedure is initially performed in the breast imaging suite, where a wire is placed in the breast adjacent to the imaged abnormality. The patient is then transferred to the OR, where the surgeon uses the wire as a guide to removal of the abnormality. A mammogram of the excised lesion is performed to confirm its removal. Wire-guided diagnostic surgical procedures have now been largely supplanted by stereotactic and ultrasound-guided percutaneous core biopsy techniques, which are less invasive, less expensive, and more expedient. With any of these approaches, however, it is important to verify that the interpretation of the imaging abnormality is in concordance with the pathologic analysis of the specimen. Follow-up should be based on the pathologic findings and on the appearance of the abnormality on breast imaging.

Management of Specific Breast Problems

PALPABLE MASS

The workup and management of a discrete breast mass are governed by the age of the patient, the physical characteristics of the palpable lesion, and the patient's medical history. The likelihood of malignancy is greater when the patient is 40 years of age or older, when the mass has irregular borders, or when skin dimpling or enlarged axillary nodes are present. A prebiopsy mammogram is indicated for women older than 35 years and for those younger than 35 years who have a strong family history of premenopausal breast cancer.

with indistinct walls or intracystic solid components are more likely to be associated with carcinoma, and therefore, either image-guided or excisional biopsy is warranted.

Solid Masses

If a discrete mass in the breast is believed to be solid, either on the basis of ultrasonographic findings or because attempts at aspiration yield no fluid, a tissue diagnosis is necessary to rule out malignancy. Physical examination alone is insufficient: it correctly identifies masses as malignant in only 60% to 85% of cases.²⁹ Furthermore, experienced examiners often disagree on whether biopsy is needed for a particular lesion: in one study, four surgeons unanimously agreed on the necessity of biopsy for only 11 (73%) of 15 palpable masses that were later shown by biopsy to be malignant. Tissue diagnosis may be accomplished by means of FNA biopsy, core-needle biopsy, or open surgical biopsy [see 3:5 *Breast Procedures*].

Phyllodes tumor The phyllodes tumor is a rare fibroepithelial breast lesion that clinically mimics a fibroadenoma. Most phyllodes tumors present as palpable, solitary, well-defined, mobile, and painless breast masses. With the widespread availability of screening mammography, an increasing number of these tumors are being discovered mammographically. Large phyllodes tumors may be associated with visible venous dilation in the skin overlying the tumor. Palpable axillary lymph nodes are encountered in 20% of patients with phyllodes tumors, but histologic evidence of malignancy is encountered in fewer than 5% of axillary lymph node dissections for clinically positive nodes. The non-tumor-containing palpable nodes are enlarged as a result of necrosis of the primary tumor.

Tumors are classified histologically as low, intermediate, or high grade on the basis of five criteria: stromal cellularity, stromal atypia, the microscopic appearance of the tumor margin (infiltrating, effacing, or bulging), mitoses per 10 high-power fields, and the macroscopic size of the tumor. Structural³¹ and cytogenetic³² studies of constituent cells have demonstrated similarities between fibroadenomas and phyllodes tumors, and there is evidence that certain fibroadenomas develop into phyllodes tumors. FNA is usually nondiagnostic, primarily because of the difficulty of obtaining adequate numbers of stromal cells for cytogenetic analysis. Although most phyllodes tumors have minimal metastatic potential, they have a proclivity for local recurrence and should be excised with at least a 1 cm margin. Local recurrence has been correlated with excision margins but not with tumor grade or size.³³ The most common site of metastasis from malignant phyllodes tumors is the lungs (via the hematogenous route).

The diagnosis of phyllodes tumor should be considered in all patients with a history of a firm, rounded, well-circumscribed, solid (i.e., noncystic) lesion in the breast. Simple excisional biopsy should be performed if aspiration fails to return cyst fluid or if ultrasonography demonstrates a solid lesion. Because phyllodes tumors mimic fibroadenomas, they are often enucleated or excised with a close margin. If an adequate margin is not obtained after examination of the permanent section, the patient should undergo reexcision to obtain wider margins and avoid a 15% to 20% recurrence rate. If a simple excision cannot be accomplished without gross cosmetic deformity or if the tumor burden is too large, a simple mastectomy should be performed. Radiation therapy may have a role in the management of patients with chest wall invasion. Chemotherapy, which is reserved for patients with metastatic disease, is based on guidelines for the treatment of sarcomas, rather than breast adenocarcinomas.

ABNORMAL SCREENING MAMMOGRAM

The increased use of screening mammography has led to a dramatic rise in the number of nonpalpable breast lesions that call for tissue acquisition. Generally, 5% to 10% of all screening mammograms are abnormal, and 10% of women with abnormal mammograms have breast cancer.³⁴ Currently, an abnormal screening mammogram is the most common initial presentation for women with breast cancer. In the Breast Imaging Reporting and Data System (BIRADS), developed by the American College of Radiology, six different assessments (numbered 0 through 5) are used in the interpretation of a screening mammogram [see Table 3].³⁵ Women with either a negative or a benign assessment (category 1 or 2) should undergo routine screening mammography in 1 to 2 years. Women with a possibly benign assessment (category 3) should undergo a repeat study in 6 months, at which time the mammographic abnormality is assessed for stability.

In general, whenever the radiologist states that a lesion identified on mammography is suspicious, a tissue diagnosis should be obtained by means of either open needle-localized biopsy or mammographically guided stereotactic core-needle biopsy [see 3:5 Breast Procedures]. Findings especially suggestive of malignancy include the presence of a localized soft tissue mass within the breast that either is new or has changed in size or appearance, architectural distortion with irregular borders producing a stellate-appearing lesion, and clustered microcalcifications, with or without a new or changed mass or architectural distortion.

VAGUE THICKENING OR NODULARITY

Normal breast texture is often heterogeneous, particularly in premenopausal women. Consequently, vague thickenings or tender or non-tender areas of nodularity are frequently detected by the patient or the clinician. It is important to distinguish this vague breast thickening or nodularity from a discrete or dominant breast mass. A dominant breast mass is defined as a discrete lump that is distinctly different from the surrounding breast tissue. Overall, approximately 10% of dominant breast masses are malignant. The incidence of cancer in a dominant breast mass increases with age: in women 55 years of age or older, more than 30% of masses are malignant.³⁶

In clinical practice, the first step in evaluating a nodular area is to compare it with the corresponding area of the opposite breast. Symmetrical tender nodularity—for example, in the upper outer quadrant of both breasts—is rarely pathologic. These areas often represent fibrocystic changes that may resolve with time and thus should be followed clinically. Asymmetrical areas of vague thickening in premenopausal women should be reexamined after one or two menstrual cycles. If the asymmetrical thickening persists, the possibility of malignancy is increased, and biopsy should be performed. Women 35 years of age or older who have not had a mammogram in the past 6 months should undergo mammography to rule out synchronous lesions. The accuracy of a negative FNA biopsy in the presence of a vague thickening (as opposed to a discrete mass) is questionable; therefore, open biopsy is generally required for adequate sampling.

Table 3 American College of Radiology Breast Imaging Reporting and Data System (BIRADS)

Category	Assessment	Description/Recommendation
0	Additional imaging evaluation required	Additional imaging recommended
1	Negative finding	Nothing to comment on; routine screening recommended
2	Benign finding	Negative mammogram, but interpreter may wish to describe a finding; routine screening recommended
3	Probably benign finding	Very high probability of benignity; short-interval follow-up suggested to establish stability
4	Suspicious abnormality	Probability of malignancy; biopsy should be considered
5	Abnormality highly suggestive of malignancy	High probability of cancer; appropriate action should be taken

NIPPLE DISCHARGE

Nipple discharge is a common breast complaint, occurring in approximately 20% to 25% of women.³⁷ It may be classified as physiologic discharge, pathologic discharge, or galactorrhea. Although the actual incidence of malignancy in women with nipple discharge is low, this complaint produces significant anxiety among women because of the fear that it may be a harbinger of breast cancer. Galactorrhea can be a complex diagnostic challenge for the clinician; a thorough history, a focused physical examination, and appropriately chosen investigative studies are required for diagnosis.

Nipple discharge should be evaluated with respect to its duration, character (i.e., bloody, nonbloody, or milky), location (i.e., unilateral or bilateral), and precipitating factors (i.e., whether it is spontaneous or expressed). Because endocrine disorders (e.g., hypothyroidism and hyperprolactinemia) can produce galactorrhea, symptoms indicative of these conditions (e.g., lethargy, constipation, cold intolerance, and dry skin) should be looked for. The patient should also be questioned about symptoms of an intracranial mass, such as headache, visual field disturbances, and amenorrhea.

Numerous medications are associated with galactorrhea, including various antidepressants (e.g., fluoxetine, buspirone, alprazolam, and chlorpromazine). Other classes of drugs associated with nipple discharge include antihypertensives, H₂-receptor antagonists, and antidopaminergic medications (e.g., metoclopramide).

A focused physical examination is the next step in the evaluation of nipple discharge; obviously, a detailed breast examination is essential. If nipple discharge is not immediately apparent, the clinician should attempt to elicit the discharge by gently squeezing the nipple. The clinician should then attempt to determine whether the discharge is limited to a single duct or involves multiple ducts. Attention should also be paid to any physical findings suggestive of endocrine imbalance, such as thyromegaly (hypothyroidism) or visual field deficits (prolactinoma).

Nipple discharge is physiologic during pregnancy, developing as early as the second trimester and sometimes continuing for as

long as 2 years post partum. Therefore, evaluation of nipple discharge in women of childbearing years should include a pregnancy test. Elevated thyroid stimulating hormone (TSH) levels associated with hypothyroidism can increase prolactin secretion and produce galactorrhea. Accordingly, women with nipple discharge should undergo thyroid function testing. When the level of suspicion for a prolactinoma is sufficiently high, the serum prolactin level should be checked. If the serum prolactin level is elevated, MRI of the head (i.e., of the sella turcica) is indicated to determine whether a prolactin-secreting pituitary tumor is present.

Mammography is the first imaging study performed to evaluate nipple discharge. It may reveal nonpalpable masses or microcalcifications that necessitate biopsy. Because most pathologic causes of nipple discharge are located close to the nipple, magnification views of the retroareolar region may help identify the underlying condition. The absence of any mammographic abnormalities, however, should not lead to a false sense of security; further evaluation is still required.

The role of exfoliative cytology in the management of nonlactational galactorrhea is unclear. Although cytology can be diagnostic of cancer, its utility is limited by its low sensitivity. The high false negative rate mandates further evaluation when the findings from cytology are negative or nondiagnostic. Discharge that is bloody, unilateral, and spontaneous is more likely to yield a diagnosis of cancer.

Ductography, or galactography, consists of mammography performed after the offending lactiferous duct has been cannulated and filled with a contrast agent. It can be performed only when active discharge is present and when the secreting duct can be identified and accessed. Not infrequently, ductography is technically impossible, or else the images are uninterpretable as a consequence of incomplete ductal filling or contrast extravasation. Solitary papillomas, the most common cause of abnormal nipple discharge, typically appear as a ductal cutoff or filling defect on ductography. Unfortunately, a normal ductogram does not exclude a pathologic condition, and as with a normal mammogram, further evaluation is still required.

Advances in endoscopic technology have made visualization and biopsy of the mammary ducts possible.³⁸ Flexible fiberoptic ductoscopy [see 3:5 *Breast Procedures*] may permit direct identification and treatment of pathologic conditions affecting the ducts. At present, this technology is available only at a few centers, and as with all new technologies, there is a learning curve associated with its use. Further experience with ductoscopy is required to determine its precise role in the evaluation and management of nipple discharge.

After a thorough history, a focused physical examination, and appropriate diagnostic studies, pathologic nipple discharge that persists should be treated surgically. Operative therapy can resolve the discharge and provide a diagnosis. Excision of a duct or ducts can usually be performed with the patient under local anesthesia supplemented with intravenous sedation (so-called monitored anesthesia care [MAC]). The traditional surgical management of pathologic nipple discharge is a central duct excision, which effectively removes all of the central lactiferous ducts and sinuses, thereby preventing further discharge [see 3:5 *Breast Procedures*]. Single-duct excision, or microdochectomy, can be performed when the offending duct is clearly identified. The advantage of this latter procedure is that it conserves breast tissue and causes only minimal deformity; the nipple-areola complex remains intact, so that the patient retains the ability to breast-feed. The main disadvantage of single-duct excision is that the discharge may be more likely to recur than it would be after central duct excision.

BREAST PAIN

Breast pain, or mastalgia, is one of the most common symptoms for which women seek medical attention. At present, the causes of breast pain are poorly understood. Although pain is not usually a presenting

symptom for breast cancer, it still warrants a comprehensive evaluation. The elements of the history that are important in the evaluation of breast pain are the location, character, severity, and timing of the pain. Breast pain occurring in a predictable pattern just before the menstrual cycle is called cyclical mastalgia and is probably hormonally mediated. Notably, however, several studies have shown no differences in circulating estrogen levels between women with mastalgia and pain-free control subjects. It has been postulated that in women with breast pain, progesterone levels may be decreased or prolactin release may be increased in response to thyrotropin-releasing factor hormone.³⁹ Although histologic findings consistent with cysts, apocrine metaplasia, and ductal hyperplasia have been noted in the breasts of women with mastalgia, there is no convincing evidence that any of these pathologic changes actually cause breast pain.

Mammography and physical examination usually yield normal results in patients with breast pain. The likelihood of malignancy is increased when a patient with mastalgia is postmenopausal and not taking estrogens or when the pain is associated with skin changes or palpable abnormalities; however, these situations are uncommon.

For most women with breast pain, treatment consists of relieving symptoms and reassuring the patient that the workup has not identified an underlying breast carcinoma. Nonsteroidal anti-inflammatory drugs and supportive bras are helpful. Several lifestyle interventions have been proposed as effective breast pain treatments. Dietary recommendations, such as avoidance of methylxanthines (found in coffee, tea, and sodas), are not evidence based.⁴⁰ However, oral ingestion of evening primrose oil has been reported to produce significant or complete pain relief in about 50% of women with cyclic mastalgia.⁴¹

For the rare patients who have severe pain that does not respond to conservative measures, administration of hormones or drugs may be appropriate. Danazol has been successful against breast pain and should be considered the first-line agent, though its androgenic effects may be troubling to many women.⁴² Bromocriptine (a prolactin antagonist) and tamoxifen have also been used to treat mastalgia.⁴³ Pharmacotherapy for mastalgia is contraindicated in patients who are trying to become pregnant.

BREAST INFECTION OR INFLAMMATION

Breast infections can be divided into two general categories: (1) lactational infections and (2) chronic subareolar infections associated with duct ectasia.

Both cellulitis and abscesses may occur in lactating women, either during weaning or when engorgement occurs. In the absence of an abscess, breast infections are treated by (1) giving oral antibiotics that cover gram-positive cocci, (2) applying warm packs to the breast, and (3) keeping the breast emptied. Weaning is not necessary, because the

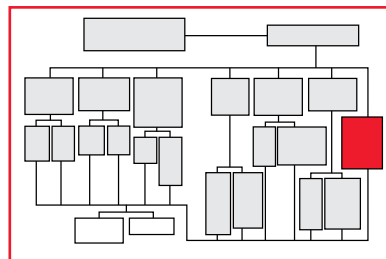

infant is not adversely affected by nursing from an infected breast.⁴⁴ A diagnosis of mastitis in a nonlactating woman must be viewed with suspicion, and the possibility of inflammatory breast cancer must be excluded. Inflammatory breast cancer is a clinicopathologic variant of breast cancer that is clinically characterized by the rapid onset of an erythema, edema, and increased temperature in the breast, with or without a palpable mass. The diagnosis is made by means of a skin biopsy; the pathologic hallmark is tumor cell invasion of the dermal lymphatics.

Once a breast abscess forms, however, surgical drainage is necessary. Because of the network of fibrous septa within the breast, breast abscesses in lactating women rarely form fluctuant masses. The clinical picture of breast erythema, tenderness, fever, and leukocytosis establishes the diagnosis. General anesthesia is usually required for optimal abscess drainage because of the tenderness of the affected area and the amount of manipulation necessary to break up the loculated abscess cavity. As with any abscess, a culture should be performed and the cavity should be packed open.

Nonlactational infections of the breast often present as chronic relapsing infections of the subareolar ducts associated with periductal mastitis or duct ectasia. These infections usually involve multiple organisms, including skin anaerobes.⁴⁵ Retraction or inversion of the nipple, subareolar masses, recurrent periareolar abscesses, or a chronic fistula to the periareolar skin may result, as may palpable masses and mammographic changes that mimic carcinoma. In the acute phase of infection, treatment entails incision, drainage, and administration of antibiotics that cover skin organisms, including anaerobes. In cases of repeated infection, the entire subareolar duct complex should be excised after the acute infection has completely resolved, with antibiotic coverage provided during the perioperative period. Whether drain placement is necessary remains debatable. Even after wide excision of the subareolar duct complex and intravenous antibiotic coverage, infections recur in some patients; excising the nipple and the areola can treat these.⁴⁶

HIGH-RISK PATIENTS

Despite significant progress in management, at least one third of women with breast cancer will ultimately die of their disease. This harsh reality has led to efforts aimed at providing primary prevention to high-risk women. Genetic testing and the use of mathematical models have significantly improved our ability to define breast cancer risk. The Gail model,⁴⁷ which relies on data from the Breast Cancer Detection Demonstration Project, and the Claus model,⁴⁸ which relies on data from the Cancer and Steroid Hormone Project, are two of the tools that have been used to make this determination. At present, there are three treatment options for women at high risk for breast cancer: (1) close surveillance, (2) prophylactic mastectomy, and (3) chemoprevention with tamoxifen or other agents in the setting of a clinical trial. Currently, no evidence-based conclusions can be made as to which of these management strategies is superior. Research involving high-risk women includes few randomized controlled trials, and many reports are based on uncontrolled studies of selected populations with varying degrees of breast cancer risk. Although most women at high risk choose the option of close surveillance, the growing body of data on chemoprevention and prophylactic mastectomy may increase selection of the other two options.

For women with a previous diagnosis of breast cancer, surveillance protocols are described elsewhere [see Management of the Patient with Breast Cancer, Follow-up after Treatment, below]. For women with lobular carcinoma in situ (LCIS) or a family history of breast carcinoma, surveillance should include twice-yearly physical examinations. Mammography should be performed annually after the diagnosis of LCIS or atypical hyperplasia. For women with a family history of breast cancer, mammography should be performed annually, beginning at least 5 years before the earliest age at which cancer was diagnosed in a relative and in any case no later than the age of 35 years.⁴⁹ For women who carry *BRCA1* or *BRCA2* mutations and other women from families with an autosomal dominant pattern of breast cancer transmission, annual mammographic screening should begin at least 10 years before the earliest age at which the cancer was diagnosed in a relative and no later than 25 years of age.⁴⁹

Long-term results of prophylactic mastectomy in high-risk women indicate that breast cancer risk was reduced by at least 90% in women at high or very high risk who underwent this procedure, compared with women who did not, with risk predicted by the Gail model.⁵⁰ Mathematical modeling suggests that prophylactic mastectomy could translate into improved survival for women at very high risk if it confers a 90% reduction in risk.⁵¹ There is, however, no clear consensus on the indications for risk reduction surgery; the benefits of prophylactic mastectomy must be weighed against the irreversibility and psychosocial consequences of the procedure.

Chemoprevention may be defined as the use of nutrients or pharmacologic agents to augment physiologic mechanisms that protect against the development of malignancy. Chemopreventive strategies are designed either to block the initiation of the carcinogenic process or to prevent (or reverse) the progression of the premalignant cell to an invasive cancer.⁵² Chemoprevention began with the development of the antiestrogen tamoxifen. The efficacy of tamoxifen in ER-positive breast cancer patients was recognized early on, but its chemopreventive potential was not established until some time later.

The first—and still the most extensive—study to be published on breast cancer chemoprevention was the National Surgical Adjuvant Breast and Bowel Project (NSABP) P-1 trial, in which women at increased risk for breast cancer were randomly assigned to receive either tamoxifen, 20 mg/day, or placebo.⁵³ Increased risk was determined on the basis of (1) age greater than 60 years, (2) a 5-year predicted incidence of breast cancer of at least 1.66% (determined according to Gail's criteria), or (3) a personal history of lobular carcinoma in situ. After a median follow-up of 55 months, the overall risk of breast cancer was decreased by 49% in the tamoxifen group, and the risk of noninvasive breast cancer was decreased by 50%. The reduction in breast cancer risk was limited to ER-positive breast cancers. Several adverse side effects were noted in the tamoxifen group, the most worrisome of which were a threefold increase in the incidence of endometrial cancer, a higher incidence of deep vein thrombosis and pulmonary embolism, and a higher incidence of stroke. Although two subsequent trials, one from the United Kingdom⁵⁴ and one from Italy,⁵⁵ did not confirm these findings, the Food and Drug Administration (FDA) found the results of the NSABP P-1 trial to be compelling enough to warrant approval of tamoxifen as a chemopreventive agent in high-risk women.

Concerns about the side effects of tamoxifen have generated interest in the use of selective estrogen receptor modulators (SERMs) as chemopreventive agents.⁵⁶ It appears possible that such so-called designer estrogens may have fewer side effects than

tamoxifen while reducing the rate of new breast cancers and lowering the incidence of osteoporosis and cardiovascular disease. One of the SERMs, raloxifene, has been approved by the FDA for the treatment of postmenopausal osteoporosis and is known also to exert beneficial effects on lipid profiles. Unlike tamoxifen, raloxifene appears not to have stimulatory effects on the endometrium. Moreover, the Multiple Outcomes of Raloxifene Evaluation (MORE) trial found that fewer breast cancers were noted in women treated with raloxifene than would have been expected without such treatment.⁵⁷

On the basis of findings from osteoporosis trials, the NSABP incorporated raloxifene into an extensive multi-institutional chemoprevention trial that began enrolling patients in 1999. The Study of Tamoxifen and Raloxifene (STAR) trial is a randomized, double-blind trial whose purpose is to compare the effectiveness of raloxifene with that of tamoxifen in postmenopausal women at increased risk for breast cancer. Entry criteria are similar to those for the NSABP P-1 study. A total of 22,000 postmenopausal high-risk women will be randomly assigned to receive either tamoxifen, 20 mg/day orally, or raloxifene, 60 mg/day orally, for 5 years.

A number of newer agents may possess some capacity for breast cancer chemoprevention. Aromatase inhibitors, which have been used as second-line therapies after tamoxifen in cases of advanced breast cancer, may exert chemopreventive effects by inhibiting parent estrogens and their catechol metabolites, thereby preventing cancer initiation.⁵⁸ In addition, gonadotropin-releasing hormone agonists, monoterpenes, isoflavones, retinoids, rexinoids, vitamin D derivatives, and inhibitors of tyrosine kinase are all undergoing evaluation in clinical or preclinical studies with a view to assessing their potential chemopreventive activity. Whether any of these compounds will play a clinically useful role in preventing breast cancer remains to be seen.

Management of Breast Cancer

STAGING

In patients with newly diagnosed breast cancer, it is important to determine the overall extent of disease before embarking on definitive therapy. This process, referred to as clinical staging, includes (1) physical examination to identify any areas of palpable disease in the breasts or the axillary and supraclavicular nodes, along with a detailed clinical history to identify symptoms that may suggest metastatic disease; (2) imaging studies, including mammography, chest x-ray, and sometimes bone scans or CT scans of the chest, the abdomen, or the head; and (3) laboratory studies, including a complete blood count (CBC) and liver function tests.

The extent of preoperative staging should be guided by the size and other characteristics of the primary tumor and by the patient's history and physical examination. The majority of patients with breast cancer present with early stage I or II disease and a low probability of metastatic disease; therefore, extensive testing adds cost without offering much benefit. For patients with stage I or II disease, mammography and routine preoperative blood work should be performed before definitive surgical therapy is initiated; further imaging studies should be reserved for patients who have abnormal test results or clinical symptoms that suggest metastatic disease (e.g., bone pain). For patients with

Table 4 American Joint Committee on Cancer TNM Clinical Classification of Breast Cancer

Primary tumor (T)	TX	Primary tumor cannot be assessed	
	T0	No evidence of primary tumor	
	Tis	Carcinoma in situ; intraductal carcinoma, lobular carcinoma in situ, or Paget disease of nipple with no associated tumor*	
	T1	Tumor ≤ 2.0 cm in greatest dimension	
		T1mic:	microinvasion ≤ 0.1 cm in greatest dimension
		T1a:	tumor > 0.1 cm but ≤ 0.5 cm in greatest dimension
		T1b:	tumor > 0.5 cm but ≤ 1.0 cm in greatest dimension
		T1c:	tumor > 1.0 cm but ≤ 2.0 cm in greatest dimension
	T2	Tumor > 2.0 cm but ≤ 5.0 cm in greatest dimension	
	T3	Tumor > 5.0 cm in greatest dimension	
T4	Tumor of any size with direct extension to (a) chest wall† or (b) skin		
	T4a:	extension to chest wall	
	T4b:	edema (including <i>peau d'orange</i>) or ulceration of the skin of the breast or satellite skin nodules confined to the same breast	
	T4c:	both of the above (T4a and T4b)	
	T4d:	inflammatory carcinoma‡	
Regional lymph nodes (N)	NX	Regional lymph nodes cannot be assessed (e.g., previously removed)	
	N0	No regional lymph node metastasis	
	N1	Metastasis to movable ipsilateral axillary lymph node(s)	
	N2	Metastasis to ipsilateral axillary lymph node(s) fixed to each other or to other structures	
	N3	Metastasis to ipsilateral internal mammary lymph node(s)	
Pathologic classification of lymph nodes (pN)	pNX	Regional lymph nodes cannot be assessed (not removed for pathologic study or previously removed)	
	pN0	No regional lymph node metastasis	
	pN1	Metastasis to movable ipsilateral axillary lymph node(s)	
		pN1a:	only micrometastasis (none > 0.2 cm in greatest dimension)
		pN1b:	metastasis to lymph node(s), any > 0.2 cm in greatest dimension
		pN1bi:	metastasis in 1 to 3 lymph nodes, any > 0.2 cm and all < 2.0 cm in greatest dimension
	pN1bii:	metastasis to 4 or more lymph nodes, any > 0.2 cm and all < 2.0 cm in greatest dimension	
	pN1biii:	extension of tumor beyond the capsule of a lymph node metastasis < 2.0 cm in greatest dimension	
	pN1biv:	metastasis to a lymph node ≥ 2.0 cm in greatest dimension	
	pN2	Metastasis to ipsilateral axillary lymph node(s) fixed to each other or to other structures	
pN3	Metastasis to ipsilateral internal mammary lymph node(s)		
Distant metastasis (M)	MX	Presence of distant metastasis cannot be assessed	
	M0	No distant metastasis	
	M1	Distant metastasis present (includes metastasis to ipsilateral supraclavicular lymph nodes)	

* Paget disease associated with a tumor is classified according to the size of the tumor.

†The chest wall includes ribs, the intercostal muscles, and the serratus anterior, but not the pectoral muscle.

‡Inflammatory carcinoma is a clinicopathologic entity characterized by diffuse brawny induration of the skin of the breast with an erysipeloid edge, usually without an underlying palpable mass. Radiologically, there may be a detectable mass and characteristic thickening of the skin over the breast. This clinical presentation is attributable to tumor embolization of dermal lymphatics with engorgement of superficial capillaries.

higher-stage disease at presentation, the use of additional staging studies should be guided by the patient's clinical situation.

Changes in American Joint Committee on Cancer Breast Cancer Staging System

A number of evidence-based changes to the sixth edition of the American Joint Committee on Cancer (AJCC) TNM staging system for breast cancer were adopted for use in tumor registries in January 2003 [see Tables 4 and 5].⁵⁹ These changes reflected growing use of sentinel lymph node (SLN) biopsy and of immunohistochemical and molecular technologies to detect nodal metastases. They also included quantitative criteria for distinguishing micrometastases from isolated tumor cells and specific identifiers for recording the use of SLN biopsy, immunohistochemical staining, and molecular biologic techniques. In addition, the classification of lymph node status was modified to include the number of affected axillary lymph nodes, and changes were made to the classification of level III axillary lymph nodes and lymph nodes outside of the axilla. These modifications of the staging system should bring standardization to the collection of important clinicopathologic information.

TREATMENT OPTIONS

Mastectomy versus Limited Surgery

Several randomized prospective studies have documented that segmental resection (lumpectomy), axillary dissection, and postoperative irradiation of an intact breast result in disease-free and overall survival rates equal to those of modified radical mastectomy.⁶⁰⁻⁶³ Although most women with stage I and II breast cancers—indeed, most women with breast cancer—are candidates for breast conservation therapy [see Table 6], some still require or desire mastectomy. When a patient is eligible for limited surgery, the decision between mastectomy and breast conservation with radiation therapy is made on the basis of patient and physician preference, access or lack of access to radiation therapy, and the presence or absence of contraindications to breast conservation.

Contraindications to breast conservation Patients for whom mastectomy is still clearly the treatment of choice fall into four broad categories: (1) those in whom radiation therapy is contraindicated, (2) those in whom lumpectomy would have an unacceptable cosmetic result, (3) those for whom local recurrence is a concern, and (4) those high-risk patients in whom surgical prophylaxis is appropriate [see Management of Specific Breast Problems, High-Risk Patients, *above*].

Radiation therapy may be contraindicated for any of several reasons. Some patients choose not to undergo radiation therapy, either because it is inconvenient or because they are concerned about potential complications (including the induction of second malignancies). Some patients simply do not have access to radiation therapy, either because they live in a rural area or because they have physical conditions that make daily trips for therapy onerous. Time and travel issues related to weeks-long courses of conventional radiotherapy have led to studies investigating partial-breast or limited-field irradiation after breast-conserving surgery.⁶⁴ Data from randomized prospective trials are required before this technique can be recommended in women with early-stage breast cancer. Other patients have medical or psychiatric disorders that would make it extremely difficult for them to comply with the daily treatment schedule. Still others have specific medical contraindications to radiation therapy, including pregnancy, collagen vascular disease, or previous irradiation of the

chest wall (as in a woman with a local recurrence of a breast carcinoma that was treated with radiation therapy). Although there are some clinical data supporting the use of repeat local excision without further irradiation to treat local recurrence after radiation therapy, most authorities favor mastectomy.⁶⁵

When resection of the primary tumor to clean margins would render the appearance of the remaining breast tissue cosmetically unacceptable, mastectomy may be preferable. This is likely to be the case, for example, in patients with large primary tumors relative to their breast size: resection of the primary tumor would remove a substantial portion of the breast tissue. Another example is patients with multiple primary tumors, who would have not only an increased risk of local recurrence but also poor cosmetic results after multiple wide excisions. Patients with superficial central lesions, including Paget disease, are eligible for wide excision (including the nipple and the areola) followed by radiation therapy, provided that clean margins are obtained. The survival and local recurrence rates in these patients are equivalent to those in other groups of patients undergoing lumpectomy and radiation.⁶⁶⁻⁶⁸ In many cases, the cosmetic results of this procedure are preferable to those of immediate reconstruction, and there is always the option to reconstruct the nipple and areola later.

Patients who are at high risk for local recurrence often choose mastectomy as primary therapy. Features of primary tumors that are associated with higher local recurrence rates after limited

Table 6 Determinants of Patient Eligibility for Lumpectomy and Radiation Therapy

- Primary tumor ≤ 5 cm (may be larger in selected cases)
- Tumor of lobular or ductal histology
- Any location of primary within breast if lumpectomy to clean margins (including central lesions) will yield acceptable cosmetic results
- Clinically suspicious but mobile axillary nodes
- Tumor either positive or negative for estrogen and progesterone receptors
- Any patient age

surgery and radiation include gross residual disease after lumpectomy, multiple primary tumors within the breast, an extensive intraductal component, large tumor size, lymphatic vessel invasion, and lobular histologic findings.⁶⁹

In practice, obtaining tumor-free margins is probably the most critical factor in decreasing the risk of local recurrence. The difficulty of obtaining microscopically clean margins in tumors with an extensive intraductal component and in lobular carcinomas may account for the higher local recurrence rates sometimes seen with these tumors. Histologic analysis of mastectomy specimens from patients with tumors with an extensive intraductal component has shown a high rate of multifocality within ipsilateral breast tissue; this residual disease is thought to be the nidus for local recurrence.⁷⁰

The long-term benefits of choosing mastectomy to reduce local recurrences are not clear. Whereas the appearance of distant metastases typically heralds incurable and ultimately fatal disease, local recurrence after breast conservation appears to have little, if any, impact on overall survival. Prospective, randomized trials have had difficulty showing a statistically significant reduction in survival in women who have had a local recurrence after limited surgery and radiation. It has been suggested that additional follow-up may eventually confirm reduced survival in some patients with local recurrences. Still, most of the evidence suggests that local recurrences are not the source of subsequent distant metastases. It is worthwhile to keep in mind, however, that even if mastectomy to prevent local recurrence does not actually improve survival, it may nevertheless provide significant benefit by reducing patient anxiety, the amount of follow-up testing required, and the need for subsequent treatment.

Options for axillary staging The histologic status of the axillary nodes is the single most important predictor of outcome in breast cancer. Traditionally, axillary dissection has been a routine part of the management of breast cancer. It has been used to guide subsequent adjuvant therapy and provide local control, and it may have contributed a small overall benefit in terms of survival.⁷¹ Unfortunately, axillary dissection can be associated with sensory morbidities and lymphedema.

SLN biopsy is a minimally invasive, less morbid, and quite accurate method of detecting or ruling out occult lymph node metastasis [see 3:6 *Lymphatic Mapping and Sentinel Lymph Node Biopsy*]. It is based on the principle that the SLN is the first node to which the tumor spreads; thus, if the SLN is tumor free, the patient can be spared the morbidity of an axillary dissection. There is a learning curve associated with this technique, however, and discussion continues as to the most appropriate way of integrating it into general practice.⁷² SLN biopsy identifies an increased number of patients with micrometastases, with some identified by immunohistochemical staining alone. Treatment of patients who have only micrometastases to axillary nodes remains a topic of debate, addressed in an ongoing clinical trial of SLN biopsy by the American College of Surgeons Oncology Group.

Breast reconstruction after mastectomy Advances in reconstructive techniques have made breast reconstruction increasingly popular [see 3:5 *Breast Procedures*]. Reconstruction may be done either at the time of the mastectomy (immediate reconstruction) or later (delayed reconstruction). In the past, reconstruction was generally delayed for 1 to 2 years after mastectomy; now, it is most often performed immediately after mastectomy. In general, immediate reconstruction should be reserved for patients who are not likely to require postoperative adjuvant therapies,

because radiation can produce capsular contracture in patients undergoing prosthetic reconstruction.

Prosthetic reconstruction involves the use of an implant to restore the breast contour. It is technically the simplest type of reconstruction but can still result in complications such as contracture, infection, and rupture, which may necessitate further surgery. Autologous reconstruction involves the transfer of the patient's own tissue to reconstruct the breast. Tissue from various sites (e.g., the transverse rectus abdominis and the latissimus dorsi) has been used for breast reconstruction. Skin-sparing mastectomy with immediate reconstruction consists of resection of the nipple-areola complex, any existing biopsy scar, and the breast parenchyma, followed by immediate reconstruction. The generous skin envelope that remains optimizes the cosmetic result after breast reconstruction. The procedure is oncologically safe and does not lead to an increase in the incidence of local recurrence.⁷³

Radiation Therapy

Current radiation therapy regimens consist of the delivery of approximately 5,000 cGy to the whole breast at a dosage of approximately 200 cGy/day, along with, in most cases, the delivery of an additional 1,000 to 1,500 cGy to the tumor bed, again at a dosage of 200 cGy/day. Axillary node fields are not irradiated unless there is evidence that the patient is at high risk for axillary relapse—namely, multiple (generally more than four) positive lymph nodes, extranodal extension of tumor, or bulky axillary disease (i.e., palpable nodes several centimeters in diameter). Because the combination of surgical therapy and radiation therapy increases the risk of lymphedema of the arm, it is appropriate only when there is sufficient risk of axillary relapse to justify the increased complication rate. As a rule, supraclavicular node fields are irradiated only in patients with multiple positive axillary nodes, who are at increased risk for supraclavicular disease. The role of prophylactic irradiation of the internal mammary nodes remains controversial.

Postmastectomy radiation therapy involves the delivery of radiation to the chest wall after mastectomy; it is mainly reserved for patients with T3 or T4 primary tumors or multiple positive lymph nodes. Such therapy is recommended particularly when there are multiple positive axillary lymph nodes: significant axillary disease predicts higher rates of chest wall recurrence after mastectomy. Two series^{74,75} have suggested that postmastectomy radiation therapy significantly improves survival in premenopausal women with any positive axillary nodes.

Irradiation of the breast or chest wall is generally well tolerated: most women experience only minor side effects, such as transient skin erythema, mild skin desquamation, and mild fatigue. Because a small amount of lung volume is included in the irradiated fields, there is usually a clinically insignificant but measurable reduction in pulmonary function. In addition, because the heart receives some radiation when the left breast or left chest wall is treated, there may be a slightly increased risk of future myocardial infarction. There is also a 1% to 2% chance that the radiation will induce a second malignancy (sarcoma, leukemia, or a second breast carcinoma). These radiation-induced malignancies appear after a long lag time, generally 7 to 15 years or longer.

Systemic Drug and Hormone Therapy

Despite the success of surgical treatment and radiation therapy in achieving local control of breast cancer, distant metastases still develop in many patients. Various drugs and hormones have therefore been used to treat both measurable and occult metastatic disease. Now that many clinical trials have demonstrated a sur-

vival benefit, more and more women are receiving adjuvant cytotoxic chemotherapy. It became clear in early trials that multiple-agent (or combination) chemotherapy was superior to single-agent chemotherapy.^{76,77} It also became clear that chemotherapy and hormone therapy were limited in their ability to control large tumor masses, though on occasion, patients with large tumor masses showed dramatic partial responses or even complete responses to therapy.

With the goal of eradicating breast cancer metastases while they are still microscopic, systemic therapy is now administered in a so-called adjuvant setting—that is, when there is no evidence of distant metastases but there is sufficient suspicion that metastasis may have occurred. Until the late 1980s, adjuvant chemotherapy was given primarily to women who had axillary node metastases but no other evidence of disease. In node-positive premenopausal women, adjuvant chemotherapy appeared to be significantly more beneficial than adjuvant hormone therapy. In node-positive postmenopausal women, on the other hand, hormone therapy appeared to be as beneficial as chemotherapy and less toxic.

This approach to adjuvant systemic therapy changed in 1988, when the NCI issued a clinical alert stating that there was sufficient evidence of benefit to allow recommendation of adjuvant chemotherapy or hormone therapy for even node-negative breast cancer patients.⁷⁸ By that time, a number of studies had shown that adjuvant chemotherapy could improve survival in node-negative breast cancer patients.⁷⁹⁻⁸¹ A consensus conference of experts in the field suggested that such therapy be reserved for node-negative women with primary tumors larger than 1 cm in diameter.⁸² In 1992, a meta-analysis that reviewed the treatment of 75,000 women in 133 randomized clinical trials of adjuvant therapy for breast cancer concluded that in node-negative premenopausal women, overall long-term survival was 20% to 30% higher in those who received chemotherapy than in those who did not.⁸³ This benefit also appeared to extend to postmenopausal women between 50 and 60 years of age. A 1998 overview of the use of adjuvant tamoxifen in randomized trials demonstrated that in women with ER-positive tumors, those given tamoxifen for 5 years had a 47% reduction in tumor recurrence and a 26% reduction in mortality, compared with those women who were given placebo.⁸⁴ In this analysis, the effects of tamoxifen on recurrence and survival were independent of age and menopausal status. Tamoxifen did not appear to improve survival, however, in women with ER-negative tumors. These results, together with data on the efficacy of tamoxifen for chemoprevention, have led to increased use of tamoxifen for premenopausal women and for women with small tumors.

TREATMENT OF NONINVASIVE CANCER

Ductal Carcinoma in Situ

Before mammographic screening was widely practiced, ductal carcinoma in situ (DCIS) was generally identified either as a palpable lesion (usually with comedo histology) or as an incidental finding on a biopsy performed for another lesion. With the increasing use of mammography, DCIS is accounting for a growing proportion of breast cancer cases. The diagnosis of DCIS is now made in 6.6% of all needle-localized breast biopsies and 1.4% of breast biopsies for palpable lesions. About 30% of all mammographically detected malignancies are DCIS.¹⁷

It was recognized early on that DCIS had a very favorable prognosis compared with other forms of breast cancer: long-term survival approached 100% after treatment with mastectomy. Axillary lymph nodes were positive in only 1% to 2% of patients,

most of whom had large or palpable lesions or comedo histology. The prognosis for DCIS continues to be very favorable in relation to that for invasive breast cancers. In theory, there is no potential for metastatic disease with a purely in situ lesion. In practice, however, axillary node metastases continue to be found in 1% to 2% of patients thought to have pure DCIS, presumably arising from a small area of invasion that was missed on pathologic evaluation.

DCIS is believed to be a true anatomic precursor of invasive breast cancer. There are at least two lines of evidence that support this conclusion. First, when DCIS is treated with biopsy alone (usually because it was missed on the initial biopsy and not found until subsequent review), invasive carcinoma develops in 25% to 50% of patients at the site of the initial biopsy; all these tumors appear within 10 years and are of ductal histology. Second, when DCIS recurs locally after breast conservation, invasive ductal carcinoma appears in about 50% of patients. The true relationship between DCIS and invasive ductal carcinoma awaits a better understanding of the molecular biology of breast cancer development.

The consequence of the view that DCIS is a precursor of invasive cancer is that treatment is required once the diagnosis is made. Treatment options for DCIS are similar to those for invasive breast cancer [see *Figure 1*]; however, it should be remembered that although the risk of local recurrence is greater after breast conservation for DCIS than after mastectomy, the likelihood of metastatic disease is very small. Wide excision to microscopically clean margins followed by radiation therapy has become an accepted alternative to mastectomy. Smaller areas of DCIS, particularly of low to intermediate nuclear grade, are increasingly treated with wide excision without radiation.⁸⁵ If clean margins cannot be obtained or if the cosmetic result is expected to be poor after excision to clean margins, mastectomy should be performed. The NSABP B-17 study,⁸⁶ which examined the role of radiation in the treatment of DCIS, found that the addition of radiation therapy to wide excision reduced the recurrence rate at 43 months after operation by approximately half, from 16.4% with wide excision alone to 7.0% with wide excision and radiation. The report also suggested that the addition of radiation therapy might reduce the incidence of invasive recurrences.

Most patients in whom DCIS is identified mammographically can choose between mastectomy and wide excision with or without radiation, either of which yields excellent long-term survival. Given the lack of any significant difference in survival between the two options, the patient must weigh her feelings about the risk of a local, possibly invasive, recurrence after breast conservation against her feelings about the cosmetic and psychological effects of mastectomy. Mastectomy remains a reasonable treatment even for patients with very small DCIS lesions if the primary concern is to maximize local control of the cancer. Breast reconstruction after mastectomy for DCIS is an option that is open to most such patients.

Axillary dissection is not usually performed in conjunction with lumpectomy for DCIS, because the probability of positive nodes is low: it increases morbidity and expense while providing little prognostic information. On the other hand, low axillary dissection is often included in mastectomy for DCIS: a level I axillary dissection adds little morbidity to a mastectomy, and many surgeons believe that dissection must be carried into the low axilla to ensure that the entire axillary tail of the breast is removed.

In some patients with areas of mammographically detected DCIS lesions measuring less than 2.5 cm in diameter, it may be possible to omit radiation therapy, particularly if the lesions do

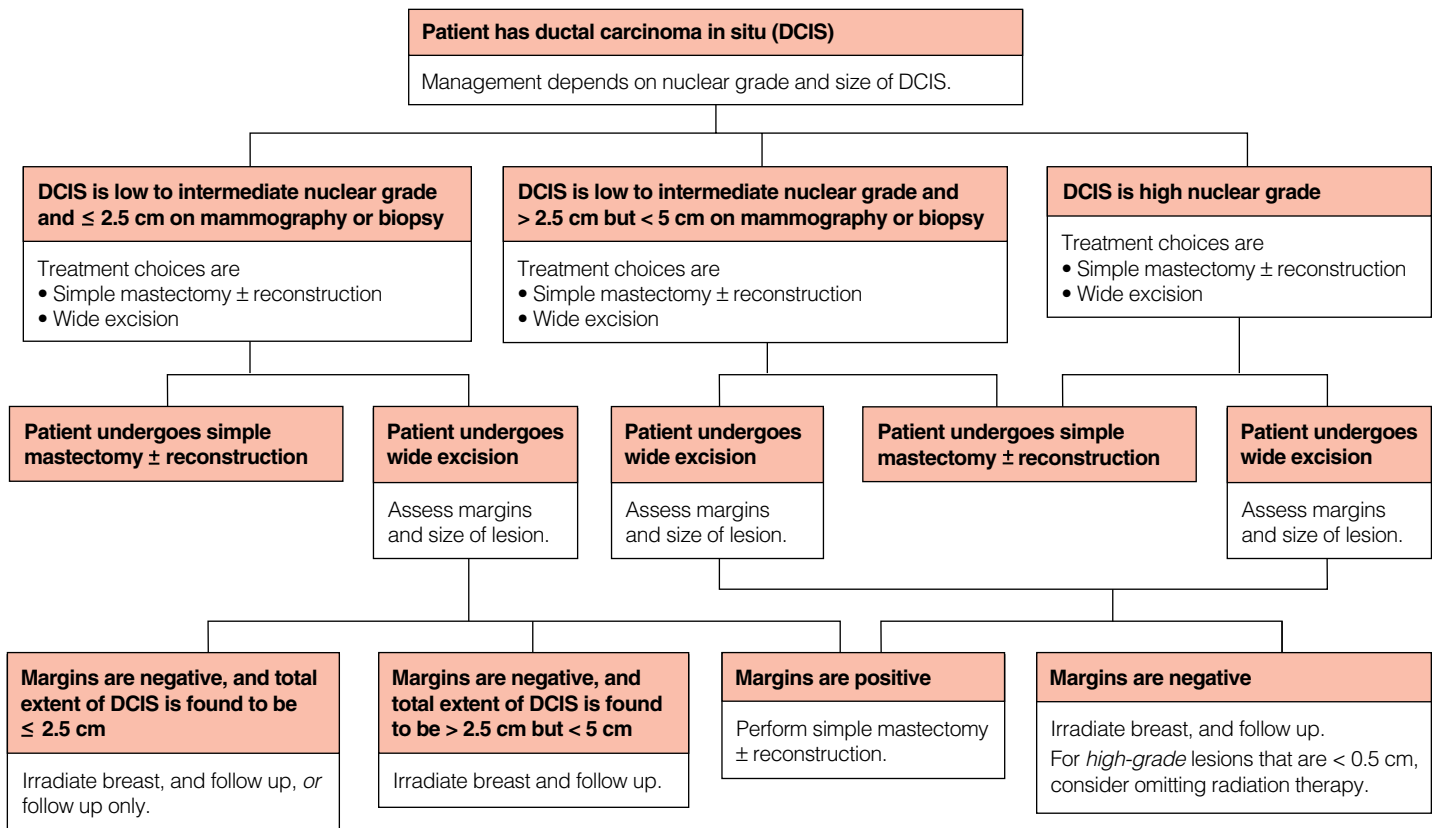

Figure 1 Algorithm illustrates the approach to managing ductal carcinoma in situ.

not have comedo histology. Omission of radiation therapy is a complex decision that should be based on the individual patient's histology, the presence or absence of other risk factors, the presence or absence of contraindications to radiation therapy, and the degree to which the patient is willing to accept a higher local recurrence rate. This option is probably best pursued in the context of a clinical trial.

There are certain patients with DCIS for whom mastectomy remains the preferred treatment, such as those who have lesions larger than 5 cm in diameter. Some surgeons would also include in this category those who have comedo lesions larger than 2.5 cm and those who present with palpable DCIS. In these patients, the local recurrence rate after breast conservation, even in conjunction with radiation therapy, remains high. As many as half of these recurrences will contain invasive cancer with metastatic potential. These also are the DCIS patients who are at highest risk for positive axillary nodes. For this reason, an axillary node sampling is often performed in conjunction with the mastectomy.

Lobular Carcinoma in Situ

LCIS, also referred to as lobular neoplasia, does not have the same clinical implications as DCIS, invasive ductal carcinoma, or invasive lobular carcinoma. It is now generally accepted that LCIS is a predictor of increased risk of subsequent invasive breast carcinoma rather than a marker of the site at which the subsequent carcinoma will arise. Most of the carcinomas that develop after a biopsy showing LCIS are of ductal histology.⁸⁷ The increased risk of subsequent carcinoma is equally distributed between the breast undergoing biopsy and the contralateral breast and is thought to be between 20% and 25% in patients with LCIS and no other risk

factors; it may be additive with other risk factors [see Risk Factors for Breast Cancer, above]. Because the two breasts are at equal risk for future carcinoma, unilateral mastectomy is inappropriate. Appropriate treatment options include (1) careful observation coupled with physical examination two or three times annually and mammograms annually, (2) prophylactic bilateral simple mastectomies with or without reconstruction, and (3) chemoprevention with tamoxifen or participation in chemoprevention trials with other agents. Most patients choose the first option, but there are some patients for whom prophylactic mastectomy is still preferable, either because of anxiety or because of concurrent risk factors.

Management of tumors that contain LCIS mixed with invasive carcinoma of either lobular or ductal histology is dictated primarily by the features of the invasive carcinoma. Staging is not affected by the presence of LCIS.

TREATMENT OF INVASIVE CANCER

Although the optimal treatment regimen for breast cancer continues to be the subject of active investigation, there is at least a partial consensus regarding current treatment options for the various stages of breast cancer.

Early-Stage Invasive Cancer

Local treatment In patients with stage I or II breast cancer, lumpectomy to microscopically clean margins combined with axillary dissection and radiation therapy [see Figure 2] appears to yield approximately the same long-term survival rates as mastectomy. Patients undergoing lumpectomy and radiation are, however, at risk for local recurrence in the treated breast, as well as for

the development of a new primary tumor in the remaining breast tissue. Local recurrences can generally be managed with mastectomy; overall survival is equivalent to that of women who underwent mastectomy at the time of initial diagnosis. There may, however, be a significant cost to the patient in terms of anxiety about recurrence, as well as the morbidity and potential mortality associated with undergoing a second surgical procedure.

On the other hand, patients who choose mastectomy as their initial surgical treatment face the psychological consequences of losing a breast. Although they are at lower risk for local recurrence than patients who choose lumpectomy, axillary node dissection, and radiation, their overall survival does not seem to be significantly improved. Each physician and each patient must weigh the inconvenience and potential complications of radiation therapy and the risk of local recurrence against the value of breast preservation, keeping in mind that the choice between procedures appears to have no significant effect on survival.

Adjuvant therapy It is generally agreed that adjuvant chemotherapy, adjuvant hormone therapy, or both should be considered for all women with tumors larger than 1 cm in diameter, even those with negative axillary lymph nodes. For patients with tumors that have a very favorable prognosis (i.e., that are smaller than 1 cm or have a favorable histology), the potential benefits of

adjuvant therapy are probably outweighed by its risks. Tamoxifen therapy is being reconsidered for women with such low-risk tumors, given the data on the efficacy of this agent for both treatment and prevention of breast cancers. In premenopausal women, adjuvant therapy should consist of combination chemotherapy, with hormone therapy reserved for clinical trials; in postmenopausal women, hormone therapy (generally consisting of tamoxifen, 10 mg twice daily) is the first-line treatment. However, the idea that menopause should be an absolute cutoff point for consideration of chemotherapy is being reassessed. For healthy postmenopausal women, particularly those between 50 and 60 years of age, the decision between hormone therapy and chemotherapy plus hormone therapy is made on an individual basis and takes into account the woman's overall health and the specifics of her tumor.

In cases of node-positive disease, combination chemotherapy is used for premenopausal women and for healthy postmenopausal women up to 60 years of age or even older. Hormone therapy is generally the treatment of choice in postmenopausal women who are older than 60 years and in poor health, particularly those with ER-positive tumors. Renewed interest is being expressed in other hormonal manipulations, such as oophorectomy and chemical castration, for premenopausal women who are at high risk for metastatic disease.⁸⁸

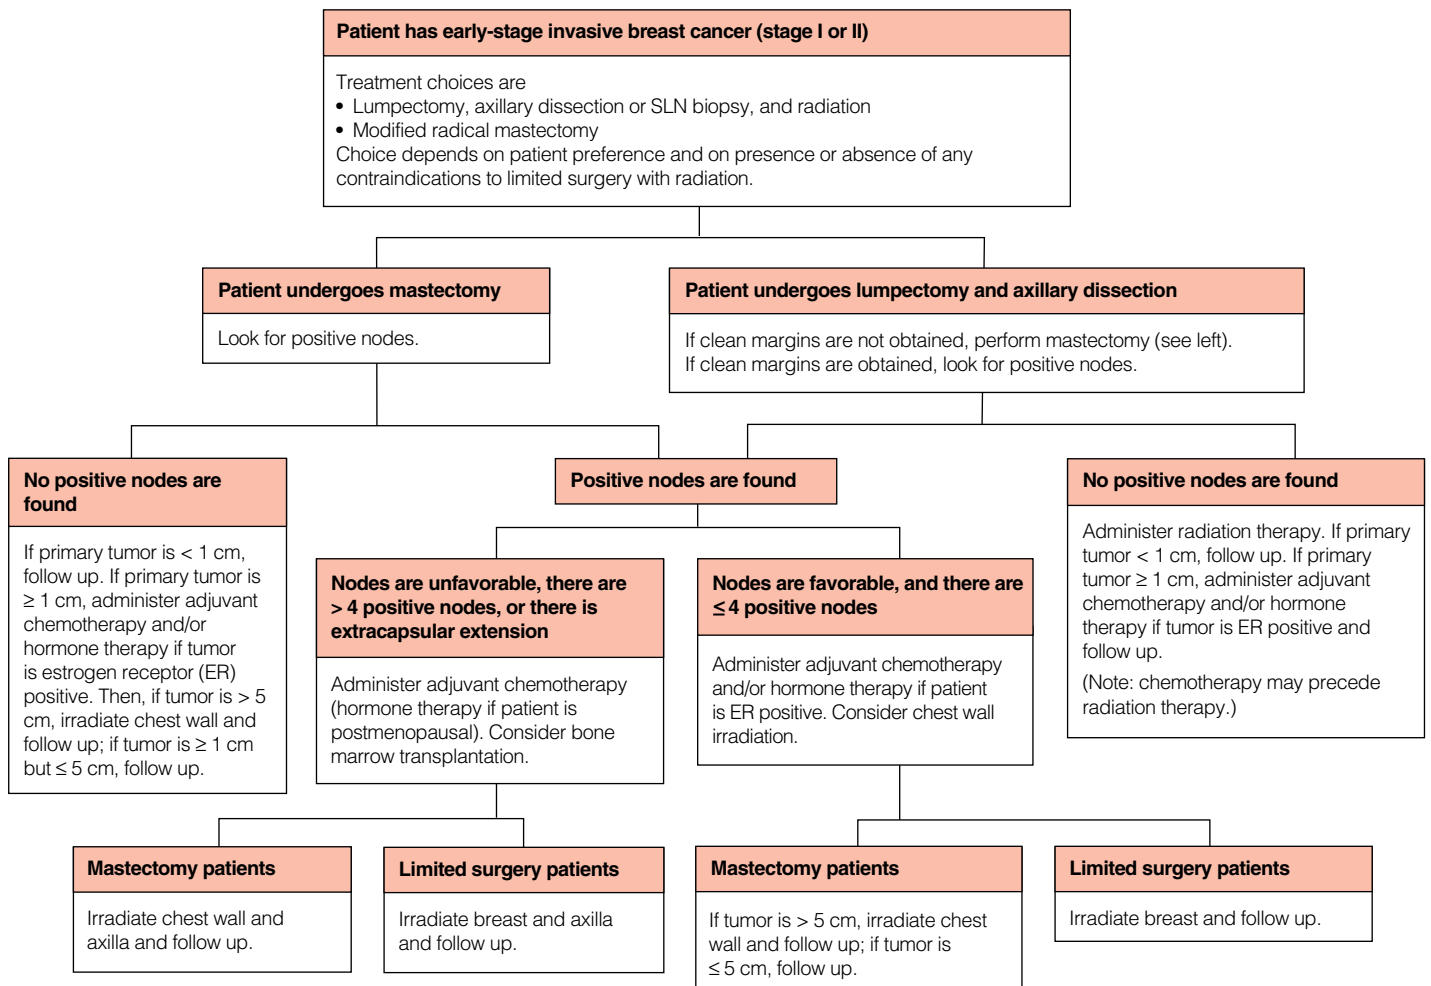

Figure 2 Algorithm illustrates the approach to managing early-stage invasive breast

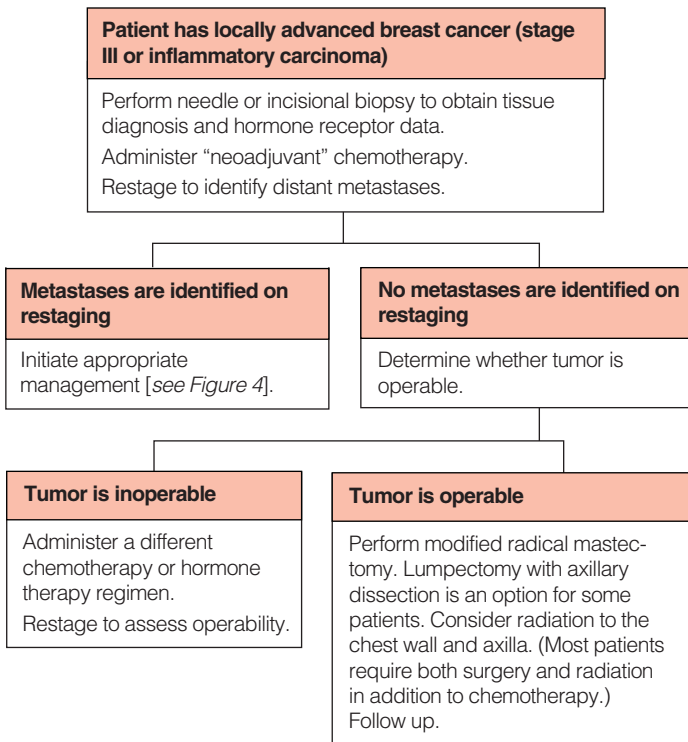

Figure 3 Algorithm illustrates the approach to managing locally advanced breast cancer.

Locally Advanced Cancer

Patients with locally advanced breast cancer include those with primary tumors larger than 5 cm (particularly those with palpable axillary lymph nodes), those with fixed or matted N2 axillary nodes, and those with inflammatory breast carcinoma. These patients are at high risk for systemic disease, as well as for local failure after standard local therapy. Current practice is to administer multimodality therapy, with chemotherapy as the first treatment modality [see Figure 3]. This so-called neoadjuvant chemotherapy often has the effect of downstaging local disease, in some cases making inoperable tumors amenable to surgical resection. Patients are treated with FNA, core-needle, or open incisional biopsy to obtain a tissue diagnosis, hormone receptor data, and HER-2/*neu* status; they then undergo careful restaging after systemic therapy to identify any distant metastases. If the tumor responds to chemotherapy, the patient may then undergo radiation therapy, surgery, or both. Most patients require all three modalities for optimum local and systemic control.

The optimum treatment of patients with stage IIIa breast cancer remains controversial. Some practitioners favor neoadjuvant chemotherapy, whereas others favor surgery followed by chemotherapy and radiation therapy. The choice of surgical procedure for women with locally advanced breast cancer is also controversial. Whereas many surgeons favor mastectomy for all tumors larger than 5 cm, others offer wide excision with axillary dissection to patients in whom excision to clean margins will leave a cosmetically acceptable breast.

Stage IV Cancer

Patients with distant metastases, whether at their initial presentation or after previous treatment for an earlier-stage breast cancer, are rarely cured. Before treatment begins, a tissue diagnosis consistent with breast cancer must be obtained from the primary lesion

(at the initial presentation of the disease) or from a metastasis (if there is any doubt about the metastatic nature of the lesion or the source of the metastatic disease). Any tissue samples obtained should be sent for estrogen and progesterone receptor assays.

The usual first-line treatment for metastatic breast cancer is cytotoxic chemotherapy or hormone therapy [see Figure 4]. Radiation therapy may be used to relieve pain from bone metastases or to avert a pathologic fracture at a site of metastatic disease. There is also occasionally a role for so-called toilet mastectomy for patients who have metastatic disease and a locally advanced and ulcerated primary tumor if the condition of the primary tumor prevents the administration of needed chemotherapy.

Treatment for stage IV breast cancer should be on protocol whenever possible. For patients who are ineligible for therapy on protocol, palliative chemotherapy or hormone therapy may be the best treatment option.

TREATMENT OF MALE BREAST CANCER

Fewer than 1% of all breast carcinomas occur in men. Predisposing risk factors include conditions associated with increased estrogen levels (e.g., cirrhosis and Klinefelter syndrome) and radiation therapy.⁸⁹ In addition, an increased incidence of male breast cancer has been reported in families in which the *BRCA2* mutation has been identified. As with breast cancer in women, the most common tumor type is infiltrating ductal cancer. Because breast cancer tends to be detected at a later stage in men than in women, there is a misconception that male breast cancer has a worse prognosis. Stage for stage, however, the prognosis for men with breast cancer is similar to that for women with breast cancer. To prevent late detection, men with a breast mass must be evaluated with the same degree of suspicion as women with a breast mass are.

Surgical treatment includes mastectomy. In the absence of clinically palpable nodes, SLN biopsy is appropriate for staging the axilla. A large majority of male breast cancers are ER positive, and decisions regarding adjuvant systemic treatment should be made on the same basis as for breast cancer in women.

FOLLOW-UP AFTER TREATMENT

Patients who have been treated for breast cancer remain at risk for both the recurrence of their original tumor and the development of a new primary breast cancer. The rate of recurrence of

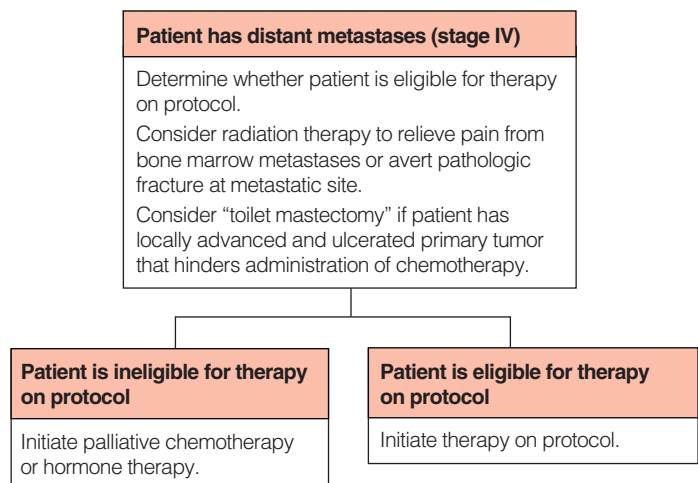

Figure 4 Algorithm illustrates the approach to managing stage IV breast cancer.

breast cancer is nearly linear over the first 10 years after treatment. Recurrence becomes less likely after the first decade, but it continues at a significant rate through the second decade and beyond. In patients who have undergone limited surgery and radiation therapy, radiation-induced breast and chest wall malignancies begin to appear 7 or more years after treatment and continue to appear for at least 20 years after treatment.

Unfortunately, there is little in the way of evidence-based guidance to help the clinician determine the optimal posttreatment surveillance strategy for breast cancer patients. As a result, practice patterns vary considerably with respect to the use of follow-up tests in this population. Exhaustive posttreatment testing does not seem warranted in early-stage breast cancer patients. There is no evidence to support the use of routine bone scans, CT, PET brain imaging, and serum tumor markers in asymptomatic patients after treatment for early-stage disease. The use of such intensive surveillance is based on the presumption that detecting disease recurrence at its earliest stage would offer the best chance of cure, improved survival, or, at least, improved quality of life. Given that the majority of recurrences are detected by patients themselves, educating patients about the symptoms of recurrent disease is likely to be a more effective strategy.

Follow-up of early stage breast cancer patients should include a thorough history and physical examination and mammography. For patients treated with breast conservation, annual mammography is appropriate, beginning after any acute radiation reaction has resolved (generally 6 to 9 months after completion of radiation therapy). For patients treated with mastectomy, mammography should be continued on an annual basis for the contralateral breast. Physical examination and review of symptoms are generally performed at 3- to 6-month intervals for the first 5 years after completion of therapy, though these intervals have not yet been tested in a prospective fashion.

Although there has been little debate about the value of early detection of a local recurrence within the treated breast or of a new primary tumor in either breast, there has been a great deal of debate about the value of early detection of metastatic disease. Two prospective, randomized trials addressed this issue. In one, a group of breast cancer patients was intensively followed with blood tests every 3 months and with chest x-rays, bone scans, and liver ultrasonography annually.⁹⁰ There was no difference in survival or quality of life between this group and the control group, and metastatic disease was diagnosed, on average, less than 1 month earlier in the intensively followed group than in the control group. In the second study, a group of breast cancer patients received chest x-rays and bone scans every 6 months for 5 years.⁹¹ Pulmonary and bone metastases were detected significantly earlier in this group than in the control group, but there was no improvement in survival. This study demonstrated that early detection of metastatic disease could be achieved with short-interval screening, but given current therapeutic options, early detection had no beneficial effect on survival. Both studies concluded that at present, there is no role for routine imaging studies in the follow-up of breast cancer patients and that imaging studies should be ordered only as prompted by clinical findings.

FUTURE DIRECTIONS IN TREATMENT

Breast cancer management is constantly evolving. The trend continues to be toward less extensive and less invasive surgical interventions, without compromising patient outcomes. Ongoing trials are examining the need for radiation therapy after lumpectomy for tumors in elderly women or tumors consisting of pure DCIS. In addition, the use of percutaneous extirpative and abla-

tive local therapies in the management of highly selected patients with breast cancer is being investigated. The need for axillary dissection continues to be questioned, and more and more, the features of the primary tumor, rather than axillary node status, are being used to establish the prognosis and determine the need for adjuvant therapy. Trials of SLN biopsy are under way. Data are also being accumulated on the clinical significance of micrometastatic and molecular amounts of tumor in the SLN.

Many ongoing trials of chemotherapy for breast cancer focus on increasing the efficacy of treatment through dose intensification. Very high dose chemotherapy, in conjunction with administration of growth factor or autologous bone marrow transplantation, is being assessed in the hope that higher-dose chemotherapeutic regimens will improve response rates and duration of response.

The early results from studies of bone marrow transplantation have been somewhat disappointing: median survival is prolonged by only 7 to 10 months beyond what is achievable with more standard chemotherapy.⁹² There is, however, a small but significant group of long-term survivors who remain free of disease for more than 5 years after undergoing bone marrow transplantation to treat breast cancer with 10 or more positive lymph nodes at initial presentation. Trials of improved bone marrow transplantation regimens continue in the hope that the toxicity and cost of the treatment can be reduced and the number of long-term survivors increased.

Immune therapy using antibodies to HER-2/*neu* protein, alone or in conjunction with chemotherapy, is being evaluated for tumors that overexpress the oncogene HER-2/*neu*. At present, there is no definitive evidence that the biologic therapies and immune therapies now available are of significant value in the treatment of breast cancer. These types of therapy continue to be actively explored.

Even more exciting than the prospect of improved therapy is the concept of chemoprevention [see Management of Specific Breast Problems, High-Risk Patients, *above*]. Positive results of trials using tamoxifen for chemoprevention have raised hopes that many breast cancers can be prevented and have increased interest in identifying additional agents that can reduce breast cancer risk with minimal side effects. These results underscore the importance of understanding breast cancer risk factors (including gene mutations) for better identification of women who might benefit from chemoprevention. Ultimately, improved comprehension of the pathophysiologic mechanisms of breast carcinogenesis is essential to the development of biologically based methods for the prevention and treatment of breast cancer.

MULTIDISCIPLINARY BREAST CANCER CARE

Contemporary management of breast cancer demands a multidisciplinary approach involving several specialists, including surgeons, radiation oncologists, medical oncologists, radiologists, and pathologists. It is essential that each specialist have a working knowledge of the others' disciplines as they relate to breast cancer care. This team of physicians, in consultation with the patient, determines the selection and timing of individual treatments. This process is greatly simplified when the physicians concerned are able to coordinate their visits with the patient, thereby both saving time for the patient and facilitating decision making among the various specialists. A number of centers have established multidisciplinary breast centers that allow a patient to see all the specialists in a single visit while also allowing the physicians to consult with each other in reviewing the clinical data, imaging studies, and pathology and in determining treatment options.

Patient education is also becoming more and more critical in the management of breast cancer. Patients are increasingly being asked to participate in decision making, and as hospital stays for breast cancer treatments become shorter, patients are also being asked to participate more actively in their own care. To participate effectively, patients must be educated about the advantages and disadvantages of the various aspects of cancer management. The

shifting of a larger proportion of cancer care to the outpatient setting also necessitates the use of other support services, such as visiting nurses, social workers, and outpatient infusion services. How best to coordinate these complex services while maintaining a focus on the problems and needs of the individual patient remains one of the major challenges faced by physicians caring for patients with breast cancer.

Approach to the Patient with Soft Tissue Infection

Soft tissue infections are a diverse group of diseases that involve the skin and underlying subcutaneous tissue, fascia, or muscle. Such infections may be localized to a small area or may involve a large portion of the body. They may affect any part of the body, though the lower extremities, the perineum, and the abdominal wall are the most common sites of involvement. Some soft tissue infections are relatively harmless if treated promptly and adequately; others can be life-threatening even when appropriately treated. The symptoms and signs range from subtle or nonspecific indicators (e.g., pain, localized tenderness, and edema without fever) to obvious features (e.g., necrosis, blistering, and crepitus associated with systemic toxicity).

Soft tissue infections were first defined as such slightly more than a century ago. In 1883, Fournier described a gangrenous infection of the scrotum that continues to be associated with his name.¹ In 1924, Meleney documented the pathogenic role of streptococci in soft tissue infection.² Shortly thereafter, Brewer and Meleney described progressive polymicrobial postoperative infection of the muscular fascia with necrosis³ (though the term necrotizing fasciitis was not introduced until more than 25 years later⁴). The association between toxic-shock syndrome and streptococcal soft tissue infection was delineated as this disease reemerged in the 1980s.⁵

Various classification systems and eponyms are used to describe specific forms of soft tissue infection [see Discussion, Etiology and Classification of Soft Tissue Infection, below]. In our view, however, it is more important to develop a common approach to the diagnosis and treatment of these conditions than to refine the minor details of classification. For therapeutic purposes, the primary consideration is to distinguish between necrotizing soft tissue infections and nonnecrotizing infections. Nonnecrotizing soft tissue infections involve one or both of the superficial layers of the skin (epidermis and dermis) and the subcutaneous tissue, and they usually respond to antibiotic therapy alone. Necrotizing soft tissue infections may involve not only the skin, the subcutaneous tissue, and the superficial fascia but also the deep fascia and muscle, and they must be treated with urgent surgical debridement. At times, it is difficult to distinguish between these two categories of infection, especially when obvious clinical signs of necrotizing soft tissue infection are absent.

In this chapter, we review diagnosis and management of the main soft tissue infections seen by surgeons, including both superficial infections (e.g., pyoderma, animal and human bites, and cellulitis) and necrotizing infections involving superficial and deep tissues [see Table 1].

Clinical Evaluation

The diagnosis of soft tissue infection is usually made on the basis of the history and the physical examination. Patients typically seek medical attention because of pain, tenderness, and erythema of recent onset. They should be asked about environmental factors that may have disrupted the normal skin barrier [see

Table 2], as well as about any host factors that may increase their susceptibility to infection and limit their ability to contain it. It is particularly important that they be questioned about specific clinical scenarios associated with unusual pathogens, such as an animal bite (associated with *Pasteurella multocida*), a human bite (*Eikenella corrodens*), chronic skin disease (*Staphylococcus aureus*), saltwater exposure (*Vibrio vulnificus*), and freshwater exposure (*Aeromonas hydrophila*).

Physical examination usually reveals erythema, tenderness, and induration. Vesicular lesions and honey-colored crusted plaques are seen in patients with impetigo. Intense, sharply demarcated erythema is characteristic of erysipelas. A tender, swollen erythematous papule, often containing a visible hair shaft, is indicative of folliculitis. A single painful, tender, indurated, erythematous skin nodule suggests a furuncle, and the presence of multiple inflammatory nodules with sinus tracts is consistent with a carbuncle. Cellulitis in association with a decubitus ulcer or an ischemic leg ulcer frequently signals a polymicrobial infection with gram-negative organisms. An erythematous linear streak, characteristic of lymphangitis, usually indicates a superficial infection secondary to *Streptococcus pyogenes*; associated lymphadenopathy may be present as well.

Patients with necrotizing soft tissue infections often complain of severe pain that is out of proportion to their physical findings. Compared with patients who have nonnecrotizing infections, they are more likely to have fever, bullae, or blebs [see Figure 1]; signs of systemic toxicity; hyponatremia; and leukocytosis with a shift in immature forms. Physical findings characteristic of a necrotizing infection include tenderness beyond the area of erythema, crepitus, cutaneous anesthesia, and cellulitis that is refractory to antibiotic therapy.⁶ Tenderness beyond the borders of the erythematous area is an especially important clinical clue that develops as the infection in the deeper cutaneous layers undermines the skin.

Table 1 Common Soft Tissue Infections

Burns
Skin diseases (e.g., atopic dermatitis, tinea pedis, eczema, scabies, varicella infection, or angular cheilitis)
Decubitus, venous stasis, or ischemic ulcers
Contaminated surgical incisions

Early in the course of a necrotizing soft tissue infection, skin changes may be minimal despite extensive necrosis of the deeper cutaneous layers. Bullae, blebs, cutaneous anesthesia, and skin necrosis occur as a result of thrombosis of the nutrient vessels and destruction of the cutaneous nerves of the skin, which typically occur late in the course of infection.

Clinicians should be mindful of certain diagnostic barriers that may delay recognition and treatment of necrotizing soft tissue infections.⁷ In particular, such infections may have a variable clinical presentation. Although most patients present with an acute, rapidly progressive illness and signs of systemic toxicity, a subset of patients may present with a more indolent, slowly progressive infection. Patients with postoperative necrotizing infections often have a more indolent course. Moreover, in the early stages, underlying necrosis may be masked by normal-appearing overlying skin. As many as 20% of necrotizing soft tissue infections are primary (idiopathic) and occur in previously healthy patients who have no predisposing factors and no known portal of entry for bacterial inoculation. Finally, crepitus is noted in only 30% of patients with necrotizing soft tissue infections.

Investigative Studies

Diagnostic studies have a low yield in patients with superficial soft tissue infections. They are rarely necessary and are used only in specific clinical circumstances. Either needle aspiration at the

Figure 1 Lower-extremity necrotizing fasciitis is characterized by bullae, blebs, and discolored skin.

advancing edge of erythema with Gram staining and culture or full-thickness skin biopsy and culture may be helpful when cellulitis is refractory to antibiotic therapy or when an unusual causative organism is suspected. Because of their low yield, blood cultures are obtained only in patients with signs of systemic toxicity, those with buccal or periorbital cellulitis, and those with infection suspected of being secondary to saltwater or freshwater exposure; these clinical situations are associated with a higher likelihood of a positive culture.

When the characteristic clinical features of necrotizing soft tissue infection are absent, diagnosis may be difficult. In this setting, laboratory and imaging studies become important [see Figure 2]. In one study, logistic regression analysis showed that a white blood cell (WBC) count equal to or greater than 15,400/mm³ and a serum sodium level lower than 135 mmol/L at the time of hospital admission were predictive of a necrotizing soft tissue infection.⁸ A WBC count lower than 15,400/mm³ and a serum sodium level equal to or greater than 135 mmol/L in a patient without obvious clinical signs of a necrotizing soft tissue infection had a negative predictive value of 99%. A normal serum creatine kinase (CK) level rules out muscle necrosis.

A plain x-ray of the involved area demonstrates soft tissue gas in only 15% to 30% of patients with necrotizing infections [see Figure 3].⁶ Computed tomography is more sensitive in identifying soft tissue gas, but other CT findings are seldom diagnostic.

Magnetic resonance imaging is currently the preferred imaging study for documenting deep necrotizing infections [see Figure 4]. The presence of soft tissue gas on MRI is diagnostic of a necrotizing soft tissue infection. Edema and inflammatory changes of the deep soft tissues identified by MRI are suggestive of necrotizing soft tissue infection. High signal intensity on T₂-weighted images and tissue enhancement after gadolinium administration are indicative of inflamed soft tissue. The absence of gadolinium enhancement on T₁-weighted images is indicative of nonperfused tissue and necrosis.^{9,10} The sensitivity of MRI in this setting is 89% to 100%, and the specificity is 46% to 86%.^{9,11}

The finding of soft tissue gas on diagnostic imaging warrants immediate operative exploration and debridement. Because of the high sensitivity of MRI, necrotizing infection can be excluded when no involvement of the superficial fascia, subcutaneous tissue, or the deeper cutaneous layers is demonstrated. However, the inflammatory changes seen on MRI when necrotizing soft tissue infection is present may also be seen in patients with non-necrotizing infections, as well as in those with other inflammatory conditions affecting the deep soft tissues. Because of the relatively low specificity of this study, biopsy of the deeper cutaneous layers, with frozen-section examination and culture, may be needed to diagnose or rule out soft tissue infection [see Figure 2]. This procedure may be performed at the bedside with local anesthesia. The observation of necrotic or infected tissue through the biopsy incision indicates that immediate debridement is needed.

General Management of Nonnecrotizing and Necrotizing Soft Tissue Infection

NONNECROTIZING INFECTION

Antibiotic therapy is the cornerstone of treatment for patients with nonnecrotizing infections. Such patients usually require antibiotics that are effective against group A streptococci or *S. aureus*. Topical, oral, or intravenous preparations may be employed, depending on the nature and severity of the disease process [see Management of Specific Soft Tissue Infections, below]. If polymy-

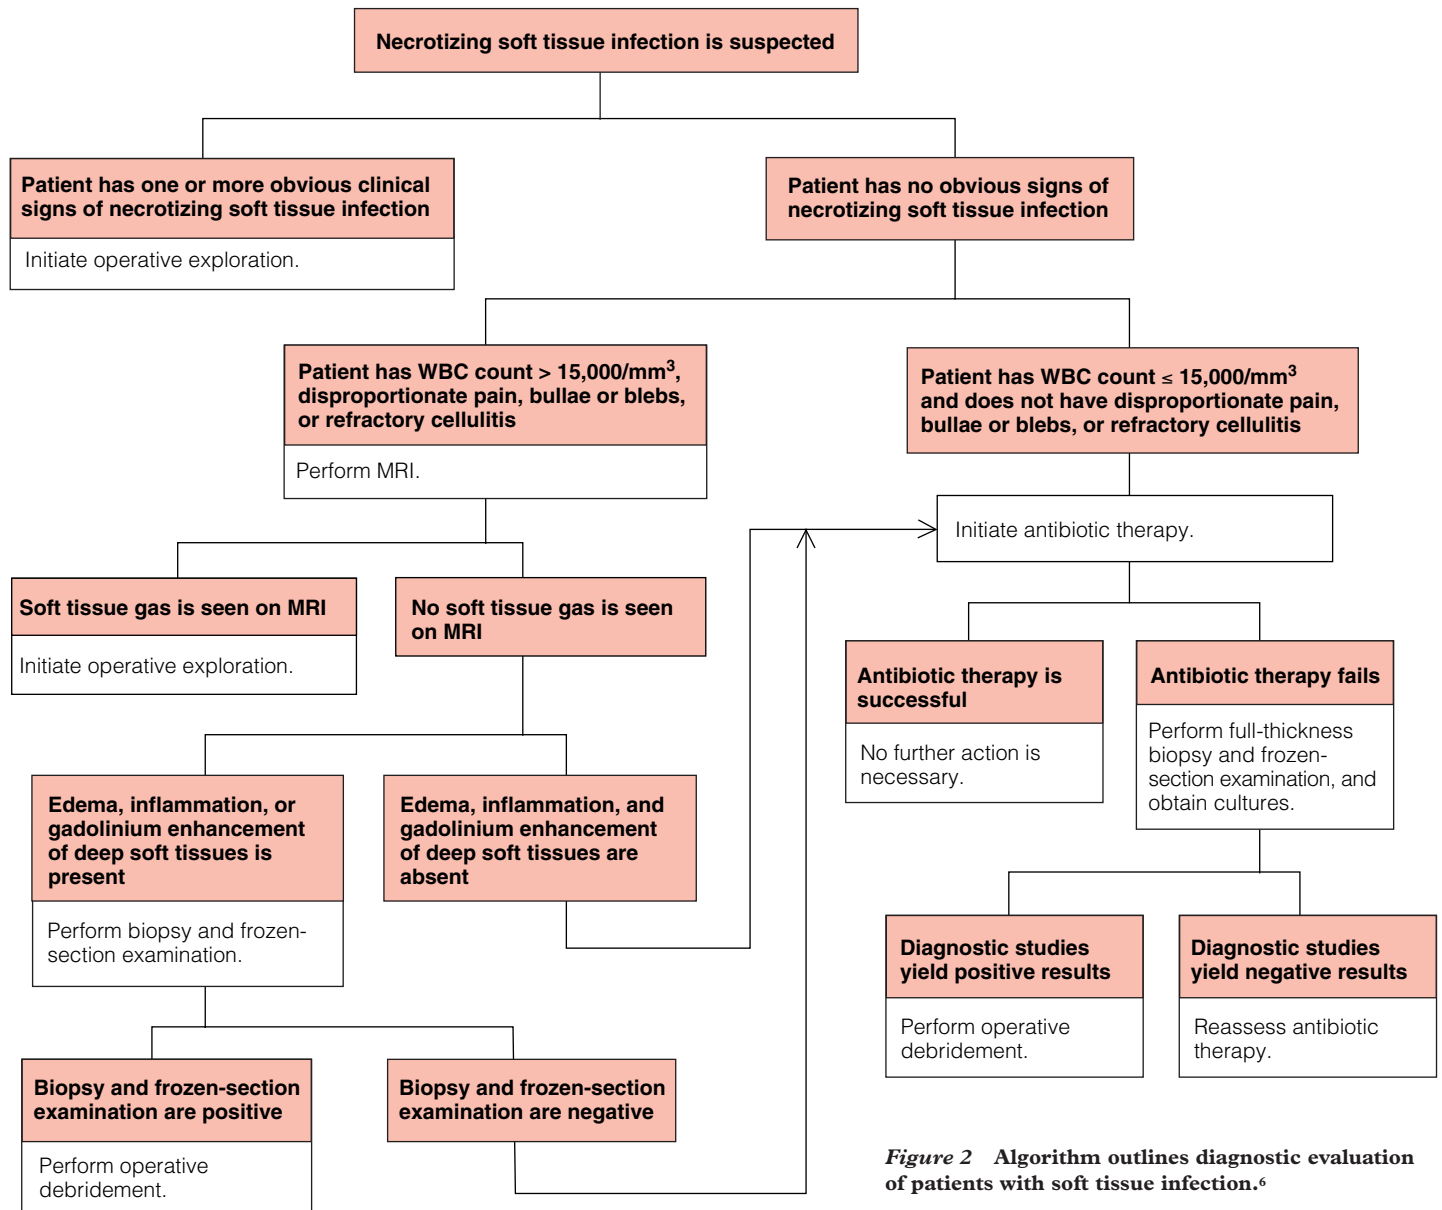

Figure 2 Algorithm outlines diagnostic evaluation of patients with soft tissue infection.⁶

crobal infection is suspected, broad-spectrum antimicrobial agents should be given, either alone or in combination.

NECROTIZING INFECTION

Management of necrotizing soft tissue infections is predicated on early recognition of symptoms and signs and on emergency operative debridement. Once the diagnosis of necrotizing soft tissue infection is established, patient survival and limb salvage are best achieved by means of prompt operation; precise identification of the causative bacteria and correct assignment of the patient to a specific clinical syndrome are unnecessary. The delay between hospital admission and initial debridement is the most critical factor influencing morbidity and mortality: a number of reports have demonstrated a strong correlation between survival and the interval between onset of symptoms and initial operation.¹²⁻¹⁵

The components of treatment of necrotizing soft tissue infection are (1) resuscitation and correction of fluid and electrolyte disorders, (2) physiologic support, (3) broad-spectrum antimicrobial therapy, (4) urgent and thorough debridement of necrotic tissue, and (5) supportive care [see *Figure 5*].

Nonoperative Measures

Patients with necrotizing soft tissue infections frequently present with tachycardia and hypotension, reflecting depleted intravascular volume and possible septic shock. Such patients often exhibit extensive extracellular fluid sequestration within the affected area, as well as more generalized sequestration resulting from sepsis. A balanced isotonic electrolyte solution, such as lactated Ringer solution (or 0.9% normal saline, for patients with renal dysfunction), is administered to replace these fluid deficits. The adequacy of intravascular volume repletion is often assessed by monitoring urinary output; however, it sometimes proves necessary to use a central venous catheter to monitor central venous or pulmonary arterial pressure in patients with associated myocardial dysfunction, septic shock, chronic pulmonary disease, renal insufficiency, or other severe chronic illnesses.

Hyponatremia is usually corrected by infusing isotonic fluids. Hypocalcemia, which can result from calcium precipitation in patients with extensive fat necrosis, is usually corrected by administering I.V. calcium gluconate. Hyperglycemia is corrected with insulin, given via either subcutaneous injection or, for patients with

Figure 3 Upper-extremity x-ray of a patient with necrotizing soft tissue infection demonstrates soft tissue gas outlining the muscles.

Figure 4 Lower-extremity MRI of a patient with necrotizing fasciitis of the left leg demonstrates inflammatory changes typical of necrosis.

more severe abnormalities, via I.V. infusion. Lactic acidosis generally responds to fluid administration. Renal function is assessed by measuring blood urea nitrogen (BUN) and serum creatinine concentrations. CK levels should be monitored and a qualitative evaluation of urine myoglobin done if muscle necrosis is suspected or renal failure is present. Myoglobinuria and elevated CK levels are suggestive of myonecrosis. Anemia is treated with packed red blood cell transfusions.

Patients whose hypotension does not resolve with appropriate intravascular fluid resuscitation often experience septic shock. In these circumstances, low dosages of I.V. dopamine (5 to 10 $\mu\text{g}/\text{kg}/\text{min}$), vasopressin (0.1 to 0.4 IU/min), or norepinephrine (0.02 to 0.08 $\mu\text{g}/\text{kg}/\text{min}$) are useful for raising blood pressure and improving myocardial function.

Patients with traumatic wounds or other contaminated sites should receive tetanus toxoid or human tetanus immunoglobulin, depending on their immunization status.

Hyperbaric oxygen has been advocated as adjunctive therapy for extensive necrotizing infections, particularly those caused by clostridia.¹⁶ The beneficial properties of hyperbaric oxygen include inhibition of bacterial exotoxin production [see Discussion,

Pathogenesis of Soft Tissue Infections, *below*], improved leukocyte function, and attainment of tissue oxygen levels that are bactericidal for *Clostridium perfringens* and bacteriostatic for other anaerobic bacteria. Hyperbaric oxygen does not, however, neutralize exotoxin that has already been released.¹⁶ At present, except for some data from retrospective studies, there is little evidence supporting the benefits of hyperbaric oxygen therapy. Such therapy has not been demonstrated to improve survival or to bring about earlier resolution of necrotizing soft tissue infection, and it has been associated with barotrauma, pneumothorax, and oxygen toxicity. Accordingly, we believe that operative debridement should not be delayed to accommodate hyperbaric oxygen therapy and that such therapy should not be considered a substitute for complete debridement of infected nonviable tissues.

I.V. antimicrobial therapy is indicated in all patients with necrotizing soft tissue infections [see Table 3]. Such therapy is important, but it is not a substitute for prompt and adequate operative debridement. Necrotizing soft tissue infections are usually caused by a mixed polymicrobial bacterial flora [see Table 4]. Approximately 25% to 30% of necrotizing soft tissue infections are monomicrobial. Although *S. pyogenes* is the bacterium most frequently involved, the microbiology of the infections often cannot be accurately predicted before final identification of organisms on culture. Thus, the empirical antibiotic regimen chosen should be effective against a diverse group of potential pathogens.¹⁷ In addition, because these patients have a high incidence of associated nosocomial infections and even of metastatic infections, it is

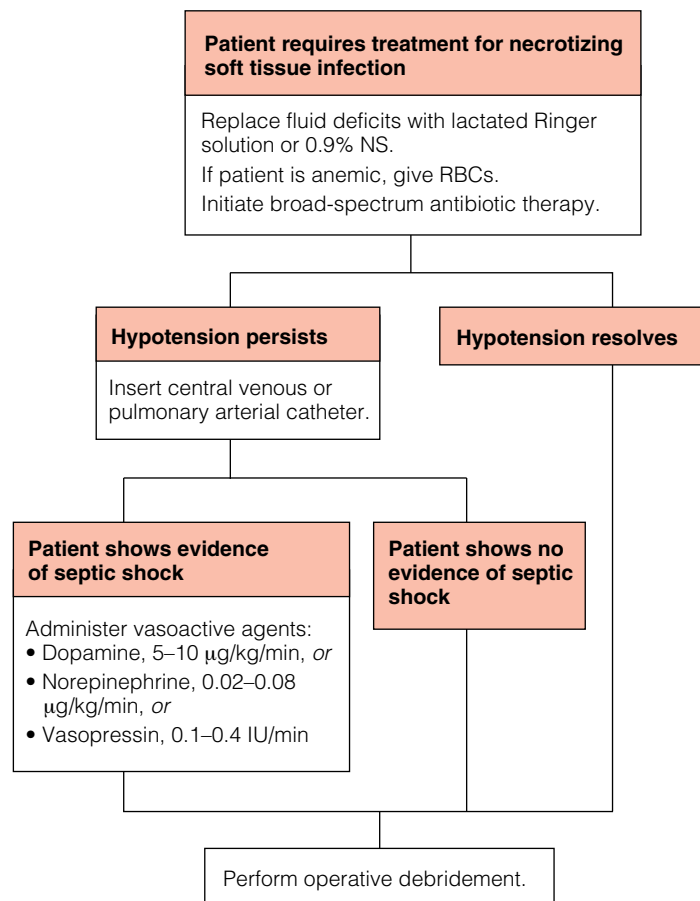

Figure 5 Algorithm outlines treatment of necrotizing soft tissue infection.

Table 3 I.V. Antibiotic Dosages for Adult Patients with Necrotizing Soft Tissue Infection and Normal Renal Function

Single agents	Ampicillin-sulbactam Imipenem-cilastatin Meropenem Piperacillin-tazobactam Ticarcillin-clavulanate	3 g q. 6 hr 500–1,000 mg q. 6 hr 1 g q. 8 hr 3.375 g q. 6 hr 3.1 g q. 6 hr
Agents used in combination regimens	Aerobic/facultative coverage Ampicillin Cefotaxime Ceftazidime Cefuroxime Ciprofloxacin Gentamicin Vancomycin Anaerobic coverage Clindamycin Metronidazole	2 g q. 6 hr 1–2 g q. 8 hr 1 g q. 8 hr 1.5 g q. 8 hr 400 mg q. 12 hr 1.7 mg/kg q. 8 hr 1 g q. 12 hr 900 mg q. 8 hr 500 mg q. 6 hr

important to ensure that the dosage is high enough to achieve adequate serum concentrations.^{13,14} Once the results of intraoperative culture and antimicrobial sensitivity testing become available, antibiotic therapy is adjusted accordingly. This adjustment can be challenging, in that all of the pathogens identified must be treated.

I.V. antimicrobial therapy is continued until operative debridement is complete, there is no further evidence of infection in the involved tissues, and signs of systemic toxicity have resolved. Topical antiseptic agents (e.g., Dakin solution and Burrow solution) may help control infection that progresses despite adequate debridement and I.V. antibiotics. Topical application of mycostatin powder may help control progressive fungal infection. When patients are able to resume oral intake, they can often be switched from I.V. to oral antimicrobial therapy.

Operative Treatment

The most critical factors for reducing mortality from necrotizing soft tissue infections are early recognition and urgent operative debridement.^{12,13,15,18} The extent of debridement depends on intraoperative findings and cannot be accurately predicted before operation. Operative intervention serves to limit tissue damage by removing necrotic tissue, which serves as a nidus for infection.

Thorough exploration is necessary to confirm the diagnosis of necrotizing soft tissue infection and determine the degree of involvement. Aggressive, widespread debridement of all apparent necrotic, infected tissue is essential; antibiotics will not penetrate dead tissues. The underlying necrosis of subcutaneous tissues, fascia, and muscle typically extends beyond the obvious limits of cutaneous involvement. Operative debridement should therefore be continued until viable tissue is reached. The presence of arterial bleeding generally indicates that tissues are viable; in the absence of arterial bleeding, tissues are nonviable even if venous bleeding is present. With deep necrotizing infections, debridement of the necrotic fascia and muscle may create large skin flaps that are poorly perfused. It is best to preserve as much viable skin and subcutaneous tissue as possible because these tissues can be essential for later coverage of the wound. Nonviable skin, however, should be resected.

Wound drainage or exudate should be submitted for Gram staining, as well as for aerobic, anaerobic, and fungal cultures and antimicrobial sensitivity testing. Fasciotomy is rarely required. The presence of subcutaneous gas extending beyond areas of

nonviable tissue does not necessitate debridement if the surrounding tissues are viable. It is sometimes helpful to perform an exploratory incision over an area beyond the limits of debridement when it is uncertain whether necrosis is undermining viable skin. If no necrotizing infection is found, the incision may be closed primarily.

Reexploration should be routinely performed within 24 to 36 hours to ensure that all necrotic tissue has been debrided. Debridement is repeated as necessary until the infection is controlled. If repeated debridement does not control infection, if there are persistent, fulminant infections of the extremities, or if an extremity remains nonfunctional after debridement has been completed, amputation can be lifesaving. Amputation is most often required for patients with clostridial myonecrosis and for diabetic patients with necrotizing fasciitis.¹⁵ In two large series of patients with necrotizing soft tissue infections, the incidence of amputation was approximately 15% to 25%.^{12,13}

Patients with necrotizing soft tissue infections involving the perineum and perirectal areas may need a diverting colostomy to prevent tissue contamination resulting from defecation and to control local infection. Overall, this measure is required in fewer than 25% of cases.¹³

After debridement, the exposed areas should be treated with 0.9% normal saline wet-to-dry dressings. Once the initial infection has been controlled and debridement is no longer necessary, dressing changes can often be performed at the bedside after sufficient analgesics have been given to achieve adequate pain management. Patient-controlled analgesia is frequently useful early in the course of treatment. Propofol or ketamine can be given in the intensive care unit to facilitate pain control during dressing changes.

Early enteral or parenteral nutritional support should be instituted to optimize recovery. Nutritional support should begin once resuscitation is complete, the infection is adequately controlled, and the signs of sepsis have resolved. Because it frequently proves necessary to return the patient to the operating room, enteral feeding tubes should be placed beyond the pylorus so that enteral nutrition can be provided without interruption. Alternatively, parenteral nutrition may be employed.

Once the localized infection is under control and the patient is recovering, the exposed soft tissues should be covered. This is

Table 4 Organisms Causing Necrotizing Soft Tissue Infection

Aerobes	Gram-positive Group A <i>Streptococcus</i> <i>Enterococcus</i> species <i>Staphylococcus aureus</i> Group B <i>Streptococcus</i> <i>Bacillus</i> species Gram-negative <i>Escherichia coli</i> <i>Pseudomonas aeruginosa</i> <i>Enterobacter cloacae</i> <i>Klebsiella</i> species <i>Serratia</i> species <i>Acinetobacter calcoaceticus</i> <i>Vibrio vulnificus</i>
Anaerobes	<i>Bacteroides</i> species <i>Clostridium</i> species <i>Peptostreptococcus</i> species

most commonly done with split-thickness skin grafting, though other reconstructive procedures (e.g., rotational flaps) [see 3:7 *Surface Reconstruction Procedures*] can be effective in this setting as well. Vacuum-assisted closure devices can reduce the exposed surface area and lessen the need for skin graft coverage. Exposed tendons, nerves, or bone often should be covered with full-thickness skin to prevent desiccation and preserve limb function. Premature closure of highly contaminated or persistently infected sites usually fails and leads to recurrence of infection and a greater likelihood of death.

When the abdominal or chest wall has been excised to control infection, reconstruction is necessary. Polypropylene prosthetic mesh is useful for restoring continuity of the abdomen or the chest wall, and overlying moist dressings can help prevent desiccation of underlying viscera. Some have advocated using absorbable mesh for restoration of abdominal wall continuity; however, we prefer to use permanent mesh in most circumstances.¹³

Mortality from necrotizing soft tissue infection ranges from 21% to 29%.^{12,13,15,18,19} Risk factors for mortality include age greater than 60 years, the presence of associated chronic illnesses, a relatively high percentage of total body surface area involved, and, most important, delays in recognition and treatment.^{12,13,15} Patients with truncal involvement or positive blood cultures also have a higher mortality.^{12,19}

Management of Specific Soft Tissue Infections

Normal skin functions as a protective barrier that prevents microorganisms from causing soft tissue infection. The skin, or cutis, is made up of two layers, the epidermis and the dermis [see *Figure 6*]. The epidermis, the outer avascular epithelial layer, functions as a permeability barrier for the rest of the body. The dermis, the inner layer, contains blood vessels, lymphatic vessels, sweat and sebaceous glands, and hair follicles. The subcutaneous tissue separates the skin from the deep fascia, muscle, and bone. Typically, soft tissue infections result from disruption of the skin by some exogenous factor; less commonly, they result from extension of a subjacent infection or hematogenous spread from a distant site of infection.

SUPERFICIAL INFECTIONS

Superficial infections constitute the majority of soft tissue infections. They primarily involve the epidermis or dermis (pyoderma) or the subcutaneous tissue (cellulitis) and secondarily occur in skin damaged by animal or human bites. Nonnecrotizing superficial soft tissue infections are principally treated with antibiotics. Necrosis is rare but may develop in superficial infections that are inadequately treated or neglected.

Pyoderma

Pyoderma is a general term referring to a bacterial infection of the skin. It may be divided into several subcategories, such as impetigo, erysipelas, folliculitis, and furuncles and carbuncles.

Impetigo Impetigo is a highly contagious bacterial infection that is confined to the epidermis and that usually involves the face or the extremities. It is most common in infants and preschool children and is seen more frequently in patients with preexisting skin conditions (e.g., eczema, atopic dermatitis, varicella infection, angular cheilitis, and scabies). Warm and humid weather, crowded living conditions, and poor hygiene can all contribute to the development of impetigo.²⁰ The dominant pathogen is *S. aureus*, which causes either a bullous or a nonbullous form of the

Figure 6 Depicted is the normal anatomy of the skin and the deeper cutaneous layers.⁶

disease; a less common pathogen is *S. pyogenes*, which causes a nonbullous form.²¹

Impetigo usually occurs in areas of skin breakdown, though *S. aureus* may give rise to de novo infection in normal skin. Bullous impetigo is manifested by numerous blisters or bullae that rapidly become pustules, then rupture within 1 to 2 days to form a thick, honey-colored, crusted plaque that remains for days to weeks. Nonbullous impetigo is characterized by erythema and tiny, less prominent vesicles that progress to crusted erosions in the skin. The skin lesions are intensely pruritic, and local spread may occur as a result of scratching and release of infected fluid from the blisters, bullae, or vesicles. Associated regional lymphadenopathy is common. Glomerulonephritis may complicate streptococcal-induced impetigo.^{21,22}

The diagnosis is established by Gram stain and culture of the vesicular fluid or the crusted plaque. The skin lesions usually resolve spontaneously within 2 to 3 weeks.²² Antibiotic therapy accelerates the resolution of these lesions. Mupirocin ointment (2%) is applied topically three times a day until the lesions clear. This agent possesses excellent *in vitro* activity against both staphylococci and streptococci and achieves high rates of cure in patients with localized disease. Erythromycin and clindamycin ointments are acceptable alternatives [see *Table 5*]. For patients who have disseminated impetigo or impetigo of the scalp or mouth and those in whom topical therapy fails, an oral antibiotic (e.g., dicloxacillin, cephalexin, cefadroxil, erythromycin, or clindamycin) may be used [see *Table 5*]. A 7-day course of oral antibiotic therapy is usually sufficient.²²

Erysipelas Erysipelas is an acute bacterial infection that principally involves the dermis. It is almost invariably caused by *S. pyo-*

genes. Most cases are preceded by influenzalike symptoms. Infection extends through the dermal lymphatic vessels and is typically manifested by a tender, pruritic, intensely erythematous, sharply demarcated, and raised plaque. Patients complain of pain, often in conjunction with high fever, increased skin warmth, and leukocytosis. Lymphangitis and lymphadenopathy are sometimes present as well. The leg is the most common site of involvement, but erysipelas may also occur on the face, the arms, and the upper thighs.

The factors predisposing to the development of erysipelas of the extremity include local conditions such as tinea pedis (athlete's foot), leg ulcers, and venous stasis dermatitis.²³ Erysipelas tends to be more common in the presence of associated conditions such as lymphedema, diabetes mellitus, alcoholism, immunocompromise, and obesity,^{21,23} and it is more likely to recur in patients with these associated diseases and in those whose underlying skin conditions are inadequately treated. Erysipelas recurs in 10% of patients within 6 months of their first episode and in 30% within 3 years.²³

The standard antibiotic treatment for uncomplicated erysipelas is penicillin, which is effective in at least 80% of cases. Oral and intravenous antibiotic regimens are equally efficacious. Amoxicillin appears to work as well as penicillin. Patients with erysipelas of the lower extremity should be placed on bed rest, and the involved leg should be elevated to reduce edema and pain. Once the patient is able to resume normal activities, he or she should be fitted with elastic stockings, which help reduce the recurrence of edema and lower the risk of lymphedema. For patients with tinea pedis, a topical antifungal agent is used to treat the infection and prevent recurrence.

Folliculitis Folliculitis is an infection of the hair follicle that is typically caused by *S. aureus*. It is characterized by a painful, tender, erythematous papule with a central pustule. A shaft of hair is often seen in the center of the pustule. Shaving, plucking, waxing, heat and humidity, the use of corticosteroids or antibiotics, immunosuppression, and occlusion of the skin by clothing, adhesives, or plastics may predispose to folliculitis.²⁰ Single or multiple lesions may occur in the skin of any hair-bearing area. If the pustule ruptures, superficial erosion often ensues. Infection that principally involves the deeper part of the hair follicle is characterized by a tender, swollen papule without an associated pustule at the skin surface.

In rare cases, folliculitis is caused by pathogens other than *S. aureus*, such as *Pseudomonas aeruginosa*, *Klebsiella* species, *Enterobacter* species, *Proteus* species, yeasts, and fungi. *Pseudomonas* folliculitis usually results from exposure to inadequately chlorinated water in swimming pools, hot tubs, or whirlpools. Patients with this infection have multiple papular or pustular lesions on the back, the buttocks, and the extremities, along with fever and malaise appearing 6 hours to 3 days after exposure.^{22,24} Organisms may be cultured either from the pustules or from the infected water. *Klebsiella*, *Enterobacter*, and *Proteus* species can cause folliculitis in patients receiving long-term antibiotic therapy for acne vulgaris.²¹ Yeast folliculitis and fungal folliculitis tend to occur in immunocompromised patients.²¹

In most patients, folliculitis resolves spontaneously within 7 to 10 days.²² Topical therapy with clindamycin, erythromycin, or mupirocin ointments or benzoyl peroxide in combination with warm soaks may accelerate resolution [see Table 5]. Isotretinoin can be used to treat gram-negative folliculitis. Gentamicin cream may be helpful in drying out the pustular lesions in patients with *Pseudomonas* folliculitis.

In patients with refractory or disseminated follicular infections, oral antibiotic therapy is indicated. When *S. aureus* is considered the most likely pathogen, dicloxacillin, erythromycin, cephalexin, cefadroxil, or clindamycin may be given; oral ciprofloxacin is indicated for the treatment of gram-negative folliculitis [see Table 5]. Elimination of predisposing factors is important for reducing the likelihood of recurrence.

Furuncles and carbuncles Furuncles and carbuncles are deeper infections of the hair follicle that extend beyond the hair follicle to involve the subcutaneous tissue. For both, *S. aureus* is the usual causative organism.

A furuncle, or boil, is a small abscess, manifested as a firm, tender, erythematous nodule that tends to occur in skin areas exposed to friction (e.g., the inner thighs and the axilla). Furuncles also may occur on the face, the neck, the upper back, and the buttocks. Possible predisposing factors include increased friction and perspiration (as seen in obese individuals or athletes), corticosteroid use, diabetes mellitus, and inherited or acquired defects in neutrophil function.^{20,22}

Initial treatment consists of applying warm compresses to help promote drainage and administering an oral antimicrobial agent that is effective against *S. aureus* (e.g., dicloxacillin, cephalexin, cefadroxil, erythromycin, or clindamycin) [see Table 5]. With time, the furuncle becomes fluctuant, and the pus coalesces at the skin surface. An incision-and-drainage procedure is necessary when these lesions do not drain spontaneously. This procedure should be performed with local anesthesia, and care should be taken to open the abscess cavity completely. Lesions that have drained spontaneously should be examined to confirm that the cavity has been opened sufficiently. Failure to drain these lesions adequately

†Adult dosage and pediatric dosage are the same.

ly may result in recurrence, as well as in progression to a more serious infection.

A carbuncle is a deep cutaneous infection involving multiple hair follicles that is characterized by destruction of fibrous tissue septa and consequent formation of a series of interconnected abscesses. It is typically manifested by a painful, red, tender, indurated area of skin with multiple sinus tracts. Systemic manifestations (e.g., fever and malaise) are common. Carbuncles occur most frequently on the nape of the neck, the upper part of the back, or the posterior thigh. The thickness of the overlying skin in these areas leads to lateral extension of the infection and loculation. Patients commonly present with relatively large skin lesions that represent a confluence of inflammatory nodules. These lesions are associated with chronic drainage, sinus tracts, and scarring.

An incision-and-drainage procedure is recommended when a fluctuant carbuncle is present. A thorough search for loculated areas should be undertaken to facilitate drainage of deeper accumulations of pus and to ensure adequate treatment. Wide local excision of the involved skin and subcutaneous fat is often necessary to prevent recurrent disease. An oral antistaphylococcal agent should be given. All patients with hair follicle infections should cleanse the site with chlorhexidine or an iodine-containing solution.

Infections Developing in Damaged Skin

Damage to skin as a result of animal or human bites predisposes patients to soft tissue infection. An estimated 50% of all Americans will be bitten by an animal or by another human being during their lifetime.²⁵ Animal and human bites account for approximately 1% of all emergency department visits.²⁵ Soft tissue infection is the most common complication of such bites. The risk of infection depends on the type of bite, the site of injury, the time elapsed from the bite until presentation, host factors, and the management of the wound [see Table 6].

Most animal and human bites produce minor injuries for which patients do not seek medical attention. The overall risk of infection after a bite is estimated to be 5% to 15%²⁶; however, among the subset of patients who seek medical attention, estimated infection rates range from 2% to 20% for dog bites, from 30% to more than 50% for cat bites, and from 10% to 50% for human bites.²⁷ Most patients with an infected bite can be managed on an outpatient basis with oral antibiotic therapy and elevation of the involved site.

Animal bites In the United States, dog bites account for 80% to 90% of all animal bites, cat bites for 3% to 15%.^{27,28} Nondomestic animals are responsible for only 1% to 2% of all animal bites. Patients with infections resulting from animal bites typically present with significant pain, soft tissue swelling, and tenderness; they may also have associated injuries to nerves, tendons, bones, joints, or blood vessels. Bites involving the hand are associated with an increased risk of tenosynovitis, septic arthritis, and abscess formation.²⁷

Infections that occur after a dog or cat bite are usually polymicrobial, involving a mixture of aerobes and anaerobes [see Table 7]. *P. multocida* is the major pathogen, isolated from 50% to 80% of infections related to cat bites and from 25% of those related to dog bites.^{25,27} Infection with *P. multocida* is characterized by the acute onset of severe pain, tenderness, and swelling, usually within 12 to 18 hours of the bite. In rare cases (usually involving immunocompromised patients), *Capnocytophaga canimorsus* causes soft tissue infection after a dog or cat bite. *C. canimorsus* infection can be quite serious, leading to overwhelming sepsis; the associated mortality is 25% to 30%.²⁷⁻²⁹

Table 6 Risk Factors for Soft Tissue Infection Complicating Animal or Human Bite

Location on the hand or the foot or over a major joint	Immunosuppression
Location on the scalp or the face of an infant	Chronic alcoholism
Puncture wound	Diabetes mellitus
Delay in treatment lasting longer than 12 hr	Corticosteroid use
	Preexisting edema in an affected extremity

Wounds resulting from animal bites should immediately be washed with soap and water. When seen early, dog bites should be copiously irrigated, debrided, and, in most circumstances, closed. Infected wounds, wounds older than 12 hours, cat bites, and bites on the hand should be left open. In all cases of infection related to an animal bite, aerobic and anaerobic cultures should be obtained from the site of infection. Tetanus immune status should be determined, and immunization against tetanus should be provided when appropriate. In cases of bites from nondomestic carnivores (e.g., bats, skunks, raccoons, foxes, or coyotes), wounds should be irrigated with povidone-iodine to reduce the transmission of rabies, and immunization against rabies should be provided.

Patients with established soft tissue infection and patients with noninfected bites who have risk factors for infection should receive antibiotic therapy [see Table 6]. A broad-spectrum antibiotic effective against aerobic and anaerobic organisms should be chosen [see Table 5]. Amoxicillin-clavulanate is the antibiotic of choice because of its broad spectrum of activity against common pathogens; trimethoprim-sulfamethoxazole, doxycycline, and ciprofloxacin are also used [see Table 5]. Infections secondary to *P. multocida* respond to oral treatment with penicillin V, amoxicillin, cefuroxime, or ciprofloxacin.²⁷ Infections secondary to *C. canimorsus* respond to penicillin, ampicillin, ciprofloxacin, erythromycin, or doxycycline. Whether antibiotics are indicated for a fresh animal bite in a patient with a low risk of infection is controversial. Because it is difficult to predict which bite wounds will become infected, some experts advocate routine antibiotic treatment of all dog bites for at least 3 to 5 days.²⁵

Human bites Human bites may be classified as either occlusional bites (in which teeth puncture the skin) or clenched-fist injuries (in which the hand is injured after contact with teeth).^{27,29}

Table 7 Organisms Most Frequently Isolated from Dog- and Cat-Bite Wounds

Aerobes	<i>Pasteurella multocida</i> <i>Corynebacterium</i> species <i>Staphylococcus</i> species <i>Streptococcus</i> species <i>Capnocytophaga canimorsus</i> (rare)
Anaerobes	<i>Bacteroides</i> species <i>Prevotella</i> species <i>Porphyromonas</i> species Peptostreptococci <i>Fusobacterium</i> species <i>Bacteroides fragilis</i> <i>Veillonella parvula</i>

Occlusional bites carry roughly the same risk of infection as animal bites, except when they occur on the hand. Clenched-fist injuries and all hand injuries are associated with a higher risk of infection. Clenched-fist injuries typically occur at the third metacarpophalangeal joint. Penetration of the metacarpophalangeal joint capsule may occur, with subsequent development of septic arthritis and osteomyelitis.²⁵

Soft tissue infections resulting from human bites are polymicrobial, involving a mixture of aerobes and anaerobes. On average, five different microorganisms are isolated from a human-bite wound²⁷—significantly more than are usually isolated from an animal-bite wound. In addition, the concentration of bacteria in the oral cavity is higher in humans than in animals. The anaerobic bacteria isolated from human-bite wounds are similar to those that cause infection after dog and cat bites, except that *Bacteroides* species are more common [see Table 7]. Unlike the anaerobic pathogens in dog and cat bites, however, those involved in human-bite infections often produce β -lactamases.²⁷ The predominant aerobic organisms in human-bite infections are *S. aureus*, *Staphylococcus epidermidis*, α - and β -hemolytic streptococci, *Corynebacterium* species, and *E. corrodens*. *E. corrodens* is a fastidious facultative aerobic gram-negative rod that is cultured from approximately 25% of clenched-fist injuries and frequently causes a chronic indolent infection.²⁷ It typically is susceptible to amoxicillin-clavulanate, trimethoprim-sulfamethoxazole, doxycycline, and ciprofloxacin but resistant to dicloxacillin, nafcillin, first-generation cephalosporins, clindamycin, and erythromycin. Other pathogens may also be transmitted as a result of contact with blood or saliva, including hepatitis B and C viruses, *Mycobacterium tuberculosis*, and, possibly, HIV.

Management of human-bite wounds is similar to that of animal-bite wounds. The wound must be thoroughly irrigated, preferably with 1% povidone-iodine, which is both bactericidal and viricidal. Puncture bite wounds should be irrigated with a small catheter to achieve high-pressure irrigation. If the wound appears infected, aerobic and anaerobic cultures are obtained. Devitalized tissue should be debrided, and the wound should be left open, whether infected or not. The injured extremity should be immobilized and elevated.

Because of the high degree of contamination and local tissue damage associated with human-bite wounds to the hand, antimicrobial therapy is indicated for all such injuries. A prospective, randomized study of 45 patients with human bites to the hand seen within 24 hours after injury and without evidence of infection, tendon injury, or joint capsule penetration demonstrated that infection developed in 47% of the patients who did not receive antibiotics but in none of those who did.³⁰ Patients with an uncomplicated human bite to the hand should receive a broad-spectrum oral antimicrobial agent, such as amoxicillin-clavulanate (or doxycycline if they are allergic to penicillins).

Patients with human-bite wounds at sites other than the hand who have risk factors for infection [see Table 6] should also receive antimicrobial therapy. However, minor bite wounds in patients who have no risk factors for infection do not call for antibiotic therapy. As with animal-bite wounds, tetanus immunization status should be determined, and tetanus toxoid, tetanus immunoglobulin, or both should be administered as indicated.

Patients with systemic manifestations of infection (e.g., fever or chills); severe cellulitis; compromised immune status; diabetes mellitus; significant bites to the hand; associated joint, nerve, bone, or tendon involvement; or infection refractory to oral antibiotic therapy should be admitted to the hospital for I.V. antibiotic therapy.²⁷ Appropriate choices for I.V. treatment include cefoxitin,

cefotetan, and piperacillin-tazobactam. Tenosynovitis, joint infections, and associated injuries to deep structures must also be treated if present.

Cellulitis

Cellulitis is an acute bacterial infection of the dermis and the subcutaneous tissue that primarily affects the lower extremities, though it can affect other areas as well (e.g., the periorbital, buccal, and perianal regions; the areas around incisions; and sites of body piercing).³¹ The most common causes of cellulitis are (1) soft tissue trauma from injection of illicit drugs, puncture wounds from foreign bodies or bites (animal, human, or insect), or burns; (2) surgical site infection; and (3) secondary infection of preexisting skin lesions (e.g., eczema; tinea pedis; and decubitus, venous stasis, or ischemic ulcers). Less common causes include extension of a subjacent infection (e.g., osteomyelitis) and bacteremia from a remote site of infection. Predisposing factors for the development of cellulitis include lymphatic disruption or lymphedema, interstitial edema, previous irradiation of soft tissue, diabetes mellitus, immunocompromise, and peripheral vascular disease.

Nonnecrotizing The overwhelming majority of patients with cellulitis have a nonnecrotizing form of the disease. Patients typically present for medical attention because of pain and soft tissue erythema, and they often have constitutional symptoms (e.g., fever, chills, or malaise). Physical examination reveals erythema with advancing borders, increased skin warmth, tenderness, and edema. Lymphangitis may also be present, manifested as an erythematous linear streak that often extends to a draining lymph node basin; associated lymphadenopathy, fever, and leukocytosis with a shift to immature forms may be apparent.

Cellulitis is usually caused by a single aerobic pathogen. The organisms most frequently responsible for cellulitis in otherwise healthy adults are *S. pyogenes* and *S. aureus*. Of the two, *S. pyogenes* is the more common and is the usual pathogen in patients with associated lymphangitis. *S. aureus* is usually present in patients with underlying chronic skin disease. Other microorganisms may cause cellulitis on rare occasions but usually only in specific clinical circumstances. *Haemophilus influenzae* sometimes causes cellulitis in children or adults infected with HIV.³² *Streptococcus pneumoniae* may cause this condition in patients with diabetes mellitus, alcoholism, nephrotic syndrome, systemic lupus erythematosus, or hematologic malignancies.³³ *P. multocida* may cause cellulitis as a complication of dog or cat bites. *S. epidermidis* is a recognized cause of cellulitis among immunocompromised patients, including those with HIV infection and those receiving organ transplants.³⁴ *V. vulnificus* occasionally causes cellulitis in patients who have ingested raw seafood or who have experienced minor soft tissue trauma and are exposed to sea water.³¹ *A. hydrophila* may cause cellulitis in patients with soft tissue trauma who are exposed to fresh water.³¹ Cellulitis that complicates decubitus or other nonhealing ulcers is usually a mixed infection that includes gram-negative organisms.

In most situations, cellulitis is treated with empirical antibiotic regimens that include agents effective against *S. pyogenes* and *S. aureus*. Attempts to isolate a causative pathogen are usually unsuccessful; needle aspiration and skin biopsy at an advancing margin of erythema are positive in only 15% and 40% of cases, respectively.³⁵ Bacteremia is uncommon, and as a result, blood cultures are positive in only 2% to 4% of patients with cellulitis.^{31,36} Blood cultures are obtained selectively when the patient has high fever and chills, preexisting lymphedema, or buccal or periorbital cellulitis or when a saltwater or freshwater source of

infection is suspected. In all of these clinical situations, the prevalence of bacteremia is higher.³⁶ Radiologic examination should be reserved for patients in whom it is difficult to exclude a deep necrotizing infection.

In an otherwise healthy adult, uncomplicated cellulitis without systemic manifestations can be treated with an oral antibiotic on an outpatient basis. Because the vast majority of cellulitides are caused either by *S. pyogenes* or by a penicillinase-producing *S. aureus*, one of the following agents is usually given: dicloxacillin, cephalexin, cefadroxil, erythromycin, or clindamycin [see Table 5]. The margins of the erythema should be marked with ink to facilitate assessment of the response to treatment. For lower-extremity cellulitis, reduced activity and elevation are important ancillary measures. Appropriate analgesic agents should be given.

Patients who are diabetic or immunocompromised and those who have high fever and chills, rapidly spreading cellulitis, or cellulitis that is refractory to oral antibiotic therapy should be admitted to the hospital for I.V. antibiotic therapy [see Table 8]. Nafcillin is the preferred I.V. agent. Cefazolin or ampicillin-sulbactam is recommended if gram-negative organisms are suspected pathogens, as when cellulitis complicates a decubitus or a diabetic foot ulcer. Clindamycin is recommended for patients with infections caused by methicillin-resistant *S. aureus* (MRSA) and those with serious penicillin allergies. Vancomycin is reserved for patients in these subgroups who are intolerant of or allergic to clindamycin.

Necrotizing Necrotizing cellulitis is similar to nonnecrotizing cellulitis in etiology and pathogenesis but is more serious and progressive. Necrosis generally occurs when the infection is neglected or inadequately treated. The microbiology of necrotizing cellulitis is also similar to that of nonnecrotizing cellulitis, except that *C. perfringens* and other clostridial species may be involved when necrosis is present. In addition to antimicrobial therapy [see Table 8], urgent operative debridement is indicated. In other respects, necrotizing cellulitis is treated in much the same way as deep necrotizing infections are (see below). In some patients with necrotizing fasciitis, the skin is involved secondarily.

DEEP NECROTIZING INFECTIONS

Infections that involve the soft tissues deep to the skin tend to become apparent after necrosis has developed. It is possible that deep necrotizing infections begin without necrosis but progress rapidly as a result of intrinsic factors. Alternatively, such infections may develop as a result of delayed recognition attributable to the tissue depth at which the process takes place and the lack of specific early signs and symptoms. The relatively poor blood supply to subcutaneous fat makes this tissue more susceptible to microbial invasion. Contamination of the deep soft tissues occurs either through neglect or inadequate treatment of cutaneous or subcutaneous infections or through hematogenous seeding of microorganisms in an area of injury.

Most deep necrotizing soft tissue infections are polymicrobial and occur on the extremities, the abdomen, and the perineum.^{12,13,15} Necrotizing infections that involve only muscle are uncommon; therefore, necrotizing fasciitis can be considered the paradigm for these infectious processes.

The early signs and symptoms of deep necrotizing soft tissue infection are localized pain, tenderness, mild edema, and erythema of the overlying skin. These characteristics may be subtle, and this diagnosis may not readily come to mind. Sometimes, there is a history of previous injury to the area of suspected infection, which can lead to confusion about the diagnosis. The more clas-

Table 8 Suggested Parenteral Antibiotic Regimens for Treatment of Cellulitis in Adults

Agent	I.V. Dosage
Nafcillin	2 g q. 4 hr
Cefazolin	1–2 g q. 8 hr
Clindamycin	900 mg q. 8 hr
Vancomycin	500–1,000 q. 12 hr
Ampicillin-sulbactam	3 g q. 6 hr

sic findings associated with these infections—skin discoloration, the formation of bullae, and intense erythema—occur much later in the process. It is important to understand this point so that an early diagnosis can be made and appropriate treatment promptly instituted.

Necrotizing Fasciitis

Necrotizing fasciitis is characterized by angiothrombotic microbial invasion and liquefactive necrosis.⁶ Progressive necrosis of the superficial fascia develops, and the deep dermis and fascia are infiltrated by polymorphonuclear leukocytes, with thrombosis of nutrient vessels and occasional suppuration of the veins and arteries coursing through the fascia; bacteria then proliferate within the destroyed fascia. Initially, tissue invasion proceeds horizontally, but as the condition progresses, ischemic necrosis of the skin develops, along with gangrene of the subcutaneous fat and dermis (characterized by progressive skin necrosis, the formation of bullae and vesicles, and occasional ulceration [see Figure 1]).

Myonecrosis

Myonecrosis is a rapidly progressive life-threatening infection of skeletal muscle that is primarily caused by *Clostridium* species. The classic example of myonecrosis is clostridial gas gangrene, a disease that was common in World War I soldiers who sustained extremity injuries that were contaminated with soil. Delays in definitive treatment and the use of primary closure for these contaminated wounds contributed to the severity and mortality of these infections.³⁷ Clostridial myonecrosis may also occur as a deep surgical site infection after contaminated operations, particularly those involving the GI tract or the biliary tract. Devitalized tissue is a perfect environment for clostridial proliferation. A rare form of this disease occurs in patients with colon cancer in whom myonecrosis caused by *Clostridium septicum* develops in the absence of tissue damage. Myonecrosis may also result from the spread of contiguous fascial infections.

Clostridial myonecrosis has a notably short incubation period: severe progressive disease can develop within 24 hours of contamination. This condition is characterized by acute catastrophic pain in the area of infection, with minimal associated physical findings. Systemic signs of toxicity (e.g., confusion, incontinence, and delirium) often precede the physical signs of localized infection. The skin initially is pale, then gradually becomes yellowish or bronze. Blebs, bullae, and skin necrosis do not appear until late in the course of the disease. Edema and tenderness occur early, and the absence of erythema distinguishes clostridial infections from streptococcal infection. A thin serosanguineous discharge is present in involved areas and may emanate from an involved incision. Gram stain reveals gram-positive coccobacilli with few leukocytes.

When clostridial myonecrosis is suspected or confirmed, peni-

cillin G, 2 to 4 million U every 4 hours, should be given immediately; clindamycin, 900 mg every 8 hours, should be added. When *C. septicum* is identified on culture, a search for an occult GI tract malignancy should be made. Clostridial myonecrosis is the one

soft tissue infection for which hyperbaric oxygen is recommended, though as yet, there is little evidence that this modality improves outcomes. If hyperbaric oxygen therapy is to be used, it should not be given before operative debridement.

Discussion

Etiology and Classification of Soft Tissue Infection

Soft tissue infection commonly results from inoculation of bacteria through a defect in the epidermal layer of the skin, such as may occur with injury, preexisting skin disease, or vascular compromise. Less commonly, soft tissue infection may be a consequence of extension from a subjacent site of infection (e.g., osteomyelitis) or of hematogenous spread from a distant site (e.g., diverticulitis or *C. septicum* infection in patients with colonic carcinoma). It may also occur de novo in healthy patients with normal-appearing skin, often as a result of virulent pathogenic organisms.³⁸

Conditions that disrupt the skin and alter its normal barrier function [see Table 2] predispose patients to bacterial contamination. Host factors may increase susceptibility to infection and limit the patient's ability to contain the bacterial inoculum. Clinically occult infection or inadequate treatment of other conditions may also lead to secondary development of soft tissue infection (as is sometimes seen in patients with diverticulitis; perirectal, pilonidal, or Bartholin's cyst abscesses; strangulated hernias; or panniculitis). Delayed or inadequate treatment of superficial infections (e.g., folliculitis, furuncles, carbuncles, cellulitis, and surgical site infections) may lead to more severe necrotizing infections.

Soft tissue infections may be classified as superficial or deep, as nonnecrotizing or necrotizing, as primary (idiopathic) or secondary, and as monomicrobial or polymicrobial. Superficial infections involve the epidermis, dermis, superficial fascia, or subcutaneous tissue, whereas deep infections involve the deep fascia or muscle [see Figure 6]. Necrotizing soft tissue infections are distinguished by the presence of extensive, rapidly progressing necrosis and high mortality. Such infections are termed necrotizing cellulitis, necrotizing fasciitis, or myonecrosis according to whether the deepest tissue layer affected by necrosis is subcutaneous tissue, deep fascia, or muscle, respectively.

Primary (idiopathic) soft tissue infections occur in the absence of a known causative factor or portal of entry for bacteria. Such infections are uncommon and are believed to result from hematogenous spread or bacterial invasion through small unrecognized breaks in the epidermis.^{38,39} Soft tissue infection caused by *V. vulnificus* is an example of a primary soft tissue infection: it is attributed to bacteremia developing after the ingestion of contaminated raw seafood. Only 10% to 15% of all necrotizing soft tissue infections are idiopathic; the remaining 85% to 90% are secondary infections, developing as a consequence of some insult to the skin that predisposes to infection. Secondary soft tissue infections may be further categorized as posttraumatic, postoperative, or complications of preexisting skin conditions.

Soft tissue infections are classified as monomicrobial when they are caused by a single organism and as polymicrobial when they are caused by multiple organisms. Most superficial soft tissue infections are caused by a single aerobe, usually *S. pyogenes* or *S. aureus*. Exceptions to this general rule include infections associated with skin damaged by animal or human bites, cellulitis

associated with decubitus or other nonhealing ulcers, and infections in immunocompromised patients. These infections are typically polymicrobial, often involving aerobic or facultative gram-negative organisms and anaerobes in addition to aerobic gram-positive bacteria.

Deep necrotizing soft tissue infections are polymicrobial 70% to 75% of the time. They are caused by the synergistic activity of facultative aerobes and anaerobes [see Figure 7].^{40,41} *S. aureus*, *S. pyogenes*, and enterococci are the most common gram-positive aerobes. *Escherichia coli* is the most common gram-negative enteric organism. *Bacteroides* species and peptostreptococci are the most common anaerobes.^{13,18,41} The remaining 25% to 30% of deep necrotizing infections are monomicrobial. Most primary necrotizing soft tissue infections are monomicrobial.³⁸ These infections are more fulminant and are notable for their acute onset, rapid progression, and systemic toxicity. Their characteristic clinical manifestations are related to exotoxin production by the pathogen involved [see Table 9 and Pathogenesis of Soft Tissue Infections, below]. *S. pyogenes* is the pathogen in more than half of monomicrobial infections; *S. aureus*, *C. perfringens*, *V. vulnificus*, and *P. aeruginosa* are less common.

Pathogenesis of Soft Tissue Infections

Soft tissue infections generally induce localized inflammatory changes in the involved tissues, regardless of the species of bacteria involved. As the infection progresses, tissue necrosis occurs as a result of (1) direct cellular injury from bacterial toxins, (2) significant inflammatory edema within a closed tissue compartment, (3) thrombosis of nutrient blood vessels, and (4) tissue ischemia.

Figure 7 Meleney's ulcer is characterized by central necrosis, erythema, and edema.

Table 9 Major Exotoxins Associated with Organisms Causing Monomicrobial Necrotizing Soft Tissue Infection

Bacterium	Exotoxins
<i>Streptococcus pyogenes</i>	Pyrogenic exotoxins A and B, hemolysin, fibrinolysin, hyaluronidase, streptokinase
<i>Staphylococcus aureus</i>	Hemolysins (intravascular hemolysis and local tumor necrosis), coagulase
<i>Pseudomonas aeruginosa</i>	Collagenase (local tissue damage and necrosis)
<i>Clostridium perfringens</i>	α -Toxin (lecithinase causing tissue necrosis, intravascular hemolysis, hemoglobinemia, and acute renal failure)

The exotoxins produced by gram-positive cocci and some gram-negative bacteria are powerful proteolytic enzymes. *S. pyogenes* produces hemolysins, fibrinolysins, hyaluronidases, and streptolysins. *S. aureus* and *P. aeruginosa* produce coagulases that result in local tissue damage and necrosis. *C. perfringens* produces numerous exotoxins. The α -toxin, a lecithinase enzyme, is highly lethal: it destroys cell membranes, causes hemolysis, and alters capillary permeability. Other clostridial toxins lyse red blood cells and have direct cardiotoxic effects. These toxins also cause platelet aggregation and fibrin deposition, with resultant vascular thrombosis and necrosis. Production of the θ -toxin leads to intravascular leukostasis and inhibits diapedesis of white blood cells into infected tissue. This unique collection of bacterial toxins accounts for the rapid progression of *C. perfringens* infection in a setting of minimal inflammatory changes.

That most necrotizing soft tissue infections involve multiple bacterial species strongly suggests that bacterial synergy plays an important role in their pathogenesis. Toxin-induced cellular necrosis establishes an anaerobic environment that facilitates the growth of both facultative and anaerobic bacteria. These anaerobes elaborate additional enzymes and other by-products that facilitate tissue invasion and destruction.

Preexisting local tissue damage frequently serves as a nidus for soft tissue infection. The reduced oxygen tension of this abnormal environment allows pathogens to proliferate. In addition, various patient factors predispose susceptible individuals to these infections. Chronic illnesses can contribute to a diminished immunologic response. Peripheral vascular disease impairs the local blood and oxygen supply. Diabetes mellitus inhibits white blood cell function. Chronic pulmonary disease can result in systemic hypoxemia. Patients with congestive heart failure or significant coronary artery disease may be unable to increase their cardiac output in response to infection. Malnutrition can result in a lack of nutrients and critical enzymatic cofactors involved in the normal cellular response to infection. Each of these patient factors impairs the host response and thereby increases the likelihood that infection will develop.

In the 1920s, Meleney demonstrated that injection of animals with pathogens isolated from patients with infectious gangrene reproduced the characteristics of infection.² Decades later, the importance of bacterial synergy and exotoxins was demonstrated in experiments performed by Seal and Kingston,⁴² who showed that a spreading infection developed in 12% of animals that received an intradermal injection of group A β -hemolytic streptococci. When *S. aureus* was coinjected with β -hemolytic streptococci,

spreading infections developed in 50% of animals, and when the α -lysin of *S. aureus* was coinjected with streptococci, spreading infections developed in 75%.

Streptococcal Toxic-Shock Syndrome

Hemolytic streptococci were originally described by Meleney as the cause of a “synergistic gangrene.”² The current resurgence of necrotizing soft tissue infections attributed to so-called flesh-eating bacteria probably represents an adaptation of group A streptococci to the contemporary environment.⁴³ Streptococcal toxic-shock syndrome (STSS) is defined as the isolation of group A streptococci from a normally sterile body site in conjunction with hypotension and either renal impairment, acute respiratory distress syndrome, abnormal hepatic function, coagulopathy, extensive tissue necrosis, or an erythematous rash.³⁵ STSS is considered the probable diagnosis when these abnormalities occur in conjunction with isolation of group A streptococci from non-sterile body sites. More than 60% of patients with STSS have bacteremia.

Population-based studies in North America and Europe documented a nearly fivefold increase in group A streptococcal infections between the late 1980s and 1995.⁴⁴ The current incidence of group A streptococcal infections in the population of Ontario, Canada, is estimated to be 1.5 per 100,000.⁴⁴ STSS develops in approximately 10% to 15% of these patients, necrotizing fasciitis in about 6%.⁴⁵ It is likely that the rise in serious group A streptococcal infections reflects an antigenic shift that has increased the virulence of these organisms.

Soft tissue infections associated with STSS typically involve an extremity. Approximately 70% of patients will progress to necrotizing fasciitis or myositis and will require operative treatment. Only about 50% of patients with streptococcal soft tissue infections have a demonstrable portal of entry for bacteria.^{38,46}

Severe pain is the most common initial symptom of STSS. It is of sudden onset and generally precedes tenderness or other physical findings. Fever is another common early sign. About 80% of STSS patients show clinical signs of soft tissue infection (e.g., localized swelling, erythema, and tenderness) [see Figure 8]. In approximately 50%, blood pressure is initially normal, but hypotension invariably develops within 4 to 8 hours after presentation.

Hemoglobinuria and an elevated serum creatinine concentra-

Figure 8 Shown is the superficial appearance of streptococcal gangrene of the posterior thigh.

tion are hallmarks of renal involvement. Even when adequate resuscitation is provided and antibiotics and vasopressors are given, hypotension persists in the overwhelming majority of patients. Renal dysfunction can persist or progress for 48 to 72 hours despite treatment. Hypoalbuminemia and hypocalcemia are common. Mild leukocytosis is present initially; however, the percentage of immature neutrophils is generally 40% or higher.

S. pyogenes can be classified into more than 80 different strains, or M types, on the basis of the M proteins expressed. M proteins impede phagocytosis of streptococci and induce vascular leakage by forming complexes with fibrinogen.⁴⁷ They also cleave nicotinic acid dinucleotide (NAD), thereby interrupting elemental cellular processes. The M proteins M1 and M3 are associated with the majority of streptococcal necrotizing soft tissue infections.⁴³ Streptococcal pyrogenic exotoxins (SPEs) are produced by most streptococci that cause severe soft tissue infection and can be transmitted by bacteriophages to different M types. They are the cause of the fever, shock, and tissue injury associated with these infections. SPE-A and SPE-B induce the synthesis of tumor necrosis factor- α (TNF- α), interleukin-1 β (IL-1 β), and IL-6. Peptidoglycan, lipoteichoic acid, and killed organisms also are capable of inducing TNF- α production.

It has been proposed that M proteins or SPEs act as superantigens. These exotoxins, along with certain staphylococcal toxins (e.g., toxic-shock syndrome toxin-1 [TSST-1] and staphylococcal enterotoxins), can stimulate T cell responses through conventional antigen-presenting cells, as well as through direct binding to the V β region of the T cell receptor. Conventional T cell activation through antigen-presenting cells is a multistage process that stimulates a relatively small percentage of T cells and limits the magnitude of the resultant cytokine response. In contrast, superanti-

gens bypass the normal antigen presentation pathway and do not undergo phagocytosis. The superantigen processing pathway can stimulate more than a thousand times more T cells than the conventional antigen pathway and thus can trigger a massive release of cytokines. The idea that T cell stimulation by superantigens can explain the severe degree of illness and exaggerated response seen in these patients is attractive, but at present, there is no definitive proof that this process occurs in humans.

Although *S. pyogenes* is susceptible to penicillin and other β -lactam antibiotics in vitro, clinical treatment failure sometimes occurs when penicillin is used alone against *S. pyogenes* infections.⁴³ Such failure is a particular problem with more aggressive group A streptococcal infections and may be attributable to the large inoculum size (the so-called Eagle effect). These large inocula reach the stationary growth phase very quickly. Penicillin and other β -lactam antibiotics are ineffective in the stationary growth phase because of the reduced expression of penicillin-binding proteins in this phase. Moreover, toxin production is not inhibited by β -lactam antibiotics during the stationary growth phase. In contrast, antibiotics that inhibit protein synthesis have been associated with improved survival after serious group A streptococcal infections.

Clindamycin is more effective than β -lactam agents in managing experimental and clinical infections caused by group A streptococci, particularly when necrosis is present.⁴⁸ Clindamycin inhibits protein synthesis, and its efficacy is unaffected by inoculum size or the stage of bacterial growth. In particular, it suppresses bacterial toxin synthesis and inhibits M-protein synthesis, thus facilitating phagocytosis of *S. pyogenes*. Clindamycin also suppresses synthesis of penicillin-binding proteins, and it can act synergistically with penicillin.

3 OPEN WOUND REQUIRING RECONSTRUCTION

Joseph J. Disa, M.D., F.A.C.S., Eric G. Halvorson, M.D., and David A. Hidalgo, M.D., F.A.C.S.

Approach to Surgical Reconstruction

Acute Reconstruction

EVALUATION AND INITIAL TREATMENT OF OPEN WOUND

Problem wounds are characterized by one of the following: large size that precludes direct primary closure, gross infection or uncertain bacteriologic status, or threatened loss of critical structures exposed as a result of insufficient soft tissue coverage. Surgically created wounds, which generally pose less of a problem from a bacteriologic standpoint than traumatic wounds, are best managed by an immediate coverage procedure when direct closure is impossible.

Traumatic wounds are more difficult to evaluate than surgical wounds for several reasons. First, the potential for infection is high because of the environment in which the wound is created, the mechanism of injury, and the time that elapses before operative intervention. Second, the mechanism of injury (e.g., crush, avulsion, or gunshot) may extend the zone of injury beyond what is immediately apparent [see Figure 1]. Serious postoperative infection may develop in these cases if definitive wound coverage is provided in the absence of adequate debridement. Third, whereas accurate assessment of the chances for recovery of specific structures within the wound is vital for selecting the optimal method of acute treatment, such assessment is often difficult immediately after injury.

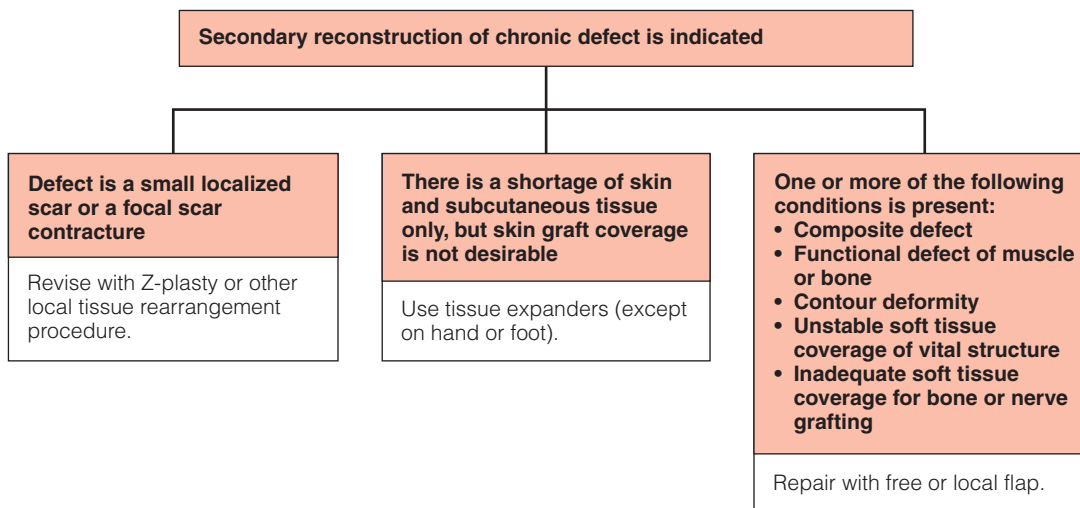

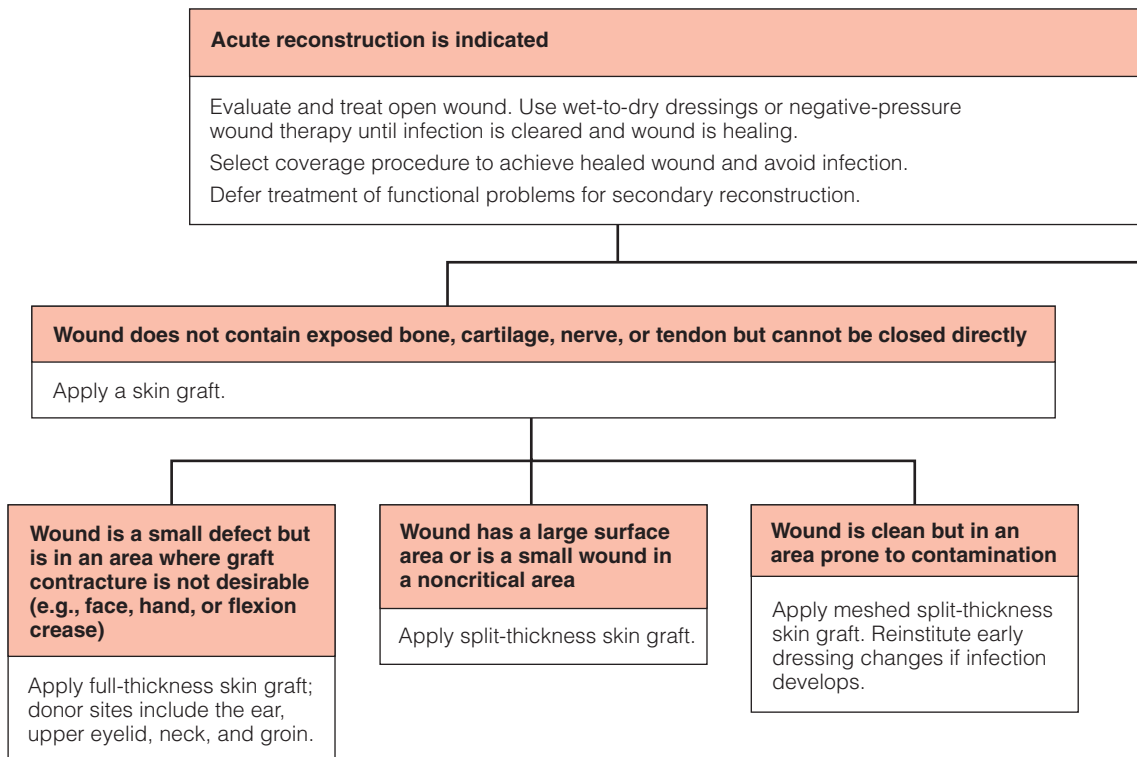

Evaluation

The initial step in the management of problem wounds is to decide whether the wound is suitable for immediate soft tissue coverage. Wounds that are surgically created during the course of an elective procedure are almost always best treated with primary definitive coverage. Traumatic wounds that present within 1 or 2 hours of injury and have a minimal crush component are also best treated with a primary definitive coverage procedure after thorough operative debridement (if the patient's hemodynamic status permits).

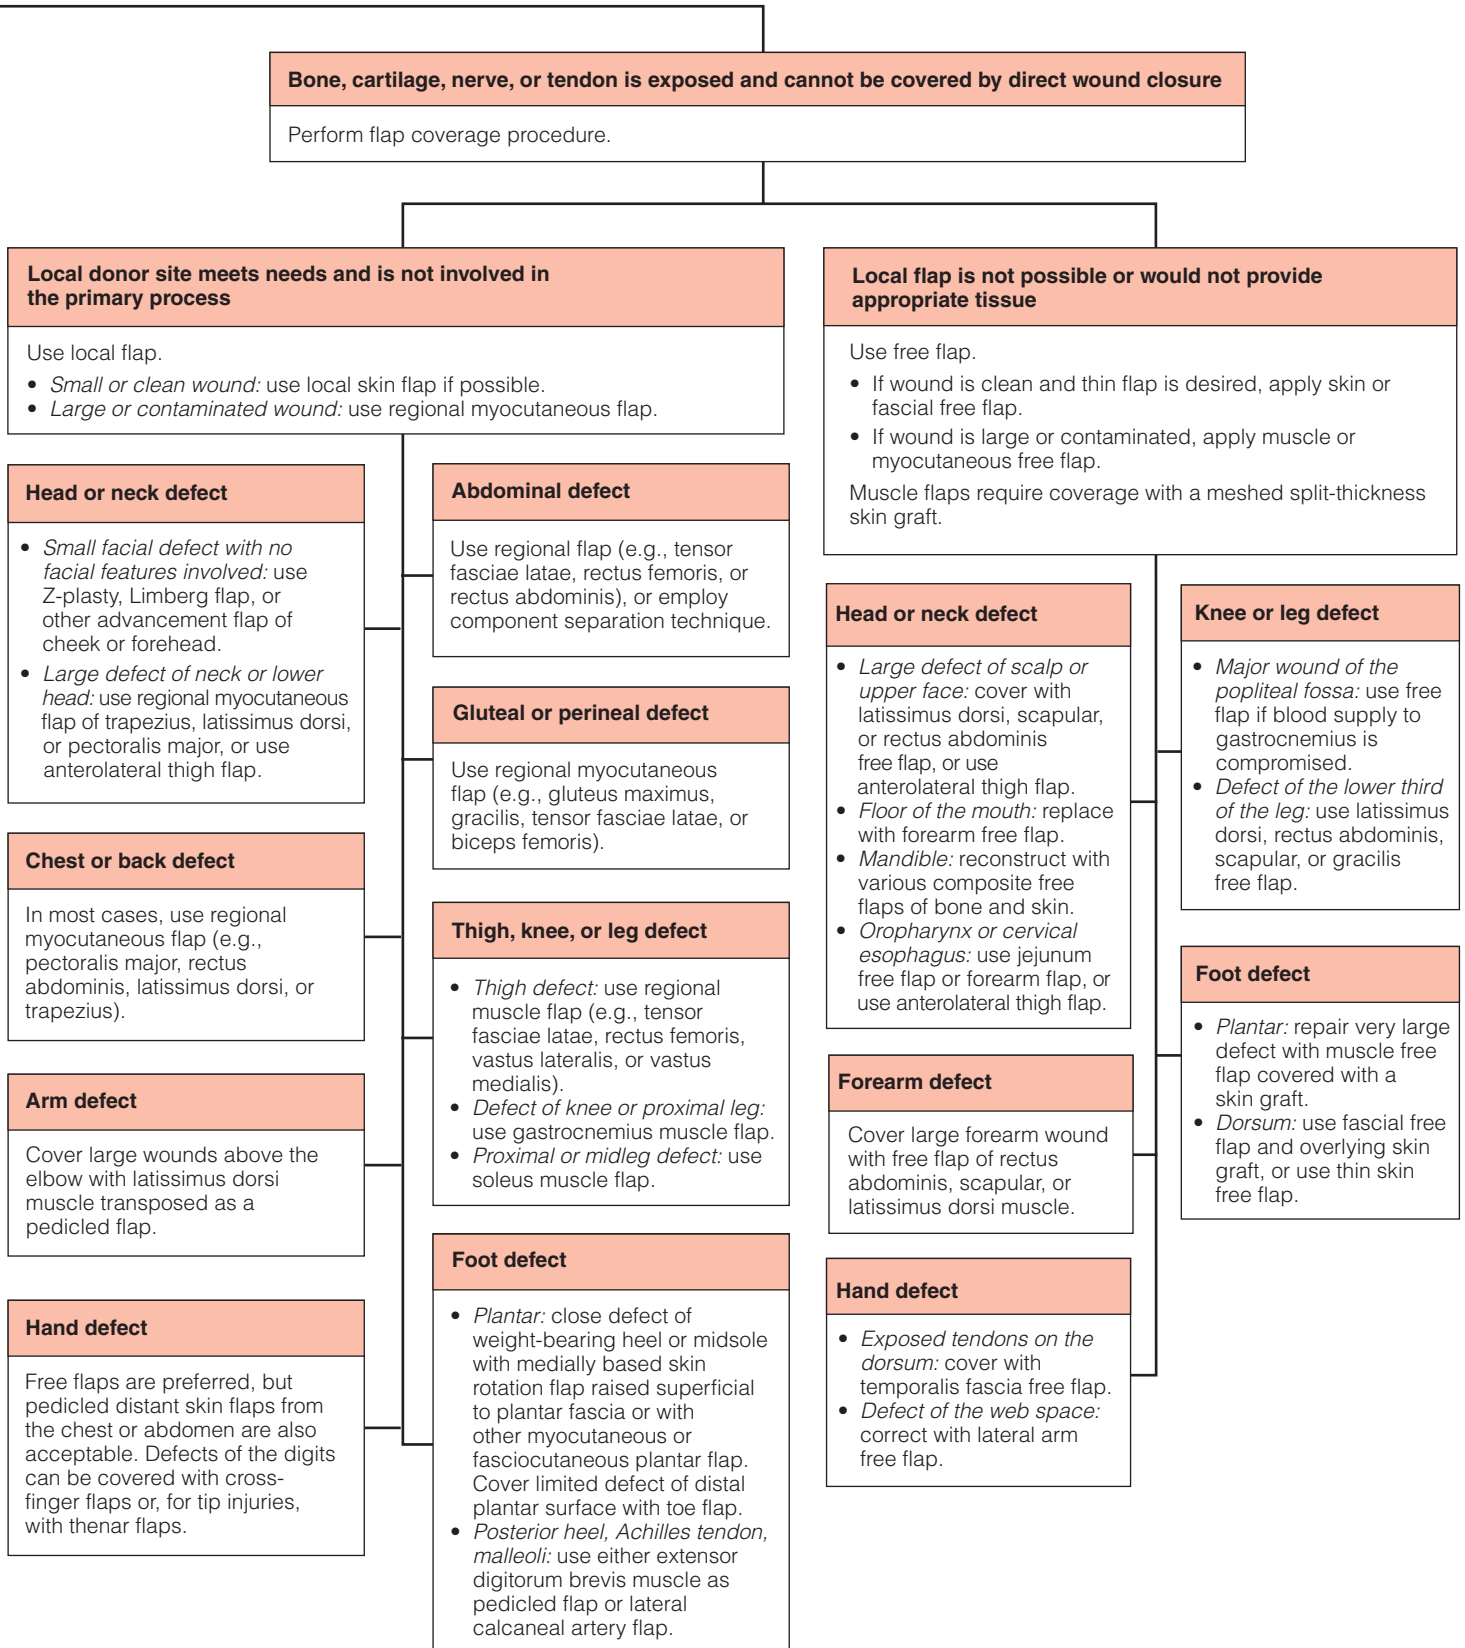

Injuries with a significant crush component and exposure of critical structures (e.g., nerves, vessels, tendons, or bone) are best treated more aggressively. In these cases, thorough debridement requires considerable surgical experience because the tendency is to debride inadequately. The accuracy with which tissue viability can be assessed varies from one type of tissue to another. For example, skin can be evaluated by its color, the nature of its capillary refill, the quality of its dermal bleeding, or its bleeding response to pinprick. After I.V. fluorescein injection, skin viability can also be assessed qualitatively, with a Wood light, or quantitatively, with a dermofluorometer. Muscle is the most difficult tissue to evaluate. Color, capillary bleeding, and contractile response to stimulation are not always reliable indicators of muscle viability. In severe injuries, they can be misleading. Inadequate debridement may lead to severe consequences resulting from infection. Therefore, serial debridement at 24- to 48-hour intervals is essential for accurately establishing the limits of muscle injury. Efforts should be made during debridement to preserve tissues such as major nerves and blood vessels unless they are severely contused. These structures are vital for function

Figure 1 (a) A so-called bumper injury of the leg is shown after initial debridement and bony stabilization (2 days after injury). (b) After the second debridement, the true extent of devitalization of bone and soft tissue is apparent (4 days after injury). (c) A latissimus dorsi free flap has been used to reconstruct the soft tissue defect (5 days after injury).

Approach to Surgical Reconstruction

and are of small mass compared with other tissues (e.g., skin, fat, and muscle) at risk for necrosis and subsequent infection.

Wound debridement, therefore, should involve careful analysis of the injury from an anatomic point of view; debridement should not consist of indiscriminate excision of blocks of tissue. Between debridement procedures, the wound should be treated with sterile dressings but in an open manner, with either dressing changes or negative-pressure wound therapy (NPWT) if conditions permit. A definitive soft tissue coverage procedure should then be performed as soon after the initial injury as wound conditions permit. When thorough debridement and definitive coverage can be completed within less than 1 week, the wound will generally heal uneventfully. Inadequate debridement frequently results in the loss of any additional tissue invested to achieve acute soft tissue coverage. The wound becomes grossly infected, and important functional structures within the wound are reexposed.

Infected surgical wounds, neglected wounds, or other complex wounds in which initial wound management fails should be debrided and then treated by open methods. Proper care of these wounds is achieved by a multifaceted approach aimed at converting established gross infection to a much lower level of bacterial contamination, which is then compatible with successful secondary wound closure. For example, advances in the use of NPWT [see Initial Treatment, Negative-Pressure Wound Therapy, *below*] have simplified the management of complex lower-extremity traumatic wounds, reducing the use of free tissue transfer.¹

Initial Treatment

Debridement Devitalized tissue provides an ideal culture medium for bacteria and isolates them from host defense mechanisms. Surgical debridement must be performed aggressively—and on a serial basis if necessary—to remove all necrotic tissue.

High-pressure irrigation A useful adjunct to debridement is high-pressure irrigation, which has been shown experimentally to reduce wound infection rates significantly.^{2,3} The necessary pressure of 8 psi can be achieved by forceful irrigation through a 35 ml syringe fitted with a 19-gauge needle. Low-pressure irrigation with a bulb-type syringe, for example, has not proved to be beneficial. An antibiotic-containing solution is commonly employed.

Quantitative bacteriology The degree of bacterial wound contamination can be accurately quantified. The standard technique of quantitative bacteriology requires several days to complete and is therefore of somewhat limited utility in the management of acute wounds. In addition to a count, it provides identification and antibiotic sensitivities of the organism. As an alternative, quantitative bacteriology can be performed by using the rapid slide technique, which provides valuable information about the wound within 20 minutes.^{4,5} The level of bacterial contamination has been shown to be a significant predictor of outcome in wound closure by either skin-graft or flap-coverage techniques. According to the golden-period principle of wound closure, a minimum time interval is necessary for bacteria to proliferate to a certain threshold level. Contaminated wounds take a mean time of about 5 hours to reach a bacterial count of 10^5 /g of tissue. Attempts to close wounds that have counts higher than 10^7 /g of tissue will fail 75% to 100% of the time, whereas attempts to close wounds with lower counts are successful more than 90% of the time.⁶ β -Hemolytic streptococci are an exception in that much lower concentrations of these organisms consistently result in failure of wound closure. When a β -hemolytic streptococcus is the

dominant isolate, the wound should generally be treated openly until cultures become negative.

Systemic antibiotics The role of systemic antibiotics in wound management is not clearly defined. Broad-spectrum antibiotics should be given in cases of severe trauma or established, uncontrolled infection. They may also be useful for minor wounds that cannot be closed within 3 hours of injury.

Topical antibiotics Certain antibiotics provide broad-spectrum activity when applied topically. Neomycin, 10 mg/ml, or a combination of bacitracin, 50 U/ml, and polymyxin B, 0.05 mg/ml, kills most common wound pathogens. These solutions can be used when wet dressings are indicated. In the past few years, numerous antibacterial dressings have been developed, including an antibacterial NPWT sponge. Such dressings may prove useful in the treatment of open, contaminated wounds; however, discussion of these products is outside the scope of this chapter.

Topical antiseptics A variety of topical antiseptics have been used empirically in wound care. In the concentrations usually recommended, however, these solutions are detrimental to wound healing. Povidone-iodine (1%), hydrogen peroxide (3%), acetic acid (0.25%), and sodium hypochlorite (0.5%) all have been shown to be lethal to fibroblasts, as well as to bacteria. More dilute concentrations of povidone-iodine (0.001%) and sodium hypochlorite (0.005%) are effective against bacteria while being safe for fibroblasts.⁷ A number of these agents also inhibit normal white blood cell function in the wound.

Wet dressings Open wounds can be treated with wet dressings, generally consisting of gauze soaked in saline or an acceptable topical antiseptic. Wet-to-wet dressings prevent desiccation of exposed vital structures or freshly placed skin grafts. Wet-to-dry dressings are useful for assisting in daily wound debridement. These dressings are allowed to dry on the wound; when they are removed, adherent fibrinous debris is removed with the dressing. Wet dressings of either type should be changed at least twice a day.

Small wounds can be expected to close by contraction and secondary epithelialization after appropriate open management with the techniques described. Large wounds will improve with aggressive open care but will then stabilize into a chronic state of wound colonization of varying degrees. A soft tissue coverage procedure may then be necessary to complete closure in these cases.

Negative-pressure wound therapy In the past 10 years, the vacuum-assisted closure device (VAC Abdominal Dressing System; Kinetic Concepts Inc., San Antonio, Texas) has gained widespread acceptance for the treatment of open wounds. Because this device does not accomplish debridement to any significant degree, it should be applied only to a clean wound that has no necrotic debris. If any significant necrotic tissue remains after sharp debridement, wet-to-dry dressings may be employed until the wound is clean and granulating. Dressing changes are typically carried out every 2 or 3 days; this is a significant advantage, given that conventional dressing changes are generally done at least twice daily. Exudate is removed and quantified by the suction device, and more robust wound granulation and contraction can be observed. After treatment with a VAC device, wound closure can be accomplished secondarily with a skin graft, local flaps, or free tissue transfer, depending on the clinical situation. The disadvantages of NPWT include the need for specialized equipment and training and the increased cost.

SELECTION OF COVERAGE PROCEDURE

The main goals of coverage procedures [see 3:7 *Surface Reconstruction Procedures*] in the management of both acute and chronic wounds are (1) to achieve a healed wound and (2) to avoid infection. The treatment of functional problems is generally deferred for secondary reconstruction.

The method of coverage depends on whether vital structures (e.g., vessels, tendons, nerves, and bone) are exposed in the wound. If no vital structures are exposed, skin-graft coverage is indicated. Skin grafts can also be used over tendon if the paratenon is intact, over nerve if the epineurium is intact, and over bone if the periosteum is intact. Skin grafts are the most expendable type of soft tissue available for the coverage of open wounds. They allow the wound to heal completely and set the stage for secondary reconstruction, during which more valuable tissue can be used to achieve other goals at minimal risk. When vital structures are exposed in the wound, a flap is preferred because it provides more substantial soft tissue coverage of the structure. The choice of flap depends on the location of the wound and on its overall size, depth, and topographic configuration (see below).

Skin Grafts

Skin grafts may be either partial thickness (i.e., split thickness) or full thickness [see 3:7 *Surface Reconstruction Procedures*]. Split-thickness grafts are preferred for wounds with a large surface area. Full-thickness grafts are suitable only for small defects because their donor sites must be closed primarily; the most common donor sites for full-thickness grafts are the ears, upper eyelids, neck, and groin. Full-thickness grafts contract less with time than split-thickness grafts and are therefore particularly suitable for wounds of the hands, extremity flexion creases, nose, eyelids, and other areas of the face.

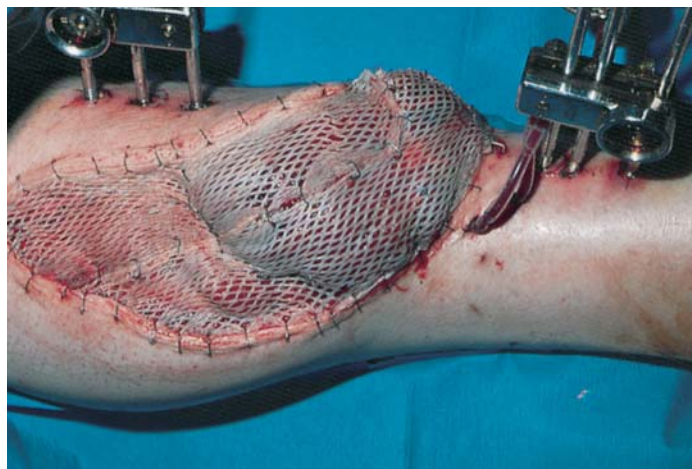

Figure 2 A meshed (1.5:1 ratio) skin graft has been secured to the irregular contour of a muscle free flap with staples. No additional immobilization of the graft is needed. The interstices of the graft allow free drainage of serous exudate from the muscle.

Successful healing of skin grafts requires immobilization of the recipient site to prevent shearing in the plane between the graft and the wound bed. Although complete immobilization is desirable, the required dressings may preclude observation of a wound that is known to be significantly contaminated. In such cases, a meshed split-thickness graft is indicated, and the wound should be treated in an open fashion. A meshed graft can be placed directly over the muscle of a flap and secured over its irregular contour with staples [see Figure 2]. Because the graft is meshed, serum can escape between the interstices and there is little risk of separation from the underlying tissue. A meshed graft is also less vulnerable to disruption by shear forces. An additional advantage of a meshed graft is that it permits the wound to be treated with wet dressings if there is still risk for infection. A mesh expansion ratio of 1.5:1 is generally preferred, except when the surface area of the wound is very large and the availability of donor sites is limited.

Flaps

Flaps consist of tissues that have a self-contained vascular system [see 3:7 *Surface Reconstruction Procedures*]. They permit a more substantial transfer of tissue bulk than do skin grafts and may consist of skin and subcutaneous tissue, of fascia, of muscle, of bone, or of a combination of several of these tissue types. Local flaps consist of tissue that is mostly detached from surrounding tissue but retains enough connection to preserve an adequate blood supply to the entire flap. Local flaps are either transposed, rotated, or advanced into adjacent defects for purposes of reconstruction. Island flaps are local flaps that are based only on their skeletonized axial blood supply. Once created, an island flap is transferred through a subcutaneous tunnel into the defect. The skeletonized pedicle remains in the subcutaneous space while the cutaneous portion of the flap fills the defect. Free flaps, in contrast, are totally detached; their blood supply is reconnected at the recipient site by means of surgically performed microvascular anastomoses between recipient-site blood vessels and the major vessels that supply the flap.

Local flaps consist of tissue that is mostly detached from surrounding tissue but retains enough connection to preserve an adequate blood supply to the entire flap. Local flaps are either transposed, rotated, or advanced into adjacent defects for purposes of reconstruction. Island flaps are local flaps that are based only on their skeletonized axial blood supply. Once created, an island flap is transferred through a subcutaneous tunnel into the defect. The skeletonized pedicle remains in the subcutaneous space while the cutaneous portion of the flap fills the defect. Free flaps, in contrast, are totally detached; their blood supply is reconnected at the recipient site by means of surgically performed microvascular anastomoses between recipient-site blood vessels and the major vessels that supply the flap.

Local flaps versus free flaps The choice between a local flap and a free flap is determined by the amount and the type of tissue needed, as well as by the availability of flaps in the immediate area of the wound [see Figure 3]. The availability of local flaps, in turn, is determined by the nature of the regional blood supply. The vascular anatomy of a particular area determines the availability of arterialized skin flaps, fasciocutaneous flaps, myocutaneous flaps, and other forms of composite flaps. Local flaps can be grouped regionally by the types of tissue that they provide [see Table 1].

A local flap is generally preferred over a free flap if the two provide similar tissue, primarily because of the additional effort required to transfer a free flap. A free-flap procedure commonly takes twice as long as a local-flap procedure.

Free flaps are indicated in areas where local flaps are unavailable (e.g., the distal third of the leg) or when an extremely large flap is needed but cannot be obtained locally. When regional donor sites are affected by the primary process, free tissue transfer allows healthy, well-vascularized tissue to be brought into the compromised area. Moreover, if free tissue is transferred, the size of the wound is not extended, because the donor site is not contiguous but instead is located at a distance from the wound.

If expertise in microvascular surgery is available, free flaps are frequently a first-line choice. Free flaps allow selection of the appropri-

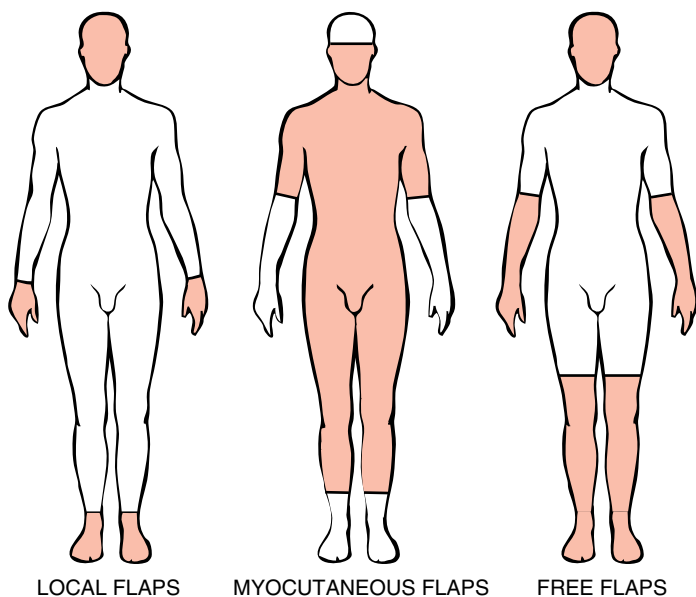

Figure 3 Regional alternatives in flap selection are illustrated. Defects in the central portion of the body are treated with myocutaneous flaps primarily; defects of the peripheral areas are treated with either local flaps or free flaps. In some areas, several options exist, and the choice is influenced by the size of the defect and the specific tissue requirements.

ate type of tissue in the most suitable size and configuration for the specific reconstructive problem. Compared with free flaps, local flaps are inefficient ways of moving tissue because only a small portion of a local flap actually reaches the defect itself. The choice of donor site is greater with free flaps because the limitations imposed by local availability are avoided.

Free flaps used in acute reconstruction can be grouped into three major types [see Table 2]. The soft tissue coverage requirements of

most wounds can be met by so-called workhorse free flaps. These flaps typically have the advantages of large size, ease of dissection, and a vascular pedicle that is long and of large diameter. The disadvantages, such as awkward patient positioning for flap harvest, are minor. Most workhorse flaps consist of muscle with an optional skin component; they are the flaps of choice for contaminated wounds [see Figure 4]. A second group of free flaps is useful for acute reconstruction of unusually large wounds. These flaps consist of combined vascular territories supplied by a single vascular pedicle. A third category consists of smaller free flaps that provide tissue that is superior in either amount or type to the local flaps that are otherwise available. An additional advantage of these flaps is that they tend not to be bulky. They are frequently used in areas such as the head, hands, distal third of the leg, and feet [see Figure 5].

Flap coverage procedures are illustrated in greater detail elsewhere [see 3:7 Surface Reconstruction Procedures].

Regional alternatives in flap selection *Head, neck.*

Facial defects of small to moderate size are best treated with local skin flaps. A variety of flaps are available for reconstruction of limited defects of the eyelids, cheeks, nose, and mouth.⁸⁻¹⁰ Small

facial defects that do not directly involve the facial features can often be closed with any of several types of flaps that rearrange the existing tissue in the area—for example, a Z-plasty or a Limberg flap. Tissues that are difficult to match (e.g., those of the eyelids or lips) can often be reconstructed with flaps that borrow tissue from their opposite, intact counterparts (e.g., the Abbe lip flap).

For coverage of some large defects in the head and neck region, the trapezius, the latissimus dorsi, and the pectoralis major can be used. Each muscle can be raised with an optional skin island. These flaps are generally too bulky to be used on the face, and their reach

Table 1 Selection of Local Flaps by Region and Tissue Type

Site	Skin Flaps	Muscle and Myocutaneous Flaps	Fascial and Fasciocutaneous Flaps
Head and neck	Scalp; forehead; nasolabial; cervicofacial; Mustardé; eyelid; lip	Trapezius; latissimus dorsi; pectoralis major	Superficial and deep temporal fascia
Chest and back	Lateral thoracic; deltopectoral	Trapezius; pectoralis major; latissimus dorsi; rectus abdominis (superiorly based)	Scapular
Arm	Medial arm (Tagliacozzi)	Latissimus dorsi; pectoralis major	Lateral arm; forearm
Hand	Cross-finger; thenar; neurovascular island; fingertip advancement	—	Forearm
Abdomen and perineum	Groin	Rectus abdominis (inferiorly based); tensor fasciae latae; rectus femoris; gracilis	Medial thigh
Gluteal area	Sacral; thoracolumbar	Gluteus maximus; gracilis; tensor fasciae latae; biceps femoris	Gluteal thigh
Thigh	—	Tensor fasciae latae; rectus femoris; vastus lateralis; vastus medialis; gracilis; biceps femoris; rectus abdominis	Anterior thigh; anteromedial thigh; posterior thigh; anterolateral thigh
Knee and proximal leg	—	Gastrocnemius	Saphenous artery; posterior calf
Midleg	—	Soleus; tibialis anterior	Anterior leg; lateral leg; posterior leg
Distal leg	—	—	—
Foot	Dorsalis pedis; plantar rotation; lateral calcaneal artery; plantar V-Y	Flexor digitorum brevis; abductor hallucis; abductor digiti minimi; extensor digitorum brevis	—

Table 2 Free Flap Selection for Soft Tissue Coverage*

Requirement	Specific Flap	Advantages	Disadvantages
Reliable workhorse flaps	Latissimus dorsi	Ideal pedicle [†] ; ease of dissection	Awkward patient positioning
	Rectus abdominis	Ideal pedicle; supine position; ease of dissection	No major disadvantages
	Scapular	Ideal pedicle; skin flap only	Awkward patient positioning
Flaps of very large surface area	Combined latissimus dorsi and scapular	Independent component inset [‡] ; primary donor-site closure possible; ideal pedicle	Awkward patient positioning
	Extended tensor fasciae latae and partial quadriceps	Supine position; large skin flap component	Donor-site healing [§] ; pedicle configuration
Small flaps	Gracilis	Small muscle	Small vessels
	Lateral arm	Thin, sensate; convenient for hand trauma	Small vessels; donor-site scar
	Forearm	Thin skin flap; ideal pedicle	Minor hand morbidity; poor donor-site appearance
	Temporalis fascia	Thinnest flap; ideal coverage for exposed tendons [¶] ; can transfer hair-bearing scalp	Variable donor-site scar alopecia
	Anterolateral thigh	Thin; moderate surface area available for harvest; minimal donor-site morbidity	Variable anatomy; possible requirement for perforator dissection

*Includes only the more commonly used free flaps for purposes of comparison.

[†]Characterized by large-diameter vessels and long pedicle length.

[‡]Each part can be arranged and sewn into the wound separately.

[§]Donor-site closure requires a skin graft, which may result in delayed healing.

^{||}Pedicle enters middle of undersurface of flap.

[¶]Permits tendon gliding underneath if used on dorsum of the hand or of the foot.

is limited when used as pedicled flaps: none of them can cover major portions of the scalp or comfortably reach the upper face.

Latissimus dorsi, scapular, and rectus abdominis free flaps are useful for very large defects of the scalp or upper face. Smaller defects of the scalp are best treated with local scalp flaps.

Other free flaps of a specialized nature are superior for reconstruction of the floor of the mouth and mandible, even though local myocutaneous flaps will reach this area. For example, the forearm free flap based on the radial artery is quite thin and pliable and therefore provides an ideal replacement for the floor of the mouth. Composite free flaps that contain both bone and skin (e.g., those taken from the scapula, the ilium, the radius, and the fibula) provide tissue of the appropriate type and proper configuration for defects of the lower face in which the mandible must be reconstructed along with the intraoral lining, the external skin, or both.

Chest, back. Most clean defects of the chest and back are amenable to treatment with local myocutaneous flaps because of the wide arc of rotation of muscles located in these areas.¹¹ In the presence of contamination, open wound management is indicated. Traditionally, this has

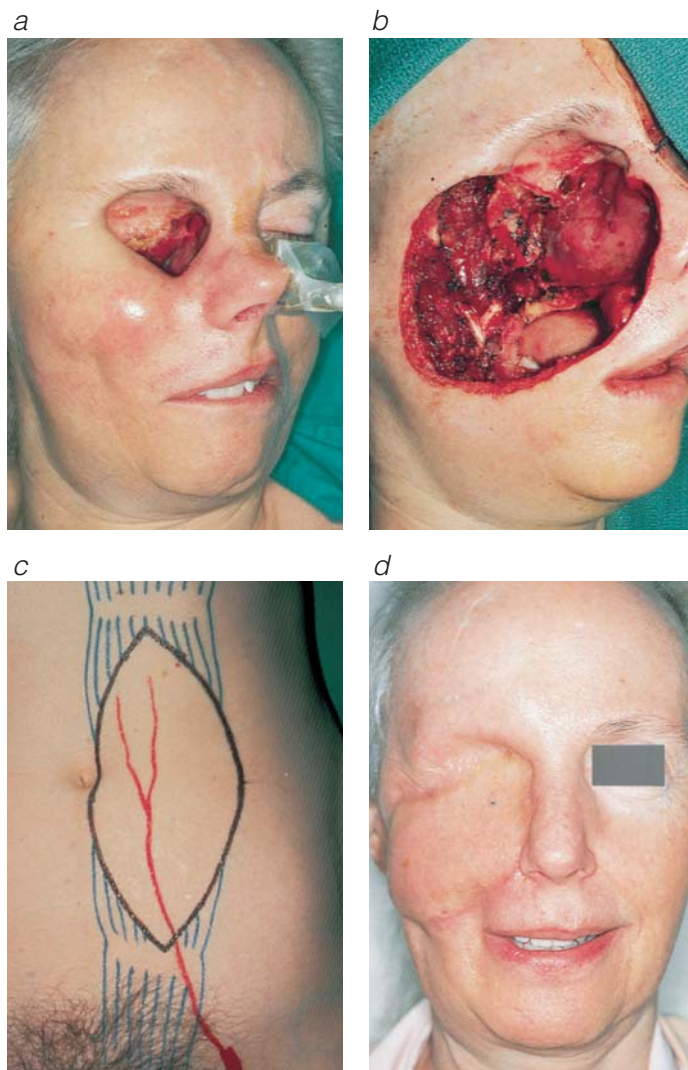

Figure 4 (a) Shown is a facial tumor that has recurred after previous orbital exenteration. (b) The defect has been resected. Local flaps and regional myocutaneous flaps are not available for this defect. (c) A rectus abdominis myocutaneous free flap is designed. This flap can be designed in other sizes and configurations depending on specific needs. The vascular pedicle is long and of large diameter, and the flap is easily accessible in the supine patient. (d) After surgery, soft tissue coverage with a reasonable restoration of facial contour has been achieved.

Figure 5 (a) A soft tissue sarcoma has recurred in the scar of a previous excision. (b) Reexcision of the defect has exposed bone and tendons. No regional flaps are available for satisfactory coverage of this defect. (c) The forearm is a source of small, thin free flaps. (d) Flap transfer is complete. The radial artery and venae comitantes have been anastomosed to their dorsalis pedis counterparts.

been accomplished with wet-to-dry dressing changes, which are especially effective for superficial debridement. Currently, these wounds are increasingly being managed with NPWT after all necrotic tissue is debrided. A common example is the wound resulting from the treatment of poststernotomy mediastinitis. After sepsis is eliminated and the wound is granulating, definitive flap closure can be performed.^{12,13} Midline sternal wounds can be covered with either pectoralis major or rectus abdominis flaps; lateral chest defects with latissimus dorsi or pectoralis major flaps; and midline back defects with latissimus dorsi or trapezius flaps. To cover midline defects, the pectoralis major, the latissimus dorsi, and the trapezius can be divided from their primary vascular supply and folded over as local flaps based on their medial intercostal secondary blood supply.

Arm, forearm. Large wounds above the elbow can be covered with a latissimus dorsi myocutaneous flap transposed as a pedicled flap, provided that the vascular pedicle of the muscle has not been affected by the injury. Forearm wounds that require flap closure are best treated with free flaps. A rectus abdominis, scapular, anterolateral thigh, or latissimus dorsi muscle flap can be used for large defects of the arm or forearm. Although soft tissue coverage with simultaneous functional forearm muscle replacement

can be achieved with a single flap (e.g., a gracilis muscle flap), this procedure is not generally recommended; rather, a skin flap (e.g., a scapular free flap) is preferred as a first stage of reconstruction to achieve wound healing.

Hand. Both free flaps and pedicled skin flaps are useful for soft tissue coverage of hand wounds. A temporalis fascia free flap is particularly thin and is ideal for coverage of exposed tendons on the dorsum of the hand. A lateral arm free flap is ideal for reconstruction of a large defect of the first web space; it has sensory potential because it contains a large sensory nerve. Both of these free flaps are small. Pedicled distant skin flaps from the chest or abdomen are available as an alternative form of coverage of sizable hand defects. However, pedicled skin flaps have major disadvantages: wound care is difficult, edema persists because elevation and movement of the hand are seldom possible while it is attached to the trunk, and a second procedure is needed to divide these flaps.

Digital injuries with exposed tendons can be closed with a variety of cross-finger flaps of skin and subcutaneous tissue raised from either the volar or extensor aspect of an adjacent digit. Because these flaps do not contain a great deal of subcutaneous tissue, they are preferred for coverage of digits proximally, where a thick subcutaneous pad is not essential. A thenar flap is useful for fingertip in-

juries in which the soft tissue pad of the fingertip is lost and bone is exposed. This flap provides an ideal pulp replacement, as well as better sensory recovery than skin grafts. Fingertip injuries can also be closed with several types of V-Y advancement flaps that can be raised from either the volar surface or the lateral surfaces of the end of the finger.

Abdomen. Clean defects of the abdominal wall that require flap closure are best treated with local muscle flaps such as the tensor fasciae latae and the rectus femoris from the thigh. The rectus abdominis also can occasionally be transposed to cover an abdominal defect. Each of these flaps is harvested along with skin, although a large tensor fasciae latae flap will probably necessitate skin-graft closure of the donor site. The tensor fasciae latae flap has the advantage of including the thickened deep fascia (iliotibial band) of the thigh, which can provide additional strength for abdominal wall closure. Midline defects resulting from previous operation or trauma can often be closed by means of the component separation method. The external oblique fascia is divided lateral to the lateral edge of the rectus sheath, and the bloodless plane between the external and internal oblique muscles is developed. This maneuver mobilizes the recti toward the midline, usually allowing primary closure.

As a consequence of the growing realization of the benefits of the open abdomen, increasing numbers of patients treated for abdominal trauma, sepsis, and compartment syndrome are presenting for management and closure. With contaminated wounds, the use of permanent meshes for reconstruction is contraindicated, and definitive flap closure is best delayed. In these difficult situations, the wound must be treated in an open manner, with close attention paid to the unique vulnerability of the intestines to fistula formation. Many treatment options are currently available for the open abdomen [see 7:9 *Operative Exposure of Abdominal Injuries and Closure of the Abdomen*]. Important considerations for any treatment modality include whether the method controls abdominal contents, whether it avoids promoting fistula formation, whether it achieves skin and fascial closure, whether it removes and quantifies exudate, whether it controls infection, and whether it promotes wound healing. The VAC device performs well with respect to all of these considerations, perhaps because of reverse tissue expansion and full-thickness wound contraction.^{14,15} Once all acute problems have been addressed and recovery is well under way, an absorbable mesh is commonly applied, followed by dressing changes or NPWT. To protect the underlying bowel, a layer of nonstick gauze should be applied before dressings or NPWT sponges. Once granulation is achieved, a skin graft can be placed. Chronic hernia formation is the rule; the hernia can generally be treated as a stable chronic ventral hernia, provided that the wound is closed and free of infection.

Gluteal area, perineum. Local muscle flaps with or without skin are indicated for defects in the gluteal area or the perineum. Such flaps are preferable to large, random-pattern advancement skin flaps from the posterior thigh and thoracolumbar ro-

tation skin flaps. The gluteus maximus, for example, can be used as a rotation flap, a V-Y advancement flap, or a turnover flap in the treatment of pressure sores. As a turnover flap, it can be proximally or distally based, or it can be split along its longitudinal axis so that only a portion of it is used. Also useful for covering defects in the gluteal area and the perineum is the myofasciocutaneous gluteal-thigh flap, which is a combination of a gluteus muscle flap and a fasciocutaneous flap from the posterior thigh that is supplied by an extension of the inferior gluteal artery. Because of its size and location, the gracilis muscle is well suited for coverage of defects of the perineum. The gracilis and the biceps femoris are generally secondary choices for the treatment of pressure sores over the ischium. The tensor fasciae latae is frequently used for treating open wounds over the greater trochanter. The entire quadriceps can be used to close defects resulting from hemipelvectomy.

Thigh. Flaps are rarely required for soft tissue coverage in the thigh area, because critical vital structures are located deep within the thigh and are rarely exposed by injury or by surgical procedures. A number of regional muscle flaps are available for coverage in this region, however, including the tensor fasciae latae, the rectus femoris, the vastus lateralis, and the vastus medialis. The gracilis and posterior thigh muscles are rarely used in this area. An anterior defect that involves exposure of the femoral vessels can be covered with either an ipsilateral or a contralateral rectus abdominis myocutaneous flap. The rectus femoris may also be divided distally and turned over to provide coverage of exposed femoral vessels or grafts. A number of smaller local skin flaps that are supplied with blood from the deep fascia can be raised over portions of the thigh. The anterolateral thigh flap is the most commonly employed thigh flap; however, it is typically used for free tissue transfer to distant areas.

Knee, proximal leg, midleg.

The two heads of the gastrocnemius can be used either together or independently to cover defects of the knee and the proximal third of the leg. The soleus is useful for coverage of defects of the proximal and middle thirds of the leg. Local flaps should not be used for major leg wounds if the extent of the injury suggests involvement of the muscle donor site. Instead, a free flap should be used to bring healthy tissue into the area. Therefore, free flaps are a first choice, for example, for coverage of major wounds of the popliteal fossa, knee, and proximal leg that involve the sural artery blood supply to the gastrocnemius; they are also highly useful for coverage of defects in the distal third of the leg. Traumatic wounds of the distal lower extremity can also be managed with NPWT. Increased use of this modality has been associated with the performance of fewer free tissue transfers and more delayed local flap procedures for definitive closure.¹

Skin flaps fed by the fascial blood supply can also be raised over the leg.¹⁶ A number of fasciocutaneous flaps have been described in this area, but they tend to be smaller than muscle flaps and generally less reliable. These flaps are longitudinally oriented over the course of the anterior tibial artery or the peroneal artery. The maximum length at which such fasciocutaneous flaps are safe and their specific applications have not been well established.

Foot. The foot is as complex as the hand and the face in that it is composed of separate regions, each of which has a unique set of alternatives for reconstruction. These regions include the plantar surface; the dorsum; and the posterior (non-weight-bearing) heel, Achilles tendon, and malleoli.

Superficial defects that lie completely within the non-weight-bearing portion of the midsole do not need flap coverage. Defects of the weight-bearing heel and midsole area that are less than 6 cm in diameter can be closed with a medially based skin rotation flap that is raised superficial to the plantar fascia.¹⁷ This flap maintains plantar sensation. Limited defects of the distal plantar surface can be treated with local toe flaps that also maintain sensation. Very large plantar defects are best resurfaced with a muscle free flap (e.g., latissimus dorsi or rectus abdominis) covered with a skin graft. Although this type of flap lacks sensation, it appears to provide the most durable form of coverage because it resists shear forces well.¹⁸

Defects of the dorsum that require flap coverage are best covered either with a fascial free flap (e.g., temporalis fascia) and an overlying skin graft or with a skin free flap that is thin (e.g., from the forearm or the anterolateral thigh). The extensor digitorum brevis can be raised from the dorsum as a pedicled flap fed by the dorsalis pedis artery. This flap, which measures approximately 5 × 6 cm, has an arc of rotation that makes it useful for the coverage of defects of the malleolus or the Achilles tendon area. A narrow transposition skin flap fed by the lateral calcaneal artery is useful for coverage of defects approximately 3 cm in diameter that lie over the Achilles tendon or the non-weight-bearing posterior heel. A distally based reverse sural artery flap transfers skin, subcutaneous fat, and fascia from the proximal posterior calf and can also be used for defects of the ankle; however, this flap is prone to venous congestion.

Secondary Reconstruction

Selection of the proper method for secondary reconstruction requires analysis of the type and extent of tissue deficiency that is present and consideration of the functional goals that are involved. Superficial defects may require replacement or supplementation of only skin and subcutaneous tissue, whereas more complex defects may require replacement of several types of tissue. Specialized tissue, such as vascularized nerve (i.e., a nerve free flap) or intestine, may be necessary to provide a functional reconstruction in some cases (see below).

SMALL LOCALIZED SCAR

When reconstruction is indicated for a small localized scar, soft tissue coverage is generally sufficient and poses no threat of breakdown leading to exposure of important structures. Instead, the reconstructive problem is generally functional in nature. An example is a tight scar band across a flexion crease, which is commonly seen after a burn injury. A local procedure that rearranges the existing tissue can relieve the tension by making more tissue available in one direction, though the amount of tissue in the area is not actually increased.

The Z-plasty is an example of such tissue rearrangement [see 3:7 *Surface Reconstruction Procedures*]. Multiple Z-plasties or other procedures, such as W-plasty, may be useful for some localized scars.

SHORTAGE OF SKIN AND SUBCUTANEOUS TISSUE

A shortage of skin and subcutaneous tissue may result from excision of a large scar or a large congenital defect (e.g., a nevus). Mastectomy commonly leaves a shortage of skin that prevents creation

of a breast mound. In these cases, extra tissue can be created locally with the use of tissue expanders. These devices are inflatable plastic reservoirs of various shapes and volumes that are implanted under the skin. The skin over the expander is stretched during a period of several weeks as the expander is gradually filled by percutaneously injecting saline into an incorporated or remote fill port. The expander is then removed as a second procedure, and the expanded area of skin is advanced to cover the defect. The process of tissue expansion results in thinning of all layers of tissue overlying the expander—except for the epidermis, which actually thickens.

A number of important principles govern the use of tissue expanders. The expanders must be placed so as to allow expansion only in normal skin adjacent to the defect, not in the defect itself. To ensure adequate expansion, a sufficiently large expander or multiple expanders must be used. Complications associated with the use of tissue expanders include infection, extrusion, deflation, flipped ports (remote type), and hematoma formation.¹⁹

Tissue expanders are used in secondary reconstruction only; they play no role in acute wound management. They are not indicated for contour defects (see below), because the tissue they provide is two-dimensional and lacking in bulk. Nor is expanded tissue adequate for coverage of chronically exposed structures (e.g., bone). Tissue expanders do not provide adequate replacement tissue to establish a suitable bed for nerve or bone grafting. Therefore, they are not a substitute for flaps in general.

The scalp is an ideal location for the use of tissue expanders because no equivalent substitute for this type of hair-bearing tissue exists. Expanders work effectively when implanted over the hard calvarium and are useful in cases of burn alopecia and large nevi involving the scalp. Expanders are also useful for breast reconstruction, for carefully selected large lesions of the face, and for certain scars of the limbs. They are generally not indicated for use in the hands or feet. Although some local flap donor sites (e.g., the forehead) can be expanded before flap transfer, there is a loss of tissue pliability that appears to limit the usefulness of this particular application.

COMPLEX DEFECTS

Certain reconstructive problems require substantial amounts of tissue of one or more types or of a very specialized type. Either local or free flaps are used to meet these tissue requirements.

Composite Defect

A composite defect may result from resection of an intraoral carcinoma with loss of the mandible and either the lining of the mouth or external skin. Another example is a crush injury of the leg with loss of soft tissue and a segment of weight-bearing bone. These defects require that a composite flap be brought to the area to meet more than one type of tissue deficiency. Local flaps generally do not provide the necessary types of tissue or permit the freedom of design possible with free flaps. The wide variety of free flap donor sites that

exists allows selection of tissue in the appropriate quantity and configuration for a particular defect [see Figure 6].

Functional Defect

Functional defects require repair with specialized flaps. Free flaps are frequently used because the specific tissue requirements usually cannot be satisfied by a local flap. A functional defect may result, for example, in the cervical esophagus from tumor resection or in the forearm from Volkmann’s contracture. A segment of small intestine can repair the esophageal defect; transfer of a vascularized and innervated muscle (e.g., the gracilis) can replace forearm muscle.²⁰

Contour Defect

Contour defects, such as those that result from mastectomy or from trauma to the lower extremity, can be reconstructed with either local or free flaps. A mastectomy defect, because of its location on the chest, is suitable for reconstruction with one of several myocutaneous flaps from either the back or the abdomen [see 3:5 Breast

Procedures]. A free flap from the abdomen or the gluteal area is another alternative. The best reconstructive solution for a particular person is determined by variables such as body habitus and the size and configuration of the contralateral breast.

A contour defect of the lower extremity is best reconstructed with a large myocutaneous free flap that provides tissue of sufficient quantity and flexibility to allow sculpting into the appropriate shape. An excellent example is the latissimus dorsi free flap, which provides a large volume of thin, pliable muscle, which can be wrapped around orthopedic hardware.

Unstable Soft Tissue Coverage

Marginal soft tissue coverage (e.g., skin grafts) may break down after repeated minor trauma. Bones may become exposed and are then at risk for osteomyelitis. This situation can be avoided by elective replacement of the tissue at risk with a more substantial soft tissue covering. As in acute reconstruction, local flaps are the first choice for lesions of the trunk or the proximal ex-

Figure 6 (a) A chronic draining sinus of the ulna with poor overlying soft tissue coverage is shown. Simultaneous replacement of both bone and overlying soft tissue with a composite tissue flap is needed. (b) A radiograph shows nonunion of the ulna with orthopedic hardware. (c) A fibular free flap provides bone and skin in the appropriate amount and configuration for replacement of the affected tissues in a single stage. (d) The segment of ulna and overlying skin has been replaced. (e) A radiograph shows the vascularized fibula in place.

tremities, whereas free flaps are often more appropriate for lesions of the distal extremities.

Soft tissue coverage is sometimes inadequate even in a healed wound. For example, certain procedures (e.g., nerve or bone grafting) require an ideal soft tissue bed to promote adequate graft revascularization. In some cases, it may initially be necessary to replace the existing soft tissue coverage as a first-stage procedure be-

fore grafting a bone or nerve gap. A skin or muscle flap is most commonly used in such cases. This problem is most common in areas such as the distal extremities, where native soft tissue coverage is not overly abundant and is easily lost as a consequence of trauma or tumor resection. Free flaps are usually chosen to provide a healthy, well-vascularized soft tissue bed before further functional reconstruction is undertaken.

Discussion

Wound Healing

The wound healing process consists of several identifiable phases [see 1:7 *Acute Wound Care*]. The first phase is an inflammatory response that includes both vascular and cellular components. The second stage is fibroplasia, during which collagen deposition by fibroblasts increases the tensile strength of the wound. The maturation phase of wound healing begins at about 3 weeks, when the rate of collagen degradation begins to balance the rate of collagen production. The previously random arrangement of collagen fibers becomes more organized, and the ratio of type I to type III collagen returns to normal. The wound gradually progresses from a raised, indurated, red scar to a mature form that is flat, soft, lighter in color, and of increased tensile strength. The maturation phase continues for more than a year. The final strength of a scar is typically about 80% of the normal strength of the skin.

Contraction of open granulating wounds is caused by myofibroblasts, which are modified fibroblasts that have smooth muscle characteristics. The number of myofibroblasts within the wound is proportional to the rate at which the wound contracts.^{21,22} These cells are scattered throughout the wound and pull the edges of the wound toward the center. Skin grafts inhibit wound contraction, apparently by accelerating the life cycle of the myofibroblast.

Postoperative Management Issues

SKIN GRAFTS

Contraction and Reinnervation

Split-thickness skin grafts include the epidermis and only a portion of the dermis, whereas full-thickness skin grafts include the entire dermis. Skin grafts contract to a degree that is related to their thickness. After their harvest from donor sites, full-thickness grafts contract to a surface area as small as 40% of their original surface area, whereas split-thickness grafts contract only about half as much. This reduction in area, referred to as primary contraction, is a passive phenomenon caused by elastin within the dermis of the graft. Secondary contraction occurs as a graft heals at the recipient site. Full-thickness grafts undergo minimal secondary contraction, whereas split-thickness grafts contract to a degree that is inversely proportional to their dermal content. In other words, thick split-thickness grafts contract less than thin split-thickness grafts.

Skin grafts gradually regain sensation through reinnervation from the wound bed. Thick grafts and healthy wound beds contribute to greater sensory recovery; however, even after healing is complete, the degree of sensation in the graft does not equal that of normal skin. Graft thickness also affects recovery of certain other functions of normal skin, such as secretion from sweat glands and sebaceous glands, and of hair growth. These processes will be active only in full-thickness and thick split-thickness grafts. Secretion from sweat glands depends on sympathetic reinnervation of the graft and follows the sweat

pattern of the recipient site. Sebaceous glands, on the other hand, secrete independently of graft reinnervation by the recipient bed. Thin split-thickness skin grafts tend to be quite dry because they contain inadequate numbers of functioning sebaceous glands, which are more abundant in thicker grafts. For this reason, such grafts may require application of a moisturizer for an indefinite period.

Revascularization

A phase of serum imbibition lasts for the first 2 days after placement of a skin graft. During this period, the graft is nourished by passive absorption of nutrients from serum in the recipient bed, not by direct vascular perfusion. Absorption of fluid causes the graft to increase in weight by as much as 40%. Vessels within the graft gradually dilate and fill with static columns of blood. A fibrin network in the wound bed causes graft adherence during this early phase.

The next phase in revascularization is a period of inosculation, during which anastomoses are formed between vessels in the graft and those in the wound bed. It is not clear, however, whether connections are established between existing vessels in the recipient bed and graft or whether new vessels grow into the graft from the recipient bed. Both processes may occur, and both may be important in graft revascularization. In any case, circulation is sluggish during postoperative days 3 and 4 but gradually increases during postoperative days 5 and 6 to become essentially normal by day 7.²³

Lymphatic drainage from the graft is established at approximately the same rate as the circulation of blood. Lymphatic flow is present by postoperative day 5 or 6, and the graft starts losing the extra fluid weight it has gained. The graft begins to resume its normal weight by postoperative day 9.

Factors Affecting Graft Survival

Hematoma formation beneath a skin graft is the most common cause of graft failure. Blood accumulation interferes with graft adherence, as well as with both imbibition and inosculation. Early evacuation of blood from beneath a skin graft can result in graft survival. Shear forces that result from inadequate immobilization cause graft failure by preventing or disrupting developing communications between vessels of the graft and the recipient bed. Infection of the recipient bed makes the bed unsuitable for grafting, and such infection is another major cause of graft failure. Proteolytic enzymes produced by microorganisms destroy the fibrin bond between the graft and the recipient bed. Bacteria such as β -hemolytic streptococci and *Pseudomonas* are particularly virulent because they produce high levels of plasmin and other proteolytic enzymes. The type of organism present may actually be a more important factor in graft failure than the number of organisms present.²⁴

Healing of Donor Sites

Donor sites for split-thickness grafts heal by reepithelialization. Epithelial cells from remaining portions of skin appendages (e.g., hair follicles, sebaceous glands, and sweat glands) migrate across the ex-

posed dermis to establish a new epidermis. Donor sites for thin grafts heal more rapidly and leave less of a scar than those for thick grafts, which take longer to heal and can be associated with significant scarring. The epidermis of a healed donor site is fully differentiated within 3 to 4 weeks; however, the dermis shows little evidence of regeneration. An occlusive dressing such as OpSite (Smith & Nephew, Hull, United Kingdom) promotes more rapid healing of the donor site than coverage with fine mesh gauze and is potentially less painful.²⁵

FLAPS

Resistance to Infection

In experimental settings, skin flaps, myocutaneous flaps, and fasciocutaneous flaps have been shown to vary in their resistance to bacterial infection.²⁶ Random-pattern skin flaps are not as resistant as myocutaneous flaps. The cutaneous portions of myocutaneous and of fasciocutaneous flaps have similar levels of resistance, but the muscle component of myocutaneous flaps is more resistant than the fascial component of fasciocutaneous flaps in situations where the flap lies over a focus of infection within the wound. Muscle therefore appears to be the type of flap that is most resistant to infection. Such resistance is of clinical significance in cases of exposed bone with chronic osteomyelitis, for example. This condition can be successfully treated by debridement and immediate coverage with a muscle flap.

Free Flaps and Concept of No-Reflow

Free tissue transfer is unique in that the flap is completely ischemic for a given period. How long ischemia can be tolerated without resultant flap failure (despite technically satisfactory microvascular anastomoses) is an important clinical question. An increasing

duration of ischemia has been associated experimentally with obstruction to blood flow in the microcirculation.^{27,28} This obstruction results from cellular edema, increased interstitial fluid pressure, and sludging of blood and thrombus formation. This phenomenon is initially reversible but becomes irreversible as the duration of ischemia increases. After 12 hours of ischemia under experimental conditions, obstruction to blood flow has been demonstrated to be complete, preventing successful reperfusion of the flap. How long uninterrupted ischemia can safely continue in a clinical setting is not precisely known, and evidence suggests that different types of tissue have different levels of tolerance for ischemia. For example, flaps that are primarily bone are more durable than muscle or bowel flaps. Evidence gained by clinical experience indicates that most free flaps can safely tolerate up to 4 hours of ischemia.

Tissue Expansion

Histologic changes noted in expanded skin include thinning of the dermis but not of the epidermis,²⁹ suggesting a permanent net gain in epidermal tissue only. The mitotic rate in the epidermis has been shown to increase with expansion, but the mechanism for this increase is unclear.³⁰

The circulation of expanded skin also changes. The increase in vascularity observed in expanded tissue is partially explained by the fact that tissue expansion is a form of delay procedure. Experimental studies suggest, however, that an increased potential for flap survivability is directly attributable to the expansion process and not merely to its delay component.³¹⁻³³ The fibrous capsule that forms around the prosthesis during expansion appears to contribute to the increased vascularity of these flaps, and the increased pressure around the expander may stimulate angiogenesis.

4 MALIGNANT SKIN LESIONS

Jennifer A. Wargo, M.D., and Kenneth Tanabe, M.D., F.A.C.S.

Given the variable natural history and prognosis of skin malignancies, clinical assessment and management of these lesions can be challenging. Malignant skin lesions have become increasingly prevalent over the past several years. In the United States, approximately 1.2 million cases of nonmelanoma skin cancer are diagnosed annually.¹ More alarming is the observation that approximately 80,000 cases of melanoma are now diagnosed each year²—a figure that has been steadily rising,³ to the point where the current lifetime risk for the development of melanoma is 1 in 75.² This disturbing increase in the incidence of both nonmelanoma skin cancer and melanoma can largely be attributed to prevailing social attitudes toward sun exposure.⁴

Given the increasing prevalence of skin cancers and the pivotal role surgeons play in their treatment, it is critical that surgeons be well informed about the recognition, workup, and management of these conditions. Accordingly, in what follows, we address evaluation and management of malignant skin lesions in detail; management of benign skin lesions is beyond the scope of this chapter.

Assessment of Potentially Malignant Skin Lesions

CLINICAL EVALUATION

History

A careful history should be obtained, with particular attention paid to the extent of previous sun exposure. A history of blistering sunburn in childhood or adolescence is a significant risk factor and is reported by virtually all white persons with melanomas.⁵ A personal or family history of skin cancer is also a risk factor: the likelihood that melanoma will develop is increased eight- to 12-fold when a first-degree relative has a history of melanoma.⁶ Previous immunosuppression or transplantation should be inquired about as well; both place the patient at higher risk for the development of skin cancer.

A detailed history of the lesion's development, starting with the time when it was first noted and including any changes in its size or appearance, should be elicited. Such a history will help the clinician make the initial judgment regarding whether the lesion is suspicious or nonsuspicious. Generally speaking, lesions are considered nonsuspicious if they remain stable and uniform in terms of their physical characteristics (e.g., size, shape, color, profile, and texture). An example of a nonsuspicious lesion is a simple nevus, which typically becomes apparent at 4 to 5 years of age, darkens with puberty, and fades in the seventh to eighth decades of life. Pigmented lesions that have an irregular border or demonstrate a change in size, color, or texture are considered suspicious. Careful attention should also be paid to constitutional symptoms. Patients who present with metastatic disease may have systemic or focal complaints, such as headaches or, in the case of melanoma that has metastasized to the brain, visual changes.

Physical Examination

Physical examination should include a complete skin examination, as well as examination of mucosal membranes. In the case of a possible melanoma, particular attention should be paid to the presence or absence of surrounding nodules or nodules between the skin lesion and the closest nodal basins that may represent in-transit metastases. Attention should be paid to the draining nodal basins because lymph node metastases are known to occur in both squamous cell carcinoma (SCC) and melanoma.

If the lesion is not clinically suspicious, conservative monitoring through patient self-examination and regular follow-up with a healthcare provider is appropriate.

INVESTIGATIVE STUDIES

Biopsy

Any clinically suspicious lesion should undergo either excisional biopsy (if the lesion is small) or incisional biopsy (if the lesion is large). Excisional biopsy typically incorporates a 1 to 4 mm margin of normal skin, depending on the clinical characteristics of the lesion. With some types of lesions (e.g., a dysplastic nevus), the use of this margin may eliminate the need for subsequent reexcision if the lesion proves to contain high-grade cytologic atypia. In any case, no attempt should be made to perform a definitive radical excision until a diagnosis is established by means of biopsy.

A full-thickness excision that extends into the subcutaneous fat should be performed, and the specimen should be marked for orientation to help the pathologist evaluate the margins for possible microscopic involvement with tumor cells. As a rule, electrocauterization should not be employed to remove the specimen, because it creates artifacts that can substantially distort cells at the margins. Shave biopsy is discouraged for evaluation of pigmented lesions because it may create a positive deep margin, thereby compromising determination of the true depth of penetration of a melanoma. In the case of an elliptically shaped excisional biopsy on an extremity, the long axis of the specimen should be oriented along the long axis of the extremity to facilitate subsequent reexcision if necessary.

EXCISION OF MALIGNANCY

If the lesion proves to be benign, no further treatment is usually required. If it proves to be malignant, further excision with appropriate margins is usually necessary, and tumor staging becomes an important concern. Appropriate excision margins for different skin cancers are discussed in more detail elsewhere [see Management of Specific Types of Skin Cancer, *below*].

For lesions excised in an ellipse of skin and fat, the length of the ellipse should be approximately 3.5 to 4 times the width to allow tension-free closure without dog-ears. If an area cannot be closed primarily, skin grafting may be necessary [see 3:7 *Surface Reconstruction Procedures*]. For very large lesions or lesions in difficult areas (e.g., the face), specialized flaps may be required.

Management of Specific Types of Skin Cancer

BASAL CELL CARCINOMA

Incidence and Epidemiology

Basal cell carcinoma (BCC) is the most common malignancy in white persons⁷ and the most prevalent type of skin cancer overall. The incidence varies widely across the globe (e.g., 146/100,000 in the United States, compared with 726/100,000 in Australia).⁸ The lifetime risk of BCC for a white person in the United States is approximately 30%.¹ Although BCCs have a very low metastatic potential, they impose heavy economic and social burdens on patients and society.

The vast majority of BCCs are found on the head and neck. There is no known precursor lesion. The risk of development of BCC seems to be most closely related to exposure to ultraviolet radiation. Whereas substantial sun exposure during childhood and adolescence increases the risk of BCC, no studies have demonstrated any significant correlation between the development of BCC and cumulative exposure to ultraviolet light in adulthood.⁹ Several heritable conditions are associated with an increased risk of BCC, including albinism, xeroderma pigmentosum, and Gorlin syndrome. Patients with Gorlin syndrome typically have multiple BCCs, as well as anomalies of the spine and the ribs, jaw cysts, pitting of the palms and the soles, and calcification of the falx cerebri. This syndrome is inherited in an autosomal-dominant fashion.¹⁰

Histologic Subtypes

Several subtypes of BCC have been identified. Typical patterns seen in more mature lesions include nodular or cystic BCC, superficial BCC, morpheaform BCC, and pigmented BCC. Nodular BCC, also known as rodent ulcer, is the classic type. Nodular BCCs typically present as solitary lesions, often on the face, and are usually shiny and red with central telangiectasias [see Figure 1a], an indurated edge, and an ulcerated center. If the contents of the lesion are soft and can be expressed, the condition is referred to as cystic BCC. Superficial BCC is typically found on the trunk and appears as a slow-growing erythematous patch that is often mistaken for eczema or psoriasis.¹⁰ Morpheaform BCC [see Figure 1b] accounts for only a minority of these lesions, but it exhibits clinical features that are especially noteworthy for surgeons. In particular, morpheaform BCCs

often turn out to be larger than they appear clinically, and they generally have a more aggressive natural history than other BCCs; as a result, complete excision can be highly challenging.

Treatment

Surgical excision remains the mainstay of treatment for primary BCCs. Typically, a surgical margin of 4 mm is recommended when possible.¹¹ With small defects, primary closure is generally feasible; with larger defects, rotation flaps or skin grafting may be necessary. Lymphatic spread identified in the primary tumor, though present only in extraordinarily rare cases, may be an indication for lymphatic mapping.¹²

Other surgical techniques used to treat BCC include cryosurgery, curettage and cauterization, and Mohs' micrographic surgery. Cryosurgery and curettage are generally contraindicated for large or morpheaform BCCs or tumors in high-risk areas (e.g., the central face), because surgical margins cannot be assessed. Mohs' micrographic surgery involves excision of serial sections with intraoperative histologic examination of frozen sections to control surgical margins. It is particularly useful in treating morpheaform BCCs, recurrent BCCs, and BCCs in high-risk sites (with 5-year cure rates approaching 95%).¹³

Nonsurgical modalities available for treatment of BCC include radiotherapy, photodynamic therapy, and the application of topical agents (e.g., 5-fluorouracil [5-FU], imiquimod, and intralosomal interferon alfa [IFN- α]). Radiation therapy is generally reserved for elderly patients with extensive lesions that preclude excision; 5-year cure rates in this population approach 90%.¹⁴ Photodynamic therapy involves the application of a 20% emulsion of δ -aminolevulinic acid to the lesion, followed by exposure to light in the wavelength range of 620 to 640 nm. This therapy is based on the uptake of the porphyrin metabolite by the tumor with subsequent conversion to protoporphyrin IX, which results in destruction of the tumor in the presence of light.¹⁰ The response rates observed with photodynamic therapy are somewhat lower than those observed with other therapies: the overall clearance rate is 87%, but the clearance rate for nodular BCC is only 53%.¹⁵ 5-FU, in the form of a 5% cream, may be used in the management of multiple BCCs of the trunk and limbs. Imiquimod is also given in a 5% cream to treat BCCs, with clearance rates ranging from 70% to 100%.¹⁶ INF- α may be administered directly into the lesion; in a series of 140 patients treated in this manner, a 67% cure rate was reported.¹⁷

Figure 1 Shown are (a) a typical basal cell carcinoma and (b) a morpheaform basal cell carcinoma.

Figure 2 Shown are squamous cell carcinomas related to (a) radiation exposure and (b) sun exposure.

Patients who have been treated for any skin cancer, including BCC, are at higher risk for the development of additional skin cancers and should therefore perform self-examinations at frequent intervals to check for suspicious lesions. Such patients should also receive counselling to reduce sun exposure, with the aim of limiting further damage from ultraviolet irradiation. High-risk patients (e.g., those with Gorlin syndrome and those who are receiving immunosuppressive therapy after renal transplantation) should be offered oral retinoid therapy in an effort to prevent the development of other nonmelanoma skin cancers.¹⁷

SQUAMOUS CELL CARCINOMA

Incidence and Epidemiology

SCC of the skin is the second most common form of non-melanoma skin cancer overall. It is the most common tumor in elderly patients, probably as a consequence of cumulative doses of sun exposure over the course of their lifetimes. In white persons, the lifetime risk for the development of SCC is nearly 10%.

The majority (50% to 60%) of cutaneous SCCs are found on the head and neck. In one series, nearly 50% of fatal cases of SCC occurred in patients in whom the lesion arose on the ear.¹⁸ The mortality associated with SCC is estimated to be approximately 1/100,000.¹⁹

Precursor Lesions

Unlike BCCs, SCCs often arise in precursor lesions, such as actinic keratoses.²⁰ Actinic keratoses, sometimes referred to as solar keratoses, develop in chronically sun-damaged areas of the body. These lesions are often multiple, are generally ill-defined and irregular, and may range in size from about 1 mm to a few centimeters. They have a scaly appearance and exhibit a wide variety of colors, from dark brown to flesh-pink. Biopsy may be necessary to rule out the presence of a SCC. Although the rate at which actinic keratosis undergoes malignant transformation to SCC is less than 0.1% per year,²¹ lesions should nevertheless be treated to reduce the chances of progression. Treatment options include cryotherapy, curettage, and topical therapy. Surgical excision of actinic keratoses is rarely necessary but may be indicated if there is a high level of suspicion for concurrent SCC.

Intraepithelial SCC (carcinoma in situ), also known as Bowen disease, is thought to be the next step in the progression from actinic

keratosis to invasive SCC. The lesions are typically located on sun-exposed areas of the head, neck, trunk, or legs; when they are located on the genitalia, the condition is referred to as erythroplasia of Queyrat. Lesions that develop on non-sun-exposed areas may be associated with internal malignancy.²² Intraepithelial SCCs typically appear as erythematous, slightly keratotic plaques and are usually larger than the lesions of actinic keratosis. They should be excised with a 5 mm to 1 cm margin.

Diagnosis

As noted (see above), SCCs are most often associated with sun exposure, though they may also be seen in patients with old scars, radiation-damaged skin [see Figure 2a], or chronic open wounds.²³ Chronic inflammation and irritation appear to be the common denominators. SCC that arises in a burn scar or a chronic, open wound overlying osteomyelitis is often referred to as a Marjolin ulcer. SCCs that develop from Marjolin ulcers are characterized by aggressive regrowth after incomplete biopsy.

SCCs typically appear as reddish-brown, pink, or flesh-colored keratotic papules [see Figure 2b]; ulceration is sometimes, though not always, present. If there is extensive hyperkeratosis, a cutaneous “horn” may be evident.¹⁸ Symptoms that may suggest malignant transformation of actinic keratosis into SCC include pain, erythema, ulceration, and induration. Histologically, SCCs are characterized by nests of atypical keratinocytes that have invaded into the dermis, which may be either well or poorly differentiated.

Once the diagnosis of SCC is suspected, careful attention should be paid to the draining nodal basins with the aim of detecting possible lymph node metastasis. The risk of such metastasis is between 2% and 4% overall but is somewhat higher in patients with relatively large and poorly differentiated lesions and in patients with lesions located on the scalp, the nose, the ears, the lips, or the extremities. The most common sites of metastasis are regional lymph nodes, the lungs, and the liver. When metastasis or recurrence develops, it is typically within 3 years after treatment of the index lesion.

Treatment

For primary SCC, as for BCC, surgical excision remains the mainstay of treatment; however, the recommended margin of excision for SCCs is generally larger than that for BCCs, ranging from 0.5 to 2 cm. Smaller lesions can often be closed primarily; larger lesions may require rotation flaps or skin grafting.

Nonexcisional therapeutic options for SCC are similar to those for BCC. Surgical choices include cryosurgery, curettage and cauterization, and Mohs' micrographic surgery. Nonsurgical choices include radiotherapy, photodynamic therapy, and topical therapy with agents such as 5-FU, imiquimod, and intralesional IFN- α .

Posttreatment recommendations for SCC patients are essentially the same as for BCC patients [see Basal Cell Carcinoma, Treatment, above]: frequent self-examination to look for suspicious lesions, counseling to reduce sun exposure, and the offer of oral retinoid therapy for high-risk patients.¹⁷

MELANOMA

Incidence and Epidemiology

Although melanoma is less common than BCC or SCC, it is clearly more deadly than either. It is currently the sixth leading cause of cancer-related death in the United States, and its incidence is increasing faster than the incidence of any other malignancy. Melanoma is slightly more common in men than in women, and the median age at diagnosis is 57 years.⁶ An average of 18.8 life-years are lost for each melanoma death,²⁴ and it is estimated that one United States citizen dies of melanoma every hour.²⁵

Melanoma results from the malignant transformation of melanocytes, which are responsible for pigment production. The genetic factors implicated in this transformation have not been well characterized. As noted [see Assessment of Potentially Malignant Skin Lesions, Clinical Evaluation, History, above], patients with a family history of melanoma are at substantially higher risk for the development of melanoma.⁶ Somatic mutations in the *p16* tumor suppressor gene have been identified in both familial and sporadic cases of melanoma.²⁶ Environmental factors—specifically, exposure to ultraviolet radiation—are also implicated in the malignant transformation of melanocytes. Increased risk of melanoma is associated with intermittent intense sun exposure rather than with the cumulative effect of long-term mild exposure, though the exact mechanism behind the pathogenesis remains unknown.

Screening and Diagnosis

In one study, multivariate analysis identified the following six risk factors as important in the development of malignant melanoma²⁷:

1. A family history of melanoma;
2. A history of three or more blistering sunburns before the age of 20;
3. Blonde or red hair;
4. The presence of actinic keratosis;

Table 1 ABCD Guidelines for Pigmented Lesions

Characteristic	Comments
Asymmetry	Most early lesions grow at uneven rate, resulting in an asymmetrical appearance
Border irregularity	Uneven growth rate also results in irregular border
Color variegation	Irregular growth also causes new shades of black and of light and dark brown
Diameter	Lesions with ABC features and diameter > 6 mm should be considered suspicious for melanoma

5. A history of 3 or more years of an outdoor summer job as a teenager; and
6. Marked freckling on the upper part of the back.

For a person with one or two of these factors, the risk of melanoma is increased 3.5-fold; for a person with three or more, the risk is increased 20-fold.

The recommended frequency for melanoma screening should be based on these six risk factors. Routine screening of low-risk patients through total body skin examinations performed by healthcare providers is not a supported practice. Self-screening, however, is clearly recommended, and excellent educational materials on this subject are available from the American Academy of Dermatology and the American Cancer Society. Nevertheless, physicians should take every opportunity to screen patients as the occasion arises; in general, the lesions found by physicians are significantly thinner than those detected by patients or their spouses.²⁸

For effective treatment of melanomas, early recognition is critical. The ABCD (Asymmetry, Border irregularity, Color variegation, Diameter) guidelines for pigmented lesions are frequently used as aids to melanoma identification [see Table 1].²⁹ Melanomas often occur on sun-exposed areas of the upper trunk and the extremities, and they are typically asymmetric, with irregular borders and variegated pigmentation [see Figure 3a]. Occasionally, they lack pigmentation or are associated with significant gross ulceration. Any lesion that appears suspicious for melanoma should undergo biopsy. Histologically, melanomas are characterized by atypical melanocytes with mitotic figures. Special staining, most commonly with HMB-45 or S100, may also be performed.

Histologic Subtypes

Melanoma may be classified into histologic subtypes on the basis of growth pattern and anatomic location. It should be kept in mind,

Figure 3 Shown are (a) a typical melanoma and (b) an acral lentiginous melanoma.

Table 2 Clark System for Staging Melanoma

Clark Level	Degree of Tumor Invasion	5-Year Survival (%)
Level I	Malignant melanocytes are confined to epidermis	99
Level II	Malignant melanocytes infiltrate papillary dermis singly or in small nests	95
Level III	Malignant melanocytes fill and expand papillary dermis, with extension of tumor to papillary-reticular dermal interface (usually signifying vertical growth phase)	82
Level IV	Malignant melanocytes infiltrate reticular dermis in significant fashion	71
Level V	Malignant melanocytes infiltrate subcutaneous fat	49

however, that the specific subtype a tumor falls into, in itself, is not as important as the pattern of growth (i.e., radial versus vertical) and the depth of penetration.³⁰ The main subtypes are lentigo maligna melanoma, superficial spreading melanoma, acral lentiginous melanoma, and nodular melanoma. Of these, superficial spreading melanoma is the most common, accounting for more than 70% of melanomas. These lesions occur most frequently in white adults, typically on the back or the legs. Nodular melanoma is the second most common subtype, accounting for between 15% and 30% of all melanomas. These lesions often appear dome-shaped and may occur anywhere on the body. They typically manifest an early vertical growth phase and thus tend to invade the dermis early in their natural history. Lentigo maligna melanoma accounts for approximately 5% of all melanomas and is believed to arise in a focus of lentigo maligna (Hutchinson freckle). These lesions demonstrate a prolonged radial growth phase before exhibiting an invasive component. Acral lentiginous melanoma occurs on the hands or the feet [see Figure 3b], often under the nailbed, where the dermis is thinner (subungual melanoma). There also exists a relatively rare histologic subtype known as desmoplastic melanoma, which typically occurs in areas of sun damage and tends to recur locally more often than other subtypes do.

Staging and Prognosis

An important variable in the prognosis of melanoma is the thickness of the primary tumor, as assessed by means of either the Bres-

low system or the Clark system [see Table 2]. In the Breslow system, a calibrated ocular micrometer is employed to measure tumor thickness from the epidermal surface to the deepest point of the tumor's extension into tissue.³¹ In the Clark system, the levels are defined by the presence or absence of malignant melanocytes in each of the following layers: epidermis, papillary dermis, reticular dermis, and subcutaneous fat [see Figure 4].³²

Over the past several years, extensive research has been conducted on factors that affect prognosis in both early-stage and late-stage melanoma. Clinical factors that have been shown to possess significant prognostic value include age, sex, the location of the melanoma, the number of lymph nodes involved, the presence of distant metastasis, and the serum lactate dehydrogenase (LDH) level.³³ In general, the prognosis is better when the patient is younger than 65 years of age, when the patient is female, when the tumor is located on an extremity, when no lymph nodes are involved, when there is no evidence of distant metastasis, and when the serum LDH level is normal.

Melanomas are usually staged according to the system developed by the American Joint Committee on Cancer (AJCC), the latest version of which was approved in 2002 [see Tables 3 and 4].³⁴ The AJCC stage correlates well with the 5-year survival rate [see Table 5].³⁴

Stage I and II melanoma The vast majority of melanoma patients have a clinically localized form of the disease (i.e., stage I or II). Several clinical factors have been identified and employed for risk stratification and prognosis in this heterogeneous group. The most important prognostic factors in early-stage melanoma are tumor thickness (T1 through T4) and the presence or absence of ulceration: 5-year survival in patients with stage I and II melanomas falls significantly as tumor thickness increases and is substantially reduced (from 80% to 55%) in the presence of ulceration.³⁰ In the past few years, the mitotic rate in the primary tumor has also been identified as an important prognostic factor, one that may eventually prove more important than the presence or absence of ulceration in this population.³⁵ Accordingly, it is likely that tumor mitotic rate will be incorporated into the next iteration of the AJCC's melanoma staging system.

Study of thin (< 1 mm) melanomas, in particular, has led to further refinement of risk stratification. The Clark level has prognostic implications for these lesions, in that tumors extending to Clark level IV are considered T1b regardless of their actual thickness and are associated with a worse prognosis. A 2004 report from the University of Pennsylvania described a prognostic model that made use of a

Figure 4 The Clark system classifies skin tumors according to the level of invasion, determined by the presence or absence of malignant melanocytes in the epidermis, papillary dermis, reticular dermis, and subcutaneous fat.

Table 3 American Joint Committee on Cancer TNM Clinical Classification of Melanoma⁸⁵

Primary tumor (T)	TX	Primary tumor cannot be assessed (e.g., shave biopsy or regressed melanoma)
	Tis	Melanoma in situ
	T0	No evidence of primary tumor
	T1	Lesion thickness ≤ 1.0 mm T1a: ulceration absent and Clark level II or III T1b: ulceration present or Clark level IV or V
	T2	Lesion thickness 1.01–2.0 mm T2a: ulceration absent T2b: ulceration present
	T3	Lesion thickness 2.01–4.0 mm T3a: ulceration absent T3b: ulceration present
	T4	Lesion thickness > 4.0 mm T4a: ulceration absent T4b: ulceration present
	Regional lymph nodes (N)	
	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
Distant metastases (M)	N1	1 metastatic lymph node N1a: micrometastases present N1b: macrometastases present
	N2	2 or 3 metastatic lymph nodes N2a: micrometastases present N2b: macrometastases present N2c: in-transit metastases or satellite metastases present without metastatic lymph nodes
	N3	≥ 4 metastatic lymph nodes; matted lymph nodes; or combinations of in-transit metastases, satellite metastases, or ulcerated melanoma and metastatic lymph nodes
	MX	Distant metastases cannot be assessed
	M0	No distant metastasis
	M1	Distant metastases M1a: metastases to skin, subcutaneous tissues, or distant lymph nodes M1b: metastases to lung M1c: metastases to all other visceral sites or distant metastases at any site associated with elevated serum LDH

LDH—lactic dehydrogenase

risk-stratification algorithm based on four factors: (1) mitotic rate (0% versus ≥ 1%), (2) growth pattern (radial or vertical), (3) gender, and (4) tumor-infiltrating lymphocyte (TIL) activity (brisk, non-brisk, or absent).³⁶ For minimal-risk and low-risk patients, the predicted risk for metastasis was less than 4%, whereas for moderate-risk and high-risk patients, the predicted risk for metastasis was 12% and 30%, respectively.³⁶

Intermediate-thickness (1 to 4 mm) melanomas are clearly associated with a worse prognosis than thin melanomas: the 5-year survival rate is 89% for patients with nonulcerated T2 lesions and 77.4% for those with ulcerated lesions. For patients with ulcerated T3 lesions, the predicted 5-year survival rate is 63%.

For node-negative patients with thick (> 4 mm) lesions, the 5-year survival rate is 67.4%; this figure drops to 45.1% if the lesion is ulcerated.³⁴

Stage III melanoma Stage III melanoma is characterized by the presence of nodal metastases (micrometastases or macrometas-

tases), with or without in-transit or satellite lesions. The presence of lymph node metastases is associated with a substantially worse prognosis, with fewer than 50% of node-positive patients surviving for 5 years.³⁴ The number of involved nodes is also a significant prognostic factor and is included as such in the current version of the AJCC melanoma staging system.

Four prognostic factors have been identified that influence survival in patients with stage III melanoma: (1) the number of lymph nodes with metastases; (2) the presence of microscopic tumor deposits in lymph nodes, as opposed to macroscopic deposits; (3) the presence of in-transit or satellite metastases; and (4) the presence of ulceration in the primary lesion.³⁴ At one time, the size of the involved lymph node was believed to be a significant prognostic factor, and it was included in earlier staging systems; currently, it is understood that this variable does not in fact exhibit a significant correlation with survival.³⁷ However, macroscopic disease (i.e., disease that is identified clinically and confirmed histologically) does have a significant impact: the survival rate is much poorer in patients with macroscopic disease than in those with microscopic disease.³⁴

In-transit and satellite metastases represent dissemination of tumor via lymphatic channels. The 5-year survival rates observed in patients with these findings are similar to those observed in patients with lymph node metastases. If in-transit or satellite metastases are present in association with lymph node metastases (N3), the survival rate is markedly reduced.³⁴

Stage IV melanoma For stage IV melanoma, the most important prognostic factors appear to be (1) the site at which a distant metastasis occurs and (2) the serum LDH level. Within this group, patients with cutaneous metastases and normal serum LDH levels have by far the most favorable prognosis. There are significant differences in 1-year survival between patients who have cutaneous, subcutaneous, or distant nodal metastases (M1), those who have lung metastases (M2), and those who have any other visceral metastases or who have any metastases in association with an elevated serum LDH level (M3). The predicted 1-year survival rates for M1, M2, and M3 patients are 59%, 57%, and 41%, respectively.³⁴

Initial Evaluation

For initial evaluation of patients with thin melanomas (< 1 mm), no routine laboratory or radiologic tests are recommended. For patients with thicker melanomas (≥ 1 mm), some clinicians recommend a chest x-ray. For patients with stage III disease, chest radiography or computed tomography of the chest, the abdomen, and the pelvis may be performed and are indicated for any signs or symptoms of metastases. If inguinal lymphadenopathy is apparent, pelvic CT should be performed to assess the iliac lymph nodes.³⁸ For patients with stage IV disease, chest radiography should be performed and serum LDH levels obtained. Magnetic resonance imaging of the brain and CT of the chest, the abdomen, and the pelvis should be performed to address any signs or symptoms of metastases and before any therapy is initiated. Any other imaging done will be guided by protocol if the patient is enrolled in a clinical trial.³⁸

Treatment

Surgical treatment of stage I and II melanoma *Margins of excision.* Surgical excision remains the mainstay of treatment for melanoma. The width of the recommended surgical margin depends on the thickness of the lesion and has been well defined by a series of prospective randomized clinical trials.³⁹ According to most current recommendations, a 0.5 cm margin is adequate for melanoma in situ, a 1 cm margin is suggested for melanomas thinner than 1.0 mm, a 1 or 2 cm margin should be obtained for melanomas between 1 and 2 mm thick, and a 2 cm margin is required for melanomas thicker than 2 mm.³⁹

Sentinel lymph node biopsy. An important issue in the surgical management of melanoma is the use of sentinel lymph node biopsy (SLNB) [see 3:6 *Lymphatic Mapping and Sentinel Lymph Node Biopsy*], which has essentially replaced elective lymph node dissection. Sentinel lymph node (SLN) status is the single most important predictor of survival in patients with melanoma⁴⁰ and is now considered a standard approach in the United States. A positive result is defined as the presence of identifiable melanoma cells on routine hematoxylin-eosin staining, immunohistochemical staining with S100 or HMB-45, or both. Preoperative lymphatic mapping via lymphoscintigraphy is often quite helpful, in that many lesions have variable drainage basins that cannot be predicted clinically, and some lesions even drain to contralateral nodes.⁴¹ The greatest accuracy is achieved with SLNB when both radioactive colloid and blue dye are used.⁴²

SLNB should not be performed in patients with clinically positive nodes or in those who would otherwise not be considered for lymphadenectomy. It is generally recommended for patients who are at moderate or high risk for harboring occult regional node metastases. In patients with T1 primary tumors, SLNB may be considered in selected scenarios (i.e., primary tumor ulceration or extensive regression, a high mitotic rate, a Clark level IV lesion, or a positive deep margin).³⁸
