AIDS and Other Manifestations of HIV Infection
Fourth Edition, edited by Gary P. Wormser
Elsevier Science © 2003

Chapter 14

HIV Disease in Women

Lisa Ferrigno and Jack A. DeHovitz

The prevalence of HIV infection in the United States has increased among women, while decreasing among white men such that women now represent an estimated 30% of new HIV infections in the U.S., and an increasing proportion of new AIDS cases.

This chapter will focus on those facets of HIV that may differ between men and women as well as on clinical issues speciÞc to women in order to provide guidelines for their care. It should be emphasized that, except regarding those issues that are sex-speciÞc, treatment algorithms for HIV-infected women do not differ from that of men. Discussions about the changing epidemiology of HIV will provide the clinician with a framework to determine who may be at risk and to inform the application of guidelines to prevent subsequent HIV transmission. Although antiretroviral recommendations currently remain the same for men and women, the review of Þndings regarding early HIV infection and the reported discrepancy in HIV viral load will allow the clinician to interpret forthcoming data appropriately and to address misinformation or misinterpretation of these data by patients. Finally, much of the chapter will deal with sex-speciÞc issues, such as the differential presentation of gynecologic problems in the HIV-infected woman and a brief summary of obstetric considerations.

Importantly, the needs of all women seeking primary care should not be overlooked in the context of HIV infection. While much emphasis has recently been placed on the role of the HIV-experienced provider in providing HIV care, it is also important to insure that patients can obtain womenÕs health care at the same or adjacent settings. An emphasis on providing Òone-stop shoppingÓ for care, will ensure, to the extent possible, both coordinated and high quality care. In addition, the importance to provide an atmosphere of trust and conÞdentiality.

Lisa Ferrigno, MD, MPH: State University of New York
Jack A. DeHovitz, MD, MPH: State University of New York

EPIDEMIOLOGY

It is estimated that approximately 25% of the 800,000 to 900,000 Americans living with HIV infection are women. While AIDS rates in women are lower compared to men (9.3 per 100,000 women vs. 32.4 per 100,000 men in 1999), the cumulative percentage of AIDS cases in women almost tripled from 6.7% in 1986 (1) to 18% in 1999 (2). Women of color represent the majority of AIDS cases in women and their proportion continues to increase. In 1999, for example, African-American women accounted for 63% of newly reported AIDS cases (2). In the same year the case rate for Latinas (14.9 per 100,000) was more than six times the rate for white women. In 1998 HIV was the third leading cause of death among African-American women ages 25Ð44 (3).

The mode of acquisition of HIV in American women has evolved over time. Early in the epidemic, the majority of female AIDS cases were due to injection drug use (IDU). However, by 1995 the proportion of women infected through the heterosexual route surpassed that of IDU (4). As of 1999, the proportion of women who had known sex with an HIV-infected partner or an individual at high risk was approximately 40% as compared to 30% who had used injection drugs. Of note, however, is the fact that the proportion of those with no known risk according to the surveillance deÞnition has increased to slightly greater than 30% in 1999. Studies suggest that at least 50% of these individuals may have acquired HIV heterosexually (5). This is supported by a report by the Centers for Disease Control and Prevention (CDC) which estimates that 81% of those reporting no ascertained risk were infected via heterosexual sex (6). While non-injected drugs are not a vehicle for infection, cohort studies have revealed that much of the heterosexual risk of HIV is associated with use of drugs, such as alcohol and cocaine.

Other important trends characterize the epidemic in women. For example, there is an increasing proportion of AIDS cases occurring in women in the South, perhaps reßecting the dramatic increase in other STDs Þrst seen in that region a decade ago (7). Insurance status also varies by gender. Women are more than twice as likely to be covered by Medicaid, as are men and half as likely to be privately insured (8). These data reinforce the fact that the intersecting epidemics of poverty, drug use, and sexually transmitted diseases will continue to affect the evolution of the HIV epidemic in women in the U.S.

RESEARCH AND WOMEN

Concerns have been raised that research about AIDS in general and studies describing the natural history of HIV infection and the favorable outcomes of HAART utilization in particular, have under-represented women (9). Indeed, most of the initial cohorts (such as the Multicenter AIDS Cohort Study-MACS) assembled to assess the natural history of HIV infection were comprised exclusively of men. As a result, much of the early data supporting the use of biological markers such as CD4 cell count and plasma HIV RNA level (viral load) were developed from exclusively male cohorts. To begin to answer gender speciÞc questions, population based studies were stratiÞed by gender. A prominent example of this was a study of injecting drug users, the AIDS Link to Intravenous Experience (ALIVE) study, which closely examined both behavioral and clinical differences between male and female drug users (10). However, by the early 1990s two large prospective cohort studies were assembled that were comprised exclusively of women with HIV disease and as well as women at risk. These two studies were the HIV Epidemiology Research Study (HERS) (11) funded by the CDC and the WomenÕs Interagency HIV Study (WIHS) (12) funded primarily by the NIH. While the HERS study was discontinued, the WIHS study remains in the Þeld and has recently been expanded to enroll a younger cohort.

Perhaps more difÞcult to examine, however, is the impact of representation of women in clinical trials. Most NIH funded clinical research has included women at rates similar to the proportion of women infected across the country (e.g. by 1998, approximately 20% of ACTG trial participants were women, roughly the proportion of those making up the proportion of women infected). Community based clinical trials, such as the Community Programs for Clinical Research on AIDS (CPCRA) and AmFARÕs community based clinical trials network, as well as industry studies, have as part of their mission to include classically under-represented persons, such as minorities, women, and people with current or history of injection or other drug use. Equal representation, however, does not necessarily translate into ability to detect gender differences in study outcomes (13). Of course, this is not only true for studies of HIV; however, caution is urged in imposing standards for studies to be able to detect gender differences as the number of patients required to demonstrate small differences may be prohibitive (14). While most indications are that women will respond similarly to men for studied regimens, differences found in Òreal practiceÓas compared to the clinical trials setting may be exaggerated in women (15). In the clinical setting implementation of strategies used by clinical trials to encourage follow-up should be initiated.

NATURAL HISTORY OF HIV INFECTION IN WOMAN

Early in the epidemic several studies suggested that women with HIV might have worse outcomes than men (16,17). However, subsequent studies that controlled for access to medical care and other characteristics have not revealed differences in the rate of disease progression (18,19). While the natural history may not vary between men and women, several studies suggest that important surrogate markers such as CD4 + count and viral load may have gender-speciÞc differences.

As CD4 counts may differ by gender even in a healthy population, this may to some degree account for the lack of differences in natural history reported in the studies cited above. For example, it has been documented that immunocompetent women tend to have signiÞcantly higher CD4 counts than men (20) and women infected with HIV maintain a slightly higher CD4 cell count than men (21).

Viral load following HIV seroconversion has been shown to be an independent predictor of the risk of progression to AIDS and death (22). Although conßicting data exist, collective evidence to date indicates that there are differences in viral load, particularly within the Þrst Þve years of infection in women as compared to men. Early studies, such as those published by Bush (23) and Lyles (24) found no signiÞcant difference in the baseline viral loads of men and women. However, in both studies, although non-signiÞcant, the viral loads of women off treatment were approximately one-half that of the men; in BushÕs study, this discrepancy persisted after the participants received therapy. The lack of signiÞcance in these studies might be explained by the small sample sizes.

One of the Þrst studies to show a discrepancy in viral load was a report from the ALIVE cohort, a prospective study following HIV seropositive and seronegative injection drug users. In this cross-sectional study, Farzedegan et al. found that among 421 men and 106 women, baseline viral load in women was almost 40% lower than that of men (25). A more deÞnitive characterization of this phenomenon came from a subsequent prospective study from the same cohort (26). Of 3,380 IDUs, a total of 202 (77% men and 23% women) seroconverted and met inclusion criteria for the analysis. Women were signiÞcantly younger at seroconversion (36.7 years vs. 32.6

years). At the first visit after seroconversion, none was utilizing antiretroviral therapy (ART), whereas proportions utilizing ART were similar at subsequent visits. At the initial visit after seroconversion, it was found that the viral load was significantly lower in women as compared with men. This effect persisted throughout the second year after seroconversion although it became less pronounced several years out. Importantly, there was no difference with regard to time to clinical progression at these visits or subsequently.

Similar results emerged from a comparative study of the WIHS and MACS cohort (26). This study examined the impact of gender on HIV progression. After adjustment for differences in measurement, HIV-1 RNA levels were 32–50% lower in women than men with CD4+ counts of greater than 200 but not at counts lower than that. Women were also noted to have more rapid declines (almost twofold) in CD4+ counts than men. While all studies controlled for possible confounding factors, of note is that the WIHS/MACS comparative study also found that injection drug use was independently associated with a lower viral load, as was being non-white. Furthermore, women tend to be younger at seroconversion than men, which was the case in the ALIVE cohort. In male cohorts, CD4 counts tend to be higher in younger patients, again underscoring the possibility that women may have a larger early decrease.

The basis for differences in viral load response by gender is unknown. It has been suggested that the differing hormonal milieu of women and men may have an effect on viral replication (25). Reproductive hormones have been shown to have an impact on lymphocyte function and cytokine production (28,29). The underlying questions are whether these early differences in immunologic and virologic markers have any significance for eventual clinical outcomes and whether antiretroviral therapy should be initiated at a lower viral load than is currently recommended for men. Several factors need to be considered when addressing these critical questions. First, as noted above, it appears that men and women have a similar rate of progression to AIDS, even in the studies reporting discrepant viral loads for the first several years of infection. Second, a viral load cut-off above which rapid progression to AIDS can be predicted has not yet been identified. Third, differences in viral load appear to be most pronounced during the first few years of infection when the risk of progression to AIDS and death is lowest. Fourth, numerous studies have confirmed that the CD4+ cell count appears to be a better predictor than viral load. Finally, recent treatment recommendations have altered cutoff values for consideration of treatment of HIV disease. As a result, treatment is generally not recommended until later in the disease, a setting where viral load levels of men and women tend to be similar for a given CD4+ count. Thus, at this time, there are no differential therapeutic recommendations for HIV therapy based on gender.

DIFFERENCES IN OPPORTUNISTIC INFECTIONS

Rates of HIV-associated illnesses are generally similar between men and women. Nonetheless, there are some differences. Historically, women have experienced lower rates of Kaposi's sarcoma (KS) (30). Although KS remains rare in women, unusual presentations have been noted, including KS presenting as a vulvar mass and diagnosis by cervical biopsy (31,32). Although rates of KS in women have increased somewhat, they remain substantially below that of men, a phenomenon that is thought to be due to a lower prevalence of HHV-8 the putative etiologic agent of KS. However, HHV-8 is present in women. In a recent study from the WIHS, HHV-8 infection was noted in 15% of HIV-infected women and in 6.3% of those without HIV infection (33). Sexual acquisition of HIV appeared to be the strongest risk factor for serologic reactivity to HHV-8.

Rates of other opportunistic infections (OI) are approximately equal in men and women. Early studies suggested that that esophageal herpes and candidiasis were more common in women (34,35). More recent data, obtained after the widespread availability of HAART, indicate that some differential rates may exist, but may not be solely attributed to gender. Data from the Adult Spectrum of Disease study, the largest database of patients receiving care for HIV disease in the United States, examined rates of opportunistic infections over the time of availability of HAART (36). From 1996 to 1998, it was found that women experienced a higher incidence of esophageal candidiasis, tuberculosis, cryptosporidiosis, and toxoplasmosis. Not noted was whether these incident OIs were presenting conditions for the population studied or whether they occurred at follow-up when the patients were under care. Most important, variations appear to be associated with risk, but not necessarily gender. Injection drug users (particularly active users) may be more likely to experience certain OIs, but these rates are similar between men and women.

GENITAL TRACT INFECTIONS

Gynecologic infections are frequently found in women at risk for HIV, as well as those with HIV infection. The immunosuppressive effects of HIV can alter both their frequency and natural history. Given the risk factors for HIV, sexually transmitted diseases (STDs) represent a significant concern. Nonetheless, available data suggests that new STDs occur with approximately equal frequency in HIV-infected and uninfected women (37,38).

Bacterial Vaginosis

Bacterial vaginosis (BV), although not considered a sexually transmitted disease, is the most frequent cause of

vaginal symptoms among women of childbearing age (39). It is thought to result from a disruption of the normally acidic vaginal environment created by lactobacilli. For reasons that are not clear, disruption of the microßora occur resulting in the overgrowth of such organisms as *Gardnerella vaginalis*, anaerobes and *Mycoplasma hominis*. Subsequent data have borne out important perinatal sequelae of untreated BV, including premature rupture of membranes, preterm delivery and chorioamnionitis.

There is no speciÞc evidence that BV pursues a more aggressive course in HIV-infected women. However, several studies have found that women with BV appear more susceptible to infection with HIV (40Ð43). Sewankambo et al. reported on approximately 4,000 women in Uganda; of those with severe BV, HIV prevalence was 26.7% as compared to 14.2% in those with normal vaginal ßora (40). In a prospective study in Malawi, of 1,159 HIV seronegative women, only one woman with no symptoms associated with microßora changes associated with BV became HIV infected; in the group meeting all criteria for BV, 10 of 274 seroconverted, yielding an odds ratio of 3.72 (41). This increase in susceptibility is thought to be secondary to changes in vaginal ßora, including lack of lactobacilli, leading to a less acidic vaginal environment. More recent work suggests that the organisms that become active in the altered vaginal ßora associated with BV may promote HIV-1 expression through the production of a cytokine-like substance, termed by some as ÒHIV inducing factor (HIF)Ó(42,43). Treatment of BV as delineated by the Centers for Disease Control is outlined in Table 14.1.

Trichomoniasis

Trichomonas is also a frequent cause of vaginitis, and is found in women at high risk for sexually transmitted diseases (44). As with BV, studies have suggested that women with trichomoniasis are at higher risk of sexual acquisition of HIV (45). Trichomoniasis is thought to create an easier portal of entry for HIV by causing inßammatory changes in the vaginal mucosa, such as punctate hemorrhages and local cellular inÞltration. As a result of local inßammation, bidirectional increased risk is thought to occur, leading to an increased chance for infection of the partner of HIV-infected women, thus underscoring the importance of treatment of the patient and her partner expeditiously. As with BV, trichomoniasis may pursue a more aggressive course in the HIV-infected patient. Both patient and sexual partner should be treated with either a single 2-gram dose or a seven-day course (500 mg twice daily) of metronidazole, if infection is identiÞed.

Although STDs causing genital lesions may lead to increased rates of HIV infection, both trichomoniasis and BV may result in more HIV infections because of their much greater prevalence (46).

TABLE 14.1. *Recommended management for bacterial vaginosis*

- Metronidazole 500 mg po twice a day for seven days
- Clindamycin cream 2%, 5 g intravaginally at bedtime for seven days
- Metronidazole gel 0.75%, 5 g intravaginally twice a day for ve days

Note: Clindamycin cream is oil-based and may weaken latex condoms and diaphragms.
Alternative regimens: metronidazole 2 g po × 1 dose, or clindamycin 300 mg po twice a day for 7 days.
Source: CDC, 1998.

Vulvovaginal Candidiasis

Several reports early in the AIDS epidemic indicated that HIV-infected women with mild to moderate immune deÞciency have higher rates of vulvovaginal candidiasis (VVC) and may be more recalcitrant to treatment than their HIV-negative counterparts (47Ð49). The frequency of VVC has been shown to signiÞcantly increased only in those HIV-infected women with a CD4+ count of less than 100/mm^3 (50). However, a more recent study utilizing the HERS cohort, with the beneÞt of physical exam, cultures and a HIV-seronegative control group, did not Þnd that vaginal candidal disease is more frequent in HIV seropositive women (51). Although HIV-positive women were more likely to report a history of VVC (84% vs. 77%), the rate of women with VVC at the time of the cross-sectional examination was identical for the HIV seropositive and negative groups (9%). Although HIV-infected women appear to be more likely to be colonized with candida (37% vs. 21%), these colonization rates were similar regardless of CD4 count; thus, the signiÞcance of this is uncertain. Also, women reporting a history of frequent VVC infections were not more likely to be colonized at time of exam. Of interest, HIV seronegative women were more likely to be colonized with a non-albicans species (most frequently *C. glabrata*), although a common perception holds that the opposite is true, e.g. that HIV-infected women harbor more atypical strains.

Therapy should be initiated with topical azoles and may be more effective if given for at least seven days. Persistent or recurrent infections may be treated with oral azoles, particularly one dose (150 mg) of ßuconazole. In this case, conÞrmation of diagnosis by culture with species identiÞcation and susceptibilities may prove useful, although recent application of antifungals may inhibit growth. Recent data indicate that VVC was decreased in an *in vitro* model with indinavir and ritonavir, which strongly inhibit an enzyme considered to be a virulence factor of pathogenic Candida species (52).

Factors promoting VVC in any patient population should be identiÞed and controlled, if possible. Examples of co-factors would be concomitant diabetes, steroid use,

tight-Þtting clothing, douches and pregnancy. Although ßuconazole, 200 mg po weekly was found to be effective in preventing recurrent VVC and oral candidiasis, it is thought by some to be unnecessary (46). Consideration for prophylaxis might be given if antibiotics are prescribed and the patient has a history of VVC with antibiotic administration.

Ulcerative Diseases

Genital ulceration in the context of HIV infection is perhaps best recognized for its facilitative role in the HIV transmission (53Ð55) and may increase the risk of both acquisition (in the HIV-negative woman) as well as transmission.

In the evaluation of the immunocompromised woman with genital ulceration, a complete history and a full evaluation including cultures and appropriate blood work are appropriate as the presentation may not be classic. Complete examination should include a dark-Þeld examination or direct immunoßuoresence test for *T. pallidum*, HSV culture or antigen tests, as well as consideration of *H. ducreyi* culture. Multiple agents can be present in as many as 20% of patients.

Idiopathic genital ulcers have been described in women with advanced HIV disease (56,57). They present as intractable ulcers that can progress to Þstula formation and have been reported to cause severe bleeding. Clinical responses have been noted following coricosteroid treatment, initiation of antiretroviral therapy, and thalidomide (58).

Herpes Simplex Virus

Ulcer disease caused by HSV is common: data from the National Health and Nutrition Exam Survey (NHANES III) (59) revealed an HSV-2 seroprevalence of 21.9% among 13,000 participants. Additionally, one of the strongest predictors of positive serologic status was female sex. In immunocompetent people genital ulceration tends to be secondary to HSV-2; however, as immunosuppression progresses, HSV-1 also frequently presents as a genital ulcer. Severe herpetic outbreaks may indeed herald the onset of severe immunosuppression. The extent of disease in severity and locale may make it difÞcult to differentiate HSV infection from zoster. HIV-infected women with genital HSV-2 infections are more likely to shed HSV and to have more frequent recurrences than are HIV-negative women. Recurrences have been shown to increase in patients with lower CD4+ counts (60).

Although several antiviral agents newer than acyclovir are on the market, given its low cost, it should be considered the Þrst-line agent. Other agents such as famciclovir or valacyclovir can be considered if the patientÕs pill burden is such that it would preclude adequate adherence. (Treatment with acyclovir requires dosing at three to Þve times per day versus other agents requiring BID dosing.) Similarly, for successful suppressive therapy, the once a day dosing of valacyclovir may be better suited for selected patients than the increased dosing required for the other medications. Treatment and suppressive therapy guidelines are listed in Table 14.2.

Acyclovir resistance is not uncommon and can be observed in 11Ð17% of HIV-infected patients (61).

TABLE 14.2. *Recommended management for HSV*

	Drug	Dose
First clinical episode	Acyclovir	400 mg po three times a day for 7 to 10 days
	Acyclovir	200 mg po five times a day for 7 to 10 days
	Famciclovir	250 mg po three times a day for 7 to 10 days
	Valacyclovir	1 g po twice a day for 7 to 10 days
Recurrent episodes	Acyclovir	400 mg po three times a day for 5 days
	Acyclovir	200 mg po five times a day for 5 days
	Acyclovir	800 mg po twice a day for 5 days
	Famciclovir	125 mg po twice a day for 5 days
	Valacyclovir	500 mg po twice a day for 5 days
Daily suppressive therapy	Acyclovir	400 mg po twice a day
	Famciclovir	250 mg po twice a day
	Valacyclovir	500 mg po once a day
	Valacyclovir	1000 mg po once a day
Severe disease	Acyclovir	5 to 10 mg/kg body weight IV every 8 hr for 5 to 7 days or until clinical resolution is achieved
Acyclovir-resistant HSV	Foscarnet	40 mg/kg body weight IV every 8 hr or 60 mg/kg IV every 12 hr for 3 wk
	Topical Cidofovir gel 1%	Applied to lesions once a day for 5 consecutive days

Source: CDC, 1998.

TABLE 14.3. *Recommended management for syphilis*

Stage	Treatment
Primary and secondary syphilis and early latent	Benzathine penicillin G 2.4 million units IM (single dose); additional treatment recommended by some (i.e. three weekly doses of penicillin)
If penicillin-allergic (nonpregnant patients only)	Doxycycline 100 mg po twice a day for 2 wk, OR tetracycline 500 mg po 4 times a day for 2 wk
Late latent syphilis or syphilis of unknown duration (including tertiary syphilis)	Examination of the CSF must be performed before initiating treatment. If the CSF examination is negative, patients should be treated with 7.2 million units of benzathine penicillin G IM (three weekly doses of 2.4 million units each)
Neurosyphilis	Aqueous crystalline penicillin G 18 to 24 million units a day (administered as 3 to 4 million units IV every 4 hr) for 10 to 14 days. Administration of benzathine penicillin 2.4 million units IM after completion of the IV regimen recommended by some.
	Recommended follow-up
Primary and secondary syphilis	HIV-infected patients require clinical and serologic evaluation for treatment failure at 3, 6, 9, 12, and 24 mo after treatment. Treatment failures necessitate a CSF examination and retreatment (three weekly doses of 2.4 million units of benzathine penicillin G if CSF examination is negative). The latter regimen should also be considered for patients whose titers do not decrease fourfold within 6 to 12 mo.
Latent syphilis	HIV-infected patients require clinical and serologic evaluation at 6, 12, 18, and 24 mo after treatment. The CSF examination should be repeated and appropriate treatment instituted if clinical symptoms develop, titers rise fourfold, or if titers fail to decline fourfold between the evaluations at 12 and 24 mo.
Neurosyphilis	CSF examination should be repeated every 6 mo until the cell count is normal. Retreatment should be considered if the cell count has not decreased after 6 mo or if the CSF is not entirely normal after 2 yr.

CSF, cerebrospinal uid.
Source: CDC, 1998.

HIV-infected women who do not respond to standard therapy should have the diagnosis conÞrmed by culture. In the absence of clinical response, alternatives such as intravenous acyclovir, foscarnet, topical trißuride or topical cidofovir should be considered (62).

Syphilis

Clinical manifestations of syphilis in the HIV-infected patient appear similar to those of HIV-negative women. However, the diagnosis of syphilis may be complicated by a higher rate of false-positive serologic tests, presumably secondary to HIV-induced polyclonal activation (63). The recognition, treatment, and evaluation of syphilis in immunocompromised individuals should be aggressive and consistent with guidelines promulgated by the CDC. Neurosyphilis should always be considered in light of abnormal neurologic Þndings in the HIV-infected person. Also, it is not unusual, particularly in the immunocompromised person with HIV, that symptoms usually attribute to particular stages of syphilitic infection may occur in tandem, not at all, or in a more accelerated fashion.

The CDC has outlined alternative treatment options for individuals with penicillin allergies, which are presented in Table 14.3. If the history indicates mild to moderate penicillin sensitivity, with no history of life-threatening respiratory involvement or Stevens Johnson syndrome, desensitization may be considered. As concern exists about the possibility of higher relapse or non-response rates in HIV-infected persons (64), follow-up after treatment should be vigilant and include clinical and serologic evaluation.

Chancroid and Other Causes of Ulcerative Diseases

Chancroid, although relatively rare, should be considered in the differential diagnosis of ulcer disease. Of 143 men evaluated in an outbreak of genital ulcer disease, Mertz, et al. (65), found that 39% were positive for *Haemophilous ducreyi*, the causative organism of chancroid. The genital ulcer surveillance group found ulcers positive for *H. ducreyi* greater than 10% of the time in Chicago (12%) and Memphis (20%) (65). Chancroid should be suspected as the etiology of genital ulcerative disease in patients with a history of a singular tender

pustule subsequently becoming ulcerated or multiple ulcers with lymphadenopathy when herpes infection has been ruled out. Culture is not universally available; laboratories should be notiÞed if *H. ducreyi* is being considered. The degree of suspicion should be raised if the patient originates from an area where *H. ducreyi* is endemic and as common as gonorrhea, such as parts of Africa and Asia.

Anecdotal reports suggest that patients with HIV and chancroid require more prolonged therapy than HIV-uninfected patients (66). Nonetheless, treatment failure was not associated with HIV seropositivity in a randomized, controlled trial of the treatment of chancroid comparing ciproßoxacin with erythromycin (67).

Both lymphogranuloma venereum (LGV) and granuloma inguinale (donovanosis) are rare conditions in the U.S. In addition to genital ulcerations, LGV presents with painful lymphadenopathy, usually unilateral; additionally, Þstulae or strictures may be present. Diagnosis is through exclusion of other causes and appropriate serology. Treatment is erythromycin or doxycycline for three weeks; however, HIV-positive persons may require extended courses of treatment. Ulcers in donovanoisis tend to be painless and friable and without associated lymphadenopathy. Diagnosis is with site biopsy. Treatment is also for three weeks, with either TMP-SMX or doxycycline; the CDC also recommends adjuvant aminoglycoside in those with HIV infection.

Pelvic Inßammatory Disease

Pelvic inßammatory disease (PID) is a severe complication of STDs. Concomitant HIV infection is frequently seen in patients with PID with rates ranging from 8% in the U.S. to as high as 29% in Africa (68,69). As a result, serologic testing for HIV should be offered to women with a diagnosis of PID.

HIV infection appears to alter the course of PID. For example, in one study of matched autopsy specimens, HIV-infected women had a higher prevalence of endometritis than did HIV-negative patients (70). It also appears that HIV-infected women may be more likely to develop complications of PID such as a tubo-ovarian abscess (TOA). In the PID-HIV infection study, comparing 44 HIV-infected women and 163 non-infected women, rates of sonogram-conÞrmed TOAs were higher (bordering on signiÞcance), with 45.8% of HIV-infected women having TOAs versus 27.1% of the HIV-negative group ($p = 0.07$) (71). Similarly, an earlier study reported that HIV-infected women had a higher rate of TOA (22.6% vs. 13.7%; $p = 0.24$), as well as more frequent surgical interventions (26.6% vs. 8.4%; $p = 0.058$) (72). These and other studies have also noted higher fevers, lower white blood cell counts, and higher erythrocyte sedimentation rates in HIV-infected women, compared to seronegative controls (73).

Although studies such as those cited above suggest a more aggressive course, prospective studies have shown little difference between HIV-positive and HIV-negative women in response to antibiotic therapy. As a result, outpatient therapy has been used with success in HIV-infected women (71,73).

HPV, CERVICAL DYSPLASIA AND CERVICAL CANCER

Cervical dysplasia, a precursor of cervical cancer is strongly associated with HIV infection. The prevalence and incidence of cervical and squamous intraepithelial dysplasia is also strongly associated with declining CD4 count, a higher plasma HIV viral load and the presence of human papillomavirus (HPV) (74,75). Progression to invasive cervical cancer (ICC), is usually associated with oncogenic strains of HPV such as HPV-16 or HPV-18 and progresses in a largely stepwise fashion, with progression through mild atypia, low and high grade dysplasias, *in situ* carcinoma, and Þnally to invasive carcinoma.

Given the incidence and prevalence of other STDs in HIV-infected women, one might expect the rates of HPV to be similar to that of HIV-negative women. As highlighted in this section, rates of HPV incidence, carriage, as well as the prevalence of the spectrum of HPV related disease is disproportionately higher in HIV-infected women. With the publication of studies demonstrating increased rates of pre-cancerous cervical lesions and a small number showing increased rates of ICC, cervical cancer was added to the AIDS case deÞnition in 1993. As will be discussed below, this inclusion may have been somewhat premature. While rates of all HPV-associated lesions are higher in HIV-infected women, invasive cervical cancer rates may not be increased.

Squamous Intraepithelial Lesions/Oncogenic HPV Carriage

Incident and prevalent cervical squamous intraepithelial lesions (SIL) are found more frequently in the HIV-infected woman (76). In one study, which assessed the cervical manifestations, the investigators compared 328 HIV-infected and 325 HIV uninfected women with negative Pap smears at baseline. Using polymerase chain reaction (PCR), 54% of HIV-infected women had HPV detected as compared with 32% of the HIV-negative women. During follow-up, 20% of HIV-infected women showed biopsy conÞrmed SIL compared to 5% of HIV-negative women. This and other studies have found oncogenic types of HPV more frequently in HIV-infected women. Utilizing the same cohort as referred to in the above study, Sun et al. found that rates of oncogenic types of HPV was higher in HIV-infected women (77).

Cancer

Although rates of cervical intraepithelial neoplasia (CIN) have been shown to be higher and more persistent in

HIV-infected women, follow-up studies have not definitively shown higher rates in women with HIV disease. One early study in Brooklyn, New York, showed rates of cervical cancer significantly higher than that expected in that community (78). A subsequent study in Germany found that of 111 HIV-infected women 4% presented with ICC as compared to none of 76 hospitalized injection drug using women and 0.4% of HIV-negative women presenting to an outpatient clinic (79). Several more recent studies (80,81), however, failed to show increased rates of cervical cancer. Possible reasons for this discrepancy include the long length of time for full carcinomatous changes to develop coupled with a relative shorter life expectancy of HIV-infected women. In a study of participants in Cote dÕIvoire, ICC was not found to be associated with HIV-1, but was significantly associated with HIV-2, leading some to speculate that those infected with HIV-1 would die from other AIDS related causes prior to developing cervical cancer in contrast to the slower disease course allowed by HIV-2 (80). An additional study revealed that the rate of abnormalities by Pap smear was 81% when women were HIV-infected and had carriage of an oncogenic HPV type (81). Surveillance in the form of screening at adequate intervals through provider awareness of the inclusion of cervical cancer in the AIDS case definition, may also have largely precluded advancement of potential lesions to the invasive stage. Thus, early fears that fulminate cervical cancers would result from aggressive and accelerated HPV progression have not been borne out.

Extracervical Disease

Areas outside of the cervix, including the vulva and the vagina, have been reported to show abnormal changes associated with HPV in patients with HIV. For example, one study reported HPV-induced changes in extracervical areas (vulvar, vaginal, perianal, or multicentric) as being much more common than in HIV-negative controls (8% vs. 1%, respectively) (82). Of note, most women who developed extracervical disease had a history of CIN.

HPV associated genital warts are also detected more frequently in HIV-infected women. Chirgwin et al. (83), found the prevalence of warts to be 8.7% in HIV-infected women as compared with 1.2% in HIV negatives. Chiasson et al., using a different NYC cohort, also found the difference to be significant between HIV-positive and -negative women (5.6% vs. 0.8%, respectively) (84).

A more recent examination of the cohort reported on by Chirgwin et al. yielded an odds ratio of 9.33 for the incidence of genital warts in HIV-infected women (11.4% vs. 1.4%) as compared to those uninfected (85). Indeed, of all the gynecologic disorders examined by this cohort, those attributable to co-infection with HPV constituted the three highest increased risks (genital warts, OR = 9.33; abnormal Pap, OR = 7.76; presence of oncogenic HPV, OR = 2.0).

Smoking has previously been shown to increase the risk of cervical cancer, presumably via its impact on HPV. Similar findings have been noted in smokers with HIV and genital warts. One study demonstrated rates of genital warts that were three times higher in female smokers for both HIV-positive and -negative women (86). The relative risk was greatly increased (5.2) when adjusted for HIV status and foreign versus American born status.

Persistence

Persistence of HPV carriage is increased, and recurrences of cervical HPV associated lesions occur more frequently in HIV-infected women. The previously mentioned Ellerbrock study (76) showed that among women with HPV detected at baseline, a greater proportion of HIV-infected women persistently shed HPV compared with their HIV-negative counterparts (61% vs 23%, respectively). Recurrences of HPV mediated cervical disease are also more frequent. In a group of women with identified CIN who underwent treatment and follow-up, 69% of the HIV-infected women had subsequent abnormal Pap smears compared to 31% of HIV-negative women (87).

Mechanism

Based on the fact that rates of nonviral STDs are not generally increased in the HIV-infected woman, exposure to new strains of HPV probably only plays a minor role in the increased rates of carriage and HPV disease seen in HIV-infected women. It has been suggested (88), that viral interplay may Ònunmask Ólatent HPV infection; specifically, that the tat region of HIV may upregulate the E6 and E7 regions of HPV. As HIV needs only to be active and replicating for this to happen, this upregulation may occur early in infection, accounting for the increased incidence of HPV shedding earlier, rather than later, in the course of disease.

CD4/VL Association

Rates of HPV carriage, especially of oncogenic types, appear to be associated with decreasing CD4 counts and a higher HIV RNA load (89,90). Luque et al. showed that of 74 women with HIV RNA measurements available, 59% with HIV RNA greater than 10,000 copies/ml had detection of oncogenic HPV types as compared to 19% whose viral load was less than this number (81). Of note, 81% of those in the higher viral load bracket had an abnormal Pap smear compared to 24% of those in the lower category.

Depressed CD4 counts may also predict higher rates of recurrence of disease and persistence of HPV infection.

Fruchter et al. (87) showed that in women with CIN and a CD4 count of less than 200, rates of recurrence were as high as 87%. Sun et al. (91) similarly demonstrated higher rates of persistence of HPV shedding in women with CD4 < 500 as compared to HIV-negative women or HIV-infected women with a CD4 > 500. Interestingly, rates of detection of new oncogenic HPV have been shown to be inversely correlated with CD4 decline; that is, detection of new oncogenic HPV in women with CD4 greater than 500 was 45.3/100 person years as compared to 20.6/100 patient years in those with CD4 less than 200 (90). The authors suggest that ÒnewÓ detections may actually represent reactivation of old infections and that the viral interplay thought to precipitate this reactivation is likely to occur earlier, rather than later in HIV infection. The study by Luque et al. which demonstrated a relationship between viral load and presence of oncogenic HPV, did not reveal a similar relationship to CD4; however, the sample size was smaller and the study was cross-sectional, and therefore unable to comment on incidence or recurrence with time and changing CD4 (81).

Screening

Screening recommendations for HPV-mediated disease are based on recommendations which have been outlined by the U.S. Public Health Service (92). A Pap smear should be included in the initial work-up after HIV infection is conÞrmed. An additional Pap smear in the Þrst year should be obtained regardless of an initial negative result and if the results are normal, annually after that. More frequent Pap smears should be obtained after the evaluation and/or treatment of abnormal results. For patients whose Pap smears are interpreted as atypical squamous cells of undetermined signiÞcance (ASCUS), several management options are available; the choice depends in part on whether the interpretation of ASCUS is qualiÞed by a statement indicating that a neoplastic process is suspected. Follow-up by Pap tests without colposcopy is acceptable, particularly when the diagnosis of ASCUS is not qualiÞed further or the cytopathologist suspects a reactive process. In such situations, Pap tests should be repeated every four to six months for two years until three consecutive smears have been negative. If a second report of ASCUS occurs in the two-year follow-up period, the patient should be considered for colposcopic evaluation.

Patients with Þndings of ASCUS or low grade SIL should have follow-up four to six months after identiÞcation of the initial lesion. Those with higher-grade lesions should receive subsequent Pap smears after treatment at three to four month intervals; if subsequent Pap smears are negative, a reduction in frequency to every six months is appropriate. Colposcopy is warranted after a single Pap demonstrating cytologic atypia and may be warranted after a smear revealing severe inßammation. All women with a diagnosis of SIL should have colposcopy.

Treatment

As with other opportunistic infections in HIV-infected patients there is evidence of improvement in HPV associated lesions with the use of HAART. In one study of 168 women with median follow-up of 17.7 months, women with both high and low grade lesions were found to regress twice as fast if using a PI or NNRTI inclusive regimen (93). Regression to normal was 23.8% for high grade and 14.8% for low grade lesions. HAART was found to be associated with regression when other factors, such as CD4 count and HIV-RNA levels, were controlled for (93). Other studies have presented similar results (94); however, at least one study did not Þnd an associated decrease in progression or increase in regression with the use of HAART (95). Nonetheless, the use of antiretroviral therapy does not modify recommended treatment and surveillance algorithms for HPV mediated disease.

Table 14.4 summarizes treatment and follow-up recommendations. High-grade lesions should always be treated with coninization or loop excision. Cryotherapy has yielded rates of recurrence over 50%, which increases with degree of immunosuppression (96,97). Topical 5-ßououracil (5-FU) has been shown to decrease rates of recurrence following treatment for high-grade lesions (98). Its role as prophylaxis in low-grade lesions remains controversial and is probably not warranted at this time because of irritant effects on vaginal mucosa and the possibility of increased rates of transmission of HIV with administration. Patients with invasive carcinoma are best treated

TABLE 14.4. *Recommended management for abnormal Pap smears*

Pap Smear Result	Management (Based on Histologic Findings)
Severe in ammation	Evaluate for infection; repeat Pap if inadequate
Atypia, atypical squamous cells of undetermined signi cance	Colposcopy, biopsy if indicated; follow with Pap q 6 mo
Low-grade squamous intraepithelial	Colposcopy, biopsy if indicated; follow lesion (CIN 1) with Pap q 6 mo: consider repeat colposcopy annually
High-grade squamous intraepithelial lesion (CIN 2 or 3), carcinoma *in situ*	Colposcopy, biopsy; treat with loop excision or conization
Invasive carcinoma	Colposcopy with biopsy or conization; treat with surgery or radiation (referral to gynecologic oncologist needed)

Source: CDC, 1998.

by gynecologic oncologists; referral should be made appropriately.

SEX-SPECIFIC ISSUES

Menstrual Effects

Chronic diseases that do not directly affect the reproductive tract can result in menstrual dysfunction. Both renal and hepatic diseases have been reported to cause menstrual abnormalities. Early reports suggested that HIV-infected women experienced menstrual abnormalities more frequently than HIV-negative counterparts (99). Subsequent cross-sectional studies using retrospective data were contradictory with one study reporting an association (100) and another reporting no association between the presence of oligomenorrhea, amenorrhea, menorrhagia or dysmenorrhea and HIV serostatus or CD4+ cell counts (101). In a single site study Chirgwin et al. utilized prospectively recorded menstrual calendar data and noted that HIV-infected women were more likely to experience long cycles and amenorrhea (102).

In order to further deÞne the impact of HIV on the menstrual cycle, a prospective study of participants in the HERS and WIHS cohorts was initiated utilizing menstrual diaries. HIV infection was associated with very short cycles (< 18 days) (103), although the odds of this Þnding were of borderline signiÞcance after controlling for multiple factors, including age (OR, 1.45; CI, 1.00Ð2.11). However, women with a CD4 count less than 200 were more likely to have cycles greater than 40 days. Higher viral load was associated with very short cycles, longer mean cycle length and more variable cycles. Thus, these Þndings suggest that menstrual dysfunction is primarily associated with advanced HIV disease. Other determinants, such as age, substance use, and body mass index probably represent more important etiologic factors causing menstrual dysfunction.

Hypermenorrhagia may lead to anemia; if dysmenorrhea is not identiÞed as the source, erroneous decisions may be made regarding the etiology of the anemia with subsequent inappropriate decisions such as changing ART or attributing anemia to disease progression. Although menstrual irregularities may be overlooked as minor, ascertainment of the origin of such changes is warranted. Decreased estrogen levels may predispose women to a number of adverse outcomes and should be regarded similarly as in the HIV-negative woman. Premenopausal, sexually active women should have pregnancy ruled out, and in the case of evidence of anovulatory cycles, the issue of desire for reproductive capability should be addressed. Known disturbances to the hypothalalmic-pituitary axis leading to menstrual changes (particularly oligo- or amenorrhea) should be evaluated. For example, ascertainment of psychological stress or changes with age and addressing those issues may be more appropriate than dismissal of symptoms to advancing HIV disease. Furthermore, female-speciÞc adverse events of certain drugs should be discussed with patients. Megace, a progestin based agent used frequently for wasting, may cause irregular bleeding.

Reports of night sweats in conjunction with irregular or absent menses in the pre- or peri-menopausal woman should prompt the clinician to conÞrm whether the reported symptoms may be an indication of Òhot ßashesÓ rather than assuming night sweats. Estrogen deprivation, especially prematurely, is being investigated as a cause of many adverse outcomes, some of which may mimic or exacerbate HIV-related conditions. The lipodystophy syndrome may promote advanced or early cardiovascular disease, as does a lack of estrogen. Osteoporosis is a concern for all women with decreased estrogen and may be likely as HIV-infected women live longer. It may be secondary to poor nutrition and inability to perform weight-bearing exercise. In prescribing hormone replacement therapy, care must be used in using these agents in combination with HAART, as drug interactions may occur. For example, known interactions exist with some oral contraceptives (OCPs) and ARTs: nevirapine decreases levels of ethinyl estradiol (104), as does ritonavir. Conversely, indinavir may to lead to an increase in the estrogen component of OCPs, although the clinical signiÞcance is unknown (105). These studies suggest that interactions such as those described may alter the levels of endogenous hormones. However, drug therapy has not been speciÞcally linked with the relevant clinical outcomes.

Determinants of HIV Shedding in the Female Genital Tract

As heterosexual transmission is the major worldwide mode of transmission of HIV (106) and most perinatal infection is thought to occur after exposure during delivery (107), determinants of predicting risk of exposure to HIV in the female genital tract are important. As discussed previously, epidemiologic studies have elucidated some determinants of increased risk of transmission, such as diseases leading to inßammation of the genital tract. More recently, investigators have added to these observational data through quantiÞcation of HIV in the female genital tract.

Several studies have demonstrated a positive correlation between HIV-1 RNA plasma levels and those found in cervical, vaginal or lavage specimens (108Ð111). These studies have shown demonstrable viral shedding between 29%Ð62% for vaginal swab or lavage samples and between 32%Ð67% for cervical samples. Some of the variation is attributable to differences in the sensitivity of the assays used. Hart et al. demonstrated that samples taken after initial swabbing have more blood present and

may account for higher viral counts (111). This point may be important as another study (112) demonstrated an increase in viral shedding if blood was present, irrespective of the quantity. This finding may be important in interpretation of data from another study suggesting that transmission of HIV occurs equally in a bi-directional manner between men and women in heterosexual activities (113). Thus, the presence of a minor amount of RBCs, as might be expected to occur during vaginal intercourse, might facilitate the sexual transmission of HIV.

Investigators evaluated Kenyan HIV-infected prostitutes (114) and found that gonococcal and candidal infections were associated with increases in genital HIV detection (OR = 3.1 (1.1–9.8) and 2.6 (1.2–5.4), respectively). Viral shedding was highly correlated with decreased CD4 count and symptomatic HIV disease; however, plasma viral loads were not performed as part of this study. Use of OCPs and depot medroxyprogesterone acetate (DMPA) were also associated with higher rates of viral shedding; this effect was still significant after controlling for CD4 count, as women with a higher CD4 count were more likely to use these contraceptive forms. Aforementioned studies in the United States (112) and elsewhere (109), however, did not document the same effects with the use of hormonal contraceptives. An increase in HIV shedding was also not seen with concomitant STDs when the studies controlled for viral load or CD4 (111).

Examination of the use of antiretrovirals has shown mixed results. In univariate analyses, the use of combination antiretroviral therapy has been associated with decreased viral shedding in some studies (112) but, when controlled for in a multivariate analysis with viral load, use of combination therapy lost its effect. One study evaluated changes in viral shedding when a new antiretroviral regimen was initiated and found that in 10/14 individuals changing therapy, the amount of viral shedding decreased to below the level of detection, which was significant when compared to the group who did not change therapies ($p = 0.006$) (111).

Despite the fact that there is a demonstrable correlation between plasma virus load and genital viral shedding, with presumed infectivity, exceptions do exist. Almost one-third of women with undetectable viremia (lower limit of assay 500 copies/ml) had detectable genital viral RNA (112). This suggests the possibility of a separate micro-environment reservoir for HIV and that eradication of viremia may not correlate with elimination of sexual transmission. Further studies should implement newer assays that allow for quantification of virus at a lower level and more sensitive, standardized assays for genital specimens to facilitate comparisons.

Lipodystrophy Syndrome in HIV-Infected Women

Lipodystrophy first attracted wide attention as a result of case reports describing "buffalo humps" (115) referring to fat accumulation along the upper back, and increased abdominal girth, characterized as "protease paunch" (116) or "Crix belly" (117), referring to increased abdominal girth associated with protease inhibitors (PI) or, for the latter term, indinavir (brand name, *Crixivan*). Associated metabolic abnormalities may include frank diabetes mellitus, hyperinsulinemia, dyslipidemia, (notably hyperlipidemia, with the exception of HDL, which tends to be reduced). Interestingly, although reports of gross redistribution of fat first brought this syndrome to attention, one of the first such published reports was not of truncal or dorsocervical fat pads, but of breast enlargement (118). Hypertrophy of the breasts of women has been described elsewhere and only in women (119–121) suggesting a hormonal influence.

As noted, these changes were first described in association with protease inhibitor use, although associations with nucleoside analogs have been found in some studies (122–125). Additionally, data reported from a retrospective case series prior to the introduction of protease inhibitors suggests the process may be linked to HIV disease and not to antiretroviral drug use, as there were indications of the existence of changes in body composition and metabolic abnormalities (126). Studies investigating the mechanism of these physical and metabolic changes suggest a causative effect of protease inhibitors on the metabolism of retinoic acid, disrupting subsequent steps in the differentiation and function of peripheral adipocytes (127). Hyperlipidemia results, in turn promoting hyperinsulinemia and diabetes in those with a pre-existing propensity; central fat accumulation occurs in some as those fat stores are thought to be more metabolically active and accumulate fat by default.

Initial characterizations of the body composition changes were done by case report, cross-sectional and case control studies. Often, patients were "self-diagnosed" or identification made by clinicians without objective measures, which has led to the large variability in the reported prevalence of these changes (from 2–84%) (128,129). In one prospective study of 494 patients, all of whom were taking a PI throughout the duration of the study period, the syndromes of lipoatrophy, lipodystrophy or mixed were detected by patients and confirmed by study clinicians, although objective measures, such as thigh and/or waist circumference, were not used (130). Seventeen percent of patients were found to experience lipodystrophy. Of the factors examined with regard to risk of developing lipodystrophy, female sex carried one of the largest hazard ratios (1.70, $p = 0.021$ in univariate analysis; 1.87, $p = 0.028$ in multivariate analysis). In a post-marketing report by Merck & Company, Inc., characterizing adverse event reports of lipodystrophy associated with indinavir use, the rate of fat redistribution in women was five times that seen in men (360/100,000 vs. 67/100,000) (131).

One study sought to describe body composition, metabolic parameters and selected sex hormone levels in a group of HIV-infected women in comparison to weight

matched HIV-negative controls (132) in which a large subset of the case patients (59 of 75) were considered to have wasting syndrome (less than 90% of ideal body weight or loss of greater than 10% of body weight prior to infection). Overall body fat percentage and lean body mass was similar between cases and controls; however, cases had signiÞcantly higher truncal fat and trunk to extremity fat ratio with a lower average extremity fat. Interestingly, there was no association with regard to PI use, although a signiÞcant correlation existed between duration of PI use and triglyceride levels. The relatively short duration of PI use (six months) may account for the lack of a statistical Þnding. Average insulin levels were higher in HIV-infected persons, which remained true after age matching with controls and 30% of the HIV-infected women were considered to be hyperinsulinemic. Insulin levels remained signiÞcantly higher in the subgroups analyzed, including those considered to have wasting disease and in those with an abnormal fat distribution (increased trunk-to-extremity fat ratio). Similarly, triglyceride levels in HIV-infected women were higher than those in controls; this effect was also seen in those with wasting as compared with controls.

These authors also examined many of these metabolic and hormone measures in eumenorrheic and amenorrheic case patients (132). Insulin levels were more significantly increased in amenorrheic patients, suggesting a contributing hormonal component, but other measures, including weight, truncal-to-extremity fat mass and testosterone levels were not different between these groups.

A subsequent study by the same authors (133) did demonstrate increased free testosterone in lipodystrophic women with HIV, as compared with either HIV-infected women without lipodystrophy and HIV-negative age and weight matched controls. Additionally, the LH : FSH ratio was increased in a similar manner. Estradiol levels were not signiÞcantly different among groups. Importantly, hormone levels were obtained at a standardized time during the menstrual cycle, in the early follicular phase, in contrast to other studies evaluating these same measures but which did not show differences. The possibility of hormonal contribution to the lipodystrophy syndrome is important to consider as similar metabolic abnormalities are found in women with hormonal disturbances, notably polycystic ovary syndrome (134,135).

This brief review underscores the need for further studies in this area, powered to detect an increased risk of the lipodystrophy syndrome in women. If hormonal mechanisms contribute to this process, this might guide research into interventions. The implications of this syndrome are great: hyperlipidemia, insulin resistance and central fat accumulation are factors known to lead to vascular complications (136,137). Interventions may be possible. In a small study (138) non-diabetic HIV-infected persons with hyperinsulinemia or abnormal glucose tolerance tests showed improvement in several parameters when treated with metformin compared to subjects receiving placebo. Reductions in insulin levels, weight and diastolic blood pressures were seen.

OBSTETRIC ISSUES

A singular milestone in the obstetric care of the HIV-infected woman was the ACTG 076 study reported in 1994, demonstrating a decrease in the rate of transmission of HIV infection from mother to infant from 25.5% in controls to 8.3% in women treated with ZDV during the third trimester and labor, plus administration of ZDV to the newborn (139). Although a challenging regimen, and amidst fears that more widespread use of the regimen would reveal unforeseen fetal outcomes, after the expeditious translation of these results into clinical guidelines, beneÞcial outcomes persisted in various contexts (140Ð142).

When assessing the pregnant woman with HIV infection, it is important to keep in mind that pregnancy itself does not affect progression of HIV disease (143,144). Pregnant women should, in general, receive the same therapy for HIV infection as they would if not pregnant. However, metabolic differences, speciÞc concerns about the teratogenic potential of certain drugs as well as considerations related to the prevention of perinatal transmission, need to be taken into consideration. For example, physiologic changes in pregnancy may affect the pharmacokinetics of antiretroviral drugs. In addition, some antiretrovirals should not be used in pregnancy. Efavirenz, for example, has been reported to cause teratogenic defects in animal studies and should not be used in pregnant women. If a woman becomes pregnant while on this agent, counseling regarding associated risks should be undertaken, and, should the pregnancy be continued, ultrasound performed to rule out anomalies (145). Hydroxyurea may also be teratogenic and should be avoided.

Since the publication of the ACTC 076 study (139), a number of Þndings have helped to deÞne the determinants of perinatal transmission of HIV. For example, while it is known that HIV can be transmitted from mother to child throughout pregnancy, studies suggest that the majority of HIV infected infants are infected during the intrapartum and post-partum periods. Together with data demonstrating a time dependency factor for seroconversion in neonates up until 90 days, it has been suggested that between 40Ð80% of transmission occurs in the peripartum period. This has been supported by a retrospective analysis of short courses of ZDV which indicated that administration of ZDV to the newborn or during the intrapartum period to the mother and subsequently to the neonate conferred rates of transmission lower than if not administered until three days of life (9.3%, 10.0%, and 18.4%, respectively) (140). Nonetheless, it appears that the mother's plasma viral load may be the most powerful predictor of the risk of perinatal transmission. If the viral load can be reduced to an undetectable level, the risk of mother-to-child transmission is extremely low (146,147).

Interpretation of data suggesting a beneÞcial effect on transmission of Cesarean section (C-section) is more complicated. As noted above, perinatal transmission usually occurs during the peripartum period. Several studies have now been published linking an increased period (>4 hours) of rupture of membranes to an increase in transmission rates (148,149). The beneÞts of C-section have now been conÞrmed in several prospective studies and meta-analyses (150Ð153). These studies have demonstrated a reduction in risk of transmission by odds ratios of between 0.2Ð0.45 for C-sections performed electively (prior to the onset of labor and/or rupture of membranes). In women receiving ZDV prophylaxis, this has resulted in transmission rates of 0 to 2%. It should be noted that the beneÞt of C-section has been more consistently seen with elective section. Although HIV-infected women have not been deÞnitively shown to experience perioperative infections at higher rates, the American College of Obstetrics and Gynecology (ACOG) has suggested that prophylactic antibiotics may be useful (154). Because of the multiple timepoints during gestation and delivery that transmission might occur and their relationship to absolute viral load, use of C-section should be considered secondary in importance to maximizing viral load reduction during pregnancy.

Ideally, assessment of maternal HIV serostatus and viral load should be made as early in pregnancy as possible. Current data neither support removing viral suppressive therapy nor denying initial therapy, even early in pregnancy (155), with the exception of efavirenz, which has been found to cause severe anomalies in monkeys with use in early pregnancy. Registries and animal safety data have not led to similar contraindications in any trimester of pregnancy for other antiretroviral agents.

With the utilization of measures adjunctive to the 076 protocol guidelines, such as maximal viral reduction and prudent use of C-section, it is highly likely that perinatal transmission will be dramatically reduced in this country. Although there has been improvement in the identiÞcation of HIV-infected women who are pregnant prior to childbirth since the implementation of ACTG 076 Þndings (70% in 1993 compared to 80% in 1996), progress in the identiÞcation of these women could still be made. The issue may be one primarily related to public health and education since the majority of those not tested prior to delivery have little or no prenatal care (1 prenatal visit) (156). New York State has addressed this issue by mandating that all women have access to knowledge of their HIV serostatus within 48 hours of giving birth. In this way, reduction of perinatal transmission will hopefully continue, even in light of lack of prenatal care and identiÞcation of HIV in the prenatal period.

Other studies of short courses of antiretrovirals are mainly being conducted in the developing world, where drug availability is more limited. Examples of successful regimens include a course of twice daily ZDV beginning at 36 weeks and during labor to nonbreastfeeding women. The rate of perinatal transmission in one such study was reduced by 50% (157). Other agents have also been studied to determine if they could play a role in short-course therapy. One such drug is nevirapine, a nonnucleoside reverse transcriptase inhibitor. In a Ugandan study, the effectiveness of short-course nevirapine (one dose of 200 mg to mother at the onset of labor and one dose of 2 mg/kg to babies within 72 hours of birth) was compared to zidovudine. Resulting transmission rates were 8.1% for nevirapine vs. 10.3% (158) for zidovudine. This study provided hope that an inexpensive and effective alternative to the 076 protocol would be available for the developing countries. Other short-course trials are ongoing. However, the effectiveness of all such regimens in the developing world is reduced because of breastfeeding-mediated transmission.

Breastfeeding

One of the oldest and strongest pieces of evidence for the dangers of breastfeeding comes from a study early in the epidemic in which women who contracted HIV via blood transfusion postpartum, then breastfed, and subsequently transmitted HIV to their infants. The risk of transmission after incident infection was 29% (159). The breast milk of women infected with HIV has been demonstrated to contain HIV (160) and there is clearly a continuing risk. A prospective cohort study in Africa found that in the Þrst six months of life there was a 0.7% per month incidence of HIV transmission (161). As a result of these and other studies, breastfeeding is proscribed in women with HIV infection.

Although this recommendation is a major issue in some developing countries, it should not be an issue in any country with a clean water supply and adequate nutritional supplementation available. Periodic reminders about the risks of breastfeeding, for pediatricians in areas with high rates of HIV as well as for women from areas where formula is not available, may be warranted.

Chapter 15

Aids Manifestations

Sharon Nachman

In a discussion of human immunodeÞciency virus (HIV) infection in infants, children, and adolescents, one must be cognizant of the fact that information on prevention and transmission, treatment of opportunistic infections, primary therapy, and toxicities from medications is constantly changing and expanding. This chapter will discuss HIV infection in infants, children, and adolescents. Several websites are available including: www.cdc.gov, www.hivatis.org, and www.pedhivaids.org for updating of this knowledge base.

EPIDEMIOLOGY AND TRANSMISSION

The cumulative number of AIDS cases reported by June 2001 to the CDC was 793,026. Adult and adolescent AIDS cases accounted for about 784,000, with the remainder of them (9,000) being children under 13 years of age (1). Of the children with AIDS, 26% were from New York, 16% were from Florida, 9% were from New Jersey and 7% were from California. The estimated total number of HIV-infected children in the U.S. is currently between 10,000 and 20,000. Most of these are between the ages of 7 and 15 (1). With the aging of the perinatally infected population and the increasing number of adolescents infected through adult behaviors, it is anticipated that the number of adolescents with HIV infection will increase over the next decade.

Although fewer than 1% of the current reported cases of AIDS in the U.S. have been among adolescents, the impact of HIV infection in this age group is more serious than this Þgure might suggest. Adolescence is a developmental stage of life normally characterized by experimentation, risk taking, and sexual exploration within the context of feelings of invulnerability, which makes it a uniquely high-risk period for acquisition of HIV. Of all reported AIDS cases in the U.S. through 2000, 18% were among those aged 20Ð29, with almost 4% of the total among those aged 20Ð24. The latency period from acquisition of HIV infection to development of AIDS in adults suggest that a signiÞcant proportion of HIV-infected young adults aged under 29 years will have acquired their infection as teenagers.

Seroprevalence data from the Job Corp in the U.S. indicates that disadvantaged and out-of-school youth are at highest risk for HIV infection (2). The rising rates of other sexually transmitted diseases (STDs) and unplanned pregnancies among adolescents are suggestive of a substantial risk for sexually transmitted HIV infection in this age group. Sexual exposure, including heterosexual, homosexual, bisexual, and sexual abuse, has been a prominent mode of HIV transmission among adolescents with AIDS, with heterosexual transmission the identiÞed risk factor in 33% of adolescent females with AIDS and homosexual transmission in 42% of adolescent males diagnosed with AIDS in 2001. Although IV drug use is relatively uncommon among adolescents, the disinhibiting effects of drug use, particularly alcohol, cocaine, and crack, as well as the cost of dependence result in increased sexual risk taking, including prostitution, and contribute to the further spread of HIV (3).

Approximately 8,000 infants are born to HIV-infected women in the U.S. each year. In 1994 the Pediatric AIDS Clinical Trials Group demonstrated that zidovudine therapy administered to selected HIV-infected pregnant women and their newborn infants reduced the rate of perinatal HIV transmission from 25% to 8% (4). In 1995, the U.S. Public Health Service published the Þrst set of guidelines calling for universal, routine HIV counseling and voluntary HIV testing of pregnant women. The rapid implementation of these guidelines by health care workers (and acceptance by HIV-infected pregnant women) has resulted in a dramatic decrease in perinatal HIV transmission in the past seven years. Prior to the routine use of antiretrovirals in pregnancy, perinatal transmission of HIV occurred in 25% of all deliveries. Since the advent of

Sharon Nachman: Department of Pediatrics, HSC T11-031, Stony Brook University, Stony Brook, New York 11794, USA.

routine use of HAART in these women, transmission now occurs in less than 5% of all pregnancies (5). This interruption of transmission is the single most important development in the care of HIV-infected women and their families. Between 1992 and 1998, perinatally acquired AIDS cases declined 75% in the United States. For further discussion of prevention of perinatal transmission please refer to the current guidelines on the Web @ http://www.hivatis.org.

Postpartum transmission of HIV infection from mother to newborn via breast-feeding has been reported and documented in women who acquired HIV infection after delivery through sexual relations (6) and blood transfusion (7,8). In an Australian cohort of 11 women with documented postpartum acquisition of HIV who were breast-feeding their newborns, three transmitted HIV to their infants, yielding an estimated risk of 27% for breast-feeding during primary maternal HIV infection. These cases may be accounted for by the signiÞcant HIV viremia and presumed increased level of infectivity in the Þrst three to six months after acquisition of HIV infection (9). Whether breastfeeding is a signiÞcant mode of transmission in women who are already HIV-infected during pregnancy and clinically stable was recently elucidated. A metanalysis of studies with varying perinatal transmission rates from different parts of the world suggests that breastfeeding increases the rate of perinatal transmission of HIV by 14% (95% conÞdence interval 7Ð22%) (10). This risk was highest in women who intermittently breastfed their infants. The risk-beneÞt ratio for breast-feeding in HIV-infected women is affected by the infant mortality rate associated with infectious disease or malnutrition in conjunction with the relative risk for bottle-fed infants (11). Where sterile formula is readily available, this ratio clearly favors bottle-feeding, and infected women should bottle-feed rather than breastfeed their infants. For parts of Africa and many other Third World areas, however, the situation is much less clear and favors breastfeeding in areas where the infant mortality attributable to bottle-feeding is greater than one in seven (12).

Iatrogenic acquisition of HIV through transfusions and the use of non-sterile needles are ongoing problems in many countries where blood products are not screened and disposable needles are not used. Reports of hospital-acquired HIV infection in Romania and the former Soviet Union are examples of this problem. The scope of this problem may be even larger than anticipated with many third world countries lacking the resources to obtain sterile needles for routine use in clinics or hospitals. Data on needle stick injuries have not revealed any transmission of HIV to a child from an infected health care provider (13).

More than 200,000 children are sexually abused in the U.S. each year (14), and sexual abuse of infants, children, and adolescents is a documented mode of transmission of HIV infection (15,16). Nonetheless, sexual transmission of HIV is not a reportable category of HIV exposure for children, and many barriers exist to identifying children infected with HIV through sexual abuse (17).

Recent guidelines regarding both needle stick injuries and sexual post exposure prophylaxis are now available on the Web @ http://www.hivatis.org.

DIAGNOSIS

In adolescents, children, and infants older than 18 months, deÞnitive diagnosis of HIV infection is made in the same was as it is in adults, by using the enzyme-linked immunosorbent assay (ELISA) and Western blot assays, which provide serological conÞrmatory evidence of a humoral immune response to HIV by detecting HIV-speciÞc IgG antibodies; however, because maternal IgG antibody is transferred to infants across the placenta, all infants born to HIV-infected women are antibody positive at birth. An IgG antibody response cannot be used to diagnose HIV infection in infants until they are 18 months of age, when maternal antibody is no longer present and the infantÕs own humoral immune response should have been mounted. To determine infection status before age 18 months, several viral detection assays are currently used, including HIV DNA PCR, HIV RNA PCR and HIV viral culture.

HIV DNA PCR is the preferred virologic method for diagnosing HIV infection during infancy. A meta-analysis of published data from 271 HIV-infected children indicated that HIV DNA PCR was sensitive and speciÞc for the diagnosis of HIV infection during the neonatal period. 38% of infected children had positive PCR tests by age 48 hours. The sensitivity of this test increased by the second week to 93% testing positive by 14 days of life (18).

It can be argued that HIV RNA PCR can also be used to identify HIV-infected infants, however, data are limited comparing it to HIV DNA PCR in this age group. Thus a positive HIV RNA PCR is indicative of HIV infection, but a negative test (below the limits of detection = 400 copies /ml) is not indicative of the absence of infection.

The use of these assays for diagnostic purposes has been recommended for all infants born to HIV-infected women (19). A presumptive diagnosis of HIV infection can be made with one positive HIV culture or PCR assay on non-cord blood and a deÞnitive diagnosis made with a conÞrmatory test on a different blood sample. HIV infection can be reasonably excluded with two negative HIV culture or PCR results, one obtained at age 1 month or later, the other at age four months or later (20). Some experienced clinicians are comfortable in excluding HIV infection using these assays at earlier ages. The current standard of care requires a negative HIV ELISA and Western blot at age 18 months to exclude HIV infection deÞnitively.

TABLE 15.1. *Immunologic categories for HIV-infected children based on age-speciÞc CD4 T-lymphocyte counts and percentage of total lymphocytes*

Immunologic Category	Age		
	< 12 Months Cells/mm^3 (%)*	1–5 Years Cells/mm^3 (%)	6–12 Years Cells/mm^3 (%)
No evidence of suppression	> 1,500 (> 25)	> 1,000 (> 25)	> 500 (> 25)
Evidence of moderate suppression	750–1,499 (15–24)	500–999 (15–24)	200–499 (15–24)
Severe suppression	< 750 (< 15)	< 500 (< 15)	< 200 (< 15)

* Percentage of total lymphocytes.

Viral culture is performed on peripheral blood mononuclear cells co-cultured with uninfected mononuclear cells that can support HIV growth and detect latent HIV-infected cells by stimulating viral replication. Evidence of p24 antigen, reverse transcriptase activity, or syncytium formation indicates the presence of HIV in such samples. The sensitivity of this test is age dependent. Results of studies indicate a sensitivity of 24% during the Þrst week of life, 85% at one month, exceeding 90% in infants by two to three months of age, and nearly 100% by six months of age (21,22). In one large cohort study, two negative cultures taken between one and six months of age had a speciÞcity of 99.2Ð100% in deÞning an uninfected infant (22).

HIV culture is more complex and expensive to perform than DNA PCR, and deÞnitive results may not be available for two to four weeks. Although use of standard and immune-complex dissociated p24 antigen tests are highly speciÞc for HIV infection, the sensitivity of these tests is less than the sensitivity of other HIV virologic tests (23). The use of p24 antigen testing alone is not recommended to exclude infection in infants less than one month because of a high frequency of false negative assays during this time.

HIV exposed infants should be tested soon after birth, at age one to two months, and again at three to six months. Some investigators suggest that in addition to testing soon after birth, testing at two weeks should also be included as part of a diagnostic evaluation.

In developing countries, virologic diagnostic assays are unfortunately not universally available to many practitioners, and a presumptive diagnosis frequently requires correlating clinical symptomatology with surrogate laboratory parameters in HIV-exposed infants. In these settings, diagnosis of HIV may include CD4 cell depletion, clinical symptomatology and a positive HIV ELISA and Western Blot.

The 1994 CDC classiÞcation system for HIV infection for infants deÞned an HIV-infected infant using HIV-speciÞc clinical symptomatology in conjunction with laboratory evidence of both cellular and humoral immune dysfunction. The most frequently used laboratory parameter of immune function is the CD4 + lymphocyte count. In infants and children, as in adults, a depressed CD4 + lymphocyte count or reversed CD4/CD8 ratio is indicative of immunocompromise; however, healthy infants and children normally have much higher CD4 cell counts than healthy adults. The median CD4 + lymphocyte count for adults in a sample of uninfected subjects was 1,027, whereas the median CD4 + lymphocyte count for infants aged one to six months in the same study was 3,211 and for those aged seven to twelve months 3,128. Whereas the absolute number of CD4 + lymphocytes is higher in infants and children, the percentage of CD4 + lymphocytes is relatively stable from infancy to adulthood. It is important to be familiar with the normal age-speciÞc lymphocyte counts when evaluating the immune status of infants and children. This classiÞcation system (Table 15.1) includes three immunologic categories of HIV-infected children based on age-adjusted CD4 + cell values (24).

Most infants and children with HIV infection have hypergammaglobulinemia, which is indicative of polyclonal B-cell activation (25,26). Hypergammaglobulinemia has been described as the most common laboratory abnormality in HIV-infected children followed by a reversal of CD4/CD8 ratio (27). Normal immunoglobulin levels in infants and children are also age speciÞc and need to be considered when evaluating a child for hypergammaglobulinemia. Elevated beta-2-microgloublin and neopterin levels have been reported in HIV-infected children. Other laboratory abnormalities commonly seen in pediatric HIV infection (some of them nonspeciÞc) include (1) hypogammaglobulinemia, seen in 3Ð5% of cases; (b) anemia, which is usually secondary to chronic disease and has been associated with disease progression (other causes, such as iron deÞciency, sickle cell, and lead toxicity must be ruled out); (c) thrombocytopenia, seen in about 10Ð20% of HIV-infected children and documented to be associated with antiplatelet antibody in 80% of these (28); and (d) leukopenia. Other clinical manifestations possibly indicative of pediatric HIV infection are discussed below. The laboratory abnormalities seen in adolescent HIV infection are similar to those seen in adults and discussed elsewhere in this volume.

TABLE 15.2. *1994 revised HIV pediatric classiÞcation system clinical categories*

Category N: Not Symptomatic

Children who have no signs or symptoms considered to be the result of HIV infection or who have only one of the conditions listed in Category A

Category A: Mildly Symptomatic

Children with two or more of the following conditions but none of the conditions listed in Categories B and C:

- Lymphadenopathy (> 0.5 cm at more than two sites; bilateral = one site)
- Hepatomegaly
- Splenomegaly
- Dermatitis
- Parotitis
- Recurrent or persistent upper respiratory infection, sinusitis, or otitis media

Category B: Moderately Symptomatic

Children who have symptomatic conditions other than those listed for Categories A or C that are attributed to HIV infection. Examples of conditions in clinical Category B include but are not limited to the following:

- Anemia (< 8 gm/dL), neutropenia (< 1,000 mm^3), or thrombocytopenia (< 100,000 mm^3), persisting > 30 days
- Bacterial meningitis, pneumonia, or sepsis (single episode)
- Candidiasis, oropharyngeal (i.e. thrush) persisting for more than two months in children aged more than six months
- Cardiomyopathy
- Cytomegalovirus infection with onset before age one month
- Diarrhea, recurrent or chronic
- Hepatitis
- Herpes simplex virus (HSV) stomatitis, recurrent (i.e. more than two episodes within one year)
- HSV bronchitis, pneumonitis, or esophagitis with onset before age one month
- Herpes Zoster (i.e. shingles) involving at least two distinct episodes or more than one dermatome
- Leiomyosarcoma
- Lymphoid interstitial pneumonia (LIP) or pulmonary lymphoid hyperplasia complex
- Nephropathy
- Nocardiosis
- Fever lasting more than one month
- Toxoplasmosis with onset before age one month
- Varicella, disseminated (i.e. complicated chickenpox)

Category C: Severely Symptomatic

- Children who have any condition listed in the 1987 surveillance case de nition (51) for acquired immunode ciency syndrome, with the exception of LIP (which is a Category B condition)

CLINICAL MANIFESTATIONS AND PRESENTATIONS

In infants and children, HIV infection is a chronic disease with multiorgan system involvement; indeed, there is probably not an organ system that is not affected by HIV. As in adults, HIV disease presents in infants and children with a broad spectrum of manifestations, some speciÞc to young people. The 1994 CDC classiÞcation system (24) (Table 15.2) of HIV disease in children divides cases into four clinical categories: (a) *N* for no signs or symptoms, (b) *A* for mild signs or symptoms, (c) *B* for moderate signs or symptoms, and (d) *C* for severe signs or symptoms (25). Most of the symptomatic clinical manifestations of pediatric HIV disease are related directly to HIV infection or to the immunosuppression secondary to it. There is a wide range of clinical symptomatology from nonspeciÞc Þndings to severe manifestations of common childhood illnesses, AIDS-deÞning conditions, and end-organ dysfunction.

In general there are two common patterns of presentation of HIV infection in children. One pattern, representing about a third of all perinatally acquired infections, involves early onset of severe disease with rapid progression and, if untreated with antiretrovirals, poor prognosis. Infants in this group usually present with severe opportunistic infections (most often *Pneumocystis carinii* pneumonia (PCP)) or encephalopathy within the Þrst two years of life. Data from the Pediatric Spectrum of Disease Project delineate this group of patients as rapid progressors, i.e. those with early onset of disease manifestations and death before 48 months of age (29). Many of these children become identiÞed as HIV infected because of severe illnesses that arise abruptly. In this group, PCP is seldom insidious; infants may be seen by a physician during one week with some mild general symptoms and have fulminant, life-threatening PCP the next. It is because of the presentation of illness in this group of patients that early PCP prophylaxis is required. These children are rarely seen in the post perinatal prophylaxis era, with most HIV infected women receiving antiretroviral therapy

during pregnancy, labor and delivery and babies receiving ART therapy for six weeks postnatally. When infants are identiÞed as HIV infected during the postnatal period, their virus is often sensitive to most antiretroviral therapies (30). However, most experts agree that it is reasonable to evaluate for presence of resistant virus when designing treatment regimens for these infants (31).

The second presentation pattern of pediatric HIV infection involves later onset of disease symptomatology and is associated with a better prognosis. These children generally present after the Þrst year of life with a more indolent disease course, consisting of a variety of the more general clinical manifestations including failure to thrive, severe varicella (or zoster), or recurrent bacterial infections. Relative to children diagnosed with AIDS in the Þrst year of life, LIP is more common in this group, as are other signs of lymphoproliferation, such as generalized lymphadenopathy and parotitis. It is not unusual for school-aged children to be identiÞed with perinatal HIV infection as a result of this type of presentation; some of these children are not diagnosed with AIDS or HIV infection until they are aged 10 or 11 years. In a cohort of 42 perinatally infected children aged 9Ð16 years followed up at CHAP in NJ, the mean age at diagnosis with HIV infection was 88 months. Although most children in this cohort had HIV-related symptomatology, many with signiÞcant disease, almost a quarter of the children remained asymptomatic with relatively intact immune systems at a mean age of 136 months (32). Children who present later in life may be clinically similar to asymptomatic adults or show only subtle HIV-related signs and symptoms before presenting with more obvious conditions, such as thrush. Recurrent bacterial infections are likely to occur as AIDS-deÞning conditions in both early and late onset presentations of HIV. Renal and cardiac involvement may occur as later manifestations of illness after other signiÞcant HIV-related disease is diagnosed (33).

A number of factors are believed to contribute to the rapidity of clinical progression in some children compared with others. Rapid progressors are suspected to have been infected during the early prenatal period or to have been born to women with more advanced disease. An analysis of 162 HIV-infected infants from the French Prospective Multicenter Cohort revealed that the infantsÕ risk of opportunistic infection (OI) or encephalopathy in the Þrst 18 months of life correlated directly with the degree of maternal HIV-related symptomatology and p24 antigen level, and inversely with maternal CD4+ lymphocyte count at the time of delivery. Fifty percent of infants in this study born to mothers with AIDS developed OIs or encephalopathy by 18 months compared with 14% of infants born to mothers who were either asymptomatic or had generalized lymphadenopathy (34,35,36). Recent data indicate that infants who have positive virologic tests within the Þrst week of life are more likely to progress rapidly to AIDS within the Þrst year (37). A prospective study evaluating RNA PCR levels in HIV-infected infants reported higher levels than in adults, with almost all infants having levels over 100,000 copies/ml (38). Rapidly progressing infants have higher peak plasma HIV RNA copy number, with a peak viral load of 724,000 copies/ml, compared with a peak of 219,000 copies/ml in slower progressors (38,39). Additionally, no infant in that study with a peak HIV RNA copy number of less than 80,000 copies/ml had rapidly progressive disease.

Two major clinical factors affect the prognosis of children with HIV infections: their speciÞc HIV-related diseases and their age at presentation. A study of 172 perinatally infected children treated at a Miami hospital (40), prior to HAART therapy availability, showed median survival rates from diagnosis of one month for those with PCP, Þve months for those with nephropathy, 11 months for those with encephalopathy, 12 months for those with candida esophagitis, 50 months for those with recurrent bacterial infections, and 72 months for those with LIP. Thus, both later presentation and later infection appear to be associated with longer survival.

It is important to note that an AIDS diagnosis in and of itself is not an accurate prognostic indicator for children. The variability in prognosis is a function of the conditions responsible for the AIDS diagnosis. Although OIs, encephalopathy, and recurrent bacterial infections are all AIDS-deÞning conditions, the Þrst two were often associated with a signiÞcantly worse prognosis than the latter. However, this is no longer the case with most children, who, after being identiÞed as HIV infected are treated and despite initial severe depletion can repopulate their CD4 cell populations.

Common signs and symptoms seen in children with HIV infection that are not AIDS deÞning include lymphadenopathy, hepatomegaly, splenomegaly, parotitis, recurrent diarrhea, failure to thrive, and recurrent fevers. It is important to evaluate children for speciÞc infectious etiologies for these conditions, although HIV or the ensuing immunodeÞciency may be the sole cause. Common oropharyngeal signs include persistent thrush, severe painful gingivitis, HIV-speciÞc periodontal disease, recurrent aphthous stomatitis, and recurrent herpetic gingivostomatitis. Some of these conditions are extremely common and, as with adults, lymphoproliferation manifesting as lymphadenopathy may be the Þrst objective sign of disease.

As in other immunosuppressed conditions, children with HIV infection may have severe manifestations of relatively self-limited and usually non-life-threatening conditions common in childhood. There are several childhood illnesses that manifest themselves more seriously in children with HIV infection and include severe recurrent fungal skin and nail infections (tinea, candida), recalcitrant molluscum contagiosum, severe condylomata, recurrent and chronic otitis media and sinusitis, recurrent upper respiratory tract infections, and asthma.

Also included in this group are severe and life-threatening manifestations of varicella and measles. While most HIV-infected children have little problem with varicella, prolonged disease with varicella may be seen in those children with severe immune compromise. In one study of HIV-infected children with varicella, seven of eight children had evidence suggestive of varicella pneumonitis (41). In another study, seven of 17 HIV-infected children with varicella developed chronic, recurrent, or persistent disease (42). Some clinicians suggest treating all HIV-infected children with varicella aggressively with acyclovir as soon as there is evidence of disease. Varicella-exposed severely immune compromised children should be given varicella zoster immune globulin in an attempt to prevent or modify the course of disease. The incidence of zoster in HIV-infected children is close to that of children with leukaemia (42).

Measles can also be life-threatening in the severely immune compromised HIV-infected child (43). Even with appropriate immunization, many HIV-infected children, especially those with low CD4+ lymphocyte counts, do not mount protective antibody responses against most routine childhood vaccinations and continue to be susceptible because of their impaired humoral immune response (44). Any HIV-infected child who is exposed to measles should receive intramuscular immune globulin as prophylaxis. Children already on intravenous gamma globulin (IVIG) therapy may be protected but should receive an additional dose of IVIG if the exposure occurs more than two weeks after their last infusion.

In both adults and children, the OIs related to the immunodeficiency caused by HIV are varied and frequently difficult to treat. In children, AIDS-defining OIs often represent primary infection with the organism rather than the recrudescence that is typically the case in adults, which may be why PCP is a more severe illness in infants than in adults. Adult OIs that are rarely seen in children aged under eight years include toxoplasmosis, cryptococcal disease, and other disseminated fungal infections, such as coccidioidomycosis and histoplasmosis. Their relative scarcity in children probably relates to lack of exposure to the etiologic agents. These infections, however, are seen in adolescents. On the other hand, tuberculosis has become a problem in children born into households in which adults may be infected with both HIV and tuberculosis. HIV-infected children, like adults, are more susceptible to the rapid progression of *Mycobacterium tuberculosis* from infection to disease (tuberculosis) (45). Whereas space limitations preclude a comprehensive review of OIs in children, OI prevention and treatment guidelines are available on the web.

In the pre-HAART era, the most common OI in infants and children was PCP 20. Before widespread use of PCP prophylaxis beginning in 1991–1992, PCP accounted for a higher percentage of reported AIDS indicator diseases and up to 65% of OIs in the pediatric population (40,46,47). Currently, the most common infections seen in HIV-infected infants and children are those of bacterial origin, specifically pneumococcal.

RECURRENT BACTERIAL INFECTIONS

HIV infection is associated with significant abnormalities in B-cell-mediated immune responses. In infants, laboratory-documented B-cell dysfunction usually precedes T-cell abnormalities (48,49), possibly the result of an interference with normal B-cell maturation, as humoral immune responses are incomplete at birth. The normal maturation of B cells, including the ability to produce antigen-specific antibodies, requires lymphokines produced by functioning CD4+ lymphocytes. Most adults with HIV infection were exposed to the common bacterial pathogens before becoming HIV infected; therefore, they tend to have circulating protective antibodies against them and circulating B cells with a retained anamnestic response to these pathogens. Thus, adults tend to get serious bacterial infections with common pathogens only late in the course of disease, when they are severely immunocompromised. With improved survival in a more immunocompromised state, however, the problem of severe bacterial infections in adults is on the rise.

In contrast, HIV-infected children have defective primary and secondary antibody production to T-cell-dependent and independent antigens (48,50); when children are exposed to common bacterial pathogens for the first time, these abnormalities result in severe manifestations of infection early in the course of their HIV infection. Since 1987, recurrent serious bacterial infections have been part of the CDC case definition of AIDS for children (51). The most common infections that meet the case definition are bacteremia and pneumonia. The most common organisms include *Streptococcus pneumoniae, Haemophilus influenzae, Salmonella* spp., and *Staphylococcus aureus* (52,53).

CENTRAL NERVOUS SYSTEM

CNS involvement is a more common manifestation of HIV infection in infants and children than in adults, and although its true incidence is unknown, it is believed to occur in most of those infected. HIV is believed to enter the CNS through HIV-infected macrophages, which can cross the blood-brain barrier. In infants, entry of HIV into the CNS may be facilitated by infection with HIV in utero before establishment of this barrier (53a). It is unclear exactly how HIV causes neurological dysfunction; direct HIV effects and indirect effects through cells of the macrophage lineage and the elaboration of toxic cytokines have been postulated.

There is a broad clinical spectrum of neurological abnormalities seen in pediatric HIV infection (54–58). There may be relatively normal development suddenly

followed by either loss of milestones or failure to attain new milestones. The onset of developmental delay may be followed by periods of relative stability in neurological function or rapid neurodevelopmental deterioration. Pyramidal tract involvement may be seen, with resulting spastic paresis. Hypertonicity and hyperreßexia are common manifestations of motor involvement.

Prior to the widespread use of antiretrovirals, static encephalopathy was seen in about one quarter of children with HIV infection. It is characterized by developmental delay of varying severity without loss of previously attained milestones. Children in this group can have improvement in neurological function with continued acquisition of developmental skills, but usually in a delayed fashion. Progressive encephalopathy, characterized by progressive deterioration in cognitive, motor, or language skills and loss of previously attained developmental milestones, often is seen in patients with severe immune compromise (59). Progressive encephalopathy, which is associated with a poor prognosis, can be characterized by a plateau course without continued loss of milestones, or a rapidly progressive course. Neuroimaging studies of HIV infection in children include Þndings of ventricular enlargement, cerebral atrophy, white matter attenuation, and cerebral and basal ganglia calciÞcation (60). The possibility of CNS lymphoma (61) always must be considered in the child who develops new neurological signs and symptoms.

Antiretroviral therapy improves the neurodevelopmental functioning of infants and children with HIV infection (62Ð64). Children can regain lost motor and developmental milestones with therapy. In some children, this is dramatic, with the reversal of incontinence, gait abnormalities, or lost cognitive milestones after initiation therapy (65,66).

GROWTH

Assessment of growth is an integral part of the care of any pediatric patient. This is especially true in the care of HIV-infected children. Growth delay is common in HIV-infected children and thought to be due to disease progression (67Ð69). The basal metabolism of children with HIV infection is increased when compared to uninfected children, and when stressed, caloric needs increase, on average 12% for each degree Celsius increase in temperature, 25% for acute diarrhea and 60% for sepsis (70Ð72). Growth failure is often the Þrst sign of HIV associated symptoms. However, recent data seem to suggest that antiretrovirals may also play a part in growth delay, as even a cohort of children with undetectable virus in plasma continued to have growth failure (73).

HEMATOLOGIC

Anemia in patients with HIV infection is not uncommon and may be due to many causes. The most common causes include nutritional deÞciencies such as iron, folic acid and B_{12}, and immune hemolysis, hemorrhage, drug toxicities and Þnally bone marrow suppression secondary to HIV infection itself. Other causes of anemia such as parvovirus infection, *Mycobacterium avium* complex infection, CMV and malignancy may also need to be investigated.

Evaluation for anemia typically includes a complete blood and reticulocyte count, iron level, total iron binding capacity and transferrin level. It is recommended to evaluate the erythropoietin level as well. If the erythropoietin level is less than 500 IU/L a trial of erythropoietin may be warranted.

Neutropenia, like anemia, is a common Þnding in HIV-infected children. It is deÞned as an absolute neutrophil count of less than 1500 cells/mL. It can be seen secondary to infection, nutritional deÞciencies or drug toxicity. In some cases neutropenia may respond to initiation or a change in antiretroviral therapy. It is recommended that granulocyte colony stimulating factor be used to treat neutropenia instead of dose modiÞcation of antiretrovirals, because of the narrow therapeutic range of these drugs (74).

Thrombocytopenia may also be seen in HIV-infected children, and this used to be a common presenting sign of HIV infection (75). Intervention is usually not required, especially if the platelet count exceeds 50,000. In some cases the thrombocytopenia responds to initiation of HAART therapy. For those children whose platelet counts do not respond to HAART therapy, RHo (D) immune globulin is suggested. Other treatment options may include IVIG and steroids (see Chapter ??).

PULMONARY

Pulmonary complications from HIV range from chronic lymphocytic inÞltrative disease of the lung (LIP) to bacterial pneumonias to opportunistic infections such as PCP and MAC. The diagnosis of LIP is usually based on a typical chest radiograph with persistent reticulonodular bilateral inÞltrates. Treatment includes HAART therapy and prednisone if hypoxia is present. When evaluating bacterial pneumonias, blood and sputum cultures should be sent. Therapy is directed at the speciÞc pathogens isolated. Unfortunately, these cultures yield an organism in $<30\%$ of cases and therapy must be directed at the usual pathogens involved in community acquired pneumonias. Special care must be taken to consider expanding therapy to cover resistant pneumococci when warranted. Children with HIV infection who have bronchiectasis or frequent episodes of bacterial pneumonia may beneÞt from daily prophylaxis with TMP/SMX. Patients with severe immune depletion may present with PCP or MAC, and bronchoscopy or bronchoalveolar lavage may be needed in order to make the correct diagnosis. Updated guidelines for the prophylaxis and treatment of opportunistic infections can be viewed @ http://www.hivatis.org

RENAL

HIV associated nephropathy in children presents as a spectrum of disease that ranges from mild to moderate proteinuria that is persistent, hematuria, renal tubular acidosis and end-stage renal disease. Because the progression of disease in children is not as rapid as in adults, the first approach is to observe these patients over a period of time, monitoring electrolytes, blood urea nitrogen and creatinine. Drug toxicity often contributes to hematuria and certain antiretroviral and other drugs should be avoided in these patients. When end stage renal disease has developed these patients must be managed in conjunction with the pediatric nephrology team. In the future, decisions regarding renal transplants must be considered, especially in patients with successful long-term suppression of viral load and a normal CD4 cell repertoire.

CARDIAC

Cardiac involvement in HIV infection has been known since 1983. The spectrum of cardiac disease ranges from silent lesions to dilated cardiomyopathy to myocarditis (76,77). Depressed left ventricular function is common in HIV-infected children, and has lead to some experts recommending yearly cardiac echocardiograms in these children. Other factors that could be involved in the pathogenesis of cardiomyopathy include infections such as Coxsackie B, CMV, Epstein-Barr virus, toxoplasma, pulmonary diseases, wasting, nutritional deficiencies (selenium and carnitine), antiretrovirals (and other pharmacological agents such as pentamidine, amphotericin B, or foscarnet), and illicit drug use.

Mild manifestations of congestive heart failure (CHF) are treated with angiotensin-converting enzyme inhibitors. The two most commonly used agents are enalapril and captopril. Renal function, electrolytes and blood pressure must be closely monitored. Antihypertensive and antiarrhythmic agents are prescribed when appropriate in conjunction with a pediatric cardiologist.

ROUTINE EVALUATION

It is suggested that all HIV-infected infants and children be managed by an expert in Pediatric HIV infection. Ideally the pediatric care team should consist of physicians and other experts in pediatrics, social workers, a nutritionist as well as a psychologist. This team should be able to consult with other pediatric subspecialists, as children with HIV often will have multi-organ involvement from their HIV infection.

The following tests and services should be performed for all HIV infected children:

¥ Chest x-ray (78)
  This test identifies mediastinal enlargement, lung lesions and cardiomegaly. Patients with chronic lung disease should have pulse oximetry measured routinely as well.
¥ Baseline brain CT (79)
  This scan may show calcification as well as brain atrophy. It may be more helpful in the perinatally infected adolescent who comes in with new CNS signs and symptoms.
¥ A regular strength tuberculin skin test (78)
¥ Visual screening (78)
¥ Children with immune category 3 may need to be examined every six months, especially if they are seropositive for CMV or toxoplasmosis.
¥ Psychometric testing (80,81)
¥ GYN exam (78)
  Female adolescents should be referred for GYN care. Baseline and annual GYN visits should be provided for all adolescents who are sexually active to evaluate for STDs and for performing cervical PAP smears.
  All adolescents should be aware of their diagnosis and receive counseling regarding transmission of HIV, safe sex practices, birth control and the risk of perinatal transmission during pregnancy.
¥ Baseline antibody titers should be considered to evaluate toxoplasma, CMV, Epstein-Barr virus, varicella-zoster virus and hepatitis viruses (78).
¥ In addition, annual visits to a dentist are also strongly suggested (82-84).

Routine evaluations should occur at three to four month intervals and should include a complete physical exam (including height, weight and vital sign monitoring), and routine labs such as CBC, liver function profile, and HIV RNA viral load and CD4 cell count. Other laboratory tests may include cholesterol, triglyceride and glucose monitoring, as well as urinalysis and electrolyte monitoring. Other non-routine evaluations may include EKG and echocardiograms (78).

PCP Prophylaxis

In children with HIV infection, PCP is associated with a high rate of morbidity and mortality. It often presents acutely with a peak incidence in the first three to six months of life. In March 1991 recommendations for PCP prophylaxis for infants and children were based on age-dependent CD4+ lymphocyte counts (84a), which differ from values in adults. The guidelines called for initiation of PCP prophylaxis for HIV-exposed children aged 1 to 11 months with CD4+ counts below 1,500 cells/ul, for children 12 to 23 months of age with CD4+ lymphocyte counts below 750, for those aged 24 months to five years with CD4+ lymphocyte counts below 500, and for children aged six years or older with CD4+ lymphocyte counts below 200.

In 1994, these guidelines were revised to recommend that all HIV-infected infants be placed on prophylaxis regardless of CD4+ lymphocyte counts, beginning at one month of age (19). Because it was difficult to determine with certainty which infants born to HIV-infected women were themselves infected, and especially those who are uninfected, these new guidelines recommended initiating prophylaxis in all infants born to HIV-infected women at one month of age and continuing prophylaxis until HIV infection can be reasonably excluded. After the first year of life, the use of prophylaxis is recommended in HIV-infected children based on CD4+ lymphocyte values.

A detailed discussion of prophylaxis and treatment of other OIs in infants and children is beyond the scope of this chapter and is covered elsewhere in this volume as they relate to the adult population.

TREATMENT OF HIV

HIV-Specific Treatment

At least 11 of the antiretroviral agents approved by the U.S. Food and Drug administration for treatment of HIV infections are approved for use in children. Two classes of drugs target the reverse transcriptase enzyme, while a third class targets the viral protease enzyme. Unfortunately, more information is still needed regarding optimal dosing in children due to the wide variability of drug absorption and metabolism among children and drug interactions that affect pharmacokinetic parameters.

When to Initiate Therapy

There is much discussion in the literature regarding the best time to start antiretroviral therapy in children. Unfortunately, there is no one correct answer. Most experts agree that treatment should be initiated in children with severe immune suppression or those with clinical disease progression, but for those children with good immune function and no clinical symptoms, no such clear consensus is available.

Antiretroviral therapy has provided substantial clinical benefit to HIV-infected children. Initial clinical trials with monotherapy demonstrated clinical improvement in growth, neurodevelopmental, immunologic and virologic parameters. Subsequent clinical trials have demonstrated combination therapy to be superior to monotherapy. In a longitudinal study which evaluated children in the pre-HAART and post HAART era, HAART therapy has been demonstrated to enhance survival. Mortality was only 1% in 1997/1998 compared to 5% in 1995/1996 (47).

Data from clinical trials of antiretroviral therapy with one and two drug combinations (in antiretroviral children) (84b) and three and four drug combinations (in nucleoside alone exposed) children (84c) showed that initiation of therapy may be able to produce long-term suppression of viral replication and preservation of immune function in some children. However, the potential problems with early therapy include the risk of short-term and long-term adverse effects, and concerns about viral mutation, especially in populations who will be on lifelong therapy.

Over the past several years, members of the Working Group on Antiretroviral Therapy and Medical Management of HIV Infected Children have developed guidelines for initiation and treatment of HIV-infected children. These guidelines are updated frequently, and the reader is advised to look on the web for the most current guidelines at www.hivatis.org. These guidelines take into account clinical and immunologic status as well as virologic results. Available guidelines for adults are applicable only to newly infected adolescents and most children identified after three years of age. However, due to generally higher viral load measurements in neonates and infants, most experts suggest that babies identified as HIV positive in the first year of life be placed on HAART therapy despite normal CD4 markers.

Aggressive antiretroviral therapy with at least three drugs is recommended for initial treatment of infected children because it provides the best opportunity to preserve immune function and delay disease progression. The goal of therapy is to suppress viral replication maximally while preserving immune function and minimizing drug toxicity.

Biologic variation in plasma HIV RNA within a person is well documented and repeated measurements of HIV RNA levels in a clinically stable adult can vary by as much as 0.5 log 10. This biologic variation may be greater in infected infants and young children. In children with perinatal infection, RNA copy number rapidly declines during the first 12–24 months after birth (0.6 log 10 per year), then continues to decline slowly over the next three to four years (0.3 log 10 per year), but persists at higher levels than most infected adults. Thus, only changes greater than 0.7 log 10 in infants aged less than two years and greater than 0.5 log 10 in children over two years of age are biologically real (Table 15.3). However, no change in therapy should be made as a result of HIV copy number unless confirmed by a repeat test.

A few children and adults with HIV infection do well clinically without therapeutic intervention. They are referred to as long-term nonprogressors. It is estimated that they make up 5% of patients with HIV infection. There are many different theories as to the genetic, immunologic and virologic mechanism of host resistance to disease progression, but unfortunately, clinicians are unable to predict accurately which patient will be part of this cohort of patients. There is no plasma RNA threshold below which an individual is likely to experience long-term nonprogression. Most experts therefore agree that early aggressive therapy in children and adults allows for

TABLE 15.3. *Viral load reduction conversions**

Viral Load Reduction From Baseline (Logs)	Viral Load Reduction From Baseline (%)	Viral Load Reduction From Baseline (-Fold)	Remaining Viral Load Number
0.3 log	50.0%	2-fold	50,000 c/mL
0.5 log	75.0%	3-fold	25,000 c/mL
0.7 log	80.0%	5-fold	20,000 c/mL
1.0 log	90.0%	10-fold	10,000 c/mL
1.5 log	96.8%	32-fold	3,200 c/mL
2.0 log	99.0%	100-fold	1,000 c/mL
2.5 log	99.7%	316-fold	300 c/mL
3.0 log	99.9%	1,000-fold	100 c/mL

* In a hypothetical patient with a starting viral load of 100,000 copies/mL.

the best opportunity for long-term nonprogression, preservation of the immune system and minimization of the risk for antiretroviral resistance.

Issues relating to treatment adherence are important in considering when to initiate therapy and what that therapy should be. Lack of adherence to therapy may enhance the development of drug resistance. Participation by the family and child, when appropriate, in the decision making process, is especially important in situations for which deÞnitive data concerning new treatments are not available.

Despite having been treated with agents from all three classes of FDA-approved antiretroviral agents, a growing number of HIV-infected children are not able to sustain viral replication below the level of quantiÞcation. Although incomplete adherence may be a factor in some of these cases, other factors include the previous use of these agents in the child (i.e. sequential mono or dual therapies or addition of new agents without changing the backbone of the regimen), inadequate dosing due to poorly described pharmacokinetic parameters, and toxicity management. In these cases, the pros and cons of continuing a treatment regimen versus switching to an alternative treatment regimen need to be closely considered and discussed with the child and family.

There is no consensus as to the best approach to treat these patients. Choice of the new regimen should be guided by the childÕs antiretroviral drug history and results from resistance assays. If the child has been exposed to all three available groups of antiretroviral agents, it is unlikely that a simple three- or even a four-drug regimen will sustain suppression of virus to undetectable levels. In this setting, viremia alone, in the face of stable clinical and immunologic status, does not require a medication change in a heavily pre-treated child.

Reasonable approaches to these patients include:

¥ Continuing a regimen that allows viral replication at a level that will not cause additional immunologic or clinical deterioration while waiting for newer therapeutic approaches and agents to be developed.

¥ Choosing an aggressive regimen of four to six agents in an attempt to suppress viral replication to undetectable levels with an acceptable level of toxicity. This regimen may contain two nucleoside reverse transcriptase inhibitors, a non-nucleoside reverse transcriptase inhibitor and two to three protease inhibitors.

¥ Opting for a complete drug holiday (months) with the expectation that wild-type virus will once again predominate in the patient. After this interim period, an aggressive regimen can then be instituted. There are limited clinical data on this approach in adults and children, although it is expected that resistant virus is archived in the genome of the patientÕs cells and will reappear in due time.

Which agent(s) should be used as second- and third-line therapy depends on which agents(s) the patient was started on initially, the resistance proÞle of the circulating virus and the availability of other agents. A physician experienced in pediatric HIV disease should be consulted when these decisions are made.

Intravenous Immune Globulin Therapy

Intravenous immune globulin (IVIG) is often standard therapy for children and adults with primary humoral immunodeÞciency disorders such as BrutonÕs agammaglobulinemia. Passive immunotherapy in the form of IVIG provides protection against a wide range of bacterial and viral pathogens. As discussed above, children with HIV infection often have functional abnormalities of their B-cell-mediated immune system that place them at risk for infections that require an intact humoral response system. Although most children with HIV infection have elevated immunoglobulin levels, this is believed to represent nonspeciÞc polyclonal B-cell activation. Many children fail to mount an antibody response to routine childhood immunizations (50), indicating a functional immunodeÞciency.

The National Institute of Child Health and Human Development (NICHD) completed a placebo-controlled

trial using IVIG in HIV-infected children. This trial was completed prior to the availability of HAART therapy. The trial found that IVIG prolonged the time free from serious laboratory-proven bacterial or clinically diagnosed serious or minor bacterial and viral infections in symptomatic HIV-infected children with CD4 counts greater than 200 (85,86). Unfortunately, this trial did not separately evaluate the efficacy in children with documented B-cell defects but looked only at groups based on CD4 counts.

Based on clinical experience in treating children with humoral immunodeficiency and HIV with IVIG and the results of the above reports, a group of pediatric HIV specialists agreed that IVIG should be considered for use in HIV-infected children with the following conditions: (a) evidence of humoral immunodeficiency as defined by severe recurrent bacterial infections, hypogammaglobulinemia, poor functional antibody responses to documented infections or a lack of response to immunizations; (b) thrombocytopenia; or (c) chronic bronchiectasis (87).

Childhood Immunizations

Immunizations represent the cornerstone of preventive medicine for children. The recommended childhood immunization schedule of the Advisory Committee on Immunization Practices and the American Academy of Pediatrics should be used in HIV-infected children with the following alterations. Paralytic poliomyelitis is a potential complication of the oral polio vaccine (OPV) for both the immunocompromised patient and the immunocompromised family members through virus excreted in stool. Use of inactivated polio vaccine (IPV) instead of OPV is recommended for HIV-infected infants and children as well as uninfected infants and children living in households with infected adults. In the early years of the HIV epidemic, infected children in the U.S. received both primary and booster doses of oral polio vaccine without complications, and in developing countries OPV is still considered standard of care for all children.

The measles mumps rubella vaccine is a live attenuated viral vaccine given between 12–15 months of age, with a booster at four to six years of age. In areas where there is a high prevalence of measles it may be given as young as six months of age. There has been one reported case of measles pneumonitis following measles, mumps, and rubella vaccine (MMR) in a severely immunocompromised 20-year-old HIV-infected man. Although the use of MMR is recommended for most HIV-infected children, the CDC currently recommends considering withholding MMR in severely immunocompromised HIV-infected children (88).

The Advisory Committee on Immunization Practices (ACIP) recommends that the varicella vaccine be considered for asymptomatic or mildly symptomatic HIV-infected children, with an age specific CD4 T lymphocyte percentage greater than 25% (89,90). The vaccine should be administered in two doses with a three-month interval between the doses. It is strongly recommended for HIV negative siblings and household members of HIV-infected individuals. Susceptible children with HIV infection exposed to varicella should be considered for passive immunization with varicella-zoster immune globulin. If a child has received IVIG within three weeks before the exposure, then VZIG is not necessary.

A yearly inßuenza vaccine is recommended for infants and children with HIV infection who are over six months of age. Children less than nine years of age who have never received the vaccine should be given two doses, one month apart. For children previously immunized, one dose per year is sufficient.

The newly licensed pneumococcal conjugate vaccine should be given to all HIV-infected infants and young children as per ACIP guidelines. A clinical trial is underway evaluating this vaccine in HIV-infected children over the age of two years. However, current recommendations are to give the pneumococcal polysaccharide vaccine every 5 years in HIV-infected children.

Other vaccines such as hepatitis B, pertussis, tetanus and *H. inßuenzae* type B are the same as for noninfected children. Bacillus Calmette-Guerin (BCG) is a live attenuated vaccine and is contraindicated for children with HIV living in the U.S.. The World Health Organization has continued to recommend this vaccine to be given at birth to children living in countries with a high prevalence of tuberculosis.

NUTRITIONAL ISSUES IN CHILDREN WITH HIV INFECTION

Pediatric HIV infection frequently results in nutritional deficiencies and growth failure. Weight loss and failure to gain weight can occur as early as the first four months of life as well as in children who become symptomatic at an older age. Failure to thrive and malnutrition are due to a number of factors, including (a) decreased intake resulting from oral and gastrointestinal pathology that cause nausea, anorexia, pain, and deceased taste as well as neurological complications that result in ineffective swallowing mechanisms; (b) impaired absorption resulting from HIV-related enteropathy and gastrointestinal infections; (c) increased metabolic requirements secondary to the chronic HIV-related inßammatory illness; and (d) decreased intake resulting from side effects and toxicities (such as nausea, anorexia, vomiting, hepatitis, and pancreatitis) of various medications used to treat HIV infection and its complications. Particularly in children in end-stage disease, it is important for the clinician to consider these adverse reactions within the risk-to-benefit ratio of therapy with a specific agent. These physical complications of HIV infection further contribute to the marginal nutritional balance frequently seen in children living in communities affected by poverty. Besides protein and caloric deficiencies, a number of trace element and vitamin

deÞciencies may complicate the clinical course of HIV infection (91). SpeciÞc nutritional deÞciencies of selenium, iron, zinc, vitamin B6, vitamin A, and vitamin E may result in neurological or cardiac abnormalities and contribute to the rashes and cytopenias commonly seen in HIV infection. In young infants, when CNS growth is still occurring, nutritional deÞciencies may have profound long-term effects.

Based on these factors, there should be an aggressive approach to nutritional support for HIV-infected infants and children that includes (a) proactive nutritional assessment including anthropomorphic measurements and dietary intake history with each physician visit and periodic selected laboratory parameter monitoring; (b) diagnosis and treatment of oral-gastrointestinal disease, with special attention to pain management; and (c) aggressive replacement and nutritional supplementation beginning with oral supplementation and progressing as necessary to nasogastric/gastrostomy tube feeding and in advanced disease with malabsorption to total parenteral hyperalimentation. Nutritional care of HIV-infected children needs to receive the attention of the research community as well as those providing direct care. Recently physicians have started evaluating the use of gastrostomy tubes for administration of both medication and food supplementation (92).

DRUG TOXICITIES

One of the emerging new syndromes arising from HIV and its treatment is that of lipodystrophy (93). This syndrome, initially thought to be exclusively associated with protease inhibitor therapy, can now be seen with all classes of antiretrovirals. Common signs include extremity fat wasting and excessive deposition of fat on back and trunk. Common metabolic abnormalities include insulin resistance, elevated cholesterol, triglycerides, and abnormal bone metabolism (94).

Nucleoside Analogs

Nucleoside analogue drugs are known to induce mitochondrial dysfunction, as these drugs have varying afÞnity for mitochondrial gamma DNA polymerase. This afÞnity can result in interference with mitochondrial replication, resulting in mitochondrial DNA depletion and dysfunction (95). The relative potency of the nucleosides in inhibiting mitochondrial gamma DNA polymerase *in vitro* is highest for zalcitabine (ddC), followed by didanosine (ddI), stavudine (d4T), lamivudine (3TC), zidovudine (ZDV) and abacavir (ABC) (96). Toxicity related to mitochondrial dysfunction has been reported in infected patients receiving long-term treatment with nucleoside analogues, and generally has resolved with discontinuation of the drug or drugs; a possible genetic susceptibility to these toxicities has been suggested (95). These toxicities may be of particular concern for pregnant women and infants with *in utero* exposure to nucleoside analogue drugs.

Clinical disorders linked to mitochondrial toxicity include neuropathy, myopathy, cardiomyopathy, pancreatitis, hepatic steatosis, and lactic acidosis. Among these disorders, symptomatic lactic acidosis and hepatic steatosis may have a female preponderance (97). These syndromes have similarities to the rare but life-threatening syndromes of acute fatty liver of pregnancy, and hemolysis, elevated liver enzymes and low platelets (the HELLP syndrome) that occur during the third trimester of pregnancy. A number of investigators have correlated these pregnancy-related disorders with a recessively-inherited mitochondrial abnormality in the fetus/infant that results in an inability to oxidize fatty acids (98,99). Since the mother would be a heterozygotic carrier of the abnormal gene, there may be an increased risk of liver toxicity due to an inability to properly oxidize both maternal and accumulating fetal fatty acids (100). Lactic acidosis with microvacuolar hepatic steatosis is a toxicity related to nucleoside analogue drugs that is thought to be related to mitochondrial toxicity; it has been reported in infected individuals treated with nucleoside analogue drugs for long periods of time (more than six months). Initially, most cases were associated with ZDV, but subsequently other nucleoside analogue drugs have been associated with the syndrome, particularly d4T. In a report from the FDA Spontaneous Adverse Event Program of 106 individuals with this syndrome (60 patients receiving combination and 46 receiving single nucleoside analogue therapy), typical initial symptoms included one to six weeks of nausea, vomiting, abdominal pain, dyspnea, and weakness (97). Metabolic acidosis with elevated serum lactate and elevated hepatic enzymes was common. Patients in this report were predominantly female gender and high body weight. The incidence of this syndrome may be increasing, possibly due to increased use of combination nucleoside analogue therapy or increased recognition of the syndrome.

PAIN MANAGEMENT

Pain management is an especially important but frequently undertreated clinical problem in HIV-infected infants. The prevalence of pain in adults with AIDS ranges from 40Ð60%, depending on the stage of illness (101). Physicians in general are poorly trained in the control of pain by medication, and many do not appreciate that newborns and infants experience pain. Whereas many fear they will make their patients drug addicts, only 0.4% of patients given narcotics in hospitals ever have a problem with opiate dependence.

A much more aggressive approach must be taken to controlling pain in children. SpeciÞc barriers to management of pain in HIV-infected children include: (a) the

difficulty of assessing pain in young children; (b) the difficulty of assessing pain in children with neurological impairment; (c) parental denial of their children's disease; (d) resistance to the use of narcotics by families who have a history of drug use; and (e) resistance by clinicians to treat pain in children because of myths like the following: Children lie about pain to get attention; if children deny pain or do not complain, they are not in pain; and children who can fall asleep or who can play cannot be in pain. Vigorous and proactive use (preferably before the onset of anticipated pain) of appropriate pain medications using weight-adjust dosages, including aspirin, acetaminophen, codeine, ibuprofen, morphine, and methadone, is essential to the overall quality of life for HIV-infected children. The use of EMLA cream as a local anesthetic for blood drawing can make the difference between an agonizing or enjoyable visit to the doctor for a child with chronic illness.

Nonpharmacological approaches to pain management (including relaxation, hypnosis, play therapy, visualization, and distraction) also should be applied in pain control, especially when the pain is related to procedures.

ADHERENCE

Rates of adherence (102) to antiretroviral therapy have been correlated with virologic success. There is considerable interest in clinical strategies to promote improved adherence (Table 15.4). Interventions have included scripted telephone reminder calls, once daily versus twice daily therapies, directly observed therapy (DOT), and reminders via alarm watches. Unfortunately, none has been remarkably successful. Often individuals with worst adherence discontinue therapy sooner than more adherent patients, resulting in less resistance among poorly compliant patients and increased resistance in partially compliant patients (103). Adherence in young children depends on the child's care provider administering the medications. This can be especially difficult if the medications are bad tasting or smelling, must be given constantly during the day, have large volumes, or cannot be taken with food. This may be compounded by the care providers needs if they are also HIV-infected (104).

TABLE 15.4. *Factors affecting adherence*

- Availability of liquid product vs. pills
- Quantity (volume) of therapy
- Frequency (qd, bid, tid, qid)
- Ability to swallow pills/soft gel caps
- Taken with or without food, acidity
- Storage (e.g. refrigeration)
- Disclosure
- Psychosocial factors
  - Parental health
  - Parental treatment
  - Parental perception of antiretroviral therapy
  - Child's development stage
  - Belief that medications are bene cial
  - Reliability of a parent/guardian
  - Foster care/consent
  - School/day care
  - Reputation of therapy in community
  - Medical provider accessibility

SOCIAL ISSUES IN THE DELIVERY OF CARE

The conditions of poverty, including inadequate housing, may interfere with the delivery of optimal health care. Typically, mothers are the strongest advocates for their children, but this advocacy may be hindered by the fact that mothers of HIV-infected children are often single parents and poor (105). In some cases, symptomatic HIV infection or drug use may interfere with a mother's ability to care properly for her child; more often, however, mothers are assertive in seeking care for their children while neglecting their own needs (106). The general shortage of openings in drug treatment programs is especially severe for women who are HIV infected, pregnant, or have children. All these socioeconomic conditions must be addressed in designing effective health care systems for families with HIV infection.

Families also can benefit from psychosocial support in dealing with many aspects of an HIV diagnosis in a child. The diagnosis may be the first evidence that a parent is infected and may give rise to guilt or anger, leading to further disruption of the family unit. Apparently resolved emotional issues may require periodic reexamination, as, for example, when parents are confronted repeatedly by the differences between a child who is developmentally delayed and healthy peers. Decisions about the disclosure of an HIV diagnosis may arise on multiple occasions as different audiences are encountered such as family, friends, siblings of the infected child, the child himself or herself, day-care workers, school nurses, and teachers (107). Many parents choose to disclose the diagnosis on a need-to-know basis; however, children and their siblings often find it less stressful to know the diagnosis than to be left in the dark about something unnamed but apparent. Counseling may help parents decide whether and how to disclose the diagnosis, which should be done in a developmentally appropriate way. Clinical experience suggests that under the proper circumstances it is beneficial for children with normal cognitive development to have the opportunity to discuss aspects of their illness with trusted adults. The issue of disclosure of diagnosis is particularly pressing because perinatally infected children live into mid and late adolescence. In a cohort of 42 perinatally infected children aged nine through 16 years followed at CHAP, Newark, NJ, fewer than 60% were specifically told their diagnosis. Uninfected but HIV-affected siblings often have mental health needs as well, especially when they face the eventual loss of siblings and one or both parents. A failure to deal successfully with

psychosocial issues may impede families from seeking optimal medical care for their children.

CHALLENGE OF HIV INFECTION IN ADOLESCENTS

Like other HIV-infected persons, adolescents with HIV infection come disproportionately from minority communities. As a group, adolescents are at high risk of acquiring HIV by nature of their developmental stage. The Agency for Health Care Policy and Research guidelines on Evaluation and Management of Early HIV Infection details the unique set of issues in caring for adolescents with HIV infection. These include: (a) differences in the epidemiology of HIV infection among youth; (b) special barriers to youth both in receiving care for their HIV infection and in prevention services, including counseling and testing, resulting from variable laws regarding consent and conÞdentiality for those aged under 18 years; (c) lack of HIV-speciÞc clinical services for adolescents; and (d) the limitation on youths participating in clinical trials. One of the major challenges facing those caring for adolescents is the prevention of HIV transmission, both primary and secondary. In general, preventive programs have relied on incomplete or limited information services not linked to care or programs that teach and encourage behavior change. Successful adolescent HIV programs have employed voluntary, conÞdential, or anonymous counseling and HIV testing with direct linkage to adolescent speciÞc care. Although speciÞcs of medical management of HIV-infected adolescents, in terms of medication use and disease assessment, are similar to those used for adults, many aspects do differ from that which is appropriate for children and adults. The history and physical examination need to be interpreted in the context of age-speciÞc differences and pubertal stage. History-taking from adolescents needs to detail sexual and drug-using behavior, recognizing the psychosocial and cognitive-developmental stage that may inßuence the accuracy of the information obtained, and incorporate counseling and coping mechanisms employed by the adolescents. There should be an awareness of the potential for other sexually transmitted diseases. Issues relating to treatment adherence are especially important in caring for adolescents.

Of interest are recent data suggesting that perinatally infected adolescents may also exhibit delay in pubertal development, not related to clinical or immunologic conditions or antiretroviral therapy (108).

Perhaps most importantly, services for adolescents need to be provided by an experienced physician comfortable in dealing with youth and issues of adolescent sexuality within the context of a developmentally appropriate environment.

DEVELOPING STANDARDS OF CARE FOR CHILDREN WITH HIV

Twenty years ago, 95% of children with leukemia died; today, up to 85% are cured. The intensity of effort put into controlling childhood leukemia should serve as a template for our efforts to treat HIV-infected children. Efforts to improve quality of life while working toward a cure for HIV will require a multidisciplinary approach, calling on the skills of physicians, nurses, social workers, nutritionists, pharmacists, dentists, and developmental specialists. This effort must take the childÕs entire family into consideration, whether it is the family of birth or a foster family.

At most large HIV centers a team approach to the child and the childÕs family has resulted in better communication, compliance and better management of children with HIV infection. Team members may include clinicians, nurse and nurse practitioners, psychologists, social workers, nutritionists and dental hygienists. This family centered team approach may be even more necessary in the future with the aging into adolescence of the majority of perinatally HIV-infected children.

Chapter 16

Pulmonary Complications of HIV Infection

Krystn R. Wagner and Richard E. Chaisson

Pulmonary diseases are common complications of infection with human immunodeficiency virus (HIV). These include both opportunistic infections, such as *Pneumocystis carinii* pneumonia (PCP), as well as other complications such as Kaposi's sarcoma (KS), non-Hodgkin's lymphoma (NHL) and changes in pulmonary function. Since 1996, the widespread use of highly active antiretroviral therapy (HAART) has had a significant impact on the epidemiology of HIV-associated opportunistic infections (1). Overall, there has been a substantial decline in the incidence of PCP, community acquired pneumonia, and other pulmonary complications of advanced HIV disease in populations with access to HAART. The risk of opportunistic infections among patients with depressed CD4 cell counts, particularly <200 cells/mm^3, however, remains similar to that in the pre-HAART era. As a result, it remains essential to understand the distinctive clinical features, diagnosis and treatment of common pulmonary complications in patients with HIV infection.

The occurrence of opportunistic disease in patients with HIV infection is a function of underlying host immunodeficiency, as well as exposure to potential pathogens, pathogen virulence and antimicrobial susceptibility, as well as other modifying factors such as chemoprophylaxis and cigarette smoking. The epidemiology of pulmonary complications in patients with HIV infection varies among geographic regions. This is a function of environmental conditions, such as exposure to indigenous pathogens, as well behavioral and socioeconomic factors, such as access and adherence to antiretroviral therapy. Due to the lack of universal access to HAART, chemoprophylaxis, or vaccinations, there is a widening gap between the incidence of HIV-associated complications in industrialized versus developing countries. In this chapter, we discuss the pulmonary complications of HIV infection in populations with access to HAART, while acknowledging that the large burden of HIV disease exists in the developing world. With increasing availability of prophylaxis and HAART in currently resource-poor nations, however, the pulmonary and other complications of HIV infection will more closely resemble those seen in developed nations.

Potential respiratory pathogens in patients with HIV infection are listed in Table 16.1. The risk of each complication correlates with the individual's degree of immunosuppression. The absolute CD4 cell count (or CD4

cell percentage) remains the best surrogate marker for assessing the risk of HIV-associated complications (2Þ4). With CD4 cell counts greater than 500/mm^3, there is an increased risk of infections with more virulent organisms capable of causing disease in immunocompetent persons, such as *Streptococcus pneumoniae* or *Mycobacterium tuberculosis*. When the CD4 cell count falls to less than 200/mm (3), the risk of opportunistic pathogens that rarely cause disease in normal hosts, such as *Pneumocystis carinii*, signiÞcantly increases (5). The HIV plasma RNA (viral load) is predictive of the long-term rate of loss of immune function and is an independent risk factor for opportunistic infections (6). However, the viral load has less prognostic value for the risk for opportunistic infection at a given point in time than the CD4 lymphocyte count.

APPROACH TO DIAGNOSIS

An approach to evaluating the patient with HIV-related pulmonary disease is depicted in the algorithm shown in Fig. 16.1. After conÞrmation of pulmonary disease from abnormalities on a chest radiograph, documented defects in oxygen transport or evidence of parenchymal inßammation by CT scan, secretions from the respiratory tract are usually examined for the presence of pathogens. For patients with expectorated sputum, Gram stain and acid-fast bacilli smears and cultures are appropriate. For patients who do not produce spontaneous sputum, sputum induction is a common procedure with a reasonably high sensitivity for some respiratory pathogens including *P. carinii*. The negative predictive value of sputum induction for PCP is moderately low, however, and infection cannot be excluded by a negative test result. If a speciÞc diagnosis is not established, bronchoalveolar lavage (BAL) is extremely sensitive and speciÞc for identifying HIV-related pulmonary pathogens. Transbronchial biopsy may increase the yield of bronchoscopy for some diagnoses, although complications of this procedure occur in as many as 10% of patients. The use of high resolution CT scanning has improved the noninvasive approach to evaluating patients with pulmonary symptoms, but this technique can only suggest speciÞc etiologies of pulmonary opportunistic diseases on the basis of characteristic Þndings. A

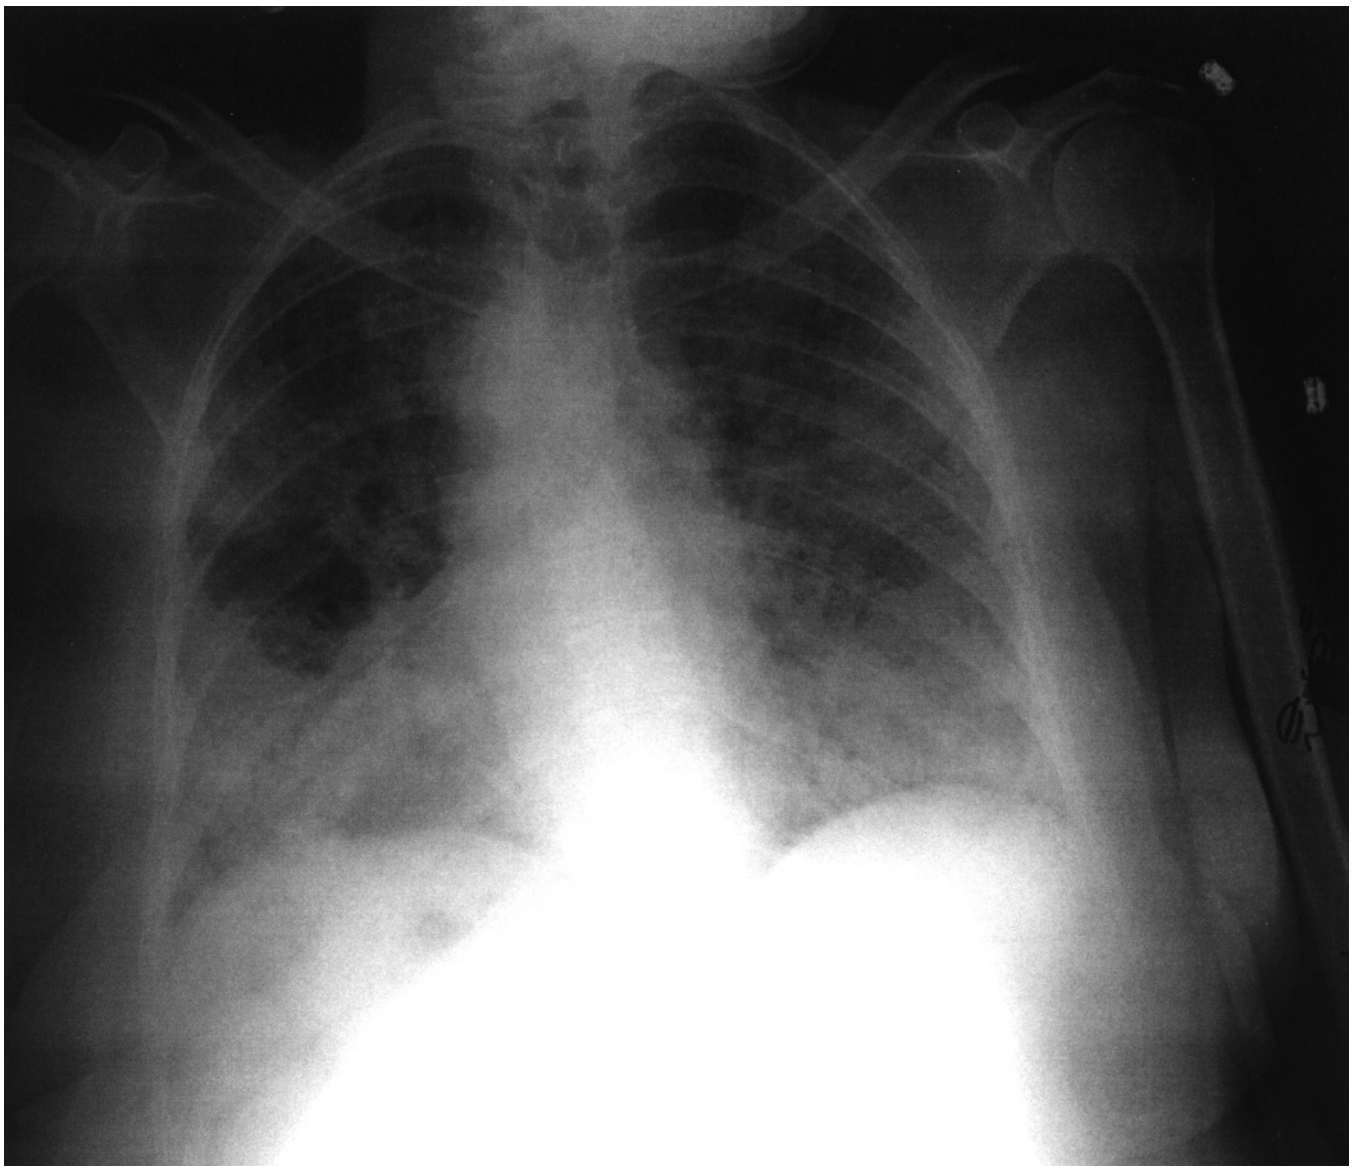

FIG. 16.1a. A 55 year old woman with advanced HIV infection presented with three weeks of dry cough, breathlessness, hypoxemia and fever. Her chest radiograph shows diffuse interstitial in ltrates. Induced sputum revealed *P. carinii*.

speciÞc diagnosis still requires microbiological or histopathological conÞrmation.

Infectious Pulmonary Complications of HIV

Pneumocystis carinii Pneumonia

P. carinii was previously classiÞed as a protozoan based on its morphologic appearance and response to antiprotozoal drugs. Genetic analysis of ribosomal RNA and mitochondrial DNA, however, suggests that *P. carinii* is a fungus. While the environmental reservoir and transmission patterns are unknown, approximately 80Ð90% of children are exposed to *P. carinii* before age three. The organism does not cause disease in immunocompetent persons. Prior to the AIDS epidemic, there were approximately 100 cases of PCP per year in the United States. These cases were typically associated with a variety of conditions accompanied by defects in cell-mediated immunity.

In 1981, clusters of PCP in Los Angeles, San Francisco, and New York heralded the beginning of the AIDS epidemic. Before the widespread use of chemoprophylaxis in the early 1990s, PCP was the presenting manifestation of HIV infection in 60% of AIDS patients. Approximately 95% of patients who present with PCP have CD4 cell counts less than 200/mm^3, and the incidence increases as the CD4 cell count declines further. Since the introduction

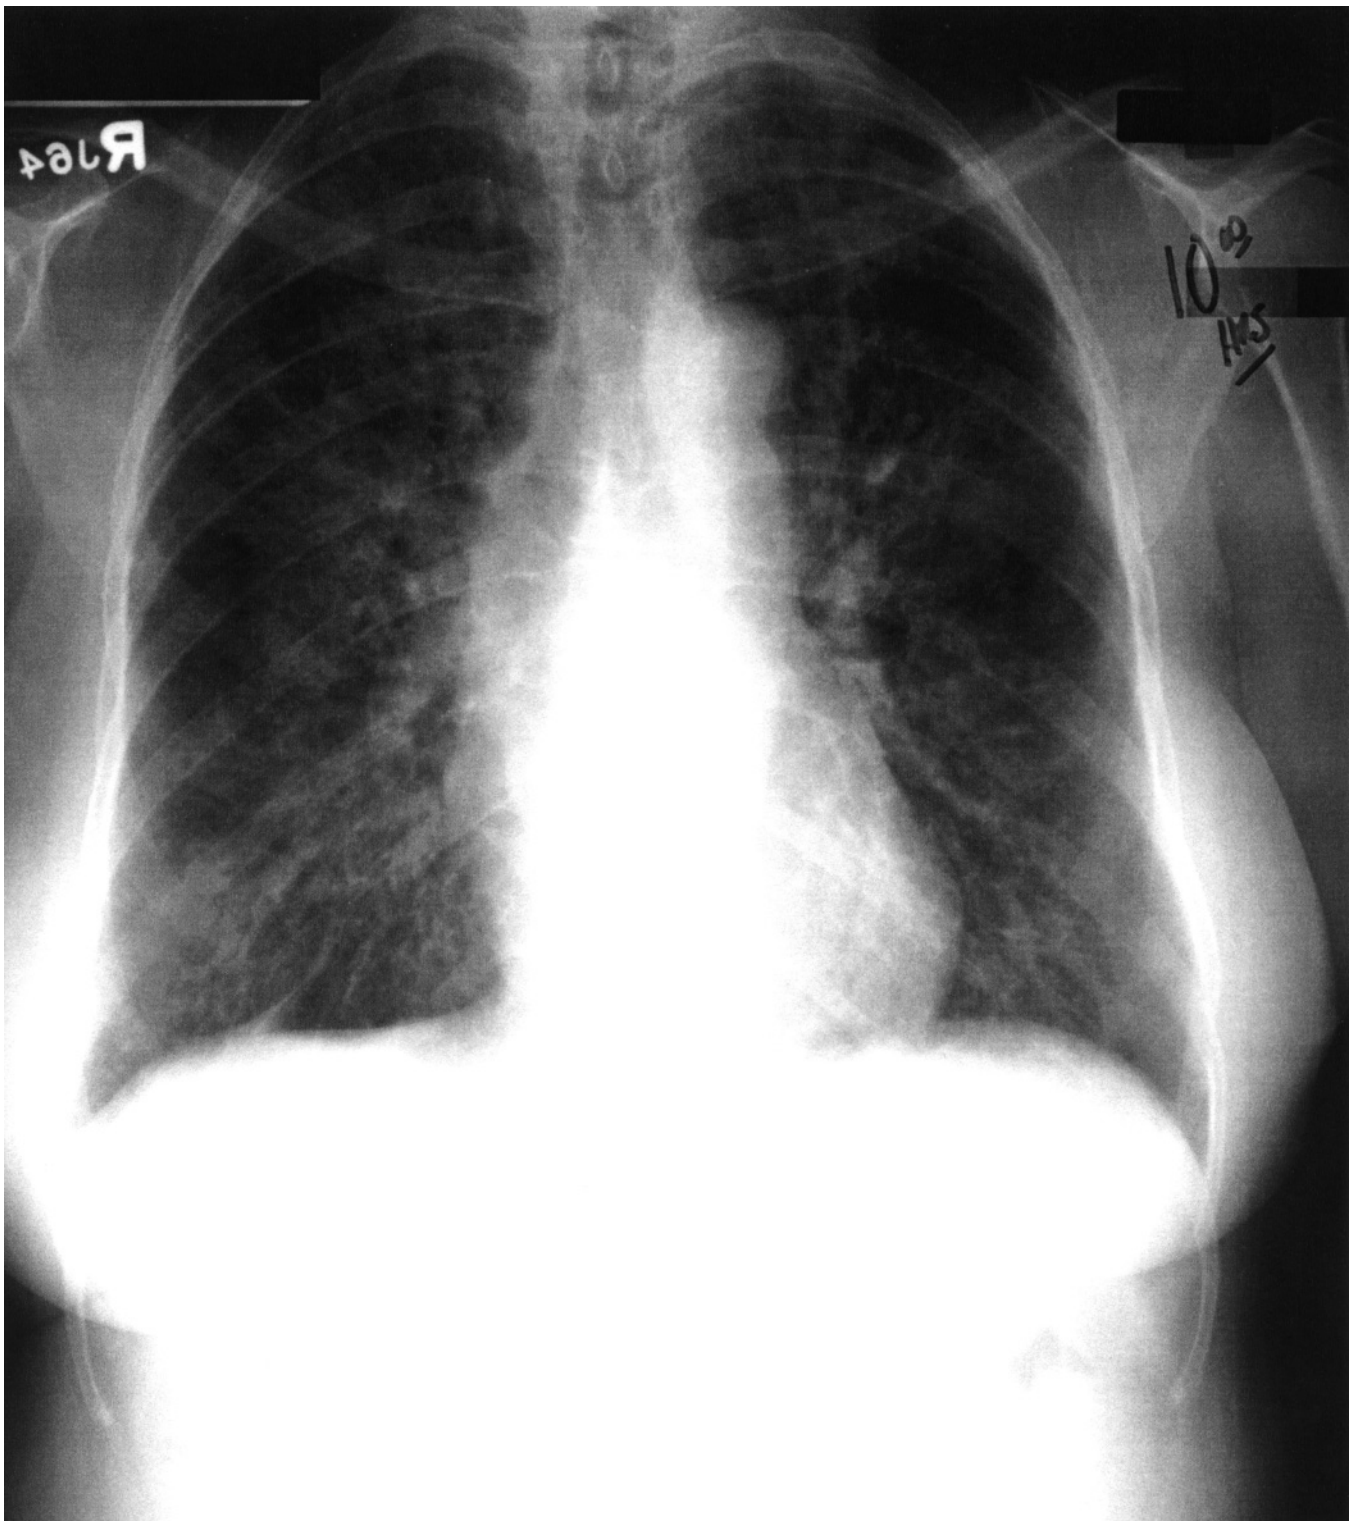

FIG. 16.1b. The same patient ve days later. Despite intravenous cotrimoxazole and oral prednisone, she became progressively hypoxemic and her chest radiograph reveals worsening in ltrates. She subsequently improved without a change in therapy, and did not require mechanical ventilation.

of HAART, the incidence of PCP, along with other opportunistic infections, has fallen dramatically.

Despite these epidemiological changes, the risk of PCP remains essentially the same for individuals with low CD4 cell counts. PCP remains a frequent clinical presentation in patients without a prior diagnosis of HIV infection. In addition, lacks of access to or adherence with prophylaxis and antiretroviral therapy contribute to new cases of PCP.

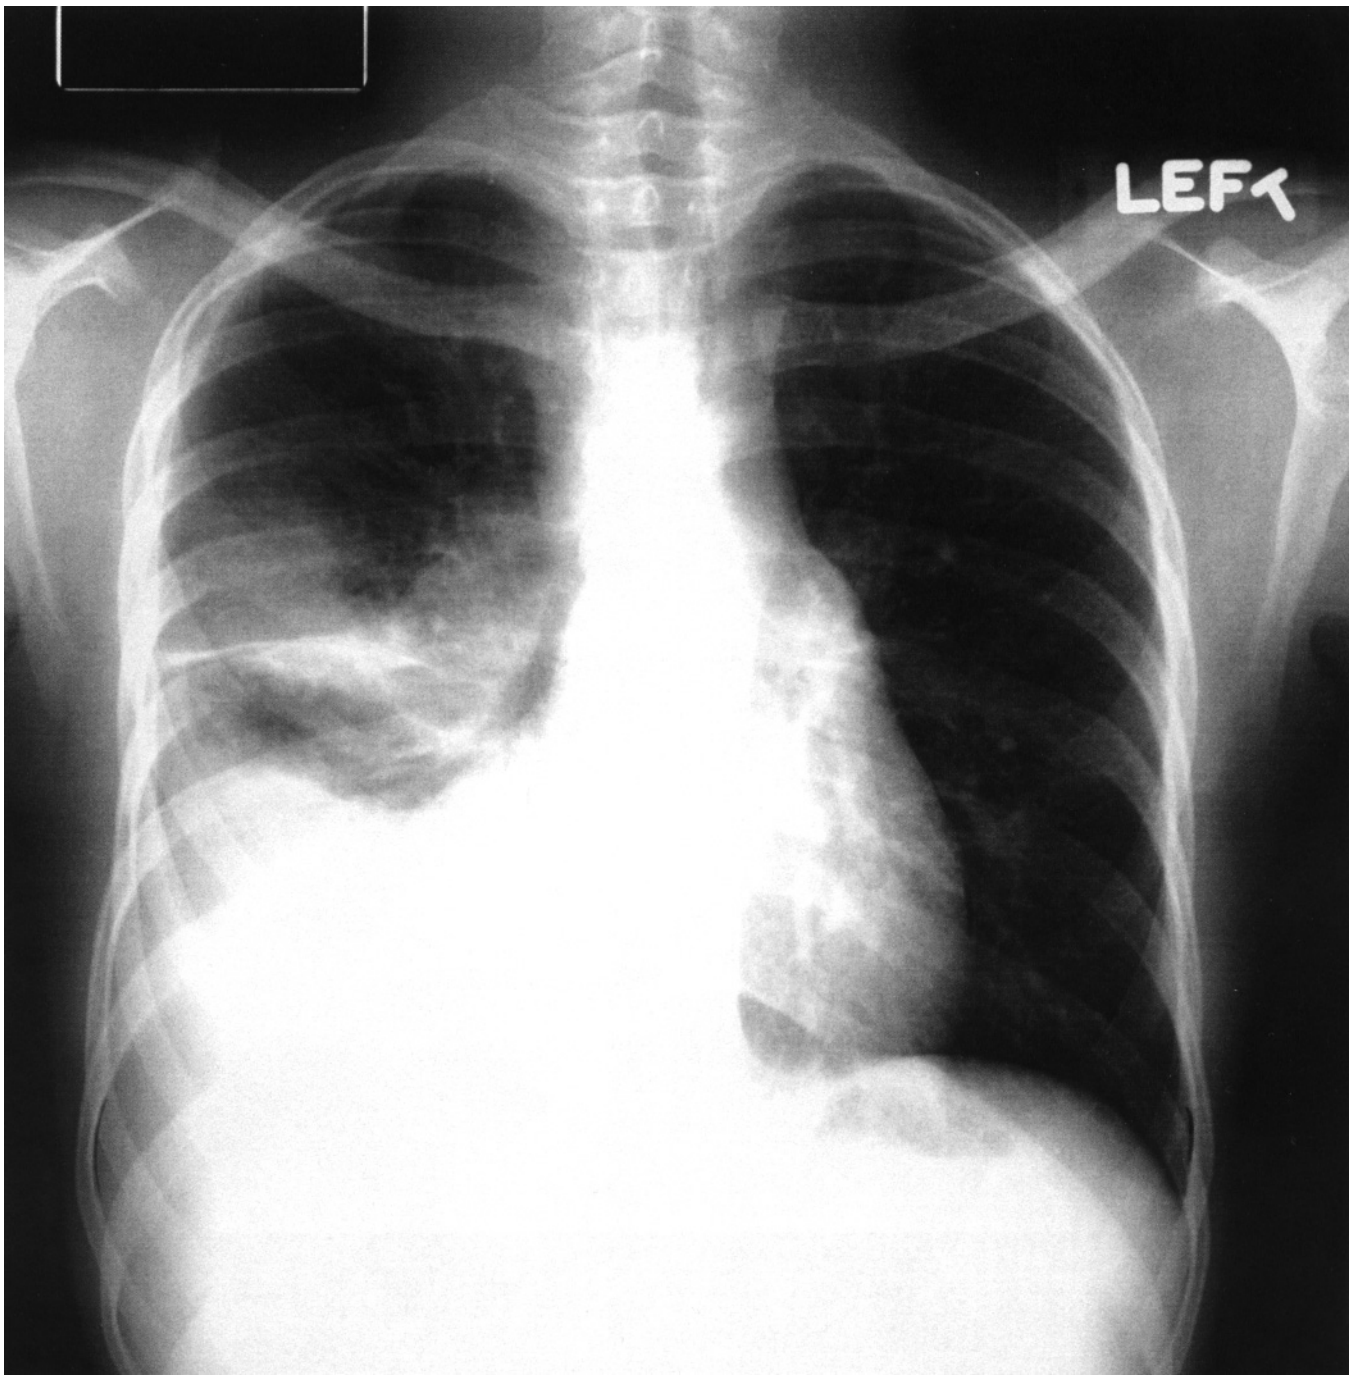

FIG. 16.1c. A 22 year old man admitted to the hospital for fevers, cough, chest pain, cervical adenopathy and weight loss. His chest radiograph shows right paratracheal and hilar adenopathy, a right pleural effusion with loculation and adjacent in ltrate. He was found to have HIV infection with a CD4 cell count of 133 per cubic milliliter. Cultures of sputum, pleural uid and lymph node all grew *M. tuberculosis*. He was treated with standard therapy and responded well, and antiretroviral therapy was initiated after two months without complication.

Clinical and Laboratory Manifestations

In patients with HIV infection, PCP is characterized by a slow, indolent time course with clinical symptoms progressing over weeks to months. Typical manifestations include fever, dyspnea, and nonproductive cough. Other symptoms include fatigue, chest tightness, night sweats, anorexia and weight loss. Presenting symptoms and time course are variable, however, and symptoms may develop over several days, suggesting acute community acquired pneumonia.

The clinical signs of PCP include hypoxia and tachypnea, with a resting $PaO_2 < 80$ mm Hg found in 80% of cases. Desaturation with exercise, such as stair-climbing,

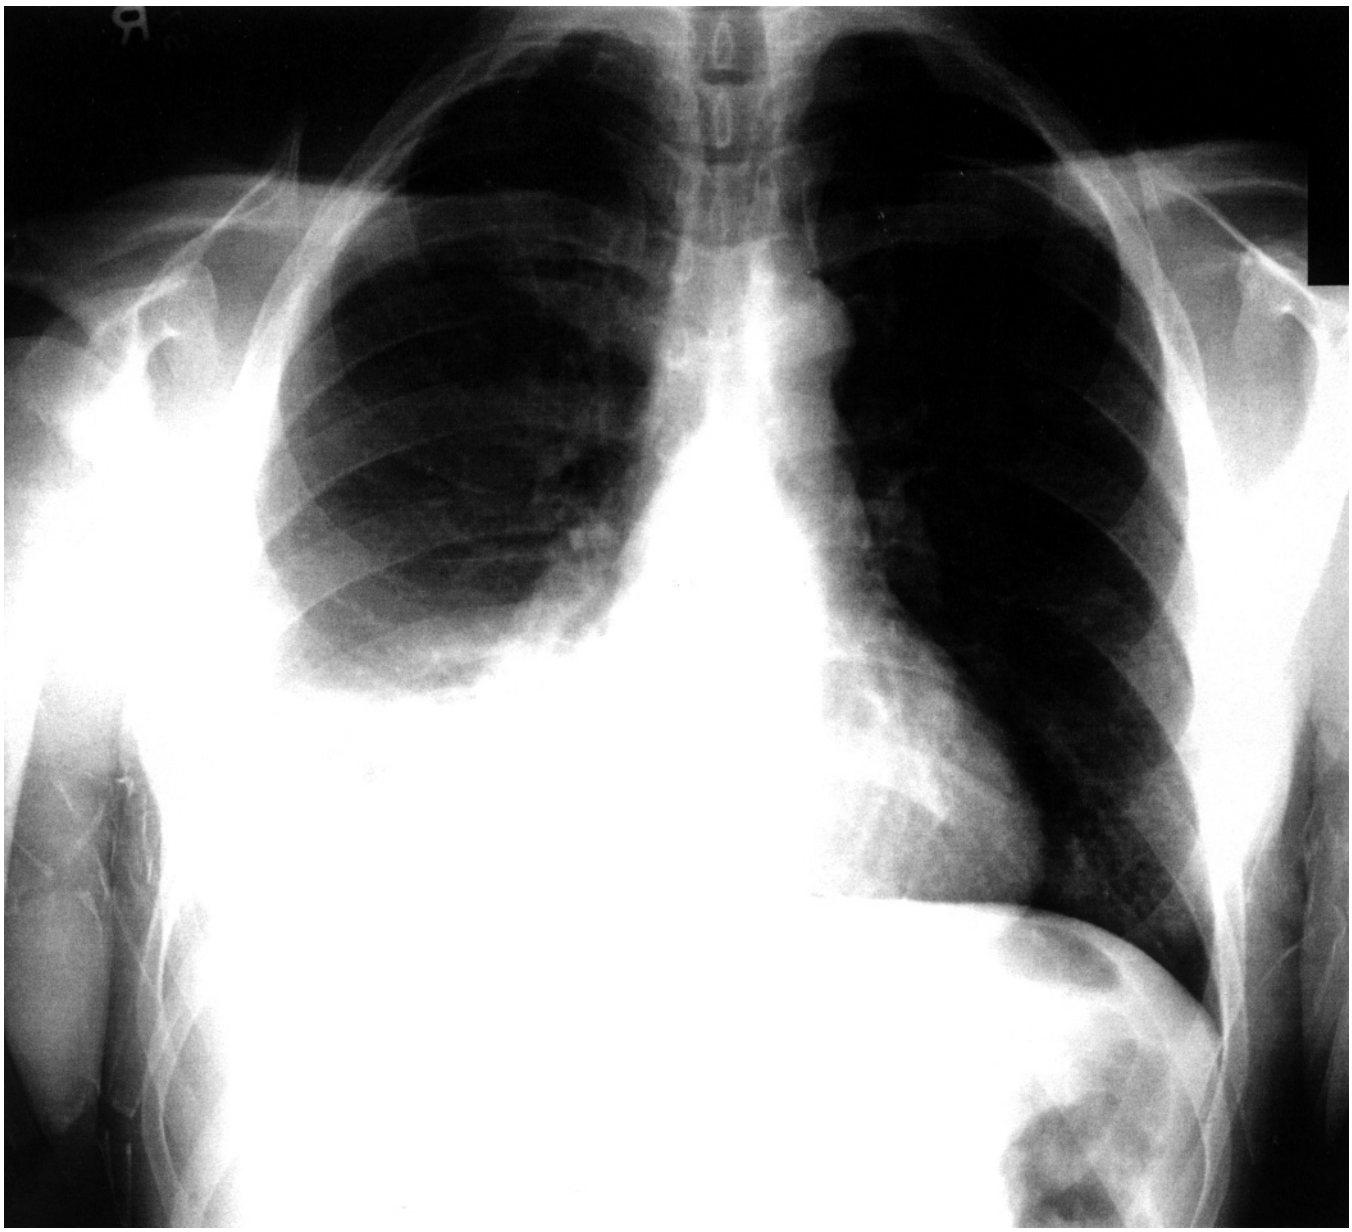

FIG. 16.1d. A 44 year old man with HIV infection and CD4 count of 326 per cubic milliliter presented with a two-day history of fever, productive cough and chest pain. His chest radiograph shows a right middle lobe in ltrate and a large rght pleural effusion. Blood cultures grew *S. pneumoniae*. After drainage of 0.5L of pleural uid and treatment with ceftriaxone, the patient improved.

is a highly sensitive marker of PCP, even if the PaO_2 is normal (7,8). Fever is observed in 80Ð90% of cases. The chest examination is often unremarkable; however, physical diagnosis may reveal other signs of advanced HIV infection, such as oral thrush or oral hairy leukoplakia. The presence of such signs is of particular signiÞcance when evaluating a patient not yet known to be HIV seropositive or with an unknown CD4 cell count. As when evaluating patient symptoms, the clinician should be alert to atypical clinical signs of PCP.

Chest radiographs typically show bilateral diffuse inÞltrates in an interstitial or interstitial-alveolar pattern. In patients receiving aerosolized pentamidine prophylaxis, the inÞltrates may be conÞned to the lung apices, radiographically mimicking pulmonary tuberculosis. The chest X-ray may be normal in as many as 30% of cases, usually in association with mild disease (9). Other radiographic Þndings may include pneumothorax, nodules, cavitation, and patchy or nodular ground glass inÞltrates on computerized tomography scan. Laboratory Þndings in PCP are generally non-speciÞc. The white blood cell count is typically normal or reduced with a marked lymphopenia. Serum lactate dehydrogenase (LDH) level is typically elevated in PCP, with a sensitivity

of 78–100%. However, LDH is not a specific marker for PCP. LDH elevations are a surrogate for radiographic severity and are not useful in differentiating PCP from other illnesses (10). The degree of elevation, however, correlates with disease severity and predicts mortality at diagnosis.

P. carinii cannot be cultured using fungal or other media. Diagnosis depends on cytopathology of induced sputum or BAL. The diagnostic algorithm typically begins with a sample of sputum induced using nebulized hypertonic saline. Expectorated sputums are generally not available from patients with PCP. Traditional stains used to identify PCP include toluidine blue-0 and methenamine silver, which stain the cyst wall. Giemsa stains identify trophozoite forms and have been useful in identifying *P. carinii* in sputum specimens. More recent technology uses monoclonal antibodies for direct and indirect immunofluorescence. The sensitivity of induced sputum for PCP varies greatly among different centers but approaches 90% at some institutions. A positive result, however, obviates the need for bronchoscopy or additional diagnostic evaluation. The cytopathology associated with PCP is not altered by antipneumocystis therapy; therefore, empiric treatment is recommended in patients with suspected PCP prior to diagnostic test results. Future diagnosis of PCP may incorporate the use of polymerase chain reaction (PCR) on respiratory specimens and/or serum. The role of PCR in the diagnostic algorithm for PCP remains to be established.

Given the variable negative predictive value of induced sputum for PCP, early fiberoptic bronchoscopy is recommended for patients with negative induced sputum. BAL has a high sensitivity for diagnosing PCP, with sensitivities typically exceeding 95%. Bilateral and/or site directed BAL improves the yield. In nearly all cases, a negative BAL result for PCP obviates the need for treatment. However, BAL may identify other pathogens or provide other diagnostic information. A review of PCP diagnosis in San Francisco found that induced sputum identified 80% of cases and BAL found *P. carinii* in 32% of patients with negative induced sputa (11). Other pathogens were identified in 24% of patients. Of the 95 patients who stopped antipneumocystis therapy after a negative BAL, only two developed PCP at more than 6 weeks after bronchoscopy.

Empiric PCP treatment without BAL is controversial. A number of authors have argued that for patients with clinical features strongly suggestive of PCP, empiric therapy is warranted and provides effective treatment with minimal morbidity (12). Others have noted that among patients with a "classic" presentation of PCP, more than 25% do not have the disease, and that empiric treatment would delay the diagnosis of other illnesses. In addition, treatment for PCP is associated with potential adverse reactions. BAL may successfully identify other pulmonary complications of HIV that can mimic PCP, such as community acquired bacterial pneumonia, cryptococcal pneumonia, tuberculosis and tracheobronchial Kaposi's sarcoma. Failure to perform early BAL may result in clinical worsening of the patient beyond the point where bronchoscopy may be safely performed.

Treatment

The medical management of PCP includes the decision whether to hospitalize the patient. Indications for the hospitalization of HIV-infected patients with PCP include hypoxia ($PaO_2 < 70$), requirement for parenteral antibiotics, uncertainty regarding the diagnosis, and risk of medical non-compliance. Trimethoprim-sulfamethoxazole (TMP-SMX) is the preferred initial treatment for PCP. The recommended regimen is trimethoprim 15 mg/kg per day plus sulfamethoxazole 75 mg/kg daily for 21 days in three to four divided doses. In patients with severe PCP, initial treatment should be parenteral due to the risk of erratic oral absorption. Mild to moderate PCP may be treated effectively as an outpatient with oral antibiotics. The typical oral regimen is two double-strength tablets of TMP-SMX three times per day.

Patients with AIDS have a high incidence (25–50%) of adverse reactions to trimethoprim-sulfamethoxazole, including fever, skin rash, bone marrow suppression, and elevation of liver enzymes. For patients intolerant of TMP-SMX, there are a number of alternative regimens. In patients with mild to moderate PCP, effective alternatives include trimethoprim (15 mg/kg/day) plus dapsone (100 mg/day) and oral or intravenous clindamycin (300–450 mg po every six hours or 600 mg IV every eight hours) combined with oral primaquine (30 mg base/day). Potential adverse reactions to dapsone include hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, methemoglobinemia and hepatotoxicity. Primaquine may also cause hemolytic anemia in persons with G6PD deficiency, as well as fever, rash, methemoglobinemia, and diarrhea. Atovaquone which may be used for the treatment of mild to moderate PCP (see Chapter 00) is generally well tolerated but has less efficacy and greater cost than TMP/SMX.

TMP/SMX remains the treatment of choice for severe PCP. The addition of corticosteroids is indicated for patients with $PaO_2 < 70$ mm Hg or an A-a gradient > 35 mm Hg (13). The initiation of antipneumocystis therapy often results in a decline in PaO_2 of 10–30 mm Hg. This decline is thought to be due to pulmonary inflammation and edema in response to dying *P. carinii*. Corticosteroids started within 72 hours will prevent or reduce the decline in PaO_2, improving pulmonary function and survival. The recommended regimen is prednisone 40 mg twice daily for five days, then 40 mg daily for five days, followed by 20 mg daily for the remainder of the treatment. Adjuvant corticosteroids for PCP may result in increased mucocutaneous HSV, oral or esophageal candidiasis, acute psychosis and hyperglycemia; however, an increased risk of other opportunistic infections is not apparent.

An alternative regimen for the treatment of severe PCP is intravenous pentamidine 3Ð4 mg/kg daily for 21 days. Pentamidine is also associated with a high incidence of adverse reactions including azotemia, hyperglycemia or hypoglycemia, pancreatitis, hypotension and bone marrow suppression. The clinical response to effective anti-pneumocystis therapy is typically slow. Treatment failure is deÞned as progressive deterioration four to Þve days into therapy or lack of clinical or radiographic improvement after seven to ten days. Secondary processes should be considered, including concurrent infections, congestive heart failure, pulmonary embolus, and other underlying lung diseases. In addition, PCP is associated with the development of pneumothoraces. If a patient with conÞrmed PCP is deteriorating on Þrst-line therapy (TMP/SMX or pentamidine), there are no criteria to guide a switch in therapy. No change is recommended for at least Þve to seven days. If a patient has residual respiratory symptoms or requires supplemental oxygen at the end of 21 days of therapy, the treatment course should be lengthened to four to Þve weeks. Repeat bronchoscopy during or at the completion of therapy frequently demonstrates the presence of *P. carinii*. In patients doing well clinically, this is not an indication for continuation of therapy beyond three weeks.

TMP/SMX resistance in PCP may explain some cases of AIDS patients who fail TMP/SMX prophylaxis and/or treatment. Sulfamethoxazole (SMX) and dapsone act on dihydropteroate synthase (DHPS), a key enzyme in folate metabolism. Point mutations in the *P. carinii* dihydropteroate synthase (DHPS) gene have been associated with the failure of sulfa or sulfone prophylaxis in AIDS patients (14). Kazanjian et. al. ampliÞed and sequenced DHPS genes from 97 AIDS patients with PCP between 1991 and 1999. DHPS mutations were found in 76% of isolates from patients with prior sulfa or sulfone exposure versus 23% of isolates from unexposed individuals ($p = 0.001$) (15). DHPS mutations in *P. carinii* impact response to sulfa/sulfone prophylaxis and treatment as in other bacteria and *Plasmodium* species.

Prevention

In 2002, the U.S. Public Health Service (USPHS) updated the guidelines for the prevention of opportunistic infections in persons with HIV (16). These guidelines include new recommendations for primary and secondary PCP prophylaxis. Chemoprophylaxis against PCP should be initiated when the CD4 cell count is less than 200/ul or there is a history of oropharyngeal candidiasis. In addition, patients with a CD4 cell percentage of less than 14% or another AIDS-deÞning illness should be considered for prophylaxis. TMP-SMX is the preferred prophylactic agent. One double-strength tablet per day is recommended but one single-strength tablet per day or one double-strength tablet three times per week are also effective regimens and may be better tolerated. In a patient who has had an adverse reaction to TMP-SMX, if clinically feasible, it is desirable to continue or reinitate TMP-SMX prophylaxis, sometimes following one of several desensitization protocols or a reduction in drug dose or frequency. Alternative prophylactic regimens include dapsone 100 mg daily, dapsone plus pyrimethamine and leucovorin (if patient is toxoplasma IgG positive), aerosolized pentamidine 300 mg monthly administered via the Respirgard II[a] nebulizer, and atovaquone 1500 mg daily (see Chapter 00).

The updated USPHS/IDSA guidelines recommend that primary pneumocystis prophylaxis should be discontinued in patients who have responded to HAART with an increase in CD4 cells to > 200 cells/mm^3 for at least three months. As the guidelines point out, this recommendation is largely based on observational and randomized trials in which most patients were taking a protease inhibitor and many had sustained virologic suppression below the assayÕs limit of detection. Primary prophylaxis should be reinstituted if the CD4 cell count declines to below 200 cells/mm^3 or the patient otherwise meets criteria for PCP prophylaxis.

Secondary prophylaxis is recommended for patients with a history of PCP, regardless of CD4 cell count, using TMP-SMX or one of the alternative drug options for primary prophylaxis. Secondary prophylaxis should be discontinued when the CD4 cell count exceeds 200/mm^3 for at least three months in response to HAART. If the episode of PCP occurred with CD4 > 200 cells/mm^3, it is currently recommended to continue life-long secondary prophylaxis regardless of recovery in CD4 cell count.

BACTERIAL PNEUMONIA

As a result of defects in both cell-mediated and humoral immunity, persons with HIV infection are more susceptible to bacterial infections, particularly those with encapsulated organisms. Bacterial pneumonia is a common complication of HIV infection and can occur within all CD4 cell strata. Recurrent bacterial pneumonia (≥ 2 episodes in 12 months) is included in the CDC surveillance case deÞnition of AIDS.

In a prospective study of more than 1,200 patients with and without HIV infection, the rate of pneumonia in the HIV-positive group was 5.5 episodes per 100 person-years, as compared to 0.9 per 100 person-years in the HIV-negative group ($p < 0.001$) (17). Among HIV-infected patients, the rate of bacterial pneumonia was inversely related to the baseline CD4 cell count, with the highest risk among patients with a CD4 cell count less than 200/mm^3. Injection drug use was also associated with an increased risk of bacterial pneumonia in all strata of CD4 cell counts. The study also found an increased risk associated with cigarette smoking among patients with CD4 cell counts less than 200/mm^3. Although there has been a signiÞcant

decline in the incidence of bacterial pneumonia since the introduction of HAART, the same risk factors for bacterial pneumonia are assumed to operate.

The most common pathogen causing bacterial pneumonia in patients with HIV infection is *Streptococcus pneumoniae* (18). Persons with HIV have an incidence of pneumococcal bacteremia that is approximately 100 times greater than that found in the general population. Other etiologic agents include *Haemophilus inßuenzae*, *Staphylococcus aureus*, *Klebsiella* species, *Pseudomonas aeruginosa*, *Rhodococcus equi*, and *Nocardia* species. The frequency of pneumonia due to atypical pathogens including *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and *Legionella* species appears to be extremely low.

Clinical and Laboratory Manifestations

HIV-infected patients with bacterial pneumonia generally have a similar clinical presentation as patients without HIV infection. Common signs and symptoms include fever, rigors, dyspnea, productive cough with purulent sputum, and pleuritic chest pain. Patients typically present with an acute syndrome of less than one weekÕs duration, in contrast to the more indolent course associated with PCP. The physical examination may reveal fever, tachypnea, and evidence of consolidation on chest examination.

Laboratory Þndings associated with bacterial pneumonia often include an elevated leukocyte count with a predominance of neutrophils and immature forms. The absolute leukocyte count may be relatively low, however, in patients with advanced immunodeÞciency.

The chest radiograph is variable, depending on the etiologic agent. Pneumococcal pneumonia is typically associated with radiographic Þndings of focal segmental or lobar consolidation with or without pleural effusion. Nodular or cavitary lesions are found in association with *Staphylococcus aureus*, *Nocardia* species and mycobacterial infections.

The diagnostic algorithm begins with an analysis of the gram-stained sputum and sputum and blood cultures. Prior antibiotics usually preclude culture growth; therefore, sputum and blood samples should be collected prior to the initiation of empiric antibiotic therapy.

Bacteremia is a more frequent complication of pneumonia in patients with HIV infection. The mortality rate with bacteremic pneumococcal pneumonia is 5% to 11%. It is recommended that blood cultures be obtained early in the evaluation of a patient with pneumonia.

Treatment

The sputum Gram stain and local antibiotic resistance patterns will guide the choice of antibiotic. For example, if *S. pneumoniae* is suspected from the sputum analysis, preferred treatment options include a third generation cephalosporin, such as cefotaxime or ceftriaxone, a ßuoroquinolone, or a macrolide. Patients with pneumococcal pneumonia resistant to penicillin or a seriously ill patient in a region with high rates of resistance should be treated with a parenteral third generation cephalosporin or a newer ßuoroquinolone (levoßoxacin, gatißoxacin, moxißoxacin). Empiric antibiotic therapy may be revised based on the sputum culture data and antibiotic susceptibility testing. HIV-infected patients with community acquired bacterial pneumonia usually respond rapidly to treatment. Clinical failure on appropriate antibiotics for likely bacterial pathogens should prompt additional diagnostic tests and expanded therapy for possible co-pathogens or other pulmonary processes. In earlier studies, approximately 5% of patients with bacterial pneumonia also had PCP.

Prevention

Prevention of pneumococcal disease with pneumococcal polysaccharide vaccine has been recommended for patients with HIV infection for some time, though controversy exists regarding vaccine efÞcacy. Several early studies showed poor antibody responses to the vaccine, particularly in patients with advanced HIV disease. A case-control study in the early 1990s found a beneÞcial effect of vaccination for patients with CD4 cell counts above 200, but no beneÞt, and possible harm, for patients with CD4 counts below 200 (19). A subsequent case-control study by the CDC found that the overall efÞcacy of pneumococcal vaccination was 49% (95% CI, 12%Ð70%) (20). However, a prospective, placebo-controlled trial performed in Africa found an *increased* risk of both pneumococcal infections and all bacterial pneumonia in patients randomized to vaccination (21). Studies of the efÞcacy of protein-polysaccharide conjugate pneumococcal vaccines have not been completed, though evidence from *Haemophilus* conjugate vaccine studies suggest that this approach may be more efÞcacious.

Despite the Þndings from the placebo-controlled trial in Uganda, the Infectious Diseases Society of America and the U.S. Public Health Service recommend that the 23-valent pneumococcal polysaccharide should be given to all HIV-infected patients with a CD4 cell count $\geq$200 cells/mm^3 and should be considered for patients with CD4 cell counts $<$200 cells/mm^3. This recommendation is based on the consistency of observational studies and concerns about the applicability of the Ugandan trial to circumstances in the United States.

In persons with HIV infection, the duration of antibody responses to the pneumococcal antigens in the vaccine is unknown. Revaccination is suggested at Þve years, although there is limited clinical data to support this practice. A recent randomized, placebo-controlled trial evaluated the potential risks and beneÞts of reimmunization in patients with HIV infection (22). Antibody levels

measured prior to immunization were similar to those in unimmunized patients. The increase in serum IgG to four pneumococcal capsular polysaccharides at two, six, and twelve weeks achieved statistical signiÞcance in the reimmunized patients compared to baseline values. However, the antibody levels did not differ signiÞcantly between the revaccinated patients versus those receiving saline placebo. This suggests that reimmunization produces only a modest increase in capsule-speciÞc IgG levels which may have little or no clinical beneÞt. At the same time, revaccination produced only minor side effects including soreness, erythema, or swelling at the injection site and fever. No adverse effects on CD4 cell count or plasma HIV-RNA levels were observed.

Patients who receive TMP-SMX for PCP prophylaxis, compared to aerosolized pentamidine, have a lower incidence of bacterial respiratory tract infections, as do patients receiving azithromycin or clarithromycin for prevention of *Mycobacterium avium*-complex infection. The use of prophylactic antibiotics for prevention of bacterial pneumonia *per se* is not recommended, however, since this practice could promote the development of resistant organisms.

NOCARDIA

Nocardia Asteroides

Nocardiosis is described in HIV infection and it is an indicator disease for AIDS. In most cases, disease occurs in patients with advanced immunodeÞciency (ie, CD4 cell count $< 200/mm^3$) (23,24). Patients typically present with an indolent course and nonspeciÞc constitutional complaints. Pulmonary symptoms, such as cough or dyspnea, may develop. As in patients without HIV infection, the lung is the most common site of disease, although dissemination is common in HIV-infected patients. Radiographic Þndings include nodules, cavities, and diffuse or focal inÞltrates (25). A case of pulmonary and disseminated disease due to *N. farcinica* in an HIV-infected patient has been reported (26).

The diagnosis is suspected if Þlamentous, beaded, branching, gram-positive, acid-fast rods are seen on Gram stain or on modiÞed acid-fast stain of sputum or other respiratory specimens. Because of the slow growth of the organism, cultures should be held for four weeks if nocardiosis is suspected. Culturing sputum for mycobacteria and fungi will improve the chances of isolating *Nocardia* sp.

Sulfonamides are the mainstay of therapy for nocardiosis. Although TMP-SMX is synergistic against *N. asteroides in vitro*, the combination is no more effective than any of the sulfonamides alone. Minocycline is active against *Nocardia in vitro* and has been used successfully in HIV-infected and other patients. Other agents demonstrating *in vitro* activity against *Nocardia* include cefotaxime, ceftriaxone, imipenem, and amikacin, though clinical experience with these agents is more limited.

The optimal duration of therapy for nocardiosis has not been determined for immunocompromised patients (27,28). Some investigators recommend treatment for six to twelve months for patients with pulmonary nocardiosis, regardless of their immune status. Others recommend indeÞnite therapy in the setting of immunocompromise in general. The former recommendation (a six to twelve-month course of therapy) may be most appropriate for HIV-infected patients who successfully recover lost immune function with HART. The use of TMP-SMX for prophylaxis of PCP may help to prevent nocardiosis, although data are limited. Nocardiosis has been described in patients who were prescribed TMP-SMX prophylaxis.

Rhodococcus equi

R. equi (formerly *Corynebacterimi equi*) was Þrst reported to cause disease in an AIDS patient in 1986 (29). Since then, several cases have been reported (30Ð35). The organism is a gram-positive, aerobic, nonmotile, non-spore-forming, pleomorphic bacillus. On Gram stain, its appearance varies from cocci to short rods. Infection typically presents as pneumonia, with unilobar, often upper lobe, pulmonary inÞltrates, which progress over several weeks. Multilobar involvement may develop, and cavitation, pleural effusion, empyema, and bacteremia are common. Of 12 HIV-infected patients with *R. equi* infections, one had cavitary disease, and three had culture-positive pleural effusions (33,34).

Resistance to beta-lactam antibiotics develops frequently. Effective antimicrobial agents include erythromycin, vancomycin, clindamycin, chloramphenicol, and TMP-SMX. Rifampin has been used in combination with other agents and is probably synergistic when given with erythromycin. Prolonged courses of parenteral antibiotics are recommended, and surgical intervention is sometimes necessary for persistent abscesses. Recurrence is not uncommon, even after several weeks of antibiotic therapy.

PSEUDOMONAS AND OTHER UNUSUAL ORGANISMS

Nosocomial pneumonia in patients with AIDS is usually caused by gram-negative bacilli, including *P. aeruginosa*, or by *Staphylococcus aureus* (36,37). As with other hospitalized patients, risk factors include neutropenia, the use of broad-spectrum antibiotics, and the presence of central venous catheters. Nosocomial pneumonia has a higher morbidity and mortality than community-acquired pneumonia.

Pneumonia due to *Pseudomonas* is not uncommon among HIV-infected patients and does not always appear

to be hospital acquired or fulminant in its presentation. Baron and Hollander described 16 patients with advanced HIV disease (mean CD4 count, 25/mm^3) and *P. aeruginosa* pneumonia, diagnosed by Gram stain and culture of sputum or bronchoscopic washings (38). In 12 of the 16 patients, the pneumonia was community-acquired, and Pseudomonas was the sole pathogen in 14 cases. Only four patients, two of whom had community-acquired pneumonia, presented with fulminant pneumonia and sepsis. The remaining 12, all with community-acquired pneumonia, had a more indolent presentation, with a mean duration of symptoms of two weeks. Prior hospitalization, an indwelling catheter, neutropenia, and corticosteroid use have all been associated with the development of deep-seated *P. aeruginosa* infections in patients with HIV (39). Relapses of infection are common.

In a prospective study of patients admitted to Johns Hopkins Hospital with community-acquired pneumonia, Mundy and colleagues reported that gram-negative bacilli were a signiÞcantly more common cause of pneumonia in patients with HIV infection than in uninfected patients (9% vs. 3%) (40). Gram-negative bacteremia may originate from a pulmonary infection, or bloodstream infection may secondarily infect the lungs. Risk factors for gram-negative pulmonary infections in HIV-infected patients include recent hospitalization, venous catheters, intubation and other factors known to increase risk in non-HIV-infected populations.

Pneumonia due to *Salmonella typhimurium* has been reported as well (41,42). Other bacterial pathogens reported to cause pneumonia in patients with HIV infection include *Bordetella bronchiseptica*, *Morancella catarrhalis*, group B *Streptococcus*, *Mycoplasma pneumoniae*, and *Streptomyces* species (43Ð47).

Pneumonia due to *Legionella pneumophila* has been reported in patients with HIV infection, but it does not appear to be common outside of epidemic foci in the community. Cavitary pneumonia due to *Legionella micdadei* and *L. pneumophila* has been described (48,49).

TUBERCULOSIS

Tuberculosis is one of the most common AIDS-related opportunistic infections worldwide, and is the leading cause of death from AIDS in sub-Saharan Africa (50). The incidence of tuberculosis in populations of HIV-infected people is a function of the local prevalence of latent tuberculosis infection and the risk of exposure to tuberculosis in the environment. Patients with HIV infection have an enormously elevated risk of progression of recent tuberculosis infection to active disease and of reactivation of latent tuberculosis infection. Among HIV-infected patients with latent tuberculosis, the risk of reactivation is 3Ð15% per year, higher than in any other patient population ever described. People with advanced HIV infection who acquire new tuberculosis infection have a risk of developing active disease that may be as high as 45%. Thus, HIV infection has a dramatic impact on the natural history of *M. tuberculosis* infection and disease.

Clinical and Laboratory Manifestations (see Chapter 00)

The clinical features of tuberculosis in HIV-infected patients vary with the degree of immunosuppression. Fever for greater than seven days along with weight loss as presenting complaints are more predictive of pulmonary TB than of PCP or community-acquired pneumonia due to pyogenic bacteria. In patients with mildly or moderately depressed CD4 counts, the presentation of tuberculosis is similar to that seen in other populations. Most have disease conÞned to the lungs, with upper lobe inÞltrates that are sometimes cavitary on chest radiograph (51,52). In patients who develop tuberculosis at a more advanced stage of HIV infection, often after the development of other opportunistic infections, tuberculosis tends to be more disseminated and clinical features are less typical. In these cases, although pulmonary infection is common, the radiographic Þndings may be atypical or may mimic those of primary tuberculosis. Cavitary disease is unusual in advanced AIDS, but lower lobe inÞltrates or miliary patterns occur frequently. Intrathoracic adenopathy and involvement of extrapulmonary sites are also common. HIV-infected patients with smear-positive pulmonary tuberculosis have been reported to present with normal chest radiographs, though this appears to be unusual (53).

Extrapulmonary tuberculosis is seen in 24% to 48% of HIV-infected patients (54), although in patients with more advanced stages of immunosuppression, it may occur in more than 70% of cases (55). As with tuberculosis in other populations, the lymphatic system is the most common site of extrapulmonary involvement. HIV-infected patients are more likely to have disseminated, genitourinary, intraabdominal, and mediastinal tuberculosis, with or without concomitant pulmonary disease, than patients without HIV infection (55Ð58). Bacteremia occurs in 26% to 42% of HIV-infected patients with tuberculosis. Tuberculous abscesses of the brain parenchyma or spinal cord may occur, appearing as ring-enhancing or hypodense mass lesions. Tuberculous meningitis is more common in HIV-infected patients, and it has been reported in patients with acellular cerebrospinal ßuid.

Diagnosis and Treatment

The Þrst step in the diagnosis of pulmonary tuberculosis is examination of sputum for acid-fast bacilli, followed by mycobacterial culture. The diagnostic yield of the sputum smear is comparable to that found in HIV-negative patients, but in more advanced stages of HIV disease, the sensitivity may be lower. Sputum culture has a yield of

approximately 90%. BAL may increase the sensitivity of smear and culture. Because bacteremia occurs in a substantial proportion of HIV-infected patients, blood cultures for acid-fast bacilli should be performed for all patients in whom tuberculosis is suspected. A positive puriÞed protein derivative tuberculin test may support a diagnosis of tuberculosis, but a negative result of the skin test should never be used to exclude tuberculosis, because patients may become anergic with progression of HIV disease and decline in the CD4 count. Radiographic Þndings vary considerably, especially in patients with advanced immunodeÞciency. Typical Þndings of apical cavitary disease are unusual in these patients. Patients with acid-fast bacilli present on smears or culture of respiratory specimens should usually be treated for presumed tuberculosis until speciation (either by DNA probe testing or by culture) proves a nontuberculous cause. Therapy for tuberculosis is discussed in Chapter 00.

Non-Tuberculous Mycobacteria

Mycobacterium avium complex (MAC) is a common cause of morbidity in advanced HIV disease though disease is nearly always systemic and not conÞned to the lungs. Although it is frequently isolated from sputum or bronchial washings in colonized patients or patients with disseminated infection, it has only rarely been reported to cause lung disease. However, endobronchial lesions containing granulomas, as well as granulomatous disease of the pulmonary parenchyma, have been reported and represent a Þnding requiring systemic MAC therapy (59). The growth of MAC from respiratory specimens without histopathologic evidence of disease is not an indication for treatment although it may predict later dissemination. The same is true for many other nontuberculous mycobacterial species, such as *M. gordonae*, *M. fortuitum*, *M. chelonei*, *M. xenopi*, and *M. haemophilum*, which rarely cause isolated pulmonary disease in HIV-infected patients. Prevention of MAC with azithromycin or clarithromycin therapy is recommended for patients with CD4 cell counts < 50; prophylaxis can be discontinued when the CD4 has increased to > 100 after the initiation of HAART.

M. kansasii is a cause of serious pulmonary disease in AIDS patients with advanced immunodeÞciency. Disseminated M. kansasii infection is an AIDS-deÞning condition, and it occurs as an index AIDS diagnosis in $< 0.5\%$ of cases in highly endemic areas. There are few data on the incidence of pulmonary disease, but it appears to be considerably more common than disseminated infection. In some series, M. kansasii was isolated more frequently than M. tuberculosis in HIV-infected patients.

Of 19 cases of *M. kansasii* infection reviewed at the Johns Hopkins Hospital, 17 patients had pulmonary disease (60). The clinical features and response to therapy was similar to that of patients with pulmonary tuberculosis. The radiographic features included diffuse interstitial or apical inÞltrates, with or without cavities. Thin-walled cavities were common and thought to be an important diagnostic clue in patients with pulmonary disease and advanced HIV infection. No cavities were seen in the 6 patients with pulmonary *M. kansasii* infection in a series at Parkland Hospital (60a). Radiographic Þndings in that series included nodular, interstitial, or diffuse parenchymal inÞltrates, and one patient had a pleural effusion. In patients with HIV infection, *M. kansasii* disease is associated with a greater degree of immunosuppression than tuberculosis. In the Johns Hopkins series, all patients with *M. kansasii* disease had CD4 lymphocyte counts of less than 200 cells/ mm^3, and the median CD4, count was 49 cells/mm^3.

Extrapulmonary disease due to *M. kansasii* also occurs. In the Hopkins series, Þve patients had extrapulmonary infections, and three of whom had concomitant pulmonary infections. Other sites from which *M. kansasii* was isolated included bone, urine, stool, lymph nodes, and blood. In the Parkland series, four of nine patients showed evidence of extrapulmonary dissemination, with isolation from blood, lymph nodes, pleural ßuid, liver, and cerebrospinal ßuid (60a).

A regimen of isoniazid, rifampin, and ethambutol is effective in the treatment of pulmonary *M. kansasii* infection. Many isolates demonstrate *in vitro* resistance to isoniazid, but the clinical signiÞcance of this resistance pattern is not known. The organisms may be susceptible to sulfonamides and the newer macrolides, and clinical responses have been observed in patients treated with TMP-SMX for presumed or concomitant *P. carinii* pneumonia. Therapy with clarithromycin has been suggested for patients who do not respond to standard regimens.

FUNGAL PULMONARY INFECTIONS

In addition to *Pneumocystis carinii* pneumonia, there are several fungal pulmonary infections in HIV infection typically associated with advanced immunodeÞciency. Beginning with inhalation of organisms from the environment, the respiratory tract is the entry site for most fungal infections. For some fungi, such as *Histoplasma capsulatum*, pulmonary disease may occur at the time of primary infection or during reactivation with progressive immunodeÞciency. Treatment of systemic fungal infections in HIV-infected in adults typically consists of an induction phase followed by lifelong maintenance therapy. It is not yet known in all cases whether maintenance therapy can safely be discontinued in a patient with immune reconstitution as a consequence of HAART. In general, antifungal primary prophylaxis is not recommended in patients with advanced HIV infection.

Cryptococcus neoformans

Unlike the endemic mycoses, *Cryptococcus neoformans* is an encapsulated fungus that is widespread in the environment. An immunocompetent host inhales the cryptococcus and, by virtue of the cell-mediated immune system, successfully kills the organism. In HIV-infected persons (typically with CD4 cell counts less than 100 cells/mm^3), the fungus can disseminate widely, most commonly causing subacute meningitis or meningoencephalitis. Pulmonary cryptococcosis typically presents in a chronic or subacute fashion with cough and non-speciÞc symptoms including fever, sweats and fatigue. The chest radiograph most commonly shows diffuse alveolar or interstitial inÞltrates; although nodules, pleural effusions, cavities and lymphadenopathy have also been observed. Diagnosis requires culturing the organism from respiratory specimens using selective fungal media. Histopathologic evidence is also provided by direct visualization of the yeast in clinical specimens with mucicarmine stains. The serum cryptococcal antigen test is usually positive in cryptococcal infections; however, a negative antigen test does not rule out cryptococcal pneumonia. HIV-infected patients with cryptococcosis at any site should have a lumbar puncture to exclude concurrent cryptococcal meningitis.

Treatment of AIDS-associated cryptococcosis with meningitis requires intravenous amphotericin B 0.7Ð1.0 mg/kg daily plus ßucytosine 25 mg/kg every six hours for two weeks, followed by oral ßuconazole 400 mg per day for eight to ten weeks (See Chapter 00). Lifelong suppressive therapy with ßuconazole 200 mg daily is recommended. According to the 2002 USPHS/IDSA guidelines for the prevention of opportunistic infections among HIV-infected persons, discontinuation of secondary prophylaxis may be considered in patients who successfully completed initial therapy for cryptococcosis and remain asymptomatic, and have a sustained increase (e.g. $\geq$6 months) in their CD4 cell count to $>$100Ð200 cells/mm^3 after HAART (16). Some specialists advise a lumbar puncture prior to discontinuing therapy to establish that the cerebrospinal ßuid is culture-negative. In any case, maintenance ßuconazole should be reinitiated if the CD4 cell count falls below 100Ð200 cells/mm^3 (16).

Histoplasma capsulatum

Pulmonary histoplasmosis is common among AIDS patients living in endemic areas, namely the Mississippi and Ohio River valleys. Spores are inhaled into the lung where they convert to the yeast form. Primary infection may be asymptomatic or may present as a mild respiratory illness. Most cases of histoplasmosis in AIDS represent reactivation of previously acquired infection. Disseminated histoplasmosis rarely occurs in immunocompetent persons but is the most common manifestation in HIV-infected persons with advanced immunosuppression.

Clinical manifestations may consist of constitutional symptoms including fever and weight loss. Respiratory symptoms occur in approximately 50% of cases. Chest radiographs are variable and include diffuse nodular inÞltrates, focal inÞltrates, nodules, and cavities. Physical examination may reveal evidence of disseminated disease including lymphadenopathy, mucocutaneous lesions, and hepatosplenomegaly. Laboratory evaluation often reveals pancytopenia, reßecting bone marrow involvement and elevation in liver enzymes. Approximately 10% of patients present with a sepsis-like syndrome with laboratory evidence of disseminated intravascular coagulation or multiorgan failure.

The diagnostic evaluation includes culture of *H. capsulatum* or histopathologic examination of characteristic yeast forms in biopsy specimens or lavage ßuids. The serum and urine *Histoplasma* polysaccharide antigen tests have high sensitivity and speciÞcity in disseminated histoplasmosis. This test is available through MiraVista Diagnostics in Indianapolis, Indiana (317) 407Ð4629.

Treatment of disseminated histoplasmosis in AIDS consists of intravenous amphotericin B 0.7Ð1.0 mg/kg per day for greater than or equal to three to fourteen days. Lifelong suppressive therapy with oral itraconazole is recommended and serum itraconazole levels and drug interactions should be monitored. In cases of mild to moderate histoplasmosis without meningitis, itraconazole may be used as primary therapy (200 mg three times a day for three days, then 200 mg twice daily for twelve weeks, then 200 mg a day for maintenance). At this time, there is insufÞcient data to recommend discontinuation of maintenance therapy following immune reconstitution in response to HAART.

It is recommended that HIV-infected persons avoid activities associated with increased risk of exposure to histoplasmosis, including exploring caves and cleaning chicken coops. A prospective randomized controlled trial demonstrated that itraconazole reduced the frequency of histoplasmosis among patients with advanced HIV infection who lived in an endemic area but provided no survival beneÞt (61). According to the 2002 USPHS/IDSA guidelines, itraconazole prophylaxis for histoplasmosis may be considered in patients with CD4 cell counts less than 100 cell/mm^3 who live in hyperendemic areas (greater than or equal to ten cases per 100 patient-years) or are at high risk of occupational exposures (16).

Coccidioides immitis

Coccidioides immitis is a dimorphic fungus endemic to the semiarid regions of the southwestern United States, including Arizona, New Mexico, southern California and western Texas. Airborne arthroconidia are inhaled, typically resulting in an asymptomatic infection or a self-limited inßuenza-like illness. In HIV-infected patients with impaired cell-mediated immunity, the arthroconidia

develop into multiple endospores within the pulmonary alveoli. These endospores rupture, leading to widespread dissemination. Disease may occur during both primary infection and reactivation from prior exposure. Pulmonary disease is usually present.

The clinical manifestations of coccidioidomycosis are very similar to those of histoplasmosis, including the chronic constitutional symptoms of fever and weight loss. Respiratory symptoms, including cough and dyspnea, are usually present. The chest radiograph typically shows a diffuse reticulonodular inÞltrate but focal inÞltrates, cavities and hilar lymphadenopathy are sometimes present. Physical examination may reveal generalized lymphadenopathy, skin manifestations including nodules or ulcers, and chronic or subacute meningitis.

The diagnostic approach includes culture of sputum, bronchoalveolar lavage ßuids or transbronchial biopsy specimens. Of note, *Coccidioides immitis* is easily transmissible from positive cultures and requires special handling in the microbiology laboratory. Diagnosis is sometimes made by visualization of giant coccidiodal spherules in respiratory secretions or tissue using stains such as methanamine-silver. Coccidioidal serologies may be positive, but false-negatives occur more frequently with advanced immunodeÞciency.

The preferred treatment of coccidioidomycosis in HIV-infected patients with locally severe or extensive disease consists of amphotericin B 1.0 mg/kg per day. Oral ßuconazole 400 to 800 mg daily is preferred for patients with meningitis (62). Intrathecal amphotericin B should be added for coccidioidomycosis meningitis that fails to respond to ßuconazole. Fluconazole 400 mg daily or itraconazole 200 mg twice a day maintenance therapy is required for life (63). Again, there are insufÞcient data to warrant discontinuation of secondary prophylaxis in patients responding to HAART. Prophylactic azole therapy is not routinely recommended.

Aspergillus

Although pulmonary complications from *Aspergillus* are common in other immunocompromised patients, they are relatively infrequent in HIV-infected patients. Most cases of respiratory aspergillosis are caused by *Aspergillus fumigatus*. A nested case-control study within the Pulmonary Complications of HIV Infection Study identiÞed risk factors associated with *Aspergillus* identiÞcation in respiratory specimens. This study conÞrmed that neutropenia, CD4 cell count less than 30 cells/mm^3, chronic corticosteroids, and prior PCP are risk factors for *Aspergillus* respiratory infection (64).

Isolation of aspergillus from respiratory sites may indicate airway colonization and is not synonymous with invasive *Aspergillus* infection. Diagnosis of aspergillosis therefore requires biopsy evidence of tissue invasion. In cases of pulmonary disease, chest radiographs may show diffuse or focal inÞltrates and cavities. Recommended therapy for invasive pulmonary disease is intravenous amphotericin B 0.7Ð1.4 mg/kg daily. Alternative agents include itraconazole, lipid formulations of amphotericin, and caspofungin. In a recent study in non-HIV infected patients with invasive aspergillosis, initial therapy with voriconazole led to better responses and improved survival than initial therapy with amphotericin B (65). Treatment of any predisposing factors (e.g. neutropenia with G-CSF) is also recommended. In the absence of immune reconstitution, the prognosis for invasive aspergillosis is poor.

VIRAL PNEUMONIAS

Cytomegalovirus

Cytomegalovirus (CMV) is a common isolate from respiratory specimens but a rare cause of clinical pneumonia in persons with advanced HIV infection. Patients with CMV pneumonitis typically present with shortness of breath, dyspnea on exertion, a non-productive cough, and hypoxemia. Chest radiographs may show interstitial inÞltrates. Diagnosis of CMV pneumonitis is challenging and generally requires histologic evidence of CMV cytopathic inclusions in lung tissue or BAL macrophages, pulmonary inÞltrates, and the absence of another pathogen. The practical decision to treat CMV pneumonitis is often based on failure to respond to treatment of a copathogen such as *Pneumocystis carinii*. The recommended treatment for CMV pneumonitis is intravenous ganciclovir 5 mg/kg twice a day for at least three weeks. Alternative treatments are foscarnet 60 mg/kg intravenously three times daily or 90 mg/kg twice-daily for the same duration.

Long-term maintenance therapy for CMV pneumonitis is usually not recommended unless there is a relapse or extrapulmonary disease.

Inßuenza

Inßuenza is a common cause of upper respiratory tract infections and bronchitis. Symptoms include fever, mylagias, and a nonproductive cough. Inßuenza pneumonia is rare and HIV-infected adults do not appear to be at increased risk of developing lower respiratory tract involvement. Cases of inßuenza pneumonia may be complicated by bacterial superinfection with *S. pneumoniae*, *S. aureus*, and *H. inßuenzae*. Typical Þndings on chest radiographs include interstitial inÞltrates and bronchopneumonia. Diagnosis can be made by culture of sputum or nasopharyngeal washings, or by a rapid test for inßuenza antigen. Suspected or proven cases should be treated within the Þrst 48 hours of illness. Treatment options for inßuenza A and B include the neuraminidase inhibitors, oseltamivir or zanamivir, or for inßuenza A only, rimantadine or amantadine.

All HIV-infected patients should receive inßuenza vaccination annually, prior to the inßuenza season. An inactivated trivalent inßuenza virus vaccine is administered in one annual dose. Alternative preventive regimens for those patients with hypersensitivity to henÕs eggs (ie precluding inßuenza vaccination) include oseltamivir 75 mg daily for inßuenza A and B or rimantadine/amantadine 100 mg twice daily (or 100 mg daily in patients older than 65 years) for inßuenza A only. A number of studies have demonstrated conßicting results regarding a transient elevation in HIV-plasma viral load in response to inßuenza vaccination. Kolber et. al. evaluated whether a rise in plasma viral load in patients with previously undetectable viral loads could result in the development of new resistance mutations (66). In this study, 34 patients with undetectable viral loads on HAART had repeat plasma viral loads measured at two and four weeks post-vaccination. Seven out of 34 patients had elevations in their viral loads and two of the patients revealed new reverse transcriptase inhibitor or protease inhibitor mutations. Although there is a concern that vaccination may result in low-level viremia and the development of antiretroviral resistance, the same phenomenon may occur with equal or greater frequency during live inßuenza infection.

HIV-ASSOCIATED MALIGNANCIES

KaposiÕs Sarcoma (KS) and non-HodgkinÕs Lymphoma (NHL) are two of the most common HIV-associated malignancies. Patients with disseminated KS and NHL frequently develop pulmonary involvement. In addition, there are case reports of AIDS-related primary pulmonary lymphoma. Some of the tumors, including large cell NHL and KS, have viral associations: Epstein Barr Virus (EBV) and human herpes virus 8 (HHV8) respectively.

KaposiÕs Sarcoma

Pulmonary involvement with KaposiÕs sarcoma generally follows the appearance mucocutaneous lesions and occurs in approximately 20Ð40% of patients with mucocutaneous KS and pulmonary symptoms. The clinical and radiographic presentation is similar to PCP. Symptoms include shortness of breath, dyspnea on exertion, and dry cough, as well as constitutional symptoms such as fevers, night sweats and weight loss. Hemoptysis is a serious potential complication of pulmonary KS. Chest radiograph Þndings include nodular inÞltrates that extend along bronchovascular bundles, interstitial or alveolar inÞltrates, cavitary lesions, hilar adenopathy, and pleural effusions. On Þberoptic bronchoscopy, characteristic red or purple ßat lesions may be seen in the central airways. Biopsies are not routinely performed since the yield is only 20Ð30%, accompanied by a substantial risk of bleeding. The presence of a pulmonary inÞltrate on chest radiograph with a negative gallium scan is highly suggestive of KS.

KaposiÕs sarcoma is associated with human herpes virus 8 (HHV8). HHV8 DNA has been detected in sarcoma tissue and in the bronchoalveolar lavage ßuid of patients with pulmonary KS. A Swiss prospective study determined the speciÞcity, sensitivity, and predictive values of using HHV8 DNA detection in the BAL to diagnose pulmonary KS (67). Seventy-two immunocompromised patients underwent BAL for diagnostic evaluation of fever, respiratory symptoms and/or inÞltrates, including 38 HIV-infected patients. BAL ßuids were analyzed for the presence of HHV8 DNA using a nested polymerase chain reaction technique. On bronchoscopy, four patients had characteristic KS lesions and the corresponding BAL samples were positive for HHV8. One additional BAL sample of an HIV-infected patient with no evidence of KS was HHV8 positive. These results suggest the potential role of HHV8 DNA detection for diagnostic purposes in pulmonary KS.

Systemic chemotherapy is recommended for patients with pulmonary KaposiÕs sarcoma. Treatment options include liposomal daunorubicin or doxorubicin; taxol; or adriamycin, bleomycin and either vincristine or vinblastine. The prognosis is generally poor in patients with advanced HIV infection. Therapy is discussed in more detail elsewhere in this volume.

Non-HodgkinÕs Lymphoma

NHL usually develops at an advanced stage of HIV disease with extensive involvement at extranodal sites. Other common sites of involvement include the gastrointestinal tract, bone marrow, central nervous system, and mucocutaneous sites. Radiographic features may include well-delineated pulmonary masses or nodules, hilar and mediastinal lymphadenopathy, parenchymal inÞltrates, and pleural effusions. Diagnosis generally requires either transthoracic or open lung biopsy. Chemotherapeutic regimens are discussed elsewhere in this volume.

Primary pulmonary lymphoma is rare. In a large French cohort study of 4,700 HIV-infected adults, there were 12 cases of primary pulmonary lymphoma diagnosed between 1986 and 1996 (68). All twelve cases were high-grade NHL and occurred in patients with a CD4 cell count of □200 cells/mm^3. Diagnostic criteria were: (1) histologically proven pulmonary lymphoma; (2) absence of mediastinal and/or hilar adenopathy; and (3) absence of extrathoracic lymphoma. Histologic specimens were obtained by transbronchial biopsy or open lung biopsy. Routine bronchial biopsies were negative. Subacute symptoms included respiratory and constitutional complaints. In contrast to disseminated NHL, LDH levels were rarely and only moderately elevated. All cases of primary pulmonary lymphoma had evidence of latent EBV infection.

LYMPHOCYTIC AND NONSPECIFIC INTERSTITIAL PNEUMONITIS (LIP AND NIP)

Interstitial pneumonias other than PCP are seen in a small proportion of patients with advanced HIV disease. Lymphocytic interstitial pneumonitis is an unusual complication of HIV infection in adults, and is more frequently seen in younger children. It is characterized by reticulonodular pulmonary infiltrates, decreased diffusing capacity, and alveolar lymphocytic hyperplasia. Nonspecific interstitial pneumonitis is seen in adults with clinical features suggesting PCP, though gas exchange defects are usually milder and the CD4 count is often >200. Histologically the syndrome is characterized by mononuclear infiltrates and interstitial edema. The etiology is unknown, and treatment is supportive.

Chapter 17

Mycobacterial Disease in Patients with HIV Infection

David Ashkin, Yvonne Hale, Elena Hollender, Michael Lauzardo, Masahiro Narita, Arthur E. Pitchenik, Max Sal nger and Jerry Jean Stambaugh

HIV infection has been one of the principal reasons for the recent increase in incidence of mycobacterial diseases worldwide. Tuberculosis (TB) and HIV have become two of the leading causes of mortality in the world from any single infectious agent. Other non-tuberculous mycobacteria, once considered rare have now become more prevalent. The goal of this chapter is to review important aspects of the interplay of HIV infection with mycobacteria, speciÞcally focusing on features that are clinically relevant.

TUBERCULOSIS AND HIV INFECTION

Understanding TB in patients infected with human HIV is important from many standpoints. First, among tuberculous-infected individuals, immunosuppression because of HIV is the greatest known single risk factor for progression to TB disease (1Ð4). Predictably, the incidence of TB has risen signiÞcantly in areas where HIV and infection with TB is prevalent (i.e. sub-Saharan Africa, parts of tropical Americas, and many urban areas of the United States with large populations of intravenous (IV) drug users and/or socioeconomically depressed minority groups) (1Ð14). Second,TB differs from other HIV-related infections in that it is spread respiratorily from person to person both in normal and immunocompromised hosts. There is, therefore, signiÞcant potential for an aerosol-transmitted disease such as TB to spread rapidly among HIV-infected persons exposed to each other and to/from them to non-HIV infected contacts (e.g. household members, health care personnel). Third, mycobacterial disease in HIV-infected patients often presents with an atypical clinical picture: tuberculin skin anergy is common, the chest radiograph is often atypical, and there is a high incidence of extrapulmonary and disseminated disease, all contributing to confound the diagnosis (1,9,12,14Ð17), which may easily be missed unless these features are appreciated. Thus, there must be a high index of suspicion for TB among persons who are HIV-infected or who belong to Acquired Immune DeÞciency Syndrome (AIDS) risk groups. Fourth, and most importantly, TB is a preventable and curable disease, even in an HIV immunosuppressed population (13,15,18,19).

Controlling TB among HIV-infected populations demands (1) early recognition and preventive treatment for latent tuberculosis infection (LTBI) in persons dually HIV and tuberculous infected (e.g. widespread tuberculin skin testing and preventive therapy programs among HIV risk groups), (2) early recognition and treatment of HIV-infected patients with TB disease (e.g. aggressive TB case Þnding), and (3) strict attention to adherence to anti-TB therapy (often including directly observed therapy). Controlling TB in this population also requires the institution and maintenance of strict administrative and environmental TB control measures in HIV clinics and other physical locations (such as medical wards and health care settings), where HIV immunosuppressed patients at high risk of contracting TB are recurrently exposed to one another (20Ð26). ControllingTB in HIV-infected populations requires dealing with the HIV disease component as well. Efforts must be aimed at prevention of new HIV

infections through public education, screening the blood supply (which is not universal in some developing countries) (7,8) and through the treatment of HIV disease itself.

Pathogenesis of Tuberculosis

Transmission of Mycobacterium tuberculosis

The likelihood of transmission of *M. tuberculosis* is influenced by the following four factors: (1) the number of organisms entering the air, (2) the concentration of organisms in the air, determined by the size of the space and the adequacy of ventilation, (3) the length of time an exposed person breathes air containing tubercle bacilli, and (4) questionably, the immune status of the exposed individual (26–29). Some believe, though it has not been definitively proven, that HIV-infected persons and others with impaired cell-mediated immunity may be more likely to become infected with *M. tuberculosis* after an exposure than persons with normal immunity. It is well documented, however, that HIV-infected persons and others with impaired cell-mediated immunity are more likely to develop TB disease if they are infected (see below) (27,30–33).

Risk factors for acquiring tuberculosis infection, a prerequisite for the development of disease, are related to the likelihood of contact with a person with active, untreated pulmonary TB disease ("source case"). In the United States, risk factors include: known close contact to an active case of pulmonary tuberculosis, immigration from endemic areas (e.g. Africa, Asia or Latin America), exposure to untreated tuberculosis patients in congregate living facilities (e.g. homeless shelters, correctional facilities, nursing homes or other healthcare facilities), older age, residence in areas with a higher incidence of TB (e.g. inner cities) and travel to foreign endemic areas (34).

Tuberculosis is usually spread person to person, through the air by droplet nuclei, particles 1 to 5 μm in diameter that contain *M. tuberculosis* bacilli (35). *M. tuberculosis* enters the air when patients with active pulmonary tuberculosis disease cough, speak, talk, sneeze, or sing, though coughing remains the most effective method of aerosolization (35–37). Droplet nuclei may also be produced by aerosol treatments, sputum induction, aerosolization during bronchoscopy or through manipulation of lesions during the processing of tissue or secretions in the hospital or laboratory. These droplet nuclei are so small that air currents normally present in an indoor environment can keep them airborne for long periods of time (26,38). Individuals who are in prolonged, close contact with patients with TB disease, especially in environments with poor ventilation are most likely to inhale the organism and become infected with TB (especially in congregate settings such as jails, prisons, shelters and hospitals) (39). However, only approximately one third of all individuals who are in close contact with a person with TB disease for a prolonged period of time become infected (40,41). In countries where TB is endemic, the chances of exposure to a person with TB disease are higher, thus increasing the chances for transmission.

When a person inhales a droplet nucleus, which may contain between 1–400 organisms, it usually is trapped in the upper respiratory tract and then removed by mucociliary clearance (42,43). Organisms deposited on intact mucosa or skin do not invade tissue. Only the smallest droplets, those less than 5 μm, make it to the alveoli.

Response to Inhaled Tubercle Bacilli

Inhaled tubercle bacilli that reach the alveolar spaces are usually ingested by alveolar macrophages, where they may be killed immediately (*natural immunity*) (44,45). If not killed, they may persist or replicate within macrophages, which then may lyse them and infect other alveolar macrophages. From this initial site of deposition in the alveoli, the tubercle bacilli then are transported within macrophages to the regional lymph nodes, and from there may be widely disseminated hematogenously throughout the body. Most primary pulmonary and extrapulmonary lesions remain asymptomatic and are contained due to the development of T-cell immunity (*granulomatous reaction*) during a two- to eight-week period after primary infection. Evidence of primary tuberculosis may be seen on radiographs as a lower lobe pulmonary infiltrate, or later as a focal granuloma which may or may not calcify (Ghon foci) and occasionally with an associated ipsilateral calcified hilar node lesion after dissemination (Ranke complex). Also during this time the tuberculin skin test should become positive, documenting the occurrence of latent tuberculosis infection (LTBI). In general, 5% of persons develop TB disease within the first two years following primary infection, and an additional 5% develop TB disease at some later time during the course of their lives. If a tuberculous-infected person also becomes infected with HIV, they have a much greater likelihood for reactivation TB to occur at some point during the slow progression of HIV-induced immunosuppression. In this situation, the incidence of TB has been shown to be approximately 8% per year in the absence of HIV therapy (46). If a patient is severely HIV immunosuppressed at the time of initial infection with tuberculosis, then rapid progression to TB within weeks to months is expected (19,30–32,47–49).

Macrophages are pivotal in the generation of an immune response against mycobacteria (44,50–53). Macrophages phagocytose and process mycobacterial antigens, which then are presented to antigen-specific T-helper (CD4) lymphocytes within lymph nodes. T-helper lymphocytes with specific receptors recognize the mycobacterial antigens as well as human leukocyte antigen DR locus (HLA-DR or "self") proteins on the macrophage membranes and become activated. T-cell activation also

requires the synthesis and release of interleukin-1 (IL-1), a soluble cytokine, from macrophages. Once T-helper cells are activated, they produce soluble factors (lymphokines) that promote both further clonal T-cell proliferation (IL-2) and increased macrophage antigen presentation, recruitment, and effector reactivity (γ-interferon, macrophage activating factor, macrophage chemotactic factor, and macrophage migration inhibition factor) (54–56).

In response to immunologically competent T lymphocytes in areas of infection with TB, monocytes enter the area and undergo transformation into activated macrophages and subsequently into specialized histiocytic cells, which are organized into granulomas (tubercles). These lymphokine-activated macrophages exhibit increased metabolic and enzymatic activities, including the release of tumor necrosis factor alpha and have an enhanced ability to ingest tubercle bacilli and inhibit their growth. Further multiplication and spread of mycobacteria are usually then arrested within the microscopic granulomas at the initial site of pulmonary infection, in regional lymph nodes, and at distant extrapulmonary sites. A small number of living organisms persist in dormant foci (*latent infection*), often for the life of the patient, and may reactivate at any time if host defenses decline. This cellular immune response not only confers protection against mycobacterial disease but also is intimately linked with cellular hypersensitivity as expressed by a positive tuberculin skin test reaction, formation of tissue granulomas, caseation necrosis, and liquefaction and cavity formation. Although activated macrophages limit replication of mycobacteria, they are also responsible, through the liberation of enzymes, for much of the local tissue damage. Paradoxically, if the immune-mediated tissue damage is too extensive (e.g. caseous necrosis and cavity formation), a favorable environment for the multiplication of mycobacteria may result, leading to classic Þbrocavitary TB in a relatively immune competent host.

Role of HIV

One of the most signiÞcant contributions to the resurgence of TB has been the emergence of HIV (57) and the association between the two organisms which augments each of their deadly potentials. HIV, by destroying the CD4 cells of the hostÕs immune system, allows the TB that may be dormant in the patient to activate and rapidly cause disease. In response to reactivation of TB, the CD4 cells become stimulated and begin to replicate. This activation of CD4 cells further renders these cells vulnerable to infection by HIV and allows the HIV to replicate further within them. This leads to a vicious cycle of increasing viral load causing a further deterioration of the hostÕs immune system and leading to increased vulnerability to infection and neoplasms.

Studies have shown that the one-year mortality rate for HIV-infected patients who have completed therapy for TB ranges from 20–35% despite being cured of TB, and this rate shows little variation between cohorts from industrialized and developing countries.(58–64) Studies have also shown up to a four times greater mortality rate among TB patients who are infected with HIV compared to those who are not coinfected (58,61,64,65). The risk of death for persons with HIV-related TB follows a bimodal distribution, peaking within the Þrst three months of initiation of antituberculosis therapy and then again after one year (62). Although the cause of death in the initial period of therapy may be a result of the TB (61), death after the initial few weeks of antituberculosis therapy usually is attributed to morbidity from the progression of HIV disease, itself enhanced by the TB (60,66,67).

HIV infection causes a profound immune defect by producing a qualitative and progressive quantitative deÞciency of the CD4+ T-lymphocyte population, which in turn results in the impairment of B-cell function, cytotoxic T-cell function, natural killer (NK) cell function and macrophage function, including macrophage antigen presenting capabilities, recruitment, and activation (68–71). The immune defect involving both CD4 cells and macrophages is most crucial in the defense against mycobacterial disease. Without recruitment and activation of macrophages by T-cell secreted lymphokines, there is poor granuloma formation, poor containment of mycobacteria, frequent reactivation of mycobacterial disease with large organism loads, spread to regional lymph nodes, and wide hematogenous dissemination with mycobacteremia. In this setting, caseation necrosis and cavity formation (e.g. in the lung) are less prominent or absent and tuberculin skin tests are often falsely negative. Among persons with mycobacterial disease, the frequency and severity of these features are correlated with the CD4+ peripheral blood count and/or function. As *M. tuberculosis* is more virulent than nontuberculous mycobacteria or other opportunistic pathogens such as *Pneumocystis carinii* (PCP), reactivation TB tends to occur relatively early in the course of HIV immunosuppression and at higher peripheral blood CD4+ lymphocyte counts (e.g. CD4 count often $>200/mm^3$) (66,72–74). There is some evidence both in animals and humans that the ability to generate an immune response to TB has a genetic basis (44,75–79). Therefore, even among HIV-infected populations coinfected with TB, there may be variabilities in the time of onset and severity of TB.

HIV also infects monocytes and macrophages that bear the CD4 surface receptor. These cells are resistant to both the cytolytic and syncytium-forming effects that HIV has on CD4+ lymphocytes. Although not destroyed, the HIV infected monocytes and macrophages are defective in chemotaxis and other cellular functions. These cells may serve as important reservoirs of persistent HIV infection, (80–83). Alveolar macrophages may also be infected with HIV both *in vitro* and *in vivo*. Therefore, it is possible that only a relatively small number of droplet nuclei containing tubercle bacilli may be necessary to infect patients with

HIV infection because of impaired alveolar macrophage function (i.e. impaired natural immunity against inhaled mycobacteria) (68,81,82). If this is true, patients with HIV infection may be at higher risk than HIV-infected persons for becoming infected with TB following exposure to a contagious patient (though this has not yet been deÞnitively shown), in addition to being at higher risk for developing TB disease after infection is established.

In some HIV-infected patients, the plasma HIV RNA level rises substantially with the progression to TB disease, and TB treatment alone may lead to reductions in viral load in these dually infected patients. (84) TB and HIV also interact in the lungs, the site of primary infection with *M. tuberculosis*. In a recently published study of HIV-infected patients with TB, researchers found that the viral load was higher in the bronchoalveolar lavage ßuid from the lung with TB disease versus the other unaffected lung, and correlated with increased levels of tumor necrosis factor in the bronchoalveolar ßuid of the lung with TB disease (85). In addition, the HIV quasispecies from the lung with TB disease differed from those in the plasma of the same patient. These data suggest that pulmonary TB might act as a potent stimulus for the cellular-level replication of HIV, and consequently may contribute to the development of resistant viral strains.

It is still too early to evaluate fully the effects of antiretroviral therapy on tuberculosis in patients infected with HIV. It is hoped that by improving the immunologic status of the host, there may be a reduction in the morbidity and mortality caused by TB. However, given the known potent interactions of HIV and TB and the resultant deleterious effects upon the host, it is of paramount importance to emphasize the need for prevention, early recognition, and effective treatment for both diseases.

Epidemiology of HIV-Related Tuberculosis

In terms of human suffering, the toll exacted by TB on mankind has been and continues to be staggering. Despite the development of an effective cure for this dreadful disease over Þfty years ago, almost eight million new cases arise worldwide each year with as many as three million deaths (86). Almost two billion people, one third of the worldÕs population, are infected with *M. tuberculosis,* and it is from this vast pool of individuals harboring latent infection that most new cases arise.

Tuberculosis has always been a disease that disproportionately affects the poor and disenfranchised, and in the early twenty-Þrst century the developing world is home to the majority of these people. Over 90% of TB cases and 95% of deaths from TB (87) occur in developing countries. Although poverty, attendant malnutrition and lack of health care services certainly are important factors in contributing to the extent of TB in the developing world, something even more insidious has become the preeminent driving force: HIV.

In the centuries-long struggle between man and the tubercle bacillus, nothing has changed the epidemiology of TB as much as HIV. In just twenty years, HIV has caused the reversal of hard earned downward rates of TB in many developed and developing countries. In some countries, health status indices of large segments of the population have been set back by thirty years.

As TB disease can complicate HIV at any level of immune suppression, rates of TB tend to increase shortly after the introduction of HIV into a population where latent TB infection is common. The overlap of these two pandemics is most pronounced in the developing world, but some sub-populations in developed countries are also involved.

Incidence of HIV/TB

The incidence of HIV-related TB depends upon the amount of overlap of the two epidemics in a given population. In the United States the degree of overlap is uncertain, as information regarding HIV infection among TB patients is not always reported. In order to overcome incomplete reporting, health departments from all Þfty states, plus New York City and Puerto Rico, worked with the Centers for Disease Control and Prevention (CDC) to cross-match TB cases from 1993Ð1994 with their respective AIDS/HIV registries (88). The analysis found that, overall, 14% (6,863) of the 49,938 cases of TB reported during that time period were found in both registries. There was a marked disparity of HIV-infection rates among TB patients found between reporting areas with a range of 0% to 31% of TB cases being concomitantly listed on AIDS/HIV registries. Six states (California, Texas, Florida, Illinois, Georgia and New Jersey) and New York City accounted for 80% of all TB/HIV cases reported during 1993Ð1994 (88). Although HIV has been implicated as a major reason for the recent resurgence of TB in the United States, the relative contribution of HIV to the TB epidemic depends, as mentioned above, on geographic location. In a multi-center cohort study, Markowitz et al. found a marked geographic discrepancy in the incidence of HIV-related TB. Residence in the eastern United States was the strongest demographic risk factor. The authors found a higher percentage of positive PPDs at baseline (12% in the east versus 3.5% in other locations) and a higher PPD conversion rate among eastern U.S. patients with HIV, which suggested a higher degree of exposure to TB in the east (89).

Epidemiological Trend in the United States

Some of the highest rates of TB among HIV-infected patients were recorded at a time when TB rates were substantially higher than they are at the time of this writing. Since a signiÞcant proportion of cases of TB

among HIV-infected individuals are the result of recent transmission (90,91), the rates and percentage of cases among HIV-infected individuals would be expected to drop as TB services improve and infectious individuals receive proper, prompt treatment. However, certain demographic groups such as the homeless and drug abusers still have higher rates of co-infection and disease. The foreign-born, a well-described risk group for TB, is one that is relatively under-represented among demographic groups with HIV/TB. Our experience in Florida is one exception where certain Haitian groups have very high rates of co-infection (92). With regard to the homeless, a study (91) in San Francisco found the incidence of TB to be 270 per 100,000 persons. The HIV-infected PPD positive individuals in this prospectively followed cohort had a TB incidence rate of 4.5% per person-year. Eighty-eight per cent of the HIV seropositive individuals had clustered restriction fragment length polymorphisms of the *M. tuberculosis* isolates indicating recent transmission.

Despite the persistence of HIV related TB in increasingly well-deÞned demographic groups, TB rates have been declining in the United States for most of the last decade. The major contributing factor to this has been the improvement of TB services around the country after years of neglect. Highly active antiretroviral theropy (HAART) promises to reduce TB related morbidity further among HIV-infected individuals. Although TB is unusual among opportunistic infections in that it can occur at any level of immune suppression, the incidence is greatest at lower CD4 levels (57,89). Reduction in viral loads and improved T-cell counts should result in lower rates of TB disease in this population. Although prospective data are scarce, data from Europe indicates that HAART is at least partially responsible for the decrease in HIV/TB rates now being seen in industrialized countries (93).

Global Aspects of the HIV/TB Epidemic

Although the HIV epidemic has left an indelible mark on the epidemiology of TB in developed countries, the convergence of these two epidemics has been most devastating in the developing world. Rates of TB around the world are illustrated in Fig. 17.1 (86). The developing world is home to the vast majority of individuals with latent TB infection, and as HIV spreads in these populations, TB rates climb inexorably. Nowhere is this more evident than in sub-Saharan Africa. Global regional TB and HIV co-infection information is shown in Table 17.1 (86).

Even before the AIDS epidemic, TB was a major cause of morbidity and mortality in Africa with a case rate that in some places exceeded 200 per 100,000 (94). This Þgure was over twenty times that found in the United States at that time. In little over a decade, HIV seropositivity rates among TB patients in sub-Saharan Africa rose from 20% to 70% (95), with a 300Ð400% increase in the number of

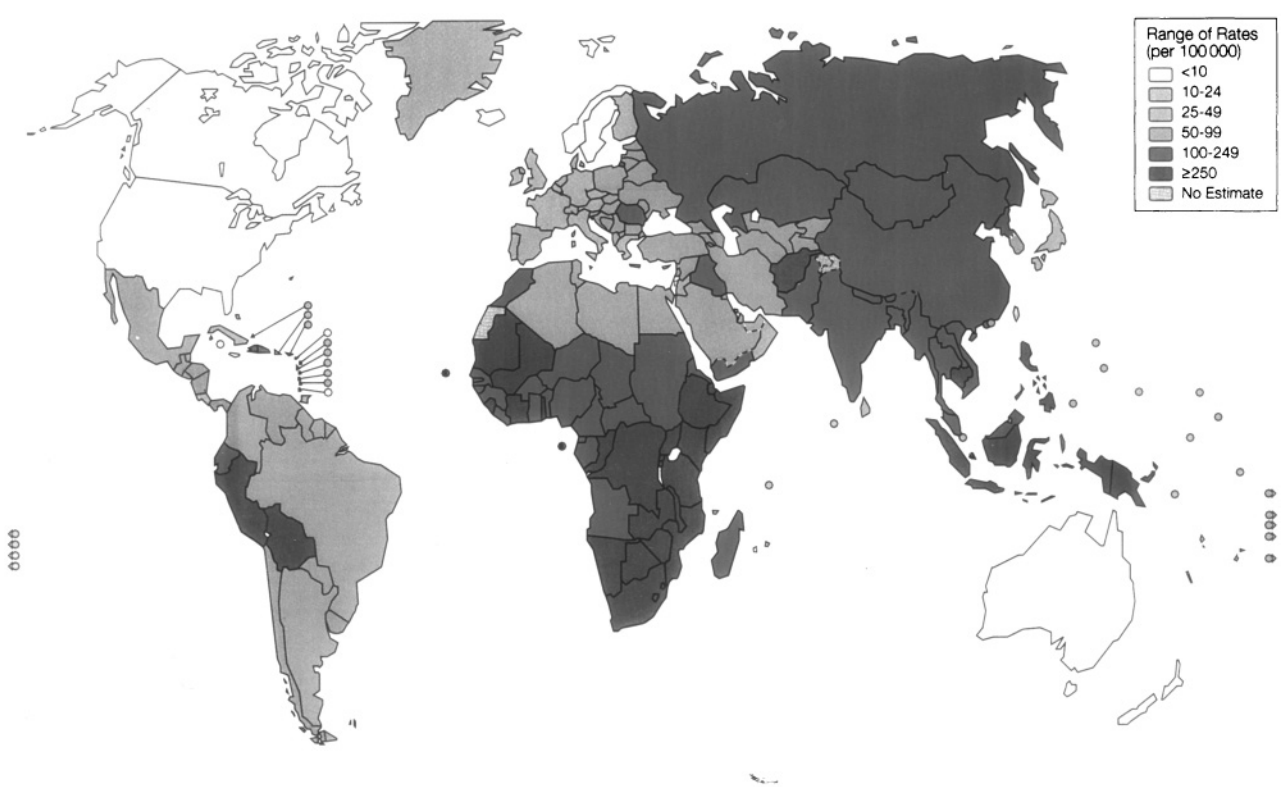

FIG. 17.1. Estimated per capita incidence rates of tuberculosis (all forms) by country in 1997 (86). Reprinted with permission form JAMA.

* These countries are ranked by number of cases and are positioned in a list of the 22 highest-incidence countries on the basis of numbers of new cases. TB indicates tuberculosis; WHO, World Health Organization; incidence, new cases; SS + , sputum smear-positive; prevalence, all forms new and existing; infection prevalence, percentage of population infected with *Mycobacterium tuberculosis* (MTB); CFR, case fatality rate among TB cases; TB/H1V, MTB/H1V co-infection; CDR all, all forms TB case detection rate (all-forms TB case noti cation/ estimated all forms incident TB); CDR SS + , smear positive case detection rate (SS + case noti cations/ estimated SS + incident TB); SEAR, Southeast Asian region; WPR, Western Paci c region; EMR, Eastern Mediterranean region; AFR, African region; EUR, European region; and AMR, American region.

patients developing TB (96). One study found that approximately one-third of patients diagnosed with HIV had TB disease at presentation (97). High rates of HIV and TB co-infection have also been observed among the children of AIDS patients. Bhat et al. showed that the co-infection rate among children may range from 10–40% (98). Even in areas with very efficient TB programs, rates of TB continue to rise in the wake of the HIV epidemic. Tanzania, with a model TB program, saw a doubling of TB cases in the early 1990s with two-thirds of the increase in smear positive cases being directly attributable to HIV infection (99). Mortality rates among HIV/TB patients is exceptionally high with almost half of all patients dead within 2.5 years, double the rate of non-HIV infected TB patients (100).

The impact of HIV in Asia has been less when compared to Africa, but it is expected to increase. This is of great concern because 60% of individuals in the world with latent TB infection live in Asia (101,102). Also of concern is the possibility that a third wave of TB consisting of multi-drug resistant TB may emerge with even greater force in this region because of significant rates of TB drug resistance in Asia.

Of the nearly five million cases of TB in Asia that occurred in 1990, only 85,000 of them were felt to be related to HIV (103).

Perhaps more significantly, in a hospital at the National AIDS Reasearch Institute in Pune, India, researchers found that the HIV seroprevalence rate among newly diagnosed TB patients rose from 3.2% in 1991 to over 20% in 1996 (104). Rates of HIV-related TB vary throughout the Indian subcontinent, with co-infection rates of 2–20% (104,105). Perhaps more significantly, in a hospital at the National AIDS Research Institute in Pune, India, researchers found that HIV seroprevalence rate among newly diagnosed TB patients rose from 3.2% in 1991 to over 20% in 1996 (104).

Similarly in Chiang Rai, Thailand, the seroprevalence rate among TB patients was 1.5% in 1990 compared with 45.5% in 1994 (107). Due to the high background rate of latent TB infection, TB has quickly become the most common HIV-related opportunistic infection in some Asian countries (108,109).

While countries in Europe have had variable rates of HIV/TB co-infection, Russia is on the verge of an epidemic of TB/HIV that could potentially compromise worldwide efforts to control the disease. Although Russian prisons have been at the epicenter of their emerging epidemic for some years, it is now clear that there is a parallel epidemic in the civilian population as well. National figures in Russia from 1997 indicated TB notification rates for incarcerated individuals and the civilian population of 4,000 and 81.3 per 100,000 respectively (110). HIV is not as yet a major contributing force to the epidemic in Russia; however, data indicate that HIV is spreading rapidly among intravenous drug users. In the first quarter of 2000, the number of newly HIV-infected individuals in Russia increased 4.6-fold over the same time period in 1999 (111).

Throughout Latin America and the Caribbean, accurate assessment of the extent of HIV/TB is hampered by incomplete reporting of HIV status (112). Co-infection rates range from less than 2% (113) to over 50% (114). Studies utilizing restriction fragment length polymorphism analysis have shown that in areas endemic for TB, most cases of TB disease are the result of reactivation of latent disease (115–117). Ferazoli and colleagues working in Brazil found that 38% of HIV positive and 25% of HIV negative TB cases had strains that appeared in clusters indicating recent transmission (115). Other workers have utilized molecular techniques to document nosocomial outbreaks (23).

Future Epidemiologic Issues of HIV/TB

The epidemiology of HIV/TB is rapidly evolving as HIV continues its march across the globe. The impact of HAART on the course of the converged epidemics in developed countries with access to these medications is unknown, but it is likely the impact will be favorable. Whether or not these drugs will become accessible to developing nations is currently an issue of intense debate. Furthermore, TB is often the sentinel infection of AIDS (even in developed countries) and appears before HAART is even considered. In developing countries, an important factor will be whether or not HIV transmission of HIV can be controlled through behavior modification education as has been reported in some areas (118,119). This is particularly relevant in areas such as Asia and Russia with higher levels of TB drug resistance and more crowded urban settings that would further foster the spread of TB. With the prospects of an effective vaccine for TB and HIV being at best many years away (120,121), action is necessary before TB and HIV become irrevocably entrenched and TB becomes untreatable because of multidrug resistance.

Clinical and Diagnostic Aspects of Tuberculosis

General

Tuberculosis disease develop at any level of CD4 count and not uncommonly heralds the diagnosis of HIV infection itself (66,74,122–126). Symptoms of TB in HIV-seropositive patients are nonspecific, commonly occur in other conditions associated with AIDS, and often are present for many weeks before the diagnosis of TB is made or even considered. In contrast to pyogenic pneumonias in which the onset is abrupt over one or two days, the onset of TB is frequently insidious. Patients often present with constitutional symptoms of fever, night sweats, fatigue, malaise, and weight loss. Patients with pulmonary

TB may have cough, sputum production, hemoptysis, pleuritic chest pain, or dyspnea. Signs and symptoms of extrapulmonary or disseminated TB depend on the organ and tissue affected (e.g. regional or generalized lymphadenopathy, hepatosplenomegaly, or CNS abnormalities).

M. tuberculosis is a more virulent organism than most other opportunistic infections that deÞne AIDS, and among tuberculous-infected patients, reactivation TB would be expected to occur at an earlier stage of HIV-induced immunosuppression, at a rate up to 8% per year (46). Since TB may be a sentinel infection in patients with HIV disease, HIV serology should always be obtained when TB is diagnosed or suspected and inquiries about clinical signs and symptoms of HIV infection should be elicited (e.g. persistent fever, chronic diarrhea, weight loss) (34).

Conversely, as both the general systemic and local organ symptoms of tuberculosis are nonspeciÞc and commonly occur in other HIV (and non-HIV) related conditions, there should be a high index of suspicion for TB among patients with known HIV infection or in those at high risk for HIV infection such as intravenous drug users. Clinicians should routinely screen for signs and symptoms of tuberculosis in patients with HIV infection, including routine, periodic tuberculin skin test (TST)s. (19,127). There is increasing evidence that patients with severe immunosuppression, and false negative TSTs, may regain their ability to react on TST when started on effective antiretroviral therapy, as part of an immune reconstitution. Thus skin testing previously anergic patients after successful HAART may be a useful diagnostic tool (19,128).

In the past, conventional theory held that TB disease was generally a result of reactivation (129,130) of a previous infection. While that still may hold true, especially in patients with higher CD4 counts, recent studies have shown that a substantial proportion of cases of tuberculosis among HIV-infected patients may be a result of recent exposure and infection (31,90,131Ð135). Using restriction-fragment-length-polymorphism analysis, it was found that nearly one-third of all TB cases in San Francisco reported during 1991 and 1992 were the result of recent infection and, among other factors, this was associated with a diagnosis of AIDS. Furthermore, few of these cases were identiÞed by conventional epidemiologic contact tracing (131).

The clinician should also bear in mind that tuberculosis, whether pulmonary or extrapulmonary, may present concurrently with one or more other opportunistic infections or tumors, either in the same or different organ or tissue, Therefore, clinical specimens should be sent for mycobacteriological testing regardless of other clinical diagnoses or suspicions.

Pulmonary Tuberculosis

Symptoms of pulmonary tuberculosis in the HIV-coinfected patient may run the gamut from those typically associated with pulmonary disease to atypical, nonspeciÞc presentations. Patients may present with any or all of the ÔclassicÕ constitutional symptoms of tuberculosis, such as fever, night sweats, fatigue, weight loss and malaise. These symptoms are not pathognomonic for tuberculosis, and may be associated with a number of HIV-related conditions; however, their occurrence should raise the suspicion for tuberculosis in the differential diagnosis. These constitutional symptoms are rarely of the acute nature seen with other bacterial, fungal or viral infections, and may be present for weeks or months prior to the diagnosis.

Pulmonary involvement occurs in 70Ð93% of HIV-infected patients with TB (34). Pulmonary-related symptoms of TB might be cough, sputum production, pleuritic chest pain, hemoptysis or dyspnea. In the absence of severe immunodeÞciency, deÞned by a CD4 count of $< 200/mm^3$, the radiographic picture may resemble that of an HIV negative patient (136Ð138), displaying inÞltrates (often upper lobe, consistent with reactivation) and even cavities. However, more commonly in advanced HIV disease, the chest radiograph is atypical (16,136Ð140). Hilar and mediastinal lymphadenopathy, paratracheal lymphadenopathy, lower lobe inÞltrates, and diffuse alveolar, linear, or miliary inÞltrates are relatively common in more severely immunosuppressed patients with HIV infection. Severe immune deÞciency often leads to a chest radiographic pattern resembling primary TB (i.e. hilar or mediastinal lymphadenopathy with or without non-cavitating pulmonary inÞltrates (Figs. 17.2 and 17.3). Unilateral or bilateral pleural effusions may occur. An enlarged cardiac silhouette should raise the possibility of tuberculous pericarditis and/or pericardial effusion. With appropriate treatment, the radiographs tend to clear. When they worsen, other pulmonary infections or etiologies should be pursued (141). However, some authorites have noted a transient worsening in chest radiographs in TB patients on appropriate TB therapy, after the initiation of antiretroviral therapy. Diagnostic evaluations in these patients may not reveal another etiology, and it is thought that these Þndings are due to immune reconstitution with an inßammatory response, which causes the new radiographic Þndings. (See section on ÒParadoxical Worsening of TB After Initiation of HAARTÓ) (142).

Extrapulmonary Tuberculosis

Extrapulmonary disease occurs in 34% to 72% of HIV-infected tuberculous patients (143Ð148), with lymphatic and disseminated forms (miliary TB or two or more noncontiguous tuberculous sites) predominating. Bone marrow, gastrointestinal tract, and the CNS are also common extrapulmonary sites among HIV-immunosuppressed patients, but TB can affect any organ system in the body and unusual clinical presentations occur frequently in this setting (66,125). The rate of disseminated tuberculosis is high in HIV coinfected patients, and clinicians

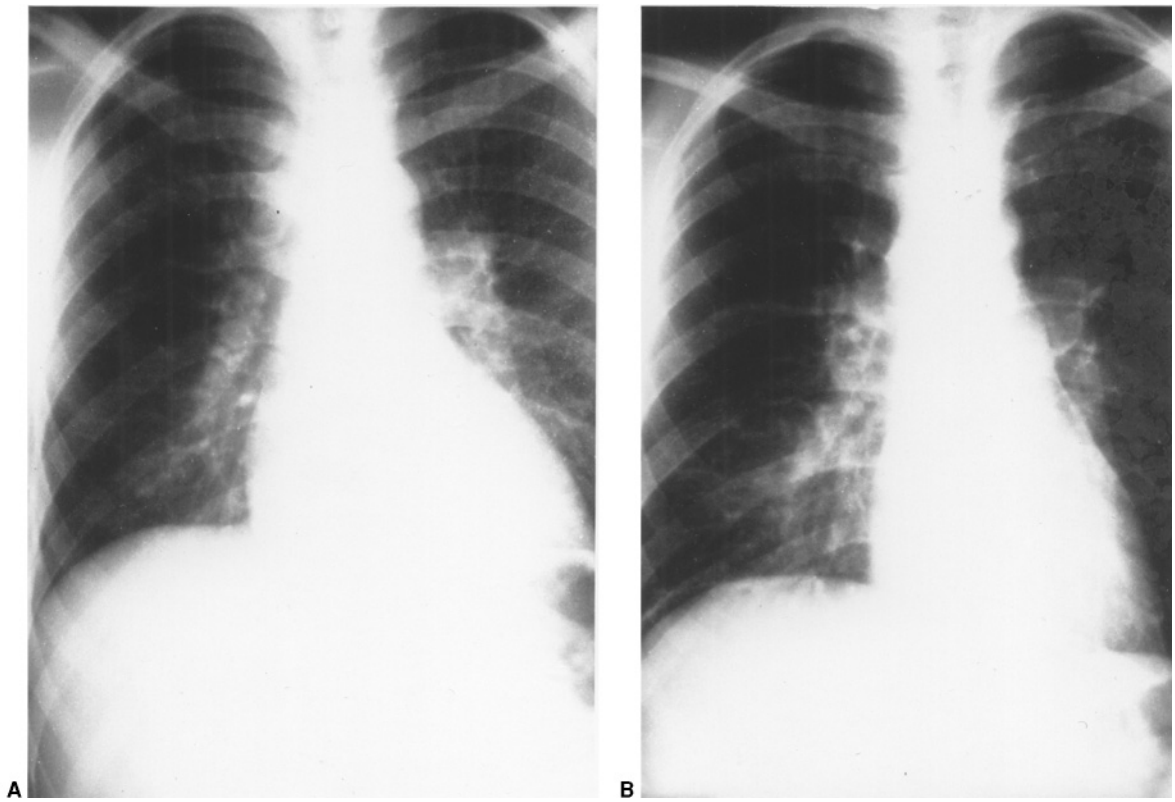

FIG. 17.2. A: Chest radiograph in a patient with tuberculosis and HIV infection. There is right paratracheal adenopathy (arrow) with clear lung fields. Sputum culture was positive for *M. tuberculosis*. B: The radiograph abnormality resolved (as did the patient's symptoms) following several months of antituberculosis drug treatment. (From ref. 1, with permission.)

should remember that pulmonary and extrapulmonary TB often present in the same patient, especially in those with advanced immunodeficiency.

Patients with extrapulmonary TB may present with the same constitutional symptoms of fever, night sweats, fatigue, weight loss or malaise as found in pulmonary tuberculosis and/or with more specific signs or symptoms related to the organs or systems involved (e.g. regional or generalized lymphadenopathy, hepatosplenomegaly or CNS abnormalities). There may in addition be symptoms of pulmonary TB along with those of extrapulmonary disease.

Diagnosis

A high index of suspicion for TB and an aggressive diagnostic approach are required to avoid missing a contagious and highly treatable disease.

Both the generalized symptoms of TB (fatigue, malaise, weight loss, fever, and night sweats) and the local symptoms of TB (cough or other local symptoms, depending on the particular organ affected) are nonspecific. In patients with known or suspected HIV infection, there should be a particularly high index of suspicion for TB in intravenous drug users, individuals born in countries with a high prevalence of tuberculosis, persons with a known past history of a significant tuberculin skin test reaction, patients with chest radiographs suggestive of old TB (e.g. apical scarring), and persons with a history of recent TB exposure (149).

Conversely, in patients with proven TB, the physician should have a high index of suspicion for concomitant HIV infection if the patient is in an AIDS risk group, has "unusual" or extrapulmonary TB (especially disseminated and lymphatic), or has any symptoms or signs that are common in HIV infection but uncommon in TB (e.g. unexplained persistent diarrhea, thrush, hairy leukoplakia of the tongue, dysphagia, or generalized lymphadenopathy).

Pulmonary Tuberculosis

Once the suspicion of tuberculosis is raised, an evaluation should be begun immediately and infection control procedures put in place. It should be emphasized that recent studies have well documented transmission of TB in healthcare settings (e.g. HIV clinics) (21,23–25, 30,33,48,150,151). If the patient is in a hospital, jail, prison or other congregate facility, s/he should immediately be placed in respiratory isolation in a negative pressure room, a chest radiograph should be obtained, if not already done, and sputum sent for mycobacteriological

testing (acid fast bacilli (AFB) smear and culture, and nucleic acid amplification (NAA) testing) (see Bacteriology Section). It should be noted that diognostic testing for tuberculosis does not have to be performed as an inpatient. In situations where the patient is living in a "safe" environment, (nobody in the household is immunosuppressed (e.g. with HIV infection or under the age of one year old)), testing can proceed as an outpatient as long as the patient understands the importance of following infection control precautions (e.g. staying in the household until being told it is safe to leave). If adequate specimens cannot be obtained, sputums may be induced (using either aerosolized hypertonic or hypotonic saline) in a negative pressure or outdoor environment. Comprehensive respiratory infection control procedures should be in place in any area that employs cough-inducing procedures (e.g. bronchoscopy, sputum induction) (see Environmental Control Section) (152).

If sputum is not obtainable, and there is evidence of pulmonary parenchymal disease (either by abnormal chest radiograph, CT or other means), then sputum collection via fiberoptic bronchcoscopy with bronchoalveolar lavage and possible transbronchial biopsy may be indicated. The specimens should again be sent for AFB smear, culture and NAA testing. Sputum induction may be as effective in making the diagnosis of tuberculosis as bronchoscopy, but if other etiologies such as malignancy are suspected, bronchoscopy may have greater utility (153–157). Smears and cultures of (post)-bronchcoscopy sputums and lavage fluid may be positive for TB bacilli even when the chest radiograph appears "normal" (16,158). Mediastinal lymph nodes may be biopsied during bronchcoscopy or at mediastinoscopy, when indicated.

CT scan results will vary depending on the degree of immunosuppression. Less immunosuppressed patients may show "classic" upper lobe densities and nodules, with or without cavitation, while patients with advanced HIV disease may only show hilar, mediastinal and/ or paratracheal lymphadenopathy. Mediastinal gas may be seen on CT scans from fistulas between tuberculous mediastinal lymph nodes and the esophagus or tracheobronchial tree (159,160).

In patients with pleural effusions, either unilateral or bilateral, a thoracocentesis with or without pleural biopsy may be indicated (obtaining pleural tissue has been shown to increase the yield of diagnosis to approximately 80–90% as opposed to approximately 50–60% with pleural fluid culture alone (161,162)). It should be noted

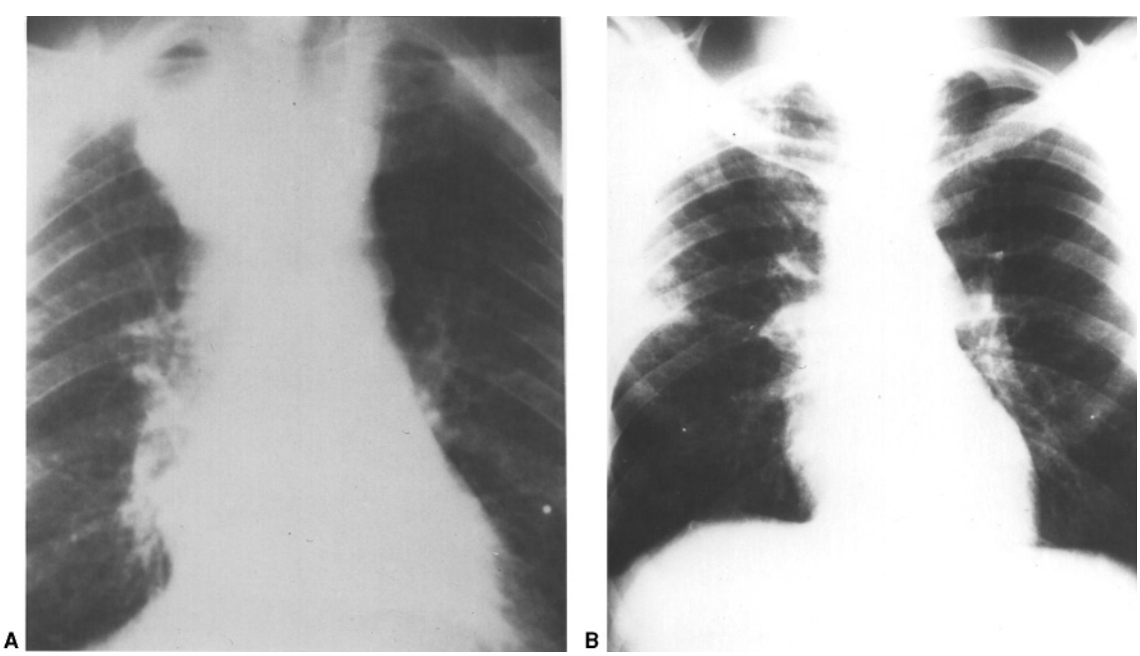

FIG. 17.3. A: Chest radiograph in a patient with tuberculosis and HIV infection. There is right paratracheal adenopathy with clear lung fields. The patient complained of dysphagia. Esophagoscopy with biopsy revealed granulomatous esophogitis with a positive tissue culture for *M tuberculosis*. A CT scan (not shown) revealed air in the mediastinum; an esophogram (not shown) revealed extravasation of barium, consistent with a tuberculous mediastinal lymph node-esophogeal fistula. The patient's symptoms and radiographic abnormalities resolved following anti-tuberculous drug treatment. (The CT scan and esophogram were previously reproduced elsewhere (1).) B: Chest radiograph in a patient with tuberculosis and HIV infection. Right paratracheal adenopathy and a right upper lobe infiltrate are present. Sputum culture was positive for *M. tuberculosis* and the patient responded to anti-tuberculous drug treatment. Although the chest radiograph resembles primary tuberculosis (i.e. noncavitary pulmonary infiltrate with ipsilateral hilar lymphadenopathy), the patient was documented to have a strongly positive PPD-tuberculin skin reaction several years previously. (He never received therapy for latent tuberculosis infection.) The chest radiograph therefore probably represents an atypical pattern of reactivation TB due to HIV-induced immunosuppression. (Part (A) from ref. 1, with permission; part (B) from Pitchenik AE, Fertel D. Tuberculosis and nontuberculous mycobacterial disease in HIV infected patients. *Med Clin North Am* 1992;76:121–171, with permission.)

however that the usual pleural ßuid Þndings of lymphocytic predominance with a lack of mesothelial cells may not always be present (163Ð166).

It should be remembered, however, that approximately 10% of the cases of pulmonary tuberculosis will turn out to be culture negative; e.g. the patient has clinical evidence of TB (symptoms, chest radiograph Þndings) and negative laboratory results (e.g. smear, culture), but has a signiÞcant clinical response to anti-TB therapy. These patients should still be considered to be cases of tuberculosis (27,167).

Patients may also present with another pulmonary infection such as PCP, with diffuse linear interstitial lung inÞltrates, which may obscure the radiographic diagnosis of concurrent pulmonary TB (168,169). Intrathoracic lymphadenopathy, diffuse miliary inÞltrates, and pleural effusions are chest radiographic features that are diagnostically helpful when they occur in the setting of HIV disease as they are typical of TB and highly atypical for PCP. Classic tuberculous upper lobe inÞltrates and cavitary lesions are also diagnostically helpful when they occur but are uncommon. Poor T-cell immune response in HIV immunosuppressed patients explains the reduced frequency of tuberculous-induced cavity formation and Þbrosis and the increased frequency of miliary inÞltrates and intrathoracic and extra thoracic lymphadenopathy representing regional and distant spread of tubercle bacilli.

Extrapulmonary Tuberculosis

Diagnosing extrapulmonary tuberculosis requires a high index of suspicion. In suspected disseminated tuberculosis, especially in advanced HIV disease, specimens from blood, urine, stool, bone marrow and liver biopsy may be sent for mycobacterial testing, when clinically indicated. Generally, *M. tuberculosis* is not cultured from blood unless the CD4 count is below 200 cells/mm^3 (170Ð173). The best yield from urine is the Þrst morning specimen, when urine and sediment have been collecting overnight (174,175). While stool cultures may reßect local disease, they may also yield positive results from sputum swallowed into the GI tract, and a pulmonary site should not be overlooked (176).

When there is evidence of local, or organ speciÞc disease, specimens should be obtained from these sites, (e.g. cerebrospinal ßuid, urine, pleural ßuid, bone marrow, liver, superÞcial cervical, intrathoracic and intraabdominal lymph nodes, pericardium and pericardial ßuid, brain, stool, seminal ßuid, skin, soft tissues, abscesses) and sent for testing. It may be prudent to remind the clinician performing the tissue biopsy not to place the specimen into formalin until tissue has been obtained for all cultures, AFB and otherwise. Formalin will preclude culture growth, but if this has already been done and repeat specimens are impossible, check with the laboratory about the possibility of NAA testing in order to attempt to conÞrm the diagnosis.

Aside from AFB results, analysis of certain ßuid specimens may give added information. CSF in suspected tuberculomas and tuberculous brain abscesses may show a pattern typical of tuberculous meningitis with pleocytosis, increased protein and decreased glucose, or may have only minor or no abnormalities (3,177). TB meningitis may present with typical CSF Þndings, or show minor or nonspeciÞc abnormalities, the latter usually in severely immunosuppressed patients. Pleural ßuid may show typical Þndings of an exudate with lymphocytic predominance and no or rare mesothelial cells (178,179). Recent studies, however, have shown that tuberculous pleural ßuid in HIV-infected patients may contain signiÞcantly fewer monocytes (180) and have higher mesothelial cell counts than in HIV uninfected patients (163).

Certain imaging studies, such as CT scans of the head, chest, spine and abdomen, MRIs of the brain, spinal cord and soft tissues, and gallium scans may help in localizing and deÞning the extent of TB disease and in directing biopsies (1,159,160,177,181Ð188). On abdominal CT scans, the presence of focal lesions in the liver, spleen, kidneys, pancreas, gastrointestinal tract or other viscera and enlarged lymph nodes with central or diffuse low attenuation suggests disseminated mycobacterial disease, particularly TB (189).

Although generalized lymphadenopathy is common in HIV disease, usually associated with HIV-related lymphoid hyperplasia, neither hilar nor mediastinal lymphadenopathy is common for HIV related lymphoid hyperplasia alone. The likelihood that a patientÕs lymphadenopathy represents a mycobacterial or another speciÞc disease increases markedly when chest concomitant radiographic abnormalities or fever are present, or when lymph nodes are tender, ßuctuant, matted, disproportionately large, or growing in a regional area (e.g. the neck or the abdomen). A lymph node aspiration may be done, followed, if necessary, by an excisional biopsy. Incision and drainage of a ßuctuant suspected TB lymph node is generally not recommended as it may lead to Þstula formation with ongoing drainage. Granulomas are usually seen on biopsy and acid-fast smears positive in 67Ð90% of cases (72,190Ð192). When hilar or mediastinal lymphadenopathy is present, neoplastic, fungal and especially mycobacterial disease should be considered.

The presence of increased adenosine deaminase activity (ADA) (an enzyme found at the cell surface of lymphocytes and macrophages that has been found to be especially elevated in ßuid which contains lymphocytes that have been activated by TB), has been reported as a useful (but at times non-speciÞc) test in the diagnosis of TB in certain body ßuids, such as cesetrospinal ßuid (193,194), and possibly pleural effusions. It also may be helpful in diagnosing TB in patients with HIV infection (195Ð200).

Bacteriology

There are conßicting reports about whether HIV-infected patients with culture-proven pulmonary TB are less likely to have positive AFB sputum smears than non-HIV infected patients with pulmonary TB. The AFB smear has been shown to be positive in 44% to 65% of HIV-infected patients (60,72,201,202). The sensitivity of acid-fast sputum smears tends to be greater in HIV-infected TB patients who are less immunosuppressed and have chest radiographs typical of reactivation TB compared with those who are more severely immunodeÞcient and have chest radiographs typical of primary or miliary TB (201Ð203). In New York City, among Þrst-time diagnosed patients with AFB positive sputum smears, only 50% are caused by MTB and 50% caused by non-tuberculous mycobacteria (NTM) (204). In patient populations with substantial smear-positivity caused by NTM, it is necessary to rapidly differentiate between TB and NTM in order to ensure proper case management and save scarce healthcare resources (i.e. utilization of negative pressure rooms and initiation of contact investigations).

Culture techniques are regularly utilized to diagnose mycobacterial infections. Recovery and identiÞcation of mycobacteria from clinical specimens and the availability of drug susceptibility results are signiÞcantly more rapid by use of BACTEC 460TB radiometric broth (BD Biosciences, Inc. Sparks, MD) (205Ð207). A combination of broth and solid medium (i.e. egg-based Lowenstein Jensen or agar-based Middlebrook 7H 10), in addition to acid-fast stains, provides a rapid and sensitive method for detecting mycobacteria. The current commercially available continuous-monitoring systems, such as the BACTEC 900MB and BACTEC MGIT (BD Biosciences, Inc.) (208), MB/BacT (Organon-Teknica, Inc., Durham, NC) (209), and ESPII (Accumed, Inc., Chicago, IL) (210) allow for more rapid turnaround time.

Nucleic acid probe kits have provided a major advance in the rapid identiÞcation of *M. tuberculosis* complex, *M. avium* complex, *M. avium, M. intracellulare, M. kansasii*, and *M. gordonae* from culture inasmuch as results are available within two hours (211). Probe technology has a sensitivity and speciÞcity of nearly 100% (212) when at least 10^5 organisms are present. Thus, these probes are not sensitive enough to be used on sputum; more helpful are NAA tests (see below).

Susceptibility testing is recommended on all initial isolates of *M. tuberculosis* from patients. (27) Results of susceptibility testing utilizing liquid broth methods may take one to two additional weeks after culture results are available and at times longer when solid culture methods are utilized. Rapid detection of rifampin resistance can signiÞcantly assist in proper patient care, as rifampin resistance will dictate longer and more complicated treatment to prevent negative outcomes (213). Somoskovi et al. (214) recently reviewed the mechanism of action and the molecular basis of resistance to rifampin and other Þrst-line anti-tuberculosis drugs. The mechanism of action of rifampin is to inhibit mycobacterial transcription by targeting DNA-dependent RNA polymerase. The development of resistance to rifampin is due to mutations in a well-deÞned 81-bp (27-codon) central region of the gene encoding the beta-subunit of RNA polymerase (*rpoB*). More than 96% of rifampin-resistant strains contain a mutation in this 81-bp region of *rpoB*, thus allowing for a straightforward molecular approach to detect rapidly rifampin resistance and/or multi-drug resistance. However, at this time, radiometric susceptibility testing for Þrst-line drugs with conÞrmation of drug resistant strains on Middlebrook 7H10 with an expanded number of compounds and drug concentrations, is still considered the gold standard (205).

Effective treatment regimens for tuberculosis are difÞcult to assess because of the slow growth rate of *M. tuberculosis* in culture and its protracted clearance from sputum. Desjardin et al. (215) measured levels of *M. tuberculosis* 85B (alpha antigen) messenger RNA, 16S ribosomal RNA, and IS*6110* DNA in patientsÕ sputum specimens as potential surrogate markers of response to anti-tuberculosis chemotherapy. Sputum specimens were sequentially collected for up to one year from 19 smear-positive pulmonary tuberculosis patients under adequate treatment. Results showed that levels of 85B mRNA declined after initiation of therapy, as did viable *M. tuberculosis* colony counts, with 90% of patients becoming negative for both markers after two months of treatment. The rapid disappearance of *M. tuberculosis* mRNA from sputum suggests that it is a good indicator of microbial viability. However, additional studies are warranted to prove the usefulness of this new Þnding, especially as a marker for rapid assessment of response to chemotherapy under program conditions.

Although not common practice before the AIDS epidemic, physicians should now routinely send blood cultures for the diagnosis of mycobacterial disease in HIV-infected patients (216Ð218). In one report, 7 (26%) of 27 HIV-infected patients with TB had positive blood cultures for *M. tuberculosis,* and in several other studies this proportion was even higher (up to 42%) (3,190,191,219). Mycobacterial blood cultures should be obtained in HIV-infected patients whenever they have unexplained fever (220Ð223). The diagnostic yield is highest in patients with fever higher than 39.5¡C, a miliary pattern on chest radiograph, and an elevated serum alkaline phosphatase or lactate dehydrogenase value (219).

Given the severe immunodeÞciency that many co-infected patients with HIV have rapid TB diagnosis is essential to decrease transmission, as well as morbidity and mortality. The modern mycobacteriology laboratory must respond to this Ònneed for speedÓ by providing studies that may hasten the diagnosis.

NAA is the newest tool available to diagnose rapidly and more speciÞcally tuberculosis disease. Results of

NAA testing may be available within four to six hours of beginning the test. Compared to smear microscopy, it has higher sensitivity and speciÞcity (224,225). NAA assays can detect tuberculosis even when AFB sputum smear microscopy is negative. Furthermore, NAA, in contrast to smear microscopy, can differentiate between *M. tuberculosis* complex and NTM, whereas AFB stains detect only the presence or absence of acid-fast bacilli.

The appropriate number of specimens to test with NAA will vary depending on the clinical situation, the prevalence of TB, the prevalence of NTM, and laboratory proÞciency (226,227). Based on available information, the following algorithm, recommended by the CDC, is a reasonable approach to NAA testing of respiratory specimens from patients with signs or symptoms of active pulmonary TB disease for whom a presumed diagnosis has not been established.

Algorithm (228):

1. Collect sputum specimens on three different days for AFB smear and mycobacterial culture.
2. Perform NAA test on the Þrst sputum specimen collected, the Þrst smear-positive sputum specimen, and additional sputum specimens as indicated below.
   a. If the Þrst sputum specimen is smear-positive and NAA-positive, the patient can be presumed to have TB without additional NAA testing. However, unless concern exists about the presence of NTM, the NAA test adds little to the diagnostic work-up.
   b. If the Þrst sputum is smear-positive and NAA-negative, a test for inhibitors should be done.
      i. If inhibitors are not detected, additional specimens (not to exceed a total of three) should be tested. The patient can be presumed to have NTM if a second sputum specimen is smear-positive, NAA-negative, and has no inhibitors detected.
      ii. If inhibitors are detected, the NAA test is of no diagnostic help. Additional specimens (not to exceed a total of three) can be tested with NAA.
   c. If sputum is smear-negative and NAA-positive, additional specimens (not to exceed three) should be tested with NAA. The patient can be presumed to have TB if a subsequent specimen is NAA-positive. This test is currently FDA-approved for negative smear respiratory specimens using transcription mediated ampliÞcation only.
   d. If sputum is smear-negative and NAA-negative, an additional specimen should be tested with NAA. The patient can be presumed not to be infectious if all smear and NAA results are negative. The clinician must rely on clinical judgement in decisions regarding the need for anti-TB therapy and further diagnostic work-up because negative NAA results do not exclude the possibility of active pulmonary TB disease.
3. If the indicated repeat NAA testing fails to verify initial NAA test results, the clinician must rely on clinical judgement in decisions regarding the need for anti-TB therapy, further diagnostic work-up, and isolation.
4. Ultimately, the patientÕs response to therapy and culture results are used to conÞrm or refute a diagnosis of TB.

NAA tests can enhance diagnostic certainty, but they do not replace AFB smear or mycobacterial culture, and they do not replace clinical judgment. Clinicians should interpret these tests based on the clinical situation. NAA tests often remain positive after cultures become negative during therapy and can remain positive even after completion of therapy (229).

Few studies have addressed the use of NAA assays for samples of non-respiratory origin (224,230,231,232). Paradoxically, it is precisely situations like TB meningitis for which a rapid and accurate laboratory diagnosis is of prime importance, since often the smear is negative and cultures grow *M. tuberculosis* only after several weeks, if at all. TB of the central nervous system remains among the most devastating forms of human TB. It causes high rates of death and neurologic disability and is often very difÞcult to diagnose (233,234). Smears of CSF are positive in less than 10% of patients in some reports (235,236). Even though culturing of CSF is also an unreliable diagnostic technique, a positive mycobacterial culture remains the gold standard of diagnosis in TB meningitis (237,238).

Recently Caws et al. reported data from a national molecular diagnostic service for TB meningitis in the United Kingdom (239). An IS*6110* targeted PCR had a sensitivity of 75% when compared to a positive culture, and 39% when compared to a Þnal clinical diagnosis of TB meningitis. In contrast, culture was positive in only 17% of clinically diognosed cases. NAA is currently the most rapid diagnostic test for TB meningitis, providing a better sensitivity compared to culture, though it is still not optimal. CSF specimens from patients suspected of having TB meningitis should be processed immediately. When a Lumbar puncture is performed at least 5ml of CSF should be submitted to the mycobacteriology laboratory as quickly as possible for growth detection and NAA testing.

1. Laboratory test results should always be correlated with the patientÕs clinical presentation, and the clinician should notify the laboratory when results are not consistent. An established and ongoing professional relationship between clinicians and laboratory personnal enables recognition of inaccurate results earlier, and therefore may minimize the potential harm to the patient. False-positive cultures of TB and other mycobacteria as a result of contaminated laboratory reagents or other technical laboratory problems have occurred. Studies (240,241) have demonstrated the occurrence of about 3Ð4% false-positive TB cultures. In studies analyzing drug-resistant TB (242) or specimens from patients with negative AFB smears and only one positive culture (243), erroneous results were reported

in 13% and 56%, respectively. However, one needs to be aware of the possibility that the error may have occurred in the pre-testing phase, such as using a nonsterile bronchoscope for specimen collection (244) or through detection of residual amplifiable *M. tuberculosis* DNA that might have remained on a sterile bronchoscope (245,246).

Laboratory results alone (i.e. positive culture, drug resistance) are not enough to dictate a particular strategy in a patientÕs care; careful clinical correlation is necessary in making the correct diagnosis.

Clinical Pathology of Tuberculosis in HIV-infected Patients

All tissue and fluid specimens from HIV-infected patients should routinely be tested for mycobacteria (smear, culture and possible, nucleic acid amplification) regardless of histologic or other microbiologic findings. Specimens from HIV-immunosuppressed patients may reveal mycobacteria on culture even though there are no AFB on smear, no granulomas are seen on histology, and evidence of coexisting nonmycobacterial infections or neoplasms are present (247).

The pathologist should have a high index of suspicion for mycobacterial disease when examining tissue from HIV-infected patients, and therefore information regarding the patientsÕHIV status and level of immunodeficiency should be considered when interpreting a result. The extent of granulomatous tissue reaction among HIV-infected patients with mycobacterial disease may depend upon their level of immune function. Although some HIV-infected patients with TB have no granulomas in infected tissue, most do (Fig. 17.4), in contrast to disseminated MAC where granuloma formation in infected tissues is usually poor to nonexistent (1) (Fig. 17.5). *M. tuberculosis* generally produces caseating granulomas, although noncaseating granulomas may also be seen.

In patients with tuberculosis, the histologic picture and frequency of granulomas will vary by the stage of tuberculosis and the site and type of biopsy. Primary pulmonary infection will result in small patches of caseous bronchopneumonia predominantly in subpleural areas in lower and middle lung fields, and in hilar lymph nodes. Miliary tuberculosis (named after the small Òmillet seedÓ appearance of lesions) occurs after hematogenous spread,

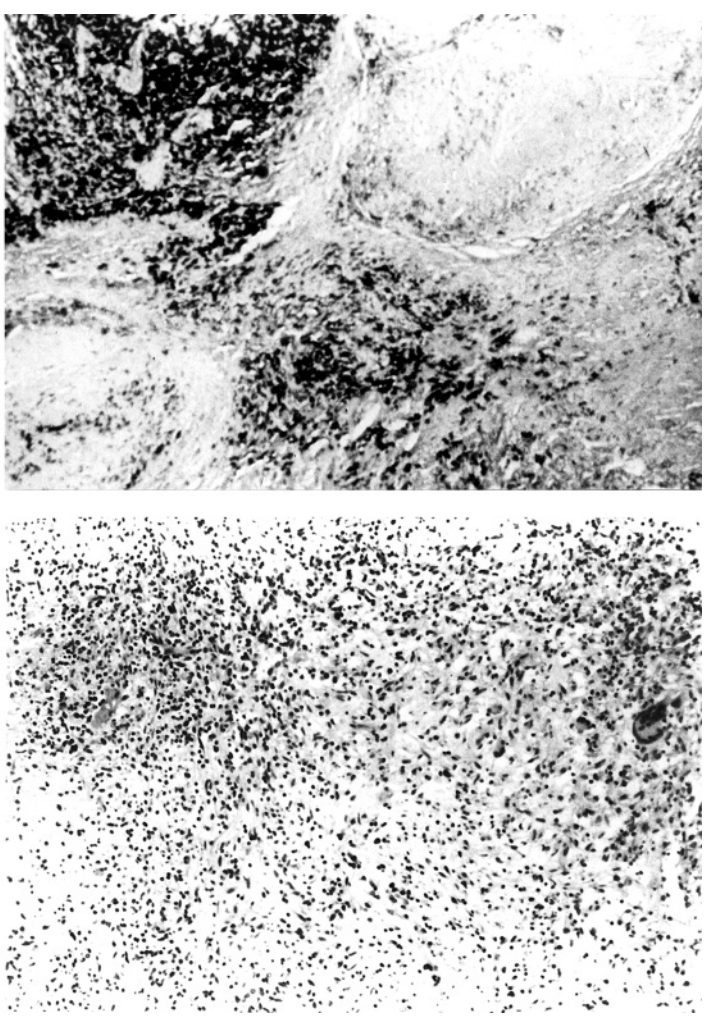

FIG. 17.4. Tuberculosis. A: Lymph node section (hematoxylin and eosin, $\times 50$) from a patient with tuberculous lymphadenitis presenting as his first AIDS-related infection. Well-formed tuberculous granulomas are seen (arrows). B: Bone marrow section (hematoxylin and eosin, $\times 700$) from a patient with disseminated tuberculosis, revealing a multinucleated giant cell (thin arrow) and caseating necrosis (thick arrow). This is in contrast to the MAC-infected tissue seen in Fig. 17.5 in which granulomas and necrosis are absent. (Part (A) from ref. 1, with permission; part (B) from Pitchenik AE, Fertel D. Tuberculosis and nontuberculous mycobacterial disease in HIV infected patients. *Med Clin North Am* 1992;76:121–171, with permission.)

but the term is often used to describe cases with typical miliary radiographic Þndings and an acute progressive course. There may be evidence of diffuse alveolar damage, and microscopically the miliary lesions are seen as small areas of necrotizing granulomatous inßammation Þlling four to Þve alveolar spaces (248). There may be seen, however, a wide spectrum of morphology, ranging from well-formed granulomas with giant cells, to suppurative necrosis with foam cells. Sites most often involved, according to one large autopsy study, in descending order,

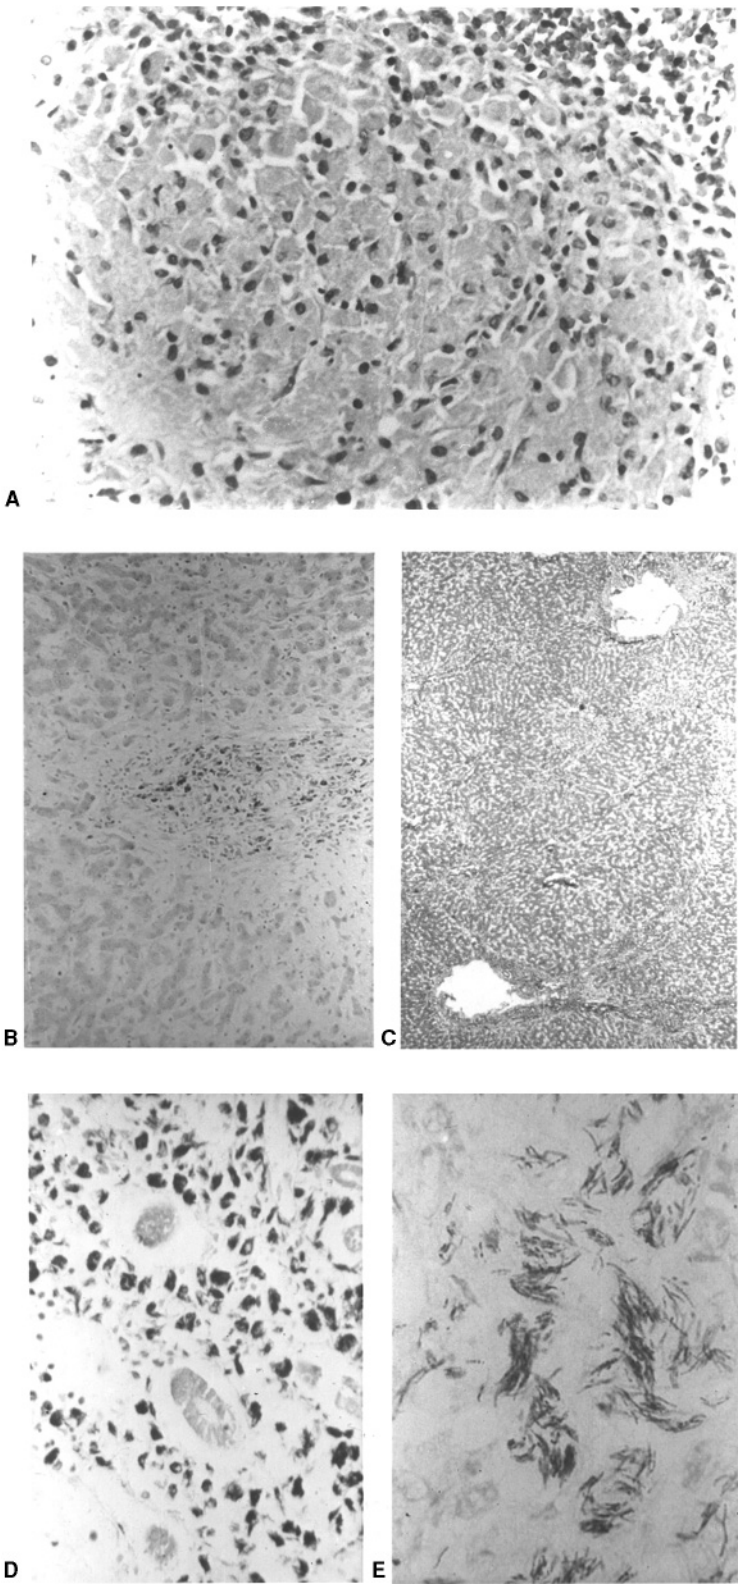

FIG. 17.5. MAC disease. A: Lymph node section (hematoxylin and eosin, ×700) from a patient with disseminated MAC presenting late in AIDS. Large histiocytes are present with abundant foamy cytoplasm. There are no formed granulomas or tissue necrosis, indicative of severe T-cell immunodeficiency. B–E: Liver, intestine, and lymph node from another patient with disseminated MAC disease and AIDS. (B) Liver section (hematoxylin and eosin, ×200) reveals no granulomas and appears essentially within normal limits. (C) Liver section (Ziehl-Neelsen, ×200) reveals numerous acidfast bacilli (arrows) proved on culture to be MAC. (D) Intestine section (Zichl-Neelsen, ×800) and (E) lymph node section (Zichl-Neelsen, ×1500) also reveals numerous acid-fast bacilli without granulomatous reaction. In (E), the acid-fast bacilli are seen, literally packing several macrophages (arrows). (Such macrophages appear large and foamy on hematoxylin and eosin staining as shown in (A).) [Parts (A) and (E) from Pitchenik AE, Fertel D. Tuberculosis and non-tuberculous mycobacterial disease in HIV infected patients. *Med Clin North Am* 1992;76:121–171, with permission; parts (B-D) from ref. 1, with permission.)

are the spleen, lungs, bone marrow and liver, with lesser involvement of skin, kidney, pancreas and joints (248). Grossly visible miliary lesions in lung tissue are not pathognomonic for tuberculosis, and may be seen in other infections (e.g. disseminated fungal infections such as histoplasmosis) or carcinoma.

ÒReactivationÓpulmonary tuberculosis is usually found in the upper lobes, and grossly appears as an acute necrotizing, pneumonic process with evidence of liquefaction and bronchial involvement and intrabronchial spread to contiguous lobes. Cavities, when present, have a wall consisting of granulation tissue, covered by a layer of Þbrous tissue. The immunologic mechanisms underlying cavity formation require a speciÞc degree of intact cellular immunity; therefore cavities are not often seen in patients with advanced HIV disease.

In one study of 11 HIV-seropositive patients who had culture-proven extrapulmonary TB (lymphatic, pleural, bone marrow, liver, and skin), biopsies from the tuberculous site revealed well-formed granulomas in ten (91%). In contrast, granulomas were found in the tissue specimens of only three (33%) of nine patients with culture-proven pulmonary TB who had transbronchial lung biopsies performed by Þberoptic bronchoscopy (72). Similar Þndings were reported by Sunderam et al. (125). This might be explained by the relatively small (millimeter) specimen size obtained by a transbronchial lung biopsy. Among HIV infected patients with disseminated TB presenting as fever of unknown origin, liver and bone marrow biopsies may furnish a rapid clue to diagnosis because of the presence of AFB or granulomas in the specimens.

Although blood cultures also represent a good diagnostic source for suspected dissemination, they generally are not positive unless the patientÕs CD4 count is < 200 cells/mm^3 (170Ð173).

Reasons for Delayed or Missed Diagnosis

Kramer et al. found that no or delayed treatment of tuberculosis in HIV-infected patients was common (48% of 52 patients) and was related more to errors in management (84% of times) than to atypical manifestations of TB (191). Of those in whom diagnosis was delayed, 45% died of TB. In most cases, delays could have been avoided if at least three sputum samples for acid-fast smear and mycobacterial culture had been obtained and if empiric therapy for TB had been given to symptomatic patients in whom chest radiographic Þndings were suggestive of mycobacterial disease.

Among HIV-infected patients with TB, acid-fast smears of sputum and bronchoscopic specimens are often negative and granulomatous reaction is frequently missed in the small transbronchial lung biopsy specimens (72,125,191). Therefore, after appropriate specimens have been obtained for mycobacterial culture, empiric anti-TB therapy should be instituted in all HIV-infected patients in whom chest radiographic abnormalities suggestive of TB are not explained by other causes (3,191). The tuberculin skin test is also seriously underused in symptomatic HIV-infected patients (249). Although anergy is common in HIV-infected patients with TB (44% to 89%), a considerable number (up to 56%) still have signiÞcant tuberculin skin reactions, which may be useful in directing care. For example, if an HIV-infected, tuberculin-reactive patient is symptomatic (e.g. fever of unknown origin) and TB disease cannot be excluded initially, anti-TB therapy should be instituted.

Treatment

Despite their immunosuppressed state, HIV-infected patients with TB who comply with a regimen of standard anti-TB drugs, including both isoniazrd?? (INH) and rifampin (RIF), have rapid sterilization of sputum, radiographic and clinical improvement and low relapse rates similar to that of TB patients who are not HIV-infected (72,123,250Ð254). Treatment for TB should be initiated promptly whenever a positive AFB smear is found in a patient with proven or suspected HIV infection. It should not be withheld on the presumption that the AFB may represent nontuberculous mycobacteria such as *M. avium* complex (MAC) (if this is a question then nucleic acid ampliÞcation testing can be performed to distinguish between TB and NTM). Initial treatment must be directed against the more virulent, contagious, and treatable *M. tuberculosis* until TB is ruled out. If the culture later reveals a nontuberculous mycobacteria, then treatment can be changed or discontinued at the physicianÕs discretion (158,255,256). Even if AFB smears are negative, empiric therapy for TB should be initiated (after specimens are obtained) pending culture results in symptomatic patients in whom chest radiographic Þndings are suggestive of TB (191).

Guidelines for the treatment of TB in the setting of HIV infection have been published by the American Thoracic Society, the CDC, and others (Table 17.2) (15,19,149,167, 257,258). Recommended treatment for TB in HIV-infected patients is now essentially the same as that for non-HIV infected patients (149): a six-month total regimen including INH, RIF, and pyrazinamide (PZA) given for two months, followed by INH and RIF alone for four more months. This is the preferred treatment for patients with fully susceptible organisms who adhere to treatment. Ethambutol (EMB) is usually included in the initial regimen until the results of drug susceptibility studies are available but may be withheld initially if it is known that there is less than 4% primary resistance to INH in the community, and the patient has had no previous treatment with anti-TB drugs, is not from a country with a high prevalence of drug resistance, and has had no known exposure to a drug-resistant case.

TABLE 17.2. *Treatment regimens for human immunodeÞciency virus (HIV) related tuberculosis (TB)*

Six-month rifamycin-based therapy for TB susceptible to INH, RIF and PZA*

Rating[a] (Evidence)[Δ]	Induction Phase Drugs	Induction Phase Interval and Duration	Continuation Phase Drugs	Continuation Phase Interval and Duration	Consideration for HIV Therapy	Comments
A(II)	• INH • RIF or RFB • PZA • EMB (or SM)‡	Daily for two months or Daily for two weeks then two times/ week for six weeks. (Twice weekly therapy should be administered by DOT.)	• INH • RIF or RFB	Daily or two times/week for four months. (Twice weekly therapy should be administered by DOT.)	See Table 17.4 for Coadministration with Antiretroviral Therapy	

Six-Month Rifamycin-based therapy for TB susceptible to INH, RIF and PZA*

Rating[a] (Evidence)[Δ]	Induction Phase Drugs	Induction Phase Interval and Duration	Continuation Phase Drugs	Continuation Phase Interval and Duration	Consideration for HIV Therapy	Comments
B(II)	• INH • SM • PZA • EMB	Daily for two months (eight weeks)	• INH • SM • PZA	Two to three times/week for seven months	See Table 17.4 for Coadministration with Antiretroviral Therapy	SM is coniraindicated for pregnant women SM should be used for the total duration of therapy. When SM can not be used, EMB and INH should be used for at least 12 months

EMB = ethambutol; INH = isoniazid; PZA = pyrazinamide; RFB = rtfabutin; RIF = rifampin; SM = streptomycin.
* Duration of therapy should be prolonged for patients with delayed response to therapy If still culture positve on a sputum collected after two months of therapy, patient should be assessed for non-adherence, malabsorption or drug resistance and therapy should be prolonged for at least four months after cultures become negative CONSULTATION WITH A SPECIALIST IS STRONGLY ADVISED IN THESE CASES.
‡ EMB or SM may be stopped a er susceptibility test results indicate susceptibilty to INH and RIF.
[a] A = preferred; B = acceptable alternative; C = offer when A and B cannot be given.
[Δ] I = randomized clinical trial data; II = data from clinical trials that are not randomized or were conducted in other populations; III = expert opinion.
Adapted from American Thoracic Society/Centers for Disease Control. Treatment of Tuberculosis and Tuberculosis Infection in Adults and Children. *Am J Respir Crit Care Med* 1994;149: 1359-1374.

It should be emphasized that in the presence of HIV infection it is essential to assess the clinical and bacteriologic response. If there is evidence of a slow or optimal sub response (e.g. sputum cultures have not become negative after two months of treatment), therapy should be prolonged as judged on a case-by-case basis (19). Furthermore, DOT is strongly recommended for all HIV-infected TB patients and is mandatory when therapy is administered intermittently on a twice or thrice weekly schedule rather than on a daily basis (19,149). DOT is *routinely* recommended for all HIV-infected TB patients treated in Florida and is considered to be the *community standard* (259). For two weeks, INH, RIF, PZA, and EMB are given daily, followed by twice weekly administration of the same drugs for six weeks, and subsequently twice weekly administration of INH and RIF for 16 weeks, for a total of six months of therapy. Alternatively, INH, RIF, PZA, and EMB can be given three times weekly for six months for patients with fully susceptible tubercle bacilli. Recommended drug dosages for INH, RIF, PZA, and EMB when administered daily, two times per week, or three times per week are outlined in Table 17.3 (19,149).

If public health resources are strained (e.g. in developing countries or rural communities) and insufficient to provide for DOT when needed, responsible family members or other lay persons (e.g. former TB patients known to be responsible) might be recruited for this purpose, perhaps on a paid, "per patient cured" basis (260,261). If DOT is not possible, the use of fixed drug combinations (i.e. INH-RIF-PZA (Rifater); INH-RIF (Rifamate)) should be used routinely, which enhances patient adherence and reduces the risk of inappropriate monotherapy and drug resistance (149,262).

Drug susceptibility tests should be performed routinely on all initial isolates and the treatment regimen revised if there is resistance to any of the drugs being used. When isolated INH resistance is documented, INH should be discontinued (though this has been argued not to be necessary by some (263)) and RIF, EMB, and PZA continued for at least the entire six-month duration of therapy (149). (Some authorities have recommended extending therapy with RIF, EMB, and PZA for at least nine to twelve months in HIV-infected TB patients with INH-resistant organisms (264,265).) Institutions that are experiencing outbreaks of TB resistant to both INH and RIF may need to begin five- or six-drug regimens as initial therapy pending drug-susceptibility test results. If there is resistance to both INH and RIF demonstrated with or without resistance to other first-line anti-TB drugs, treatment becomes less effective, more complicated, and more expensive and requires consultation with a TB expert (266). In general, therapy for multidrug resistant disease (resistant to at least INH and rifampin) should include at least two or three oral drugs to which the organism is susceptible. These drugs should be continued for 18–24 months following sputum conversion to negative. In addition, an injectable drug to which the organism is susceptible (e.g. aminoglycoside) is included for the first four to six months as tolerated (149,267,268). When resistance occurs to the first line agents, second line agents must be included in the treatment regimen. Second line agents are generally less effective and more toxic than first line agents. Second line agents include ethionamide, cycloserine, para-aminosalicylic acid (PAS), capreomycin and kanamycin (or amikacin). The fluoroquinolones (ciprofloxacin, ofloxacin, levofloxacin, moxifloxocin, and sparfloxacin) are newer additions to the treatment arsenal and have been shown to be both effective and well tolerated. (149,269–271). Two new rifamycins, rifabutin and rifapentine, have been introduced and offer alternatives to rifampin. Rifabutin has a longer half-life (45 hours) (272) than rifampin (four hours) and has about one-third of the effect on the hepatic CYP450 enzymes (273). Rifapentine has a pharmacokinetic profile midway between rifampin and rifabutin. Resistance to rifampin usually confers resistance to both rifabutin and rifapentine (274). At least one study using once weekly INH and rifapentine showed an increased rate of resistance to rifapentine in the HIV+ study arm, and it is currently recommended that rifapentine not be used in HIV+ patients (275,276). All patients with drug-resistant TB should have DOT whether or not they are HIV-infected.

The more common adverse effects (Table 17.3) of INH include hepatitis and peripheral neuropathy. Vitamin B6 (25–50 mg per day) is often given with INH in order to prevent or treat the peripheral neuropathy (routinely given to HIV-infected individuals). One study showed that the incidence of drug induced hepatitis during treatment with INH was increased five-fold in the presence of hepatitis C virus infection and was increased four-fold when the patient was infected with HIV. If the patient was infected with both hepatitis C and HIV, the risk of drug-induced hepatitis was increased 14-fold (277). Rifampin treatment is associated with rash, pruritis, muscle stiffness, arthralgias, hepatitis and thrombocytopenia. PZA causes an increase in serum uric acid levels that can lead to a gouty arthritis, and it also maybe associated with hepatitis. Ethambutol (EMB) can cause an optic neuritis with loss of red-green color discrimination and visual acuity that can lead to blindness if not detected early. The aminoglycosides are associated with otic, vestibular, and nephrotoxicities. The dosages of EMB, cycloserine, ofloxacin, levofloxacin, and the aminoglycosides should be reduced in renal insufficiency (274).

Anti-TB drug toxicity (e.g. fever or hepatic, hematologic, or dermatological reactions) may be difficult to monitor in HIV-infected patients because of multiple and recurrent nontuberculous infections, non-TB drugs used concurrently, and the fact TB itself may produce similar abnormalities. However, with some exceptions (60,66), most studies show that anti-TB drugs are reasonably well tolerated, and because they are vital, they should not be discontinued because of mild symptoms or mild laboratory abnormalities (73,123,125,278). It has been suggested, and

it has been our experience as well, that signiÞcant adverse reactions to anti-TB drugs (especially to RIF) are more frequent among the more immunosuppressed patients with TB (i.e. those who contract TB in the later stages of AIDS) (279). In one retrospective study, 90% of adverse reactions (mostly to RIF) were seen during the Þrst two months of treatment (190). Concurrent therapy with various antiretroviral and anti-TB medications seems to be well tolerated (258,280).

In most cases, mild adverse effects can be treated symptomatically with prokinetic agents such as metoclopramide for GI distress, non-steroidal antiinßammatory

TABLE 17.3. *Medications for the treatment of Tuberculosis (TB) and latent TB infection*

Drug	Dose in mg/kg (Maximum Dose) Daily children	Daily adults	2 Times/week* children	2 Times/week* adults	3 Times/week* children	3 Times/week* adults	Adverse Reactions	Monitoring	Comments
INH	10–20 (300mg)	5 (300mg)	20–40 (900mg)	15 (900mg)	20–40 (900mg)	15 (900mg)	Hepatic enzyme elevation Hepatitis Peripheral neuropathy Mild effects on central nervous system Drug Interactions	Baseline measurements of hepatic enzymes for adults Repeat measurements: • if baseline results are abnormal • if patient is at high risk for adverse reactions • if patient has symptoms of adverse reactions	Hepatitis risk increases with age and alcohol consumption Pyridoxine can prevent peripheral neuropathy
RIF	10–20 (600mg)	10 (600mg)	10–20 (600mg)	10 (600mg)	10–20 (600mg)	10 (600mg)	GI upset Drug Interactions Hepatitis Bleeding problems Flu-like symptoms Rash	Baseline CBC measurements for adults • CBC and platelets • hepatic enzymes Repeat measurements: • if baseline results are abnormal • if patient has symptoms of adverse reactions Monitor for decreased antiretroviral activity if taken with ART	See Table 17.4 when administered with ART Signi cant interactions with: • methadone • birth control pills • many other drugs Colors body uids orange May permanently discolor soft contact lenses
RFB	5 (300mg)	—	5 (300mg)	—	5 (300mg)	—	Rash Hepatitis Fever Thrombocytopenia Orange coloured body uids With increased levels of rifabutin: • Severe arthralgias • Uvetitis • Leukopenia	Baseline CBC measurements for adults • CBC and platelets • hepatic enzymes Repeat measurements: • if baseline results are abnormal • if patient has symptoms of adverse reactions Monitor for decreased antiretroviral activity if taken with ART	See Table 17.4 when administered with ART Signi cant interactions with: • methadone • birth control pills • many other drugs Colors body uids orange May permanently discolor soft contact lenses
PZA	15–30 (2g)	15–30 (2g)	50–70 (4g)	50–70 (4g)	50–70 (3g)	50–70 (3g)	Hepatitis Rash GI Upset Joint aches Hyperuncemia Gout (rare)	Baseline measurements for adults • uric acid • hepatic enzymes Repeat measurements: • if baseline results are abnormal • if patient has symptoms of adverse reactions	Treat hyperuricemia only if patient has symptoms
EMB	15–25	15–25	50	50	25–30	25–30	Optic neuritis	Baseline and monthly tests • visual ability • color vision	Generally not recommended for children too young to be monitored for changes in vision unless TB is dnug resistant
SM	20–40 (1g)	15 (1g)	25–30 (1.5g)	25–30 (1.5g)	25–30 (1.5g)	25–30 (1.5g)	Ototoxicity (hearing loss or vestibular dysfunction) Renal toxicity	Baseline and repeat as needed • hearing • kidney function	Avoid or reduce dose in adults > 60 years old or in individuals with renal disease

Note: Children □ 12 years old. Adjust weight-based dosages as weight changes.
* All regimens administered two to three times a week should be used with DOT.
EMB = ethambutol; INH = isoniazid; PZA = pyrazinamide; RFB = rifabutin; RIF = rifampin; SM = streptomycin; ART = antiretroviral therapy; DOT = Directly Observed Therapy.

agents for muscle and joint pain, and with antihistamines (diphenhydramine, hydroxyzine) for itching or rash. Desensitization can be tried in the event that an allergy occurs to one of the agents in the treatment regimen (281,282). It may be necessary to discontinue INH, RIF, and/or PZA if clinically signiÞcant hepatitis (development of signs and/or symptoms of hepatitis at any transaminase level, or transaminase levels above Þve times the upper limit of normal) occurs. In this event, treatment may continue with EMB, streptomycin, and either oßoxacin or levoßoxacin. Once the hepatitis is resolved, INH, RIF, and PZA can be reintroduced, one at a time, as the patient tolerates. If RIF cannot be used, or if PZA cannot be used for the Þrst two months of therapy, the duration of treatment must be extended (see Table 17.2). Patients who cannot tolerate RIF may be able to tolerate twice weekly RBT. If there is underlying infection with hepatits B or C and elevated transaminases occur, treatment for hepatitis B and/or C, may permit a safe reintroduction of INH, RIF, or PZA for the duration of TB treatment (277).

Drug interactions can be problematic in the TB-HIV coinfected patient. Ketoconazole inhibits the absorption of RIF and can result in failure of TB treatment if the drugs are taken together (283). In some patients, INH and RIF can reduce serum ketoconazole and ßuconazole concentrations, resulting in ineffective antifungal therapy (283,284). RIF is well known as an inducer of CYP450 enzymes resulting in low serum drug levels of many other drugs. On the other hand, INH is an inhibitor of the CYP450 enzymes and can cause an increase in serum levels of certain drugs. Among the the drugs most affected by INH and RIF include phenytoin, theophylline, warfarin, hormone-based contraceptives, opiates, and sulfonylureas as well as the HIV nonnucleoside reverse transcriptase inhibitors used and protease inhibitors (274). It has been shown that protease inhibitors in the treatment of HIV infection cause rifamycin levels (e.g. Rifampin) to be increased and rifamycins cause protease inhibitor levels to be decreased, leading to rifamycin toxicity and HIV resistance to protease inhibitors. To address this problem, the CDC in a consensus statement, recommended three options for the concomitant treatment of HIV infection and TB (19,285,286). Rifabutin may be used as an alternative to rifampin when patients are receiving nonnucleoside reverse transcriptase inhibitors or protease inhibitors. Rifabutin has less of an effect on the CYP450 system than does rifampin and although similar drug interactions occur, they are of a lesser magnitude. It has been our experience that rifabutin can be safely used with most of the currently available anti-retroviral agents when doses are adjusted to correct for the interactions. (19,258,287). Possible exceptions for the safe co-administration of HIV and TB drugs might be saquinavir (except when boosted by ritonavir) and full dose ritonavir. It has been our experience that nelÞnavir can be used with rifabutin (300 mg twice a week) with no need for dosage modiÞcation of the nelÞnavir. However, when rifabutin is used with indinavir, the dose of indinavir must be increased from 800 mg to 1200 mg every eight hours, but no dose change is required for rifabutin (258,280). When rifabutin is used with efavirenz, the dose of efavirenz appears to be unaffected while the dose of rifabutin frequently needs to be increased to 450 or 600 mg. Preliminary studies with a lopinavir/ritonavir combination product indicate that the dose of rifabutin should be decreased to 150 to 300 mg and given not more often than three times a week. Because of the variability of these interactions among patients as well as the large variety of different combinations of anti-retrovirals, we feel that serum drug levels may need to be measured for both rifabutin (and possibly INH) and the anti-retrovirals when combination therapy is used. It should be kept in mind that the dosage of both rifabutin and the retroviral drugs may need to be adjusted to avoid either sub-therapeutic or toxic levels (Table 17.4) (258,280,286,288).

Although HIV-infected patients rarely die from TB when it is treated appropriately, subsequent death from disease caused by nontuberculous organisms may occur within one to two years if the underlying immunosuppression is not corrected (19,60,66,72,73,125,289). Furthermore, although TB in HIV-infected patients usually responds to therapy, relapses, although uncommon, occasionally occur (60,64,72,250,254,290–293). Therefore, HIV-infected patients with TB should have regular follow-ups for life (e.g. every three to six months), and mycobacterial examinations should be repeated as clinically indicated. In addition, some consultants have suggested the use of indeÞnite continuation of INH after completion of a course of anti-TB therapy, especially if the patient is in an environment where TB exposure is common (i.e. also serves as prevention for reinfection) (294).

Clinical Response to TB Therapy

Patients need to be monitored for effectiveness of treatment and toxicity. Soon after starting therapy, patients should experience an improvement in symptoms such as cough, fevers, night sweats and weight gain. Defervesence occurs in 60–90% of patients within three weeks of starting therapy (295–297). Cough also has been shown to rapidly improve within two weeks of therapy (298). Radiographic resolution is slow and lags behind patient well-being as well as sputum smear and culture conversion. Improvement in chest radiographs may take one to three months after initiation of therapy. Thus, chest radiographs to monitor response to therapy is not routinely recommended (299). The number of bacilli seen on sputum smear has been shown to rapidly decline within two weeks of starting therapy in most patients (300,301). Cultures become negative in over 85% of patients on therapy for more than two months (149,302).

TABLE 17.4. *Recommendations for coadministering different antiretroviral drugs with the antimycobacterial drugs rifabutin and rifampin*

Antiretroviral	Use in combination with rifabutin	Use in combination with rifampin	Comments
Saquinavif			
Hard-gel capsules (HGC)	Possibly† if antiretroviral regimen also includes ritonavir	Possibly† if antiretroviral regimen also includes ritonavir	Co-administration of saquinavir SGC with usual-dose rifabutin (300 mg daily or two or three times per week) is a possibility. However, the pharmacokinetic data and clinical experience for this combination are limited.
Soft-gel capsules (SGC)	Probably§	Possibly, if antiretroviral regimen also includes ritonavir	The combination of saquinavir SGC or saquinavir HGC and ritonavir, co-administered with (1) usual-dose rifampin (600 mg daily or two or three times per week), or (2) reduced-dose rifabutin (150 mg two or three times per week) is a possibility. However, the pharmacokinetic data and clinical experience for these combinations is limited. Co-administration of sequinavir HGC or saquinavir SGC with rifampin (in the absence of ritonavir) is not recommended because rifampin markedly decreases concentrations of saquinavir.
Ritonavir	Probably	Probably	If the combination of ritonavir and rifabutin is used, then a substantially reduced-dose rifabutin regimen (150 mg two or three times per week) is recommended. Co-administration of ritonavir with usual-dose rifampin (600 mg daily or two or three times per week) is a possibility, though phammacokinetic data and clinical experience are limited.
Indinavir	Yes	No	There is limited, but favorable, clinical experience with co-administration of indinavir‡ with a reduced daily dose of rifabutin (150mg) or with the usual dose of rifabutin (300mg two or three times per week). Co-administration of indinavir with nfampin is not recommended because rifampin markedly decreases concentrations of indinavir.
Nel navir	Yes	No	There is limited, but favorable, clinical experience with co-administration of nel navif** with a reduced daily dose of rifabutin (150mg) or with the usual dose of rifabutin (300mg two or three times per week). Co-administration of nelenavir with rifampin is not recommended because rifampin markedly decreases concentrations of nel navir.
Amprenavir	Yes	No	Co-administration of amprenavir with a reduced daily dose of rifabutin (150mg) or with the usual dose of rifabutin (300mg two or three times per week) is a possibility but there is no published clinical experience. Co-administration of amprenavir with rifampin is not recommended because rifampin markedly decreases concentrations of amprenavir.
Nevirapine	Yes	Possibly	Co-administration of nevirapine with usual-dose rifabutin (300mg daily or two or three times per week) is a possibility based on pharmacokinetic study data. However, there is no published clinical experience for this combination. Data are insuf cient to assess whether dose ad)ustments are necessary when rifampin is co-administered with nevirapine Therefore, rifampin and nevirapine should be used only in combination if clearly indicated and with careful monitoring.
Detavirdine	No	No	Contraindicated because of the marked decrease in concentrations of delavirdine when administered with either rifabutin or rifampin.
Efavirenz	Probably	Probably	Co-administration of efavirenz with increased-dose rifabutin (450mg or 600mg daily, or 600mg two or three times per week) is a possibility, though there is no published clinical experience. Co-administration of efavirenz†† with usual-dose rifampin (600mg daily, or two or three times per week) is a possibility, though there is no published clinical experience.

* Usual recommended doses are 400mg two times per day for each of these protease inhibitors and 400mg of ritonavir.
† Despite limited data and clinical experience, the use of this combination is potentially successful.
§ Based on available data and clinical experience, the successful use of this combination is likely.
‡ Usual recommended dose is 800mg every eight hours. Some experts recommend increasing the indinavir dose to 1,000-1,200mg every eight hours if indinavir is used in combination with rifabutin.
** Usual recommended dose is 750mg three times per day or 1,250mg twice daily. Some experts recommend increasing the nel navir dose to 1,000mg if the three times-per-day dosing is used and nel navir is used in combination with rifabutin.
†† Usual recommended dose is 600mg daily. Some experts recommend increasing the efavirenz dose to 800mg daily if efavirenz is used in combination with rifampin.
Source: Center for Disease Control and Prevention. Updated Guidelines for the use of Rifabutin or Rifampin for the Treatment and Prevention of Tuberculosis among HIV-infected Patients Taking Protease Inhibitors or Non-nucleoside Reverse Transcriptase Inhibitors. *MMWR* 2000;49(9)1B5-189.

Reasons for Failure of TB Therapy

If a patient continues to be culture positive for tuberculosis despite "adequate" therapy, the clinician should consider one or more of the following four etiologies as a possible cause: (1) non adherence, (2) the presence of drug resistance, (3) poor penetration into the affected area (e.g. thick pleural thickening not allowing drug penetration-a rare etiology), and/or (4) lower than expected drug levels. Of the above four etiologies, in our experience, non-adherence is the most common reason for failure of TB therapy. The importance of utilizing DOT to try to minimize this risk cannot be overstated. However, despite the use of DOT, non-adherence may occur and can be difficult to detect (303). If a patient is culture positive for TB despite over two months of therapy, an evaluation searching for etiologies for this failure, including confirmation of drug susceptibilities and therapeutic drug monitoring, should be considered.

Paradoxical Worsening of TB after Initiation of HAART

Paradoxical worsening of TB symptoms, signs, and/or radiographic manifestations have been reported shortly after initiation of highly active antiretroviral therapy (HAART) (128,304–307). The proposed pathogenesis of this phenomenon is an inflammatory response to TB antigens associated with immune reconstitution caused by HAART. Paradoxical responses have been seen months after the initiation of TB chemotherapy, suggesting that TB antigens, without the existence of live TB organisms, could trigger this inflammatory response. Interestingly, PPD reactions "converting" from negative to significant induration have been observed in those patients with paradoxical responses. Our recent observations reveal that 41 of 175 (23%) HIV-infected TB patients experienced paradoxical responses, at a median of 15 days (range, 2–60 days) after the initiation of HAART. Manifestations include fever (60%), cervical and/or intrathoracic lymphadenopathies (40%), bilateral diffuse pulmonary infiltrates (usually military pattern), pleural effusion, and CNS lesions (308). When the patient's clinical course deteriorates during treatment in an HIV-infected TB individual, it is imperative to ensure that this is not due to TB treatment failure or the development of another pathological process, such as an opportunistic infection or a drug reaction. In general, paradoxical reactions are transient and no specific treatment is required. However, when severe manifestations are seen (e.g. airway or vascular compromise, CNS lesions, pericardial effusion causing cardiac tamponade), the administration of immunomodulators, such as systemic corticosteroids, should be considered along with possible discontinuation of HAART.

Primary Drug-resistant TB Acquired Late in AIDS

Immunosuppressed patients exposed to TB can be newly re-infected and contract TB despite old latent tuberculosis infection or disease that was adequately treated in the past (20,47,131,309–311), confirming that these individuals are susceptible to reinfection from subsequent TB exposure. Outbreaks of multidrug-resistant TB among HIV-infected persons have been documented in many different settings, including hospitals and prisons (23,24,32,48,312). These occurrences underscore the importance of strict adherence by institutions serving HIV-infected populations to recommended infection control procedures (26).

Value of HIV Serologic Testing in Patients with TB

All persons with TB should be questioned about risk factors for HIV infection and whether or not risk factors are elicited, urged to have an HIV serology done (314). The finding that a person with TB is HIV-infected (1) alters plans for management of the TB (choice of drugs may be different (e.g. rifampin vs. rifabutin in patients on HAART); DOT is strongly recommended, and lifetime follow-up is indicated); (2) forewarns the physician of additional nontuberculous opportunistic infections that require treatment in their own right, may confound the evaluation of anti-TB therapy, and are often responsible for a fatal outcome within two years of TB diagnosis (19,60,65,72); (3) alerts the physician to the possible need for anti-HIV therapy and PCP chemoprophylaxis; (4) establishes the diagnosis of AIDS (an AIDS diagnosis often establishes eligibility for certain social, medical, and economic benefits); and (5) often affords the earliest opportunity to counsel the patient about notification of sexual partners and risk of transmitting HIV infection to others.

Prevention of Tuberculosis in HIV-Infected Individuals

For public health, there is a hierarchy of interventions in preventing TB, especially among individuals with HIV infection. First, persons with TB disease must be found and treated before they infect others. Second, persons exposed to patients with pulmonary TB (close contacts) must be found and treated to prevent rapid progression to TB disease. Lastly, persons with a history of TB infection must be found and treated to prevent reactivation TB.

Infection with HIV is the strongest risk factor for the development of reactivation tuberculosis and for progression to TB disease after recent infection, with some studies suggesting a rate of up to 8% per year (46,315,316). In addition, other research has suggested one year mortality rates of 20–35% for HIV-infected patients with active TB

disease, even if the TB is cured (317). For these reasons, treatment of latent TB infection among HIV-infected individuals is one of the highest priorities for those programs with adequate resources (19).

Although other tests will likely be available soon (318,319), the TST (PPD) is the most well established test for diagnosing latent TB infection. Limitations of the PPD are well known and include variances in placement of the test, subsequent interpretation of the results, and cross-reactivity with non-tuberculous mycobacteria. Positive PPD testing is dependent upon an intact cell-mediated immune response. Anergy is therefore common in HIV/TB co-infected persons. However, the beneÞts of anergy testing for HIV-infected persons who are tuberculin negative have not been demonstrated, and anergy testing is not recommended (320). Newer tests involving the *in vitro* measurement of gamma interferon production from patientsÕT cells exposed to tuberculin have been developed, studied and approved for limited use for the diagnosis of latent tuberculosis infection, but have not been thorougly evaluated in patients with HIV infection (318,319).

NTM can also cause a positive tuberculin skin reaction thereby decreasing the speciÞcity of PPD testing. The prevalence of TB in various populations will also have an effect on the speciÞcity of the skin test. For these reasons various cut-off points have been established to deÞne a positive PPD reaction: 5mm or greater of induration, 10mm or greater of induration, and 15mm or greater of induration (127) (Table 17.5). The speciÞcity of the test is increased at the expense of sensitivity by increasing the amount of induration required for a positive test (321).

For those individuals with the highest risk of progressing from TB infection to active TB disease, 5mm or greater of induration is used as the cut-off for a positive test. This would include HIV-infected individuals, recent close contacts to an active case of TB disease, patients on immunosuppressive medications such as transplant recipients, and those with chest X-rays showing scarring consistent with previous TB disease that was untreated.

For other individuals at risk for progressing to active TB disease or who have a substantial risk of infection with TB as opposed to other mycobacteria, 10mm or greater is used as the cut-off. Included in this group would be recent immigrants from high-incidence countries (especially within the last Þve years), intravenous drug users, healthcare workers, those in congregate living facilities such as prisoners or nursing home residents, mycobacteriology laboratory workers, and children under four years of age who are exposed to high-risk adults. Certain

TABLE 17.5. *Criteria for tuberculin positivity, by risk group*

Reaction □□5mm of induration	Reaction □10mm of induration	Reaction □15 mm of induration
Human immunode ciency virus (HIV)-positive persons	Recent immigrants (i.e. within the last ve years) from high prevalence countries	Persons with no risk factors for TB
Recent contacts of tuberculosis (TB) case patients	Injection drug users	
Fibrotic changes on chest radiograph consistent with prior TB	Residents and employees[t] of the following high-risk congregate settings: prisons and jails, nursing homes and other long-term facilities for the elderly, hospitals and other health care facilities, residential facilities for patients with acquired immunode ciency (AIDS), and homeless shelters	
Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of □□15 mg/d of prednisone for 1 mo or more)*	Mycobacterial laboratory personnel	
	Persons with the following clinical conditions that place them at high risk: silicosis, diabetes mellitus, chronic renal failure, some hematologic disorders (e.g. ieukemias and lymphomas), other speci c malignancies (e.g. carcinoma of the head or neck or lung), weight loss of > 10% of ideal body weight, gastrectomy, and jejunoileal bypass	
	Children younger than four years of age or infants, children, and adolescents exposed to adults at high-risk	

* Risk of TB in patients treated with corticosteroids increases with higher dose and longer duration.
[t] For persons who are otherwise at low risk and are tested at the start of employment, a reaction of □15 mm induration is considered positive.
Source: Centers for Disease Control and Prevention. Targeted tuberculin testing and treatment of latent tuberculosis infection. American Thoracic Society. *MMWR Morb Mortal Wkly Rep* 2000;49:1-51.

clinical conditions increase the risk for active TB disease, and patients with these conditions would also be considered positive at 10 mm or greater. These conditions include diabetes, silicosis, renal failure, partial or total gastrectomy, intestinal bypass, reticuloendothelial malignancies, carcinoma of the head, neck or lung, and individuals who have lost more than 10% or more of their ideal body weight. All persons with any of the above criteria should be tested by tuberculin (PPD) skin testing. Those individuals without any of the risks listed above should not be routinely tested for TB infection unless TB skin testing is required (e.g. healthcare workers). If an individual without known risk factors is tested, 15mm or greater should be considered positive (Table 17.5).

In the United States, treatment of latent TB infection with isoniazid has been an important, if not underutilized strategy for over 30 years (322). The reported efficacy of INH in non-HIV infected individuals varies considerably in the literature, between 25% to almost 100%, but seems to be most dependent upon compliance (323-326). In a study conducted by the IUATLD in eastern Europe, researchers found that daily INH for one year reduced the incidence of TB by 75%, but when completion rates were factored in, the reduction was 93%, (327) and was maintained over five years of follow-up. Another study conducted among Alaskan villagers showed that the efficacy of INH was maintained for nineteen years (328).

When HIV burst onto the world stage, questions arose once again regarding the effectiveness of latent TB infection treatment. The first regimens studied were those that used INH. Pape et al, in a study conducted in Haiti, randomized 118 subjects to either 12 months of daily INH or placebo. During a mean follow-up of approximately three years, the incidence of tuberculosis was lower in those who received INH compared to those who received placebo (2.2 vs. 7.5 per 100 person-years) (329). When only those who were PPD positive were included, the difference in the two groups was more pronounced with a rate of 1.7 for the INH group and 10.0 for the placebo group. In another study, HIV-infected individuals in a methadone program were followed prospectively to determine the effectiveness of INH in preventing active TB disease. In 53.4 person-years of follow-up, HIV-positive tuberculin reactors who did not receive INH developed TB at a rate of 9.7 per 100 person-years. There were no cases of TB among the tuberculin reactors who took daily INH for 12 months; (18) other studies have shown similar results (330).

What long-term effects are there from treatment of latent TB infection with INH and is there any impact upon survival? It is difficult to answer these questions, as there are many areas with a potentially high incidence of re-infection to strains to which the individual may be exposed. Nonetheless, intriguing results have been reported. Pape and colleagues found that treatment with INH resulted in slower progression of asymptomatic HIV infection with a prolonged survival (329). Moreno et. al found similar improvements in survival among HIV-infected individuals, most significantly in tuberculin reactors, (330), although the impact on mortality is less clear in other studies (331,332). At a clinic in Haiti that specializes in the care of HIV-infected poor urban residents, patients who are HIV positive and tuberculin positive routinely receive INH treatment for latent TB infection for between six months to three years at the discretion of the physician and patient. In a retrospective review of patients attending this clinic, researchers found that 1.4% of 1,005 patients who completed a course of INH subsequently developed TB; however, importantly there was evidence of a post-prophylaxis effect of INH that appeared to be dependent upon the duration of INH therapy. Patients who took only six months of INH developed TB in a median interval time of only eight months, whereas those who received INH for 24-36 months developed TB in a median of 40 months (333).

Previous data had suggested that anergic individuals were at increased risk for the development of active TB disease (18,334). However, data from a trial in Uganda indicated that anergic subjects that completed six months of INH only had a statistically insignificant reduction of 17% in the rate of TB compared to those who received placebo (332). The cost effectiveness and efficacy of treating anergic individuals, particularly in low TB incidence areas, is questionable at best (335). Some experts, however, maintain that the epidemiological context needs to be taken into account and that care should be individualized whenever possible (336).

Despite the sustained efficacy of INH therapy in preventing the development of active tuberculosis in both HIV- and non-HIV-infected individuals, toxicity and compliance continue to thwart the attainment of its full potential as an effective public health intervention. In addition, growing concern over the expansion of INH resistance has eroded confidence in the effectiveness of INH in some populations (337). Due to its potential limitations, researchers have sought viable alternative regimens that include rifampin. A study conducted in a murine model compared the efficacy of various combinations of rifampin, pyrazinamide and INH in sterilizing the spleens of mice infected with *M. tuberculosis*. After two months of daily rifampin and pyrazinamide, 100% of the mice had negative spleen cultures, whereas only 60% of those mice treated with six months of INH had sterile spleen cultures (338). Retrospective and observational studies in non-HIV infected human populations provided further evidence that rifampin was effective in reducing the incidence of TB in at-risk individuals (339,340).

Several studies looked at the use of rifampin in HIV-infected individuals (Table 17.6). The regimens used all focused on short-course therapy to address the issue of compliance, although none of the four protocols used directly observed therapy for the whole treatment. In the largest of these studies, daily INH for 12 months was compared to daily rifampin and pyrazinamide for two

TABLE 17.6. *Results of short-course regimens to treat leatent infection in persons with HIV infection*

months. After a mean follow-up of over three years, there was no statistical difference between the INH and rifampin/pyrazinamide groups with rates of active TB disease of 0.8 and 1.1 per 100 person-years respectively (342). There was also no statistical difference between the regimens in reducing mortality, toxicity, or HIV progression (342). The regimens were generally well-tolerated except for one arm of one of the studies which utilized a three drug regimen including INH, rifampin, and pyrazinamide which found an increased rate of side effects (332).

In the studies performed in Zambia and Haiti, medications were given bi-weekly, either self-administered (343) or partially supervised (341). No difference was noted between the groups receiving INH or rifampin/pyrazinamide. The Haitian study demonstrated a rate of TB in participants in both arms of the study that was similar to the results reported by Pape in a nearby community with similar patients (329). However, because the intermittent regimens utilizing rifampin and pyrazinamide were not compared to a more prolonged course of INH, experts convened by the Centers for Disease Control have not felt that there was sufficient data to make a definitive statement on the biweekly administration of rifampin and pyrazinamide for treatment of latent TB infection in HIV-infected individuals in the U.S. (19). However, Florida has used biweekly rifampin and pyrazinamide since 1999 with toxicity levels that are equivalent to INH. This regimen has been used exclusively in the context of directly observed therapy and has resulted in a significant improvement in treatment completion rates for latent TB infection (344,345). HIV infected individuals started on treatment for latent TB infection should be on DOT whenever possible, especially when short-course therapy is used.

As short-course regimens become utilized to a wider extent, it is to be expected that toxicity will become more evident. In early 2001, the first fatal cases of hepatotoxicity from rifampin and pyrazinamide used as a short course regimen were reported (346). In a further analysis, an additional 21 cases of liver injury were reported occurring in individuals on short course regimens containing RIF/PZA (347). Although clear predisposing factors were not present in all of the cases, many patients who developed severe hepatitis continued to take the medications after the development of symptoms, a factor also found in INH-related hepatotoxicity (348). Of note, all of the reported patients who developed hepatotoxicity were HIV negative.

Based on these experiences, the following recommendations were made for the utilization of short course treatment with RIF/PZA (347):

1. The two-month RIF-PZA treatment regimen for latent TB infection should be used with caution, especially in patients concurrently taking other medications associated with liver injury, and those with alcoholism, even if alcohol use is discontinued during treatment. RIF-

PZA is not recommended for persons with underlying liver disease or for those who have had INH-associated liver injury. Persons being considered for treatment with RIF-PZA should be informed of potential hepatotoxicity and asked whether they have had liver disease or adverse effects from INH.

2. For persons not infected with HIV, nine months of daily INH remains the preferred treatment for latent TB infection; four months of daily RIF is an acceptable alternative. Two months of daily RIF-PZA may be useful when completion of longer treatment courses is unlikely and when the patient can be monitored closely.
3. Available data do not suggest excessive risk for severe hepatitis associated with RIF-PZA treatment among HIV-infected persons.
4. No more than a two-weeks supply of RIF-PZA (with a PZA dose 20 mg/kg/d and a maximum of 2 gm/d) should be dispensed at a time to facilitate periodic clinical assessments. A health-care provider should reassess the patient in person at two, four, and six weeks of treatment for adherence, tolerance and adverse effects, and at eight weeks to document treatment completion. At each visit, health-care providers conversant in the patientsÕ language should instruct patients to stop taking RIF-PZA immediately and seek medical consultation if abdominal pain, emesis, jaundice or other symptoms of hepatitis develop. Provider continuity is recommended for monitoring.
5. Serum aminotransferase levels (AT) and bilirubin should be measured at baseline and at two, four, and six weeks of treatment in patients taking RIF-PZA, as some side effects may occur in the second month of treatment. Patients need to be monitored throughout the entire course of treatment. Asymptomatic serum AT increases are expected, and usually do not require that treatment be stopped. However, treatment should be discontinued and not resumed for any of the following Þndings: AT greater than Þve times the upper limit of normal range in an asymptomatic person, AT greater than normal range when accompanied by symptoms of hepatitis, or a serum bilirubin greater than normal range.

Initiating Treatment of Latent TB infection and Screening Contacts

Active TB disease must be ruled out prior to starting a patient on treatment for latent TB infection. This can be a clinical challenge due to the atypical and protean manifestations of TB in those with immunosuppression.

Another important and often overlooked factor in the prevention of TB in HIV-infected individuals is HIV testing of contacts of active cases of TB disease. Investigators collected data from 11 urban areas in the United States over a six month period, and of 6,225 close contacts that were identiÞed, HIV status was unknown for 87%. A quarter of those that were known to be HIV positive did not receive adequate screening for the presence of TB infection (a follow up TST or chest radiograph). Of those HIV-infected contacts of an active case of TB, only a third started treatment for latent TB infection and only a sixth completed this treatment (349). In a separate study in New York, researchers found that almost 90% of patients who developed TB were diagnosed before their Þrst visit to an HIV clinic, thereby severely limiting the efÞcacy of any intervention which solely relies on tuberculin testing in HIV clinics for preventing TB (350). Both of these studies imply that more widespread HIV testing of those at risk for the development of TB may have a signiÞcant impact on TB in these groups.

Current Recommendations for Treatment of Latent TB infection

In 1997 the CDC convened a panel of experts to revise the guidelines for the prevention and treatment of TB among patients with HIV. One of the principles emphasized in the guidelines published by that panel (19) was that all HIV-infected individuals need to be screened for TB infection with tuberculin skin tests, and if positive, treated for latent TB. Once active TB disease is ruled out and there are no contraindications to therapy, the most appropriate regimen for latent TB infection should be selected. The various regimens and mode of administration are summarized in Table 17.7. The regimen selected should take into account the individual speciÞcs of the patient, the likelihood of adherence, and programmatic limitations. Monitoring, both clinically and biochemically, is important in ensuring patient safety. Recommendations for monitoring are outlined in Table 17.7. Directly observed therapy, when applied appropriately, can also aid in monitoring for toxicity since patients are being seen at least bi-weekly and many times daily by healthcare professionals.

If the patient is receiving any other medications that are metabolized by the liver, including anti-retrovirals, monthly symptom evaluation supplemented by monthly liver function studies is recommended.

Persistent clinical monitoring throughout therapy is a key to avoiding complications (127). If symptoms of toxicity develop, *medications should be discontinued immediately* and medical evaluation carried out promptly.

Treatment of Latent TB Infection in Developing Countries

Screening and subsequent treatment for latent TB infection is a key element of TB programs in developed countries with adequate resources for TB control. In

TABLE 17.7. *Regimens for treatment of latent Tuberlculosis (TB) infection for adults with HIV infection*

Rating[Δ] (Evidence)[δ]	Drug (See Table 17.2 for Dosages)	Interval and Duration	Monitoring	Comments
A(II)	INH[‡,§]	Daily for nine months	Clinical monitoring monthly Liver function tests† at baseline in selected cases* and repeat measurements if: • Baseline results are abnormal • Patient is pregnant, in the immediate postpartum period, or at high risk for adverse reactions • Patient has symptoms of adverse reactions	Rule out Active Disease before beginning therapy for Latent infection In HIV infected patients, INH may be administered concurrently with nucleoside reverse transcriptase inhibitors (NRTIs), protease inhibitors, or non-nucleoside reverse transcriptase inhibitors (NNRTIs) Hepatitis risk increases with age and alcohol consumption. Pyridoxine (vitamin B_6 10–25mg/d) might prevent peripheral neuropathy and central nervous system effects. Directly Observed Therapy (DOT) should be used when twice-weekly dosing is used.
B(II)	INH[‡,§]	Two times/week for nine months		
A(I) C(I)	Rifampin** plus pyrazinamide Rifampin** plus pyrazinamide	Daily for two months Twice weekly for two to three months	Clinical monitoring at Weeks 2, 4 and 8 when pyrazinamide is given Complete blood count, platelets, and liver function tests† at baseline in selected cases* and repeat measurements if: • Baseline results are abnormal • Patient has symptoms of adverse reactions	Rule out Active Disease before beginning therapy for Latent Infection See note below (under **) on use of this regimen with certain NNRTIs or protease inhibitors May also be offered to persons who are contacts of patients with INH resistant, rifampin susceptible TB Decreased level of many other drugs Might permanently discolor contact lenses DOT should be used with twice-weekly dosing
B(II)	Rifampin**	Daily for four months	Clinical monitoring monthly Complete blood count, platelets, and liver function tests† at baseline in seiected cases* and repeat measurements if: • Baseline results are abnormal • Patient has symptoms of adverse reactions	Rule out Active Disease before beginning therapy for Latent Infection See note below (under **) on use of this regimen with certain NNRTIs or protease inhibitors May also be offered to persons who are contacts of patients with INH resistant, rifampin susceptible TB who can not tolerate pyrazinamide Decreased level of many other drugs Might permanently discolor contact lenses

† Recommended regimen for children younger than 18 years of age.
§ Recommended regimen for pregnant women. Some experts would use rifampin and pyrazinamide for two months as an alternative regimen in HIV-infected pregnant women, although pyrazinamide ahould be avoided during the rst trimester.
† AST or ALT and serum bilirubin.
* HIV infection, history of liver disease, alcoholism, and pregnancy.
δ A = preferred; B = acceptable alternative; C = offer when A and B cannot be given.
Δ I = randomized clinical trial data; II = data from clinical trials that are not randomized or were conducted in other populations; III = expert opinion.
** Protease Inhibitors or NNRTIs should generally not be administered concurrently with rifampin; rifabutin can be used as an alternative for patients treated with these medications—see Table 17.4 for full details.

contrast, developing countries have historically used their limited resources to Þnd and treat active, usually smear positive, cases of TB disease. In light of the limited resources available, this may be the more feasible and cost-effective intervention for them. However, the HIV epidemic and the resultant rise of TB has raised the question of also treating latent TB infection in developing countries (351).

The World Health Organization (WHO) and the International Union Against Tuberculosis and Lung Disease (IUATLD) in 1994 recommended preventive treatment for PPD positive HIV-infected people who have had active TB disease ruled out (351). Despite these guidelines, there are numerous difÞculties in the widespread implementation of screening and treatment programs especially in the context of signiÞcant resistance to INH in many parts of the world.

Treatment of latent TB infection is most effective in preventing reactivation TB disease. In developing countries with a high rate of TB and HIV, recent transmission accounts for a large percentage of cases, sometimes up to 40% (352). The effect of treating latent TB in these populations is usually short lived and wanes over time (343). In certain instances, interruption of transmission is of signiÞcantly greater importance than preventing reactivation.

Many concerns exist from an operational point of view. The protean clinical manifestations of TB in the setting of HIV co-infection are well known, but will nonetheless provide formidable challenges to clinicians practicing with limited diagnostic resources at their disposal. If active TB disease is not adequately ruled out prior to starting treatment for latent TB infection, an already serious global drug resistance problem could be substantially worsened (353). Limited resources in developing countries can also be a barrier to ensuring the safety and effectiveness of therapy. Once therapy is initiated, monitoring and evaluating potential complications in large numbers of individuals will be necessary. The costs associated with this may be prohibitive for some programs.

Adherence to therapy is perhaps the biggest challenge to effective latent TB infection programs in the United States, and developing countries have problems which are similar or worse. Although feasibility studies have shown rates of compliance similar to those in the U.S. (354), some studies have shown that as many as 61Ð84% of HIV-infected patients do not even start treatment (355,356). Coordinating with the voluntary counseling and testing centers run by national AIDS programs has been proposed as a method of increasing compliance, since those voluntarily tested for HIV maybe more likely to be compliant with treatment (337).

BCG and Prospects for Other TB Vaccines

Vaccination with *M. bovis* BCG (Bacille-Calmette-Guerin) is an important part of the TB control strategy in most developing countries. BCG is a live attenuated strain of *M. bovis*, an organism closely related to *M. tuberculosis*, and is of questionable efÞcacy in all individuals and of uncertain efÞcacy and safety in HIV-infected persons. A meta analysis evaluating the efÞcacy of BCG in non-HIV infected populations showed minimal reductions in adult cases of TB, with this effect even less pronounced in tropical areas (357). The debate regarding the efÞcacy of BCG may be the result of a variety of factors, including the use of different BCG strains, the background rate of infection with atypical mycobacteria and other operational factors.

Populations infected with HIV have not been studied extensively to determine the efÞcacy of BCG in preventing TB in this group. However, a study from Malawi did show a 69% increase in active TB disease among HIV-infected persons who received a second BCG vaccine as compared to placebo (358). Dissemination of BCG in children born to HIV-infected mothers has also been described (359). A decision analysis done by Sterling and colleagues concluded that tuberculin skin testing, followed by isoniazid preventive therapy would be more effective than BCG vaccination in preventing TB in HIV-infected persons (360). In the absence of supportive data, it is difÞcult to think of BCG as an important element in the effort to reduce the incidence of TB in HIV-infected persons. BCG should not be given to any patient who is symptomatically immunosuppressed (361,362). Based on the available data, treatment of latent TB infection seems a more promising strategy than BCG vaccination; however, for most countries, BCG may be the only option despite its shortcomings. In the United States, BCG is not recommended for the general population (363).

Recent advances have increased the possibility of a new TB vaccine. Perhaps the most signiÞcant of these advances is the complete sequencing of the genome of *M. tuberculosis* (364). The DNA sequences of the 4,000 TB genes may help to identify antigens that confer protective immunity and thus lead to various types of vaccine prospects. Despite these advances, little is known about the immunologic mechanisms that confer resistance to TB.

Of the different types of potential vaccines, DNA vaccines hold the most promise. A gene encoding a protective antigen is inserted into an expression plasmid, plasmid DNA is ampliÞed in transformed bacteria, and the plasmid DNA encoding the antigen is injected into the host. The plasmid directly transfects a living cell leading to the host becoming immunized against a heterologous protein produced by his own cells.(365) Various studies utilizing a murine model have shown that DNA plasmid vaccination can lead to speciÞc T-cell responses that contain TB infection (366Ð369). The duration of this effect, however, is unknown, as are questions regarding the safety of DNA vaccines. Several concerns regard the integration of plasmid DNA into the host genome, tolerance induction and auto-immunity (370).

Despite the optimism fostered by recent scientiÞc advances, a TB vaccine that will have an impact on the epidemiology of this disease is still probably years away from becoming a reality. In addition, ethical issues will need to be addressed before vaccine trials can begin, especially as these trials will require testing in developing countries with limited resources.

Environmental Control

Recent studies have used DNA-Þngerprinting to uncover and call attention to environmental issues in the transmission of tuberculosis in HIV health care settings (371Ð376). There is a well-documented history of nosocomial outbreaks of tuberculosis among HIV-infected patients in hospitals, HIV clinics, prisons, jails, homeless shelters, and residential care facilities, and there have been hospital outbreaks of nosocomial transmission of MDR-TB in the mid 1980s and early 1990s (20,30Ð32,47Ð49, 312,377Ð383). During these outbreaks, many health care workers became infected with tuberculosis; some developed active TB disease and a few died (150,384Ð386). All these outbreaks have served to underscore the need for good environmental controls and infection control policies in order to prevent the spread of disease, both to patients and health care workers.

Upon investigation of the causes of these outbreaks, some common underlying etiologies involving programmatic and environmental factors were elucidated: (1) inadequate supervision of TB therapy and adherence, resulting in acquired drug resistance and prolonged infectiousness, (2) hospitalizing, housing or seeing patients with tuberculosis in the same care facility/area as non-tuberculous HIV-infected immunosuppressed patients, and (3) poor administrative, infection control and environmental TB control measures in those facilities. This last factor was responsible for delays in diagnosis and treatment, inadequate respiratory isolation and aerosolization of infectious material during sputum induction, all of which served to transmit tuberculosis (26).

On the basis of a comprehensive review of programmatic and environmental issues, guidelines were issued for prevention of transmission of tuberculosis in health care settings (26). These guidelines address important elements of infection control: (1) early identiÞcation and treatment of latent tuberculosis infection and active TB disease; (2) isolation rooms with negative pressure, at least 6 air exchanges per hour, non-recirculated ventilation vented to the outside, highly efÞcient particulate air (HEPA) Þlters, and ultraviolet lights in both inpatient and outpatient HIV facilities and during cough-inducing procedures; and (3) fully supervised therapy (DOT). The recent outbreaks of TB in HIV facilities support the use of strict environmental control not only in rooms speciÞcally designated for TB patient isolation and cough-inducing procedures (sputum induction, aerosol pentamidine therapy, bronchoscopy, pulmonary function testing), but also in waiting rooms, other clinic areas, and entire wards designated for HIV-immunosuppressed patients. Specialized booths, occupied only by the patient, can be used for sputum induction and aerosol pentamidine therapy (387).

Health care workers who are exposed to patients during cough-inducing procedures should wear properly Þtted N95 facemasks that can Þlter droplet nuclei (388). If it is necessary to administer aerosolized pentamidine therapy, the patient should be evaluated for the possibility of TB before therapy is initiated and again before each treatment (3). In addition, if HIV-infected TB patients are to be treated in HIV clinics of general hospitals (rather than in public health TB clinics), hospital nurses should be designated with the speciÞc responsibility for closely following these patients, as a safeguard for public health. At each scheduled appointment, it should be documented that the appointment is kept, that patients are compliant with therapy, and that they are receiving DOT as required. Surveillance of employees working in HIV areas for tuberculin skin test conversions (e.g. every six months) will identify those who need preventive therapy and also identify possible lapses in TB control.

Hospitals and in-patient facilities need to follow proper infection control procedures regarding respiratory isolation, currently recommended ventilation characteristics and sputum specimen collection. Each facility should have a written policy for initiating respiratory isolation, specimen collection, respiratory isolation practices, and criteria for discontinuing respiratory isolation. In general, however, patients with positive AFB sputum specimens should remain in respiratory isolation, if on therapy, until there is clinical improvement (e.g. reduction in cough, fever) and until three sequential sputum AFB smears on different days are negative (26,389,390). There is no clear time at which to remove suspected TB patients with negative smears from respiratory isolation; however, a clinical response to therapy and at least three days on anti-TB medications should be adequate. The role of nucleic acid ampliÞcation testing in determining when patients can be removed from respiratory isolation has not been fully elucidated, but recent recommendations suggest that individuals with two sputum specimens negative for AFB on smear and nucleic acid ampliÞcation may be considered non-infectious (228).

It should be emphasized that a hospitalized patient need not have negative AFB smears before being discharged from the hospital. If a patient is returning to an environment where there are not Òat-riskÓ individuals (e.g. a home without HIV-infected or other immunosuppressed persons, or very young children), and the health department is doing contact investigations, then AFB negative sputa are not necessary. However, if the patient is to go or return to a congregate living facility or other environment with Òat-riskÓ persons, then three AFB negative sputum smears (if previously positive) and 14 days on anti-TB therapy with a positive clinical response is warranted. In

some rare instances, patients may need to be kept in a hospital for a "fear of flight," possibly resulting in the inability to complete the necessary course of therapy. In these cases, the health department needs to coordinate a treatment plan where upon the completion of therapy can be assured.

Engineering controls should be followed regarding ventilation systems for general areas (e.g. waiting-room and emergency departments), as well as TB isolation rooms. Health-care facilities caring for populations with a high prevalence of HIV and/or TB may need to consider additional environmental methods to aid in the prevention of transmission, such as HEPA filtration or UVGI (ultraviolet lamps), or other in-room filtration (26). Respiratory protection should be available to, and used by, personnel caring for or dealing with patients with known or suspected infectious tuberculosis, and should meet criteria standards (26,388).

The Responsibility of Public Health and its Role in the Future of TB in the United States

Health departments in all fifty states are legally charged by their respective state legislative assemblies with responsibility to control TB in their communities (391). In order to do this, health departments and state TB programs must ensure the following: (1) all patients with active TB disease are diagnosed quickly and appropriately and placed on effective therapy as soon as possible in order to prevent ongoing transmission in the community, (2) all patients remain on an effective regimen until considered cured, and (3) patients with latent TB infection are identified through targeted testing of high risk groups, including contacts of active TB disease cases, and placed on effective therapy to prevent the development of active TB disease.

Health departments achieve these goals through a variety of interventions. Surveillance and the prompt reporting of cases by health care providers and laboratories to the local health department lead to the early initiation of contact investigations and the identification of other persons at risk. Diagnostic assistance is provided to community physicians either in the form of direct laboratory services (392) and/or by consultation with TB experts. Treatment is provided directly by many TB programs with medical, nursing, and outreach interventions all contributing to the cure of patients with TB. Some programs provide only nurse case management and directly observed therapy, both of which are cornerstones of treatment interventions in TB control. These interventions, along with education and consultation, are key elements to achieving the goal of controlling TB in the community. The public health infrastructure that implements these strategies is responsible for the declining rates of TB now being realized in the United States (393).

Now, in the early twenty-first century, the TB epidemic is clearly evolving. On the one hand, the United States is experiencing the lowest rates of TB ever seen, a direct result of the increased investment and commitment to TB control efforts. On the other hand, TB control may become the victim of its own success. As the incidence of a disease decreases, funding for control also decreases, resulting in an increase in the disease; this phenomenon has been referred to by Reichman as the U-shape of concern (394).

Specific recommendations on maintaining the commitment to TB control and steps necessary to achieve its eventual elimination were outlined by a report from the Institute of Medicine in 2000 (395). These recommendations fall into five main categories: (1) maintain control of TB, while adapting to a declining incidence of disease and changing systems of health care financing and management, (2) hasten the decline of TB towards its elimination through increased efforts aimed at targeted testing and the treatment of latent infection, (3) develop tools needed for the ultimate elimination of TB; new diagnostic tests, particularly for diagnosis of infection; new treatments and an effective vaccine, (4) increase U.S. involvement in global efforts to control TB, and (5) mobilize support for TB elimination and regularly measure progress toward that goal. If these recommendations are applied, it is possible that TB will cease to be a significant public health issue by the later part of this century.

MYCOBACTERIUM AVIUM COMPLEX AND HIV INFECTION

Before the AIDS epidemic, MAC disease classically presented as a slowly progressive chronic fibrocavitary pulmonary disease in middle-aged persons (men > women, rural > urban), with underlying predisposing lung conditions characterized by poor lung drainage (e.g. chronic bronchitis, emphysema, bronchiectasis, pneumoconiosis). Extrapulmonary disease occurred primarily in the form of lymphadenitis in pre-school children, and disseminated disease was rare (396,397). From 1940 to 1984, only 37 cases of disseminated MAC were described in non-AIDS patients, most of whom had other underlying immunosuppressive diseases (396). Therefore, even among immunosuppressed patients, disseminated MAC was rare before the AIDS epidemic.

With the development of the AIDS epidemic, before the widespread use of highly active antiretroviral therapy, MAC disease (particularly the disseminated form) had become common, diagnosed in 14% to 30% of HIV-infected patients during their lifetime (398–403) and in up to 50% or more of autopsy cases (399,400,402,404–409). With the increased utilization of effective therapy for HIV, associated with the concomitant improvement in immune function, rates of disseminated MAC in AIDS patients have seen a significant decline (93,410–413). In a study by Kaplan et al., in the United States, the incidence of MAC fell 39.9% in the years 1996–1998, compared to 1992–1995 (412). However, in the United States and other

developed countries, MAC is still by far the most common *Mycobacterium* species isolated from patients with AIDS and is one of the most frequent opportunistic infections reported in patients infected with HIV (398,402,414–417). (In Africa and other developing countries, *M. tuberculosis* is more frequently isolated (418–420).) Even if the HIV status is unknown, culture-proven MAC (as well as *M. kansasii)* disease, at a site other than the lungs, skin, or cervical or hilar lymph nodes, meets the CDC surveillance case deÞnition for AIDS (provided there is no other obvious cause of immunosuppression) (421,422).

In contrast to TB, MAC disease is not believed to be transmitted from person to person, is seen uniformly among AIDS risk groups, occurs late among AIDS-related opportunistic infections, and in the setting of AIDS, is manifested histologically by poorly formed granulomas and macrophages that teem with AFB (1) (see Figs. 17.4 and 17.5). Among HIV-infected patients with MAC disease (in contrast to those with TB), chest radiographs are less speciÞc for mycobacterial disease, pleuritis is uncommon, and positive stool cultures usually represent primary gastrointestinal invasion rather than infected swallowed sputum (203,423). Compared with TB, therapy for MAC disease tends to be less effective (1).

Epidemiology and Pathogenesis

MAC Disease in Patients Without HIV Disease

The true prevalence of MAC disease in the United States (among HIV and non-HIV patients) is unknown because positive MAC cultures are not routinely reported to public health departments, and the isolation of MAC (especially from sputum) may represent colonization rather than disease (424). Nevertheless, before the HIV epidemic, large nationwide skin test surveys (using PPD-S and PPD-Battey) conducted by the U.S. Navy and Public Health Service on recruits suggested that MAC infection was common (10% to 70% prevalence depending on region), occurred most frequently in the southeast United States (~70% prevalence), was more frequent in rural areas, and (in contrast to latent tuberculosis infection) was more common at younger ages (425–427). A skin test survey conducted on medical students and hospital employees in New Orleans revealed similar Þndings (i.e. PPD-Battey skin reactivity was common in this area and, among young adults, was much more common than PPD-S reactivity) (428). A nationwide survey of nontuberculous mycobacterial isolates in 1979 and 1980 revealed that MAC accounted for 60% of isolates and that MAC isolation rates were highest in the Southeast, supporting the skin test survey results (429).

In contrast to TB, MAC is not transmitted from person to person but is acquired from the environment by means not well understood. Antibodies to MAC protein antigens were detected in 70–80% of a population that did not have a prior history of exposure to infected persons (430). MAC is the most ubiquitous nontuberculous mycobacteria in the environment. It is found in domestic animals, soil, dust, dried plants, and water, especially in fresh and brackish water in warmer climates, such as in estuaries and rivers along the southeast coast of the United States (397,425, 429,431,432). There is evidence that MAC-infected aerosols are produced from these waters and that those MAC strains that are preferentially aerosolized are those more commonly isolated from persons with disease (433).

These studies considered together, and the facts that MAC disease before the HIV epidemic was most common in the southeast United States and was predominantly pulmonary, have given support to the hypothesis of airborne transmission of MAC infection from the environment to humans, at least in HIV negative patients.

MAC Disease in Patients with HIV Disease

In HIV-infected patients with disseminated MAC disease, autopsies have shown massive involvement of the small and large intestinal mucosa and submucosa and adjacent lymph nodes, disproportionate to pulmonary involvement (434,435). These patients tended to have had more gastrointestinal symptoms than pulmonary symptoms and their chest radiographs were often normal (436,437). This strongly suggests that among HIV-infected patients, at least in part infection is acquired from environmental sources via the oral route (i.e. primary gastrointestinal infection from ingesting food or water) (414,434,435). One study implicated showers in a Veteranõ3 Administration hospital as the source of disseminated MAC in HIV-infected patients (438). Other studies, however, prospectively examining environmental sources as the etiology of disseminated MAC in HIV infected patients with CD4 counts below 50 cells/mm^3, were unable to identify either food or water as a source, but suggested MAC strains residing in potted soil may be associated (439,440).

Plasmid-containing MAC strains are associated with increased virulence in animal models of disease, are usually present in isolates associated with human disease, and are much more common in aerosols than in soil or dust (425,441). Furthermore, in HIV-infected patients the prevalence of MAC disease is similar in most areas of the United States, in all HIV risk groups regardless of socioeconomic status, in males and females, and in non-Hispanic whites and blacks (only Hispanics with HIV infection have a lower prevalence) (442). This Þnding also supports the hypothesis that MAC infection is not spread from person to person but from the environment where the organism is ubiquitous (e.g. in water and/or soil) and exposure is unavoidable and common to most, if not all, groups. The similar rate of disseminated MAC among all HIV risk groups does not support homosexual intercourse as a means of transmission, as had been previously proposed (434).

Although the prevalence of MAC disease in HIV-infected patients does not seem to vary by location, race, sex, or HIV risk group, it does vary signiÞcantly by age: Higher rates are seen among younger age groups (442), suggesting that MAC frequently infects young persons, including infants and young children, and that disease results from recent infection rather than reactivation of latent infection (442). The lack of antibody response to MAC in patients with HIV disease and disseminated MAC also suggests recent primary infection, as HIV infected patients lack the ability to mount antibody responses to other primary infections, but not to reactivation infections (416,443,444). A third line of evidence suggesting primary disease from recent environmental exposure is that asymptomatic MAC colonization of respiratory secretions and stool commonly precedes MAC bacteremia among patients with HIV disease (399,407,445Ð447). In the normal host, asymptomatic MAC colonization may also occur, but without dissemination (416). It is thought that immune defenses in ÒnormalÓ human hosts are adequate to protect against MAC infection, whereas in HIV-immunosuppressed persons, MAC acts as an opportunistic pathogen.

Differences in MAC Isolates from HIV and Non-HIV Patients

In addition to biochemical and DNA probe methods used to differentiate MAC from the other nontuberculous mycobacteria, 28 types of MAC can be recognized by seroagglutination. This method has been helpful in epidemiologic studies as only a few serovars predominate in human disease. Serovars 1Ð6, 8Ð11, and 21 are *M. avium*, and serovars 7, 12Ð20, and 25 are *M. intracellulare*. (448,449). A predominance (more than 90%) of serovars 1, 4, and 8 is seen in patients with HIV disease (403,439,450,451). Serovar 4 is the most common in New York and San Francisco, while serovar 8 is the most common in Los Angeles (452). Approximately 40% of MAC isolates from non-HIV patients are *M. avium,* with the rest being *M. intracellulare,* as opposed to 98% *M. avium* among patients with HIV (453). Furthermore, the MAC isolates from patients with and without HIV differ in various ways. MAC isolates from patients with HIV disease, as compared with isolates from non-HIV patients, are more likely to be plasmid-containing, more virulent *in vitro* and in animal models, susceptible to ethionamide and cycloserine, and resistant to kanamycin and rifampin (407,416,453Ð456). Whether these differences in MAC isolates from HIV and non-HIV patients are due to different virulence factors relative to different host susceptibilities, different routes of infection, or distinct geographic preponderances of different MAC serovars remains to be determined.

Prevalence of Disseminated MAC Disease in HIV Disease

Data from the CDC revealed that between 1992 and 1997, the incidence of MAC disease was 76.6 per 1,000 person-years, whereas the incidence of disseminated *Mycobacterium* other than either *M. tuberculosis* or MAC was 6.6 per 1,000 person-years (417). This Þnding differs markedly from the distribution of disseminated nontuberculous mycobacteria before the HIV epidemic (38% MAC, 33% *M. kansasii*, 14% *M. fortuitum* complex, 13% scotochromogens) (397,442). Even in areas of the midwestern United States, where *M. kansasii* disease was relatively high before the HIV epidemic, disseminated MAC accounted for more than 90% of disseminated nontuberculous mycobacteria (442).

The cumulative incidence of disseminated MAC and HIV reported to the CDC, representing approximately 7% of all reported AIDS cases, is certainly an underestimate, (416) as disseminated MAC tends to occur in the later stages of HIV immunosuppression, a mean of 7Ð15 months after other AIDS-deÞning conditions have been diagnosed and reported to CDC. In North America, clinical studies have shown disseminated MAC in 14% to 30% of HIV-infected patients, though these may be underestimates, as autopsy series have shown disseminated MAC in as high as 50% of HIV-infected patients studied (398Ð409).

With the increased use of prophylaxis for MAC, as well as effective therapy for HIV resulting in improved immune function, rates of disseminated MAC have seen a signiÞcant decline (93,410Ð413). The CDC, in surveillance of AIDS deÞning illnesses, noted that the incidence of MAC disease decreased signiÞcantly, from 101.4 per 1,000 person-years in 1992 to 15.6 per 1,000 person-years in 1997 (417). Disseminated MAC is insidious in onset and presents late in the course of HIV disease; therefore, the diagnosis is often missed during life, and clinical studies can underestimate its true prevalence. On the other hand, autopsy data can overestimate the proportion of HIV-infected patients who develop disseminated MAC due to a bias toward patients who die with unexplained clinical syndromes (416).

In summary, MAC disease in HIV-infected appears markedly different than in HIV negative patients without AIDS (407,425,434,435,442,453Ð456): (1) it is much more common, (2) it constitutes a much higher proportion of all nontuberculous mycobacterial cases, (3) it is much more likely to be disseminated rather than a chronic Þbrocavitary pulmonary disease superimposed upon other chronic pulmonary diseases which are characterized by poor lung drainage, (4) the route of infection seems to be mainly gastrointestinal rather than respiratory, and dissemination appears to originate predominantly from the gastrointestinal source, (5) it is most common in younger age groups and its incidence appears to decrease with increasing age, rather than occurring predominantly in

those middle aged or older, (6) the geographic distribution is fairly uniform throughout the United States rather than predominantly in the southeast, and (7) the serotypes, DNA sequence, prevalence of plasmids, virulence, and drug susceptibility patterns of MAC isolates from HIV-infected patients are different from those isolated from HIV negative patients. Although the precise reasons for these differences are unclear, it is likely that HIV-infected patients have an immune defect that makes them more susceptible to MAC infection and disease, especially via the gastrointestinal route. The ability to bind to and enter intestinal epithelial cells has been demonstrated with some strains of MAC *in vitro*, a property that may contribute to the relative virulence of MAC in HIV-infected patients via the gastrointestinal tract (457–459). It is likely that once invasion of the gut epithelium has occurred, the profound immune defect in advanced HIV disease permits widespread dissemination. It is also possible that specific strains of MAC are uniquely virulent in this setting. It is clear that with improvement of the immune function in patients on HAART, the incidence of MAC is dramatically decreasing.

Clinical Features of MAC Disease

Disseminated MAC Disease

Unlike TB, disseminated MAC disease usually occurs in the later stages of HIV immunosuppression. The clinical signs and symptoms of MAC infection are nonspecific and therefore difficult to distinguish from other HIV-related conditions or drug toxicities. Nevertheless, numerous studies have revealed fairly consistent information regarding the clinical picture of MAC disease in patients with HIV disease (399–403,418,423,436,437, 458–474). Common symptoms include fever, drenching night sweats, fatigue, anorexia, malaise, and weight loss, all of which are often present for several months before the diagnosis is made (e.g. patients present with a chronic wasting syndrome). Abdominal pain and diarrhea may be prominent symptoms in patients with MAC infection of the bowel. Involvement of the small bowel can produce an illness mimicking Whipple disease, with malabsorption and similar intestinal histologic findings (399,435,474–476). Enlarged infected periportal lymph nodes may cause extra hepatic biliary obstructive jaundice (399). Despite frequent pulmonary involvement, only 9% of 114 patients with disseminated MAC disease had pulmonary symptoms and signs suggestive of pulmonary MAC (477). Diagnoses other than MAC disease should be excluded in a patient with respiratory symptoms (436,437).

On physical examination, patients are often febrile, cachectic, and may or may not have chest findings, peripheral or bulky intraabdominal lymphadenopathy, or hepatosplenomegaly. Subclinical hepatitis, thrombocytopenia, marked leukopenia, and progressive anemia including red cell hypoplasia (478) may occur, suggesting involvement of bone marrow and liver. Anemia and elevated alkaline phosphatase may be relatively more common in disseminated MAC disease compared with other HIV related opportunistic infections.

Among patients with HIV disease, MAC has also presented as localized pneumonia (447), mediastinal-endobronchial fistulas appearing as endobronchial mass lesions on bronchoscopy (479,480), mediastinal-esophageal fistulas with esophagitis (481), terminal ileitis mimicking Crohn's disease (482), pericarditis (483), meningitis (484), endophthalmitis (485), septic arthritis and osteomyelitis (486), cutaneous abscesses (487), and infections of skin, lymph node, and rectal mucosa in association with Kaposi's sarcoma (399,488). Localized disease is relatively uncommon and usually occurs in patients with higher peripheral blood CD4 counts.

MAC Colonization vs. Pathogen in HIV Disease

The approach to the patient with nontuberculous mycobacteria isolated from the airway specimen is challenging. Patients with HIV found to have nontuberculous mycobacteria in sputum or bronchoalveolar lavage with little evidence of pulmonary disease (e.g. no respiratory symptoms or radiographic parenchymal involvement) are usually felt to be without clinical significance (424). MAC rarely causes isolated pulmonary disease in patients with HIV disease. Rigsby et. al reported that 46 of 650 AIDS patients had positive sputum cultures for MAC but only two were diagnosed confidently as having pulmonary MAC disease (489).

Of note, cases of focal lymphadenitis and fever, not associated with bacteremia or other organ involvement, have been reported in patients whose CD4 count increased after the initiation of HAART; this has been considered to be due to immune reconstitution with an inflammatory response (490).

Diagnosis of MAC Disease

Disseminated MAC infection should be suspected in any HIV immunosuppressed patient who presents with unexplained systemic symptoms. The great majority of patients will have fever, debilitation, and weight loss with a peripheral blood CD4 count of less than 100/mm^3 (399,400,423,491). Of 55 patients with MAC disease, Modilevsky et al. found that 48 (87%) had another AIDS-defining illness diagnosed 2 to 37 months (mean, 7.8 months) before MAC disease was diagnosed (423). Of 50 patients with MAC disease diagnosed before death, Hawkins et al. found that 48 (96%) had an AIDS defining illness 1 to 24 months (mean, 9.3 months) before MAC disease was diagnosed (399). In two studies of patients with MAC infection, the concentration of peripheral blood

CD4 lymphocytes averaged 52 cells/mm^3 and 70 cells/mm^3 (400,423), in contrast to HIV-infected patients with TB in whom the mean or median peripheral blood CD4 lymphocyte concentration was 170 cells/mm^3 in one study and 326 cells/mm^3 in another (201,423).

Blood cultures remain the most common method of diagnosing disseminated MAC disease. One retrospective study suggested that two blood cultures will detect most cases (95%) of disseminated MAC infection (492). Laboratory testing has recently become more sensitive for mycobacterium with the BACTEC TB460, which has yielded a higher number of MAC isolates (493,494).

Although pulmonary involvement with disseminated MAC is frequent in HIV-infected patients, prominent pulmonary symptoms are rare (423,436,437). Chest radiographs may show a nodular, diffuse, or patchy inÞltrate with or without hilar or mediastinal adenopathy; commonly, they may appear normal despite the presence of disseminated disease (465). Cavitary disease, pleural effusions, and a miliary pattern are uncommon (465). Although the radiographic Þndings are nonspeciÞc, they may lead to sputum studies, bronchoscopic washings, or lung biopsy specimens.

Abdominal CT scans may show marked hepatosplenomegaly, diffuse jejunal wall thickening, and large retroperitoneal and mesenteric lymph nodes of homogeneous soft-tissue density, which are quite suggestive of disseminated MAC in this setting (495,496). Lymph nodes with central or diffuse low attenuation also may be seen in HIV patients with disseminated MAC on CT scanning, but are less common and more typical of TB, in which caseation necrosis is more frequent (495). Gallium scans may also be useful to locate infected sites (e.g. lung, lymph node, bone marrow, skin) and to direct biopsies (487,497Ð499).

Liver biopsy with acid-fast staining might be of use in HIV-infected patients with elevated liver related enzymes in order to make the diagnosis of disseminated MAC, and mycobacteria may be visible on pathologic studies. On the other hand, the diagnostic yield of a liver biopsy is very limited in patients with suspected disseminated MAC disease who have negative blood cultures and normal liver-related enzymes (500).

Microbiology

The genus *Mycobacterium* consists of close to 100 different species (230), all of which are similar in acid-fast staining. Many of these may be isolated from humans, though many are found in the environment. A specialized laboratory should be able to provide a precise species identiÞcation of most AFB isolated from humans. Clinical suspicion for a fastidious mycobacterium, such as *M. haemophilum* or *M. genevense*, needs to be conveyed to the laboratory, which in turn can inoculate special media and utilize appropriate incubation conditions. In contrast, the distinction between pathogen and saprophyte is not always clear-cut for each individualÕs isolates. Each mycobacterial isolate, like each patient, must be evaluated individually as to its potential to cause disease (424).

Among patients with disseminated MAC, the organism has been cultured from almost every body Þuid and tissue, including blood, stool, urine, sputum, CSF, lung, bone marrow, liver, lymph node, spleen, pancreas, tongue, esophagus, stomach, intestine, heart, adrenals, kidney, eye, and skin (2,73,399Ð401,407,423,431,434,446,501Ð503). A positive culture from a normally sterile site, such as blood, bone marrow, liver, or lymph node (the most commonly involved and accessible sterile sites), is diagnostic of invasive and (usually) disseminated disease. However, false-positive cultures of MAC and other mycobacteria as a result of contaminated laboratory reagents or other technical laboratory problems have occurred (504).

Blood culture is a particularly good noninvasive test for disseminated MAC in HIV-immunosuppressed patients and is the diagnostic procedure of choice in this setting; MAC bacteremia tends to be persistent and blood cultures, using a lysis-centrifugation technique (Dupont Co., Wilmington, DE, U.S.A.), are positive in the great majority of cases (e.g. 70% to 98%) (399,401,403,407,423,501,502, 505). As previously stated, one retrospective study suggested that two blood cultures will detect most cases (95%) of disseminated MAC infection (492). As MAC usually is not found free in plasma (506), a lysis-centrifugation technique is employed to increase the sensitivity of mycobacterial blood cultures and is accomplished by lysis of peripheral blood leukocytes, which releases viable intracellular mycobacteria which are then concentrated by centrifugation. The concentrate then can be plated on conventional media (eg. Lowenstein Jensen slants, Middlebrook 7H10 or 7H11 agar). Culture on agar takes 15Ð20 days. Plating on the solid agar, however, allows quantitative colony counts in blood, a useful means of determining both the magnitude of infection and the response to treatment (especially useful in clinical drug trials) (403,407,501,502,507,508).

Unprocessed blood (5 ml) also can be inoculated directly into BACTEC TB460 broth (avoiding the tedious process of lysis and centrifugation). The radiometric BACTEC 460TB system allows more rapid diagnosis by detecting growth of mycobacteria within 6 to 12 days; however, this technique precludes quantitative measurement of the bacteremia. Use of a lysis centrifugation system followed by inoculation of a BACTEC 460TB radiometric broth medium may be inhibitory and is not recommended. DNA probes for MAC can offer a rapid two-hour species identiÞcation once mycobacterial growth in BACTEC 460TB broth or on solid culture media is achieved (509,510). Auramine Þuorochrome staining of uncultured peripheral blood concentrate for AFB is insensitive for detecting mycobacteremia and generally is not done. Buffy coat smears for AFB are also insensitive

but have been reported to detect mycobacteremia in patients with AIDS (511–513).

Stool culture and AFB smear are simple noninvasive tests that may be used to investigate for invasive MAC disease if the patient has constitutional symptoms (399). Although there is some evidence that a positive AFB smear of stool (subsequently identified as MAC) is indicative of disseminated MAC disease, the predictive value of a negative AFB stool smear or a positive stool culture is poor (514). Positive MAC cultures from sputum or bronchial washings are common and raise suspicion for, but are also not diagnostic of, invasive or disseminated disease (399,409,446,465). If MAC is found in pulmonary or stool specimens, other specimens from sterile sites (e.g. blood, bone marrow) should be cultured for MAC to search for proof of disseminated disease. Positive cultures from respiratory secretions and stool commonly precede bacteremia; therefore, close clinical follow-up of patients with these findings is necessary (399,445–447). Horsburg et al. found that 8 (33%) of 24 patients colonized with MAC in sputum or stool progressed to disseminated disease with the same species of MAC with which they were colonized, whereas none of 16 patients colonized with other nontuberculous mycobacterial species progressed to dissemination with the colonizing species ($p = 0.01$). (Mean follow-up was 5.2 months for patients colonized with MAC and 7.3 months for patients colonized with other mycobacteria) (445). Disseminated MAC frequently occurs in the absence of prior detectable respiratory or gastrointestinal colonization and routine screening for colonization is felt to be impractical (515).

Currently, uniform agreement concerning the indications for susceptibility testing of clinically significant isolates of MAC does not exist (424). However, investigators who have extensively studied MAC have recommended that susceptibility testing be performed in the following situations:

i. clinically significant isolates from patients on prior macrolide therapy
ii. isolates from patients who develop bacteremia while on macrolide prophylaxis
iii. isolates from patients who relapse while on macrolide therapy
iv. initial isolates from blood or tissue (patients with disseminated disease) or from clinically significant respiratory samples to establish baseline values.

For susceptibility testing of other nontuberculous mycobacteria, the reader is referred to the Tentative Standard (M24-T2)-*Susceptibility Testing of Mycobacteria, Nocardia, and Other Aerobic Actinomyces*, of the National Committee of Clinical Laboratory Standards (516).

Pathology

Disseminated MAC in patients with HIV disease primarily involves the reticuloendothelial system (bone marrow, liver, spleen, and lymph nodes) and gastrointestinal tract. Massive MAC involvement in the intestinal Peyer's patch and regional lymph nodes, along with intestinal erosions, is common. The most common gastrointestinal site is the duodenum; the esophagus and large intestine are less frequently affected (517).

The distinctive pathologic feature of MAC disease in patients with HIV disease (on hematoxylin and eosin staining of tissue specimens) is a poorly defined granuloma consisting of pale-blue striated histiocytes filled with mycobacteria (467,473,518–521). The striations within the histiocytes represent large numbers of AFB as demonstrated on Ziehl-Neelsen staining (see Fig. 17.5). The features often described in typical granulomatous inflammation, such as lymphocytic infiltrates, caseation necrosis, epithelioid histiocytes, and Langhans giant cells, are present in only a few cases. Occasionally, there is no suggestive tissue reaction at all, despite positive AFB smears and positive cultures for MAC (423,460) (Fig. 17.5B, C). Tissue culture may be positive when the AFB smear is negative. Therefore, all specimens from HIV-immunosuppressed patients must be stained for AFB and cultured for mycobacteria, regardless of tissue reaction, AFB smear results, or concomitant nonmycobacterial pathology. Bone marrow is easily biopsied and frequently yields diagnostic specimens, as do biopsies from lung, lymph node, liver, and the gastrointestinal tract. On gross inspection, involved organs may appear yellow because of the pigmentation of the organisms (419).

When disseminated MAC is suspected, the best specimens for culture are blood, stool, bone marrow, and, if necessary, liver. Taken together, the yield should be almost 100% (399). Cultures of respiratory, stool, and sterile site specimens are frequently positive when the smear of the specimen is negative (501).

Assessment of Morbidity and Mortality from Disseminated MAC Disease in HIV Disease

In patients with HIV disease, MAC infection disseminates widely and involves many tissues and organs (eg. blood, bone marrow, liver, spleen, lymph node, and gastrointestinal tract), but the organism has relatively low virulence. Autopsy series suggest that it does not usually cause significant tissue damage or organ failure (408,522). Nevertheless, the bacterial load in disseminated MAC is formidable (as high as 10^4–10^5 colony forming units of MAC/ml blood within circulating monocytes and 10^9–10^{10} bacilli/g of tissue within fixed macrophages of the reticuloendothelial system), and clinical studies suggest that disseminated infection contributes significantly to fever and debilitation among patients in the late stages of HIV disease (436,505,523,524).

It is uncertain whether patients with disseminated MAC die of this disease or multiple other coexisting infections (eg. PCP or cytomegalovirus) (464,525). In one study from

1989, the median survival for HIV-infected patients with disseminated nontuberculous mycobacteria (almost all MAC) was 7.4 months, whereas the median survival for HIV-infected patients without MAC was 13.3 months ($p < 0.0001$) (442). The survival analyses for patients in this study, however, were challenged (525). A second similar case-controlled study calculated the median survival in these two groups as 3.5 and 9.1 months, respectively (526). In a third study involving 1,044 patients with AIDS or HIV-related condition who were started on zidovudine, 12.4% developed MAC disease during two years of follow-up, and this was a strong independent predictor of death (527). It has been suggested that the shortened survival of AIDS patients with MAC disease (which frequently involves the intestine) results from inanition (400,518,528). The preponderance of evidence suggests that MAC disease does contribute (directly or indirectly) to the morbidity and mortality of HIV disease in its late stages.

Treatment for MAC Disease

Challenges of Treatment for MAC Disease in HIV-infected Patients

Pulmonary or disseminated MAC disease has traditionally been difficult to treat in patients without HIV because of the relative drug resistance of the organism. MAC disease in patients with HIV disease responded even more poorly to antimycobacterial chemotherapy (396,529,530), primarily due to severe immunosuppression, the large number of organisms, and possibly because MAC isolates from HIV-infected patients have more virulence or different drug susceptibility patterns from those of non-HIV isolates (407,454,456). Unlike the treatment for TB, it is less clear whether various drug regimens for disseminated MAC in HIV patients have a major impact on morbidity and mortality, which drug regimens and what drug doses are most effective, and whether *in vitro* drug susceptibility results (e.g. testing single drugs or drug combinations) predict bacteriologic and clinical response to therapy (523,531). *In vitro* drug concentrations that are easily achievable as serum levels *in vivo* and that predict clinical usefulness of the drug are well established for TB but are not well defined to guide treatment for MAC disease. In MAC disease, clinical response or lack of response to a drug is often poorly predicted by the results of standard qualitative drug susceptibility tests. The *in vitro* critical drug concentrations used in these qualitative tests were originally developed and standardized for *M. tuberculosis,* not for MAC (532).

An exception may be clarithromycin. A correlation between minimal inhibitory concentration (MIC) and the microbiologic response to therapy was established in a clinical trial of clarithromycin monotherapy for disseminated MAC disease (533,534). More than 90% of patients had a significant decrease in bacteremia, and most patients became culture negative when their initial MAC isolates had an MIC of clarithromycin of 2 mcg/ml or less using the BACTEC TB460 susceptibility test system. In contrast, patients had a clinical and bacteriologic relapse when the MIC increased to 32 mcg/ml or higher. Therefore, MAC strains can be classified for accuracy and clarity as either susceptible or resistant to clarithromycin if the MIC is 2 mcg/ml, or 32 mcg/ml or greater, respectively. The clinical implications of MIC between 4 and 16 mcg/ml are unclear (535). With clarithromycin as a possible exception, conventional qualitative drug susceptibility testing (as used for *M. tuberculosis)* should not be applied to MAC (424,535); however, some centers with extensive experience believe that quantitative and combination drug susceptibility testing on MAC isolates may furnish information that facilitates the choice of drugs, drug dosages, and drug combinations that are more efficacious than standard regimens (536).

Often MAC is resistant to two of the standard first-line TB drugs, isoniazid and pyrazinamide, but shows variable susceptibilities *in vitro* to rifampin, rifabutin, ethambutol, clofazimine, ciprofloxacin, ofloxacin, levofluxacin, imipenem/cilastatin, rifapentine, cycloserine, amikacin, clarithromycin, and azithromycin (403,523,531,532, 537–541). The effects of drugs in combination are often additive and occasionally synergistic and bactericidal (542,543). Nevertheless, there have been conflicting reports on the clinical efficacy of regimens that include drugs to which MAC shows some susceptibility (399,400, 403,414,466,470,523,540,544–553). Initial reports indicated a lack of success using drug regimens that included rifabutin and clofazimine (399,551). Subsequently, several reports showed that similar drug regimens, including rifabutin and clofazimine, with or without amikacin, resulted in defervescence, a resolution of night sweats, malaise, and (less frequently) diarrhea, a decline in mycobacteremia and, in some cases, the sterilization of blood cultures without bacteremic relapses (505,528, 546–549).

Symptomatic and bacteriologic responses also have been shown using a drug regimen without rifabutin (i.e. ethambutol, clofazimine, ciprofloxacin, and rifampin) (554) and without rifabutin and clofazimine (i.e. ethambutol, rifampin and ciprofloxacin, with or without amikacin) (555,556). The more favorable results in these therapeutic studies may be explained by the use of more drugs to which MAC is susceptible (i.e. four or five), an earlier start of therapy after the onset of symptoms (i.e. within four weeks) and therapy that is continued longer (i.e. more than three months) before assessing the response to therapy (528).

Clarithromycin, azithromycin, and ethambutol (as opposed to agents such as rifampin, sparfloxacin, and clofazimine, which also have *in vitro* MAC activity) demonstrated microbiologic activity in clinical trials of short duration when used as single agents. Reduced

numbers of MAC colony forming units were found in the blood after four to six weeks of therapy, and many patients with reductions in MAC bacteremia had considerable resolution of fever and weight loss (533Ð536,557,558). Clinical and bacteriologic improvement was not sustained despite continued therapy, however, suggesting that monotherapy with these agents at the doses given, does not eradicate MAC and that resistance can develop, perhaps similar to the acquired drug resistance that occurs when monotherapy is used in the treatment of TB.

More recent studies utilizing macrolide antibiotics (e.g. clarithromycin or azithromycin) have shown signiÞcantly improved success. A randomized trial showed that the combination of rifabutin (300mg to 600mg/day), clarithromycin (1,000 mg twice a day), and ethambutol (15mg/kg/day) was superior to the combination of rifampin, clofazimine, ciproßoxacin, and ethambutol, with more rapid resolution of bacteremia and increased survival time (559). In this study, the higher dose of rifabutin was more effective, but frequently caused uveitis (559). For clarithromycin, a prospective randomized trial suggested that the maxmum dose of clarithromycin should be 500 mg twice a day, because the regimen with clarithromycin 1,000 mg twice a day had excess mortality (relative risk of 2.43) (560). Other studies have shown that initial regimens containing a macrolide (clarithromycin, azithromycin) are better than those without a macrolide, and that both clarithromycin and azithromycin are effective (561,562). At least one study has shown that cloÞzimine does not add to the efÞcacy of macrolide regimens and may actually result in excess mortality (558,563).

Probably the best results of therapy for disseminated MAC disease have been seen in patients treated with both HAART regimens and antimycobacterial agents (564). However, given the signiÞcant pharmacokinetic interactions, treatment with both classes of agents must be carefully dosed and monitored (see below).

In contrast to TB, there is no evidence that MAC is communicable to the general population, and MAC disease is less often fatal than TB when left untreated (423,565,566). Therefore, when AFB are found in any specimen from a patient with HIV disease or suspected HIV, our approach, pending culture results, is to institute promptly standard anti-TB drugs as outlined in the section on TB, though this may change with the availability of rapid nucleic acid ampliÞcation testing for TB. With rapid culture methods and speciÞc DNA probes, mycobacteria are now routinely identiÞed within one to three weeks (403,501,502,510,523). If cultures reveal MAC, which is felt to account (or probably account) for the patientÕs signiÞcant symptoms (eg. in the absence of other identiÞed opportunistic infections), the patient has reasonably intact renal and liver functions, and the patient is willing to cooperate in a multidrug treatment plan, an anti-MAC drug regimen may be initiated on a trial (e.g. three-month) basis.

The U.S. Public Health Service (USPHS) Task Force has recently published the following guidelines for the treatment and prophylaxis of disseminated MAC disease in AIDS patients which was recently revised (535,567).

1. Every regimen should include either azithromycin (500 mg daily) or clarithromycin (500 mg twice daily) with one or more other drugs. (At least two agents should be used.)
2. EMB (15 mg/kg) should be used as a second drug with the addition of one or more of the following as a third or fourth agent, especially for HIV-infected patients with severe symptoms and/or extensive disease: either rifabutin (300mg daily), or RIF (600 mg daily), ciproßoxacin (750 mg twice daily), and in some situations amikacin (7.5Ð15 mg/kg daily); INH and PZA are not used.
3. The same treatment regimen should be used for patients on rifabutin or macrolide prophylaxis for MAC who developed disseminated MAC disease despite prophylaxis. A majority of HIV-infected patients who develop disseminated MAC disease despite prophylaxis have isolates susceptible to these prior prophylactic drugs (568).
4. Therapy should continue for the duration of the patientÕs life if clinical and microbiologic improvement is observed. If CD4 counts increase to more than 100 cells/mm^3 following 6Ð12 months of HAART (minimum of 12 mo of MAC treatment should be received), discontinuation of MAC therapy could be considered if there are negative blood cultures and minimal symptoms, but available data are insufÞcient to warrant a recommendation at this time.
5. The usefulness of drug-susceptibility testing to guide the initial selection of drugs is not known.
6. Initiation of HAART regimens should be considered, if not already begun. The choice of regimen should take into account potential drug interactions and medication dosages appropriately adjusted (see TB Section).

From experience with TB-HIV coinfected patients, when these protease inhibitors are used, indinavir or nelÞnavir may be used in combination with rifabutin in order to minimize the incidence of drug interactions (see TB Section).

Clinical manifestations of disseminated MAC, such as fever, weight loss, and night sweats, should be monitored routinely during the initial weeks of therapy. The use of follow-up blood cultures every four weeks during initial therapy may also be helpful in assessing the efÞcacy of the drug regimen. Most patients who respond will show signs of clinical improvement within the Þrst four to six weeks of therapy, with the attainment of sterile blood cultures taking four to twelve weeks (535). If no clinical or bacteriologic response is noted within three months of therapy, discontinuation of the therapy should be considered at this point.

In cases of a bacteremic relapse after an initial clinical and microbiologic response, determining the MIC of azithromycin or clarithromycin is useful to indicate whether these agents will be useful in subsequent therapeutic regimens (535). There are no long-term studies to help in determining the optimal maintenance therapy regimen for disseminated MAC. The aim of treatment is to reduce the bacterial load and thereby to ameliorate symptoms and improve quality of life. These objectives, even if achievable, must be weighed against the signiÞcant toxicity of the multidrug regimen. In one multidrug clinical trial, adverse reactions requiring the discontinuation of a drug to treat MAC disease occurred in 46% of patients (554).

Overall, the eventual successful treatment and prevention of MAC will probably depend on improving immunity utilizing HAART and other interventions that encourage immune reconstitution.

Drug Toxicity and Interactions

Evidence suggests that macrolides (clarithromycin and azithromycin) are the single best agents to include in the multidrug regimen for disseminated MAC. They result in rapid sterilization of blood cultures and appear to be fairly well tolerated in patients with HIV disease. Clairithromycin and azithromycin have similar side effect proÞles, the more common being nausea, vomiting, anorexia, diarrhea, abdominal pain, headache, ototoxicity, an unpleasant bitter taste, and rarely, cholestatic jaundice. Clairthromycin, however, may be more prone to drug interactions, especially with the HIV protease inhibitors and rifabutin due to their effect on CYP450 enzymes; azithromycin has little effect on the CYP450 system. The dose of clarithromycin may need to be reduced in severe renal insufÞciency (535,569,570).

The most common adverse effects of clofazimine are pink to brownish black discoloration of skin and various other tissues and ßuids, skin dryness, rash, and gastrointestinal symptoms including nausea, vomiting, abdominal pain, diarrhea, and anorexia (531,571). Peripheral neuropathy and rarely ocular changes can also occur (535). The addition of clofazimine to a clarithromycin-containing regimen does not improve its efÞcacy and may increase mortality (563,572).

The adverse effects of quinolones include occasional nausea, vomiting, abdominal pain, diarrhea, rash, headache, and lightheadedness. The quinolones have also been associated with tendon rupture (573) and severe photosensitivity reactions have occurred. Children under the age of 18 should generally not receive quinolones because of the potential for premature closure of the epiphiseal plate resulting in diminished growth (574,575). Concurrent administration with food or magnesium or aluminum containing products such as antacids, sucralfate, or ddI will markedly diminish the absorption of ßuoroquinolones. Ciproßoxacin is an inhibitor of the CYP450 system and may increase the toxicity of many drugs such as theophylline, coumadin, and phenytoin. Newer quinolones such as levoßoxacin can be used instead of ciproßoxacin and generally have fewer and less signiÞcant drug interactions, but similar efÞcacy and adverse effects. Depending on the drug, the dose may need to be reduced in either hepatic disease or renal insufÞciency (569,570).

The major adverse effects of amikacin are nephrotoxicity and ototoxicity. Ototoxicity is frequent after eight weeks of therapy and is sometimes irreversible (528,576). The dose of amikacin should be reduced in the presence of advanced age or renal insufÞciency. (570).

The toxicities of the conventional antimycobacterial drugs rifampin and EMB are described in the ÒTreatment of TBÓsection (149,535).

Rifabutin is generally well tolerated (at least as well as rifampin), and the types of adverse reactions have been similar to those reported for rifampin. The most common adverse effects are mild elevations of liver enzymes, gastrointestinal distress (nausea, vomiting, diarrhea), and hypersensitivity reactions such as rash and fever. Reversible bone marrow suppression with leukopenia and thrombocytopenia has also been observed (577). Rifabutin used for MAC prophylaxis in HIV-infected patients has been associated with uveitis and arthritis (578). However, this has generally been at higher doses or when given concomitantly with clarithromycin and/or azole antifungal agents. (559,560,579) It has been shown that 80Ð100% of MAC strains are susceptible to rifabutin at concentrations of 1.0 mcg/ml (531). Although plasma levels of rifabutin do not reach this concentration at conventional doses, higher tissue concentrations do occur (580). Compared with rifampin, rifabutin is a weaker enzyme inducer and may be less likely to interfere with the action of multiple drugs (e.g. coumadin, oral contraceptives, methadone, oral hypoglycemics, digitoxin, quinidine, disopyramide, dapsone, ketoconazole, corticosteroids, HIV protease inhibitors and non-nucleoside reverse transcriptase inhibitors) (569Ð571,581,582). Rifabutin is excreted partly through the biliary route and partly through the kidney. In contrast to rifampin, the dose must be lowered in renal insufÞciency (577). Interestingly, rifabutin inhibits the replication of HIV, although this is not of clinical signiÞcance (583). Rifapentine, another derivative of rifampin, may also be effective against MAC. Its pharmacokinetic proÞle appears to be midway between rifampin and rifabutin; however, at least one study comparing rifampin to rifapentine in TB patients demonstrated an increased rate of relapse with mono-resistance to rifamycins occurring in HIV-infected patients receiving rifapentine and INH once a week in the continuation phase (584).

Monitoring for toxicity of antimycobacterial drugs in patients with HIV disease is often confounded by the occurrence of gastrointestinal, hepatic, hematologic, and dermatologic abnormalities from other drugs, other concommitant illnesses, or the mycobacterial disease itself.

The presence of such abnormalities is therefore not an absolute contraindication to the use of antimycobacterial agents. The physician, however, must be alert to true anti-MAC drug toxicity and to the drug interactions that occur among the multiple concomitant medications these patients take. It has been shown that patients can tolerate concurrent therapy with anti-retrovirals and conventional anti-mycobacterial drugs without unacceptable toxicity (450).

An additional problem is that of possible malabsorption of drugs. Gordon et al. demonstrated that most of the 27 patients receiving oral RIF, EMB, ciproßoxacin, and clofazimine for disseminated MAC disease had probable impairment in the absorption of some or all of their antimycobacterial agents. Most patients did not achieve the usual serum concentrations with all four drugs. Whether adjusting dosages on the basis of serum drug levels will be of clinical beneÞt needs to be further studied (585,586).

Prevention

As MAC is ubiquitous within the environment, it seems impossible to prevent exposure. Measures to prevent MAC disease in HIV-infected patients include the use of antiretroviral therapy to prevent and reverse immunosuppression, and the early preventive use of a macrolide or rifabutin when the T-helper cell count falls below 50/mm^3 (567). In two large, prospective, randomized, double blind, multi-center studies, rifabutin (300 mg/day taken orally) reduced the frequency of MAC bacteremia by half during the course of treatment (mean, 218 days). The beneÞt was limited to those patients with CD4 counts below 100/mm^3 at entry. Rifabutin also seemed linked to a clinical beneÞt (fever, fatigue, Kamofsky score, anemia, elevated serum alkaline phosphatase, and need for hospital admission). Discontinuation of rifabutin or placebo because of apparent toxicity (rash, gastrointestinal intolerance, and neutropenia) totaled 16% in the rifabutin group versus 8% in the placebo group. When MAC bacteremias occurred during rifabutin prophylaxis, the prophylaxis did not appear to have selected out for isolates with increased resistance. Although not statistically signiÞcant, there was a trend toward increased survival in the rifabutin group (587). More recently, clarithromycin (588) or azithromycin (568) have become the preferred prophylactic agents due to less frequent dosing, minimal interaction with protease inhibitors, and proven efÞcacy (improved survival in the treated group (567)).

The following are the guidelines for MAC prophylaxis from the USPHS/IDSA, published in 1999 (567).

1. MAC prophylaxis should be considered for all patients with CD4 cell counts below 50/mm^3.
2. Therapy should be initiated with clarithromycin 500mg PO twice daily or azithromycin 1200 mg PO weekly, and continued through the patientÕs lifetime unless, with HAART, a CD4 count rises above 100/mm^3 for a sustained period (e.g. more than three to six months) and there is sustained suppression of HIV plasma RNA for a similar period.
3. If clarithromycin or azithromycin cannot be tolerated, rifabutin (300 mg PO daily) is an alternative prophylactic agent.
4. Before starting preventive therapy, patients should be screened for preexisting mycobacterial disease. Screening may include a chest radiograph, tuberculin skin test, and mycobacterial blood culture.

Future Prospects

Variables such as drug-tissue concentrations and the activity of agents within macrophages inßuence the relevance of serum drug concentrations and *in vivo* drug efÞcacy (523). For example, some beta-lactam antibiotics, such as ampicillin, have promising *in vitro* activity against MAC but are not effective against intracellular organisms, thus limiting their clinical effectiveness (531). Liposome encapsulation of drugs or other carrier technology might be used in the future to enhance delivery of drugs to intracellular sites and thereby increase drug activity against intracellular mycobacteria (523,589). Liposome encapsulation of amikacin improves its activity as compared to free amikacin in the beige mouse model of MAC infection (531). Further studies are needed to determine the efÞcacy and safety of higher drug doses on an intermittent dosing schedule, and to determine the clinical relevance of obtaining serum drug levels and quantitative drug susceptibility tests for single drugs or drug combinations (590,591). As new anti-HIV and immunostimulating drugs are developed, new and existing chemotherapy regimens for MAC may become more effective, or even unnecessary, in the setting of HIV disease and may be reevaluated.

Immune Regulation and Modulation in MAC Disease

The abnormal susceptibility of HIV-infected patients to mycobacteria has been attributed in part to deÞciencies in T-lymphocyte-produced cytokines that activate macrophages. Facilitating anti-mycobacterial macrophage activity and delivering effective drugs into the macrophage appear to be critical as tissue macrophages in HIV-infected patients with disseminated MAC are literally packed with these bacilli (531) (Figs. 5CÐE). Nevertheless, the precise mechanism by which the macrophage defends against MAC is unknown.

Recombinant granulocyte-macrophage colony-stimulating factor (GM-CSF) has been shown to inhibit the growth of or kill MAC (592,593). Tumor necrosis factor (TNF) also has been shown to enhance *in vitro* killing of MAC in human macrophages, and the bactericidal effect was augmented when used in combination with antimicrobial agents (594). Furthermore, treatment of macrophages *in vitro* with TNF plus IL-2 reduces intracellular replication of MAC (593).

Bermudez and Young, and Toba et al. found that gamma-interferon does not have macrophage-activating factor activity for *M. avium* infection of human monocytes (595,596).

Nevertheless, Holland et al. (597) found that interferon-gamma in combination with conventional therapy was effective for treating cases of refractory disseminated nontuberculous mycobacterial infection, mainly MAC. These patients may have shared a common defect resulting in altered interferon-gamma production and an inability to kill mycobacteria. Not all of these patients were HIV-infected, and they probably represent only a small subset of patients with MAC disease.

Schnittman et al. (524) showed that high titered anti-MAC immune serum signiÞcantly enhanced the killing of MAC by monocytes from both HIV-infected patients and healthy controls, and also prevented the outgrowth of surviving MAC. One way microorganisms may survive intracellular killing is by inhibition of fusion of lysosomes with the phagosomes containing the organisms, thus avoiding exposure to hydrolytic enzymes (598). Schnittman et al. hypothesized that the anti-MAC antibody may alter the outer capsule of the MAC bacillus, thereby overcoming the inhibition of fusion of the phagosome with the lysosome (524).

Winter et al. found that patients with HIV disease and disseminated MAC infection had anti-MAC antibody levels similar to those of uninfected HIV patients and normal controls, suggesting an inability to mount an anti-MAC antibody response in HIV disease (444). Crowle et al. found that normal human serum inhibits the growth of *M. avium* in normal human macrophages and that sera from HIV-infected patients were deÞcient in this inhibitory property. Furthermore, macrophages from HIV-infected patients were unresponsive to the inhibitor in normal serum (599). Further studies on how normal macrophages respond to the serum inhibitor in order to suppress *M. avium* infection and studies on the clinical efÞcacy of hyperimmune (anti-MAC) gamma globulin in HIV-infected patients with disseminated MAC are needed.

The precise roles of monocyte-T-cell interactions and various cytokines and antibody-dependent mechanisms in enhancing macrophage killing of MAC and other mycobacteria are still unknown. Even though MAC and *M. tuberculosis* are both intracellular pathogens, reside in monocytes and macrophages, and presumably are controlled by cellular immune responses, they may present different challenges to the immune system and therefore may need to be handled differently.

For example, as stated above, HIV-infected patients with disseminated MAC do not produce antibodies in response to infection, and there is some evidence that humoral immunity may play a role in the defense against this organism (444,524,599). In contrast, HIV-infected patients with reactivation TB commonly have antibodies against *M. tuberculosis,* but humoral immunity seems unimportant in controlling the disease (443). Understanding the normal immune defense against MAC infection and understanding the basis of the speciÞc vulnerability of patients with HIV disease to MAC will provide insight for the development of new preventive and therapeutic strategies. In the Þnal analysis, prevention of immunosuppression or restoration of immune function will have the greatest impact on the overall morbidity and mortality of HIV-infected patients and remains the ultimate goal of therapy in this disease.

Future of Mycobacterium Avium Complex and HIV

There is still much to learn about MAC infection and disease in both AIDS and non-AIDS patients. What is the primary route of infection (pulmonary or gastrointestinal)? Do the infecting strains of MAC and the route of infection differ in AIDS and non-AIDS patients, and, if so, why? Why is the geographic distribution of MAC disease among AIDS patients different from that of non-AIDS patients? Is MAC disease usually the result of reactivation of a persistent latent infection (as in TB) or the result of direct progression of primary infection following recent exposure? What is the normal immune response to MAC infection? Why is MAC disease so common in AIDS, and why in this setting does it occur so much more frequently than other nontuberculous mycobacterial disease? Even in Midwestern United States, where *M. kansasii* infection was thought to be more prevalent (pre-AIDS epidemic), disseminated MAC is tenfold more common than disseminated *M. kansasii* in AIDS patients (425,442). Similar Þndings have been reported from England and Wales (600). Furthermore, among HIV-infected persons, colonization of stool or sputum with MAC appears much more likely to predispose to dissemination than does colonization of stool or sputum with other nontuberculous mycobacteria (445). What is the speciÞc immune defect in AIDS that speciÞcally favors disease from MAC (possibly even favoring only a few MAC serovars), and can the selective immune defect be altered? Does disseminated MAC in AIDS patients contribute to their morbidity and mortality, and does treatment make a difference? What are the best drugs, drug combinations, and dosages to use in

treatment? Is drug susceptibility testing helpful in selecting drug regimens?

Other Nontuberculous Mycobacterial Infections in HIV Disease

Other mycobacteria have been isolated much less frequently from patients with HIV infection and include *M. fortuitum*, *M. kansasi*, *M. gordonae*, *M. xenopi*, *M. chelonae*, *M simiae*, *M. haemophilum*, *M. bovis* (BCG), *M. genavense*, *M. malmoense*, *M. scrofulaceum*, *M. celatum*, *M. szulgai*, *M. marinum*, *M. βavescens*, *M. ulcerans* and *M. asiaticum* (442,503,544,601Ð611). The Þrst twelve mycobacteria listed have been reported to cause disseminated disease in patients with HIV disease. Furthermore, even patients with localized NTM disease, such as pulmonary or skin, often have positive blood cultures. Although all these organisms are potentially pathogenic in HIV-infected patients, with the exception of *M. kansasii*, there are no established guidelines for their treatment.

Pulmonary Disease

Pulmonary manifestations of NTM disease in HIV disease merit attention. A retrospective review of 19 HIV-infected patients with *M. kansasii* disease showed 14 patients (74%) had pulmonary disease exclusively with either focal upper lobe inÞltrates or diffuse interstitial inÞltrates; thin-walled cavitary lung lesions occurred in nine patients (612). The disease occurred late in the course of HIV immunosuppression; most patients (84%) had a previous diagnosis of AIDS, and the median CD4+ lymphocyte count was 49 cells/mm^3 (range, 0Ð198 cells/mm^3). Treatment with conventional therapy resulted in the resolution of fever, symptoms, and radiographic inÞltrates, and in a bacteriologic response without relapse while the patients were on therapy. In another study, treatment outcomes in HIV-positive patients were found to be similar when compared to HIV-negative patients (613). Furthermore, a Þve-year population-based study from California showed that 91% of *M. kansasii* disease was pulmonary and estimated that there were 115 *M. kansasii* disease cases per 100,000 HIV-positive persons per year, and 647 cases per 100,000 AIDS patients per year (614). The recommended treatment for *M. kansasii* disease consists of isoniazid, rifampin and ethambutol for a minimum of 18 months and for at least 15 months after culture conversion (544).

Skin Disease

Nontuberculous mycobacteria, especially *M. marinum*, *M. szulgai*, *M. chelonae*, *M. fortuitum*, *M. abscessus*, and *M. haemophilum* may cause skin disease, such as nodules, ulcers, erythema, pustules, abscesses, and panniculitis. *M. abscessus* and *M. chelonae* are typically associated with surgical wounds. *M. haemophilum* usually presents with cutaneous nodular or ulcerating lesions, joint effusions or osteomyelitis. Blood cultures are often positive in nontuberculous skin disease. Skin biopsies and blood cultures establish the diagnosis (424).

Chapter 18

Neurologic Complications of HIV and AIDS

Barbara S. Koppel and Gokhan L. Ak rat

Twenty years have passed since the Þrst reports of neurologic illness in patients with AIDS or HIV infection and much progress has been made in treatment (1Ð3). Shortly after identifying the opportunistic nature of infections of the nervous system in patients whose immune system was no longer functional, it was realized that there could be a direct destructive effect of the virus on the neuraxis. Principles borrowed from the care of immunosuppressed transplant and cancer patients, and later from virology, have worked well in the management of the neurologic complications of this disease. Now that methods of prevention and treatment of opportunistic infection and malignancy are in place, new challenges face the clinician. Less common, more resistant, opportunistic organisms are responsible for infections. To treat or prevent opportunistic disease, physicians must be familiar with the predominant infections of an immigrantÕs original country or sites visited by a traveler. In addition, patients who are fortunate enough to reconstitute their immune system will request guidelines for termination of prophylaxis or maintenance treatment of opportunistic infection (4Ð6). At the same time, clinicians of all specialties must be able to recognize late complications in patients who had no access to therapy (7) or were never aware of their HIV infection. For example, 40% of 2,223 patients newly diagnosed with HIV in Baltimore clinics already suffered from AIDS (8).

In treating HIV there needs to be an awareness of the potential neurologic side effects of certain antiretroviral agents. The importance of the degree of central nervous system (CNS) penetration of these drugs remains an important question (9), as does the role of drug resistance of the strains of HIV within the CNS (10).

This chapter will Þrst review the conditions that present with symptoms of neurologic dysfunction as a direct consequence of viral infection, discuss when these conditions can be expected to arise in the course of infection, and the relationship of certain neurologic syndromes such as dementia, myelopathy and peripheral neuropathy to the degree of immunosuppression. Diagnostic tests relevant to CNS involvement, including the use of cerebrospinal ßuid (CSF) as a proxy for brain tissue (15Ð17), as well as other functional investigations of the nervous system will be reviewed. Currently recommended treatment strategies and neurologic side effects of the antiretroviral medications will be outlined (7). In the second section, neurologic manifestations of dysregulation of the immune system will be described, including such Òauto-immuneÓ diseases as chronic inßammatory demyelinating polyneuropathy or Guillian-BarrŽ syndrome, mononeuritis multiplex, and possibly cerebellar degeneration (18). Finally the vast range of opportunistic infections and malignancies will be outlined. The various areas in which the nervous system can be injured or dysfunctional in HIV will be explained, using knowledge of neuroanatomy to envision the characteristic features of cerebral lesions, meningitis, myelopathy, neuropathy and myopathy. Understanding the predilection for various sites of the neuraxis of infectious agents and tumors, layered on the HIV-induced disruption of the nervous system (7), will facilitate a logical approach to diagnosis. Protocols that have proven useful in differentiating various opportunistic conditions will be given (7,19,20) (see Fig. 18.1 and Table 18.1).

NEUROLOGIC SYNDROMES DUE TO DIRECT EFFECT OF HIV

Early Infection

Primary HIV infection may develop as early as two weeks after exposure to the virus (21). Most patients who recognize symptoms associated with primary infection complain of mononucleosis-like symptoms including

Barbara S. Koppel MD: Department of Neurology, New York Medical College, New York.
Gokhan L. AkÞrat, MD: ??? AfÞliation required ???

Symptom		Features	Cause
Weakness →	Proximal	↑ Reflexes, Babinski	Myelopathy
		↓ Reflexes	Myopathy
	Isolated	↓ Reflexes	Mononeuritis multiplex
		Proximal or distal	
		May be asymmetric	
	Distal	↓ NCV slowed	Neuropathy (inflammatory) (HIV related)
		↓ Amplitude, NCV normal or slow	
Pain →	Bandlike	Usually thoracic	Myelopathy (compressive mass)
	Patchy	Radicular, can involve cranial nerves	Carcinomatous meningitis
	Cramps	Exertional	Myopathy
		↑ CPK	
Numbness	Distal feet>hands	Burning, numb, tingling	Neuropathy (HIV related)
	Distal (stocking/glove)	↓ All modalities	Neuropathy (HIV related)
		↓ Amplitude	
		↓ Velocity on NCV	
	Spinal level	Usually Thoracic	Myelopathy (cord compression)
Urination change	Urgency/Frequency	↓ Pin, touch	Myelopathy, rarely hydrocephalus
		Culture negative, constipation	
	Incontinence, dribbling	Flaccid bladder	CMV sacral radiculitis or cauda equina mass
Pathologic reflexes	Bilateral Babinski		Myelopathy
	Unilateral Babinski		Brain (mass or PML)
	Bilateral Babinski with		Brain (dementia, usually HIV)
	Snout, grasp, glabellar		

CMV, cytomegalovirus; NCV, nerve conduction velocity.

FIG. 18.1. Localization of neurologic symptoms.

fever, myalgia, arthralgia, a macular rash on the trunk, lymphadenopathy and headache. This headache may be nonspeciÞcally related to fever or due to aseptic meningitis, in which case it is accompanied by meningeal signs such as stiff neck, photophobia, mild confusion or lethargy (22,23). However, not all symptoms are present in a given individual (24,25); in a prospective study by Wallace (24) the distribution of associated symptoms (other than fever which was present in all) included malaise (found in 69%), pharyngitis (69%), adenopathy (59%), myalgias or headache (41%), oral lesions or rash (10%). More severe cases of meningoencephalitis may present with confusion, disorientation and lethargy rarely progressing to coma (26), facial palsy or other cranial nerve dysfunction (1,3,27) or seizures (28,29). Less than 10% of patients present with encephalopathy (23,30), polyradiculopathy or Guillian-BarrŽ(31,32), brachial plexitis (33), ganglioneuronitis (34), myelopathy (35) or myelitis (36,37), neuropathy (38), dyskinesias (39) or myositis with myoglobinuria (40). Most symptoms resolve in about one month, although chronic headache and meningitis have been noted (30). Aseptic meningitis (often asymptomatic) may last for many years based on serial lumbar punctures that show chronic CSF pleocytosis (41).

Laboratory abnormalities in the CSF that may be found in primary HIV infection include include a moderate pleocytosis of mononuclear cells and mild protein elevation with a normal glucose level; the virus may be grown or detected by elevated RNA (7,42,43). Raised levels of HIV RNA and β2 microglobulin in CSF after primary infection respond favorably to antiviral treatment (44). Electroencephalography may be normal or mildly slow, and imaging is normal. Those patients with symptomatic primary infection, without speciÞc CNS involvement, are likely to develop neurocognitive impairment at a more rapid rate. Whether this is due to an initial higher HIV load causing both a more obvious initial illness and more rapid depletion of CD4 or that symptoms of conversion correlate with a more neurotrophic or neurotoxic strain of virus is not known (24).

It is still unclear what causes the neurologic symptoms described above (45Ð48). They appear extremely early but transiently in the course of HIV infection. It has even been proposed that early neurologic complications are salutary, being a function of an effective immune reaction to viral invasion which subsequently lowers the chance of developing AIDS dementia complex or neuropathy (49).

HIV-1-Associated Cognitive/Motor Complex (HIV or AIDS Dementia Complex (ADC))

Despite the excellent response when antiretroviral therapy is effective, AIDS dementia remains a signiÞcant problem, eventually developing in up to 20% of patients with advanced HIV infection (50). Dementia emerges both in patients who have not had access to therapy, and in

TABLE 18.1. *Features of common opportunistic infections and tumors*

Complication	Occurs at CD4	Clinical Signs*	Radiographic Signs	Ancillary tests
HIV Dementia Myelopathy Neuropathy	< 200	Apathy, memory, cognition, judgment, psychomotor slowing	Atrophy on CT, periventricular hypodensity MR	CSF cytokines, PCR
Toxoplasma encephalitis	< 100–200	Focal de cit(s), seizures, depressed mental status, meningeal signs	Single or multiple ring enhancing lesions, more lesions on MRI than CT Thallium uptake on SPECT	Serum IgG titers > 1:256, brain biopsy Improvement on treatment
Cryptococcal meningitis or cryptococcoma	< 50–100	Headache and meningitis, bizarre behavior, lethargy, rare seizures, focal signs, ↑ ICP	Meningeal enhancement, hydrocephalous Enhancing lesions	Ag titer in Serum or CSF + CSF culture, + India Ink
Progressive Multifocal Leukoencephalopathy	< 100	Subacute progressive focal de cit especially posterior fossa,/parietal occipital, vision	Non-enhancing lesion(s) in white matter Hypointense on T1, Hyperintense on T2	+ PCR in CSF for JC virus, brain biopsy
Primary Lymphoma	< 100	Headache, focal signs, seizures, meningitis with random cranial nerve or root dysfunction	Single or multiple homogeneous or ring enhancing lesions, especially deep; Thallium Uptake on SPECT	EBV PCR in CSF, brain biopsy, Improvement with steroids
Herpes zoster	< 100	Paresthesias, painful rash in dermatomal distribution, rarely stroke	None	+ PCR in CSF
Syphilis	Any	Meningovascular (Stroke, Meningeal signs) Tabes dorsalis:sensory loss due to post columns Generalized Paresis Gumma (Mass lesion)	Stroke, enhancing meninges; Spinal cord atrophy Brain atrophy Mass with minimal edema	+ Serum or CSF VDRL or FTA + Monocytes, nl glucose, Pro ↑
CMV	< 50–100	Lumbosacral plexus dysfunction (Sacral root pain, accid bladder) Encephalopathy with brainstem signs	Enhancement on nerve roots or periventricular regions, especially near IV ventricle (MR)	> 500 PMNs in CSF, Glucose + PCR
Tuberculosis	Any	Meningitis, cranial nerve palsies, stroke, mental status changes Cord compression due to spine involvement	Meningeal enhancement especially at basilar cisterns, enhancing mass lesions, may calcify Vertebral body or diskitis	CSF Glu ↓ ↑ lymphocytes, ↑ protein, + PCR or probes, + Acid fast smear or culture
M. avium complex	< 50	Silent meningitis or coinfection	+ PPD	

* In order of frequency. Fever is not discriminating in any of these conditions.

those whose treatment has failed. Treatment failures may occur in patients whose antiviral medications poorly cross the blood brain barrier (51), or in those with inadequate adherence to their drug regimen (48,52) as well as in those whose viral strain became resistant or mutated to a more neurotoxic type (48,53). The exact mechanism of brain damage is still being debated (54Ð81) (see Chapter 00), and it is still not clear if minor HIV-related cognitive dysfunction, which consists of more subtle cognitive, psychiatric and motor symptoms similar to those of metabolic encephalopathy, is always a precursor of dementia (54,55).

The location of HIV within the brain correlates with entry through the endothelium and choroid plexus of the

ventricles, as deeper areas such as the basal ganglia and hippocampi are more affected (55), but indirect effects of the virus, either through infected monocytes or the cytokines they secrete, must be involved to explain the end stage symptomatology.

The normal supportive function of astrocytes, such as producing the neurotrophic factors NGF, IL-6 and leukocyte inhibitory factor, maintaining the blood brain barrier, holding microglia in a dormant, non inßammatory state and detoxifying excess excitatory amino acids such as glutamate, are all interrupted after HIV infection (79). Astrocyte failure also contributes to the remote (temporally as well as spatially) neuronal dysfunction even after successful viral suppression. Gliosis or scarring, though a nonspeciÞc response to injury, is seen early in simian immunodeÞciency virus (SIV) models and must contribute to disrupted function (56).

Clinical Course

After recovery from the neurologic complaints that may be seen during primary HIV infection, patients generally remain free of neurologic symptoms for many years, especially on therapy (other than those attributed to immune dysregulation, such as chronic inßammatory demyelinating polyneuropathy, mononeuritis multiplex, inßammatory polymyopathy, aseptic meningitis, or to antiviral drug toxicity such as mitochondrial myopathy or nucleoside neuropathy). Once the CD4+ T-cell count falls below 200/µl, patients with early dementia demonstrate motor abnormalities resembling signs seen in metabolic encephalopathy such as tremor, asterixis, ataxia or simply psychomotor slowing.

There have been many names for the symptom complex caused by brain involvement of HIV, the most commonly used being AIDS Dementia Complex (ADC). HIV-1 Associated Dementia (HAD) is popular among neurologists. Pathologic terms such as HIV encephalitis are less useful, as the neuropathologic Þndings of multinucleated giant cells, atrophy and white matter pallor can be seen in many patients who are cognitively intact. Similarly, the term HIV encephalopathy, although useful in its implication of a ßuctuating or reversible condition, is confusing in that the ßuctuations are generally due to unmasking of dementia by an unrelated condition such as meningitis, hypoxia, or even metabolic failure. The American Academy of Neurology developed staging criteria (82), along with the term HIV-1 associated minor motor/cognitive impairment, to describe AIDS patients with some symptoms of cognitive dysfunction but preserved activities of daily living or ability to work (83), but outside of longitudinal studies using sophisticated neuropsychological and motor testing, few patients meet this criteria (54). However, the importance of functional measures cannot be underestimated, as this aspect of cognitive impairment has the most direct impact on patientsÕlives. Therefore, while new scales or instruments are being tested for clinical relevance (84), discussion of ADC must take into account that symptom degree is variable. The mildest stage may represent a different condition known as HIV cognitive/motor impairment (85) that does not necessarily progress to severe ADC (86).

ADC is still found in up to 15% of patients with AIDS (50,87), although some series report a drop in incidence to under 2% (50). ADC is presenting at a higher CD4 count (170 compared to 70/mm^3 in the pre-HAART era) (88). Ironically, the incidence of ADC as the AIDS- deÞning illness is gradually going up, from 3% (89) in the early days of the epidemic to 6.5% of a series from Australia presenting in 1997 (88). If mild patients are included, about 25% of those with advanced AIDS will suffer from ADC (48,57). After diagnosis of severe ADC, even those patients receiving HAART generally still survive only six months, especially if they are injecting drug users or already have another AIDS-deÞning illness. However, in some patients, HAART may prolong survival and improve dementia, even if viral load remains elevated in plasma (7,19,90) or CSF (91).

ADC starts in the subcortical regions (55,58,92) for reasons related to the path of viral entry, which may explain the early prominence of motor, mood and behavioral abnormalities with later complaints referable to memory (93). Mood disorders more commonly found in symptomatic HIV infection correlate with slowing on quantitative electroencephalography (94). It has long been appreciated that HIV dementia resembles the subcortical dementia of ParkinsonÕs disease more than AlzheimerÕs (95). Patients describe difÞculty concentrating, sequencing or completing a task, needing to keep lists or other cues to perform previously automatic activities, and slowed thinking. Complaints such as loss of libido, loss of motivation to perform complex tasks at work or hobbies and eventually overall apathy overshadow those of memory or spatial orientation. Use of illicit drugs, especially stimulants, can accelerate the process of cognitive decline (96Ð98), and even alcohol has been shown to interfere with working memory function (99). Rare instances of agitation or mania are described (100,101). Neuropsychologic testing at this stage will display problems with retrieval of memory (not registration), manipulation of acquired knowledge such as word lists and general slowing of thought processes and psychomotor task performance. Spared are tasks measuring attention, (although one study of 29 women of low socio-economic status did Þnd impaired performance on selective attention) (102), language ability and calculation. When only cognitive symptoms such as these are complained of (that is no motor signs are present), depression must be suspected (103), as most patients with ADC simultaneously suffer earlier from motor dysfunction. These patients complain of clumsiness, difÞculty walking despite preserved strength and sensation in the legs, tremor, changed handwriting and inability to do Þne motor tasks such as

typing or playing music. Bradykinesia and bradyphrenia cause inability to perform tasks at previous speeds (104). The latter symptom manifests in performance of tasks that are time-sensitive, such as driving in fast-moving traffic. Although psychomotor slowing interferes with performance of tasks of daily living, the patientÕs apathy may make him or her an unreliable self-reporter of these difficulties.

Patients who formerly complied with follow-up appointments who begin to miss scheduled visits may be beginning to suffer from difficulty with planning associated with dementia. In patients whose viral load begins to increase there may be noncompliance, rather than mutations leading to resistance, for similar reasons.

Disruption of normal sleep patterns, including daytime drowsiness, possibly due to the somnogenic properties of cytokines or dysregulation of nighttime growth hormone secretion, can contribute to cognitive disability and feelings of malaise (105,106). Psychiatric conditions like depression, anxiety or Òdual diagnosesÓ that include alcohol and substance abuse or recreational use of marijuana (19) exacerbate these deficits. Rarely, frank psychotic symptoms such as hallucinations, paranoia or mania may occur. Both generalized and partial seizure activity have been reported (28,107).

Clinical signs that correspond to these symptoms include motor system abnormalities, such as shuffling or unsteady gait with inability to perform tandem walking, asterixis, myoclonus, action or sustension tremor (39,108) and a positive Romberg (ie. swaying after closing the eyes, with the feet in a comfortable stance). Extrapyramidal symptoms are occasionally unmasked by use of neuroleptics for control of nausea or psychiatric symptoms (109Ð111), but can be due to HIV itself (112Ð114). Frontal (primitive) reflexes such as snout, root, grasp, Babinski, palmomental and glabellar signs correlate with advancing dementia, except for the glabellar response (104,115). Saccadic eye movements may be slow (116) and not responsive to antiviral treatment (117). Bradykinesia can be extreme, and in advanced cases the face becomes expressionless. Hyperreflexia is seen in the legs, except when peripheral neuropathy causes depressed ankle jerks. Tone is increased in the legs. Often urinary frequency or incontinence is reported. Eventually patients become abulic, mute, paraplegic or quadraparetic. Mental status screening with the commonly used Mini-Mental State Examination, which is weighted to test memory for following or detecting AlzheimerÕs disease does not uncover the deficits of ADC patients. Other performance driven scales such as the Karnofsky scale (often used with tumor patients), or the Washington Clinical Dementia Rating Scale, modified by Price and Brew to use cognitive measures such as memory, orientation, judgement, problem solving, plus community affairs, home and hobbies and personal care (as motor features are unduly influenced by basal ganglia and spinal cord dysfunction), have been able to measure adequately patientsÕfunctional ability and response to treatment (7). The latter scale, going from 0 to 4, reflects Òreal lifeÓ function as well as neurologic examination results (7,86).

A scale employed by researchers in the field of neuropsychology and HIV is shown in Fig. 18.2. The ACTG (AIDS Clinical Trials Group) uses the following neuropsychological and motor tests to screen for ADC: timed gait, Trail Making Tests A and B, finger tapping (both hands), grooved pegboard and digit symbols. The Multicenter AIDS Cohort Study uses in addition to the Trail Making and symbol digit tests, the Rey Auditory Verbal Learning Test, Rey-Osterreith Complex Figure, and choice reaction times. As ADC advances, patients do worst on tests that assess motor skills such as the grooved pegboard or Trail Making Part A tests. They also have difficulty with information processing as tested by the selective reminding task, and executive function as tested with Trail Making Part B. However, motor abnormalities do not explain all of the difficulties on neuropsychological testing, as an attempt to correlate HIV myelopathy (confirmed by somatosensory evoked potentials) with cognitive impairment (confirmed on several tests) found preserved motor speed, despite the observation that 84% of patients were impaired on tests such as the Grooved Peg Board, Finger Tapping, Trail Making A and B, WAIS-R Digit Symbol, Rey Auditory Verbal Learning and FAS Verbal Fluency (118). Recognition (recall) memory is spared; more problems are seen encoding information or using Òworking memoryÓ (119). Visuospatial performance as measured by copying the Rey-Osterreith figure, WAIS-R block design and construction of figures are better preserved than tests of executive function. Of course, scores on these tests do not always represent neuropsychological abilities (120). Confounding variables that affect performance of all these tests include patient education (less education correlates with more cognitive impairment) (121,122), history of head injury (123), and fatigue and intoxication (124). Although most studies report poorer cognitive function with a history of use of illicit substances such as stimulants (124) or heroin (125), a recent Italian survey found more patients who had acquired HIV by sexual contact were at higher risk for cognitive impairment (121). They proposed that a higher mortality rate or reduced survival time among injecting drug users because of less access to HAART or complications of ongoing illicit drug use, contributes to a smaller pool of cases, accounting for this paradoxical finding (121). Evidence of advanced systemic disease (anemia or wasting) also correlates with poor performance on neuropsychological tests (126).

Ancillary tests used in ADC fall into three major categories: (1) structural: magnetic resonance imaging (MRI) or computed tomography (CT), (2) functional: single photon emission computed tomography, positron emission tomography, magnetic resonance spectroscopy, functional MRI, and electroencephalography and (3) chemical: cerebrospinal fluid.

Symptom		Features	Cause
Weakness	Proximal	↑ Reflexes, Babinski ↓ Reflexes	Myelopathy Myopathy
	Isolated	↓ Reflexes Proximal or distal May be asymmetric	Mononeuritis multiplex
	Distal	↓ NCV[a] slowed ↓ Amplitude, NCV nl or slow	Neuropathy (inflammatory) (HIV related)
Pain	Bandlike	Usually thoracic	Myelopathy (compressive mass)
	Patchy	Radicular, can involve cranial nerves	Carcinomatous meningitis
	Cramps	Exertional ↑ CPK	Myopathy
	Distal feet > hands	Burning, numb, tingling	Neuropathy (HIV related)
Numbness	Distal (stocking/glove)	↓ All modalities ↓ Amplitude ↓ Velocity on NCV[a]	Neuropathy (HIV related)
	Spinal level	Usually thoracic ↓ Pin, touch	Myelopathy (cord compression)
Urination change	Urgency, frequency	Culture negative, constipation	Myelopathy, rarely hydrocephalous
	Incontinence, dribbling	Flaccid bladder	CMV sacral radiculitis or cauda equina mass
Pathologic reflexes	Bilateral Babinski		Myelopathy
	Unilateral Babinski		Brain (mass or PML)
	Bilateral Babinski with snout, grasp, glabellar		Brain (dementia, usually HIV)

[a] NCV, nerve conduction velocity.
[b] CMV, cytomegalovirus.

FIG. 18.2. Dementia scale used in evaluation of cognitive function in HIV (with permission).

Radiographic Imaging: CT and MRI

Atrophy when present on CT (Fig. 18.3) and MRI (Fig. 18.4) does not necessarily mean a patient is demented; however the degree of atrophy does correlate with stage of ADC (127). Atrophy is most marked in the basal ganglia. MRI, which is more sensitive to changes in water, often reveals periventricular abnormalities of patchy or diffuse increased signal on T2-weighted images. Initially these were attributed to demyelination (128,129). More recently, using delayed imaging with contrast enhancement, breakdown of the blood-brain-barrier has been raised as an explanation as well (67,130), especially as the degree of enhancement has been shown to correlate with the degree of dementia (58). Improvement with HAART in white matter signal abnormalities despite progression of cerebral atrophy has been demonstrated in four patients studied by Thurnher et al, supporting the proposition that water ßux, rather than demyelination, is responsible for the white matter changes (131). Imaging, though not conÞrmatory of ADC, is of course required to rule out other causes of dementia, such as mass lesion(s), meningitis or ventricular dilatation.

Radiographic Imaging: Nuclear studies, MR Spectroscopy, fMRI

Functional brain imaging, such as nuclear scan (PET or SPECT) (Fig. 18.5), has shown both patchy defects (132) even in unimpaired subjects, and global decreased perfusion that correlates with motor performance on neuropsychologic tests (133). Possible causes of focal

abnormalities include macrophage or viral-induced neuronal damage in patches, diaschisis from subcortical damage and decreased perfusion due to inßammation of the endothelial cells of the vasculature (132). In patients with only minor HIV-1 associated motor deÞcits or no abnormality, PET scans revealed frontomesial hypometabolism in nine of 19 patients and hypermetabolism of the basal ganglia in seven. As slowing worsened clinically, this changed to hypometabolism in the basal ganglia, prestaging dementia (32). In asymptomatic patients, the increased brain activation may indicate that early injury has necessitated compensatory usage of brain reserve to maintain normal cognitive function. PET scanning has shown hypometabolic areas in the basal ganglia in late ADC and hypermetabolism in early stages (134). These decreases in basal ganglia and thalamic metabolic activity correlate with quantitative EEG changes (ie. generalized slowing in the theta range), suggesting subcortical dysfunction is responsible for symptoms of dementia (135). Due to the expense of nuclear studies, PET scans are not often used.

Alternative functional studies include MR spectroscopy (MRS) and functional MRI (fMRI). MR spectroscopy measures N-acetyl aspartate (NAA) as a surrogate marker of neuronal function, and has shown it to be decreased in frontal white matter, while choline (Cho) and myo-inositol (mI), markers for inßammation and glial activation, are elevated (136). Similar Þndings using MRSI (magnetic resonance spectroscopy imaging), which measures the distribution of choline and NAA, have found changes in the thalamus, frontal and occipital white matter (137). A decreased ratio of NAA/Cho has been found in the basal ganglia of children with HIV-encephalopathy (138). By serially monitoring changes such as increasing Cho and mI to measure inßammation and decreased NAA to measure neuronal loss, the sequence of CNS involvement in HIV infection may be observed *in vivo* (139).

Another physiologic technique, functional MRI (fMRI), determines regions of brain activation. A task known to localize to a speciÞc brain region is performed while the patient undergoes MRI. The blood oxygenation level dependent (BOLD) contrast at rest is subtracted from a fast gradient MRI done while repeatedly performing a task and thereby determines the regions of brain activation. In ChangÕs study of attention and working memory, patients with HIV showed activation in the parietal lobes for simple tasks and greater activation in additionally recruited frontal lobe regions during complex tasks. Reaction times were slower but accuracy was preserved, suggesting greater brain reserves are used to compensate for neural circuit disruptions caused by the virus or its toxins. The increased attentional modulation represented

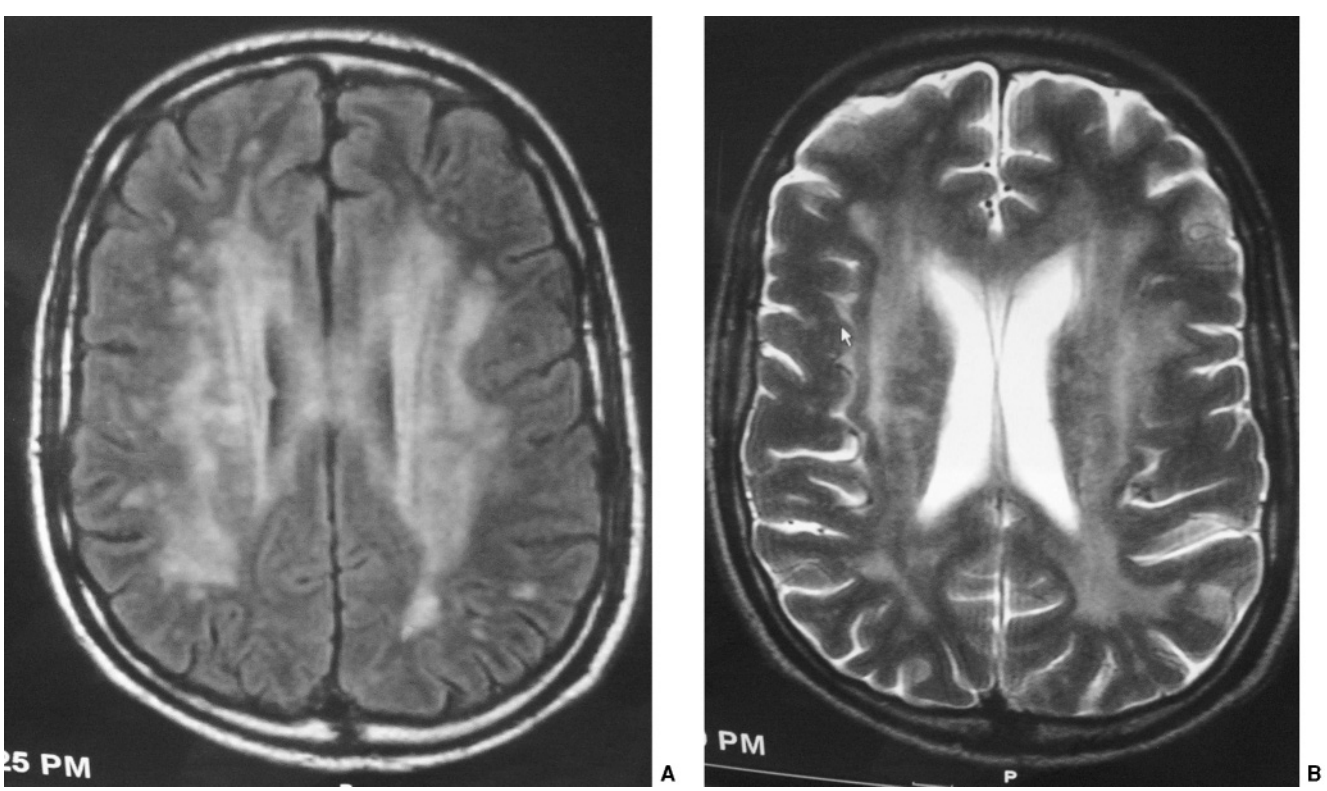

FIG. 18.3. A. ADC (Aids dementia complex): Brain MRI, Flair, of a 32 year old mildly cognitively impaired man, showing periventricular increased signal.
B. Same patient, MRI, T2-weighted, showing ventricular hypertrophy and sulcal dilatation as well as increased periventricular signal.

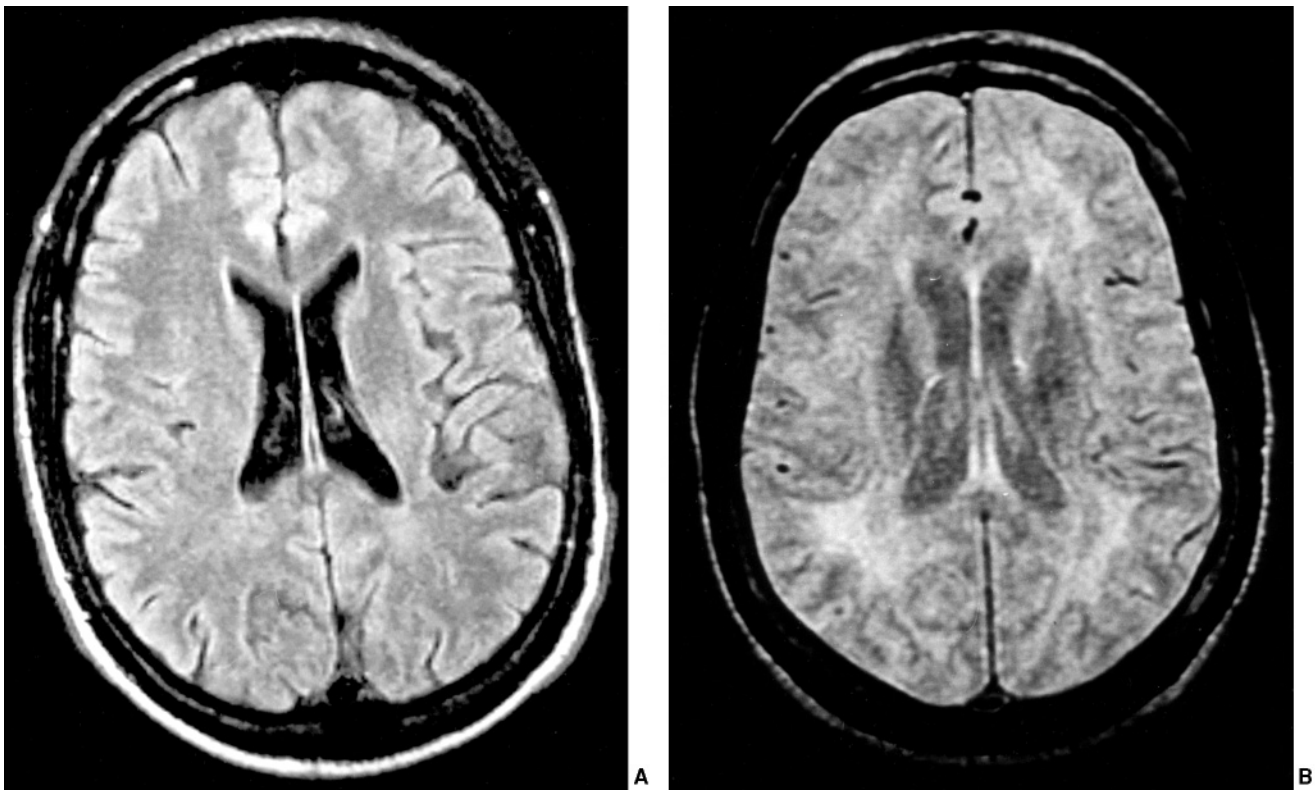

FIG. 18.4. ADC: Brain MRI, T1-weighted with gadolinium, showing increased white matter signal in the periventricular region with no enhancement.

by increased activation of the frontal areas may be due to abnormal frontostriatal connections, with little room for the additional energy required by complex tasks. This correlates with lack of initiation or enthusiasm for non-routine activities of daily living in patients with ADC.

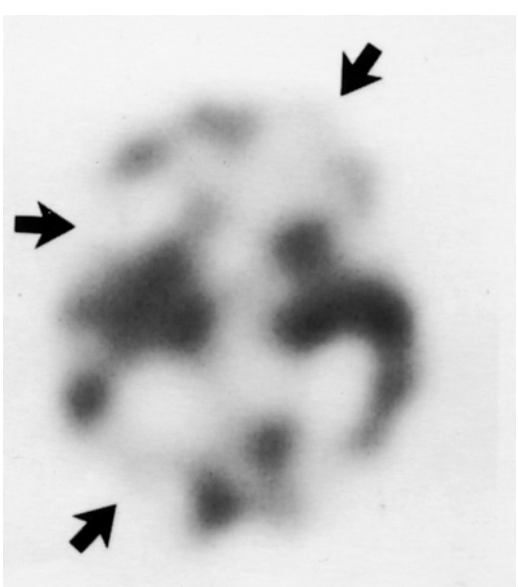

FIG. 18.5. ADC: Multifocal perfusion defects marked by arrows in a patient with dementia (courtesy of Dr Joseph Masdeu).

Functional Studies: Electroencephalography, Evoked Potentials

Neurophysiologic investigation includes electroencephalography (EEG) (Fig. 18.6), which is Òlow and slowÓin late ADC but normal in more than half of patients (140Ð143).

Quantitative electroencephalography is more sensitive but not speciÞc (144) and is not widely available. Abnormalities of spectral powers were suggestive of decreased arousal and increased fatigue in one study of HIV-infected patients (145). In another study, marked changes on quantitative EEG correlated with psychiatric symptoms in otherwise asymptomatic HIV-infected patients, thereby establishing the organic nature of the psychosis (94). In more advanced patients with CD4 < 350, abnormal EEG correlated well with poor performance on neuropsychological testing, abnormal MRI and relaxometry and spectroscopy on MRS (146), as well as with abnormalities on PET scan (135). Evoked potentials, including long-latency event-related potentials are often abnormal even in asymptomatic (non-demented) patients, so their clinical usefulness is not established (147).

Cerebrospinal Fluid Analysis

CSF must be studied, not to diagnose ADC, but to rule out conditions *not* due to ADC, such as carcinomatous,

FIG. 18.6. ADC: Electroencephalogram of a 41 year old demented man showing diffuse low-voltage slow background with loss of normal faster frequencies (courtesy of Dr Cynthia Harden).

bacterial (including treponemal or mycobacterial) or fungal meningitis (148). (A few mononuclear cells persist throughout all stages of HIV infection and are not indicative of meningitis or ADC) (15,41,149). Once these treatable conditions are ruled out, the CSF can reveal other useful information in the diagnosis of ADC, such as HIV RNA copies (viral load) (150–152), which correlates better with response to treatment than plasma levels (91). However, the correlation between virus levels present in CSF and in brain parenchyma is not exact, although levels of each correlate with the degree of dementia (153). Although a positive viral culture alone does not provide useful information, especially as the strain present in the brain parenchyma may differ from that in CSF, it is still helpful to determine resistance patterns and concentrations of antiretroviral drugs to modify the choice of therapy (10,48,120,126,154). Comparison of the plasma to CSF gradient of viral load varies with the degree of immunosuppression (the lower the CD4 count the lower the ratio of plasma to CSF viral copies). This ratio, normally 2:1 plasma: CSF in both impaired and unimpaired patients, becomes 5.1:3.8 in impaired patients with CD4 < 200, suggesting that these patients have an independent growth of virus in the CNS (155). CSF viral count is also increased when there is pleocytosis (> 4 WBCs/μL in the CSF), suggesting that leukocytes bring the virus in from the periphery (153,156). Signs of immune activation, such as oligoclonal bands, increased levels of neopterin, β-2 microglobulin and quinolinic acid, correlate with stage of ADC (15,55,157,158) or degree of inßammation. The presence of matrix metalloproteinases (MMPs) correlates with disruption of the blood-brain-barrier (159). The amount of chemotactic cytokine MCP-1 (monocyte-chemotactic protein) also correlates with neurologic disease, including opportunistic infections (91). Indirect measures of HIV-induced excitotoxicity such as glutamate levels in the CSF are used in research (80,160).

VACUOLAR MYELOPATHY AND MYELITIS DUE TO HIV

Approximately 10% of patients with advanced AIDS (CD4 < 50 cells/μl) and 30% of patients with ADC suffer from a syndrome of ataxic, spastic gait disorder with impaired proprioception. In the series reported by Banks et al., symptoms began with motor dysfunction in 41.7%, urinary dysfunction (urgency and frequency) in 29.6% and another 30% had combinations of sensory symptoms, impotence and constipation. Progression to inability to walk occurred in seven months and to incontinence in nine months, regardless of antiviral treatment (161). Many patients also suffer from distal sensory neuropathy (162) and many are also demented by the time myelopathy advances to paraparesis (163). Pathologic examination reveals vacuoles in the posterior and lateral columns of the spinal cord with macrophages carrying off the lipid from the myelin (Fig. 18.7); the thoracic cord is most often involved. No viral particles are seen (164). In more severely involved cases axonal damage is also found (165). This closely resembles the degeneration of combined systems disease due to B12 deficiency. On pathologic examination this spinal cord picture is present in up to 55% of adults with end stage AIDS, but some selection of patients for neurologic disease contributed to this high percentage (166). Children rarely report symptoms consistent with this myelopathy (167).

HIV myelitis, a separate pathologic entity occurring in 8% of spinal cords examined, occurs more commonly in drug users (168). Patients with myelitis are more likely to exhibit a sensory level at any level of the cord. Virus can be cultured from the cord or CSF of patients with myelitis.

MRI of the spinal cord should be done to rule out cord compression or intramedullary infection (169–171), tumor (3,172) or vasculitis (173). If vacuolar myelopathy is present there is increased signal in the white matter columns on T2 in most cases, and atrophy of the spinal cord is seen in up to 70% of cases. CSF studies can rule

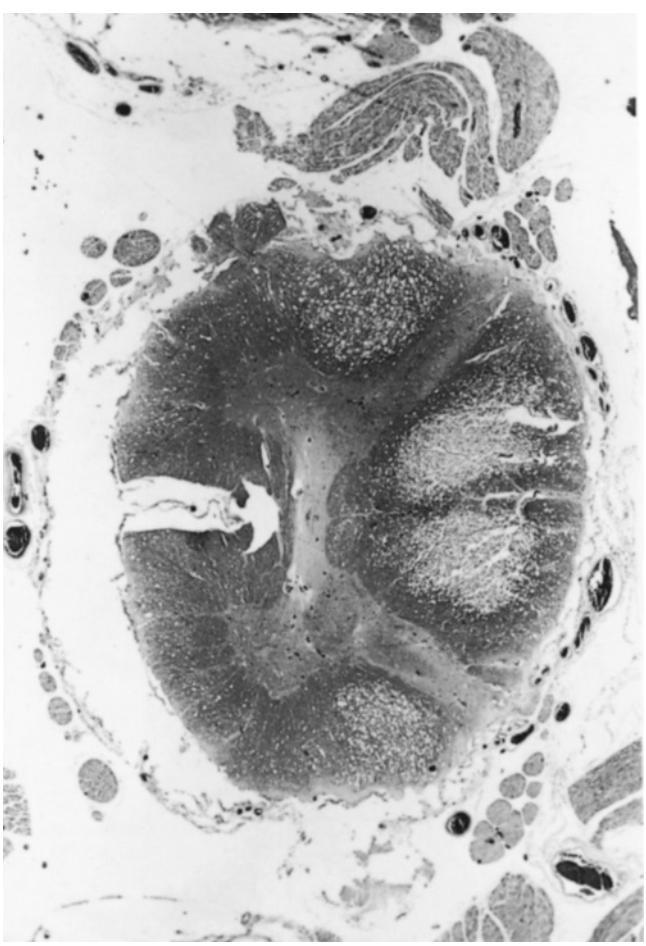

FIG. 18.7. HIV Myelopathy: Spinal cord cross section stained with hematoxylin and eosin and luxol fast blue for myelin, showing vacuolar changes in the posterior and lateral columns (courtesy of Dr Seymour Levine).

out viral causes such as HTLV-I, cytomegalovirus, herpes simplex or zoster, but CSF is normal in vacuolar myelopathy (174–176). In myelitis PCR or culture may be positive for HIV, but the diagnosis is usually made postmortem (162).

Somatosensory evoked potentials may be used to document the extent of dysfunction (177) or eventually may be helpful in predicting treatment response, if they can be shown to normalize before a clinical response is evident.

Since B12 levels are usually normal, despite the pathologic resemblance to combined systems disease, more complex deficiencies of cofactors found in the methylation sequence, such as S-adenosyl methionine, have been proposed (163,178). Even in patients with low B12, supplementation fails to improve the myelopathy (129). For example, deficiency in methylation due to mutations in genes of methionine synthetase and methylenetetrahydrofolate reductase was found in African-American patients who are genetically susceptible to myelopathy in HIV infection (179). Lack of donors for the methyl transfer cycle of oxidation can contribute to the process. Eventual depletion of S-adenosyl methionine causes failure of the trophic activity of the cord that sustains normal function. This may prevent repair of myelin that has been invoked by cytokines, free radicals or other viral products. This would account for the failure of antiretroviral treatment alone to reverse signs of myelopathy (161), with most success occurring in cases of HIV myelitis (180). However, since myelitis is rarely the sole cause of spinal cord disease, being accompanied by vacuolar myelopathy in 92% of autopies, and is basically a pathologic diagnosis (its only differentiating clinical features being a more prominent sensory level and less loss of vibration and proprioception (7)), HAART does not play a significant role in therapy of spinal cord disease (161). Intravenous immunoglobulin produced encouraging results in an open label trial (Simpson, personal communication) as has plasmapheresis (19), supplementation of methionine (161,178,180,181), but this is still under investigation.

HIV NEUROPATHY

As described in the central nervous system, the symptoms of peripheral nervous system involvement vary with the stage of HIV infection and degree of immunosuppression. In the early period of infection, inflammatory demyelinating polyneuropathy may be present in patients who are unaware of their HIV infection. This will be discussed with other "autoimmune" aspects of HIV in the next section.

By far the most common peripheral nerve involvement in HIV is distal symmetrical polyneuropathy (DSPN), which occurs in the later stages of HIV infection. One-third of patients with advanced AIDS complain of burning of the soles of the feet, especially when walking, but even light contact with the soles may trigger it. Often there are painless paresthesias and numbness, present symmetrically (182). Although referred to as a "stocking-glove" neuropathy due to the distribution, as the feet are always involved first; the "glove" or hand aspect is found only in severe cases. The painful burning is accompanied by other AIDS diagnoses or disorders of mood in many cases (183). Weakness occurs only very late in the course of neuropathy but proximal weakness and spasticity due to myelopathy may confuse the exam. The gait in neuropathy, rather than being spastic or ataxic, is usually gingerly in an effort to minimize contact between the painful soles and the floor. In 70% of Tagliati's cases, pin and temperature sensation were decreased and in 60% vibratory sensation was decreased with only 19% experiencing loss of position sense in the feet (182). In 66%, ankle jerks were diminished or lost. Electrical studies reveal an even higher prevalence of neuropathy. Nerve conduction velocities are slow, with reduced sural sensory nerve action potential amplitude (consistent with axonal loss) and decreased compound muscle action potential amplitudes on nerve conduction stimulation (182). However, there is not always a direct correlation between electrophysiologic results and clinical symptoms, as 28% of patients displayed abnormal nerve conductions without clinical signs of neuropathy, while 19% of patients with complaints had normal results on nerve conductions. One explanation for this lies in the failure of small nerve fibers, which carry painful sensation, to be easily studied electrically (182). In addition, the dorsal root ganglia or outer lamina of the spinal cord may be responsible for some of the pain in the legs (184). Electromyography may show chronic denervation but since sensory complaints overshadow motor, electromyography is often omitted due to fear of pain or risk of infection. Correlated conditions include weight loss, malnutrition, low albumin and hemoglobin, older age, and lower CD4 counts (< 100 in 66% of Tagliati's series of 251 patients) (182). Obviously other conditions that can cause neuropathy such as diabetes, renal failure or alcoholism, can act synergistically with HIV. Although numbness and paresthesias also can occur as a side effect of antiretroviral drugs, (didanosine, zalcitabine and stavudine), only 23% of patients with neuropathy in a recent series had used didanosine, and its use did not correlate with degree of symptomatology (183). The combination of these antivirals with hydroxyurea (185,186) or isoniazid (187) is particularly neurotoxic. Care must be used with chemotherapeutic agents such as vincristine, cisplatin and taxol, antibiotics such as dapsone, ethionamide, isoniazid (even with B6 supplementation), metronidazole, and streptomycin, thalidomide or the anticonvulsant phenytoin (185,188–190). Nerve biopsies are not particularly helpful, although skin biopsies have shown loss of nerve fibers (191). C fibers have been shown to be decreased in non-HIV related cases of peripheral neuropathy (192) and are

beginning to be studied in HIV (183,193). On autopsy, almost all patients have evidence of distal axonopathy (194). Loss of unmyelinated C Þbers is most likely responsible for the pain of neuropathy (182).

Isolated nerve involvement such as mononeuritis multiplex represents a separate form of HIV related neuropathy presumably due to inßammatory causes (195). The rare hyperlymphocytosis with CD8 syndrome (DILS: diffuse inÞltrative lymphocytosis syndrome) (57,196,197) also presents with nerve dysfunction and requires immunosuppressive therapy such as steroids in addition to antiviral therapy.

Autonomic neuropathy causes dizziness especially on rising, syncope, palpitations, anhidrosis, sexual and bladder dysfunction, and diarrhea or constipation due to gastroparesis (198Ð201). Autonomic dysfunction is present in up to 50% of HIV-infected patients when measured quantitatively using holter monitoring, tilt tables or nerve conduction studies (200,202). Parasympathetic and sympathetic systems are both involved, causing opposite symptoms in individual patients. Endocrine dysfunction, as measured by low levels of the adrenal hormone DHEA (dehydroepiandrosterone), can accompany autonomic failure (68). As in DSP, the differential diagnosis includes diabetes, alcoholism, vitamin B12 (203,182) or B6 deÞciency and malnutrition (202). These can act synergistically with HIV as well.

Pathologic studies of peripheral nerve biopsies occasionally show inßammatory reactions and rarely HIV particles are seen using immunostaining (7). In animal models the gp120 section of the HIV-1 envelope, introduced epineurally around the sciatic nerve, produced immediate signs of neuropathic pain and transient swelling with increased TNF-α, followed within 30 days by spinal cord gliosis (204). This may help explain why neuropathy is so common, even in patients who successfully respond to HAART, as the spinal cord pathology persists beyond viral exposure. Where direct evidence is lacking for viral presence, cytokines such as TNF-α and interleukin 1, and other inßammatory mediators are proposed as provoking neuropathy (194,205). Since many patients experience neuropathy after weight loss, with low albumin or hemoglobin (182), malnutrition is assumed to contribute to the neuropathy. Treatment is directed at lowering viral load, while minimizing the use of neurotoxic antiretroviral drugs.

Amyotrophic lateral sclerosis or motor neuron disease has been associated with HIV (206,207); antiretroviral treatment caused symptom reversal in a few cases (208,209).

Lumbosacral radiculopathy due to HIV has been described in four patients either at seroconversion or during early infection. It presented with profound weakness isolated to the legs, no sensory or sphincter complaints (unlike CMV), elevated CSF protein and pleocytosis. Electrical abnormalities, which include Þbrillations characteristic of denervation on electromyography and decreased amplitude characteristic of mild axonal neuropathy with normal F waves, differentiate this from the demylination characteristic of Guillian-BarrŽ. All recovered rapidly and almost completely, without treatment (32). Plexopathy with a relatively benign course has also been described later in infection (210).

Standard treatments for neuropathic pain are sometimes useful in DSP, including topical creams such as capsaicin, which depletes Substance P, the main transmitter of the unmyelinated C Þbers which carry painful stimuli, and lidocaine gel, a local anesthetic (211,212). Oral lidocaine (mexiletene) (213) and peptide T have failed to control symptoms (214). Recombinant nerve growth factor may help pain but not numbness, as the nerve Þbers fail to regenerate (191,215). Central pain is addressed by the use of tricyclic antidepressants such as amitriptyline (213,216) or nortriptyline in doses below 50 mg nightly (182). Newer antidepressants, such as venlafaxine, that work on norepinephrine and dopamine reuptake in addition to serotonin (217) may work as well. Wellbutrin has been shown to relieve diabetic neuropathy pain but has not yet been studied in HIV neuropathy (218). The purer serotonin reuptake inhibitors (SSRIs) such as ßuoxetine and sertraline have little effect on pain. Anticonvulsants such as gabapentin (219), valproic acid (7), phenytoin, carbamazepine or more recently lamotrigine (220) have proven useful. Lamotrigine is even more effective in patients with neuropathy due to use of neurotoxic antiretroviral drugs (221). In addition to class-associated dose-related toxicities such as drowsiness or poor concentration, or speciÞc side effects such as tremor from valproic acid, care must always be taken to respect drug interactions with other medications in the antiviral regimen. This especially applies to most anticonvulsants which increase cytochrome P activity in the liver, thereby increasing metabolism and decreasing plasma levels of antiviral medications such as protease inhibitors (14,222). In addition, some drugs such as valproic acid cause stimulation of HIV growth *in vitro* (14,222,223) but analysis of this and other anticonvulsant medications using other cell lines failed to demonstrate stimulation of HIV replication or transactivation of HIV-LTR (98). Carbamazepine has been shown to be protective against neuronal death due to Tat protein *in vitro* (98).

Acupuncture has been studied (216) and techniques of biofeedback or relaxation exercises (224) may also help avoid medication use. Orthostatic hypotension is treated by encouraging increased salt intake, modifying treatment with antidepressants with hypotension as a side effect, or drugs such as ßuorocortisone or midodrine. Osmotic agents such as lactulose or polyethylene glycol can treat constipation, as dopamine blockers such as metoclopramide, which directly stimulate intestinal nerve plexi, can cause extrapyramidal side effects such as tremor and cogwheel rigidity. Cisapride, another gastric stimulant, has been withdrawn due to cardiac side effects. Antiarrhythmics or pacemakers are rarely needed. Tricyclic

antidepressants with anticholinergic effects help relieve sialorrhea, urinary frequency and diarrhea but may exacerbate orthostatic hypotension or arrhythmias. Opiates may be used for diarrhea as well as resins such as cholestyramine and electrolyte modiÞers such as loperamide. SildenaÞl may alleviate impotence but the dose must be lowered in patients using protease inhibitors.

HIV Myopathy

Myalgias or cramps are common during the seroconversion illness of primary HIV infection, but muscle damage, as manifested by weakness, pain or exertional cramps, CPK elevation, and rhabdomyolysis, is rare (40,225). Although muscle involvement from HIV is often due to inßammatory processes, mitochondrial abnormalities may contribute, even in patients without exposure to reverse transcriptase inhibitors such as zidovudine (226Ð229). Inclusion bodies have been seen on biopsy, and nuclear scans using technetium-99m MDP have shown uptake in the muscles (230), suggesting that HIV myopathy is a form of inßammatory polymyositis (231). Because it is in the autoimmune family, this form of myopathy occurs early in the course of HIV infection, or after reconstitution, with CD4 cell counts in the range of 200Ð500/µl. Proximal muscle weakness causes difÞculty reaching up, combing hair, climbing stairs or rising out of a chair. Dysphagia (which is not painful) and neck weakness may be present (although this is more common in zidovudine-induced myopathy than HIV-myositis). EMG shows characteristic small motor unit potentials with full interference patterns on recruitment (giving effort while the muscle is being tested by needle electromyography). Fibrillation potentials occur spontaneously. Biopsy reveals necrosis, occasional inßammatory inÞltrates or inclusion bodies. The muscle breakdown product creatine phosphokinase (CPK) is raised. Nuclear imaging of the body has shown multiple extra-osseous accumulations consistent with skeletal muscle uptake (230).

Treatment with immunosuppressive agents has been successful in about half of cases (232,233). Theoretically, corticosteroids, in addition to the usual complications of hyperglycemia, osteoporosis, adrenal suppression, may accelerate the immune system changes of HIV (234), but they have been safely used at early stages of infection (235). Prolonged use of steroids can cause proximal myopathy and should be avoided. Intravenous immunoglobulin (IVIG) might not be helpful, as it has failed to improve non-HIV related polymyositis (236). Since its effects are immediately known, IVIG might still be worth trying, but its cost (approximately $1,000.00 per treatment) is high.

Drugs that exacerbate myopathy include the protease inhibitors, which gradually produce lipodystrophy that causes limb muscle wasting without much weakness, and the cholesterol-lowering statins, which are often given to offset the hyperlipidemia caused by the protease inhibitors. The symptoms of statin-induced myalgias and weakness may be helped by using the supplement coenzyme Q (50Ð130 units daily) (7).

Therapy of Neurologic Complications of HIV (Dementia, Myelopathy and Neuropathy)

Ancillary Therapy

Novel therapies, in addition to standard antiviral drugs, will become important in the future and will be discussed Þrst. Although the calcium channel blocker nimodipine failed *in vivo* (70,237), when combined with antiviral therapy it seems to slow dementia progression (238). Calcium dysregulation is still suspected to play an important role in the Þnal stage of cell destruction (16). Therefore, when calcium blockade proved unhelpful, investigators turned to triggers of the process that stimulates fatal calcium inßux, such as the excitatory transmitter glutamate (80). However, trials of the N-methyl D-aspartate receptor blocker memantine gave inconclusive results (70,239,240). The calcium channel blockers, such as nimodipine and NMDA receptor blockers, such as memantine, are too costly and cause too many adverse effects to allow continuous use, so the ideal time of use or patient who would beneÞt the most from neuroprotection needs to be determined before efÞcacy can be established.

Because inßammation plays an important role in ADC, work is being done in changing the balance of pro- and anti-inßammatory modulators, such as IFN-γ vs. IL-4 (61), or TNF-α vs. insulin-like growth factor (ILGF) (66,241). After demonstration of reduced inßammation in mouse models (242), platelet-activating factor (PAF) antagonists, such as lexipafant, and TNFα inhibitors are in clinical trials (243,244). COX-2 inhibitors are under investigation in other viral infections for their effects on prostaglandinE_2 and may display anti-inßammatory properties that will help in ADC (245). Although the weak TNFα inhibitor pentoxifylline failed to improve the clinical status of patients (246), another antagonist of TNFα, CPI-1189, has reduced apoptosis induced by gp120, TNFα and quinolinic acid in tissue culture (247) and therefore merits further investigation. Inhibition of the caspase enzymes which contribute to the apoptosis induced by gp120 may help prevent neuronal degeneration (248). Other cytokine blockers with potential beneÞt in dementia are currently being studied for systemic (nonCNS) HIV infection, including thalidomide, peptide T and nordihydroguiaretic acid (246).

The complex role of chronic oxidative stress related to depletion of endogenous antioxidants and increased production of reactive oxygen species, lucidly outlined by

Mollace and colleagues (75), may lead to treatment using free radical scavengers. Mn-SOD (Manganese superoxide dismutase) has been shown in neuronal cell culture to protect from apoptosis signaled by NF-B, in turn stimulated by the protein, TNFR-1-associated death domain (TRADD) (249). Problems of transport across the blood-brain-barrier are being addresed by macrocyclic complexes with SOD enzymic activity. Polyamine modiÞcation of superoxide dismutase also allow better access to cerebral tissue (75). Manipulation of glutathione (GSH) may also reduce oxidative stress (75). Antioxidants such as thioctic acid and selegeline are somewhat neuroprotective (239,244,250,251), and may work by reducing mitochondrial toxicity.

Growth factors have been studied indirectly by measuring the presence of Þbroblast growth factor-1 in relationship to HIV encephalitis and neurodegeneration; these pathologic studies support the idea that growth factors can protect from the neurotoxicity of HIV infection (252).

Because patients often suffer the constellation of dementia, neuropathy and myelopathy along with low serum albumin and weight loss, the importance of nutritional co-factors in these conditions is being investigated (163,182). Methyl donors such as SAMe (221,253) or cobalamin (254) are postulated to restore myelination. Other nutritional co-factors include selenium, a mineral required for glutathione production, which has decreased β2-microglobulin levels when supplemented with doses of 40Ð80 μg/kg/day (12,255). For depletion of zinc, which is associated with immunosuppression and depression (256), supplementation with 2.5 to 4.0 mg/kg/day has been recommended. Substance abusers are at increased risk of vitamin A deÞciency (257), alcoholics of thiamine deÞciency and both populations are at higher risk of general malnutrition (12), warranting special attention to these supplements in patients with the above habits. A recent case report of a 71 year old with focal dystonia and hemichorea (though not in AIDS) that improved with treatment of B_{12} deÞciency lends support to screening for B_{12} deÞciency and cyanocobalamin replacement if levels are low in the many ADC patients with asterixis, tremor and other movement disorders (258).

Ancillary treatments also include the stimulant methylphenidate for cognitive ÒslowingÓ (259), clonidine (100) or methylphenidate for hyperactivity (260) and antidepressants (261) (especially selective serotonin reuptake inhibitors) and relaxation exercises or biofeedback (224). Attention to the cognitive and extrapyramidal side effects of medications chronically used for psychosis (58,262, 263), pain (213), seizures (222), anxiety and sleep will help minimize symptoms of dementia. Prior use of illicit stimulants such as cocaine and methamphetamine may also contribute to Parkinsonism and dementia even when HAART is working to lower systemic viral load (97). Management of addiction to substances including cocaine, heroin, amphetamines and other drugs is therefore important.

Antiviral Treatment

Early treatment may be the best way to eradicate the virus, so providers (including neurologists) must be on the alert for the very Þrst symptoms, such as aseptic meningitis or myalgia (24) and test for viral antigen, rather than wait for the development of a positive serology.

With the extended life expectancy of AIDS patients, other neurologic conditions can develop, such as Alzheimer's dementia or malignancies that are unrelated to AIDS but whose treatment is affected by the virus. Conversely, older patients who present with dementia from HIV can mistakenly be assumed to have Alzheimer's, or HIV-related movement disorders can masquerade as Parkinson's disease. Rarely, a neurologic disease with unknown etiology, such as amyotrophic lateral sclerosis (208,209), may respond to antiretroviral therapy, making it seem worthwhile to perform almost universal HIV screening.

Although a dose-dependent decrease in symptoms of ADC treated with zidovudine as monotherapy has been established since the drug's introduction (264), this improvement lasted less than a year in one-third of patients (265). The high doses of zidovudine required to reach the brain parenchyma are also difÞcult to tolerate due to anemia and myopathy. Therefore, combination therapy with highly active antiretroviral drugs has revolutionized the treatment of HIV in general and CNS infection as well (126,266). A 52% decline in the incidence of dementia was seen after the introduction of HAART to participants of the Multicenter AIDS Cohort study, made up primarily of men who had acquired the virus by sexual contact, with a 43% decline in injection drug user's incidence of ADC (17,266). Use of protease inhibitors, which do not enter the brain easily, have been associated with declines in HIV dementia (50,88,267). In the HAART era, ADC has begun to occur at higher CD4 counts (201Ð350), meaning the clinician should maintain a higher index of suspicion in symptomatic patients (266). The complex pathophysiology responsible for dementia described in Chapter 00 is entirely driven by the presence of HIV or HIV-infected macrophages or microglia. Infected endothelial cells allow traffÞcking of the virus through the choroid plexus (17,48,79,86). Therefore antiviral therapy constitutes the mainstay of treatment for ADC: by decreasing systemic viral load there subsequently is less CNS seeding. If medication gains access to the brain it can also prevent the CNS from acting as a safe haven for viral replication. Failure to lower the number of copies of HIV-1 RNA in the CSF correlates with the number of drugs that penetrate that achieve adequate concentrations in CSF, and with initial higher viral load in CSF (91). However, although an increased CSF viral load has been shown to correlate with

TABLE 18.2. *Relative concentrations of antiretroviral medications in CSF (CSF/plasma ratio)*

Nucleoside reverse transcriptase inhibitors (NRTIs)

Zidovudine (0.3–1.35) > Stavudine (0.16–0.97) > Abacavir (0.3–0.42) >
Lamivudine (0.04–0.47) > Zalcitabine (0.09–0.37) > Didanosine (0.16–0.19)

Non-nucleoside reverse transcriptase inhibitors (NNRTIs)

Nevirapine (0.45) > Delavirdine (0.02) > Efavirenz (0.01)

Nucleotide reverse transcriptase inhibitors

Tenofovir (?) (not highly protein bound so CSF levels should be high)

Protease inhibitors

Indinavir(0.02–0.06) > Saquinavir = Nel navir = Ritonavir = Amprenavir = (< 0.05)

Combination medications

Abacavir/Zidovudine/Lamivudine = Zidovudine/Lamivudine > Lopinavir/Ritonavir
(Trizivir) (Combivir) (Kaletra)

Caveats:
Ratios were derived from measurement of samples in patients with variable intactness of blood-brain-barrier. CSF levels do not always re ect levels in brain parenchyma.

Levels are affected by ef ux as well as in ux of medication; this is in uenced by the presence of other medications and transporters such as P. glycoprotein.

cognitive impairment (120,246), it has not yet been shown that a decrease in CSF viral load improves cognitive performance. Pathologic studies continue to show the same manifestations in recently autopsied brains as did the initial studies (268), and virus that is latent in astrocytes can conceivably be reactivated by proinßammatory cytokines (269). Because up to half of patients fail to maintain a response to HAART, the risk of recurrence of dementia is high (270).

Including combinations, at least 18 medications are currently in use and more drugs, targeting additional sites of viral replication, are constantly being developed; a summary of web sites offering trials or therapy updates exist, such as www.neuro.wustl.edu/narc, www.clinicaltrials.gov, www.hivatis and www.actis.org/indep.html (57).

There are no speciÞc CNS antiviral medications, but the Þrst antiviral, zidovudine, was proven in a dose dependent manner (271) to slow or prevent ADC (272Ð274). Zidovudine remains the leader in CSF penetration in its class of nucleoside reverse transcriptase inhibitors (NRTI) (275), followed by stavudine and abacavir. Protease inhibitors (PI) were introduced in 1996 and non-nucleoside reverse transcriptase inhibitors (NNRTI) joined the medication armamentarium in 1998 (276,277). Results of treatment are measured by decreases in viral load and increases in CD4 cell counts, as discussed elsewhere in the book, but there is no simple measurement of the effect of new treatment protocols on ADC, myelopathy or neuropathy. Choice of appropriate therapy to treat initial infection involving the CNS, and to prevent dementia or treat its symptoms, may rest on knowledge of drug interactions, viral resistance patterns within the CNS, efÞcacy and side effect proÞle, and ability of patients with compromised mental function to comply with the regimen (9,276). In addition, the ability of a drug to cross the blood-brain-barrier (which varies with the drugÕs lipophilicity and the intactness of the blood brain barrier, presumably becoming more open as dementia advances) is a factor in choosing the best regimen to prevent neuropathy and ADC (67,278) (Table 18.2).

Other NRTIs that are effective in the CNS include stavudine (275,279) and lamivudine (280). The NRTI, abacavir, achieves excellent CNS penetration (levels up to 42% of those in plasma) (57,281). Abacavir has been shown to be effective in ADC (7). Mutations conferring resistance to antiretroviral drugs may vary between those present in CSF and those observed in plasma (10). The more discordant the viral resistance pattern in CSF and plasma, the worse the cognitive impairment, suggesting the need for appropriate testing for optimal treatment in patients with severe dementia (10,155). This problem mandates CSF analysis when patients fail to respond clinically to therapy.

Protease inhibitors have poor penetration into the CNS, but in advanced cases with presumed breakdown of the blood-brain-barrier, clinical response of ADC has been seen (282Ð284). Because it is the least protein bound, indinavir should have the best entry into the CNS (284). However, active transport systems exist that cause efßux out of the brain, such as the P-glycoprotein transporter (283). Larger amounts of protease inhibitors may gain access to the brain than predicted when these reverse

transport systems are affected by drug interactions or in the case of ritonavir, by the drug itself (285).

The NNRTIÕs nevirapine (7,280) and efavirenz (7) have been shown to improve dementia. Judgment of neurologic efÞcacy with efavirinez is limited by its common neurologic side effects of confusion, sleepiness and abnormal dreaming, but these tend to be transient (286,287).

The ribonucleotide reductase inhibitor hydroxyurea has also shown some efÞcacy in treating ADC (44,288) but not when used alone.

In addition to directly decreasing viral load, thereby deactivating macrophages that promote destruction through cytokines and halting apoptosis of astrocytes, HAART works by primarily maintaining or restoring the immune system (19,289). This is especially true in the Þrst stage of infection, when HAART can boost CD4 function and possibly eliminate viral penetration into the brain (290).

Measurement of efÞcacy of HAART has been indirect. MRI improvement was documented in four patients (131). Improvement, especially in timed motor function, has been demonstrated using neuropsychological assessment (121,274,291Ð293), including a response to protease inhibitors (293). Sensitive scales such as the Memorial Sloan Kettering and HIV-associated dementia scales showed improvement in 60% of patients treated with HAART. (The failures tended to be injection drug users by history (294).) Functional imaging with PET has not been used lately (295), but fMRI and MR spectroscopy hold promise as non-invasive methods to monitor response to therapy (137,139,296). Using the patientÕs CSF to measure mitochondrial dysfunction in neuronal cell culture may provide a functional bioassay eventually (251), and a reduction in immune activation markers such as neopterin and β_2-microglobulin may offer evidence of clinical improvement (297). Neuropathologic studies have shown decreased multinucleated giant cells after zidovudine treatment (289,298).

Myelopathy can be considered a remote effect of HIV and therefore its symptoms often fail to respond to antiretroviral treatment alone. Therefore, although it is logical to use antiviral therapy to lower the amount of virus available to decrease cytokine production by macrophages, at most the myelopathy may stabilize (161). However, cases associated with myelitis respond well to antiviral treatment (180). As is the case with dementia, agents with better penetration are recommended, but controlled trials are not yet available.

HAART has also been useful in treating the peripheral neuropathy of late infection (190), although an indirect mechanism through decreasing macrophage activation and cytokine release is probably responsible (190,300). Agents with good CNS penetration presumably also reach the peripheral nerve better, so zidovudine, lamivudine, indinavir and nevirapine are recommended. The NRTIs, including stavudine, didanosine and zalcitabine, that are responsible for causing peripheral neuropathy obviously should be avoided. Neuropathies occurring at earlier stages of infection, such as CIDP (chronic inßammatory demyelinating polyneuropathy) (190) or DILS (diffuse inÞltrative lymphocytosis syndrome), completely recover in two-thirds of cases (301). Because these are only indirectly related to the virus, the drug that is chosen does not need to cross the blood brain barrier. Mononeuritis muiltiplex is also autoimmune mediated so antivirals are only useful if the viral load is high (190).

Side Effects of HIV Medication

Along the long course of HIV infection, many direct and indirect treatment-related problems may emerge (Table 18.3). Access to virus sequestered in the central nervous system, across a blood brain barrier that has recovered to an intact state, may become difÞcult (272,275). Cumulative exposure to the mitochondrial toxicity of nucleoside reverse transcriptase inhibitors can lead to myopathy (228) or even dementia (302) in addition to the more well known peripheral neuropathy associated with didanosine and stavudine (303), especially when augmented by hydroxyurea (186). Indirect neurotoxic effects of medication used for symptomatic relief of HIV-induced complications complicate the use of drugs such as antidepressants (used for pain management as well as mood disorders), antipsychotics or dopamine blocking antiemetics (112,262,304) and anticonvulsants, some of which also promote viral replication (220,222). Cognitively impaired patients often have difÞculty adhering to complex treatment regimens, mandating the use of neuropsychologic screening and implementation of measures to insure compliance, such as directly observed therapy.

Side effects of HAART are generally systemic, but speciÞc neurologic problems are seen. The Þrst reported neurotoxicity from antiviral therapy was myopathy, quickly determined to be due to zidovudineÕs inhibition of γ-DNA polymerase in the muscleÕs mitochondrial system (228,302). Carnitine levels may also become reduced by zidovudine use (305). In early studies using high doses, myopathy was present in up to 18% of patients after about a year (306). Pain is found in half of patients, which manifests as cramps on exertion (307). Fatigue and weakness of the proximal muscles of the legs and buttocks are usually present, with eventual wasting of muscles (303). Creatine phosphokinase (CK) is markedly elevated (308), but the degree does not correlate with symptoms. Lactate may be increased at rest (303). MRS in patientsÕ muscles demonstrates phosphocreatine depletion, due to impaired oxidative phosphorylation (303). Electromyography reveals myopathic pattern, with polyphasic units, Þbrillation and positive sharp waves (307,308). Although the lower doses of zidovudine currently used are less likely to produce myopathy, the effect of combination therapy with more than one NRTI and NNRTI, or concurrent use of statins (the need for which is increased by protease

TABLE 18.3. *Neurologic side effects of antiretroviral drugs and other medications*

Type	Medication Antivirals, Other Classes	Symptom
Cognitive	Efavirenz	Dizziness, Insomnia, Vivid Dreams Depression, Confusion
	Zidovudine	Encephalopathy
	Abacavir	Seizures Profound lethargy and weakness, hypersensitivity reaction
	Antiepileptics	Sedation, Dizziness
	Benzodiazapines	Encephalopathy
Muscle	Zidovudine (Combivir,Trizivir)	Muscle cramps, Weakness (proximal) ↑ CPK
	Protease Inhibitors	Lipoatrophy
	Statins (HMG–CoA reductase inhibitors)	Myalgias, Weakness
Nerve	Didanosine, Zalcitabine, Stavudine, Lamivudine ± Hydroxyurea Thalidomide, Isoniazid, Vincristine, Taxol	Distal numbness, toes > ngers, burning paresthesias, dysesthesias, rare weakness, slapping gait lost ankle jerks. Symptoms can progress after drug stopped
	Protease inhibitors	
	Ritonavir, Amprenavir	Carpal tunnel syndrome
	Indinavir	Alteration of taste
Muscle? Nerve?	Stavudine, Didanosine Abacavir	Severe ascending paralysis, lactic acidosis, EMG c/w axonal neuropathy or myopathy
Extrapyramidal Movement Disorders	Antipsychotics Antinausea or Intestinal Motility stimulants	Tremor (resting and action), cogwheel rigidity, ↑ potential for Neuroleptic Malignant Syndrome

inhibitors inducing hyperlipidemia), is not yet known (302,309,310). Management of myopathy usually requires stopping zidovudine, as lowering of the dose usually does not result in complete improvement (311,312). Carnitine supplementation has not been systematically evaluated in patients (302,313).

The next antiviral drug introduced, didanosine (ddI), caused an irreversible peripheral neuropathy in 15% of patients (314), especially those already suffering from HIV-related DISP. The neuropathy is duration and dose related (193) and inßuenced by the degree of immunodeÞciency as well (193,315,316). B12 deÞciency contributes (203,317), as do other neurotoxic drugs such as isoniazid (even with B6 supplementation), ethambutol (190), thalidomide (188), vincristine and taxol (189,318). Newer agents, such as zalcitabine, stavudine and lamivudine also produce neuropathy (in up to 40% of patients using zalcitabine) (319), the severity of which worsens with combination regimens or when either is combined with hydroxyurea (185,186). Symptoms of numbness and paresthesias in the feet and ankles usually emerge after four to Þve months (314,315,319). Weakness is found only in severe cases (320), but ankle jerks are usually depressed or lost. Proprioception is preserved in most cases (314). After cessation of medication use, the symptoms of neuropathy may worsen temporarily, plateau for about eight weeks and then gradually improve. Nerve conduction studies are consistent with axonal neuropathy (decreased amplitude on stimulation, or lowered sural nerve sensory action potential), but may be normal (320,321). Elevated lactate has been found in 70% of patients with toxic neuropathy, but a pathogenic role is unclear (7). Stavudine especially has been responsible for production of hyperlactatemia (322), though not necessarily accompanied by neuropathy (323), but it has been described in patients using abacavir, didanosine, lamivudine and zidovudine, with or without protease inhibitors.

The pathogenic mechanism of neurotoxicity is postulated to be due to the interference with mitochondrial function. The azido group contained by NRTIs competes with natural thymidine triphosphate as a substrate for pol-γ in the synthesis of mitochondrial (mt) DNA. This mitochondrial toxicity has been demonstrated using a rat model of isolated dorsal root ganglia (324) and by measurement of a deÞciency of mtDNA on skin biopsy (325). DeÞciency of acetyl carnitine, required for mitochondrial function, also has been proposed as a factor contributing to nucleoside neurotoxicity (302,313). Patients with family members (on the maternal side) who suffer from mitochondrial diseases such as MELAS or MERFF are at increased risk of mitochondrial toxicity

from these medications. Future work using the ratio of mitochondrial to nuclear DNA may be able to predict this toxicity and govern therapy with nucleosides in patients with HIV infection (322). Screening with lactic acid levels is not helpful as these levels vary and are not predictive of future problems (283).

Hydroxyurea also decreases the intracellular dATP pool, which contributes to its additive neurotoxic effect as well as its efficacy (185).

Protease inhibitors, through their metabolic effects causing glucose intolerance or diabetes in over half of patients, or through their contribution to weight gain, have been suspected of contributing to carpal tunnel syndrome (326).

A severe, rapidly progressive, ascending paralysis resembling Guillian-Barrž has been described in patients using HAART. Stavudine (d4T) was implicated in 35 patients (of 70,000 exposures) while eight others had no specific pattern of antiviral therapy (327,328). Its mechanism is unclear and although it appears to resemble a severe primary axonal neuropathy, or myopathy, it is probably unrelated to the toxic neuropathy described above. This neuromuscular failure may be accompanied by lactic acidosis. Electrophysiology is consistent with primary axonal neuropathy or myopathy. Unlike in Guillian-Barrž, symptoms do not respond to immunotherapy such as IVIG or plasmapheresis, and the condition was fatal in six of 18 patients whose antiretrovirals were not stopped, and one of seven whose stavudine was stopped. Supplements involved with the respiratory chain of mitochondria are being tested, such as coenzyme Q, L-carnitine and riboflavin.

Profound weakness and lethargy has also been reported with abacavir as part of a hypersensitivity reaction (212).

Headache has been attributed to zidovudine in up to 35% of patients, saquinavir in up to 9% and amprenavir in 6% (212), as well as in patients taking stavudine (7).

Encephalopathy has been described in patients using the NNRTI efavirenz, both alone and in combination (277,286,287). Symptoms include dizziness, restlessness, depression, inability to concentrate, insomnia and abnormally vivid or bizarre dreaming. Sixteen of 111 patients in a private practice in California stopped the medication due to these symptoms, despite treatment for depression in 13. In another series, 18% of patients discontinued efavirenz, most due to these side effects (286). Since there is no binding of the drug to any CNS neurotransmitters, it is unclear how efavirenz causes these symptoms. Insomnia has also been reported with zidovudine and in up to 29% of patients using stavudine (212). Wernicke's encephalopathy attributed to thiamine deficiency has also been described with zidovudine (329).

Seizures have been described in patients on zidovudine (333) or didanosine (320,331), although in these early series, zidovudine may have been blamed before the relatively high frequency of recurrent seizures due to HIV dementia was appreciated. Ritonavir, amprenavir and indinavir have rarely caused alteration of taste (212).

SYNDROMES OF IMMUNE DYSREGULATION IN THE NERVOUS SYSTEM (DURING EARLY OR RECOVERING HIV INFECTION)

Viral infections have often triggered neurologic autoimmune disease (332). Immune dysregulation can lead to "attacks" on many parts of the nervous system; proposed pathophysiologic mechanisms include a general activation of B cells leading to production of antibodies that attack myelin or other parts of the nervous system, upregulation of MHC antigen expression, and molecular mimicry after incorporation of viral proteins into nervous tissue or sharing of epitopes between virus and host (332,333). As HIV infects macrophages, there is an upregulation of cytokines leading to broad-spectrum autoimmune disease. The most common sites are in the peripheral nervous system, i.e. nerves (182,334), nerve roots (335), muscle (336) and the neuromuscular junction (337,338). Mononeuritis multiplex, or involvement of isolated nerves, can be autoimmune or due to vasculitis producing infarcts of the nerve (339). Stroke can occur secondary to vascular or hematologic problems, such as thrombocytopenia (340), anticardiolipin antibodies (341) or vasculitis (47, 342–348). Speculation also exists that autoimmune disease contributes to dementia (349) or a multiple sclerosis-like syndrome found in early HIV infection (350,351). However, radiologists may overdiagnose multiple sclerosis due to the misinterpretation of ill-defined periventricular white matter abnormalities seen in up to 73% of cases of HIV dementia (350–353). Although the pathogenesis of these relapsing syndromes is unclear, an increase in τ/δ T cells has been described at the time of seroconversion, and these cells have been found in the demyelinating lesions and CSF of patients with multiple sclerosis (MS) (354,355). Also, monocyte infiltration through the blood vessels into the white matter near the ventricles may represent a more aggressive form of the usual HIV invasion and not a form of multiple sclerosis. As the number of τ/δ T cells decline along with other T cell depletion in late AIDS, MS becomes even more rare (356). Antibodies to myelin basic protein, although nonspecific, may contribute to dementia or MS-like syndromes (333). The contribution of antibrain antibodies to brain pathology and dysfunction in ADC has not been fully established (349,357). A severe leukoencephalopathy was recently described in seven patients receiving HAART unsuccessfully, which was not successfully controlling HIV replication (358).

Chronic headache in the early stage of HIV infection may be due to aseptic meningitis, which has been steroid responsive in rare cases (30,359).

Acute or relapsing inflammatory demyelinating polyneuropathy (IDP) due to HIV was for a time in the 1980s and early 1990s the most common cause of Guillian- Barrž

in New York hospitals (personal observation). This syndrome presents with rapidly progressive ascending symmetric weakness and areßexia, occasionally producing facial diplegia or respiratory compromise, and is sometimes preceded by paresthesias or numbness in the feet and legs. Loss of vibratory sense is common. A related inßammatory condition, mononeuropathy multiplex, can involve cranial as well as peripheral nerves (195,360), especially the facial nerve (7,361). At times the course may be more indolent or relapsing, and is known as chronic inßammatory demyelinating polyneuropathy (CIDP). Cerebrospinal ßuid contains increased protein, up to two or three times the normal upper limit, and mild pleocytosis (generally 10Ð50 lymphocytes), which sets it apart from non-HIV related cases of IDP. The presence of anti-peripheral nerve myelin antibodies (334) and the response to plasmapheresis or infusion of intravenous immunoglobulin (IVIG) lend support to its cause being a deranged immune response. Nerve biopsies reveal segmental demyelination, variable amounts of axonal degeneration, and the presence of macrophages (335,362, 363). The degree of immunosuppression can be used to distinguish these conditions from CMV polyradiculopathy, which is clinically similar but only occurs at CD4 counts below 50 cells/mm3.

Autoimmune causes of a motor neuron syndrome have been associated with anti-asialo-GM1 antibody (364).

Myasthenia gravis in HIV is similar to that in non-HIV infection (337), but with lower titers of acetylcholine receptor antibodies (338). Because memory Tcells are the Þrst subset to be lost in HIV (365) and these are responsible for development of myasthenia syndromes, it is not surprising that these are rare, even in early HIV infection.

Polymyositis presents as proximal limb or neck muscle weakness, accompanied at times by pain, cramps, or easy fatiguability, in up to 2% of patients (232,366). Occasionally the skin rash of dermatomyositis is also present (226). Elevated CPK in the serum was found in 92% of patients with muscle weakness, not all of whom had polymyositis (235,307,336,367). However, 5% of asymptomatic patients with HIV have elevated CPKs (307). More speciÞc anti-muscle antibodies such as Jo-1 have not been studied in HIV polymyositis (367). Muscle biopsy shows inclusion bodies (231) or other inßammatory cells (232,362); some show fragments of HIV provirus (368). The presence of pain helps distinguish polymyositis from the nonspeciÞc weakness, muscle wasting and fatigue seen late in AIDS (369).

Treatment of autoimmune disease, even in HIV, consists of immunosuppression with corticosteroids. This was effective in approximately 50% of patients with myositis (233) and up to 80% of patients suffering from CIDP (363). It also has been used safely in patients with mononeuruitis multiplex with good results (339). Stronger immunosuppression with cyclosporine has been used in CIDP (370). Because plasmapheresis is cumbersone and somewhat risky (371), although efÞcacious, it is used less commonly than intravenous immunoglobulin therapy to treat CIDP and myositis (7,335,360,372,373).

Because restoration of the immune system should ideally occur with the advent of HAART, all of these syndromes should be watched for in the months following initiation of therapy. A nonspeciÞc syndrome causing arthralgias, myalgias and encephalopathy known as Immune Reconstitution Disease can occur within eight weeks of beginning therapy, most commonly in patients with CD4 counts below 100 cells/µl and co-infection with hepatitis C (374). Symptoms may require anti-inßammatory treatment, even with steroids, in order to continue HAART (57). In addition, recrudescence of various opportunistic infections, sometimes manifesting atypically (375), can be seen with reconstitution of the immune system. This is most common with mycobacterial and CMV infection but can occur with any infection.

Focal Neurologic Syndromes

General Principles (see Table 18.1)

Clinically, the causes of focal central nervous system dysfunction such as tumor, toxoplasmosis, viral and bacterial infection cannot be distinguished from one another. At times, even stroke or hemorrhage can be atypical in patients with AIDS. As antiviral treatment has improved, the incidence of opportunistic conditions has steadily decreased. For example, the incidence of toxoplasmosis went from 5.4% of patients in the multicenter AIDS Cohort Study in the U.S. in 1990Ð1992 to 2.2% in 1996Ð1998, lymphoma from 2.8% to 0.4% and progressive multifocal leukoencephalopathy (PML) from 2.0% to 1.5% in that time period (266), and the overall incidence of opportunistic infection (not just neurologic diseases) has fallen by 55% between 1992 and 1997 (4). Therefore, clinicians must be even more aware of clues to help distinguish among these conditions, and must also keep in mind non-AIDS related conditions such as malignancy (376). In addition, even with successful control of HIV infection, questions remain about the ability of a reconstituted immune system to suppress opportunistic infections. Restored T cells may no longer have memory for speciÞc infections, and therefore would not present the correct antigen to the immune system (4,5,377).

With these caveats in mind, the clinician can use the following guidelines to uncover the suspected etiology of a given patientÕs neurologic syndrome. Elements from the patientÕs history (e.g. presence of headache, encephalopathy or obtundation, focal or generalized seizures, rate of symptom progression), symptom complex to localize the site or sites of pathology, history of prior treatment, including compliance with currently recommended treatments for speciÞc infections, geographic and lifestyle

background that would have provided opportunities for acquisition of various organisms and stage of immunosuppression all help predict the infection or tumor at hand (4,378Ð381). Once a focal syndrome is suspected, even in a patient with a currently non-focal neurologic exam, radiologic evaluation using contrast enhancement is required. Although some diseases are indistinguishable on MRI or CT scan, such as toxoplasmosis vs. lymphoma, many, such as stroke, PML and herpes encephalitis, display their usual characteristics on these images. MRI cannot be performed on patients with pacemakers or ferromagnetic devices, including bullets, near critical areas, and is very loud and difÞcult to tolerate for claustrophobic patients. While increasing the sensitivity of the exam, iodinated contrast accompanying CT carries risks of renal failure or allergy. Conversely, the gadolinium-DTPA used intravenously with MR scanning, while safe, does not increase the testÕs sensitivity but does further characterise the lesions seen on unenhanced scans. These enhanced lesions appear bright on T1-weighted pulse sequences. Other special MR techniques include proton density weighting, which is similar to FLAIR in its ability to show all the lesions, and gradient echo which produces a signal void in areas containing blood products, such as hemorrhagic aspergillosis or encephalitis or hypertensive hemorrhage.

Nuclear studies such as thallium-201 SPECT scan further help distinguish malignant from nonmalignant lesions, (the former being hyper-(hot) and the latter hypometabolic (cold)). SPECT sensitivity is aided by the use of a delayed scan which allows calculation of retention index (382). Additional information can be obtained from PCR or antibody studies, although the latter is less reliable in late AIDS. For example, toxoplasma encephalitis is unlikely with negative antibodies, while lymphoma becomes more likely if evidence for Epstein-Barr virus is present in cerebrospinal ßuid (381).

When the patientÕs clinical condition allows some time (i.e. the mass is not causing herniation or respiratory compromise), the easiest and safest way to determine the cause of a mass is a clinical trial. SpeciÞc therapy, beginning with treatment for the most likely etiology based on geographic origin, is initiated. If no response to therapy is seen in two weeks, brain biopsy is indicated. The risks and beneÞts of this procedure will be discussed below. If herniation is diagnosed, decompression is mandatory (unless the patient responds quickly to treatment with corticosteroids, mannitol, glycerol or other nonspeciÞc medical therapy). The beneÞt of decompression is that culture and pathologic analysis can then be performed on the mass.

The characteristic symptoms of a mass relate to its location, while the rate of symptom progression relates to its etiology. For example, a patient with an embolic brain infarct due to endocarditis presents with abrupt onset of deÞcits, which may partially resolve or may later gradually worsen as an abscess grows in the infarcted area. The clinical picture will depend on the location of the lesion, examples of which are given below. Most commonly, ßuctuation of symptoms is due to seizures with post-ictal (ToddÕs) deÞcit for several hours or days, with subsequent recovery to baseline levels of deÞcit. Steroids produce a nonspeciÞc restoration of the blood brain barrier and improvement in the edema surrounding a mass from any cause, and therefore can invalidate a trial of speciÞc antiprotozoan or antibacterial therapy (379).

Although neurologic dysfunction deÞnitely corresponds to the area of the brain involved, the diagnosis may be difÞcult in patients with multiple lesions, simultaneous involvement of multiple areas of the neuraxis such as brain and spinal cord, or focal lesions superimposed on HIV dementia, neuropathy or metabolic encephalopathy. Additional problems interpreting neurologic signs emerge when a patientÕs mental status is depressed by drug use, increased intracranial pressure or herniation, seizure activity or metabolic dysfunction. Nevertheless, it is worth trying to localize systematically, especially when neuroradiologic support is unavailable or clinical response will be used to follow treatment efÞcacy. Cortical lesions are known to cause dysfunction of higher cognitive processing, such as aphasia with difÞculty producing speech if the lesion is anteriorly located in the frontal lobe (BrocaÕs area) or difÞculty comprehending language if the lesion is posteriorly located in the temporal lobe (WernickeÕs area). Bilateral temporal lobe involvement leads to problems storing or retrieving memory. Non-dominant hemisphere involvement causes neglect of the opposite side, anosognosia (failure to recognize the illness or disability), and difÞculty with language prosody or comprehension of the emotional meaning of speech. Contralateral sensory impairment is not usually complained of, but is noticeable when testing for stereognosis (object recognition by touch), extinction (failure to notice stimulation to the opposite side of the body or visual Þeld when both sides are simultaneously stimulated) and dysgraphia (failure to recognize letters or numbers ÒwrittenÓ on the hand with light touch). Patients may notice difÞculty Þnding their way or interpreting a map. If the occipital lobes are affected, a contralateral loss of vision in the hemiÞeld will be found. If the deeper areas of the hemisphere are involved, which is often the case from toxoplasmosis or lymphoma, contralateral weakness, tremor, rigidity or rarely hemiballismus (violent movements of the opposite limbs) may occur (383). Cerebellar and brainstem involvement cause cranial nerve abnormalities such as dizziness or vertigo, diplopia, nystagmus, dysarthria and dysphagia, with intention tremor or incoordination, and severe limb weakness or numbness opposite to the facial weakness.

Once the presence of a lesion or lesions is documented, a decision must be made as to the most likely cause, and treatment begun. Fever and headache are nonspeciÞc and unhelpful. CD4 count provides some guidance, with PML or lymphoma occurring below 100/mm^3, fungi and

protozoan infections occurring below 200/mm^3 and bacterial, mycobacterial, syphilitic and non AIDS-related malignancy occurring at any CD4 count. The radiologic picture is very useful in determining probable etiology. Ring-enhancement when gadolinium or iodinated contrast injection is used is present in cases of lymphoma or other malignancy, toxoplasma or the more rarely seen mycobacterial, bacterial or fungal abscesses. The latter infections may appear in the cortex or deeper, while lymphoma and toxoplasma encephalitis occur singly or in multiple locations often in the basal ganglia, gray-white matter junction or deep white matter. Usually pronounced edema is seen, and the degree of enhancement is not different in tumor or infection. The scan often looks much worse than the patient. Viral infections cause enhancement only in the case of CMV, which is located periventricularly; CMV has become uncommon in the era of HAART. PML, despite its name, appears as a single lesion in 10% of patients (384), often in the posterior fossa (cerebellum or brainstem), and rarely enhances.

Although SPECT Thallium-201 scans have been studied extensively in lymphoma, the sensitivity, even in experienced centers, is only 86–96% and the speciþcity is 76% to 83% (382,385), which limits its usefulness. Although sensitivity may be improved (reaching 100%) by the addition of gallium scintography to SPECT scans, speciþcity remained at only 80% of a series of 21 patients reported by Lee et al. (386). In one series, technetium-99m sestamibi scans showed higher lesion-to-normal tissue uptake ratios than thallium-201, suggesting that this scanning technique may be more sensitive (387). Positron emission tomography is less widely available and no more successful than thallium SPECT (385,388).

Cerebrospinal ßuid analysis is similarly frustrating in diagnostic yield, other than the correlation between lymphoma and a positive PCR for EBV. Cytology is usually negative even in patients with lymphoma, as there may not be communication between a deep lesion and the ventricles or subarachnoid space (385). CSF serology for toxoplasma can be helpful in establishing diagnosis of toxoplasma encephalitis (TE), with no patients in Skiest's series of 24 patients having a postivie CSF titer when TE was not diagnosed, with only one false negative for TE. The serum results, however, were similar. It is prudent to obtain serum toxoplasma titers at the time of initial diagnosis of HIV infection to learn who is at risk for this infection. Miller et al., in a series of 32 patients, however, found toxoplasma serologic status unhelpful in distinguishing TE from lymphoma, preferring to rely on the fact that solitary lesions were more likely to be lymphoma, and high uptake ratios on thallium SPECT scans were also suggestive of lymphoma (384).

At times biopsy is required to make a deþnitive diagnosis, such as when lesions fail to respond to treatment, or in cases of conßicting results of supportive tests. If biopsy is performed stereotactically there is reduced morbidity and mortality, but complication rates still range from 12–23%, with a mortality rate within two weeks of 2–12%, a rate that is higher than non-HIV infected patients undergoing stereotactic brain biopsy (378). This is due to bleeding in most cases (389), iatrogenic bacterial infection in a few and seizures or postoperative neurologic deþcit in others (378,390–392). The diagnostic yield was excellent in Antinori's review of 160 biopsies (381), and in Zunt's (378) review of several studies of contrast-enhancing lesions (88–98%) and fair in non-enhancing lesions (67%), but it must be remembered that there may be problems in interpreting biopsy results. For instance, in patients with multiple lesions, not every lesion may be due to the same etiology found in the one selected for biopsy, some lesions have multiple etiologies, some biopsies are nondiagnostic, and not every biopsy yields a treatable cause of the lesion. Life expectancy after biopsy remained less than two months in patients suffering from lymphoma in Antinori's series (381), and even some infections fail to respond to appropriate therapy. Nevertheless, patients generally beneþt from knowing the cause of the intracranial pathology, when it is safe to discover it, even when the answer does not change their treatment.

Malignancies (Brain/Spine/Cord Compression/Meningeal)

Lymphoma

Recently, primary lymphoma has overtaken toxoplasmosis as the most common cause of mass lesions in the CNS in some series of patients (380,390). Lymphoma (Hodgkin's and non-Hodgkin's) occurs with advanced immunosuppression (<50 CD4 cells/mm^3). Since the brain contains no native lymph tissue, it is not known why there is a propensity for lymphoma to form there. Some theories include the central nervous system's isolation from the body's ability to suppress malignant clones, which then develop within the brain in the absence of immune surveillance; the transformation of lymphocytes after they have passed through the blood-brain-barrier; and the presence of cell surface markers on transformed lymphocytes that cause them to be attracted to the CNS. Most cases are associated with infection by the Epstein Barr virus, which presumably stimulates production of B-cells; these grow out of control when the T-cells that normally balance them are lost.

Lymphoma can present with focal signs, seizures in up to 15%, and at times, global impairment of consciousness. Obtundation is especially common with increased intracranial pressure, multiple lesions or much edema around lesions. Lymphomatous meningitis produces cranial nerve or spinal root abnormalities, without headache. Single lesions are found on MRI, which is more sensitive than CT, in up to 50% of patients and multiple lesions in 50–70% (393) (Fig. 18.8). These enhance in a ring or patchy pattern in $>90\%$ of cases (379,394), although 27%

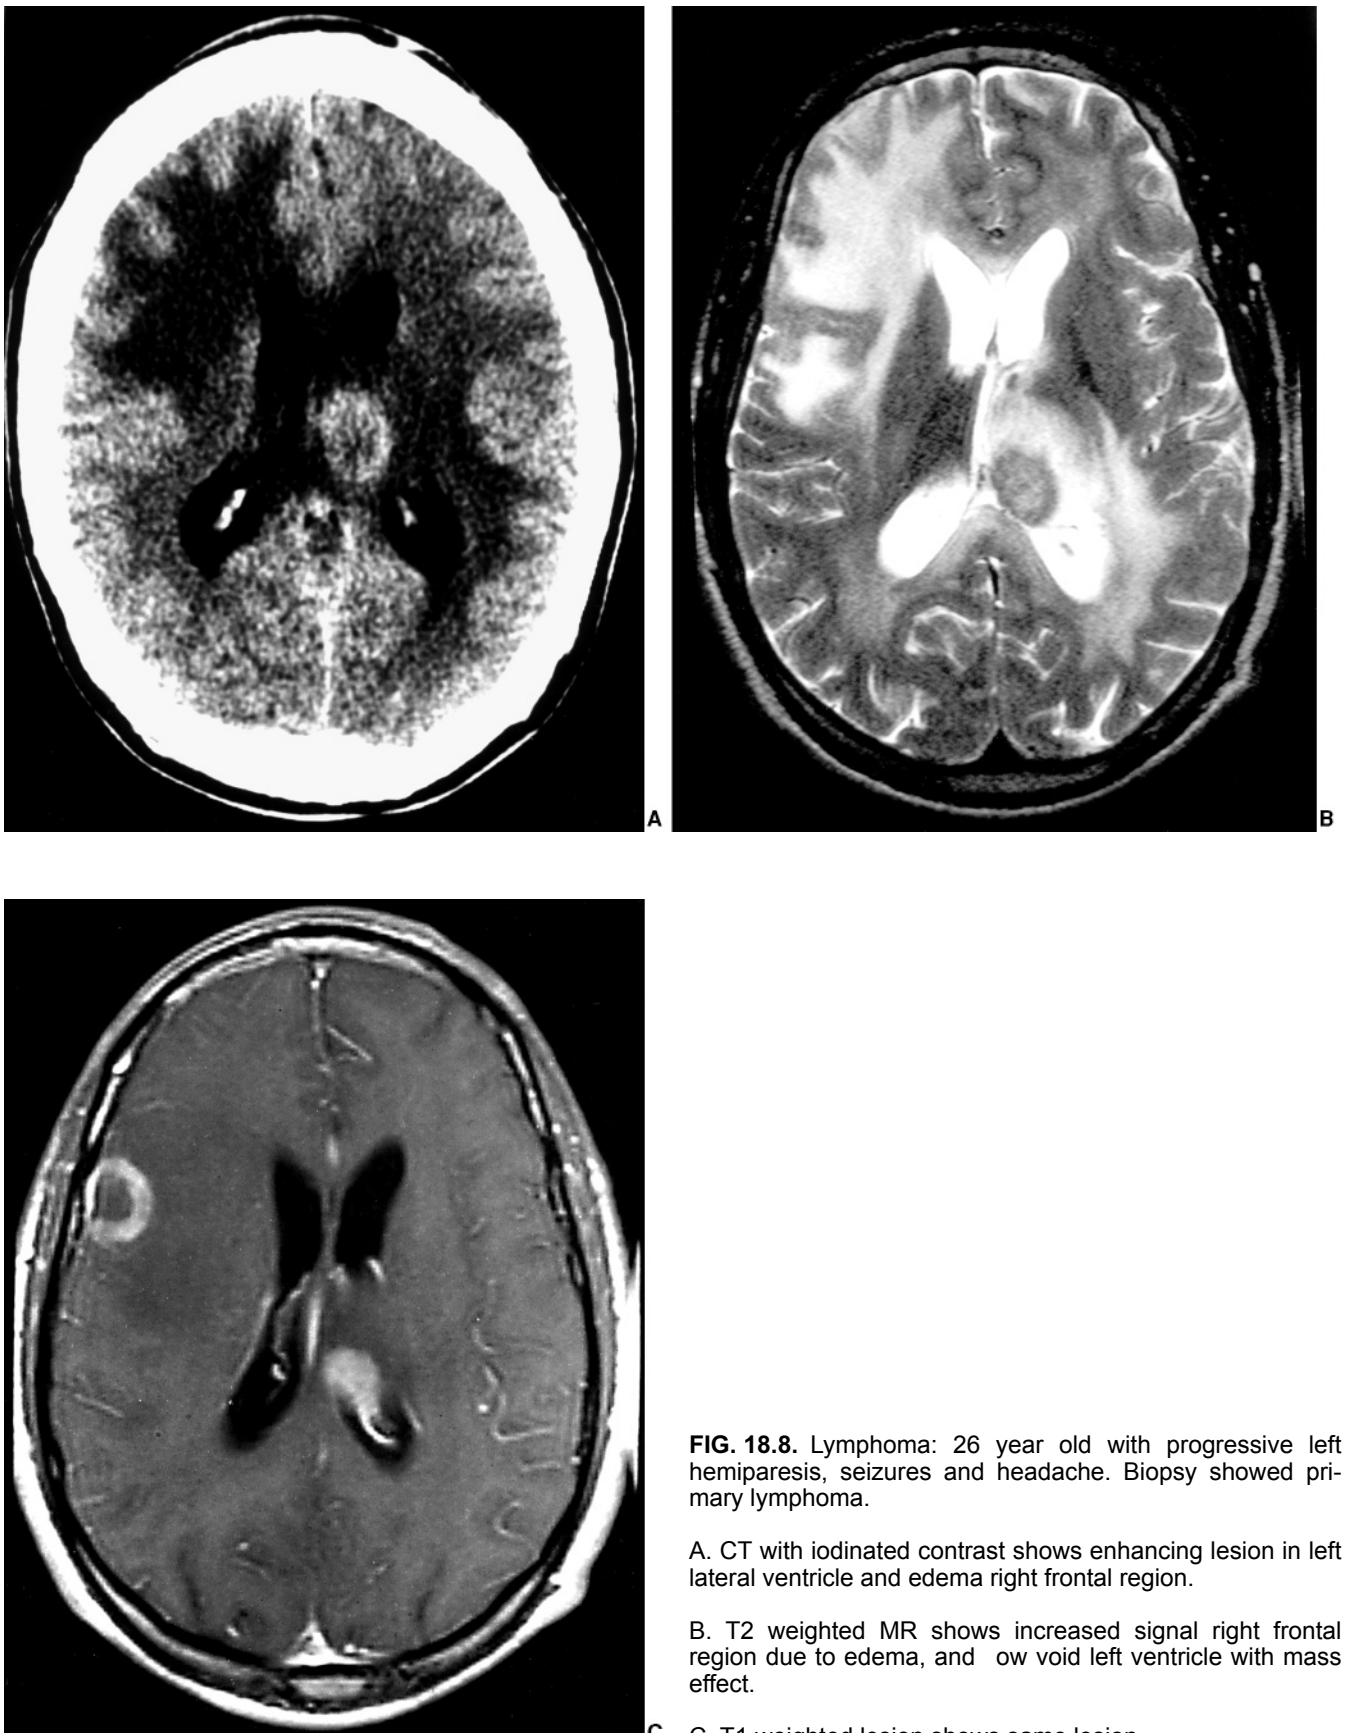

FIG. 18.8. Lymphoma: 26 year old with progressive left hemiparesis, seizures and headache. Biopsy showed primary lymphoma.

A. CT with iodinated contrast shows enhancing lesion in left lateral ventricle and edema right frontal region.

B. T2 weighted MR shows increased signal right frontal region due to edema, and ow void left ventricle with mass effect.

C. T1 weighted lesion shows same lesion.

of Thurnher's series of 60 lesions failed to enhance (395). These lesions are often found in the basal ganglia near the ependyma of the ventricles or near the meninges, and often involve the white matter (especially the corpus callosum) (396,397). There is usually marked edema and mass effect. Radiographic discrimination between tumor and infection is not possible, except in measuring the response during therapeutic trials using steroids for lymphoma and antibacterial drugs for infection. Metabolic studies are helpful, as tumor is hypermetabolic on PET, gallium and SPECT scans (385–387,398).

CSF analysis is usually nonspecific but may be required to rule out infection. Cytology for malignancy is less commonly abnormal in AIDS than non-AIDS lymphoma, where it is still only positive in less than 30% of cases (399). Occasionally lymphomatous meningitis is visible as enhanced meninges on neuroimaging, while remaining undetectable by cytologic analysis of up to 15 cc of CSF. This is attributed to the adherence of tumor cells to meningeal surfaces, preventing them from appearing in CSF (400). Using molecular techniques such as PCR-amplified nested CDR III to measure monoclonal markers of B cells, leptomeningeal involvement by tumor is more easily diagnosed (401). CSF examination is also useful in detecting PCR evidence of EB virus infection: EB viral DNA detection is both sensitive (50–100% of the time) and specific, with rare false negatives (379,381). In fact when EBV was detected in CSF, even without brain lesions, two of nine patients subsequently developed lymphoma (402). EB virus may not be the only oncogenic virus, as an isolated case of PML combined with lymphoma has suggested a possible role for JC virus (403). The same is not true of all viruses, as Kaposi's sarcoma-associated herpesvirus in CSF had no relationship to tumors in Brink's series (402). The presence of EB virus is so specific for lymphoma that a confirmatory brain biopsy is only mandated when nuclear imaging suggests malignancy, but EB virus is not detectable (392).

Once lymphoma is diagnosed, in order to direct treatment, systemic staging should be carried out and ocular and meningeal lymphoma ruled out by slit lamp exam and CSF examination, respectively. Non-Hodgkin's lymphoma occurs more often in the meninges than brain or cord parenchyma (172), while one case of angiotropic large cell lymphoma has been described in the brain (404). Survival for all patients with lymphoma used to average four to eight weeks, but in recent series this has been extended to six to twelve months, or longer with immune reconstitution.

Treatment with radiation, preceded by steroids to avoid herniation and minimize radiation induced headache, nausea and vomiting, has been successful. In cases where biopsy is not easily obtained, radiation has even been used empirically to diagnose lymphoma (4005). Radiation is given as 3–4,000 cGy in 10 fractionated sessions to the whole brain, with prolonged survival (mean 122 days) (406) in some patients, in whom death came from unrelated causes. Chemotherapy with methotrexate delivered systemically or intrathecally may achieve survivals of up to two years, but may be difficult to tolerate (407,408). Some HIV-infected patients will be able to receive chemotherapeutic regimens employed in immunocompetent patients, such as temozolomide (409) or cytarabine combined with methotrexate (410). Antiviral therapy directed against EBV (zidovudine, ganciclovir and interleukin 2) has also shown success in four of five patients treated by Raez and colleagues (411). Success can be measured by response of lesion size on follow-up imaging with MR, CT, or nuclear studies or by measurement of levels of EBV DNA in CSF (412). If HAART is successful in reconstituting the immune system, lymphoma may be contained (413–415).

Spinal cord involvement occurs with metastatic or primary lymphoma in up to 25% of cases (416), and is seen in other tumors. Presumed spread from leptomeningeal involvement is responsible, leading to patchy involvement as well as unilevel cord compression. Metastatic lymphoma is usually B-cell, immunoblastic, or occasionally small non-cleaved cell in origin (172). Radiation and chemotherapy including intrathecal methotrexate only help in 50% of patients, and survival is usually less than six months (417). HAART does not seem to improve outcome.

Lymphomatous or carcinomatous meningitis causes isolated cranial and spinal nerve root symptoms, usually without headache or meningeal signs. CSF shows an elevated protein and pleocytosis, with a low glucose present in some cases. Cytology, performed on at least 3 ccs of formalin-fixed CSF, is positive in less than 30% of patients but new molecular techniques should help improve sensitivity (400). The presence of tumor cells in CSF determines the need for intrathecal chemotherapy (407).

Kaposi's Sarcoma

Kaposi's sarcoma remains extremely rare in the nervous system (2,418,419), for unclear reasons.

Primary Brain Tumors (Glioma, Astrocytoma)

Other malignancies, including primary brain tumors, are appearing in increasing numbers of younger AIDS patients (420). In an early series, a prevalence of glioma of 0.5% among all tumors was found (421) and a total of 19 cases of glioma were reported in the AIDS literature (including postmortem and surgical pathology) up to 1994 (422). In 250 biopsies (and two craniotomies), Gildenberg diagnosed eight non-lymphomatous neoplasms (423). Up to 6% of mass lesions in two small series of AIDS patients were found to be glial cell tumors (422,424,425). Since most patients died within three months, it is unlikely that

this high frequency is simply an artifact of early discovery of tumors due to the frequent scans that AIDS patients undergo. A failure of the immune system to perform normal tumor surveillance in severely immunosuppressed patients (422) has been postulated, but not all patients have extremely low CD4 counts. In fact there is no relationship of degree of immunosuppression or CD4 count to grade of malignancy (426). Instead, HIV may play an oncogenic role for glial cells. The same cytokines involved in dementia, such as transforming GF-β, also stimulate astrocytosis and tumor growth. For example, we cared for a 35 year old woman with recurrent schwannomas in the spinal cord (427) for over ten years who finally succumbed to a highly malignant peripheral nerve sarcoma after contracting HIV, despite a relatively high CD4 count. This suggested a role for HIV in turning off an already dysfunctional tumor suppressor gene.

Metastatic Lesions

In patients who are not severely immunosuppressed, metastatic tumors must be kept in mind, especially as the risk of stereotactic biopsy in this group is low (Figs. 18.9 and 18.10) (381,392). If nuclear scans implicate malignancy and patients have negative EB virus and toxoplasma serologies, surgery is recommended. Complete removal of the lesion is especially recommended if the location is favorable, the patient medically stable and there is only one lesion. Early biopsy at least should be offered to avoid neurologic deterioration during empiric trials of antibacterial agents. If surgery is not an option, whole brain or focused beam radiation (gamma knife) may be given (428). As patients with HIV infection survive longer, disease unrelated to their infection must be kept in mind. In addition, surgery, especially biopsy, is safer and should be performed according to the standard of care.

CNS INFECTIONS (BRAIN/SPINE/MENINGEAL)

Protozoan and Helminthic Infection

Toxoplasma gondii

Until recently, toxoplasmosis was the most common cause of mass lesions in the brain of AIDS patients (429–431). In the era of HAART (surveyed in 1998), the proportion of deaths from toxoplasmosis decreased from 3.5 to 1.9% of patients in the U.S. (266,432) with a corresponding four-fold decrease in incidence in France, where up to 80% of the population is seropositive (378,433). The presentation is typical of a structural brain lesion: symptoms and signs referable to the area(s) of the brain affected, often accompanied by headache (60%), fever (70%), seizures (25%) and confusion (40%) that progress slowly over several weeks. Abrupt onset of focal deficit is described in patients with seizures or hemorrhage into a lesion. At times focal signs are superimposed on diffuse signs of HIV related dementia (379,429,430). There is a predilection for involvement of the gray-white matter junction, thalamus and basal ganglia, resulting in frequent hemiparesis or parietal signs such as neglect, denial of illness, visual field cut and hemisensory loss (379). Despite the frequency of basal ganglia lesions, movement disorders are rare (112,434). The brainstem is rarely involved (435), but sixth nerve palsies due to increased intracranial pressure are occasionally seen. Diffuse encephalitis is more rapidly progressive and often fatal (436). It was responsible for seven of 55 cases of TE in Khuong's series (437). Even before effective antiretroviral therapy was available, the widespread use of trimethoprim-sulfamethoxazole for prophylaxis of *Pneumocystis carinii* infection, which offers protection against toxoplasma as well, likely contributed to a lower incidence of toxoplasmosis (5–15%) than might have been anticipated based on seroprevalence rates (30%) in the United States (429,438–440). In addition, even in areas with much higher seroprevalence rates, such as France and Africa (presumably due to increased exposure to wild cat feces or undercooked meat), there is a variable rate of toxoplasmosis among patients with similar levels of immune depression. This suggests a role for genetic aspects of host susceptibility to infection (440), with those with histocompatibility types of HLA-DQ3 being more susceptible and those with HLA-DQ1 more resistant to encephalitis (441,442). Although the reactivation of infection, caused by the breakdown of latent cysts, followed by tachyzoite proliferation, is clearly related to failure of cell-mediated immunity due to drop in T cells, a collaboration with the humoral system, mediated through cytokines that stimulate antibody production by microglia and dendritic brain cells, has been established in animal models (441). Some variability in the severity of inflammation triggered by the tachyzoite also hinges on the parasite, as some strains use different TNF-dependent pathways to activate iNOS (441) or the transcription factor NFκB, which regulate the production of the chemokines involved in the inflammatory cascade (443). The parasite also varies in the recruitment of neutrophils across the blood-brain-barrier to suppress parenchymal infection (444).

Radiologic evaluation of toxoplasma encephalitis includes CT or MRI with contrast enhancement (Fig. 18.11), which typically reveals ring-enhancing or nodular lesions with much edema. Most patients have multiple lesions, although up to 40% may be solitary (379). On MR the lesions have decreased signal on T1-weighted and increased signal on T2-weighted images, and are typically found in the basal ganglia, thalamus or corticomedullary junction. Metabolic imaging with PET (388) or SPECT using technetium-99m sestamibi or thallium-201 (386,387) may help to differentiate TE from lymphoma or malignancy, which are found in the same locations (385).

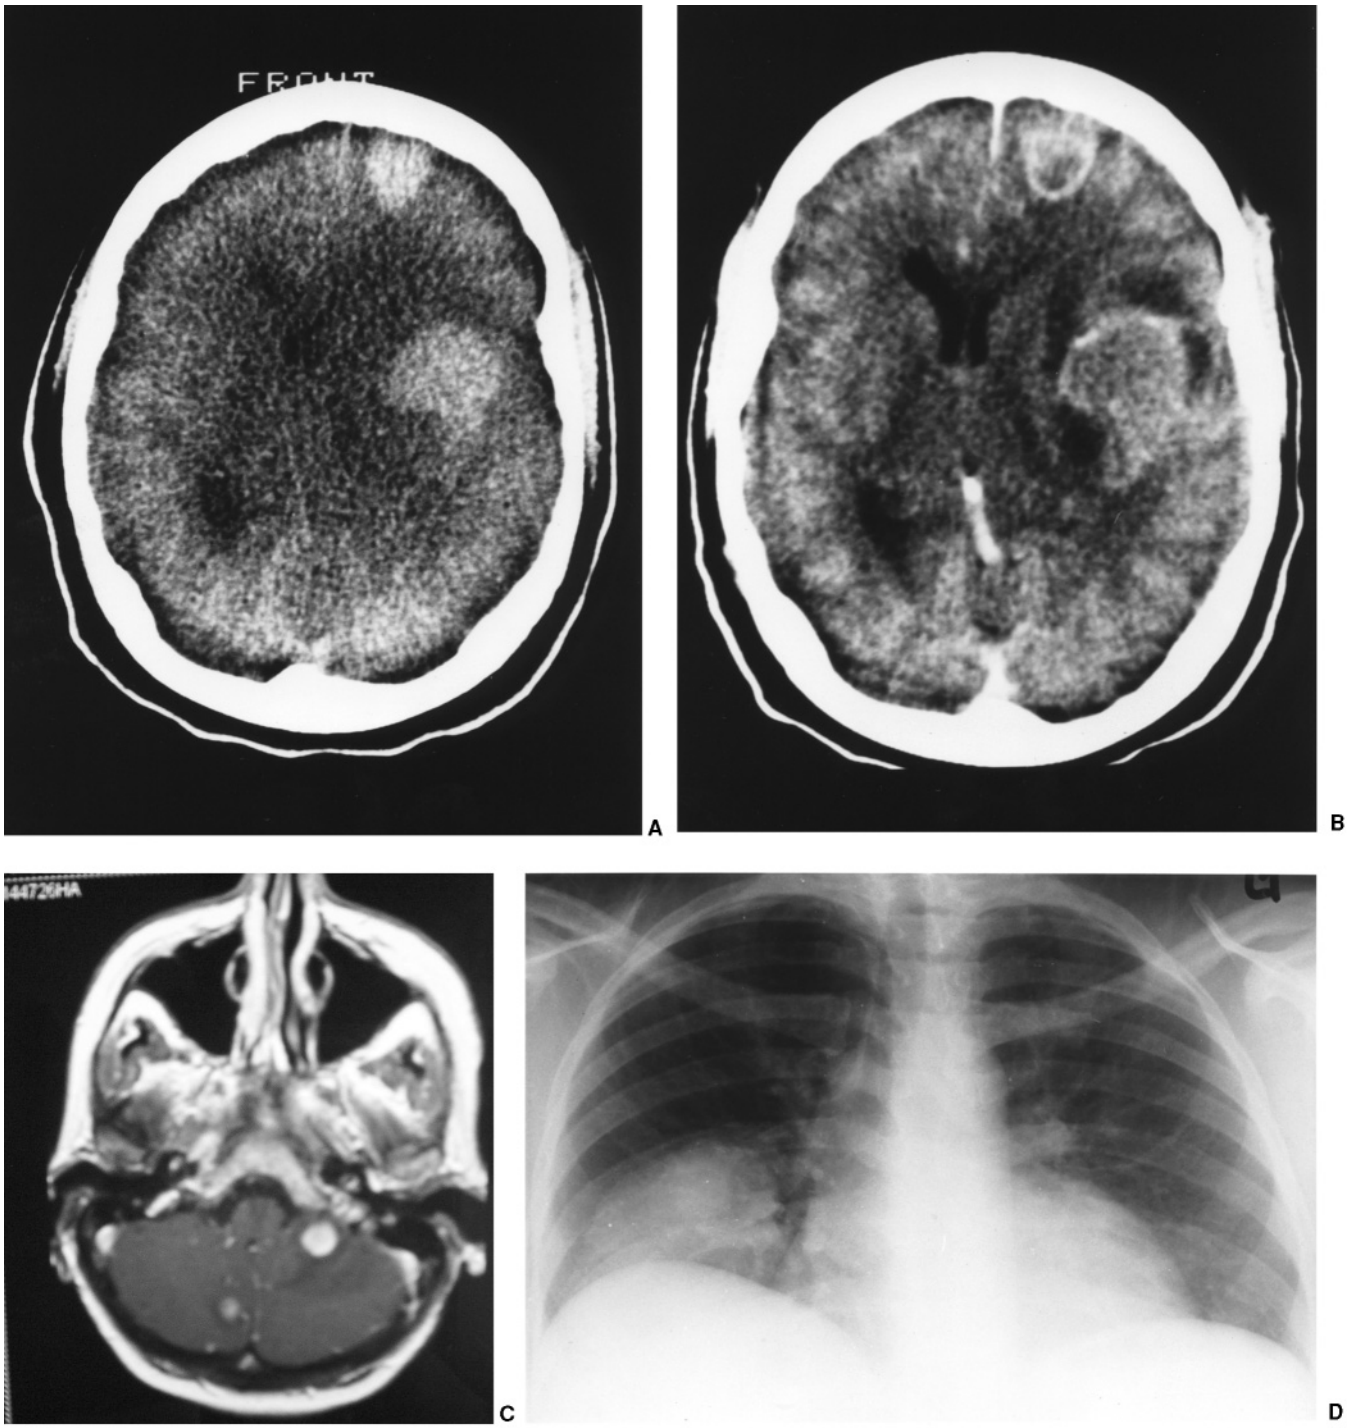

FIG. 18.9. Metastases from adenocarcinoma of lung:

A. Noncontrast CT of a 34 year old pregnant woman being treated unsuccessfully for toxoplasmosis. Hyperdense lesions are present in both frontal regions.

B. CT with iodinated contrast showing enhancement and surrounding edema of same lesions.

C. Brain MRI (T2, with gadopentate) shows two enhancing lesions in the posterior fossa. Others were seen in the cortical gray-white matter junction.

D. Chest radiograph shows large lesion in the right lower lobe, which proved to be an undifferentiated bronchogenic adenocarcinoma on bronchoscopic biopsy.

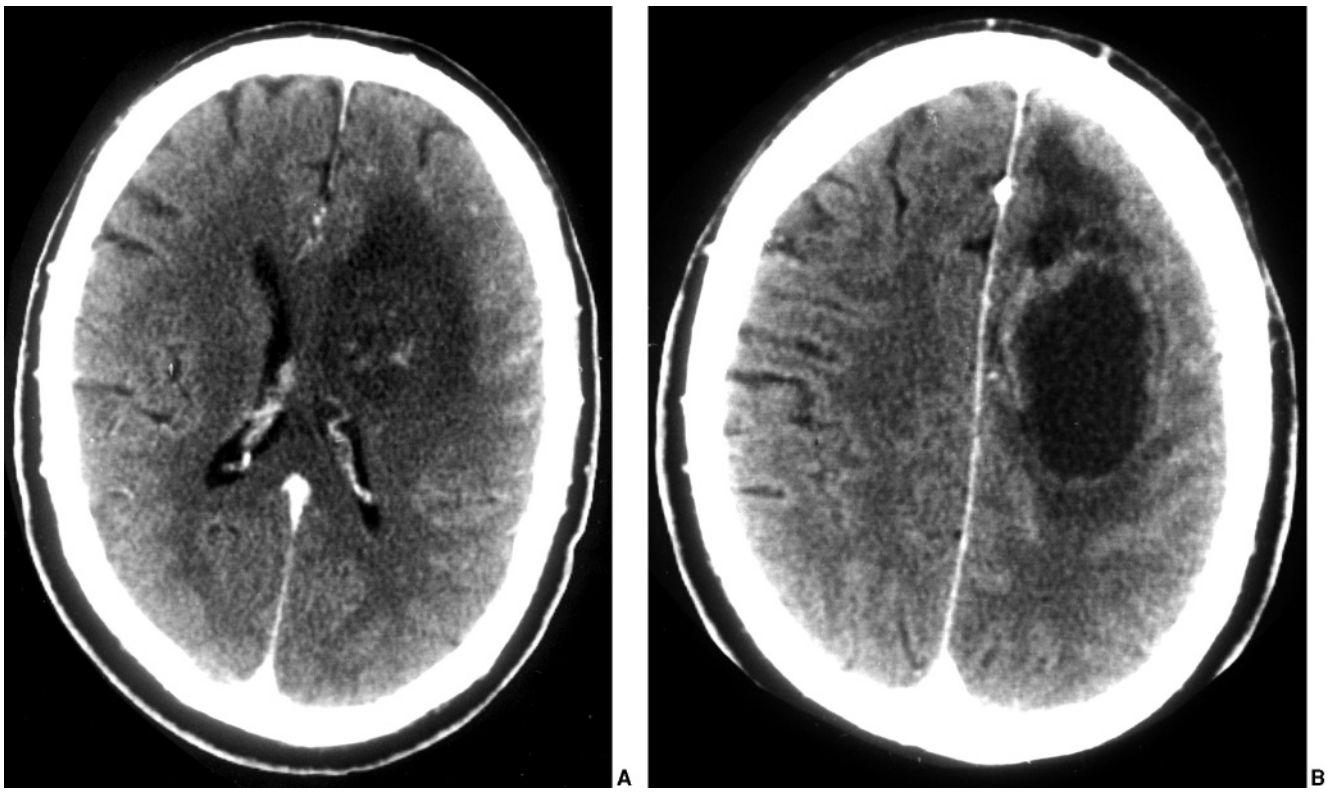

FIG. 18.10. Metastatic lesion from mucinous lung carcinoma:

A. Minimally enhancing large cystic lesion in the left basal ganglia and frontal lobe in a 54 year old heavy smoker with 900 CD4 cells.

B. Higher axial cut of same patient showing rim enhancement of lesion. Biopsy and drainage temporarily improved symptoms, which recurred two months after surgical resection. Pathology revealed mucinous adenocarcinoma.

Malignancy is hypermetabolic and infection hypometabolic. Gallium scintography also distinguishes malignancy from infection (398), but is not speciÞc for infection with *Toxoplasma gondii* as it can be positive in cases of progressive multifocal leukoencephalopathy (PML) (386) and others.

Serologic studies supplement imaging, but are not 100% sensitive. Cerebrospinal ßuid analysis using PCR plays a minor role in diagnosis (379,445) as the sensitivity, though better than that in the plasma, is only 33%. (However, a negative PCR for Epstein-Barr virus can be useful to rule out lymphoma (382,385).) Serology for IgG antibody to *T. gondii* should be performed when a patient is diagnosed with HIV, both to predict future illness (379,385,438,446) and to counsel those patients who have not been previously exposed to the parasite in avoidance techniques (379,385,438,446Ð449). Fluctuations in titer do not reßect disease activity and should not be used to measure response to treatment (447).

Treatment and prevention of TE are covered in Chapter 00 (433,450Ð452). Clinical and radiographic response is rapid, allowing a one or two week trial for diagnostic purposes. In most cases the lesions disappear completely and may calcify (435).

Spinal cord involvement (Fig. 18.12) at any level causes myelopathy or conus medullaris syndrome (171,455,456). Meningitis is rare in toxoplasma infection.

Trypanosomiasis

This protozoan, responsible for ChagasÕ disease, is endemic in Latin America and may be reactivated as patients become immunosuppressed. Two cases of enhancing mass lesions have been reported in patients with AIDS, with amastigotes seen within chronic inßammation on biopsy (457,458). One additional patient died from diffuse meningoencephalitis due to trypanosomiasis (459). An excellent review of current diagnosis and treatment strategies is presented elsewhere (460).

Schistosomiasis

A widespread infection, schistosomiasis mainly involves the liver or genitourinary system, but may produce seizures or spinal cord symptoms due to aberrant migration of worms or embolization of eggs (461). Additional neurologic symptoms due to hepatic encephalopathy may occur, as a consequence of cirrhosis and liver

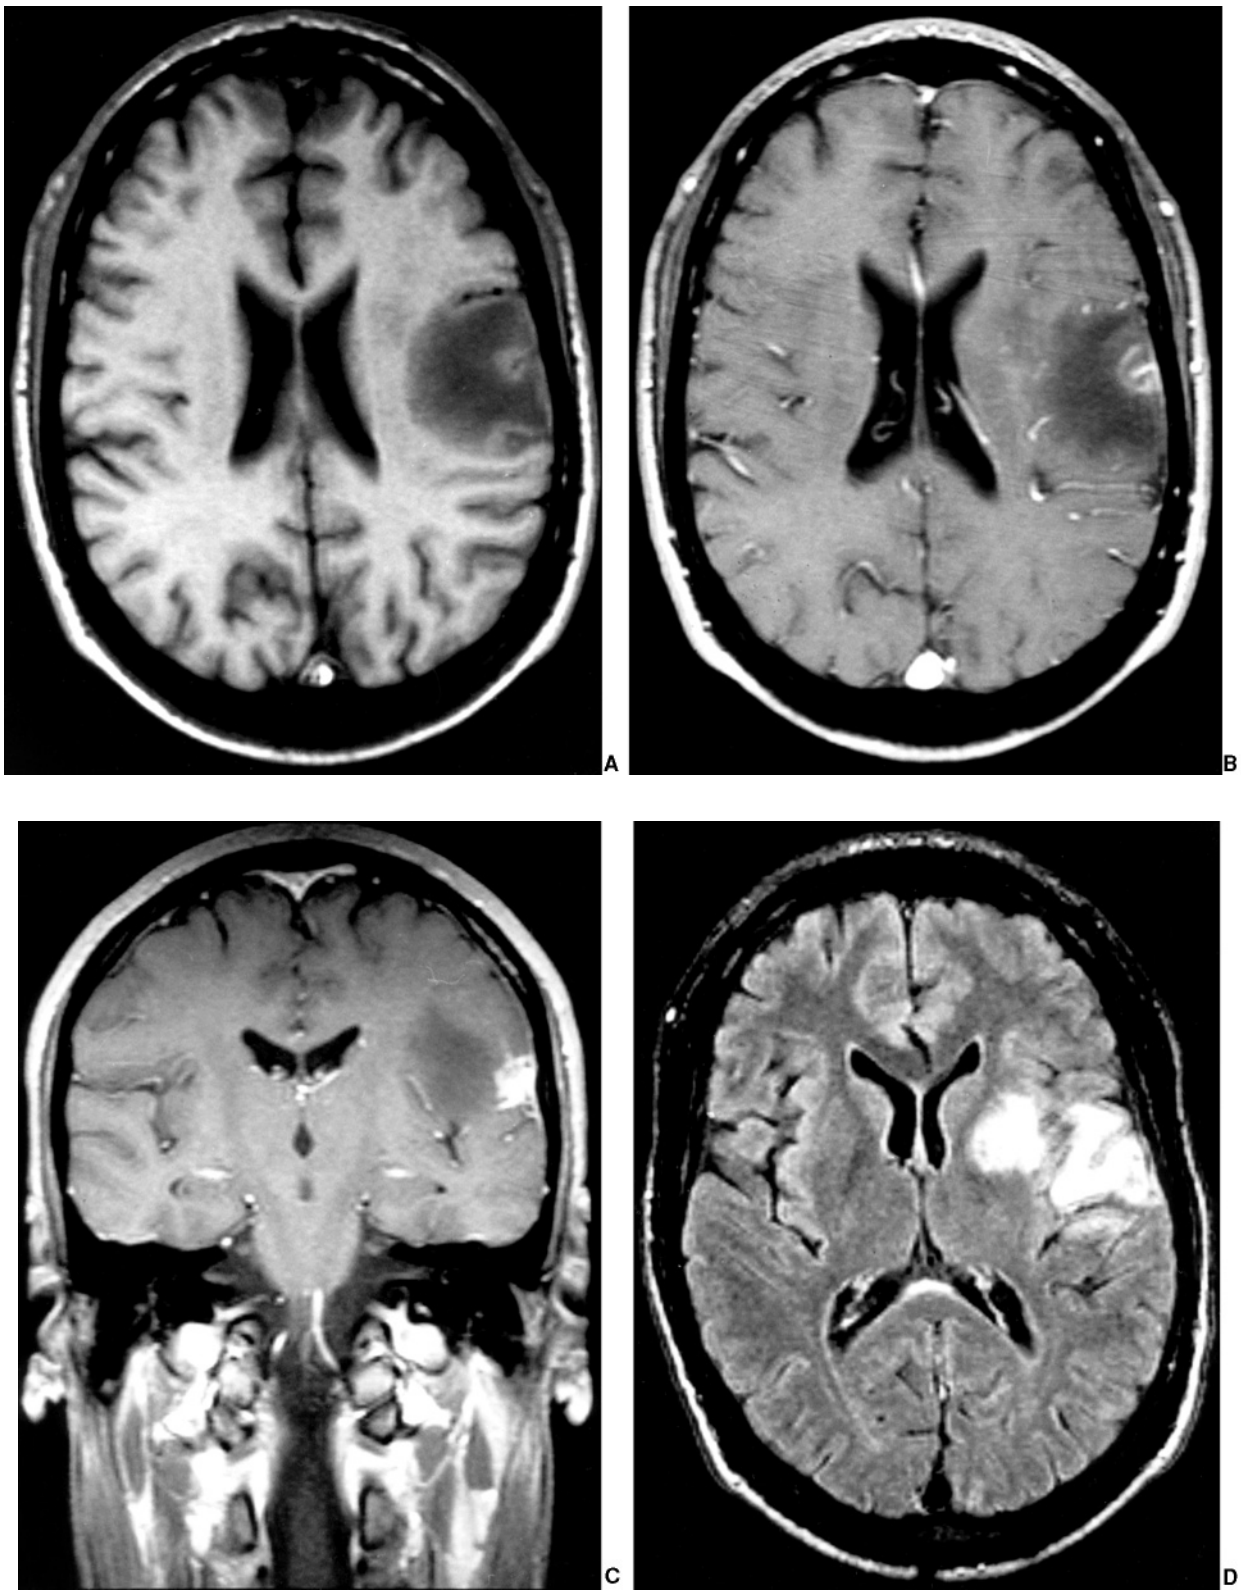

FIG. 18.11. Toxoplasmosis: 32 year old man with seizures and mild post ictal aphasia. Symptoms resolved with treatment with sulfadiazine and pyrimethamine but recurred when folic acid accidentally substituted for folinic acid.

B. Four weeks of treatment with sulfadiazine and pyrimethamine show resolution of the mass on gadolinium-enhanced MR.

failure. Treatment with praziqauntel works even in patients with HIV, and steroids are often given as well, to control cerebral edema. Alternative drugs include metrifonante and oxamniquine.

Cysticercosis

Although not an opportunistic infection and not more virulent in immunosuppressed hosts, *Taenium solium* infection is extremely common in many areas of the world and can be found on CT or MR of patients with AIDS (396). The most common presentation is seizure activity, with rare cases of focal neurologic deÞcit due to a mass lesion (462). Hydrocephalus occurs when there is blockage of CSF ßow due to intraventricular infection with the racemose form of the parasite, or incomplete absorption of CSF due to meningeal scarring. CalciÞcation on imaging means the parasite has been dead for some time. Eosinophilic meningitis may be found in immunocompetent patients.

Bacterial Infection

Although they are not considered opportunistic infections, bacteria must be kept in mind in the setting of HIV infection, as uncommon pathogens can be responsible for symptoms. This is especially true of children who have had limited exposure to opportunistic pathogens, of patients who have used medications that suppress the bone marrow, leading to neutropenia, and of injection drug users who suffer from skin ulcers or who improperly clean or share needles, resulting in injection of microorganisms (463). In addition to strokes and abscess formation from infected emboli, patients with bacterial endocarditis are at risk for mycotic aneurysms and subarachnoid hemorrhage (464). Nosocomial bacterial infections, including postoperative complications, are also seen more often in patients with AIDS.

In early series (pre-HAART), bacterial infections caused neurologic complications in 2% of patients with AIDS in Miami and 2Ð4% of those in New York, most of whom were intravenous drug users (Fig. 18.13). These bacterial infections can appear at any CD4 count; without a highly increased incidence in the HIV-infected population (465). Campylobacter infection may trigger some cases of Guillian-BarrŽ (466).

Bacterial infection of the brain or meninges tends to be due to encapsulated organisms such as *Streptococcus pneumoniae*. Because some bacteria, such as nocardia and listeria, are suppressed by prophylactic regimens for pneumocystis, the incidence of infection is extremely low (465). *Nocardia asteroides*, an aerobic gram-positive, weakly acid-fast bacillus, has rarely been reported to cause brain abscess (467,468); *Listeria monocytogenes,* an intracellular gram-positive bacterium, has caused abscess and meningitis (469Ð472). *Salmonella* (468), *Staphylococcus epidermidis* (473), *S. mitis* (474) and *S. pneumoniae* (475,476), have all caused cerebral abscesses (Fig. 18.14). *Streptococcal* and *Staphylococcal* organisms have also been cultured from spinal epidural abscesses

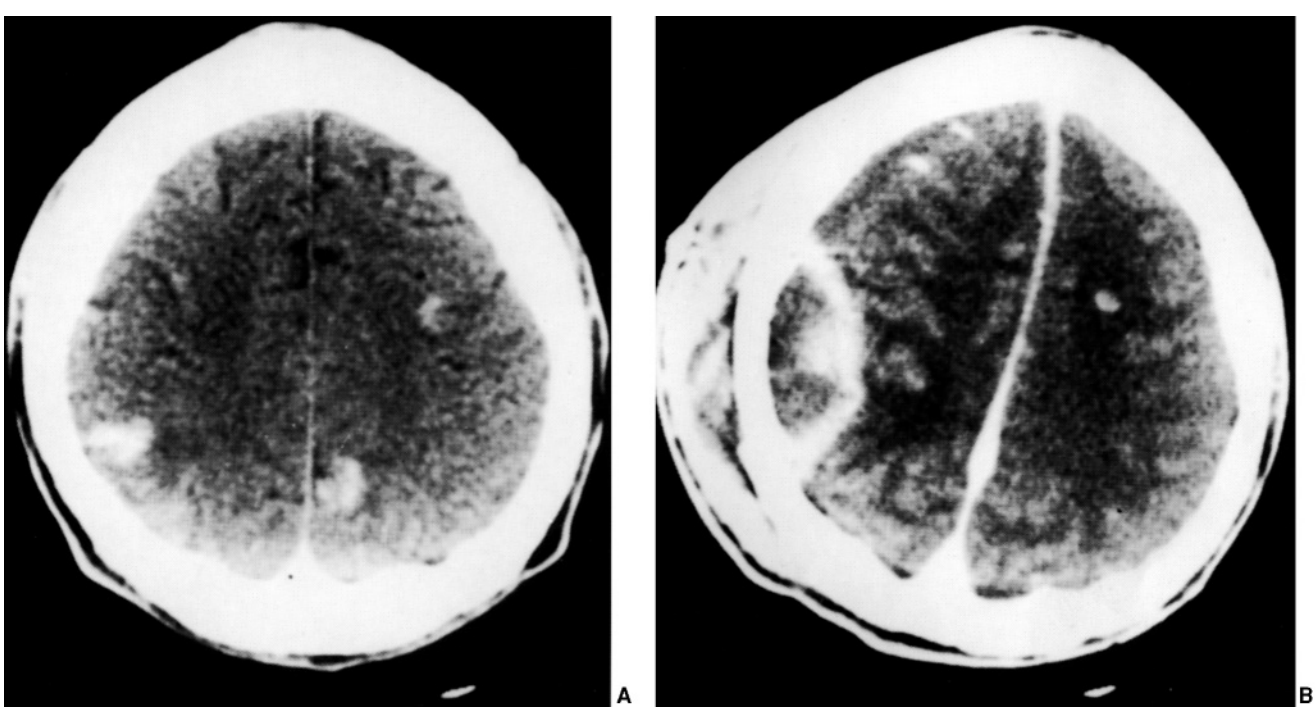

FIG. 18.13. Bacterial infection (brain abscess): CT with contrast showing enhancing lesion near craniotomy defect after a biopsy for suspected toxoplasmosis.

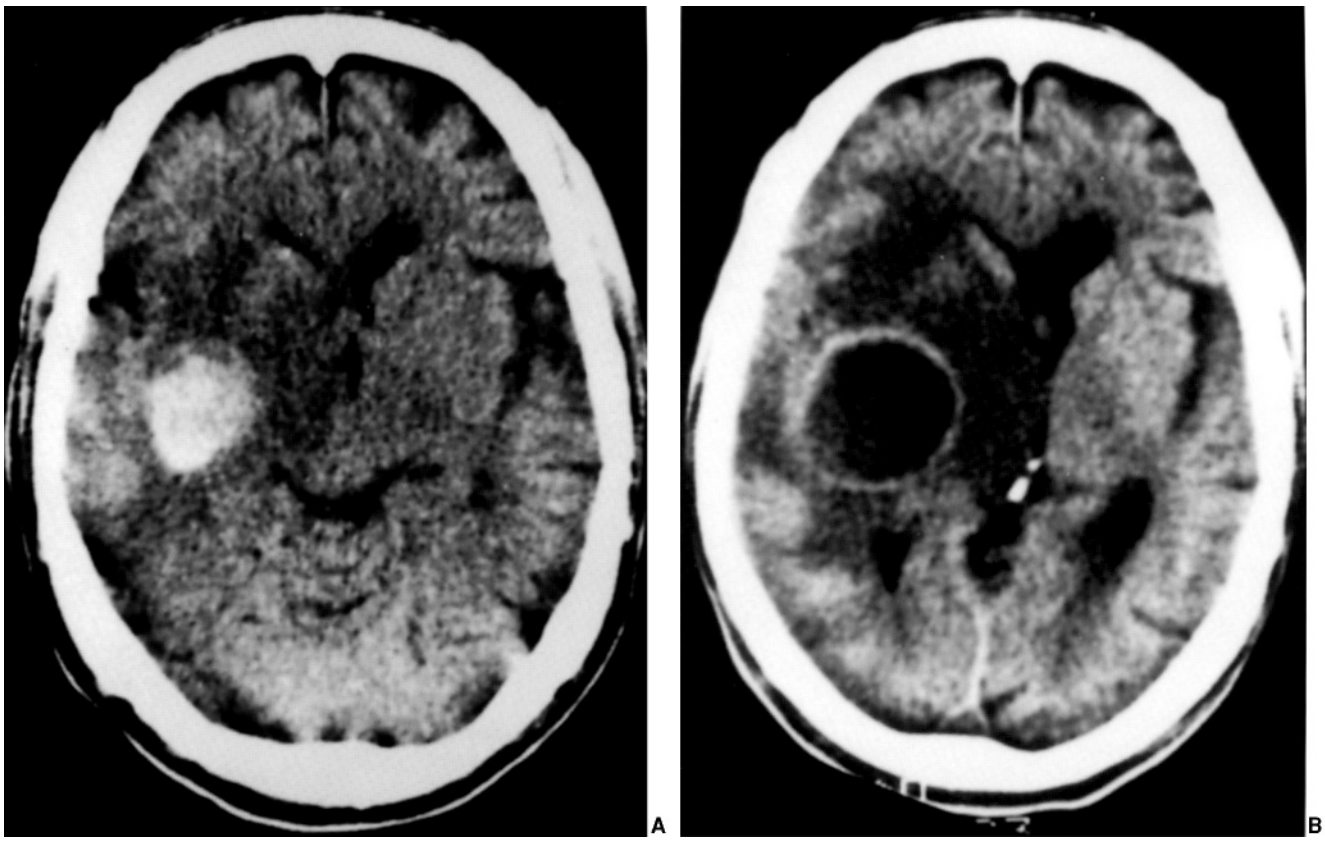

FIG. 18.14. Hemorrhage with ensuing brain abscess:

A. Noncontrast brain CT of a 40 year old hypertensive man presenting with acute left hemiplegia while septic from Streptococcus, showing hyperdense right basal ganglia mass consistent with hematoma.
B. Contrast enhanced CT of patient six weeks later when he presented with obtundation, left hemiplegia and fever. Enhancing cystic appearing mass with marked edema and mass effect appears in region of prior hematoma.

(170,477). *Escherichis coli* (478), *S. pneumoniae* and *H. inßuenzae* have produced meningitis (479). Lesions in the dural space may extend from bone involvement due to *Rochalimaea* species, which is responsible for bacillary angiomatosis and cat scratch fever (480); antibodies to this bacterium have been found in the CSF of patients with meningitis (481). Whipple's disease due to *Tropheyma whippelii*, presenting with diarrhea and a brainstem syndrome of jaw clenching, rhythmic palatal and facial myoclonus followed by supranuclear eye palsy, has been described in AIDS (112), but treatment with the appropriate antibiotics (chloramphenicol, trimethoprim-sulfamethoxazole) did not reverse the brainstem dysfunction. Many of the above infections were only diagnosed at autopsy.

In some cases, despite the inability to identify a speciÞc pathogen, features of the clinical course allow presumptive treatment of bacterial infection without culture (482). Ideally, treatment should be culture speciÞc, after drainage or resection of mass lesions and CSF analysis of meningitis.

Although not within the CNS, sinusitis is quite common and causes headache in patients with AIDS (483,484).

Spinal cord involvement generally spreads from disc space or bone infection, leading to compression of the thecal sac and underlying cord. Symptoms of epidural abscess (Fig. 18.15) include localized pain that is worse on standing, radicular pain in the area of the abscess, weakness and spasticity below the lesion, urinary frequency and urgency or a ßaccid bladder if the lumbosacral region is involved. Progression of symptoms may be acute or subacute, over a few weeks. Fever and systemic signs may be present. Tenderness and increased warmth may be present on exam, along with a sensory level to pin and temperature, upper motor neuron signs such as proximal leg weakness, Babinski signs, hyperreßexia and increased tone, or lower motor neuron signs if nerve roots are involved. Intravenous drug use, recent surgery or trauma are risks for epidural abscess in the immunocompromised AIDS patient just as they are in the general population (477). Plain radiographs may show vertebral body infection or a collapsed disc space; computed tomography with myelography or MRI with gadopentate enhancement are much more sensitive. Distortion of the spinal cord from an enhancing mass can extend for multiple levels, and is occasionally accompanied by increased signal within the

cord as well. The abscess is iso- or hypo-intense on T1 weighted image and hyperintense on T2 (485). Gallium scan can show paravertebral extension. Intramedullary enhancement is due to infection within the spinal cord itself (383).

Treatment must be determined by culture and sensitivity of infected material, which can be obtained by needle biopsy under CT guidance, or if clinically indicated, at the time of surgical decompression of the abscess. Blood cultures may be helpful. Due to the adhesions formed by these infections, decompression is often required to obtain full improvement. Duration of antibiotic use is usually six weeks, as in nonimmunosuppressed patients.

Meningitis presents with encephalopathy, the severity of which correlates with mortality. Headache, photophobia, nuchal rigidity and altered mental state all occur. The incidence of meningitis due to bacteria is not increased in HIV infection, except in children with AIDS, and is not related to T cell count (486). CSF has pleocytosis with predominance of polymorphonuclear leukocytes, hypoglycorrachia (CSF glucose $< 2/3$ serum) and an elevated protein level. Gram stain gives clues to the nature of infection, i.e. gram positive (Staphylococcus, Streptococcus, Listeria) or gram negative (Neisseria, Pseudomonas, Enterobacteriaceae) or amoebic (Naegleria, Acanthamoeba). Antibody testing is helpful for Borrelia, Treponema, and Leptospira. Bacterial antigen testing can be used if the patient has been on antibiotics at the time the culture was obtained. Adjustment in broad-spectrum therapy should be made after the results of cultures become available (usually after two to three days) (487). The exact cause of brain damage due to meningitis is unknown, but markers of excess oxidation and reactive nitrogen and oxygen correlate with outcome (488) (Fig. 18.16).

Treponemal Infection

Syphilis has long been associated with HIV infection, as chancres may facilitate acquisition of HIV and theoretically meningitis in the secondary stage of syphilis may facilitate HIV entry into the brain. In the 1980s and early 1990s the incidence of primary and secondary syphilis increased but is now stable. Controversy exists as to the reliability of serum and CSF tests in the diagnosis of neurosyphilis (490,491), and to the most effective treatment of syphilis and neurosyphilis (491–494). In the general population, syphilis progresses to neurosyphilis in less than 10% of untreated patients, an incidence that is not increased in the presence of HIV infection. For example, even in areas with high background rates of syphilis such

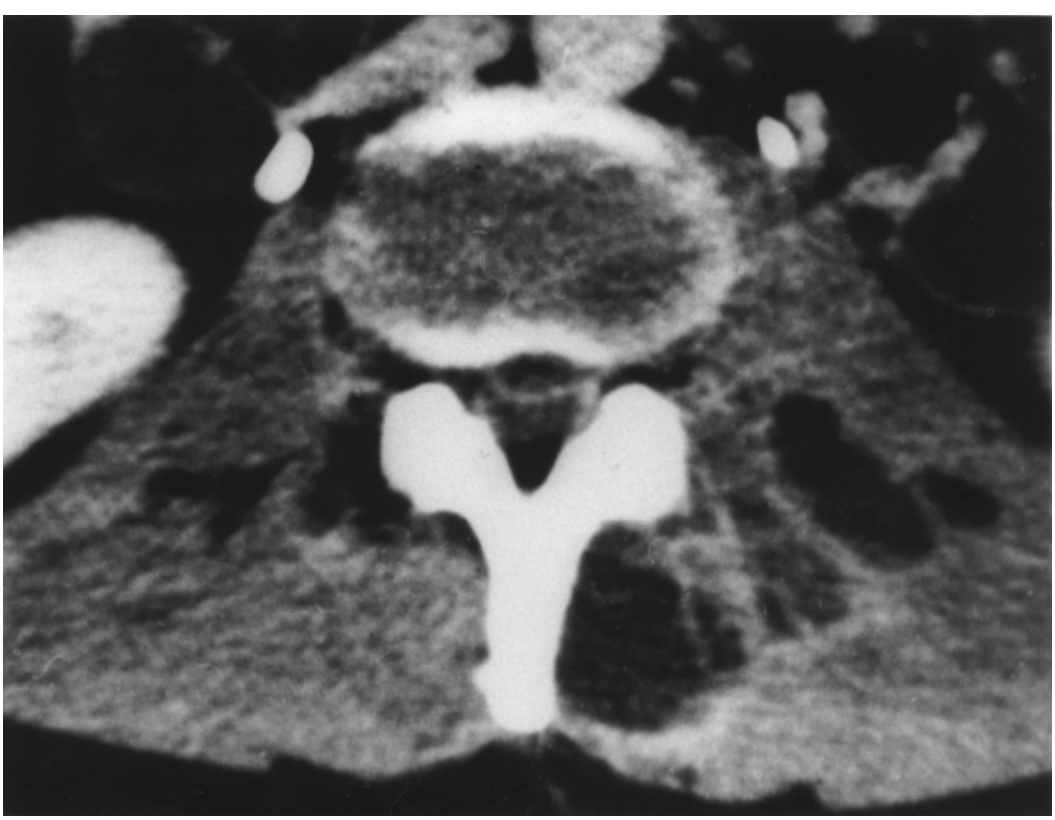

FIG. 18.15. Spinal cord epidural abscess: CT with contrast of 28 year old man with urinary hesitancy, marked back pain and mild proximal leg weakness with increased tone. Blood cultures grew *S. aureus*. Scan shows enhancing rim of dura projecting from disc space into spinal canal, and hypodense lesion with enhancing membranes in the right psoas muscle which is where abscess began.

as Miami, only 1.8% of 166 asymptomatic and 3.3% of 63 symptomatic patients in Berger's series were diagnosed with neurosyphilis based on a positive CSF FTA and VDRL (492). However, the rate of progression may be much faster, with some cases of dementia occurring within one year of onset of primary syphilis (491,495).

Symptoms of secondary or meningovascular syphilis include stroke, headache and meningeal signs. Parenchymal involvement by *T. pallidum* causes tabes dorsalis (loss of posterior column function, such as vibratory and position sense, leading to abnormal gait, lancinating pain down the back and legs, loss of bladder and bowel control and positive Romberg) and general paresis (dementia with ßorid behavior due to frontal lobe dysfunction, Argyll Robertson pupils and tremor). Gummas are very rare and act as mass lesions in the spinal cord or brain (496). CSF can have a mild mononuclear pleocytosis, mild protein elevation, increased IgG index and positive oligoclonal bands, and a reactive FTA or VDRL, although false negatives have been reported (490). Serum RPR can be negative, so a low threshold for performance of lumbar puncture is required (491,497).

High dose penicillin generally successfully treats secondary syphilis, but follow-up CSF analysis is recommended in all patients until the cell count becomes normal (498,490). Because ceftriaxone was associated with a 23% failure rate in HIV-infected patients (499), it is not recommended. Desensitization is advised for penicillin allergic patients. Maintenance therapy is not generally given, but retreatment should be given in patients whose CSF cell count fails to fall at six months, whose CSF VDRL goes up or does not decline two-fold at six months, or whose serum VDRL does not decline eight-fold at six months or rises four-fold within twelve months of treatment (500).

Neuroborreliosis

Lyme disease due to *B. burgdorferi* has been reported rarely in patients with HIV infection (501); serology is a reliable means of diagnosing extracutaneous disease. Because many people living in endemic areas are seropositive by ELISA testing, supplemental Western blot testing is necessary. The most common neurologic signs are facial palsy, meningitis, and radiculitis. Treatment is determined by the disease manifestation but most neurologic manifestations are treated with a two to four week course of ceftriaxone (502).

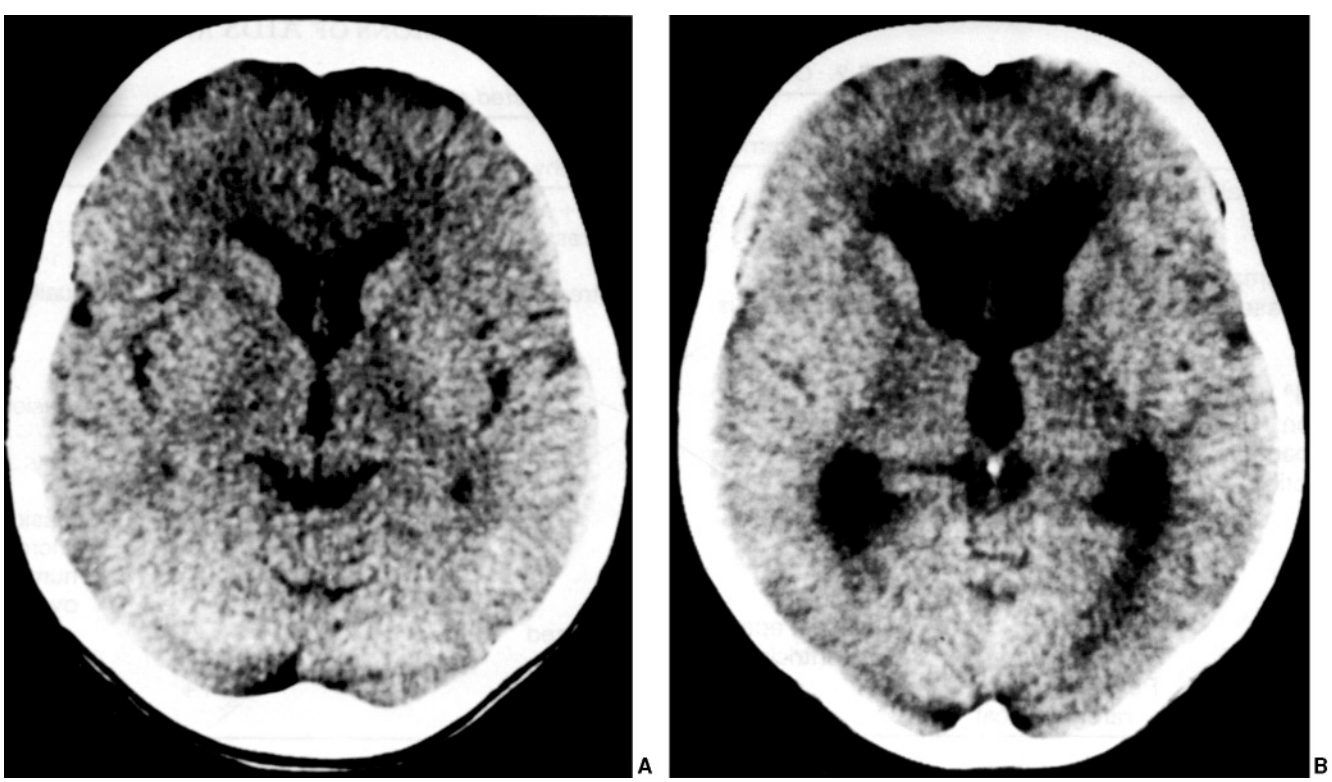

FIG. 18.16. Meningitis sequala:

A. Non contrast brain CT in a 30 year old woman with chronic otitis media due to *H. inßuenzae* showing mild atrophy and dilated sulci.
B. Same patient one month later, obtunded with increasing headache, shows communicating hydrocephalus and decreased sulci consistent with increased intracranial pressure.

Tuberculosis

Tuberculosis is still a common occurrence, especially in people immigrating to the United States (503), and occurs at increased frequency in HIV-infected patients (up to 35% overall and 6% in the CNS) (504,505). Treatment in patients with HIV infection is effective, especially if started early and drug interactions with certain antivirals are kept in mind (503,506,507). Although there are few clinical differences in TB meningitis between patients with and without HIV infection, mass lesions are somewhat more common in HIV infection, especially in intravenous drug users (508,509). Diagnosis of TB in immunosuppressed patients depends on availability of material (i.e. sputum, CSF or biopsy), for smear, culture or nucleic acid ampliÞcation techniques (510,511). Early biopsy is encouraged in the management of mass lesions, especially in patients from countries such as Haiti or India with high incidences of tuberculosis in general. CNS tuberculoma is much more common than lesions due to other members of the mycobacterium family, and can occur at any level of immunosuppression. Systemic infection due to *Mycobacterium avium* complex (MAC) does occasionally spread to the meninges or brain (478,572). Since atypical mycobacterial infection requires treatment with different agents than tuberculosis, awareness must be maintained and appropriate testing done in severely immunocompromised patients (513).

The clinical presentation of tuberculous mass lesions of the CNS shares some features with the previously described focal lesions from other opportunistic infections or tumors, such as seizures, headache and progressive neurologic dysfunction related to the region of the mass, along with fever, malaise and papilledema. What sets it apart is the accompanying presence of basilar meningitis in 10% of cases (509), especially in the basilar cisterns. This is seen in many more patients with tuberculosis than lymphoma or TE. This meningitis is particularly adhesive, leading to complications of hydrocephalous and infarction (514). Increased intracranial pressure can cause mental status changes, cranial nerve dysfunction such as abducens paresis or poor upgaze (515) and vomiting, although these are slightly less prevalent in HIV-infected patients (509).

Radiographic techniques (Figs. 18.17, 18.18A, 18.18B) useful in diagnosis of tuberculosis of the brain include MRI with contrast enhancement (514,516). Lesions are multiple and tend to be periventricular or in the corticomedullary junction. Tuberculomas are isointense on T_1 images with a hyperintense rim, and noncaseating lesions are bright on T_2, with nodular enhancement. Caseating lesions exhibit rim enhancement, and all have mass effect or edema to some degree. Tuberculous abscess results from liquiÞcation of the core of a granuloma or tuberculoma, therefore appearing larger with more mass effect or multiloculation. Computed tomography is also helpful, especially as hydrocephalous and infarction are easily detected using CT, and healed lesions may calcify (509). One study showed that SPECT is more often abnormal than CT in patients with tuberculous meningitis, but the cortical, midbrain and basal ganglia hypoperfusion that is seen does not correlate with stage of meningitis or outcome (517).

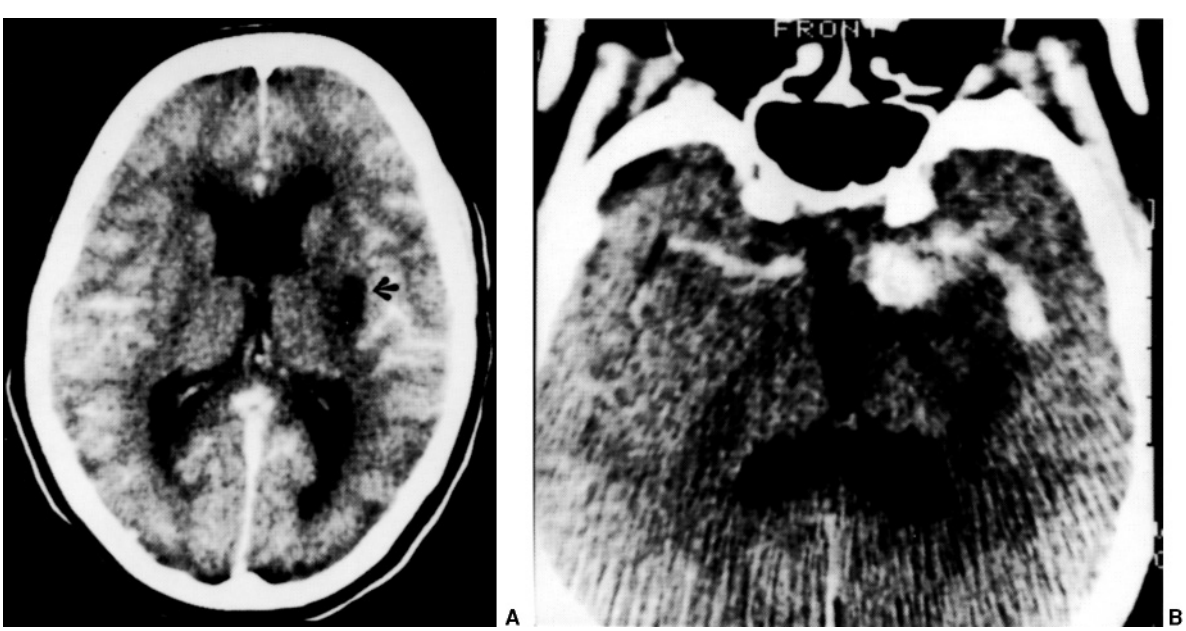

FIG. 18.17. Tuberculosis meningitis:

B. Organisms staining with Acid Fast (1000 ×).
C. Necrosis in wall of abscess (Acid Fast stain, 1000 ×).
D. Multinucleated giant cells, histiocytes and abscess wall. (H&E 325 ×).

Biopsy may be required to make a deÞnitive diagnosis, and simultaneous drainage with interruption of the thick capsule wall facilitates tissue penetration of antimycobacterial drugs (518).

Treatment of tuberculosis in extrapulmonary locations is not hindered by difÞculty with tissue penetration, especially as the blood-brain-barrier is disrupted by meningitis or but is generally prolonged beyond the standard six months for most other types of tuberculosis. Although a rifamycin-based regimen is recommended, interactions with antiretroviral agents must be watched for, especially protease inhibitors (see Chapter 00) (519).

Antimycobacterial therapy should continue for six months after cultures are negative (although if cultures were originally obtained from a brain biopsy, serial scans can be substituted). Steroids are useful to control the expansion of tuberculomas, to minimize the inßammatory meningeal response and possibly to alleviate increased intracranial pressure. Steroid use is not dangerous if given for a limited time (486).

In patients with less than 50 CD4 cells, especially those not on prophylactic therapy (520), atypical mycobacteria are also rarely pathogenic, with MAC usually causing meningitis or meningoencephalitis. *M. kansasii* has been cultured in a brain abscess (521). MAC and *M. tuberculosis* may occur (522).

Spinal cord involvement is seen in patients with disseminated TB or meningitis, or extending from vertebral body osteomyelitis (Pott's disease) (Fig. 18.19). Symptoms and signs are identical to those of spinal cord compression or myelitis described earlier in bacterial infection, but more chronic and likely to reverse with treatment, even after prolonged disability. Intramedullary involvement is rare (523,524). MRI becomes abnormal at the same time that bone and gallium scans reveal enhancement of the vertebral body, but is better at demonstrating spinal cord compression (396). Myelography is substituted in patients ineligible for MRI due to metal, pacemaker, claustrophobia or inability to hold still, or where MRI is not available (396). Treatment with

FIG. 18.19. Osteomyelitis and cord compression due to *M. tuberculum* (Pott's disease): Spine MRI with T2 weighting in a 40 year old woman with severe low back pain and urinary retention, progressing over several months. Lesion in body of T12 causing deformity of spinal column and cord compression. Other lesions present at L3 and 4, with involvement of disc space. Cultures taken at time of surgery to stabilize spine grew *M. tuberculum*.

prolonged antibiotics is required, along with spine stabilization using rods or titanium plates or cages in patients whose bone destruction renders them unstable.

Meningitis from mycobacterial infection is chronic but can become severe if unrecognized. Atypical infections are generally milder than tuberculous infection. In addition to headache, stiff neck, confusion, malaise and fever, patients can exhibit cranial nerve palsies or hemiparesis or may become comatose. Cerebrospinal ßuid is usually under increased pressure, with lymphocytic pleocytosis averaging more than 200 cells/mm^3. Neutrophils have been reported in 42% of HIV-infected patients and 27% of others (509). The average protein level is 125mg/dl in HIV-infected patients, and higher levels correlate with later stage disease. In 70% of cases the glucose level is low (525). Diagnosis of tuberculous meningitis is made by positive acid fast stain in 25% of cases (509). Cultures are positive in 60% of immunocompetent patient samples and 23% of HIV-infected patients but may take six weeks to evolve. ADA (adenosine deaminase) levels are high but non-speciÞc (509). PCR on CSF may be a more useful and rapid diagnostic test but is not 100% sensitive (526).

Treatment of meningitis is the same with or without HIV infection (See Chapter 00), but rifabutin is sometimes substituted to take advantage of its ability to treat atypical as well as tuberculous infection (509). Treatment with six months may be as effective as longer courses. Steroids diminish the inßammation and may improve cranial nerve palsies or prevent hydrocephalous. If the latter becomes symptomatic a ventricular drain or shunt may be required.

Fungal Infection

Cryptococcal infection is the most common neurologic fungal infection seen in AIDS. Other fungi also occur in severely immunosuppressed patients, and vary with the geographic exposure of the person. Most are hematogenously spread from a lung infection. Presentation and pathology can be misleading in AIDS, so various laboratory techniques are required, especially culture, which can dictate therapy. For example, a patient whose pathology and imaging suggested aspergillosis but who failed to improve on standard treatment with amphotericin, grew *Scedosporium apiospermum* from a brain abscess after two weeks, and only improved after discovering that the organism was sensitive to posaconazole (527).

Cryptococcal Infection

Cryptococcal infection has occured in up to 10% of patients with AIDS in the U.S. and 30% in Africa (528), primarily causing meningitis. However, the incidence of meningitis in the U.S. has fallen from 5.0/1,000 person-years in 1990Ð1992, to 1.5/1,000 in 1996Ð1998 (266). This decline relates to the introduction of HAART and possibly increased use of ßuconazole in this patient population (529,530). The CD4 count is <50 at presentation in most patients. Most infections are caused by reemergence of latent disease, but it is prudent to avoid exposure to bird droppings or infected soil.

Fungal meningitis symptoms are insidious, with headache, stiff neck and low-grade fever in some patients, alterations of behavior in others. The severity of symptoms, including depressed mental status, correlates with intracranial pressure elevation, as does the outcome. Seizures occur in less than 10% of patients. Meningeal signs may be absent, in which case headache is attributed to increased intracranial pressure. The latter type of headache is worse in the morning, and exacerbated by Valsalva maneuver, cough or other obstructors of venous outßow. If cryptococcal meningitis is the presenting infection of AIDS, institution of antiviral therapy may exacerbate the inßammation of meningitis, and should be delayed for several weeks. Even after initial control of cryptococcal meningitis with antifungal therapy, immune restoration with antiretroviral therapy can cause increased intracranial pressure, in the absence of meningitis. This responds well to serial lumbar punctures (531).

Lumbar puncture often reveals extremely high opening pressure, lymphocytic pleocytosis, mild protein elevation in two-thirds of patients (532) and a normal glucose level in 70% of patients (533). Yeast can appear unusual on India ink staining due to insufÞcient capsule formation. Latex agglutination is positive for cryptococcal antigen in 90% of patients with meningitis (533). Efforts to use nested and other PCR protocols may facilitate rapid diagnosis (534). The organism grows easily in culture. Poor prognostic signs found in CSF include hypoglycorrachia, white cell count $>20/mm^3$, and antigen titer $>1{,}024$ in CSF.

When the patient is very obtunded at presentation or has an exceptionally high (>500 mm/H_2O) opening pressure on lumbar puncture, it is prudent to use an effective amphotericin B preparation rather than oral ßuconazole (535Ð541), as the latter takes longer to work (536) (sterilization is accomplished by 16 days using amphotericin, instead of 30 days with ßuconazole). Although monitoring for cytopenia and treatment with growth factors is often required, the addition of 5-ßucytosine (100 to 150 mg/kg/day) for the Þrst two weeks improves outcome (533). Longer initiation treatment (six instead of four weeks of amphotericin) is recommended in patients with more than 20 white blood cells in the CSF, more than 1:32 cryptococcal antigen titer in serum or 1:8 in CSF, and a positive India ink preparation (537). Lipid preparations of amphotericin are better tolerated, with a lower incidence of chills, fever and renal failure (343,539Ð541). In those unable to tolerate amphotericin in any form, some success has been achieved with high doses of ßuconazole plus ßucytosine for the Þrst four weeks if tolerated (270,542). Response to therapy is usually based on clinical

improvement, but antigen titers in CSF can be used in uncertain cases (543).

The availability of the azole, ßuconazole, has allowed oral therapy. One obvious beneÞt of this is that indwelling venous catheters can be removed.

Attention to treatment for increased intracranial pressure also improves outcome. A CT scan is done to rule out obstructive or communicating hydrocephalous, which can be treated by ventriculostomy or shunt in the Þrst case and serial spinal taps or lumbar drain in the second. If the brain is diffusely swollen, the usual measures to lower pressure can be used, including mannitol or glycerol, steroids or possibly acetazolamide.

Once the CSF is sterile maintenance with ßuconazole, 200 mg/day (550), is recommended until there is a sustained increase in CD4 cell count (see Chapter 00). In an early study of patients followed for six months after treatment, meningitis recurred in four of 27 not receiving maintenance therapy, and none of 34 receiving ßuconazole (552).

Mass lesions, known as torulomas or cryptococcomas (Figs. 18.20A and 18.20B) are unusual and only found in chronic cases of meningitis. They are located near the brain surface or periventricular regions, probably evolving from invasion of the parenchyma from Virchow-Robin spaces of the subarachnoid space or ventricle by microcysts that are Þlled with fungi and mucus (1,468). Treatment requires prolonged antifungal therapy.

Coccidiomycosis

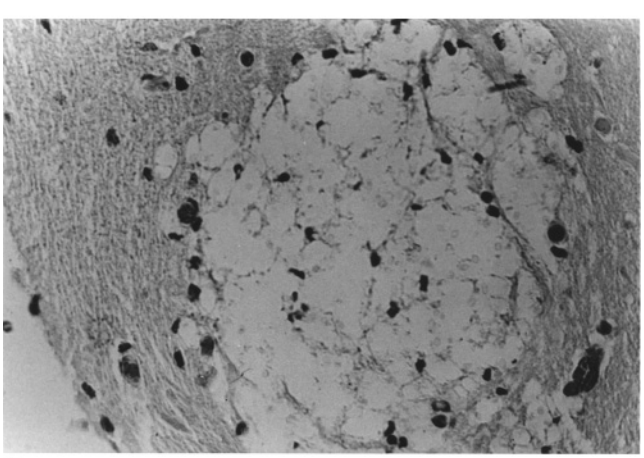
Opportunistic infection with this organism appears in patients who have lived in the southwest U.S., the Sonora desert of Mexico, or in Central and South America and whose CD4 count falls below 250. Serology with complement Þxation can be falsely negative in patients with very low counts or early in infection. Meningitis and other extrapulmonary infection develops in one of 200 patients whose skin test shows exposure to *C. immitis*, and is caused by miliary spread from the lungs (555). Meningitis had a mortality of 33% in Fish's study (556). Although meningitis in immunosuppressed AIDS patients presents in a similar fashion to immunocompetent hosts, i.e. chronic headache, fever and depression of mental status, in some patients extensive brain destruction due to associated endarteritis obliterans can occur and hydrocephalous may develop in those with ventriculitis. In patients with CD4 <250 living in an endemic area, the risk of developing active infection (pulmonary and meningeal) is 10% per year (557).

Treatment with amphotericin B infused intrathecally is traditional in meningitis, while ßuconazole at doses of 400Ð600 mg/day or itraconazole at 400Ð1200 mg/day is used in less involved patients (558). The high relapse rate mandates lifelong suppression (555).

Aspergillosis

Hematogenous spread from pulmonary or cardiac sources causes the cerebral lesions, and direct spread from the lungs is responsible for spinal cord involvement. *Aspergillus ßavus* caused cerebral lesions in two patients, and *A. fumigatus* a spinal cord mass, in a series reported by

A



B

FIG. 18.20. Cryptococcoma:

A. Contrast enhanced CT in a 32 year old with chronic cryptococcal meningitis who developed ataxic gait. Round, homogeneously enhancing lesion is seen in cerebellar vermis.
B. Biopsy of lesion shows cryptococcal yeast forms surrounding a blank space containing nonstaining capsular material (H&E 800 $\times$) (courtesy of Dr Tung Pui Poon).

Woods and Goldsmith (559). This fungal infection presents as mass lesions of the brain and spinal cord and as infarction, and is associated more with neutropenia (< 200 cells/mm^3) than with suppressed T cells, but is described in patients with CD4 < 50, or in those with neutropenia due to bone marrow toxicity of treatment, lymphoma or other bone marrow failure. In AIDS patients there are more CNS complications than in other immunosuppressed groups. Patients in the central United States are at highest risk. CT and MR findings include thick walled cavitary lesions, occasionally hemorrhagic. Precise diagnosis usually requires aspiration of tissue for culture.

A variety of treatment modalities exist but voriconazole may be the most effective (560–562). Voriconzale was recently proven effective in a trial of 277 patients, 3.8% of whom had cerebral and 5.6% sinus involvement (562).

Histoplasmosis

In endemic areas of the U.S. and Latin America, histoplasmosis becomes disseminated in up to 20% of immunosuppressed patients (563). CNS involvement occurs in 5–20% of disseminated cases and takes the form of encephalopathy, meningitis (564) and rarely abscess. Hemorrhage may occur due to associated thrombocytopenia or DIC (563). Diagnosis is made by detection of antigen or by culture of large volumes of CSF. Treatment of histoplasmosis with amphotericin has been facilitated by the introduction of lipid preparations of amphotericin B (565); abscess requires surgical debridement.

Blastomycosis, Candida, Rhizopus (Mucor) and Other Fungi

Other fungal infections causing meningitis, sinusitis or fungal CNS mass lesions are rare in AIDS, occurring in no more than 5% of patients with disseminated infection and severe immunosuppression. This is primarily attributed to lack of the main risk factor for certain fungal infections, neutropenia, in AIDS patients as compared with oncology patients. The development of resistant non-albicans candida species in those patients receiving prophylactic treatment with ßuconazole must be kept in mind (544). Special aspects of each infection include: formation of abscess more often than meningitis with blastomycosis; co-infection with candida and bacteria in brain lesions (1–3); and spread from sinus infection, with early cranial nerve dysfunction such as blindness or diplopia, in patients with the rhinocerebral form of mucor (566,567). In intravenous drug users, as well as some patients with AIDS, the cerebral form of mucor tends to involve the basal ganglia (568,569). Surgical debridement of sinus infection is often required, as endoscopic aspirations fail to diagnose the etiology of the fungus in many cases (566).

Viral Infection

Progressive Multifocal Leukoencephalopathy (PML)

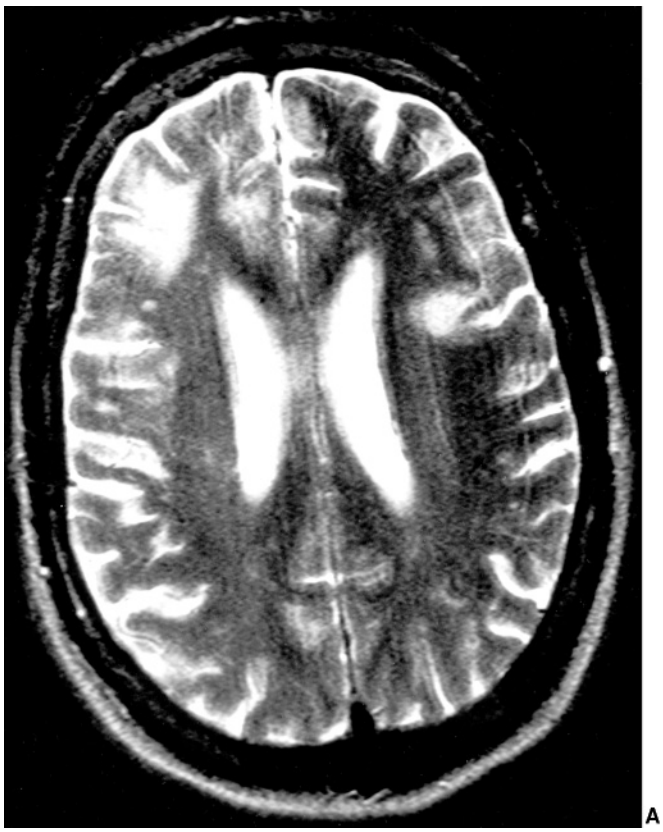
The most common viral opportunistic infection of the brain is JC polyoma virus, causing demyelinating lesions known as PML in 4% of patients with CD4 < 100. The incidence has not dropped in the era of HAART (266) but patients are surviving longer with PML (46 weeks as opposed to 11 weeks median survival) (575). PML is the AIDS defining illness in about half of patients who develop this infection (576).

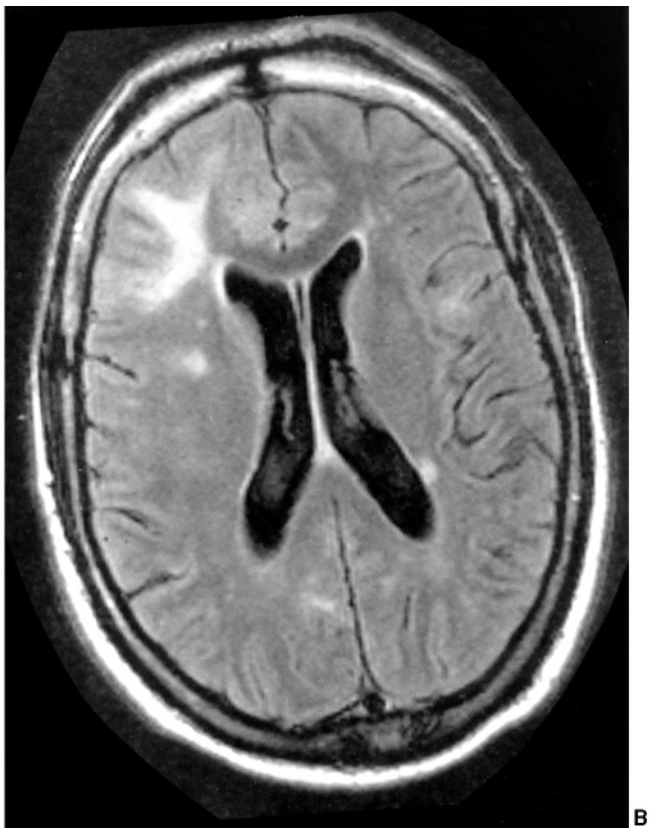
The clinical course of PML is one of insidious progression of focal signs, including hemiparesis, hemisensory loss, visual disturbance or posterior fossa signs such as diplopia, dysmetria, dysarthria, dysphagia and ataxia. Cognitive dysfunction is reported by 36% of patients and headache in 32% (576). Seizures are not seen more often than in HIV infection itself, although two patients with epilepsia partialis continua have been reported (577). A single focus is more common in AIDS patients with PML than other groups, with a predilection for the parietooccipital cortex. Involvement of white matter outside the brain, such as spinal cord or optic nerves, has not been reported in AIDS patients.

PML is suggested by the characteristic CT findings of a nonenhancing hypodense area in white matter. Hyperintense signal is seen in multiple areas on T_2 weighted images on MRI, with a single area found in about in 27% of cases (see Fig. 18.21). These generally cause no mass effect or surrounding edema and do not enhance with gadolinium, but are occasionally hemorrhagic (578). Differentiation from HIV-induced changes in the white matter include location; the demyelination of HIV is generally periventricular, not subcortical as in PML, and the demyelination is less discrete in HIV. CMV-induced white matter changes are distinguishable from PML by their location in the periventricular white matter, and by the presence of subependymal enhancement (576). Varicella virus causes demyelination by small vessel infarction, so diffusion weighted imaging can separate the MRI findings from PML (579).

Other confirmatory tests include JC virus detection in CSF (580). Amplification techniques can provide an estimate of JC viral load which correlates with the size of lesions seen on MRI, and is useful in determining prognosis (581,582). When therapy with HAART is successful in prolonging survival in PML, a lower viral load (< 4.7 log) is found at onset and the virus is cleared with therapy (583). Elevated myelin basic protein, though nonspecific, is much more common in PML than HIV or other demyelinating conditions. Similarly, MR spectroscopy reveals a homogenous pattern that is not specific for PML, but may eventually prove useful in diagnosis without biopsy (584).

The mainstay of therapy for PML is restoration of the immune system, although this transiently may exacerbate





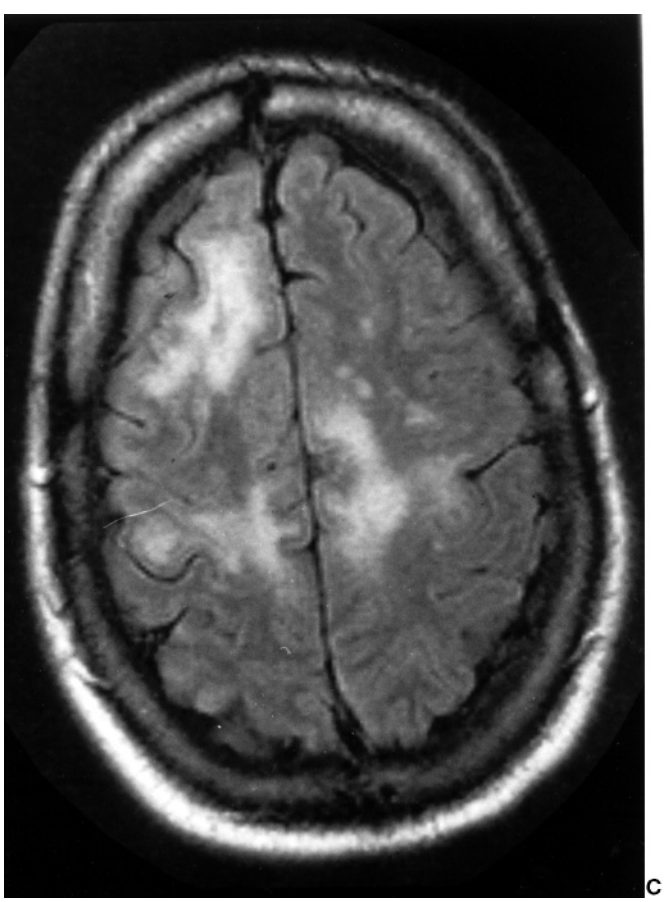


FIG. 18.21. Progressive Multifocal Leukoencephalopathy: 32 year old man with dementia and progressive left leg weakness. CT, which is not shown, revealed nonenhancing edema right frontal region.

A. T2 weighted MR shows increased signal in both frontal lobes, right larger than left.

B. FLAIR shows increased signal in right middle frontal gyrus, right corona radiata and left periventricular region.

C. Higher axial view of FLAIR shows increased signal in bilateral frontal and parietal regions.

signs of PML as inßammation occurs for the Þrst time (585). Much remains to be learned about the mechanism of HAART in PML. As HIV is often found near lesions of PML, there is evidence that the tat protein of HIV also activates JC virus, and therefore its reduction with HAART may slow the growth of JC virus (586). Evidence that improvement results from a nonspeciÞc restoration of the immune system is that agents that fail to cross the blood brain barrier, such as protease inhibitors, are more effective than CNS active antivirals such as zidovudine (587). The addition of the antiviral agent, cidofovir, promises some speciÞc efÞcacy against JC virus (583,588). Earlier trials of antivirals, including cytosine arabinoside, have all been failures (589).

Cytomegalovirus (CMV)

Although initially assumed to be the cause of dementia in AIDS, CMV has been shown to cause dysfunction of the central nervous system in only a minority of patients (590). CMV causes headache, confusion, apathy or cognitive dysfunction and rarely fever (590) and focal deÞcits that often involve the brainstem (591). Electrolyte abnormalities, speciÞcally hypo or hypernatremia, are quite common (592). Periventricular enhancement is most common (591,593), followed by enhancing mass lesions (594) or hypodense lesions similar to PML (590). CSF often has normal or mildly abnormal protein and glucose, with polymorphonuclear pleocytosis in 25% (592,593). CMV can be detected in CSF by PCR in 90% of patients (595), but false positives and negatives are common (592,593).

More commonly nervous sytem involvement of CMV is located in the spinal cord, causing myelitis with quadraplegia and a sensory level, or in the lumbar nerve roots, leading to a characteristic syndrome of polyradiculopathy (596). The latter presents in severely immunosuppressed patients (<50 CD4) with low back pain radiating in the lumbar or sacral nerve roots, followed by ßaccid paralysis of the legs and urinary retention (597). CSF reveals many polymorphonuclear cells (usually $>200/\mu l$) with low glucose (210). Although culture is not often positive (598), CMV can be detected by PCR ampliÞcation (581). MRI with contrast shows thickened nerve roots with areas of enhancement in up to one-third of patients, and should be done to exclude mass lesions (210). Electromyogram shows denervation in the paraspinal and leg muscles with normal nerve conductions (598).

Treatment of CMV infections is outline in Chapter 00 (210,598Ð602). Excellent recovery from polyradiculopathy is seen in patients whose treatment is begun early (597). HAART should be used (603) but not until speciÞc treatment for CMV has been in place for several weeks, in order to avoid the immune reconsitution disorder. The increased use of HAART has markedly reduced the incidence of CMV infection, thereby limiting accrual of patients for trials of agents (57).

Varicella and Other Herpes Viruses

Varicella zoster virus most commonly causes shingles, which is a radiculopathy syndrome with a vesicular rash in a dermatomal distribution. Shingles most frequently involves the thoracic or upper lumbar dermatomes, or the Þrst division of the trigeminal nerve. Shingles is seen in 2Ð4% of patients with HIV infection whose CD4 count falls below 200 (604), and is 17 times more common in an HIV-infected than in a non-infected homosexual population (604). Shingles presents with paresthesias (interpreted as itching), painful dysesthesias and vesicular, crusting rash in one or more neighboring dermatome distributions (Fig. 18.22) in patients with a CD4 <200, although it has been reported in HIV-infected patients with high CD4 counts as well.

Antiviral treatment limits spread from the dorsal root ganglion to the spinal cord or brain (579,605), may prevent vascular complications and decreases infectivity by clearing the virus from the vesicles (see Chapter 00) (606,607).

Adjunctive corticosteroids may be helpful in minimizing, if not preventing, postherpetic neuralgia (579). The latter chronic painful condition may be treated symptomatically with antiepileptic, antidepressant and other medications, which were discussed earlier in the section on peripheral neuropathy.

Varicella zoster virus also causes encephalitis, myelitis and stroke (especially following trigeminal neuronitis, due to granulomatous small vessel vasculopathy (579,608). Encephalitis presents with fever, ßuctuating levels of consciousness, seizures and headaches (609) but is rare, being seen in only four of 859 patients with herpes zoster radiculopathy (57).

Myelitis is seen in advanced HIV infection (610) in 1% of patients and follows the rash of radiculitis by one or two weeks. Usual symptoms such as weakness, spasticity and sensory level, relate to the level of spinal cord involved, and more rarely myoclonus is described (611). MRI may show enhancement over several levels or focally, CSF may reveal varicella DNA or antibodies (579). Overall, varicella virus is detected in 2.5Ð7% of HIV-infected patients with shingles and encephalitis, meningitis, myelitis or retinitis (612).

Herpes Simplex

Herpes simplex 2 has also caused myelitis, which is similar in presentation and treatment to zoster and CMV myelitis (174,175,613). Both *H. simplex* types 1 and 2 have caused encephalitis, usually with coinfection by CMV (614,615). A more insidious course of encephalitis in AIDS patients is not always seen (614,615), as

encephalitis can occur in patients at any level of immunosuppression. If the patient is capable of mounting an inßammatory reaction, herpes encephalitis will present typically with fever, headache, behavioral change, recurrent seizures and rapid obtundation or coma. White and red cells are present in CSF, paroxysmal lateralizing epileptiform discharges may be seen on EEG, and hemorrhagic edema is found in the temporal and frontal lobes on MRI or CT (616). CSF PCR facilitates diagnosis.

Herpes virus 6 is responsible for some cases of encephalitis (617) and myelitis (618) as well. Epstein Barr virus, though responsible for lymphoma, does not cause the ataxia, aseptic meningitis and myalgic syndromes in immunocompromised patients that it does in normal hosts.

HTLV-I or II (Human T-cell Leukemia Virus)

This chronic infection can be acquired by the same mechanisms as HIV, so coinfection with both is not unexpected (620), especially in endemic areas. Myelopathy is the most common syndrome related to HTLV-I and may be found in 73% of patients with HIV who also have HTLV-I (621). Symptoms include slowly progressive leg weakness, spasticity, urinary urgency and frequency, constipation and occasionally a concommitant neuropathy causing depressed ankle jerks and distal sensory loss. On pathologic examination the spinal cord is atrophied with loss of axons and myelin. In those whose immune function was at least partially preserved, a perivascular lymphocytic inÞltrate (622) consisting of CD4 and 8 cells surrounding HTLV-I DNA and RNA is present, with viral particles in the spinal cord as well (623).

FIG. 18.22. Rash of herpes zoster: 70 year old man with right ank pain and urinary retention, with resolving rash typical of H. zoster.

Treatment is with HAART, but corticosteroids have been tried alone or in combination with HAART, especially as there is a risk of increasing inßammation in response to HAART (624). Plasmapheresis has also been used (625) but is more difÞcult to administer.

Cerebrovascular Disease

Cerebrovascular disease is discovered on autopsy in up to 34% of patients (3,26), but is often unsuspected as a cause of transient neurologic deÞcit, possibly due to the relative youth of AIDS patients. Clinical series report stroke in 1.6% of adults (626,627) and 6% of children (626). Although stroke can occur due to risk factors unrelated to HIV infection, it should be remembered that many opportunistic infections cause arteritis or thrombosis in vessels nearby. These include tuberculosis (514), varicella (especially when the trigeminal nerve is involved) (609,579,605), aspergillosis (559), cytomegalovirus (628,629), syphilis (492,495), candida, lymphoma and of course HIV itself (173,342,627,630,631). Immune complexes or cryoglobulinemia can result from hepatitis B or C infection (173). In addition, thrombosis can occur due to dehydration protein S deÞciency (632), sepsis or other stimulators of inßammatory cytokines that increase thrombosis (633). Emboli can cause stroke in patients with endocarditis (342). Anticardiolipin antibodies can be associated with thrombosis, although these are frequently Ònnocent bystandersÓnot associated with vascular events (634). New risk factors include the hyperlipidemic changes from the protease inhibitors potentially causing accelerated atherosclerosis (323).

Hemorrhage can occur in the brain as a result of a bleeding diathesis such as disseminated intravascular coogulation and thrombocytopenia, heparin used for hemodialysis, and coagulopathies from liver failure or malabsorption of vitamin K, or drug toxicities. It presents as abruptly occurring focal deÞcits, or in the case of subarachnoid or intraventricular hemorrhage, as headache, stiff neck and depressed consciousness. Headache and seizures are not uncommon accompaniments of hemorrhage. When hemorrhage occurs in a preexisting lesion there may have been a history of dysfunction in the same region, with abrupt deterioration. Blood appears hyperdense on CT and has a progressively changing appearance on MR, initially being hypointense on T2 and hyperintense on T1. If a lesion such as lymphoma (Fig. 18.23) or brain metastasis is the cause of the hemorrhage, the early scan will show mass effect or surrounding edema several hours

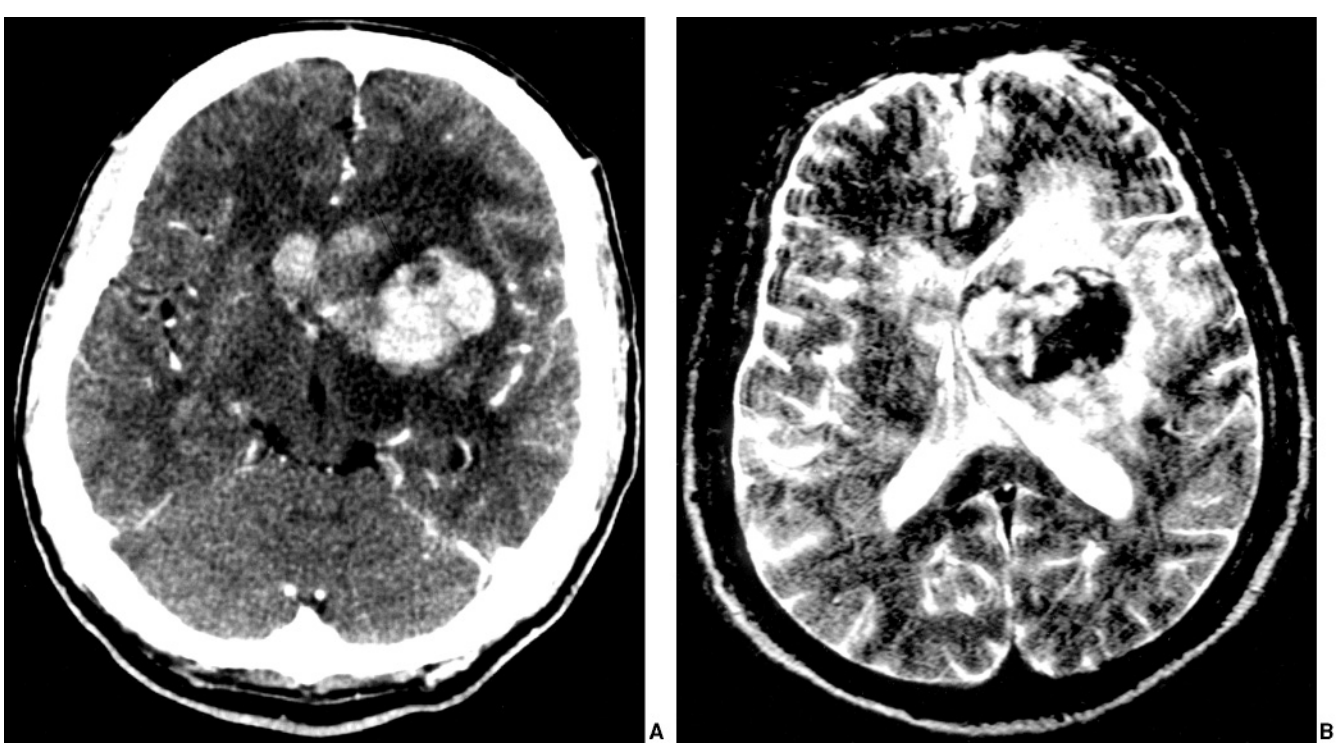

FIG. 18.23. Lymphoma with hemorrhage: 35 year old with acute onset right hemiparesis and non uent aphasia, with seizures.

A. CT with contrast shows left basal ganglia and ventricular hyperdensity consistent with blood, also in sulci. Edema surrounding lesion present on initial scan.
B. T2-weighted MR (with motion artifact) three days later shows mixed signal in lesion, consistent with resolving hemorrhage (hypointense initially, gradually lightening).

or days before it would have appeared in a spontaneous hemorrhage.

Seizures

Seizures are symptomatic of mass lesions or HIV infection itself, with peaks occurring early and late in the course of illness. Transient focal deficits may be due to seizure activity followed by Todd's paralysis. Confusion may be due to nonconvulsive status epilepticus, which is especially prevalent in patients suffering from metabolic encephalopathy, such as hepatic or hypoxic encephalopathy. Therefore, electroencephalography is mandated in the evaluation of acute confusional state in patients without witnessed seizures.

Treatment decisions are individualized based on the patient's wish to take a potentially sedating medicine, or wish to use an antiepileptic for treatment of comorbidities that can be simultaneously treated, such as pain or bipolar illness (28,29,107). Circumstances, such as need for intravenous access, will dictate the use of drugs with a parenteral form. These include phenytoin (fosphenytoin can be given intramuscularly as well as intravenously), valproic acid, phenobarbital and lorazepam or diazepam. Patients with problems with medication compliance do best with single daily dosing, which is possible with phenytoin, phenobarbital, and possibly newer agents such as leviteracetam. Patients on multiple medications may want to avoid drug interactions involving the cytochrome P450 system, which is induced by most antiepileptics, inhibited by valproic acid and not affected by gabapentin and leviteracetam. Renal failure precludes the use of the latter two drugs, and dose adjustments are required for liver failure in most others. Allergies may be increased in incidence, in HIV infection, and must be watched for.

Detoxification from epileptogenic substances, such as alcohol, cocaine or amphetamines, is also helpful where indicated.

SUMMARY

Great strides have been made in the diagnosis and management of neurologic sequelae of HIV infection, and in prevention of opportunistic infections. Unfortunately, notable exceptions remain in the areas of lymphoma, PML and other intractable infections. Even infections that have known preventive regimens, such as toxoplasmosis, present problems in terms of medication side effects, allergies, cost and the difficulties of long term maintenance of compliance. The wonderful results of efforts in new drug development are working to defeat HIV itself, thereby preserving and restoring the immune system. While these drugs have side effects and can fail due to emergence of resistance, especially within the central nervous system, they have allowed patients to reap rewards in the areas of prevention of dementia, neuropathy and other neurologic effects of the virus. The next goal will be to allow more infected people to have access to these medications, to eradicate its spread and to continue to improve diagnosis and treatment of the damaged nervous system.

Chapter 19

AIDS Psychiatry: Psychiatric and Palliative Care, and Pain Management

Mary Ann Adler Cohen and César A. Alfonso

Psychiatric factors take on new relevance and meaning as we enter the third decade of the AIDS pandemic. Persons with AIDS are living longer and healthier lives as a result of appropriate medical care and advances in antiretroviral therapy. However, in the United States and throughout the world, some men, women, and children with AIDS are unable to beneÞt from medical progress. Inadequate access to care results from a multiplicity of barriers including economic, social, political, and psychiatric. Psychiatric disorders and distress play a signiÞcant role in the transmission of, exposure to, and infection with the human immunodeÞciency virus (HIV). They are relevant to prevention, clinical care, and adherence throughout every aspect of illness from the initial risk behavior to death. They result in considerable suffering from diagnosis to end-stage illness.

Stigma, discrimination, and fear (1Ð6) in conjunction with denial, omnipotence, and lack of awareness (7Ð9) complicate and perpetuate the HIV pandemic. The creation of a supportive, nurturing, non-judgmental healthcare environment can combat stigma and provide comprehensive and compassionate care (1,10Ð15). This chapter will provide guidelines for psychiatric and palliative care and pain management to help persons with AIDS to cope better with their illnesses, live their lives to the fullest extent, and minimize pain and suffering for them and their loved ones.

DIAGNOSIS AND TREATMENT OF PSYCHIATRIC DISORDERS

Relevance of Psychiatric Care

There are 753,907 persons with AIDS and an estimated additional 900,000 persons currently living with HIV infection in the United States (16). An estimated 36,100,000 are living with HIV or AIDS worldwide (17). In the United States, AIDS has become the leading cause of death in men from age 25 to 44, the third leading cause of death in women age 25 to 44, and the leading cause of death in African-American women in that age group (18). It is the eighth leading cause of death overall (18). These Þgures are especially ominous because the fastest-growing HIV-infected population in the United States is that of women in the childbearing years (19) and a rapidly growing HIV-infected population is that of teenagers. The greatest risk of infection is in adolescence and young adulthood, most often through sexual contact. It is particularly relevant to public health because transmission of AIDS to men, women, and children is preventable through education, correct use of latex condoms (20), and treatment-on-demand of substance-related disorders. Non-adherence to antiretrovirals (ARVs) during pregnancy, labor, and delivery results in perinatal HIV transmission. The personal and societal costs to health, productivity, Þtness, careers, partners, spouses, parents, and children take an enormous toll in suffering. Related to this is the suffering of the loved ones and orphans (21) left behind by AIDS. The tragedy of preventable death in young and productive individuals is heightened by the multiplicity of infections, severity of illness, and the multisystem and

multiorgan involvement in this devastating illness. The illness is complicated by the psychological reactions to and psychiatric manifestations of HIV infection.

Psychiatric disorders can accelerate the spread of the virus by creating barriers to risk reduction. Risky sexual behaviors and sharing of needles in intravenous drug users account for the majority of new cases each year. In the United States, 40,000 new AIDS cases are reported each year (16) while 5,300,000 new cases are reported in the world (22).

The substance use disorders, including alcohol and other drug use, result in multidimensional obstacles to risk reduction and adherence to care. These include obvious barriers to prevention of transmission such as sharing of drug paraphenalia and more subtle barriers such as inability to adhere to perinatal antiretroviral therapy because of intoxication, withdrawal, and drug-seeking behaviors. Furthermore, intoxication and disinhibition associated with alcohol and drug use and exchange of sex for drugs result in risky sexual behaviors and difficulty with adherence to complex medical regimens. Cognitive disorders associated with alcohol and other drugs can also impair judgment and ability to adhere to care. Active substance use may interfere with adherence to prevention strategies, to medical care, to perinatal transmission, and to the care of children infected with the virus. Mortality trends indicate an increase in death from end-stage liver disease as a result of comorbid infection with HIV and hepatitis C. Substance use disorders are instrumental in hepatitis C transmission.

Other psychiatric disorders such as schizophrenia, bipolar disorder, post-traumatic stress disorder (PTSD), and cognitive disorders may be associated with HIV transmission and nonadherence to care. Risky behavior and nonadherence may result from poor judgment with regard to sexual partner choice, lack of attention to barrier contraception, and, at times hypersexuality, disinhibition, and multiple sexual partners. A further complication is the occurrence of dementia in persons with AIDS. Dementia can lead to poor judgment in sexual partner choice, unsafe sex, and disinhibition. Mood disorder with mania due either to HIV-related infections or prescribed or illicit drugs can result in hypersexuality, poor impulse control, and impaired judgment. Manic behavior includes hypersexuality and ÒsexualindiscretionsÓ as part of the diagnostic criteria for bipolar mania. When persons are psychotic, they may seek sexual contact or may become victims of sexual predators as a result of efforts to obtain love, affection, and attention or in attempting to relieve the anguish of psychosis. Post-traumatic stress disorder can lead to risky behaviors and decrease harm avoidance as a result of both dissociative phenomena and a sense of a foreshortened future. Persons with PTSD as a result of early childhood trauma may have difficulty protecting themselves from harm or may even unconsciously seek to reenact their early trauma in later life.

Delirium, dementia, depression, substance dependence, PTSD, and other psychiatric disorders complicate the course and add considerably to the pain and suffering of persons with AIDS. HIV infection and AIDS also are risk factors for suicide (1,3,10), and the rate of suicide has been shown to be higher in persons with AIDS (23–30). Psychiatric care can help prevent HIV transmission through recognition and treatment of substance-related disorders, dementia, and mood disorders such as mania. Comprehensive, coordinated care by a multidisciplinary AIDS team, including AIDS psychiatrists, can provide a biopsychosocial approach that is supportive to patients, families, and clinicians. Psychiatric interventions are valuable in every phase of infection, from identification of risk behaviors to anticipation about HIV testing; from exposure and initial infection to confirmation with a positive HIV antibody test; from entry into systems of care to managing complex antiretroviral regimen; from healthy seropositive to onset of first AIDS-related illness; from late stage AIDS to end-stage AIDS and death.

Prevalence of Psychiatric Disorders

The high prevalence of mental disorders in persons with HIV infection has resulted in closer clinical collaboration among primary care physicians, infectious disease specialists, and psychiatrists. While early studies in the 1980s showed a prevalence rate of 38% (31), more recent estimates show that 74% to 98% of persons with HIV infection who seek medical treatment have a psychiatric disorder (32–34). The prevalence of psychiatric disorders in persons with HIV infection varies according to the population studied. For example, there is a higher prevalence of delirium (acute confusional states) in acute general care units and a lower prevalence in nursing home and outpatient settings. Conversely, dementia is more prevalent in nursing home populations than in clinic or hospital populations. Table 19.1 summarizes the most recent research on prevalence of psychiatric disorders in persons with HIV infection in nursing home, inpatient, and outpatient inner city populations in the United States.

Psychiatric Disorders

While there are psychiatric disorders linked directly and indirectly to risk behaviors, HIV infection, or AIDS, people with HIV may have no psychiatric disorder or any disorder described in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) (35). We will describe the psychiatric disorders most prevalent in persons with AIDS and most relevant for primary physicians, infectious disease specialists, and other caregivers because of their impact on health, adherence, behavior, and quality of life.

TABLE 19.1. *Prevalence of psychiatric disorders in persons with HIV infection*

Diagnosis	AIDS nursing home[a] (1995-1996) N = 423	General hospital unit[b] (1989-1994) N = 433	Out patient clinic[c] (1999-2001) N = 558

[a] This is only a partial list of the most prevalent psychiatric diagnoses in persons with HIV infection.

Psychiatric disorders associated with HIV infection are summarized in Table 19.2. Definitions and terminology are based on those in DSM-IV (35). Psychiatric disorders may be the first and, at times, the only manifestation of HIV infection (36–38). Early diagnosis of central nervous system (CNS) HIV-related abnormalities can lead to timely introduction of treatment with antiretroviral agents (39). Early neuropsychiatric disorders have been described (36–63), in addition to later manifestations of general psychopathology (39,41–46), dementia (47–63), psychosis (64–67), depression (68,69), and mania (70–73). These disorders can be a reaction to awareness of a diagnosis of HIV infection. Alternatively, psychopathology can be related to intrinsic involvement of the brain with HIV or opportunistic infections or cancers, such as toxoplasmosis, cryptococcosis, or lymphoma. In addition, antiretroviral therapies, treatments for opportunistic infections and cancers, and treatment for comorbid hepatitis C virus infection may have central nervous system side effects, including psychiatric symptoms.

Substance Use Disorders

In the United States and in some other countries, the AIDS epidemic is inextricably linked with the epidemic of substance related disorders. As of June 1999, 26% of all reported United States AIDS cases were associated with injecting-drug use (74). The United States is in the midst of a heroin epidemic (75). A 33-year longitudinal study of 581 men addicted to heroin revealed that nearly half of them died prematurely, primarily from drug overdoses or accidental poisonings (76). The use of heroin by injection is associated with a high mortality rate from drug overdose (76,77), and the use of drugs is associated with HIV transmission through needle-sharing, sexual transmission, exchange of sex for drugs, and through perinatal transmission. Furthermore, the use of multiple substances such as combinations of alcohol, heroin, cocaine, and benzodiazepines is associated with intoxication, disinhibition, and unsafe sexual behaviors. Persons with intoxication, withdrawal, or drug-induced persisting dementia, may make inappropriate partner choice, be victims of sexual violence, become sexually and physically violent, and exchange sex for drugs. Drug and alcohol cravings may override good judgment and result in unsafe sex.

Comprehensive psychiatric care for persons with substance dependence and HIV infection may include crisis intervention, individual psychodynamic psychotherapy, supportive psychotherapy, couple therapy, family therapy, group therapy, and specialized treatment approaches to substance-related disorders (1,2,33,78–80) including Alcoholics Anonymous, Narcotics Anonymous, and other twelve-step programs. Unsafe sex may result in not only HIV transmission, but also unwanted pregnancy, use of substances during pregnancy, and inadequate attention to prenatal care, perinatal transmission, and ultimately to early childhood abuse or neglect. With comprehensive programs (81) of support, treatment, and care, pregnant and drug addicted women with AIDS can prevent perinatal transmission and become caring mothers. It is also important to recognize that persons with substance

dependence are likely to have comorbid psychiatric disorders such as bipolar disorder, post-traumatic stress disorder, or any other psychiatric diagnosis. Conversely, persons with other psychiatric disorders such as mood disorders and schizophrenia may have substance dependence as well. Additionally, persons with AIDS and substance dependence may develop dementia and delirium from either drug-related or HIV-related causes. They can beneÞt from comprehensive psychiatric care, psychopharmacologic interventions, and complementary therapies such as relaxation response, meditation, use of writing (82) and art as creative outlets (80), as well as adequate nutrition and exercise. They can also beneÞt from incorporating and maintaining spiritual and religious connections (79,83Ð87). We will present an integrated psychopharmacologic approach to some of the commonly encountered psychiatric manifestations and symptoms that cause distress and suffering to patients and present challenges to their caregivers.

Drug Craving and Withdrawal

A person with AIDS who is actively using or craving drugs or alcohol will Þnd it difÞcult to focus on obtaining medical care, keeping appointments or taking a complex drug regimen. Intoxication, dependence, withdrawal, substance-induced mood disorders as well as comorbid psychiatric disorders interfere with adherence to care. Although rare, threats of violence and attempted assaults can be frightening to caregivers and can impede development of ongoing therapeutic relationships. A comprehensive approach to drug and alcohol treatment includes medical and psychiatric care and referral for drug detoxiÞcation, outpatient drug and alcohol treatment, and 12-step programs.

Psychopharmacologic Treatment of Drug and Alcohol Craving and Withdrawal

Drug treatment approaches to drug and alcohol cravings are currently under investigation. Several studies have demonstrated the efÞcacy of naltrexone in the treatment of alcohol cravings (88Ð92). However, we do not recommend the use of naltrexone in HIV-infected alcohol dependent individuals for three reasons. The Þrst reason is the concern about hepatotoxicity and drug side effects of nausea, vomiting, and abdominal cramping. The second reason is that naltrexone is an opiate receptor antagonist and will cause persons who are opioid dependent or on methadone as agonist therapy to go into withdrawal. The third reason is that naltrexone also blocks the analgesic effects of opioid analgesics in persons who are being treated for pain. Some studies have found several other drug treatments useful to alleviate cravings, but efforts to replicate Þndings of these studies have not been successful. The tricyclic antidepressant, desipramine, was found to be useful to decrease cocaine cravings (93,94), but placebo-controlled trials have not adequately conÞrmed these Þndings. A meta-analysis of placebo-controlled studies (95) showed that desipramine was helpful with cocaine cravings but did not improve treatment adherence. Imipramine has also been shown to decrease cravings for cocaine (96) but further review of these studies indicates that depressed cocaine users have a better response than nondepressed cocaine users. Other medications that can reduce drug cravings include anticonvulsant mood stabilizers. In a 12-week randomized, double-blind, placebo-controlled study, Halikas and colleagues (97) demonstrated that carbamazepine produced a decrease in cocaine craving. Brady and colleagues (98) reported that valproate was helpful in an open label, non-blinded study of nine patients. Isolated case reports have suggested that gabapentin might be useful for cocaine (99) and alcohol cravings (100,101). The antiparkinsonian medication pramipexole has been reported to be useful for cocaine craving (102). This was a single case report and we have not used pramipexole in any of our patients with AIDS and cocaine dependence. Placebo-controlled trials of serotonin reuptake inhibitors have not indicated efÞcacy in treatment of cocaine cravings (103).

Because gabapentin is well tolerated and does not undergo cytochrome P450 metabolism, we have used it in our patients. We have used desipramine in low doses. We have also used bupropion in low doses for both cocaine and nicotine cravings. Although there are conßicting reports (104,105) about the efÞcacy of bupropion for cocaine cravings, we have found it helpful for some of our patients. Benzodiazepines are recommended for alcohol and benzodiazepine withdrawal. A summary of our recommendations for treatment of drug craving and withdrawal in persons with AIDS is presented in Table 19.3. A protocol for persons with heroin withdrawal is presented in Table 19.4. We recommend that individuals who are actively using heroin obtain methadone maintenance as agonist therapy to prevent withdrawal and relapse. Methadone is widely used as agonist therapy for heroin dependence; well-controlled clinical trials (106Ð109) have demonstrated signiÞcant symptom improvement and treatment efÞcacy. Unfortunately, many medications prescribed for AIDS patients can alter methadone blood levels and may result in opiate withdrawal in individuals who are in full sustained remission on methadone agonist therapy.

Drug-Drug Interactions in the Treatment of Drug and Alcohol Dependence

Awareness of the drug-drug interactions of antiretroviral, antituberculous, and antifungal medications can help to prevent problems of altered blood levels of methadone and other medicines by understanding which medicines inhibit or induce cytochrome P450 enzymes.

TABLE 19.3. *Use of psychotropic medication and treatment of withdrawal and craving in persons with AIDS and substance dependence*

Indication	Medication	Dose Range
Cocaine withdrawal	Desipramine (Norpramin)	50–125 mg. hs.
	Nortriptyline (Pamelor)	50–125 mg. hs.
Drug or alcohol craving	Gabapentin (Neurontin)	100–800 mg. t.i.d.
Alcohol or benzodiazepine withdrawal	Chlordiazepoxide (Librium)	25–100 mg. t.i.d.
	Lorazepam (Ativan)	0.5–10 mg. t.i.d.

TABLE 19.4. *Methadone detoxiÞcation protocol for persons with heroin withdrawal who are not on opioid agonist therapy*

1. When heroin withdrawal is clinically evident, give methadone 20 mg po immediately.
2. Re-evaluate patient in 1–2 hours. If evidence of withdrawal persists, give an additional dose of methadone 10 mg po.
3. Repeat step 2 if withdrawal persists, for a total maximum rst-day dose of 40 mg.
4. Detoxify by 5 mg decrements every other day.

Methadone is metabolized primarily by the cytochrome P450 3A4 isoenzyme (110,111). All protease inhibitors and nonnucleoside reverse transcriptase inhibitors are metabolized by the cytochrome P450 system and may have inhibiting or inducing properties (112). Some combinations of antiretrovirals can alter methadone levels by enzyme induction or inhibition. Although ritonavir has been described as the most potent enzyme inhibitor and saquinavir as the least potent inhibitor (112,113), it is difÞcult to predict the impact of antiretrovirals on methadone levels since combination therapies with protease inhibitors, nonnucleoside reverse transcriptase inhibitors, antibiotics, and antifungals result in varied effects on induction and inhibition (112,114). Ritonavir, nelÞnavir, and efavirenz are all cytochrome P450 substrates, inhibitors, and inducers. Although ritonavir is a potent cytochrome P450 3A4 inhibitor, it decreases methadone levels by both enzyme induction of cytochrome P450 2B6 and displacement of methadone from plasma protein-binding sites (115Ð117). Although nelÞnavir has been reported to have signiÞcant inhibitory effects on cytochrome P450 3A4 *in vitro* (118), a case report indicated enzyme induction with resultant methadone withdrawal six weeks after nelÞnavir was started (119). There are also individual differences in patient responses to the combination therapies with the net effects varying considerably among individual patients. A summary of antiretroviral pharmacokinetics is presented in Table 19.5.

Drugs that have an inhibitory effect on cytochrome P450 3A4 can cause an increase in methadone to unacceptably high and even dangerous levels. On the other hand, drugs that are inducers of cytochrome P450 3A4 can

TABLE 19.5. *Antiretroviral substrates, inhibitors, and inducers of cytochrome P450 isoenzyme metabolism*

result in the discomfort of narcotic withdrawal. Rifampin, an antituberculous medication, is a potent inducer of cytochrome P450 3A4 and results in narcotic withdrawal symptoms in persons on methadone. When a known potent enzyme inducer is prescribed, methadone may need to be increased at a rate of up to 10 mg per day until withdrawal symptoms are alleviated. The antifungal medication, ßuconazole, is a relatively weak inhibitor of cytochrome P450 3A4, but has been shown to increase methadone by 30% (120). It is important to ascertain whether there are interactions between antiretroviral, antituberculous, antifungal, and other medications in order to prevent accidental overdose or withdrawal (121,122). A summary of these medications is presented in Table 19.6.

Drug-Illness Interactions in the Treatment of Drug and Alcohol Dependence

Issues to be considered in the psychopharmacologic approach to the treatment of drug and alcohol dependence in persons with AIDS include an awareness of the interactions of psychotropic medications and the symptoms and illnesses that are commonly encountered. Persons with AIDS may have underlying liver disease from prior drug or alcohol dependence. Some have coinfection with hepatitis C virus. Coinfection with HIV and hepatitis C virus complicates care. A treatment currently available for hepatitis C virus infection is with the combination of interferon alfa-2b and ribavirin. Interferon alfa-2b is known to cause depression, suicidal ideation, and suicide in some individuals (123,124). Musselman and colleagues (125) found that pretreatment with paroxetine helped to prevent severe depression from developing in a double-blind study of forty patients with malignant melanoma who were treated with interferon. Although we have not seen evidence of severe depression, we have found that several of our patients developed psychosis with paranoid components about two to three weeks after beginning combination treatment with interferon alfa-ribavirin. Pretreatment with an antidepressant such as paroxetine might have complicated the picture by actually precipitating or worsening psychotic symptoms. We have used gabapentin as a mood stabilizer for pretreatment and antipsychotic medication for psychotic symptoms, adding an antidepressant only if symptoms of depression ensue. Our patients are also on a multiplicity of antibiotics, antifungals, antiretrovirals, and other medications, all of which undergo hepatic metabolism. Efforts to maximize treatment efÞcacy and minimize hepatotoxicity are meaningful considerations in choice of psychopharmacologic agent.

The vulnerability of persons with AIDS to anticholinergic, extrapyramidal, hepatotoxic, and cognitive side effects of medications makes them similar to the geriatric patient population. Since persons with AIDS are also vulnerable to HIV-insomnia and HIV-neuropathy as well as mood swings, we have found that gabapentin is useful for drug and alcohol craving and have prescribed it for cravings alone or for multiple indications. Gabapentin has the advantage of not being metabolized in the body and also can alleviate mood swings, insomnia, and neuropathic pain (126Ð138). We have also prescribed desipramine or nortriptyline alone or in combination with gabapentin for patients with both HIV neuropathy and drug cravings. Valproate-induced extrapyramidal side effects and hepatotoxicity make it difÞcult to tolerate in this vulnerable population. Carbamazepine-induced anticholinergic side effects as well as hepatic metabolism also make it harder to tolerate.

Cognitive Disorders: Delirium and Dementia

Cognitive disorders may be reversible in persons with AIDS. The cognitive disorders are comprised of delirium and dementia. Delirium has been described as a syndrome of cerebral insufÞciency or acute confusional state and is 100% reversible if an underlying cause can be identiÞed and treated. In persons with HIV infection, causes may include sepsis-induced delirium, hypoxia-induced delirium with *Pneumocystis carinii* pneumonia (PCP), or hepatic encephalopathic-induced delirium due to hepatitis C cirrhosis and end-stage liver disease.

HIV dementia, unlike dementia of the AlzheimerÕs type, does not result from a direct effect on neurons themselves and can be reversed with HAART (139Ð141). With adherence to antiretroviral therapy and decrease in viral load to undetectable, dramatic improvement in cognitive function can occur with reversal of dementia. However, unless a person with dementia receives assistance, is in a structured setting, or is under direct observation, it may be very difÞcult for a person with memory impairment to adhere to a complex regimen. Cohen and Jacobson (79) described dramatic improvement in a small population of AIDS nursing home patients. Four patients with HIV encephalopathy and HIV dementia presented with moderate to severe cognitive impairment documented on mental status examination including Bender and clock drawings.

Some were disoriented, unable to perform activities of daily living, and incontinent of urine and feces. All four made dramatic improvement on antiretroviral therapy. After only one year of combination therapy including protease inhibitors, three patients had almost no detectable cognitive impairment and were able to live independently. The fourth patient is presented in the following vignette:

> Case 1: The patient was a 37-year-old disabled investment banker who was admitted to a nursing home when he was no longer able to care for himself in the community. He was confused, wandered, and was incontinent of urine and feces. He had evidence of slowing and diminished intellectual functioning. He did not understand that he had AIDS (Ò I don't even have HIV, there must be a mistake.Ó). He had evidence of cognitive impairment including constructional apraxia on clock and Bender drawings. After two years of HAART, dementia could not be detected on psychiatric examination and he no longer had constructional apraxia. He knew his CD4 counts, viral loads, full medical history, and names and doses of his medications. He was fully able to perform activities of daily living, was no longer incontinent, and was able to move out of the nursing home and to live independently. Within three years, he went from confused nursing home patient in diapers to dapper investment banker. He resumed his career and began to resume his social life. He retained an awareness of his prior cognitive deficits and was appreciative of his recovery.

Despite their frequent occurrence in general hospital populations, cognitive disorders frequently go undiagnosed (142). Even delirium, which is associated with a high mortality rate, often is overlooked. Consultation requests for persons with delirium are most often called for isolated psychiatric symptoms, management problems, or assessment of capacity to give informed consent or to refuse treatment. The cognitive disorders associated with HIV infection are even more elusive, making it difficult for inexperienced clinicians to associate aberrant behavior, mood swings or treatment refusal with the dementias and delirium associated with HIV infection, especially because they occur in young adults. Cognitive disorders occur frequently in persons with AIDS and they may or may not be associated with neurological findings. The presence of CNS involvement with *Toxoplasma gondii*, *Cryptococcus neoformans*, HIV, or cerebral lymphoma may, or may not, be indicative of the presence of cognitive dysfunction. Although cerebral atrophy is associated with HIV dementia, the degree of atrophy may not correlate with the severity of the dementia.

Delirium

Delirium is a cognitive disorder which is frequently unrecognized or misdiagnosed in persons with AIDS. Lipowski (143,144) describes delirium as a disorder of cognition including global cognitive impairment with concurrent deficits in memory, thinking, orientation, perception, disturbances of the sleep-wake cycle, and a characteristic course marked by rapid onset, relatively brief duration, and fluctuations in the severity of the disturbance. There is impaired ability to process, retain, retrieve, and apply information about the environment, body, and self. The patient's level of awareness is reduced and there can be fluctuations in level of consciousness. Thinking, perceiving, and remembering are all impaired in delirium. Delirium is also characterized by rapid fluctuations in mood, behavior, and level of consciousness. These may occur over the course of minutes, hours, or days, and may be typified by an alert patient falling asleep midsentence. ÒNodding outÓ is a sign of delirium. Delirium may be hypoactive or hyperactive and the patient may be quietly confused or agitated. Confusion is so frequently observed, that delirium has also been described as an acute confusional state and as a state of cerebral insufficiency.

Assessment of Delirium in AIDS

Delirium is 100% reversible when an underlying cause can be identified. Factors predisposing to delirium in AIDS include addiction to alcohol or drugs, brain damage, and chronic illness. Facilitating factors are psychological stress, sleep deprivation, and sensory deprivation during intensive care unit admission. Causes of delirium (see Table 19.7) include: (a) hypoxia secondary to, for example, PCP; (b) infections such as HIV encephalopathy, bacterial or fungal meningitis, or septicemia; (c) space-occupying lesions of the brain such as toxoplasmosis and CNS lymphoma; and (d) drugs, including opiates, as well as antibiotics, chemotherapeutic agents, and antiretroviral agents; (e) end-stage liver disease and end-stage renal disease.

It is not always easy to identify the cause of delirium in AIDS as is illustrated in the following vignette:

> Case 2: The patient was a 42-year-old disabled receptionist who was admitted to a psychiatric unit with symptoms of withdrawal and mutism. The patient was confused, disoriented to place and time, and was incontinent of urine and feces. She had frequent mood swings, was emotionally labile, and cried easily. She also had fluctuations in behavior. At times she was able to speak and answer questions, although not spontaneously. Most of the time she was mute and withdrawn. Ultimately after three months during which she was transferred from an acute psychiatric unit to an acute medical unit (to evaluate for underlying medical or neurological causes for her behavior) and back to psychiatry, she recovered sufficiently to return to the community. No underlying cause was identified and

TABLE 19.7. *Causes of delirium in AIDS*

Intoxication
Drugs: antibiotics, anticonvulsants, sedative-hypnotics, opiates, phencyclidine, ketamine, antineoplastic drugs, lithium, anticholinergic agents, cocaine, alcohol
Drug withdrawal
Alcohol
Opiates
Sedative-hypnotics
Metabolic encephalopathy
Hypoxia
Hepatic, renal, pulmonary, pancreatic insuf ciency
Hypoglycemia
Disorders of uid, electrolyte and acid-base balance: water intoxication, dehydration, hypernatremia, hypokalemia, hypocalcemia, hypercalcemia, alkalosis, acidosis
Endocrine disorders
Infections
Systemic: bacteremia, septicemia, infective endocarditis, bacterial pneumonia, *Pneumocystis carinii* pneumonia, cryptococcal pneumonia, herpes zoster, disseminated *Mycobacterium avium-intracellulare* complex, disseminated candidiasis
Intracranial: cryptococcal meningitis, HIV encephalitis, tuberculous meningitis, toxoplasmosis
Neurologic
Seizures: ictal, interictal, postictal states
Head trauma
Space-occupying lesions of brain: CNS lymphomas, toxoplasmosis. cytomegalovirus infection, abscesses, cryptococcoma
Hematologic
Anemia

lumbar puncture, MRI, CT, neurologic, hematologic, and metabolic evaluations were all within normal limits. No toxicology screening had been performed. On her return to the outpatient setting, she was able to recall that she had used large amounts of cocaine prior to her admission to the psychiatric unit and attributed her behavior changes to both intoxication and withdrawal. On her return visit, she was talkative, alert, calm, euthymic, and had no evidence of cognitive impairment. Delirium was most likely due to cocaine intoxication and withdrawal.

Romano and Engel (145), Pro and Wells (146), and Obrecht, et al. (147) have stressed the usefulness of the electroencephalogram (EEG) in helping to support a diagnosis of delirium. A decrease in frequency of EEG background activity is indicative of delirium, possibly as a result of a reduction of brain metabolism. EEG changes virtually always accompany delirium and make the electroencephalogram a useful diagnostic tool in persons with AIDS who manifest a change in mental status (148,149). EEG changes can aid in identifying the speciÞc etiology of delirium. Triphasic waves are characteristic of hepatic encephalopathy and generalized fast wave activity may be indicative of delirium tremens. EEG testing may also be helpful in evaluating and monitoring the course of HIV dementia (150) or diagnosing seizure-related behavior changes. A controlled study (151) of men with asymptomatic HIV infection showed that EEG and other electrophysiologic tests were the most sensitive indicators of subclinical neurologic impairment.

Treatment of Delirium in AIDS

Treatment of delirium consists of Þrst identifying and treating the underlying cause and then of maintaining hydration, electrolyte balance, and nutrition. In addition, it is important to provide an optimal environment for the patient: a quiet, well-lit room with a dim light at night, radio or television, a large calendar, easy-to-read clock, photographs and familiar objects, and, if possible, visits from familiar people. Medical and nursing support should be directed toward orientation and companionship, as well as to adequate sleep and sedation. Olanzapine 2.5 mg may be recommended as a standing order at bedtime until identiÞcation and treatment of the underlying cause have been accomplished. Olanzapine 2.5 mg is recommended as a starting dose; this can be increased gradually if necessary. Although olanzapine usually is effective in a single dose of 2.5 to 5 mg, a dose range to 10 mg may be required in some instances. For extreme agitation olanzapine can be given in divided doses of 2.5 mg every one to six hours (up to a total dose of no more than 10 mg) with or without the addition of lorazepam 0.5 mg every four to six hours.

Dementia

Dementia is a cognitive disorder characterized by loss of intellectual abilities that is sufÞciently severe as to interfere with the individualÕs social and/or occupational

functioning (35). Dementia (152) may be regarded as a global disorder of cognition, in the sense that several cognitive functions are impaired concurrently. These include memory, attention, judgment, and abstract thinking, which are decreased relative to the individual's premorbid level of performance. In HIV dementia, apraxia, agnosia, anomia, and constructional difficulty are accompanied by dropping things and poor concentration. Denial, memory impairment, and impairment of abstraction make it difficult for some patients to comprehend a diagnosis such as AIDS. Personality changes include alteration of the characteristic personality or accentuation of personality traits. Loss of cortical inhibitions may lead to promiscuity, assaultive behavior, or lack of awareness of social amenities. There may be use of obscenities by individuals who were not known to use them before. A patient may be unaware that he or she is not adequately clothed or that breasts or genitalia are exposed. These changes have a profound impact on family members, loved ones, and caregivers who might be distressed to see such changes in the elderly, but are devastated to see them in young adults.

Dementia may be associated with specific personality or behavioral manifestations if there is invasion of certain brain areas by the infectious agents or tumors associated with AIDS. If the frontal lobes are involved, the characteristics may include reduced drive, diminished self-concern, inability to delay gratification, impulsivity, lack of judgment, shallow blunted affect, perseveration, concrete thinking, and inability to change mental set (153). Other features include depression, psychosis, and anxiety. Delusions of persecution or jealousy can occur. When a patient faces a difficult series of tasks, such as during careful psychiatric examination or neuropsychologic testing, a catastrophic reaction with regression, irritability, rage, and crying may result (154). It can be averted by an examiner who is aware of this reaction and who employs a supportive approach during evaluation of cognitive capacities. The signs and symptoms of dementia are summarized in Table 19.8. The most frequent cause of dementia in AIDS is HIV encephalopathy; the causes are cited in Table 19.9. In general, differentiation of delirium from dementia may be based on criteria that include normal state of consciousness in dementia and a rapidly fluctuating course in delirium. Although in AIDS delirium may be superimposed on dementia, it is important to understand how to distinguish the two entities (Table 19.10).

Several standardized tests have been developed to screen for dementia, including the Short Portable Mental Status Questionnaire (155), the Mini-Mental State Examination (156), and the Cognitive Capacity Screening Examination (157). Unfortunately, these tests screen for moderate-to-severe cognitive dysfunction, and were developed as evaluations for cortical dementias such as dementia of the Alzheimer type. These tests may not detect subtle signs or mild impairment in persons with mild dementia or the subcortical dementia associated with HIV. HIV dementia requires careful psychiatric examination and neuropsychologic assessment. Two screening tests have been developed for HIV dementia. The first, the Mental Alternation Test (158), is analogous to Trailmaking Part B on neuropsychological testing and is a brief standardized test for very early HIV dementia. The HIV dementia scale is another standardized brief assessment (159). These tests are meant for screening and cannot serve as substitutes for a complete comprehensive psychiatric examination but can be used in addition along with general dementia screening.

Firesetting: An Unexpected Manifestation of HIV Dementia

Firesetting is a dangerous concomitant of HIV dementia (160). We deÞne Þresetting as an accidental or deliberate ignition of a Þre during the process of smoking or lighting a match, resulting in burn-related injuries or destruction of property. Firesetting is an extremely tragic manifestation of HIV dementia in persons with nicotine dependence.

TABLE 19.10. *Differentiation of delirium and dementia in AIDS*

	Delirium	Dementia

Impaired concentration	+	+
Slow speech	–	+
Slow motor responses	–	+
Delusions	–	+
Ataxia	–	+
Leg weakness	–	+

Please note that the differentiation is *not* absolute. There is occasional overlap of symptoms and frequent appearance of delirium superimposed on pre-existing dementia in AIDS.

Fires can be set through carelessness with cigarettes even without cognitive impairment, and persons with HIV dementia and AIDS are even more vulnerable. Their vulnerability to Þresetting is multifactorial. Some individuals have HIV neuropathy and may not perceive the heat of a lit cigarette or spark, while others with visual impairment from cytomegalovirus (CMV) retinitis may not see a dangerous situation until it is too late. In persons with even mild HIV dementia, dropping things is a common manifestation of early minor cognitive/motor disorder and can result in accidental burns. Additionally, alcohol and drug intoxication can be superimposed on HIV dementia increasing vulnerability to accidental Þresetting. It is important to be aware of this dangerous concomitant of HIV dementia and to provide ßame-retardant clothing, prevent smoking in bed or in unsupervised areas, and if at all possible, to offer smoking cessation training and nicotine inhaler or transdermal system therapy to prevent Þresetting in this vulnerable population (160).

Violence

The violent patient with HIV dementia can be frightening to family members, to staff, and to other patients. Although rare, violence is extremely disruptive in the home and in the healthcare setting. Caring for the violent patient is complex and evokes strong feelings in caregivers. Education can reduce risks, prevent violence, and help to deal with trauma and its aftermath. Recognition of early warning signs and predictors of violence can help caregivers learn to defuse and deescalate potentially explosive interactions. Early warning signs include: verbal outbursts; physical aggression against objects (slamming doors, breaking objects); physical aggression toward the self; and physical aggression or threats of aggression toward others. Risk factors include prior history of violence, history of early childhood trauma, history of severe adult trauma or mortal combat, history of substance abuse, and paranoid schizophrenia. The psychiatric disorders associated with violence are summarized in Table 19.11.

Each HIV dementia patient with a history or potential for violence should be educated to become aware of precipitating factors and ways to obtain help in the face of imminent violence. The patient can be taught to reach out to staff, to use relaxation and biofeedback, and to request comforting foods such as cookies or ice cream to interrupt an escalating cycle of violence. The patient can also learn to request as needed medication or to leave an upsetting or overstimulating environment.

Caregivers should not corner a potentially violent person. Instead, they should keep at a distance of four to ten feet while speaking in a soft, reassuring, and gentle voice. The goal of the interchange is to assist the patient in regaining control and maintaining dignity. The patient

should be offered medication if it is not self-requested. Security guards, psychiatrists, and other personnel should be called promptly to minimize fear and maximize safety.

Use of creative outlets for sublimation of aggressive drives into creative activities include writing of poetry or prose, artwork, pottery, music, movement therapy, and exercise. Use of a multidimensional approach to violence includes early recognition, crisis intervention, alternative outlets, and psychotherapy. The medicines for violent behavior include combinations of antipsychotics, anticonvulsants, benzodiazepines, and β-adrenergic blockers. A summary of these recommendations is presented in Table 19.12.

Treatment of Dementia in AIDS

Gendelman and colleagues have demonstrated that HIV dementia can be reversed with HAART (141). However,

TABLE 19.12. *Guidelines for combination pharmacologic approach to violence in HIV dementia*

	Indications:	Contraindications in patients with:	Total daily dose range for standing orders oral route[a]	As needed oral Route[a]
Antipsychotics				
Haloperidol (Haldol)	Extreme agitation	Rigidity, immobility, risk for falls	0.5–20 mg	0.5–5 mg q2–4 hours
Perphenazine (Trilafon)	Little need for sedation	Rigidity, immobility, risk for falls, seizures	2–20 mg	2 mg q 6 hours
Chlorpromazine (Thorazine)	Need for sedation	Rigidity, immobility, risk for falls, seizures, endstage liver disease, cardiac disease, orthostatic hypotension	25–200 mg	10 mg q 2–4 hours
Thioridazine (Mellaril)	Need for sedation	Rigidity, immobility, risk for falls, endstage liver disease, cardiac disease, orthostatic hypotension	25–200 mg	10 mg q 2–4 hours
Olanzapine (Zyprexa)	Underlying paranoid schizophrenia with delusions and psychosis	End-stage liver disease, cardiac disease, orthostatic hypotension	10–20 mg	Not recommended
Anticonvulsants				
Gabapentin (Neurontin)	Recurrent violent and dangerous behavior	Severe renal disease	300–240 mg	Not recommended
Benzodiazepines[b]				
Clonazepam (Klonopin)	Severe agitation	Respiratory depression, liver disease, confusion, risk for falls	0.5–2 mg	Not recommended
Lorazepam (Ativan)	Severe agitation	Respiratory depression, confusion, risk for falls	1–8 mg	1 mg q 4 hours
Oxazepam (Serax)	Severe agitation	Respiratory depression, confusion, risk for falls	15–90 mg	Not recommended
Beta-Adrenergic Blockers				
Propranolol (Inderal)	Severe agitation	Asthma, emphysema, insulin-dependent diabetes mellitus, cardiac disease	10–40 mg	Not recommended

[a] Oral route is recommended to preserve dignity and autonomy.
[b] Benzodiazepines can cause paradoxical agitation in persons with delirium or dementia.

the process takes time and careful adherence to the HAART regimen. A special home care program, direct observation, or a structured setting such as a nursing home may be required in order to enable the patient to beneÞt from care if dementia impairs ability to adhere. With mild to moderate dementia, assistance from family members and reminder devices such as programmable watches or beepers and prepackaged medications may sufÞce. It is important to provide adequate care and support until cognitive function is regained. Support, psychotherapy, and family therapy must be provided for patients with AIDS-associated dementia. Ongoing therapy is beneÞcial and may lead to a less precipitous course. Antipsychotic medications help to alleviate anxiety, agitation, and psychotic symptomatology. The family should be included and caregivers should be given enough information about dementia so that they will be able to understand the patientÕs behavior and can help to orient and educate the patient as much as possible. Home care with adequate support services, nursing services, and a medical and psychiatric home care team can enable persons with dementia to function optimally and can prevent the disruption, separation, and confusion of a major environmental change.

If it is at all possible, the environment should be familiar to the patient. If the patient cannot be cared for in his or her own home, the space in a hospital or long-term care facility should be made as familiar and home-like as possible, with photographs of family members, familiar objects, and music provided. We recommend use of large clocks, calendars, televisions, and radios to ensure that the environment provides cues for orientation. Calendars should be one day per page, with only the day of the week, date, month, and year and indication of any holidays. Floors should be carpeted to prevent slips and falls. Family members should be encouraged to stay with the patient as much as possible in the Þrst few days and nights of a hospital stay. Telephones should be installed immediately upon admission. Telephones help persons with HIV dementia to maintain contact and can be programmed if telephone numbers cannot be recalled. When behavioral manifestations of dementia interfere with comfort and function and nonpharmacological interventions have been exhausted, use of antipsychotic medications is recommended. These may be helpful for psychotic manifestations of dementia, catastrophic reactions, and Òsundowning.ÓPsychotropic medication may be indicated for violence, extreme agitation, depression, anxiety, impulsivity, behavioral disinhibition, or psychotic symptomatology. Awareness of vulnerability to the extrapyramidal side effects of antidepressant, antipsychotic, and mood stabilizing medications is especially important in persons with HIV dementia.

Dementia in persons with AIDS is associated with a high suicide risk (161) and is also associated with accidental Þresetting (160). The tragedies of suicide, violence, and accidental Þresetting are compounded by the problems of loss of dignity and ability to function independently. Persons with AIDS with or without dementia can also develop depression or mania and may require treatment for mood disorders.

Mood Disorders

When depression or mania occur during the course of HIV infection, they are described as mood disorders due to medical condition if they are etiologically related to HIV, opportunistic infections, or to side effects of treatments. When an individual has had a longstanding history of recurrent or episodic periods of depression or mania that meet the DSM-IV criteria, and these have occurred prior to the onset of infection with HIV, then a recurrence would be classiÞed as either major depressive disorder or bipolar disorder, manic episode.

Major Depressive Disorder

Major depressive disorder is a mood disorder characterized by depressed mood, guilt, loss of interest in most activities (anhedonia), and hopelessness. A recent meta-analysis of ten published studies assessing the association between HIV infection and risk for major depressive disorder provided strong evidence that the frequency of major depressive disorder was twice as high in persons with HIV infection than in those who are not infected (162). There can be insomnia or hypersomnia and psychomotor retardation or agitation, diminution of self-esteem, and feelings of worthlessness and hopelessness. There may also be evidence of diminished ability to think or concentrate and suicidal ideation. Lyketsos and Treisman have described the difÞculty detecting depression especially in HIV primary care clinics where depression is often associated with substance use disorders and unemployment (163). Lyketsos and colleagues have also documented the high prevalence of depression in persons with injection drug use prior to HIV infection, upon entry to HIV primary care (164), and before progression to AIDS (165). Although research studies have not demonstrated a clear association between major depression and HIV disease progression (166), we feel that it is nonetheless important to recognize and treat depression to alleviate suffering and prevent suicide. We also have observed that depression has a negative impact on adherence which has been documented by Gordillo and colleagues (167), and ultimately this nonadherence as well as the distress of depression may contribute to illness progression as well.

Treatment for depression includes individual and family therapy and psychotropic medications. The use of antidepressants in persons with AIDS will be considered, in sections on Mood Disorder Due to Medical Condition (Section II. C. 4.).

TABLE 19.13. *Causes of AIDS-associated mania*

Illnesses	Medications
Cryptococcal meningitis	Zidovudine
HIV-encephalopathy	Efavirenz
	Steroids

Mania

Mania is a mood disorder characterized by a period of abnormally and persistently elevated, expansive, or irritable mood with grandiosity, pressure of speech, flight of ideas, decreased sleep, distractibility, buying sprees, and/or sexual indiscretions. Mania can occur early or later during the course of HIV illness, and while it is similar to the mania associated with bipolar disorder, "AIDS mania" is characterized with irritability rather than euphoria (168). The prevalence of mania is 1–2% in early HIV infection and 48% in later stages (169). The disruptive, dangerous nature of mania makes it an important diagnosis in the care of persons with AIDS. Additionally, persons with AIDS are prone to mania because of both opportunistic infections, such as cryptococcal meningitis (72,170), and medicines, such as zidovudine (73,171) and efavirenz (172). The illnesses and medicines associated with mania and AIDS are listed in Table 19.13. It is important to note that when mania is induced by an illness such as HIV encephalopathy or cryptococcal meningitis, the treatment should be directed both toward symptoms and underlying cause. It is also possible that once viral load is below detectable levels and cryptococcal meningitis has been treated, mania with mood disorders, unlike mania with bipolar disorder, is less likely to recur. Since persons with AIDS can also have bipolar disorder with manic features, this was also included.

Pharmacologic management of mania in persons with AIDS includes a combination of an anticonvulsant mood stabilizer, along with antipsychotic and antidepressant medications where indicated. Gabapentin has been investigated for use as a mood stabilizer in mania (173). Gabapentin can be started in doses of 100 mg three times a day and gradually increased to 300 mg three times a day and 900 mg at bedtime. Some individuals may require larger doses of gabapentin, up to 2,700 mg daily or more in divided doses. Although gabapentin cannot be monitored with blood levels, it is preferable to valproic acid because it has fewer side effects. Valproic acid, although highly efficacious for mania, violence, and seizures, has extrapyramidal side effects such as rigidity and tardive dyskinesia (174–176). Carbamazepine has anticholinergic side effects. Valproic acid and carbamazepine should be used with caution in persons with AIDS because of side effects and drug-drug interactions. Gabapentin can be substituted for either medication by simultaneously introducing gabapentin while tapering the other drug. Gabapentin can be started at 300–600 mg at bedtime and

TABLE 19.14. *Pharmacologic approach to mania and AIDS*

Anticonvulsant mood stabilizer[a]	Total daily dose range
Gabapentin (Neurontin)	900–2700 mg. In divided doses
Antipsychotic	
Haloperidol (Haldol)	0.5 mg.–5 mg. h.s.
Olanzapine (Zyprexa)	2.5 mg.–20 mg. h.s.
Antidepressant	
Celexa	10–40 mg. h.s.
Nortriptyline	25–125 mg. h.s.

[a] Valproic acid (Depakote) can be hepatotoxic and can cause extrapyramidal symptoms.
Carbamazepine (Tegretol) can cause central anticholinergic delirium.

TABLE 19.15. *Dangers of lithium treatment of mania and AIDS*

1. Need for electrolyte balance to prevent lithium resorption and poisoning
   - Sweating
   - Diarrhea
   - Metabolic alkalosis
   - Vomiting
2. Need for adequate renal function to permit lithium excretion
   - HIV-nephropathy
   - Heroin nephropathy
3. Similarity of symptoms of lithium poisoning to symptoms of AIDS
   - Nausea
   - Vomiting
   - Diarrhea
   - Confusion
   - Irritability

valproic acid or carbamazepine can be decreased gradually until it is discontinued, as gabapentin is titrated to therapeutic levels. The treatment of mania is summarized in Table 19.14. Lithium should be used with extreme caution in persons with AIDS because of the problems with maintaining electrolyte balance and the similarity of AIDS symptoms and symptoms of lithium poisoning. These are summarized in Table 19.15.

Mood Disorder Due to Medical Condition

In the mood disorders due to medical condition, there is a disturbance of mood with symptoms of a major depressive or manic episode. A mood disorder that occurs either after or at the onset of HIV infection is categorized as a Mood Disorder due to Medical Condition. Symptoms are identical to those described in Major Depressive Disorder or Bipolar Disorder, Manic Episode, except that they are caused by the medical condition. Mood disorder

with depression can occur with HIV infection, opportunistic infections or cancers, and many other AIDS-related illnesses. Mood disorder with mania can be caused by other AIDS-related conditions, but is more frequently associated with cryptococcal meningitis or with other cryptococcal infections. In addition, medications for AIDS-related conditions can cause both depression and mania. Some of the medications that can cause a mood disorder in persons with HIV infection are summarized in Table 19.16.

TABLE 19.16. *Medications that can cause mood disorders in persons with HIV infection*

Cephalosporins	+	+

Pharmacologic Treatment of Depression

We select antidepressants to minimize side effects and to maximize efficacy while avoiding drug-drug interactions. We make an effort to choose antidepressants that are less likely to produce side effects such as agitation, insomnia, and seizures because persons with AIDS are especially vulnerable to these. As in the elderly, persons with AIDS are also vulnerable to anticholinergic and extrapyramidal side effects as well as the potentially fatal serotonin syndrome (177). All antidepressants are metabolized by cytochrome P450 enzymes. A summary of pharmacokinetics is presented in Table 19.17. The tricyclic antidepressants are metabolized by cytochrome P1A2, 2C, 3A4, and 2D6. The selective serotonin reuptake inhibitors (SSRIs) are metabolized by cytochrome P450 1A2, 2C, 2D6, 3A4 (178). Fluoxetine, the oldest of the SSRIs, is a

potent inhibitor of cytochrome P450 2D6 and has an extended elimination half-life with a potent active metabolite, norßuoxetine. It has important drug interactions with phenytoin (increases phenytoin), carbamazepine, and antiarrhythmics (177,178). Sertraline and citalopram have fewer side effects and drug-drug interactions than ßuoxetine (177Ð181). All SSRIs can have gastrointestinal side effects of nausea, vomiting, abdominal pain, and diarrhea. Some have psychiatric side effects of agitation, anxiety, insomnia, mania, and nervousness. Most SSRIs have some effect on sleep, primarily insomnia, although some patients experience drowsiness. Other SSRI-associated side effects, include fatigue, weight loss or sometimes weight gain, sexual dysfunction, and cognitive impairment. Neurological side effects include tremor and extrapyramidal side effects (177). The serotonin syndrome can result from the direct effect of SSRIs on serotonin reuptake and their interaction with other agents that also affect serotonergic neurotransmitters (177). The syndrome is characterized by confusion, agitation, autonomic dysfunction, myoclonus, hypperreßexia, and tremor (177) and is potentially fatal. The serotonin syndrome and the agents that can precipitate it (177) are summarized in Table 19.18. Even combinations of more than one SSRI while switching from one agent to another may precipitate serotonin syndrome so that a two-week washout period is recommended for agents known to produce features of this syndrome when used in combination (177). The most severe reactions have been described from coadministration of monoamine oxidase inhibitors, but serotonin syndromes have been described from coadministration of tricyclic antidepressants and SSRIs (177). SSRIs have been prescribed and have shown to be efÞcacious in persons with AIDS (179), but awareness of side effects and drug-drug interactions suggests cautious use and assessment on a case by case basis.

Drug-Illness Interactions with Depression

The tricyclic antidepressants include the oldest ones, amitriptyline, imipramine, doxepin, and newer agents, nortriptyline and desipramine. All tricyclic antidepressants have anticholinergic side effects and can cause urinary retention, constipation, paralytic ileus, dry mouth, and confusion from central anticholinergic delirium. Side effects of tachycardia and orthostatic hypotension make patients vulnerable to falls. Amitriptyline and imipramine should be avoided if possible because they have the most potent side effects and potential for cardiac arrhythmogenicity and falls. All tricyclic antidepressants should be used with caution and in low doses. All are efÞcacious for depression and have been used for HIV neuropathy as well. Further discussion of antidepressants for neuropathy will be presented in the section on pain. A summary of our recommendations for use of psychotropic medication for depression is presented in Table 19.19.

TABLE 19.18. *Clinical charactersitics of the serotonin syndrome*[a]

Psychiatric	Neurologic	Autonomic
Confusion	Myoclonus	Diaphoresis
Mania	Hyper exia	Shivering
Agitation	Tremor	Fever
	Ataxia	Nausea
	Siezures	Vomiting
	Coma	Diarrhea
		Tachycardia

[a] Serotonin syndrome can be caused by high-dose SSRIs or by combining SSRIs with the following agents: monoamine oxidase inhibitors, tricyclic antidepressents, other SSRIs, dextromethorplan, and L-tryptophan.

In addition to depression associated with AIDS, persons with AIDS may also be vulnerable to depression associated with their concomitant illnesses such as end-stage renal disease and end-stage liver disease. These illnesses considerably complicate treatment of depression. Their treatments themselves can also induce depression such as interferon-induced depression. It is important to monitor individuals with complicated courses of illness with both AIDS and hepatitis C-associated cirrhosis who may require interferon-ribavarin treatment (182,183). Symptoms such as pruritus associated with severe liver or kidney disease can also cause distress as well as depression that can respond extremely well to the tricyclic, doxepin, in low doses of 25 mg to 75 mg at bedtime.

Suffering at the end of life may be related to the expected bereavement, a natural response to the intense awareness of anticipatory loss of life and separation from loved ones (184). Almost all persons who are terminally ill experience these feelings, but some develop major depressive disorder (185,186). Psychostimulants can be helpful to some AIDS patients who develop end-of-life depression and have only weeks to live. Psychostimulants include dextroamphetamine, methylphenidate, and pemoline. They are especially helpful in treating depression close to death because they do not take two to four weeks to develop therapeutic levels. In severe illness they can reduce distress in patients and consequently in their families (184,187Ð189). Severely cachectic and weak individuals may experience improvement in mood and energy in only 24 hours after the Þrst dose. They have been described and used in persons with AIDS (190,191) as well as cancer. Because pemoline can cause hepatocellular damage and extrapyramidal side effects and all psychostimulants can cause confusion, we would recommend the use of low dose methylphenidate only. Methylphenidate can be started at a dose of 2.5 mg and given in the morning to prevent insomnia. It can be titrated slowly up to 5 to 10 mg in divided doses to be given in the morning and at noon. Side effects include restlessness, dizziness, palpitations, insomnia, arrhythmia, tremor, and rarely, psychosis. It is generally well tolerated in low doses.

TABLE 19.19. *Pharmacologic treatment of mood disorder with depressive features and major depressive disorder in persons with AIDS*

Psychotropic medication Category	Name	Dose range	Primary indication: Depression and secondary indications
Antidepressants			
Selective serotonin reuptake inhibitors	Citalopram (Celexa)	10–40 mg	post-traumatic stress disorder borderline personality disorder
	Sertraline (Zoloft)	50–150 mg	post-traumatic stress disorder social phobia
Tricyclics	Nortriptyline (Pamelor)	25–125 mg	neuropathy cocaine withdrawal insomnia
	Desipramine (Norpramin)	25–150 mg	neuropathy cocaine withdrawal insomnia
	Doxepin (Sinequan)	25–100 mg	pruritus insomnia
Mood stabilizers	Gabapentin (Neurontin)	100–2,700 mg	mood stabilization neuropathy drug cravings
Antipsychotics	Olanzapine (Zyprexa)	2.5–20 mg	psychotic features

Adjustment Disorder with Depressed Mood

Adjustment disorder with depressed mood is deÞned in DSM-IV as a psychological response to an identiÞable stressor that results in the development of clinically signiÞcant symptoms of depressed mood, tearfulness, or feelings of hopelessness that develop within three months after the onset of the stressor. The response is either characterized by distress that is in excess of what would be expected or by signiÞcant impairment in social or occupational functions. Although, by deÞnition, adjustment disorders must resolve within six months of the termination of the stressor or its consequences, they may persist longer if they occur in response to a chronic stressor such as a chronic illness. It is of some note that the majority of persons with AIDS do not meet criteria for adjustment disorder.

Psychosis

Psychotic symptoms such as delusions or hallucinations can occur in persons with AIDS for many reasons. They can occur because of the concomitant psychiatric disorders such as substance dependence, dementia, schizophrenia, or bipolar disorder with mania and psychotic features. They can also occur with major depressive disorder with psychotic features. Psychotic symptoms such as delusions and hallucinations are also associated with some of the prescribed medications as well as drugs of abuse and dependence in persons with AIDS. Hoffman and Cohen (personal communication) have observed new-onset of treatment-emergent psychosis in four individuals with comorbid HIV and hepatitus C virus infection when they were treated with a combination of interferon-alfa and ribavirin for hepatitis C. Psychotic symptoms are frightening to patients, their families, and caregivers. Psychotic symptoms can also be concomitants of delirium or dementia. In persons with AIDS, psychotic symptoms of new onset can be manifestations of central nervous system opportunistic infections (such as toxoplasmosis) or cancers (such as CNS lymphoma) or a manifestation of new onset cytomegalovirus retinitis with visual impairment and visual hallucinations. Whatever the etiology, new onset psychotic symptoms should be evaluated from both a medical and psychiatric standpoint. Psychotic symptoms associated with longstanding psychiatric disorders such as paranoid schizophrenia should be treated with typical or atypical antipsychotic medications and ongoing psychotherapy.

Psychopharmacologic Treatment of Psychosis

The treatment of psychotic symptoms needs to be tailored to the underlying cause. Psychotic symptoms related to cognitive impairment respond well to low dose antipsychotic medications. We have found three medications particularly useful for persons with psychosis: olanzapine, haloperidol, and perphenazine in low doses. The treatment of psychosis can alleviate frightening symptoms and improve quality of life at any stage of AIDS illness.

Drug-Illness Interactions with Psychosis

Because of the vulnerability to extrapyramidal side effects as well as hepatotoxicity, we do not recommend the use of high-dose, low-potency phenothiazine or typical antipsychotics such as chlorpromazine or thioridazine. Haloperidol, a butyrophenone, can be useful in low doses but may cause severe extrapyramidal side effects. We

sometimes recommend haloperidol in doses of 0.5 mg to 5 mg for treatment of psychosis. We prefer the atypical antipsychotic, olanzapine, over risperidone because risperidone may cause extrapyramidal reactions in persons with AIDS even in low doses. Olanzapine, one of the newest atypical antipsychotics, is the least likely to cause extrapyramidal side effects but can cause treatment-emergent diabetes mellitus (192). In persons with diabetes mellitus or a strong family history of diabetes, it may be preferable to use trißuoperazine in doses from 2 mg to 10 mg Perphenazine is a low-dose, high potency phenothiazone that is well tolerated in geriatric populations, especially in low doses. Olanzapine is highly efÞcacious in psychosis in doses from 2.5 mg to a maximum of 20 mg. Although haloperidol has been most effective in delirium-induced psychosis, olanzapine may be preferable because of its side effect proÞle. Some of the side effects of olanzapine may be desirable in persons with AIDS. These include increase in appetite, weight gain, and sedation. The possibility of treatment-emergent diabetes mellitus is of concern when olanzapine is used in combination with selective serotonin reuptake inhibitors. All selective serotonin reuptake inhibitors can induce hyperglycemia or hypoglycemia and should be used with caution in the AIDS population and with frequent monitoring of blood glucose levels.

Persons with AIDS and especially persons with HIV dementia are particularly vulnerable to the extrapyramidal side effects of psychotropic medications. These include rigidity, Parkinson-like symptoms, and tardive dyskinesia. Rigidity is dangerous because it can lead to falls. Tardive dyskinesia is dangerous because it can be irreversible and can lead to potentially serious and even lethal complications. It is an abnormal involuntary mouth and body movement disorder. Complications can develop from tardive dyskinesia because of problems in swallowing and aspiration pneumonia in severe instances. All antipsychotics and antidepressants, including selective serotonin reuptake inhibitors (193) can have extrapyramidal side effects, including tardive dyskinesia, although these are relatively rare. They are more frequently observed when antipsychotic medications are prescribed. Some persons with depression may have psychotic features requiring the use of both antidepressant and antipsychotic medication and further increasing vulnerability to extrapyramidal side effects.

Post-traumatic Stress Disorder

Post-traumatic stress disorder (PTSD) is deÞned in DSMIV as a disorder resulting from the exposure to threats of death or serious injury with a response of fear, helplessness, or horror. Although not everyone exposed to trauma develops PTSD, 14% of the United States population develops PTSD at some point during their lives. Hutton and colleagues (194) described a 33% lifetime prevalence of PTSD in 59 of 177 women prisoners with HIV risk behaviors. They found that exposure to trauma alone was not found to be associated with HIV risk behavior although other studies have linked trauma and HIV risk behavior (195Ð198). In persons referred for psychiatric consultations at the Mount Sinai AIDS Center in New York City, the prevalence of PTSD was found to be high in our HIV-infected population of both men and women. Thirty-eight percent of the 558 persons referred had histories of early childhood trauma and 25% had evidence of PTSD. One patient of all those referred had combat-related PTSD but had had early childhood trauma as well. The prevalence of PTSD in our population was high in both men and women, all of whom had early childhood physical and sexual abuse and some also had adulthood trauma such as rape, gang rape, or domestic violence. The following case will serve to illustrate:

> Case 3: The patient was a 26-year-old woman who had worked as a commercial sex worker and had a history of witnessing the murder of her sister and mother when she was four years old. Her father set both his wife and two children on Þre before he self-immolated. Only the patient survived the Þres. She survived with physical and psychological scars. She was also raped by an uncle who brutally and repeatedly assaulted her from the age of seven to thirteen years. As an adult she had a series of abusive relationships. She had symptoms of easy startle, hypervigilance, dissociation, ßashbacks, nightmares, insomnia, psychic numbing, and a sense of a foreshortened future. She was initially nonadherent with both medical and psychiatric care. She gradually became more adherent with medical care after beginning individual and group psychotherapy.

The implications and meanings of PTSD for HIV are complex. If a child is traumatized severely and chronically, the child may perceive that he or she is not valued adequately and may be unable to learn to avoid harmful situations or protect himself or herself from risky ones. Victims of severe trauma may resort to use of alcohol or drugs to escape from painful situations or memories, and the use of substances may lead to more risks because of intoxication, need to obtain substances (such as exchange of sex for drugs), and disinhibition. Commercial sex work has been shown to be associated with a high prevalence of early childhood trauma.

Since persons with PTSD have a sense of foreshortened future, a tendency to take risks, and to use drugs or alcohol, they are also likely to have problems adhering to risk reduction and to medical care. The associations among childhood trauma, PTSD, HIV risk behaviors and HIV and AIDS have implications for public health that warrant further study. There is a tremendous need for more data on the prevalence of early childhood trauma and PTSD in general AIDS populations and the feasibility of prevention of childhood trauma as a cofactor in AIDS.

TABLE 19.20. *Differentiation of major depression and bereavement*

	Uncomplicated bereavement	Major depression
General	Exhaustion, lack of strength, restlessness, inability to sit still, aimless moving, decreased capacity for organized living, "going through the motions," insomnia	Insomnia or hypersomnia, psychomotor retardation or agitation, diminished ability to function, decreased libido, headache, backache
Gastrointestinal	Empty feelings in abdomen, anorexia, tightness in throat, dysphagia, constipation	Somatic delusions ("my insides are rotting away"), anorexia, weight loss, constipation
Respiratory	Sighing respirations, dyspnea	
Emotional	Sorrow, sadness, guilt over survival, loss of warmth in other relations, hostility, preoccupation with image of deceased	Sadness, depressed mood, worthlessness, hopelessness, helplessness, decreased self-esteem, suicidal thoughts or acts
Course/Treatment	Self-limiting Working through of ambivalent feelings to achieve freedom from bondage to the deceased, readjustment to environment without the deceased, formation of new relationships, no medication	Requires intervention: Therapy, antidepressants

Uncomplicated Bereavement

Although uncomplicated bereavement is deÞned in DSM-IV in relationship to the loss of a loved one, in AIDS, as in other severe illnesses, the losses of health, functioning, body integrity, and anticipatory loss of life, may have similar consequences. Additionally, many persons with AIDS have also suffered the losses of their loved ones or of friends who have died of AIDS. A full depressive syndrome can be an expected reaction to such a loss, with feelings of depression and associated symptoms such as poor appetite, weight loss, and insomnia. However, morbid preoccupation with worthlessness, prolonged and marked functional impairment, and psychomotor retardation are uncommon and their occurrence suggests that the bereavement is complicated by the development of a major depressive disorder (Table 19.20). In uncomplicated bereavement, guilt, if present, is chießy about things done or not done at the time of the death by the survivor. Thoughts of death are usually limited to the individualÕs thinking that he or she would be better off dead or that he or she should have died with the person who died. The individual with uncomplicated bereavement generally regards the feeling or depressed mood as ÒnormalÓ although he or she may seek professional help for relief of such associated symptoms as insomnia and anorexia. The duration of ÒnormalÓ bereavement varies considerably among different individuals and cultures.

Psychodynamic and Psychotherapeutic Aspects of Care

Psychiatric care should be incorporated into HIV care in every setting and at every stage of illness. Psychiatric care has been shown to be effective in a prospective study of psychiatric treatment for persons with HIV and depression (199). Psychotherapy can provide a supportive and nurturing approach to individuals with HIV and AIDS. This can augment the support provided by friends and family or can be a welcome antidote to the poison of AIDSism, discrimination, and rejection experienced by some individuals. Psychotherapy can smooth the transitions experienced by all persons with severe illness. Examples include the transition from HIV negative to positive, from healthy seropositive to symptomatic, from symptoms to diagnosis of Þrst HIV-related illness, and from late-stage illness to death.

Psychotherapeutic interventions can also enhance HIV-related communications. Persons with AIDS or HIV infection may have difÞculty communicating about their illness to partners, spouses, children, parents, or siblings. A sensitive AIDS psychiatrist can not only smooth transitions but help with communication of information. Psychotherapy can also enable persons with HIV to adapt to their illness, work through loss of health, and cope with conßicts related or unrelated to the illness. Additionally, psychotherapy is valuable as part of the comprehensive treatment of psychiatric disorders associated with AIDS such as substance use disorders, cognitive disorders, mood disorders, PTSD, and psychotic disorders.

Psychotherapeutic modalities include crisis intervention, individual psychodynamic and psychoanalytic psychotherapy, couple therapy, family therapy, and group therapy. In addition, psychiatric care should be integrated into the comprehensive treatment of every patient through collaborative work with primary physicians, infectious disease specialists, nurses, social workers, and pastoral caregivers. An integrated multidisciplinary biopsychosocial approach includes AIDS psychiatry as part of the AIDS team. Psychiatric intervention can be of help not only to patients and families, but also to caregivers. Psychiatrists can provide bereavement therapy to families left behind by AIDS and can provide support to caregivers mourning the loss of patients. Ruiz (200) has described his work with a patient who was diagnosed with HIV during

the course of his psychotherapy whom he cared for throughout the illness, from diagnosis to death. He demonstrated the value of psychotherapy from before diagnosis to bereavement therapy for the family after the patientÕs death. Psychiatric care can alleviate suffering, improve adherence, maximize life potentials, and decrease morbidity and mortality for persons with HIV and AIDS.

DISTRESS

Persons with HIV infection and AIDS have high levels of distress from multiple sources including symptoms, medical and psychiatric illness, discrimination and stigma, as well as social, occupational, and Þnancial stresses. Persons with AIDS are also subject to the same losses, stresses, and life changes as the rest of the population and because they are living longer, to middle and old age, are also subject to other non-HIV related illnesses such as heart disease, hypertension, diabetes mellitus, osteoarthritis, cancer, and chronic obstructive pulmonary disease. The symptoms of fatigue, insomnia, pruritus may occur even in the absence of speciÞc medical or psychiatric pathology. Persons with AIDS may also have symptoms related to their treatments with HAART or with interferon alfa treatment for concomitant hepatitis C. Distress, depression, and anxiety can be measured rapidly and easily by means of the Distress Thermometer (DT) and the Hospital Anxiety and Depression Scale (HADS). Roth and colleagues (201) and Cohen and colleagues (202) have demonstrated the feasibility of using these scales in waiting room convenience samples of persons with cancer and AIDS respectively. Cohen et al found a 72% prevalence of distress, 70% prevalence of anxiety, and a 55% prevalence of depression in a waiting room sample of persons registered at an HIV clinic. We have also found the DT and HADS valuable for screening persons with HIV and HCV for interferon-ribavirin treatment and for following patients during the course of the treatment to determine the need for antidepressant or antipsychotic medications. The rapidity (Þve minutes in total for both screening evaluations) and feasibility of the DT and HADS make the screening for distress a very efÞcient way to determine appropriate interventions.

RISK BEHAVIORS

Two behaviors involved with HIV transmission, unprotected sexual intercourse and sharing of needles by injecting drug users, can be changed. Public health educational efforts, outreach programs, and education at all levels, beginning in elementary school, can help prevent HIV transmission (1). Heightening awareness about HIV transmission in medical school can help create generations of physicians who are AIDS educators (203Ð211). It is known that although up to 50% of patients are hospitalized in general care as a result of substance-related disorders (212), these are not routinely recognized and, in fact, are often left out of discharge attestations, resulting in lower reimbursement rates (213). Just asking about sexual behavior and substance use in a supportive, nonjudgmental way can help an individual become aware that he or she is involved in risky behavior, and this can lead to change. The stages of change are gradual and are described by Prochaska (214) particularly in reference to substance-related disorders.

Although needle exchange programs have been shown to decrease the rate of HIV infection in injecting drug users (215Ð226), controversies have hindered widespread access to sterile needles and syringes. Psychiatric intervention can help to diminish denial and increase referrals to drug treatment programs. Intervention in general care inpatient or ambulatory settings can be most productive, because the patient may be in a crisis and at a point where he or she is ready to make a decision to get into treatment. Similarly, ofÞces and clinics for sexually transmitted diseases, infectious disease clinics, medical clinics, gynecology clinics, urology clinics, and pediatric and adolescent clinics are ideal settings to help decrease denial and heighten awareness about avoiding HIV transmission by consistent and correct condom use (20).

> Case 4: A 17-year-old high school student who was HIV seronegative admitted to having had more than 50 unprotected sexual encounters and was currently sexually active with a 14-year-old girl at the time of referral. Although he reluctantly admitted that it might be safer to use a condom, his girlfriend refused, because they were both HIV seronegative and she had had unprotected sexual encounters with only one other person. Meeting with the teenagers, individually and as a couple, and ultimately with them and their parents, led to a visit to Planned Parenthood and to consideration of both abstinence and condom use.

> Case 5: A 43-year-old physician who was HIV seronegative refused to use condoms in a relationship with a widow who was also HIV seronegative, but whose husband of 12 years died of AIDS one year before they met. He could not be convinced to consider condom use.

Age, intelligence and even educational level (227Ð230) do not necessarily correlate with safe sexual behavior. This was documented in the study (227) of Brown University women who used birth control pills as contraceptives and averaged the same numbers of sexual partners during the AIDS epidemic as they had in the 1970s. In our own case vignettes and clinical observations, we saw that some teenagers and some well-educated professionals continued to have unprotected sexual encounters, despite their intellectual awareness of how AIDS is transmitted and despite their knowledge that an HIV seronegative antibody test does not necessarily indicate absence of the virus.

Obstacles to the education needed to create an environment conducive to changing behavior (1) include epidemics of denial, ignorance, and therapeutic nihilism in addition to AIDSism (1,6,231–233). AIDSism is a new form of discrimination, built on a foundation of homophobia, addictophobia, misogyny, and fear of contagion and death. A supportive, multidisciplinary approach can help combat the epidemics of fear and discrimination that perpetuate the AIDS epidemic and prevent educational efforts from being fully effective. This approach is also helpful in suicide prevention.

SUICIDE

In individuals with HIV infection, suicidal ideation can occur at any time, from realization of being at risk to end-stage illness (23,27,234–243). From licensing of home HIV testing kits to end-stage AIDS, issues of suicide prevention are of major concern. Because it has been shown that persons become suicidal before, during, and after HIV testing (23–26,239,240), home HIV testing kits put individuals at unnecessary risk for suicide. In an AIDS orientation course given by one of the authors (MAAC) to third-year medical students from 1985 to 1995, one or two medical students each year stated that if they tested positive, they would commit suicide. The statements were entirely spontaneous and unsolicited. They were made during discussions of strong feelings aroused while caring for patients with AIDS. In a survey of 344 university students in Kenya, most students stated that they would commit suicide if they tested HIV seropositive (240).

Some persons with AIDS have risk behaviors such as drug use that have led to alienation from families or communities. They felt isolated, lonely, alienated, and expendable, even before the diagnosis of AIDS. Suicide risk has been found to be higher in persons with chronic medical illness than in the general population (241–247). Most (23–28,237–243,248–266), but not all, studies (236,267) indicate that persons with AIDS or HIV infection are also at an increased risk for suicide. Marzuk et al. (260) studied the rate of suicide in New York City during 1985. He found that the suicide rate for men with AIDS from 20 to 59 years old was 36 times that of men from 20 to 59 without a diagnosis of AIDS. CotŽ et al. (263) studied all death certiÞcates indicating both AIDS and suicide in the United States from 1987 through 1989. He found a 7.4-fold higher rate of suicide in persons with AIDS. Drug overdose accounted for 39% of suicides, followed by Þrearms (25%) and suffocation (13%). Rajs et al. (264) reviewed 21 completed suicides in Stockholm over a period of Þve years. Medicinal drug overdose was also found to be the most prevalent suicide method. Chandra et al. (238) found in a cohort in India that 14% of patients showed serious suicidal intent six weeks after learning of their HIV-seropositive status. Older individuals (237,243) and women (242) are particularly at a higher risk for suicide. In a sample of HIV-infected persons from Milwaukee, Wisconsin and New York City, Kalichman et al. (237) found that 27% of respondents reported suicidal ideation within one week prior to the survey. In a more recent New York City autopsy study, Marzuk et al. (268) found HIV positive men of African-American and Latino-American ethnicity, aged 35 to 54, to be at the highest risk for suicide.

Erfurth et al. (28) in Munich documented that the two most common reasons for psychiatric consultation in patients with AIDS were for evaluation of suicidal behavior and for treatment of depression. Suicidal behavior was present in one out of every Þve persons with HIV seropositivity or AIDS in a general hospital population (23). Woller et al. (29) studied a cohort of HIV-infected gay men and found that suicidal behavior is related more to rejection by key persons or signiÞcant others than to disease stage or immune function.

The suicidal person with AIDS is in the midst of a crisis of expendability. The concept of expendability (269,270) is conveyed to the suicidal individual in both verbal and nonverbal ways, and hopelessness develops. Once the diagnosis of AIDS is conÞrmed, alienation and expendability compound the sense of hopelessness. Risk factors for suicide in the general population include the following (271–277): hopelessness, impulsivity, substance abuse disorder, recent illness, recent hospitalization, depression, living alone, and inexpressible grief. Persons with AIDS who are nonadherent to medical care are frequently ill and hospitalized. They feel alienated and isolated because of the discrimination against them. Hopelessness is heightened by the high mortality rate associated with AIDS and its devastating downhill course. Further complicating the picture are the issues of pain, disÞgurement, blindness, weakness, and depression associated with some of the infections and cancers comprising AIDS. Suicidal behavior can be seen in end-stage AIDS:

> Case 6: A 28-year-old aspiring artist was transferred to an AIDS nursing home with progressive multifocal leukoencephalopathy, right hemiplegia, and major depression. She stated ÒI feel that I have lost all my dreams and this is my last stop. I want to die.ÓShe made an attempt at suicide, and although medically she recovered fully, she gradually deteriorated psychologically and died despite psychotherapy and antidepressants.
>
> The multiple losses of health, Þtness, vision, mobility, hope, dreams, home, job, career, friends, and loved ones can lead to depression and suicidal behavior. Some individuals can cope better than others. The patient who made her statement about her lost dreams in a support group elicited a very sensitive response from another group member, who stated, ÒYou havenÕt lost your dreams; you can convert them to small hopes.Ó

Converting lost dreams to small hopes became a major theme of the support group and a focus of dynamic

psychotherapy. With support, networking, and family and individual psychotherapy, most individuals realize that suicide is not their only option. Some persons with AIDS have lost connections to family and beneÞt from conßict resolution and reunions following long separations resulting from distance, alienation, or behavioral complication of substance-related disorders. Psychiatric diagnoses associated with increased suicide risk include mood disorders (275), alcohol and drug dependence (273,276), schizophrenia (277), and antisocial and borderline personality disorders (241,278). Posttraumatic stress disorder frequently is misdiagnosed as borderline personality disorder. Individuals with posttraumatic stress disorder, with a history of severe childhood physical and sexual abuse and with co-morbid depression, are at a high risk for suicide. In addition to these psychiatric disorders, dementia in persons with AIDS is associated with a higher suicide risk (161). HIV dementia is associated with impulsivity, impaired judgment, affective lability, and behavioral disinhibition. Other neurocognitive illnesses, such as HuntingtonÕs disease, have an increased rate of suicide (247,279). Subcortical dementia is a corollary of both HuntingtonÕs and AIDS and may make individuals more vulnerable to suicide (161). The association between delirium and suicide has not been studied in persons with AIDS. However, patients in delirium tremens who are not adequately sedated are at a high risk for suicide (280).

Management of the suicidal person with HIV infection is a sensitive and complex issue. It is crucial to remember that all suicidal individuals have mixed feelings about suicide and can vacillate from being preoccupied with hopelessness and suicide to thoughts of and plans for the future. No one is suicidal all the time. Suicide may be an effort to gain control or to alleviate pain or alienation. Suicide is also a symptom of major depression and mood disorder, as well as a reaction to a growing realization of loss of health, strength, and cognitive capacities.

The caregiver needs to feel comfortable with taking a suicide history and to discussing suicide in depth with the person with HIV infection. The steps include the following: (a) establishment of a trusting relationship, (b) discussion of suicide and death in relation to AIDS and the patientÕs philosophies and religious beliefs, and (c) realization of the value of continuity of care and reassurance that the person with HIV infection will not be abandoned.

Suicide history-taking includes the following questions:

1. Have you ever thought about killing yourself?
2. What is it speciÞcally that made you think of suicide?
3. Have you made any plans?
4. What are they?
5. Have you ever tried to kill yourself?
6. Do you feel like killing yourself now?
7. What would you accomplish?
8. Do you plan to rejoin someone who has died?
9. Do you know anyone who committed suicide?

Far from harming the patient, being able to speak about suicidal thoughts and feelings is highly relieving. Persons with HIV infection may feel isolated and alienated. Thoughts of suicide, while on the one hand providing some measure of consolation and control, may be frightening and painful on the other. Sharing suicidal feelings with an empathic listener not only is relieving but may help the person achieve a different perspective.

In order to prevent suicide in persons with AIDS, it is important to recognize dementia, delirium, depression, and posttraumatic stress disorder, as well as the vulnerability of persons with AIDS to losses and alienation. Persons with AIDS are especially vulnerable to pain, depression, and pruritus, all of which increase suicide risk. When these symptoms can be alleviated, suicidal ideation diminishes. Persons with AIDS respond well to therapeutic modalities aimed at providing support and bolstering defenses and coping strategies. These include individual and group therapy, crisis intervention, treatment of depression, and use of relaxation techniques. Psychosocial factors are relevant to both suicide prevention and immune system function.

PSYCHOSOCIAL VARIABLES AND IMMUNE FUNCTION

Separation, loss, stress, and depression have an impact on onset of illness, progression of illness, deterioration, and mortality. The effects of separation, loss, depression, and stress on the immune system have been explored by several groups (281Ð301). In the setting of HIV infection, Silberstein (294) suggested that the association of stress and depression with alterations of cell-mediated immunity might be a cofactor in AIDS. BlumenÞeld (295) proposed that psychosocial factors play a role in the onset of opportunistic infections in persons who are HIV-seropositive. Conversely, Fawzy and colleagues demonstrated less psychological distress (296) and improved immune system function (297) when individuals with recently diagnosed malignant melanoma had group therapy for six weeks. Spiegel and coworkers have shown (299Ð301) that group therapy doubled survival time in a prospective study of women with metastatic breast cancer. Group psychotherapy for persons with HIV and AIDS has been described by Alfonso and Cohen (302) as an effective means to provide support, an outlet for feelings, a common bond, and a relief from societal stigma. The groups have been gratifying for patients and caregivers alike. Group psychotherapy for persons with AIDS has also been shown to nearly double survival time (303). Additional data on the negative impact of alcohol and drugs on the immune system (304Ð321) indicate that psychiatric intervention should be beneÞcial in HIV-related illness. Psychiatric interventions should be incorporated early (2,10,199,200,322,323) into the care of persons with HIV infection, to improve the patientÕs ability to cope and

TABLE 19.21. *AIDS palliative care: a biopsychosocial approach*

Bio	Psycho	Social
Pain	Depression	Alienation
Dyspnea	Anxiety	Social isolation
Insomnia	Confusion	Stigma
Fatigue	Psychosis	Spirituality

enable the clinician to recognize and treat psychiatric disorders such as depression and substance dependence.

AIDS PALLIATIVE CARE

AIDS palliative care can be deÞned as comprehensive multidisciplinary care that focuses on alleviating suffering and maximizing life potentials independent of severity, stage, or prognosis (personal communication, Daniel Fischberg). Although most clinicians emphasize the need for palliation during the terminal stage of illness, palliative care can be more than end-of-life comfort care. SpeciÞcally, palliative care relates to providing comfort at every point from initial diagnosis to end-of-life. Comfort takes on a greater role as curative care becomes less feasible and cure, care, and palliation become a smooth continuum. This approach eliminates the ÒtransitionitisÓ that may result from an abrupt change from curative to palliative at the very end of life. A biopsychosocial approach can help to delineate the complex issues in AIDS palliative care. A brief summary of the most problematic issues is presented in Table 19.21. The use of pastoral care, hypnosis, music, relaxation response, meditation, writing, and art cannot be overemphasized. The importance of networking and providing a system of support for persons with HIV from diagnosis to end of life is signiÞcant in the comprehensive care of each individual.

AIDS psychiatric care and AIDS palliative care need to be integrated and offered to persons throughout the course of illness. There is no reason for persons with a severe illness such as AIDS to have to wait until the end of their lives to obtain relief from suffering and distress. We believe that persons with severe illness need a biopsychosocial approach to care. This approach includes alleviating distress and providing a nurturing care environment. We need to address depression, anxiety, mania, confusion, psychosis, and posttraumatic stress disorder with both psychotherapy and psychopharmacotherapy. Treatment may include crisis intervention, individual, couple, family, and group psychotherapy and the seamless integration of psychiatry into primary AIDS care. Throughout the course of illness, pain and suffering need to be alleviated. Persons with AIDS may experience pain throughout the course of the illness. Pain needs to be treated as adequately during acute illness such as esophageal candidiasis or herpes zoster as it is at the end of life.

No comprehensive approach to AIDS palliative care would be complete without addressing the spiritual aspects of care throughout the course of illness and at the end of life. Spiritual care has been shown to provide comfort and solace and to alleviate suffering in persons with cancer (325Ð336) and needs to be integrated into the care of persons with AIDS.

It is important to be aware that some of the most difÞcult and agonizing symptoms can be addressed or assuaged at any stage of illness. These include not only pain, but also dyspnea, pruritus, fatigue, hiccups, and nausea and vomiting.

Symptom management strategies need to be comprehensive and integrate adequate relief of concomitant anxiety and depression. Undertreated pain and pruritus are associated with catastrophic psychological symptoms such as depression, hopelessness, and suicidal behavior. Patients with dyspnea describe feelings of intense anxiety, panic, and fear of death by asphyxiation. Intractable hiccups can lead to overwhelming exhaustion and feelings of helplessness. Anxiety, depression, panic, fear of death, and helplessness, in turn, can exacerbate the subjective distress caused by undertreated pain, dyspnea, pruritus, nausea, vomiting, and intractable hiccups. Psychiatric interventions aimed at reducing these negative emotional states can complement palliative symptom management strategies (see Table 19.22). At the end of life, one of the most important interventions is spending time with the patient, talking if possible, holding hands, and surrounding the patient with loved ones if they are available. Being with a dying patient can alleviate the terror of abandonment and the fear of dying alone. For the clinician who can

TABLE 19.22. *Palliative careÑ symptom management*

Symptom	Treatment
Intractable hiccups	Chlopromazine, olanzapine
Dyspnea	Oxygen, morphine, fan, relaxation
Nausea	Ondansetron, olanzapine
Pruritus	Doxepin
Pain (nociceptive)	Strong opioid analgesics (e.g. fentanyl, morphine sulfate)
(neuropathic)	Adjuvant analgesics (e.g. antidepressants, anticonvulsants, stimulants, antihistamines)

cope with the poignancy, intimacy, and strong feelings evoked, the experience can be rewarding.

PAIN MANAGEMENT IN PERSONS WITH AIDS

Pain is an incapacitating symptom in persons with AIDS. Undertreated pain results in an increase in psychological distress and a reduction of the quality of life. There is evidence that even in persons with metastatic cancer and multiple complications, pain can be adequately alleviated 90% of the time (331). Acute and chronic pain syndromes are associated with increased risk of suicide in persons with HIV-seropositivity (23,332,333). Pain that is undertreated leads patients to request physician-assisted suicide (334). Pain is frequently undertreated in persons with AIDS (335), causing needless suffering and leading to the dangerous concomitant of suicide. Undertreatment of pain can be a result of inadequate assessment, unfamiliarity with management strategies, unconscious resistance and fears, discrimination and stigma, and myths about analgesic use.

Prevalence Studies

The prevalence of pain in persons with AIDS ranges from 28% to 97% in various studies (Table 19.23) (336Ð343). Newshan and Winapel (344) studied a cohort of 100 hospitalized persons with AIDS who were referred to a pain consultation service. Abdominal pain and neuropathic pain were the most common complaints, accounting for 26% and 24% of patients respectively. Odynophagia, dysphagia, headache, cutaneous Kaposiõ sarcoma pain, musculoskeletal pain, and postherpetic pain were also frequently reported in this study.

Etiology of Pain in AIDS

Pain can be mediated by nociceptive, neuropathic, or idiopathic mechanisms (345). Nociceptive pain is the physiological reaction triggered by chemical, thermal, or mechanical stimuli. Injured tissue and pain receptors release substances that modulate an inßammatory response and initiate neuronal activity leading to the perception of pain (346). Nociceptive pain modulators include: bradykinin, serotonin, histamine, potassium ions, acetylcholine, adenosine triphosphate (ATP), substance P, and prostaglandins (347). Nociceptive causes of pain in persons with AIDS are summarized in Table 19.24.

Neuropathic pain results from insult to the peripheral or central nervous system (345) and 30% to 40% of persons with AIDS have peripheral neuropathy (342). Sensory neuropathy is the most common neuropathy in persons with AIDS (348Ð351). The multicenter AIDS Cohort study (352) showed that between 1985 and 1992 the annual rate of reported cases of sensory neuropathy increased by 50%. Explanations for this upward trend include longer survival with severe immunosuppression (352,353) and the increasing use of treatment regimes with antiretroviral agents (353) that produce dose-dependent neurotoxicity (354,357).

When the cause of pain is neither nociceptive nor neuropathic, it is described as idiopathic. Idiopathic pain is not to be confused with malingering or with psychogenic pain. Idiopathic pain refers to the perception of pain in the absence of identiÞable pathology. Examples of idiopathic

pain include polyarthralgias, polymyositis, and non-inßammatory myopathy.

Pain Assessment

Inadequate pain assessment is a major factor in the undermedication of pain. In a study of cancer pain management strategies (358), 76% of physicians reported having problems with pain assessment. The use of standardized pain assessment measures and sensitive, systematic clinical interviews, lead to improvement in both pain assessment and treatment. Awareness of the myths about pain and analgesia can be helpful in overcoming barriers that hinder the assessment process. Common myths that interfere with pain assessment include:

1. Patients often exaggerate their complaints of pain.
2. Latino-Americans and African-Americans exaggerate their complaints of pain and therefore need less analgesia.
3. Patients with present or past history of addiction lie about pain as part of their drug-seeking behavior.
4. The etiology of pain is often psychogenic.
5. The etiology of pain most often remains obscure.

One common misconception is that patients tend to exaggerate their complaints of pain. Research studies of patient-controlled analgesia (PCA) (359,360) show that patients tend to avoid the prospect of the complete disappearance of pain. PatientsÕ need to Òpreserve a modicum of painÓ(361) can be understood psychodynamically as a way to maintain a sense of the self that is separate from the environment and to protect the self against the prospects of existential disintegration. Patient stoicism or need to maintain the same level of pain, at a more conscious level, could be a way to avoid excessive sedation or the other side effects of analgesia or the fear of becoming addicted to narcotics. Since patients are generally reluctant to volunteer their complaints of pain (358), physicians need to assess for pain on a routine basis. A clinical interview can be helpful in determining the cause of pain. Patients with intact cognitive function can translate pain perceptions into verbal communication. The vocabulary used to describe nociceptive pain differs from that for neuropathic pain. Table 19.25 highlights this distinction.

Just as the quality of pain is helpful in determining its etiology, so is the location of the pain. Pain can be focal or referred. Referred pain can follow a dermatomal distribution, as does postherpetic pain. Many physicians rely on non-verbal expressions of pain more than what the patient communicates verbally. Non-verbal cues include crying, moaning, yelling, grimacing, splinting, rubbing, insomnia, anergia, anorexia, apathy, anxious mood, dysphoric mood, hypertension, tachycardia, and diaphoresis. While non-verbal signs may be useful in persons with dementia, delirium, depression, or aphasia, they should not be

TABLE 19.25. *Description of pain and etiology*

Throbbing	Extreme burning pain on light touch (allodynia)
Crushing	Burning
Pressure-like	Itching
Crampy	

necessary to validate or supersede verbal complaints of pain. Cancer pain research indicates (331,362) that nonverbal cues are no more accurate than and are no substitute for a patientÕs verbal report of pain.

Pain-assessment scales can be used both for research purposes and to enhance the clinical pain interview. They are particularly useful in persons with HIV dementia, who may have difÞculty describing the intensity, location, or chronology of acute or chronic pain (363). The Wisconsin Brief Pain Inventory (BPI) has been used in clinical research for persons with cancer and AIDS (340,364,365). It helps to determine localization and intensity of pain. It also measures adequacy of analgesia and the impact of pain on quality-of-life issues such as activity, mood, ambulation, work, relationship, sleep, and enjoyment.

Treatment Strategies

Practice Guidelines for Pharmacologic Treatment of Pain

Pain is dramatically undertreated in persons with HIV infection (333,334,366). Iatrogenic addiction to narcotics is rare (365,367). Nevertheless, the most common misconception that interferes with the use of adequate analgesia in persons with AIDS is the myth that persons with severe illness and acute or chronic pain syndromes will become addicted to narcotics. Pain treatment is complicated by myths and misconceptions:

1. Patients with pain will become addicted to narcotics.
2. Opioid analgesics at recommended doses frequently cause respiratory depression.
3. Neuropathic pain does not respond to treatment.
4. Opioids should be prescribed on an Òas neededÓ basis, rather than as standing orders.
5. Patients on methadone maintenance need lower doses of analgesics.
6. Methadone and meperidine are potent analgesics.
7. There is a ceiling dose for opioids.
8. Duration of analgesia is the same as the analgesicÕs half-life.

Acute and chronic pain is best treated on an Òaround-the-clockÓ (ATC) schedule, rather than on an Òas neededÓ or Òp.r.n.Ó basis (344,368), regardless of its etiology. ÒAs neededÓ orders for analgesia result in inadequate pain control when the length of time between doses is longer than the duration of the analgesic action of the medication ordered. The importance of routine around-the-clock orders for pain management in AIDS has been described (1). It is stressful and depressing to be in pain, but it is even more upsetting to be in pain and repeatedly be faced with the humiliation of having to ask or beg for pain medication (1). As-needed orders should be reserved for the treatment of breakthrough pain in individuals who are on an around-the-clock regimen of analgesia.

The World Health Organization (WHO) recommends a stepwise approach to analgesia for patients with cancer (369). The ÒWHO analgesic ladderÓ has been accepted by oncologists (331) and other clinicians caring for persons with AIDS (342,344). The WHO guidelines recommend a three-step process to achieve freedom from pain. Step 1 includes prescription of a nonopioid, with or without an adjuvant. If pain persists, Step 2 follows with the prescription of a weak opioid, with or without an adjuvant. If pain continues after this, then Step 3 suggests prescription of a strong opioid, with or without a non-opioid with or without an adjuvant (369). Table 19.26 summarizes the weak opioid analgesics, Table 19.27 summarizes the strong opioid analgesics, and Table 19.28 lists adjuvant agents.

Common mistakes that interfere with adequate analgesia include the clinicianÕs hesitancy to move up the analgesic ladder when the patientÕs complaints of pain persist. When moderate to severe pain is evident upon initial pain assessment, Step 1 of the analgesic ladder can be bypassed and the patient can be started on a weak or strong opioid. The WHO analgesic ladder is more effective

TABLE 19.26. *Weak opioid analgesics*

	Dose[a]	Frequency[b]	Route of administration
Codeine	30–90 mg	Q4–6 h	Oral
Oxycodone	10 mg	Q4 h	Oral
Hydrocodone	10 mg	Q4 h	Oral
Methadone	30 mg	Q4–6 h	Oral

[a] Recommended starting doses; doses in this table are equianalgesic and equivalent to 10 mg of morphine.
[b] Frequency of administration is determined based on duration of analgesia and not on half-life.

TABLE 19.27. *Strong opioid analgesics*

	Dose[a]	Frequency[b]	Route of administration
Fentanyl	100 mcg/h	Q48–72 h	Transdermal patch
Morphine sulfate	30–60 mg	Q12 h	PO, sustained release capsules
Morphine sulfate	30 mg	Q3–4 h	PO, elixir
Morphine sulfate	10 mg	Q4 h	IV
Hydromorphone	3 mg	Q3–4 h	PO

[a] Recommended starting doses; doses in this table are equianalgesic.
[b] Frequency of administration is determined based on duration of analgesia and not on half-life.
PO, orally; IV, intravenously.

Antidepressants	Steroids	Other
Amitriptyline	Dexamethasone	Colchicine
Nortriptyline	Prednisone	Levamisole
Imipramine		Thalidomide
Desipramine	*Antiarrhythmics*	Proglumide
Doxepin	Mexiletine	Clonidine
	Tocainide	Baclofen
Anticonvulsants		Methocarbamol
Clonazepam	*Topical Anesthetics*	
Gabapentin	EMLA cream	
Carbamazepine	Capsaicin cream	
Antihistamines	*Neuroleptics*	
Hydroxyzine	Phenothiazines	
	Butyrophenones	
Stimulants		
Methylphenidate	*Calcium blockers*	
Pemoline	Nifedipine	

[a] Adjuvant analgesics may be used as rst-line drugs for the treatment of peripheral neuropathy.

for treatment of nociceptive pain than for treatment of neuropathic pain. Neuropathic pain responds better to adjuvant or coanalgesic agents such as tricyclic antidepressants and anticonvulsants. These agents are appropriate as Þrst-line drugs for the treatment of HIV sensory neuropathy or postherpetic lancinating pain (342,344,351).

Special Vulnerabilities to Analgesics

Nonsteroidal anti-inßammatory agents are relatively contraindicated in persons with AIDS who have speciÞc complications. These include: thrombocytopenia, bleeding diatheses, renal insufÞciency, renal failure, hepatic failure, congestive heart failure, peripheral edema, ascites, and abdominal pain. Although acetaminophen is widely prescribed for pain in persons with AIDS, it is hepatotoxic in persons with wasting, hepatic insufÞciency, and those who are on multiple medications metabolized by cytochrome p450 (phase 1 reaction) and glucuronidation or sulfation (phase 2 reaction) (370).

When antidepressants are prescribed for pain in persons with AIDS, the higher doses needed for analgesia can result in anticholinergic toxicity. Although amitriptyline is often used for neuropathic pain, nortriptyline is just as effective, has fewer anticholinergic side effects, and can be tolerated in higher doses in persons with AIDS. We do not recommend routine use of amitriptyline for neuropathic pain and have found that any tricyclic antidepressant is as efÞcacious as amitriptyline and is associated with fewer side effects in comparable or higher dose ranges. Although the sedating side effect of amitriptyline is often cited as a beneÞcial effect, all of the tricyclics have some sedative properties and, in adequate doses, can lead to freedom from pain, enabling persons with AIDS to sleep more soundly. Carbamazepine, hydroxyzine, and phenothiazines also have signiÞcant anticholinergic effects and can worsen confusion in persons with dementia and delirium. Stimulants lower the seizure threshold and can produce agitation, psychosis, anorexia, and insomnia in persons with AIDS. Steroids can cause mood elevation, mania, psychosis, and depression.

Meperidine is contraindicated as an analgesic for persons with AIDS. Its metabolite, normeperidine, is neurotoxic and can lead to confusion, tremors, and seizures. Although fentanyl transdermal system provides excellent analgesia in persons with AIDS, it has been

associated with delirium, although rarely. The absorption of transdermal fentanyl can be erratic in the febrile patient.

Non-Pharmacologic Treatments for Pain

Although most pain syndromes associated with AIDS respond to pharmacotherapy, other analgesic modalities should be considered as adjuvant therapies or in specific clinical situations. Surgical anesthetic procedures have been used extensively for the treatment of severe or intractable nociceptive and neuropathic malignant pain (331,345). Examples include nerve blocks and epidural anesthetic infusions of opioids. Jonsson and colleagues (371) described the successful treatment of intractable dysuria and vesical pain in a person with AIDS and interstitial cystitis. Analgesia was achieved with intrathecal subarachnoid morphine infusion, rather than with the more conventional epidural route of administration.

Radiation therapy aimed locally at painful cutaneous Kaposi's sarcoma (KS) lesions can provide adequate analgesia (372). Neurological stimulatory approaches can be useful in the treatment of neuropathy in some persons with AIDS. Among the techniques studied, acupuncture (373) and transcutaneous electrical nerve stimulation (344,374) alleviate pain in persons with HIV sensory neuropathy. Other nonpharmacological analgesic treatments studied in noncontrolled populations of persons with AIDS with reported relief, include massage therapy (375), use of support stockings for neuropathy (344), and aromatherapy (376).

Psychotherapeutic modalities can be useful in treating the anxiety and depression that often accompany incapacitating pain. Group therapy has been shown to reduce the perception of pain in persons with metastatic breast cancer (299–301), malignant melanoma (296–297), and AIDS (377–379). Supportive psychotherapy, cognitive psychotherapy, behavioral therapy, relaxation therapy, and hypnosis are effective as adjunctive interventions to reduce pain.

Treatment of Pain in Drug-Dependent Persons with AIDS

Drug addiction can be defined as compulsive drug-seeking behavior that interferes with judgment and social functioning, coupled with the development of tolerance due to repeated drug use and withdrawal upon the discontinuation of drug use. Drug-seeking behavior is primarily a result of drug withdrawal and secondarily a function of the development of tolerance. When drug-dependent persons with AIDS complain of pain, the clinician needs to take into account these variables. Manipulative and sociopathic behaviors diminish when pain is adequately treated in persons with AIDS and drug dependence. Clinicians often feel that drug addicted patients manipulate doctors and the healthcare system in order to obtain narcotics. Persons with AIDS who also complain of pain rarely lie or exaggerate their need for analgesics. Persons with HIV infection and opioid dependence have a higher tolerance for narcotics and need higher doses of potent analgesics to adequately treat their nociceptive pain (380). The prevalence of pain in persons with AIDS does not differ when populations of injecting drug users are compared with non-drug users (335,344, 365). However, the authors have found that pain is greatly undermedicated in drug-dependent persons with AIDS.

Pain control in persons with either a history of drug dependence or who are active drug users can be adequately achieved by setting aside unnecessary concerns or hesitations. With previously addicted patients who are now currently drug free, clinicians should follow the same guidelines for administration of analgesics that are recommended for persons who have never been addicted. For those patients who express concerns about use of opioids for pain relief, it is helpful to reassure them that adequate pain relief will not lead to relapse. Clinical research has shown that former drug users who have HIV infection do not have increased complaints of pain or greater need for opioids than those without addiction history (381). Injecting drug users with HIV infection and pain do not exaggerate their complaints and need dual treatment for addiction and pain. Agitation and behavioral dyscontrol result from both drug withdrawal states and severe pain. Agitation is not to be dismissed as manipulative behavior but be understood as an extreme manifestation of physiological distress. Injecting drug users and persons on methadone maintenance as agonist therapy for drug dependence have a high tolerance for opioids. For patients not on methadone maintenance but in heroin withdrawal, as is the case in many acute care settings in inner city hospitals, a methadone detoxification protocol is effective in treating heroin withdrawal. Guidelines for treatment of heroin withdrawal are summarized in Table 19.4.

When a person with AIDS and pain is maintained on a standing dose of methadone or treated with methadone for heroin withdrawal, the pain should be treated as a separate problem (345). The patient's methadone dose should not be thought of as analgesia, but rather as agonist therapy for relapse and withdrawal prevention. Adequate doses of weak or strong opioids should be prescribed as if the individual were not already on an opioid, even if the methadone dose is high. Methadone for relapse prevention will target opioid tolerance needs and prevent withdrawal but will not provide analgesia for pain.

CREATION OF A SPECIAL HEALTHCARE ENVIRONMENT FOR PERSONS WITH AIDS

Anyone with a severe or potentially fatal illness needs a non-judgmental, nurturing, loving environment throughout

the course of the illness. The families, loved ones, and caregivers are also in need of a special kind of understanding, gentle support, and availability. Persons with AIDS are more vulnerable because of the epidemics of fear, discrimination, ignorance, and therapeutic nihilism. They need an unconditionally loving ego-supportive environment. They need psychological, medical, spiritual, and social support. Creation of a supportive environment leads to better education, behavior change, and improved care.

Healthcare environments are not necessarily supportive even if they are designed to be. An elegant example is a controlled study (382) of the effect of operating room temperature on rate of infection, duration of healing, and length of post-operative hospital stay. The study indicated that the chilly temperatures (65¡F.) maintained to prevent heavily gowned and gloved surgeons and surgical support staff from perspiring under hot operating room lights resulted in lowering of surgical patientsÕ body temperatures while under general anesthesia. By warming intravenous ßuids administered during surgery and providing blankets, Kurz and colleagues found that the patients with the warmer environment maintained their normal body temperatures and had lower rates of wound infection, shorter lengths of postoperative stay, and faster rates of wound healing. The warming of the operating room environment was efÞcacious in decreasing both morbidity and cost of care.

Warming of the healthcare environment for persons with any illness is important, but it is crucial when the illness is associated with sex, drugs, infection, and death and has led to epidemics of fear and discrimination (1). One way to warm the environment is to create a multidisciplinary team to provide comprehensive compassionate care. The multidisciplinary team approach has been accepted in the medical community in speciÞc clinical settings. In general care and ambulatory settings, the team approach is familiar in the care of persons with cancer, end-stage renal disease, addiction, chronic pain, dementia, and eating disorders. The multidisciplinary team is particularly relevant for the HIV epidemic. Persons with AIDS are vulnerable not only to immunosuppression and opportunistic infections, but also to cancer, end-stage multiorgan disease, addiction, chronic pain syndromes, dementia, and even anorexia and malnutrition. The establishment of multidisciplinary teams to provide comprehensive compassionate care to persons with AIDS has been described as a way to combat the epidemics of AIDS and AIDSism (1). To provide a warmer environment for persons in the HIV epidemic is a major challenge; we would like to provide guidelines for creating this environment and overcoming obstacles to care.

Medical Guidelines

The care of persons with AIDS can be rewarding for physicians. When orientation, education, resources, and ongoing support are available, institutions, physicians, and persons with AIDS beneÞt. When a physician can get to know a patient with AIDS as a person, doctor and patient can develop a supportive relationship that diminishes the barriers of discrimination and AIDSism. The hallmark of this relationship is a nonjudgmental and loving connection between the doctor, patient, and the family. It is through this relationship and the use of participatory decision-making (**38?**,384) that the foundation for trust and climate for risk reduction can be established. A basic understanding that the physician will be there to provide competent care, respect the patientÕs wishes, enable participatory decision-making, and provide relief from pain and suffering, is therapeutic and diminishes requests for physician-assisted suicide.

Psychologic Guidelines

Recognition and treatment of depression, delirium, dementia, and substance-related disorders provide comfort for patients, family, and staff in the AIDS epidemic. Although some persons with AIDS have no psychiatric disorders, everyone with a risk behavior has anxiety, and nearly everyone with AIDS or other manifestations of HIV infection is under stress, anxious, sad, fearful, and even suicidal at times. It is helpful to incorporate consultation-liaison psychiatric services into both the function and leadership of comprehensive multidisciplinary programs, to provide a biopsychosocial approach and support for staff. It is especially important for psychiatric staff to take the lead in providing a loving, compassionate, and nurturing approach to care.

Spiritual Guidelines

The importance of the spiritual dimension in the comforting and healing process cannot be overemphasized. For patients who have strong religious support networks, the process of living and dying with AIDS becomes easier. For those who do not, introducing a spiritual support system may make a difference in providing solace and comfort care. Chaplains should be available in institutional settings and spirituality should be a part of an ongoing dialogue in the ambulatory setting. It is important to explore each individualÕs spiritual and philosophical belief system and to address these issues at his or her level of understanding and frame of reference (385).

The spiritual aspect of care must be entirely nonjudgmental, providing only solace and comfort, without introduction of rigid or dogmatic attitudes. It is important to integrate chaplaincy into the multidisciplinary team for a reciprocal teaching and learning process to ensue.

Ethical Guidelines

A supportive healthcare environment must ensure access to care, freedom from discrimination, and right to self-determination. Each personÕs right to autonomy and dignity must be respected throughout the course of HIV-related illness, from diagnosis to death. Ethical decision-making centers around the soundness of medical decisions by balancing beneÞcence against nonmaleÞcence. Autonomy requires that patients with capacity have the right to choose among medically indicated procedures or treatments and to refuse unwanted care.

ConÞdentiality

Our patients have taught us, all too poignantly, how important conÞdentiality is. An individual who is struggling with as devastating an illness as AIDS deserves not only humane care but also conÞdentiality. This is especially important in a society in which individuals may be discriminated against because they have AIDS. It is crucial that a patientÕs rights to privacy and conÞdentiality remain protected in the hospital setting, as well as in the community. There are several difÞculties with this because of the nature of the illness. Universal precautions should be used for all patients and in all healthcare settings. Education about universal precautions and conÞdentiality can combat discrimination. These concepts should be part of ongoing education as well as initial orientation for all hospital and healthcare employees.

Paradoxically, however, the issue of conÞdentiality has yet another aspect. Sexual partners of persons with HIV infection are at risk for AIDS. A person with HIV infection should be encouraged to inform a partner or potential partners and should be taught methods of risk reduction. Physicians should obtain consent from a patient to inform partners or trace contacts. This becomes further complicated when infected persons are illegal aliens or fugitives. In general, most people with AIDS are eager to inform their partners and to take whatever precautions necessary to prevent the spread of the illness. Unfortunately, not all infected persons have the courage, wisdom, or cognitive capacities to enable them to cooperate in this way. Issues of conÞdentiality can be exquisitely painful and may not always have simple answers.

Employees or Students with HIV Infection

Employers need to develop policies in order to prevent discrimination against employees with HIV infection. When the employers are hospitals and medical schools, AIDS policies need to emphasize conÞdentiality. The rights of employees to conÞdentiality must be protected. Employees or students with AIDS should be treated in the same way as all other employees. Persons with AIDS should be allowed to attend school or work until severe illness, disability, incapacitation, or death intervenes. The burdens and losses associated with AIDS are painful enough. There is no reason to add more losses. Employees with AIDS within our hospital systems have worked for as long as they were able to and left work only because they chose to do so. This policy was reinforced by the support of both the medical staff and administration. The preservation of a job enables a person with AIDS to continue to support himself or herself Þnancially, to maintain dignity and self-respect, and to have a sense of purpose. If the patient is also supporting a family, they too will be protected.

Ethics of HIV Testing

The HIV test is a test for antibodies to HIV. Although most individuals develop antibodies and become HIV seropositive within six weeks to six months of initial exposure, in a small fraction of cases, the time period may be longer. This latency period can present a public health hazard by falsely reassuring an individual who is infected that he or she is not. On the other hand, there are also rare false positives that may lead to unnecessary anxiety in an individual who is, in fact, uninfected.

HIV testing should be voluntary and anonymous, and it should not be used to screen prospective employees, insurance applicants, marriage license applicants (386), or students. HIV testing should not be done without both pre- and post-test counseling and written informed consent (387). ConÞdentiality of HIV test results should be carefully maintained and should not be disclosed without a speciÞc written release of information.

Early detection of HIV seropositivity can lead to early prophylactic medical intervention, prolong life, and prevent transmission of HIV (388). Voluntary anonymous testing of individuals with risk behaviors should be encouraged.

The availability of home AIDS test kits provides greater access to conÞdential testing. The beneÞts are complete conÞdentiality and easy accessibility. Ready access to testing is important because of the availability of antiretrovirals to decrease HIV transmission in pregnancy (389). It is also important because persons who are diagnosed early may beneÞt from HIV medical care and antiretroviral therapy. However, the beneÞts of home testing must be balanced against the vulnerability of individuals to anxiety, depression, and suicide. Testing is a time of crisis and turmoil and anonymous telephone counseling is far from adequate, even if it includes medical referrals. The availability of home AIDS testing kits should signal physicians and other clinicians the importance of providing HIV counseling and testing to patients with whom an ongoing relationship can help provide the necessary support and mobilize a family or social support network.

Ethical Issues and Advance Directives

The person with HIV infection needs to be able to have a way of maintaining dignity and humanity from the day of diagnosis until the day of death. Caregivers need to begin discussions early, while an HIV seropositive person is healthy and can plan for his or her future. A healthy seropositive pregnant woman needs to be able to discuss her choice of a surrogate parent for her child, should she become ill, disabled, or die. All HIV seropositive individuals should be encouraged to designate someone whom they trust to act on their behalf and to make medical decisions for them, should they no longer have the capacity to make them for themselves. The advance directives can be documented in the form of a living will or medical durable power of attorney. The designation of someone trusted can be codiÞed in a healthcare proxy, which is a document designating a healthcare agent. The process of making choices about advance directives should be part of a three-way discussion among the HIV seropositive individual or person with AIDS, his or her primary physician, and the healthcare agent. The discussion may involve the patientÕs philosophy of life and death, belief systems, and resolution of conßicts about some of these difÞcult issues. The discussion should include all forms of decision-making, including medical care and end-of-life decisions such as do-not-resuscitate (DNR) orders and foregoing life-sustaining treatment.

Ethical Issues Involved with Foregoing Life-sustaining Treatment

The evaluation of whether life-sustaining treatment should he initiated, maintained, foregone, withheld, or withdrawn depends on the values and preferences of the patient. Life-sustaining treatment is deÞned as mechanical ventilation, renal dialysis, chemotherapy, antibiotics, and artiÞcial nutrition and hydration. Patients need to understand both the risks and beneÞts of artiÞcial nutrition and hydration (390). They need to understand that tubes can be uncomfortable, that central lines can become infected, that intravenous lines can inÞltrate. Even though we advocate use of no mechanical restraints, the lines, tubes, and intravenous ßuid poles serve as tethers and anchors and tend to immobilize patients, leading to a Òcascade to dependencyÓ described by Creditor (391). No distinction is made between withholding, withdrawing, or foregoing life-sustaining treatment. There are also some indications that when artiÞcial hydration and nutrition are withheld, individuals may not be uncomfortable because of endogenous opioid secretion, as well as administration of analgesics for pain. Physicians have an obligation to relieve pain and suffering and promote the dignity and autonomy of dying patients in their care (390). This includes providing effective palliative treatment even if it may foreseeably hasten death (390). Providing a model for comfort, care, and a nurturing supportive environment includes changing many traditional healthcare practices and ensuring participatory decision-making styles.

Ethical Issues Involved with Determination of Capacity for Decision-making

Every individual should be presumed to have the capacity for decision-making and the right to self-determination. Every patient should be able to decide whether to stay in a healthcare facility, whether to accept medical care, refuse procedures, or sign out against medical advice (AMA). When it appears to the physician that the patient is unable to understand or reason about his or her medical care, the physician can make a determination of decisional capacity. This determination is an assessment of a personÕs capabilities for understanding, communicating, and reasoning about speciÞc issues. Mental illness per se, including dementia, schizophrenia, or depression, does not necessarily preclude decision-making. Any attending physician can determine decisional capacity. If an attending physician Þnds it difÞcult to make a determination, he or she can call upon a psychiatrist to assist. Guidelines for determination of decision-making capacity are summarized in Table 19.29.

One of the most frequent concerns in the healthcare setting is whether or not an individual has the capacity to decide about DNR. The patient with HIV dementia may still be able to decide about DNR. In order to be able to give informed consent for DNR or no emergency cardiopulmonary resuscitation (CPR), an individual must be able to understand the following:

1. The general nature of the illness, its severity, and implications.
2. The meaning and implication of respiratory or cardiac arrest (Òif my lungs or heart stop, I will dieÓ).
3. The distinction between CPR in an otherwise healthy person who has sudden trauma or arrhythmia and CPR in end-stage illness with severe compromise of health, immunity, organ function, and cognition.
4. The nature of CPR and the need for mechanical ventilation, intubation and external cardiac massage.
5. The consequence of a DNR order.
6. The fact that an individual can change his or her mind about DNR.
7. A DNR order does not imply withholding or withdrawing care. Those are entirely separate issues.

An individual with late-stage AIDS and HIV dementia demonstrated his capacity to understand the implication of a DNR order, in the face of cardiopulmonary arrest, by stating ÒItÕs goodbye, Charlie.Ó

Understanding issues of decisional capacity in individuals with HIV dementia can help preserve the delicate balance between safety and autonomy in the care of persons with AIDS.

TABLE 19.29. *Guidelines for determination of decisional capacity*

Who can determine decisional capacity?
- Any physician can determine decisional capacity.
- If a physician is unable to make the determination, it is appropriate to consult with a psychiatrist for assistance in the assessment.
- No psychiatric assessment is necessary if the primary physician can make the determination.
- This concept is in accord with both patient's right to self-determination and generally accepted bioethic principles.

Competency vs. Capacity
- Although the terms are often used interchangeably and have similar meanings, they are differentiated in ethics terminology.
- Capacity is a clinical determination while competency is a legal determination.

Myths about Capacity for Decision-Making
- Mental illness precludes decision-making.
- History of mental illness precludes decision-making.

Lack of decisional capacity in one area precludes decision making in another area.

Facts about Capacity for Decision-Making
- Psychopathology per se does not preclude decisionmaking.
- A person with dementia, schizophrenia or depression can make decisions unless the psychopathology interferes with the process, as in the following examples:
  - Severe depression preventing an individual from deciding to consent to care because of a clear wish to commit suicide in response to command hallucinations.
  - Severe dementia preventing an individual from understanding the illness or its treatment.
  - Schizophrenia incorporating treatment into a delusional system preventing an individual from being able to understand the illness.
- Determination of capacity for decision-making is highly speci c.

Types of Decisional Capacity
- Decisional capacity for treatment planning
- To give informed consent for a procedure
- To refuse procedures
- Decisional capacity for discharge planning
- To sign AMA
- To participate in discharge planning
- Decisional capacity for advance directives
  - To decide about DNR
  - To designate a Health Care Agent

Decisional Capacity for Other Issues
- To care for a newborn
- To handle nances
- To testify in court-testimonial capacity
- To write a will-testamentary capacity

Examples of Decisional Capacity

To give informed consent for lumbar puncture an individual must understand:
- The nature of the illnesses suspected-meningitis or infection of the brain lining.
- The nature of the procedure-a needle introduced into a space between the bones in the spine to get some uid out to test for what is wrong.
- The risks of the procedure.
- The bene ts of the procedure.
- The consequences of not having a lumbar puncture when meningitis is suspected.

To participate in discharge planning the individual must be able to understand:
- The nature of the illness or illnesses.
- The extent of his or her disability.
- The need for treatment and types of assistance required.
- The need for shelter, clothing, and speci c dietary requirements.
- How to obtain medical care.
- How to direct home help.
- How to negotiate activities of daily living.

To handle nancial affairs the individual must be able to understand:
- The nature of his or her assets.
- Where to keep assets.
- How to access assets.
- The nature of liabilities.
- Whom he or she would trust with information about resources.
- Whom not to trust and how not to become a victim of designing persons.

Each determination is speci c for the type of decisional capacity being evaluated and no blanket determination of decisional capacity is valid.

CONCLUSIONS

Persons with AIDS are living longer, healthier, lives because of good medical care, antiretroviral therapies, and prophylaxis for some of the previously fatal complications such as PCP (392). In order for persons living longer to live more comfortable lives, with preservation of independence and dignity, it is important to establish special nurturing, supportive, and loving healthcare environments. The ÒwarmingÓ of the internal and external environment for persons with AIDS can be accomplished through programs of education about psychiatric care, pain management, and decision making capacity. These special healthcare environments can enable persons with AIDS, their loved ones, and caregivers to meet the challenges of AIDS with optimism and dignity.

ACKNOWLEDGMENTS

This chapter is dedicated to the men, women, and children with AIDS whom we have cared for, to their families, and to their loved ones. We also dedicate this chapter to the devoted staff of the Mount Sinai AIDS Center. We appreciate their innate commitment to the comprehensive biopsychosocial approach to AIDS care. We give special thanks to Dr. Rosalind Hoffman for her competence and compassion. We express our gratitude to the AIDS physicians for their outstanding contributions: Drs. Fernando Borrego, Alan Cohen, Daniel Fierer, Jeffrey Gumprecht, Alexandra Gurtman, Sian Jones, Theodore Lenox, Israel Lowy, Marla Keller, Michael Mullen, Valerie Parkas, Louise Phillips. We give special thanks to Drs. Mary Klotman and Jeffrey M. Jacobson. We thank Drs. Daniel Fischberg and Diane Meier for teaching us about palliative care. We express gratitude to Debbie Indyk, Ph.D., and the HealthBridge Team for their creativity and devotion. We recognize Dr. Asher D. Aladjem, Sister Regina Burns, and Reverend Joseph Bishop for their unique contributions to AIDS care. We thank Steven C. Cohen for his editorial assistance and Angela Darling for her technical assistance.

Chapter 20

The Gastrointestinal and Hepatobiliary Systems in HIV Infection

Donald P. Kotler and Pierre M Gholam

Gastrointestinal (GI) dysfunction is common in HIV-infected individuals, with or without AIDS, as it is in other immune deÞciency disorders (1). The specialized functions of mucous membranes, such as nutrient absorption by enterocytes or gas exchange by pulmonary epithelium, require intimate contact with the external environment but render them vulnerable to pathogens. These conßicting needs, i.e. having intimate contact while remaining a barrier to the external environment, promoted the evolution of complex immunological and non-immunological defenses.

Gastrointestinal involvement in HIV infection and AIDS has serious consequences. Chronic enteropathy is associated with increased mortality (2). Progressive malnutrition, which may be associated with intestinal disease, is an independent predictor of death in patients with AIDS (3Ð5). Chronic diarrhea has been associated with diminished quality of life (6). Despite impressive advances in the treatment of the underlying viral infection, chronic diarrhea remains a source of morbidity in HIV-infected patients. In addition, new therapies have been associated with drug-induced toxicities that target the gut and liver.

The aim of this chapter is to describe the effects of HIV and AIDS upon the GI tract and the liver. Diagnosis and management are organized into a series of clinical syndromes.

MUCOSAL HIV INFECTION

The immune defenses of the mucous membranes are linked as a common mucosal immune system. The gut-associated lymphoid tissue is composed of lymphoid aggregates in the tonsils, PeyerÕs patches, and mucosal lymphoid follicles, plus diverse immunologically active cells in the lamina propria. Different subpopulations of mononuclear cells are found in the lamina propria and in the epithelium. The mucosa contains elements of both humoral (secretory) and cell-mediated immunity. The non-immunological defense system includes gastric acid, salivary, pancreatic and biliary secretions, secreted mucus, and intestinal motility. A stable lumenal ßora also contributes to homeostasis (7).

Mucosal immunity in HIV infection has received relatively little study. Studies have demonstrated decreases in CD4+ lymphocytes in intestinal mucosa, plus an increase in the population of suppressor T cells (CD8+) (8). Depletion occurs early in the disease course (9,10). Lamina propria lymphocytes, as opposed to macrophages, may be the cellular target for HIV-1 infection in intestinal mucosa. Lamina propria lymphocytes express CD4, plus chemokine receptors that are secondary receptors for HIV, including CCR5 and CXCR4 (11). In contrast, lamina propria macrophages express CD4 but not CCR5 or CXCR4. The reduced permissiveness of macrophages to HIV-1 appears to be due to the near absence of surface CCR5 on resident intestinal macrophages. Impaired permissiveness of intestinal macrophages to HIV-1 may play an important role in the low prevalence of HIV-1 mRNA-expressing macrophages in the lamina propria during HIV-1 infection *in vivo*.

Very few studies have examined speciÞc immune functions in the GI tract of HIV-infected individuals. Eriksson demonstrated normal responses to oral vaccination with cholera toxin B subunit (12) in HIV-infected subjects, which contrasts with studies demonstrating poor systemic antibody responses to tetanus vaccination (13). Evidence of speciÞc anti-HIV activity of lamina propria lymphocytes has been reported (14).

Donald P. Kotler, MD: Gastrointestinal Division, Department of Medicine, St. LukeÕs-Roosevelt Hospital Center College of Physicians and Surgeons, Columbia University, New York, NY.
Pierre M Gholam, MD: Gastrointestinal Division, Department of Medicine, St. LukeÕs-Roosevelt Hospital Center College of Physicians and Surgeons, Columbia University, New York, NY.

Many investigators have detected cellular reservoirs for HIV in the GI tract by various methods (15–20). Primary intestinal cell lines and colonic tumor epithelial cell lines have been productively infected with HIV (21). The possible role of HIV in intestinal disease is discussed below. Viral burden can be quantitated in intestinal mucosa. Rectal HIV RNA content was shown to fall to a similar extent as in peripheral blood in response to highly active antiretroviral therapy (HAART) (22).

CLINICAL SYNDROMES

General Principles of Evaluation and Treatment

Proper clinical management of the HIV-infected patient requires an appreciation of differences in disease presentation. Multiple enteric complications may coexist in AIDS patients, reaching almost one third of patients in one study (23). One organism may produce several different clinical syndromes, while many organisms can produce identical clinical syndromes. Disease complications of AIDS are notable for their chronicity, susceptibility to suppression, and resistance to cure, so that treatments must be given chronically. The speciPc pathogens producing disease in AIDS patients are different from those that usually affect immunocompetent individuals. However, HIV-infected individuals also are subject to usual illnesses. In either case, the pathologic features usually match the clinical symptoms and physical Pndings.

Pathologic processes may affect the GI tract with either a focal or diffuse pattern. Focal ulcers may be found anywhere in the GI tract. They may be infectious, noninfectious or neoplastic. Certain viral infections, such as cytomegalovirus (CMV) infection, and fungal infections, such as histoplasmosis, produce multifocal disease. The GI tract also can be involved diffusely. The most common diffuse lesion is candidiasis of the oral cavity and/or the esophagus. The epithelial cell layer of the small intestine is a target for protozoal infestations including *Cryptosporidium parvum*, *Isospora belli*, and the microsporidia, *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*. The lamina propria and submucosa may be involved by chronic infections such as *Mycobacterium avium* complex (MAC). Bacteria such as salmonella, shigella and campylobacter may cause a diffuse colitis or enterocolitis. The pathologic processes described above may lead to several types of clinical syndromes: disorders of food intake, dyspepsia, diarrhea, anorectal diseases, tumors, hepatobiliary diseases, pancreatic diseases, gastrointestinal bleeding, and the acute abdomen.

Advances in the treatment of HIV infection with highly active antiretroviral therapy (HAART) has allowed for effective suppression of viral replication, often to undetectable levels, and immune reconstitution. Mortality rates and the incidence rates for many opportunistic infections have fallen dramatically in recent years (24). However, GI problems in HIV-infected patients have not disappeared and continue to provide clinical challenges. There are several reasons. A substantial proportion of HIV-infected subjects are unaware of their infection status, so that underlying HIV infection often is part of the differential diagnosis of diarrhea in a patient not previously known to be HIV-infected. Thus, HIV infection must now be included as part of the differential diagnosis of the causes of chronic diarrhea. In addition, some people are aware of HIV infection but are not currently under medical care, or do not take HAART in spite of immune dePciency. In other patients, viral infection is resistant to available therapies and patients may suffer immune deterioration despite attempts at virologic control. In addition, HAART therapy is available to only a minor percentage of HIV-infected subjects worldwide, and the disease complications of AIDS, including diarrheal illnesses, continue unabated in most developing countries, so that HIV infection must be considered as an underlying disease in immigrants.

Which patients require extensive evaluation is an important question. Many patients develop GI symptoms at some point during the course of the illness, but a large proportion of the episodes are self-limited. Extensive evaluation in all cases is expensive, burdensome, and often unrewarding. Evaluation is mandated for patients whose symptoms are persistent, increasing in severity or associated with fever and/or weight loss. When such symptoms have been present for more than one month, it is likely that they will continue indePnitely, if untreated.

Disorders of Food Intake

Etiology and Pathogenesis

Candidiasis is a very common complication of HIV infection. Candidiasis decreases taste sensation and affects swallowing, in addition to causing oral or substernal discomfort. Most cases are due to *Candida albicans*. Hairy leukoplakia, a hyperkeratotic lesion found along the sides of the tongue or adjacent gingiva, may be mistaken for candida. As opposed to candidiasis, hairy leukoplakia is asymptomatic and does not affect food intake. Severe gingivitis or periodontitis also affect eating. Ulcerations, due to herpes simplex or CMV, and idiopathic ulcers cause pain and interfere with eating. Mass lesions, such as KaposiÕs sarcoma or lymphoma, occur in the oral cavity and can interfere with chewing or swallowing.

The esophagus is affected by the same lesions as is the oral cavity. A particularly striking lesion is the idiopathic esophageal ulcer, which may produce debilitating symptoms (25,26). As opposed to herpetic ulcers, no etiologic agent is found on biopsy of the ulcer. Studies have documented the presence of HIV RNA in these ulcers, though this Pnding is non-speciPc. HIV also has been detected in transient ulcers associated with seroconversion (27).

Patients also may experience diminished food intake in the absence of oral or esophageal disease. Focal or diffuse neurologic lesions can affect food intake, as can speciÞc medications. AIDS patients with malabsorption do not increase food intake sufÞciently to account for calories lost in feces (28). Anorexia also is a feature of systemic infections, and appears to be an effect of altered cytokine release (29).

Diagnosis

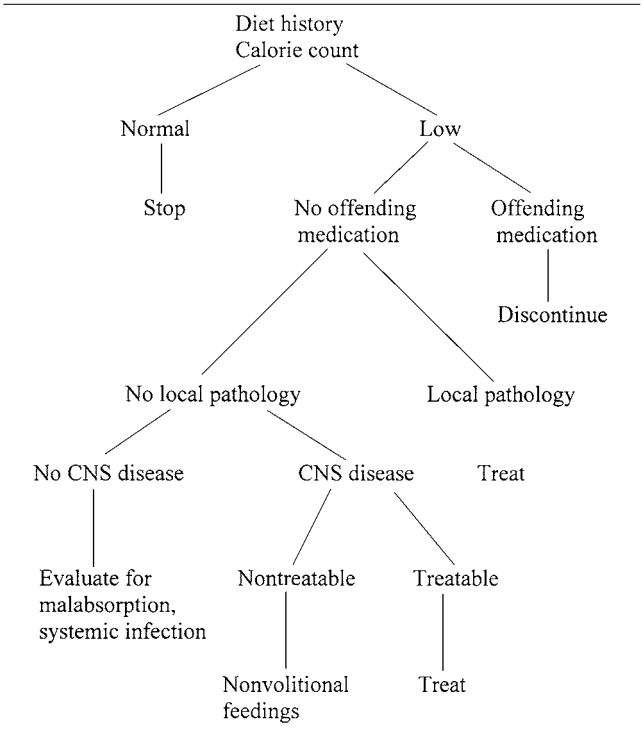
The etiologic diagnosis of disorders of food intake can be approached using a diagnostic algorithm (Table 20.1). Local disease can be discerned from a careful history and physical examination, assisted by ENT or dental consultation. The presence of malabsorption usually is suggested by history (see below) and can be conÞrmed with a small intestinal biopsy or an absorption study. Systemic disease is suggested by fever or other localizing signs and symptoms. The clinician should not conclude that anorexia is due to a medication until other possibilities are ruled out, or the patient responds positively to a supervised trial of medication withdrawal.

Candidiasis is a diffuse lesion in the esophagus and may occur independently of thrush, though the lesion is most ßorid in the soft palate and posterior pharynx. Various clinical forms are recognized including the typical plaque-like thrush, erosive candidiasis, atrophic candidiasis, and angular stomatitis. The diagnosis can be suggested by barium studies (Figure 20.1) and conÞrmed by biopsy or brushings. The lesion is quite distinct from oral hairy leukoplakia, which is found along the sides of the tongue, and, occasionally on the adjacent buccal mucosa, and has a Þssured or serrated border and cannot be scraped from the underlying mucosa. In an AIDS patient with suspected esophageal candidiasis, it is advisable to treat empirically and only evaluate patients with persisting symptoms (30).

All esophageal ulcerations should be investigated by direct examination and biopsy. Herpetic esophagitis presents as groups of small, shallow ulcers containing herpetic inclusions in the epithelial layer. CMV may produce esophageal ulcers with typical CMV inclusions in the ulcer base. No etiologic diagnosis can be reached in a signiÞcant percentage of patients with esophageal ulcers. These ulcers may be large and deep, with undermined edges and a clean base. Bleeding and perforation have occurred.

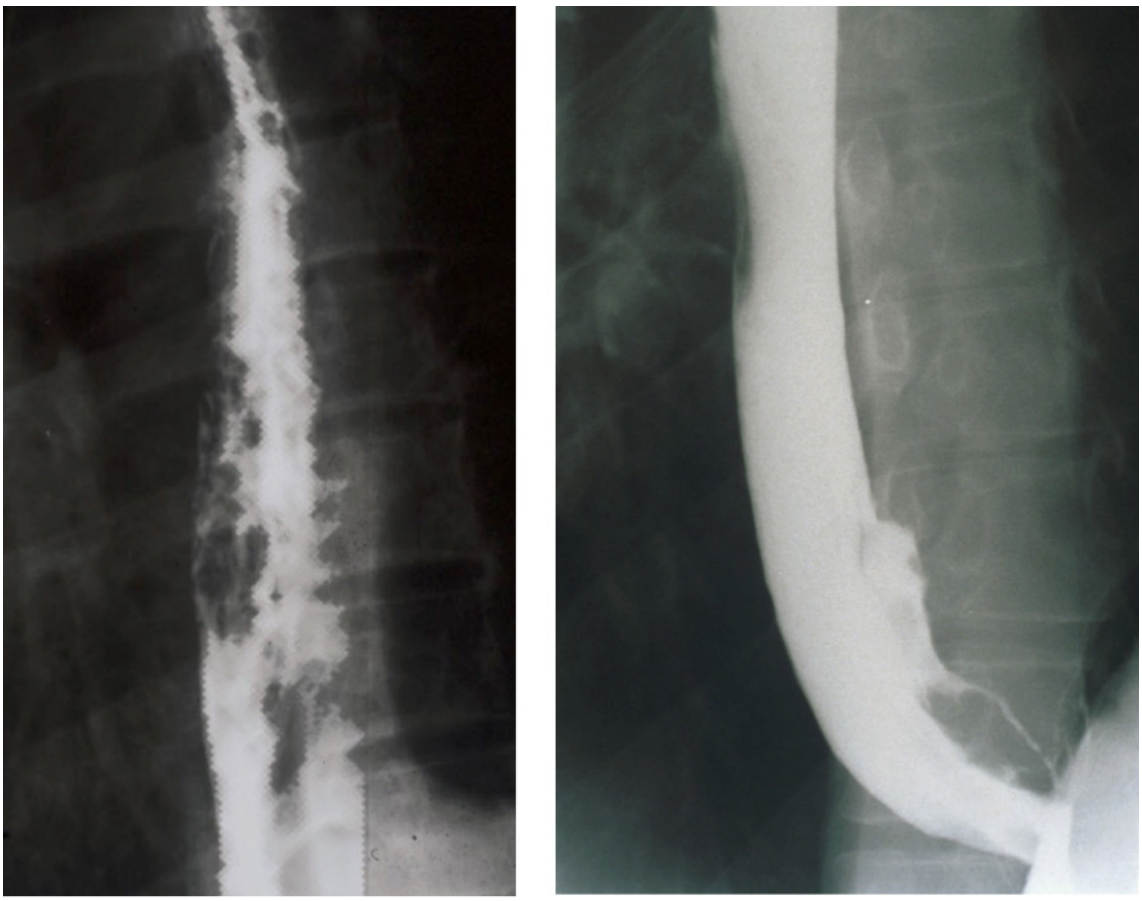
Overall, studies have demonstrated a decline in the incidence of both oral and esophageal disease in subjects on HAART, with the possible exception of HPV-induced lesions.

TABLE 20.1. *Diagnotic algorithm for disorders of food intake*



Treatment

The speciÞc management of eating disorders is based upon the precise cause of the problem. Oral candidiasis responds to a variety of antifungal therapies including the topical therapies, nystatin and clotrimazole, and the systemically active azole drugs. Esophageal candidiasis is best treated using systemically active compounds, since the organism is invasive. The infection may become resistant to azole therapy in some cases, or be due to other yeasts, such as *Candida glabrata* (31), for which intravenous amphotericin B therapy may be required. Treatment options for hairy leukoplakia include acyclovir 800 mg po 5 × /day for two to three weeks (directed to Epstein-Barr virus, the etcologic agent), then 1.2Ð2 g/day, or tretinoin (Retin A) 0.025% or 0.05% solution applied 2 to 3 × /day. Herpes simplex virus infection responds to oral treatment with acyclovir. Discontinuation of therapy after induction therapy and use of maintenance therapy only if there are frequent relapses is recommended. Ganciclovir or foscarnet are effective treatments for CMV esophageal disease (32). Deep, painful aphthous ulcers not due to an identiÞable pathogen may respond promptly to locally injected or systemic corticosteriods (25,26), though the danger of worsening immune suppression in patients with AIDS should be kept in mind. Corticosteroid therapy was associated with an increased risk of developing CMV infection in one study (33). The ulcer also may recur after steroid therapy is discontinued. Studies have shown the effectiveness of thalidomide for the treatment of idiopathic esophageal ulcers. The signiÞcant neurologic and sedating side effects of thalidomide as well as teratogenicity in women have restricted its use to registered physicians and pharmacies.



(a) (b)

FIG. 20.1. (a) Barium esophagram demonstrating diffuse mucosal involvement as a result of candida esophagitis. (b) Barium esphagram demonstrating an idiopathic ulcer plus a stula tract.

Salivary gland enlargement frequently complicates AIDS. The concerning manifestations of this entity are cosmetic appearance, pain from distension and xerostomia. For painful or cosmetically disÞguring cystic lesions, needle aspiration and CT scan will distinguish cystic and solid lesions (34). Biopsy is needed if malignancy is suspected, although most are benign cystic lesions. Fine needle aspirate permits microbiologic analysis and decompression. For xerostomia, sugarless gum and artiÞcial saliva may offer some relief. Pilocarpine may be necessary for refractory cases.

A major complication of oral and esophageal diseases is decreased food intake. Dietary consultation with creative diet planning and choice may be quite beneÞcial in milder cases. Caloric supplementation with formula diets also may be helpful. In patients with local lesions that cannot be treated successfully or in refractory cases of anorexia, some form of non-volitional feeding is required. Nutritional repletion has been reported in response to total parenteral nutrition (TPN) (35) and to enteral feeding regimens (36,37). Nasoenteric tubes can be used, though there are problems with cooperation in long-term use, plus the possibility of precipitating or exacerbating sinus disease. Percutaneous endoscopic gastrostomy feedings are efÞcacious and well tolerated by AIDS patients, and can be continued indeÞnitely.

DYSPEPSIA

Etiology and Pathogenesis

Nausea and dyspepsia are very common symptoms in AIDS but rarely dominate the clinical picture. The stomach may be involved by disseminated infections such as CMV, MAC or fungi, or by tumors. Gastritis due to *Helicobacter pylori* has been found, but its incidence may be lower in HIV-infected than in non-infected patients (38). Some medications, such as nonsteroidal antiinßammatory agents, promote gastric ulceration and produce dyspepsia. Early studies have shown a high incidence of

achlorhydria in AIDS patients (39,40). Achlorhydria was not related to diarrhea or to small bowel bacterial overgrowth in a more recent study (41).

Clinical symptoms are nonspecific. The presence of weight loss or fever implies a serious complication such as a systemic infection or ulcerating tumor. Dyspepsia is due to a low-grade pancreatitis in some patients and may precede the diagnosis of biliary tract disease in others (see below). As in the non HIV-infected person, gastric pathology may be detected even in the absence of gastric symptoms.

Treatment

Symptomatic *Helicobacter pylori* in an AIDS patient is treated in a similar manner to other patients. The diagnosis of CMV or MAC infection is an indication for systemic anti infective therapy. Widespread or ulcerating Kaposi's sarcoma is an indication for systemic chemotherapy, as is the presence of lymphoma. Associated eating disorders should be evaluated and sufficient caloric intake assured.

DIARRHEA AND WASTING

Etiology and Pathogenesis

Alterations in bowel habits are common in HIV-infected patients. Most of the available information relates to the pre-HAART era. Unexplained intestinal dysfunction and injury was an early observation (42), and the term "AIDS enteropathy" had been applied to this group of patients.

Prevalence

The prevalence of enteric pathogens varies greatly in reported series (23,43–48) and has decreased dramatically since the advent of HAART therapy (49,50). The prevalence rates and specific types of enteric pathogens differ in patients seen by primary care physicians and GI consultants due to selection of the most severe and protracted cases for referral, and elimination of those that improve or resolve after routine workup and non-specific or symptomatic treatment. We prospectively evaluated 250 HIV-infected individuals referred for GI symptoms in the pre-HAART era and identified an enteric pathogen in 83% of 141 AIDS patients with diarrhea (23). Two or more coexisting infections were found in 28% of AIDS patients with diarrhea. Thus, AIDS patients with chronic diarrhea have a very high chance of harboring one or more enteric pathogens.

A few studies in the current era have evaluated different diagnostic algorithms including type of endoscopic procedure, specific diagnostic samples, and cost-effectiveness, with no general consensus (51–53).

Small Intestinal Pathogens

Cryptosporidiosis

Cryptosporidium parvum, a coccidian related to *Toxoplasma gondi*, is a well recognized etiologic agent for chronic diarrhea (54). The illness is self-limited in immune competent patients but may be protracted in AIDS patients. The clinical course in AIDS is variable based upon immune function (55) and ranges from spontaneous remission to persistent, debilitating disease. A histopathologic study demonstrated variation in the intestinal location of cryptosporidiosis in AIDS (56). Most patients (65%) had diffuse small intestinal involvement while a smaller percentage of patients have cryptosporidial ileocolitis, without evidence of jejunal disease. Patients with small intestinal localization had more severe histopathology, malabsorption, more often received parenteral hydration or nutritional support, and had significantly shorter average survival. The factors underlying the variation in disease location are unknown.

Microsporidiosis

Microsporidia are primitive protozoa only recently recognized to infect man, though they have long been known as pathogens in animals. Two species have been identified in intestinal biopsies from AIDS patients, *Enterocytozoan bieneusi* (57) and *Encephalitozoon intestinalis* (58). While *E. bieneusi* infection is limited to enterocytes, *E. intestinalis* has been shown to disseminate. Prevalence rates in different population groups range from 2–50% (23,45,46,59–61). *E. bieneusi* has been detected in immunocompetent individuals with a self-limited diarrheal illness (62). This observation implies that human infection may be widespread and could be a significant cause of community-acquired or traveler's diarrhea.

Little is known about immunity to *E. bieneusi* infection. Resistance to Encephalitozoon infection is related to the presence of interferon-secreting lymphocytes (63).

Other Protozoa

Isospora belli has been reported frequently in AIDS patients from Haiti and West Africa, though fewer cases have been seen in the continental United States (54). The symptoms are similar to those of cryptosporidiosis. Organisms may be rare in stool specimens and in biopsies, so the diagnosis may be missed.

Giardia lamblia is not a common cause of acute diarrhea in AIDS. Drug therapy with quinacrine or metronidazole is indicated if cysts or trophozoites are found, though suspicion of other etiologies should be high. Like giardiasis, amebiasis is not a common cause of severe illness in HIV-infected patients. In the majority of cases,

Entamoeba histolytica appears to act as a commensal organism. While therapy should be given, the possibility of coexisting pathogens should be considered. Other parasites have been reported in AIDS patients, including *Strongyloides stercoralis*, which may produce a hyperinfection syndrome. *Blastocystis hominis*, which is felt by some authors to be an enteric pathogen, has been found in HIV-seropositive people with diarrhea.

Enteropathogenic Bacterial Infection

A syndrome of chronic diarrhea and malabsorption associated with bacterial-epithelial cell adherence and damage has been recognized (64–65). The infection is localized to the terminal ileum, cecum and colon. It is unclear if the same mechanism applies in AIDS patients, or if the immune deficiency renders the mucosa vulnerable to "non-pathogens." Alternatively, the problem might result from community-acquired, low-grade intestinal infection that cannot be cleared due to the severity of the immune deficit.

Enterocolitis

Cytomegalovirus

Disseminated CMV infection is a frequent and serious complication in AIDS and can present as a variety of gastrointestinal syndromes including oral and esophageal ulcers, esophagitis, gastritis, isolated intestinal ulcers, terminal ileitis, spontaneous intestinal perforation and focal or diffuse colitis. Colitis is the most common GI problem produced by CMV in AIDS patients (66). The major cell affected is the vascular endothelial cell. Clinical disease occurs as a result of vasculitis and presents as focal or multifocal ulcerations that become progressively diffuse. Colonic perforation, "toxic megacolon" or progressive wasting with refractory diarrhea are possible clinical outcomes in untreated cases.

Mycobacterium Avium Complex

Infection with *Mycobacterium avium* complex (MAC) is a common cause of intestinal disease in AIDS patients with severe immune suppression. The infection probably is acquired through the ingestion of contaminated water. Clinical disease results from infiltration of infected macrophages into tissue compartments, similar to Whipple's disease (67), and from the effects of cytokines released by the macrophages. The luminal gastrointestinal tract is involved by MAC infection. Massive thickening of the proximal intestine may occur. Small intestinal biopsy reveals infiltration of the lamina propria by macrophages containing large numbers of acid-fast bacilli.

Bacterial Enteritides

Bacterial enteritides in AIDS have distinctive features. Infections with species of salmonella, shigella or campylobacter occur in HIV-infected patients, with or without AIDS (68). In one study, shigella infections tended to occur early in the disease course, while salmonella and campylobacter infections were more common in AIDS patients. It is unclear if the incidence is increased over the surrounding population, though enhanced susceptibility could be related to decreased gastric acid secretion, as noted above. The clinical presentation of salmonella infection may be reminiscent of the classical descriptions of typhoid fever (69).

Antibotic-Associated Colitis

Antibotic-associated colitis, related to elaboration of *C. difficile* toxin, has been reported in AIDS patients (70). AIDS patients may be particularly vulnerable to this complication, as they often receive broad-spectrum antibiotics. Clindamycin use and prolonged hospitalization were found to be risk factors for its development. The clinical syndrome is similar in AIDS and non-AIDS patients.

Adenovirus

Adenoviruses are occasionally isolated from rectal swabs or biopsies from AIDS patients with diarrhea and a stable or deteriorating course. Electron microscopic studies have demonstrated cytoplasmic inclusion bodies containing adenovirus in superficial epithelial cells, including goblet cells (71).

Role of HIV in Intestinal Disease

Several authors have suggested that HIV may play a role in intestinal disease. Most AIDS patients with diarrhea but very few HIV-infected individuals without AIDS have identifiable enteric pathogens (23,72,73). HIV RNA and protein antigen expression may correlate with clinical symptoms as well as histopathologic alterations, including lymphoid cellularity and cytokine expression (72,74).

Clinical Symptoms

The ability to localize the pathologic process presumptively to the small intestine or colon is valuable in directing and streamlining a diagnostic workup. Important

information often can be obtained from the clinical history. Symptoms related to small intestinal infection are typical of malabsorption. Patients complain of three to ten nonbloody bowel movements per day, with urgency but no tenesmus. When severe, the diarrhea is associated with dehydration and electrolyte abnormalities, typically hypokalemia and hypomagnesemia. A mild hyperchloremic acidosis may be seen. Stool volume is variable but often large. Patients may have little diarrhea or even formed stools at times, yet suffer from episodes of profuse diarrhea at other times. The diarrhea does not occur consistently thoughout the day and is often worst at night or early in the morning. There may be no *speciPc* food intolerances, as diarrhea is worsened by any signiPcant food intake. However, stool volumes are decreased by fasting. In some patients, stool volumes are very high (up to 10 liters/day) and not affected by food intake, implying a secretory process. The infections producing malabsorption usually are not associated with fever or anorexia, though food intake may be decreased voluntarily to avoid diarrhea. A notable exception to this rule is MAC. Weight loss typically is slow and progressive, or patients may stabilize around a lower weight.

Enterocolitic diseases produce typical symptoms of colitis. There are numerous (up to 30) small volume bowel movements that occur at regular intervals throughout the day and night. Cramping and tenesmus may occur but usually are not severe. The clinical course often is associated with fever, anorexia, rapid and progressive weight loss and extreme debilitation.

Diagnosis

Stool examinations are an integral part of the diagnostic workup of an HIV-infected individual with diarrhea. Many organisms can be detected in the stool. Special diagnostic techniques are available for cryptosporidia and microsporidia, though there is relatively little clinical experience with the latter techniques. While molecular biological techniques are available experimentally, they have not been used in clinical situations (75). However, a substantial proportion of patients have enteric pathogens that can be detected only by intestinal biopsy (Figs. 20.2–20.6), so that negative stool examinations are incomplete as a workup. An algorithmic approach may be used to evaluate AIDS patients with diarrheal illnesses (Tables 20.2, 20.3).

The ability to diagnose *E. bieneusi* on tissue biopsy has improved greatly (Fig. 20.3). Initially, there was complete reliance upon transmission electron microscopy. The recognition of characteristic patterns of cytopathology by light microscopy, coupled with conPrmatory special stains (76) coincided with a marked increase in the number of diagnoses made. Microsporidial infection is associated with variable degrees of villus atrophy and crypt hyperplasia. There is an increased parasite burden in the proximal jejunum and distal duodenum, compared to the proximal duodenum (77). In some cases, villus heights are almost normal and there is marked crypt hyperplasia. In other cases, there is signiPcant villus atrophy, usually with less marked crypt hyperplasia. *E. bieneusi* causes a typical pattern of cellular injury, which is concentrated in the upper third of the villus. The histopathology and ultrastructural characteristics have been reviewed in detail (57,78,79).

The spectrum of endoscopic lesions in CMV colitis varies from essentially normal appearing mucosa, to scattered groups of vesicles or erosions, to broad shallow ulcerations that may coalesce. CMV usually causes a pancolitis, though the cecum and right colon may be affected earlier than elsewhere. Histopathologic examination demonstrates characteristic intracellular inclusions

(d) Transmission electron micrograph of *E. bieneusi* spores in a sloughing epithelial cell (5,000 ×).

(Fig. 20.5). Specialized immunohistochemical or in situ hybridization techniques are available and may increase the sensitivity of diagnosis.

The diagnosis of mycobacterial infection is made by culture or histology. Stool smears may demonstrate acid-fast bacilli, but the Þnding is not speciÞc for tissue invasion. Mucosal thickening on barium X-rays and thickening of the intestinal wall plus enlargement of mesenteric and retroperitoneal nodes on CT scan are characteristic of MAC, though lymphoma or fungal infections have similar appearances. Histologic demonstration of acid-fast bacilli in intestinal tissue is straightforward (Fig. 20.6). Diagnosis by biopsy often can be made in one day, as compared to cultures, which may take as long as six weeks to become positive. Molecular hybridization techniques are being developed to allow species identiÞcation on tissue sections.

The diagnosis of antibiotic-associated colitis is the same in AIDS and non-AIDS patients. The diagnosis of bacterial enterocolitis should be straightforward with routine evaluation. Blood cultures should be part of the workup of suspected infectious diarrhea with fever in an HIV-infected patient, as salmonella may be cultured from blood but not from stool. An unusual feature of salmonella infections in AIDS patients is the tendency for clinical and/or microbiological relapse after antibiotics are discontinued.

Diarrhea Induced by Antiretroviral Drugs

Diarrhea is a commonly reported complaint in subjects on protease inhibitors and nucleoside analogs. Studies done three years into the HAART era have suggested that the incidence of chronic diarrhea in AIDS patients did not change, however the etiologies of diarrhea did change signiÞcantly, with an increased incidence of noninfectious causes and a decreased incidence of opportunistic infectious causes. This shift in etiologies coincides with the introduction and increased use of HAART in the populations studied. The exact mechanisms underlying the development of drug-induced diarrhea is uncertain although fat malabsorption has been associated with HAART therapy (80). The HIV protease inhibitors saquinavir, ritonavir, and nelÞnavir but not indinavir have

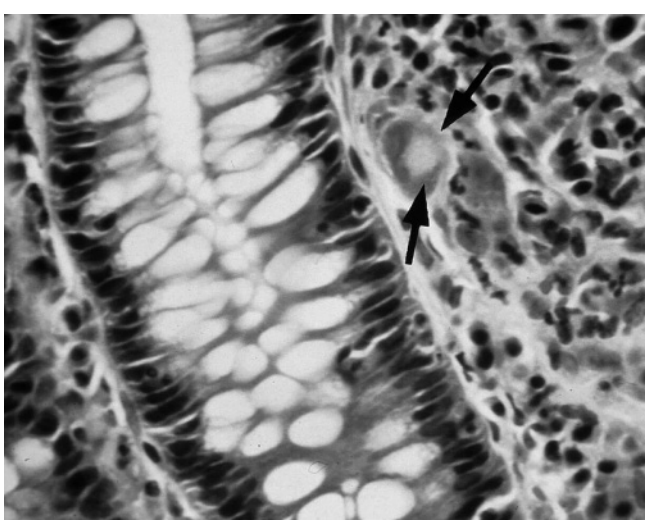

FIG. 20.5. Cytomegalovirus colitis. Intranuclear inclusion in an endothelial cell (H&E 250 ×)

been shown to impair the epithelial barrier in human intestinal cell lines (81).

Treatment

Treatments for the patients with diarrheal diseases can be divided into antimicrobial therapies, and treatments for the associated diarrhea, dehydration and malnutrition. There is no known effective therapy for cryptosporidiosis. Many agents have been tried, and the results have been disappointing. Some patients improved during treatment with paromomycin (Humatin, Parke Davis) while controlled trials showed only modest improvement and no

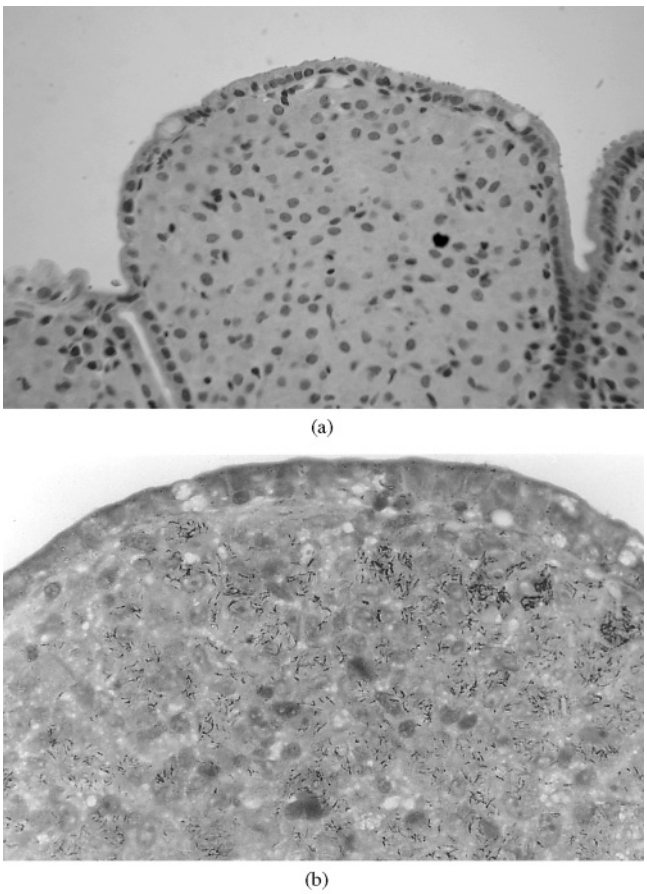

FIG. 20.6. (a) *Mycobacterium avium complex* infection of the small intestine. Foamy macrophages located in the super cial lamina propria (H&E 200 ×). (b) *Mycobacterium avian complex* infection of the small intestine. Acid fast organisms by Ziehl Neilson (H&E 200 ×).

cures (82,83). An uncontrolled trial of paromomycin plus azithromycin showed good response in terms of clinical symptoms and oocyst excretion (84). Azithromycin alone is ineffective. Clarithromycin or rifabutin prophylaxis for MAC prophylaxis may reduce risk of cryptosporidiosis (85). Nitazoxanide (Unimed Pharmaceuticals, Buffalo Grove, IL) has been reported as effective in the treatment of cryptosporidiosis but is not approved by the FDA and clinical trial data, including ACTG 192, shows minimal or no beneÞt. Overall, HAART with immune reconstitution is

[2] Concurrent or recent antibiotic use.

the only consistently effective treatment for cryptosporidiosis (86Ð88).

Few studies of drug therapy of *E. bieneusi* infection have been published (89). Albendazole (Glaxo Smith Kline) is ineffective as treatment, but is effective therapy for *E. intestinalis* infection (90). Anecdotal success in the treatment of *E. intestinalis* has been reported with itraconazole, ßuconazole, atovaquone, and metronidazole (91). Experimental drugs include Fumagillin, TNP-470, and Ovalicin. HAART with immune reconstitution is best therapy, especially for the 80Ð90% of cases involving *E. bieneusi* (92Ð94).

Isosporiasis may be treated with trimethoprim sulfa. Due to a high rate of recurrence, repeated courses or chronic maintenance with this drug may be needed. Some have advocated treatment indeÞnitely unless there is immune recovery. The optimal duration of high-dose therapy is not well deÞned. There has been one case report of refractory infection that responded to pyrimethamine plus sulfadiazine (95).

CMV colitis appears to occur less often in subjects on PIÕs and also has a lower rate of recurrence in subjects on HAART. Survival outcomes are also signiÞcantly better in patients with CMV colitis who are on HAART. Two agents are clinically effective in the treatment of CMV colitis. The most widely used is ganciclovir. A double-blind, placebo-controlled trial demonstrated clinical and antiviral beneÞts of ganciclovir therapy (96). Ganciclovir therapy also has been associated with nutritional repletion and with prolonged survival. Oral ganciclovir is available for maintenance therapy. Other analogues with better bioavailability have been developed. Foscarnet also has activity against CMV as well as HIV.

Several drugs have *in vitro* efÞcacy against MAC including the macrolide clarithromycin (Biaxin), as well as ethambutal (Myambutal), rifabutin (Mycobutin) and clofazimine (Lamprene). Other drugs with *in vivo* or *in vitro* efÞcacy include amikacin, ciproßoxacin, cycloserine, and ethionamide. Three drugs: azythromycin, rifabutin and clarithromycin, have been shown to be effective prophylactic agents. Combination of azithromycin plus rifabutin was associated with an even higher reduction in the expected number of cases of disseminated MAC at the expense of reduced tolerability (97). In a double-blind, placebo-controlled trial, clarithromycin prevented 69% of expected cases of *M. avium* complex disease. In another

placebo-controlled study of prophylaxis, azithromycin prevented 59% of expected cases. Either drug was more effective than rifabutin, although rifabutin prevented 55% of expected cases (98). Prophylaxis failures with rifabutin usually involve clarithromycin sensitive strains; failures with clarithromycin or azithromycin often involve clarithromycin-resistant strains. In the setting of immune reconstitution, primary prophylaxis may be discontinued when the CD4 count increases to $>100/mm^3$ for >3 months (99,100,101). It appears that secondary prophylaxis (prior disseminated MAC) may also be discontinued when the CD4 count is >100 plus HAART $\times$ 6Ð12 months.

The treatment of enterocolitis due to *Salmonella*, *Shigella*, or *Campylopbacter* sp. is modiÞed in that intravenous therapy with antibotics is used commonly, due to the frequent occurrence of bacteremia. In addition, repeated or chronic courses of antibotics such as trimethoprim sulfa or ciproßoxacin often are needed because of disease recurrence. Since many enteric bacterial pathogens are intracellular pathogens, it is possible that disease recurrence is a function of impaired intracellular macrophage killing due to deÞcient T cell help. Furthermore, the intracellular reservoir may protect the organisms from lysis by antibiotics. Further studies are needed to determine if complete eradication of the enteric bacterial pathogens in AIDS is possible, or if chronic suppressive therapy will be needed.

Treatment of chronic bacterial enteropathy with broad spectrum antibiotics has brought clinical improvement in several patients. The difÞculty in choosing antibiotics is the inability to determine which bacteria in stool are the offending organisms. In addition, the widespread use of antibiotics could lead to the development of multi drug resistance strains (102).

Other Therapies

Maintenance of adequate ßuid balance and nutritional status are important clinical tasks, especially in patients with malabsorption syndromes. Oral rehydration solutions may help maintain hydration status, but are hypocaloric and may promote wasting if used excessively. The goal of hydration therapy is to maximize ßuid intake while minimizing diarrheal losses. A low fat, lactose-free diet may be beneÞcial and medium chain triglycerides are useful adjuncts in the treatment of patients with signiÞcant malabsorption. On the other hand, polymeric formula diets generally are tolerated poorly and lead to substantial diarrhea. A variety of anti-diarrheal therapies may be used. Some patients with non-speciÞc diarrhea or ileal dysfunction respond well to the bile salt binding resin cholestyramine. The most commonly used antidiarrheal agents are loperamide and opiates, though escalating doses often are required. Octreotide has been used in the treatment of diarrhea of several etiologies, with mixed results. However, excess ßuid losses from the small intestine due to malabsorption or abnormal secretion will overcome any pharmacologically produced inhibition of motility and lead to diarrhea.

Nutritional therapy of AIDS patients with diarrhea depends entirely upon the pathogenic mechanism underlying the diarrhea. Different approaches are required in patients with and without malabsorption. Nutritional maintenance may be impossible by the enteral route in patients with severe small intestinal disease, and parenteral nutrition may be required (36). However, the use of elemental diets, which contains simple sugars, amino acids and medium chain triglycerides, may give similar results to TPN in some cases (103).

Nutritional support is less effective in patients with enterocolitis associated with systemic infections. The metabolic rate is elevated, and metabolic derangements promote protein wasting irrespective of intake. Alterations in lipid metabolism often result in the development of fatty liver when nutritional support is attempted. In one study, total parenteral nutrition resulted in weight gain, but the increase was due entirely to an increase in body fat content, while body cell mass did not change (36). While nutritional support might help prevent progressive protein depletion, the key to successful therapy is proper diagnosis and treatment of the speciÞc disease complication.

Treatment of PI-associated diarrhea is largely nonspeciÞc; most of the available literature is published only in abstract form and is based primarily on retrospective and survey data. Agents for which some efÞcacy has been shown for treatment of PI-associated diarrhea include oat bran, psyllium, loperamide, calcium carbonate, and pancrealipase.

ANORECTAL DISEASE

Etiology and Pathogenesis

Anorectal diseases seen in AIDS patients include both infections and tumors. Herpes simplex virus is the most common infectious agent found. The primary lesion occurs at the pectinate line. Vesicles in the anal canal may be missed as they rupture during defecation or examination. Herpes infection in AIDS patients most often presents as a painful, shallow spreading perineal ulcer. A smaller group of patients present with idiopathic ulcers, originating at the anorectal junction. Perianal and intraanal condylomata occur in AIDS patients as well as non-AIDS patients and are related to infection with human papilloma virus. The lesions may be enlarged and ßat (leukoplakia) and may show dysplasia on histologic examination. The lesions are likely precursors to squamous cell cancers. Tumors in the anorectal region include Kaposi's sarcoma, lymphoma, and squamous cell carcinoma or its variants.

Hemorrhoidal disease also is seen frequently. Factors predisposing to hemorrhoids may have predated the HIV

infection. Severe diarrhea or proctitis may promote local thrombosis, ulceration and secondary infection. Fleshy skin tags, resembling those seen in Crohn's disease, also are seen. Thrombosed hemorrhoids occur frequently, but it is unclear if the incidence is higher in AIDS patients than in a comparable population.

A variety of classic venereal diseases can produce anorectal ulcerations. Diagnosis and therapy of *Neisseria gonorrhoese* proctitis is similar in AIDS and non-AIDS patients. Syphilis may have an atypical presentation in HIV-infected subjects, and serologic diagnosis is affected by the presence of immune deficiency. Chlamydia are prevalent in sexually active groups. The frequency of chancroid, caused by *Hemophilus ducrei*, in HIV-infected patients is unknown. Rectal spirochetosis has been recognized in homosexual men with or without HIV infections (104). The infection usually is asymptomatic and an incidental finding on evaluation.

Diagnosis

In many cases, the correct diagnosis can be made by inspection. If necessary, the diagnosis can be confirmed by culture or biopsy. Specialized techniques, such as in situ hybridization, are available for the diagnosis of papilloma virus infection but are rarely needed clinically.

Treatment

Resolution of herpetic lesions occurs after treatment with oral or intravenous acyclovir. Herpes simplex virus resistant to acyclovir has been demonstrated in patients with refractory ulcerations. The use of foscarnet or ganciclovir may bring resolution. Anorectal ulcers containing CMV respond to antiviral therapy. Symptomatic idiopathic ulcers may respond promptly to intralesional corticosteroid therapy and healing may occur after repeated treatments. Areas of leukoplakia can be followed clinically while large or enlarging lesions should be excised. Some caution should be placed on surgical therapy. Poor wound healing may occur, especially in severely malnourished patients, patients with serious, untreated diseases such as CMV, and patients with continued diarrhea due to nutrient malabsorption.

Epidermoid cancers, including squamous cell and cloacagenic cancer, occur in anal skin and rectal glands, respectively. While these cancers rarely metastasize in immunocompetent persons, they may do so in patients with AIDS. For these lesions, management after diagnostic biopsy includes excision, chemotherapy, or laser photocoagulation. Laser therapy of rectal Kaposi's sarcoma also is effective.

TUMORS

The incidence of Kaposi's sarcoma in AIDS has declined in the HAART era. Kaposi's sarcoma in AIDS is indistinguishable, histopathologically, from classic Kaposi's sarcoma, endemic forms of Kaposi's sarcoma found in Africa, or the form that occurs during immunosuppressive therapy. Visceral involvement in AIDS patients with Kaposi's sarcoma is more common than in non HIV-infected individuals (105). Visceral involvement may be asymptomatic. The diagnosis is made by visual inspection and confirmed by biopsy, though endoscopic biopsy may be falsely negative if the tumor is in the submucosa. No treatment is needed in most cases. Kaposi's sarcoma is responsive to chemotherapy, which can be used in symptomatic patients or in the event of rapidly progressive disease. Pegylated liposomal doxorubicin (PLD, Caelyx) in the treatment of AIDS-related KS is more effective and less toxic than bleomycin plus vincristine (BV) or adriamycin plus bleomycin plus vincristine (ABV). Cost-effectiveness analysis suggests that PLD is preferable over liposomal daunorubicin, and other regimens and seems to offer a better quality of life.

A high prevalence of extranodal, high-grade non-Hodgkins B cell lymphomas has been noted in AIDS patients. Gastrointestinal lymphomas in AIDS are biologically aggressive, especially the Burkitt's subtype. The lesions may respond to chemotherapy, using combination therapies. Sporadic reports of AIDS patients with carcinomas in the gastrointestinal tract have been published but a heightened incidence has not been documented convincingly.

HEPATOBILIARY DISEASES

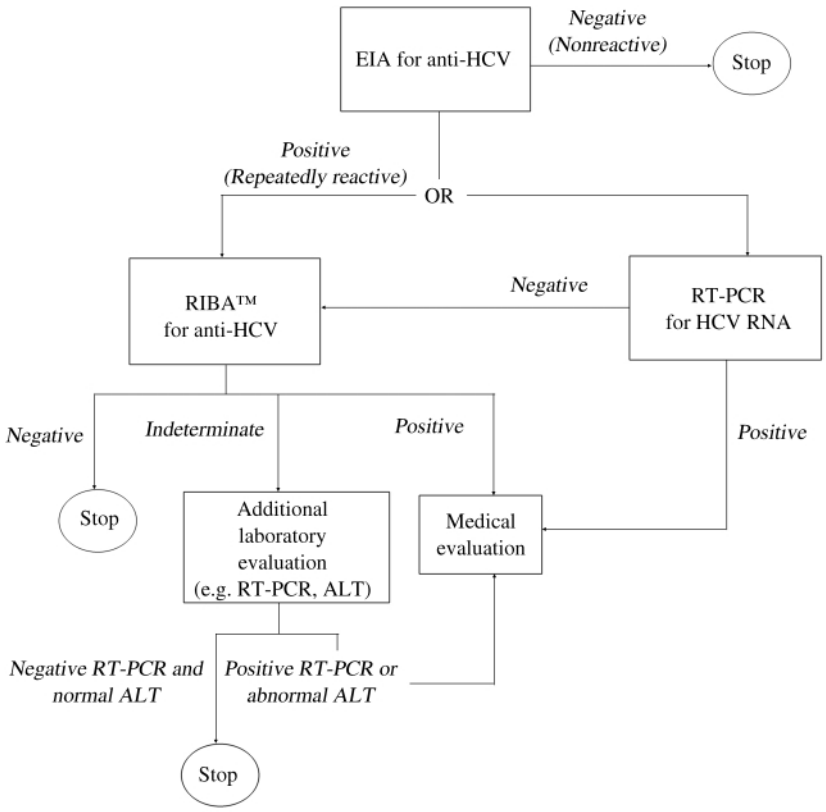
Etiology and Pathogenesis

Liver dysfunction is common in AIDS patients. Paradoxically, the perceived and documented morbidity and mortality from liver disease in HIV-infected individuals has grown in magnitude and importance during the era of HAART as the incidence and severity of other opportunistic infections has decreased. In general, HAART does not influence the long term outcomes of hepatitis B or C.

There are three distinct clinical syndromes of AIDS-related hepatobiliary disease: diffuse hepatocellular injury, granulomatous hepatitis and sclerosing cholangitis. Drug-induced liver injury also may occur, and is most commonly reported with nevirapine (Viramune, Boerhinger Ingelheim, Ridgefield, CT) and ritonavir (Norvir, Abbott Laboratories, Chicago, IL).

Many HIV-infected patients have had prior exposure to hepatitis B. A relatively high percentage of HIV-infected individuals have circulating hepatitis B surface antigen and e antigen. There is no evidence that immune deficiency will cause a reactivation of prior hepatitis B. On the other hand, hepatocyte injury as a direct result of viral or other cytopathy is unaffected by the immune deficiency so that delta hepatitis and drug-induced hepatitis are as severe in HIV-seropositive as in HIV-seronegative people.

TABLE 20.4. *Hepatitis C virus (HCV)-infection-testing algorithm for asymptomtic persons*



Granulomatous hepatitis in AIDS occurs in the setting of disseminated systemic infection. The causative organisms include mycobacteria and fungi, such as *Histoplasma capsulatum*, *Coccidiodes imitis*, and *Cryptococcus neoformans*. Viral diseases such as CMV also may affect the liver. Rare cases of disseminated protozoal infection has been reported. Disseminated pneumocystosis also may involve the liver.

A syndrome of sclerosing cholangitis has been recognized to occur in AIDS patients (106). The disease in AIDS bears a striking resemblance to the non-AIDS variety, though the disease in AIDS may be more rapidly progressive. The etiology and pathogenesis of sclerosing cholangitis are as obscure in AIDS patients as they are in non-AIDS patients. Some patients have been shown to have biliary involvement with protozoa, namely cryptosporidia and microsporidia. Other patients have been shown to have CMV infection of the liver and biliary tree. In other patients, no etiologic agent is identified.

Chronic hepatitis is believed to be one of the leading causes of morbidity and mortality in HIV infected subjects in the HAART era. An unexpected development of the application of HAART therapy was the observation that liver disease has become one of the most common underlying cause for death in HIV-infected individuals. The improvement in survival in patients on HAART has led to the development of chronic liver disease in many of the estimated 60% of HIV patients who are co-infected with chronic hepatitis C. Factors that promote HCV progression are HIV-co-infection and alcohol ingestion of $\geq$50 gm ETOH/day (107–109). HCV has a disputed effect on HIV progression.

USPHS/IDSA guidelines recommend that all HIV-infected persons should be tested for HCV infection using the EIA screening assay for anti-HCV antibodies; positive tests should be confirmed by either the recombinant immunoblot assay (RIBA) or by reverse transcriptase PCR (RT-PCR) for HCV RNA (110). The CDC-recommended algorithm for detecting HCV is summarized in Table 20.4. HCV RNA assays (quantitative and qualitative) are required to confirm chronic hepatitis C infection. Serologic tests for anti-HCV may be negative with acute HCV infection and with severe immunosuppression (CD4 $<100/mm^3$); HCV RNA may be useful in these settings. Quantitative HCV RNA assays are widely available using RT-PCR or b DNA technology. These tests show a threshold of detection of 100–1,000 copies/mL and they are positive in 75–85% of persons with anti-HCV and $>95\%$ of persons with acute or chronic hepatitis C. Rigorous quality control is necessary for these assays in terms of specimen preparation for laboratory submission. Genotype assay identifies six genotypes and >90 subtypes. Genotype 1 accounts for 70% of HCV infected

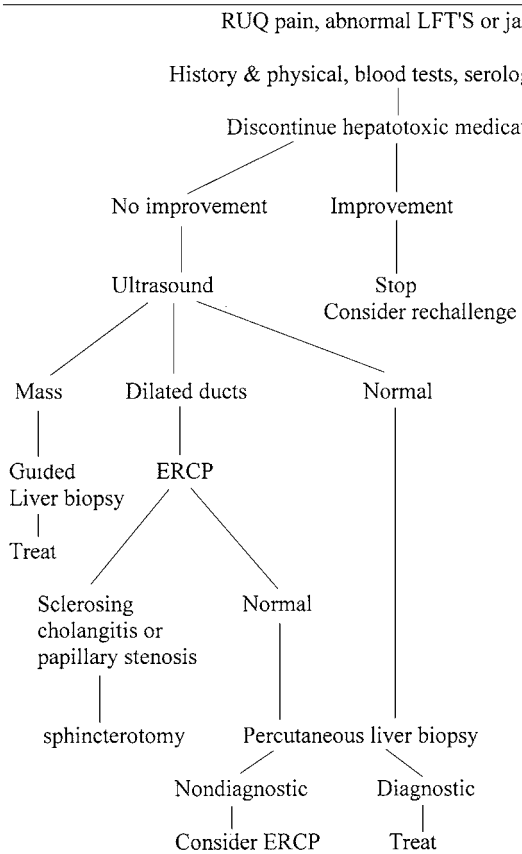
persons in the United States and is associated with a poor response to therapy compared to genotypes 2 and 3.

Patients co-infected with HCV and HIV should be advised not to drink excessive amounts of alcohol, be evaluated for HCV treatment with interferon plus ribavirin, and be vaccinated for hepatitis A, if susceptible.

Indications to treat in HCV/HIV co-infection include biopsy evidence of bridging Þbrosis or moderate inßammation and necrosis. HCV RNA levels and ALT levels do not adequately predict prognosis. Ribavirin appears to work as well in HIV-infected patients as in non-HIV patients, but causes more anemia in the presence of HIV (111). Peggylated interferons have a longer half-life than interferon, permitting once weekly adminstration. Comparative trials with peginterferon (180 μg SC q wk) vs. interferon alfa 2-a (3Ð6 million units SC $3\times$/wk) $\times$ 48 wks in patients with chronic HCV, in the absence of HIV infection, showed peginterferon to be superior in terms of virologic response and liver function tests (ALT) at 72 weeks (112,113). The results of peg interferon monotherapy are inferior to those of interferon and ribavirin.

Other patients with abnormal liver chemistries have macrovesicular or microvesicular fatty inÞltration, or other nonspeciÞc changes. Peliosis hepatis has been described in AIDS patients and is associated with infection by a rickettsia-like organism (114).

TABLE 20.5. *Algorithm for hepatobiliary disease in AIDS*



Clinical

There are few speciÞc clinical signs to indicate liver involvement except in cases of diffuse hepatocellular injury or obstruction with jaundice. The suggestion of liver disease usually is based upon the Þndings of abnormal liver function tests in serum samples. Mild hepatomegaly and abnormalities in liver function tests are seen commonly and often are of no clinical importance. When part of an obvious systemic process with chronic fevers and wasting, the presence of progressively rising serum alkaline phosphatase activity and an enlarged liver provide the opportunity for performing diagnostic procedures with a high yield of diagnoses expected. Patients with sclerosing cholangitis present with non-speciÞc abdominal complaints, sometimes associated with pruritis. Severe liver dysfunction with liver failure is rare but can occur in patients with hepatitis C or delta hepatitis infections, and has been seen in a few patients with sclerosing cholangitis.

Diagnosis

Evaluation for liver disease can be approached with the assistance of an algorithm (Table 26.5). The indication for biopsy is a progressive rise in liver function tests, not the absolute level of these enzymes. The techniques used to diagnose liver and other visceral diseases are the same in AIDS and non-AIDS patients. Focal lesions may be detected with ultrasound of CT scans and approached by directed biopsy. Percutaneous liver biopsy has been used to diagnosis MAC, tuberculosis, and fungal infections. Liver biopsy reveals focal collections of histiocytes, which may be organized into poorly formed granulomas, scattered throughout the parenchyma. Giant cells are seen only rarely. The responsible organisms often can be identiÞed by special stain on the biopsy. Mycobacteria are the most common organisms detected in clinical series (115). Acid-fast stains usually disclose large numbers of organisms, especially in cases of MAC. This Þnding differs from the usual paucity of acid-fast bacilli in non-AIDS related tuberculosis (116). Since tuberculosis cannot be differentiated from MAC by biopsy alone, culture of the liver also should be done and therapy based upon clinical judgement until results are known. Histoplasmosis and coccidiodomycosis can be diagnosed with great certainty on biopsy using speciÞc histologic stains. However, an aliquot also should be cultured for fungi. In addition to percutaneous liver biopsy, percutaneous needle aspiration of retroperitoneal nodes using sonographic or CT guidance is an effective means of making a diagnosis of infection or tumor.

The diagnosis of sclerosing cholangitis (AIDS cholangiopathy) can be made by ERCP (Fig. 20.7), though

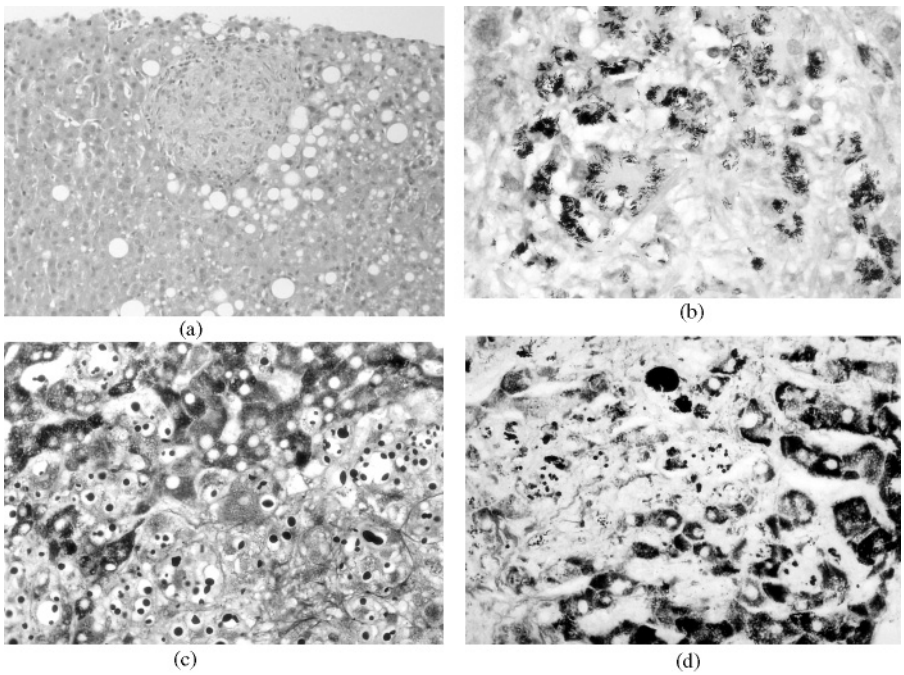


FIG. 20.7. Granulomatous hepatitis. (a) Granuloma located in the hepatic parenchyma (H&E 250×). (b) Acid fast bacilli located in macrophages (Zhiehl Nielson 480×). (c) Cryptococcal hepatitis (GMS 250×). (d) Histoplasma hepatitis (GMS 250×).

sonographic or CT studies also may support the diagnosis. Endoscopic retrograde cholangiography demonstrates multiple areas of narrowing and dilatation of the intrahepatic and/or extrahepatic ducts, sometimes with ulceration and plaque formation. Examination of bile and pancreatic juice may reveal bacterial overgrowth, viruses, and/or cryptosporidia. The absence of ductal dilatation on imaging studies does not rule out sclerosing cholangitis.

Treatment

The diagnosis of mycobacterial or fungal infection is indication for antimicrobial therapy. Likewise, the diagnosis of lymphoma or widespread Kaposi's sarcoma is indication for systemic antineoplastic therapy. Ongoing studies will determine the efficacy of treating hepatitis C in co-infected patients. Treatment of cholangiopathy is limited to sphincterotomy for pain relief, which does not affect disease progression. The question of liver transplantation has arisen, because patients with progressive liver disease, but stable HIV infection, are being seen in increasing numbers, and clinical experience in organ transplantation and its postoperative management is increasing.

PANCREATIC DISEASES

Pancreatic disease in AIDS has received little attention and may not be recognized pre mortem. The pancreas may be involved in systemic diseases such as CMV, MAC, fungi, Kaposi's sarcoma, or lymphoma. Drug-induced pancreatitis is the most commonly recognized form. Hyperlipidemic pancreatitis has been observed. There are no reports of chronic pancreatitis occuring as a specific complication of HIV infection. Pancreatic insufficiency is an uncommon cause of fat malabsorption in AIDS patients.

GASTROINTESTINAL HEMORRHAGE

Etiology and Pathogenesis

Gastrointestinal hemorrhage is not a common consequence of AIDS, but serious or life-threatening bleeding does occur (117,118). Bleeding may result from the same conditions occurring in the non-HIV infected patient as well as the tumors and ulcers seen in AIDS. Many causes of GI bleeding associated with complications of AIDS have been reported, including localized solitary ulcers in the esophagus or bowel, bleeding duodenal or gastric ulcers with or without associated use of nonsteroidal antiinflammatory agents, and extensive mucosal KS.

The clinical presentation of gastrointestinal hemorrhage in an AIDS patient is the same as in a non-AIDS patient and the basic concepts of resusitation also are the same.

Diagnosis

The endoscopic and radiologic techniques available for the evaluation of GI hemorrhage should be used. Bleeding lesions often can be visualized by endoscopy and controlled locally, while diagnostic material is obtained.

Treatment

The basic approach to GI hemorrhage is the same in AIDS and non-AIDS patients. The proper manangement

of GI bleeding depends upon the precise cause and undoubtedly is related to local expertise. An attempt to determine the cause should be made in every case of hemodynamically signiÞcant bleeding. In addition to possible local control, the nature of any underlying lesions must be determined. If related to a solitary ulcer, surgical excision should be considered. Proper management of bleeding neoplasms involves effective local control followed by systemic chemotherapy. Techniques that have been utilized successfully include injection sclerotherapy of bleeding lesions of KS, and angiographic embolization of a bleeding ulcer. Thus, the proper approach to GI bleeding in an AIDS patient probably is not different from an immunocompetent patient.

THE ACUTE ABDOMEN

Etiology and Pathogenesis

Abdominal pain is an important symptom in AIDS patients. The major enteric pathogens such as cryptosporidium, CMV, salmonella, and shigella cause abdominal *cramps* and not *pain*, though widespread MAC infection may present with chronic abdominal pain. Severe acute abdominal pain often is a sign of a signiÞcant pathologic process, such as a perforated viscus. The clinical signs of abdominal tenderness, guarding and rebound have the same signiÞcance in AIDS patients as in immunocompetent patients. It is important to remember that AIDS patients may develop peritonitis for the same reasons as patients without AIDS, plus reasons speciÞc for AIDS itself. Cholecystitis may occur but usually is acalculous. Perforated viscus occurs in AIDS, but the cause may be a solitary intestinal ulcer rather than peptic ulcer disease or diverticulitis. Malignant intestinal obstruction usually is due to Kaposi's sarcoma or lymphoma rather than adenocarcinoma. Kaposi's sarcoma and lymphoma also may be responsible for perforation (119) or be the leading edge in an intussusseption.

Clinical

The clinical presentations of appendicitis, cholecystitis or generalized peritonitis are the same in AIDS and non-AIDS patients and the correct diagnosis can be made using similar criteria. It is important to recognize that extensive MAC infection in the retroperitoneum may lead to liquefaction necrosis of retroperitoneal nodes and the production of peritonitis similar to that seen in tuberculosis peritonitis. In this circumstance, surgery is not helpful and should be avoided.

Diagnosis

While the physical Þndings in a patient with an acute abdomen may be unaffected by the presence of AIDS, the laboratory Þndings may differ. This is particularly true of the blood count. Elevations of the leucocyte count with a left shift count may be absent, especially if there is preexisting leukopenia or prior treatment with myelosuppressive drugs such as zidovudine. Imaging studies such as CT scan may be valuable in detecting extraluminal collections of pus or ßuid. Isotopic imaging studies such as an indium-labeled white blood cell study or gallium scan may be falsely negative in the presence of severe leukopenia.

Treatment

While the indications for surgery are the same in the AIDS and the non HIV-infected patient, the expected results may differ. The possibility of unusual pathogens is higher in AIDS patients, and the possibility of impaired wound healing is increased in debilitated patients, irrespective of HIV infection. The reported incidence of postoperative complications and mortality was high in the pre-HAART era (119), but this is due, at least in part, to the seriousness of the underlying illness, and other complications. However, recovery after surgery is possible and may be followed by prolonged survival.

Some centers approached the question of laparotomy in AIDS patients with caution (120,121), while other centers have shown that speciÞc subgroups of patients, such as patients undergoing splenectomy for refractory thrombocytopenia, had an acceptable postoperative mortality (122Ð125). Further experience has shown that, with the appropriate indication and clinical status, laparotomy can be carried out with expectation of clinical beneÞt. Laparoscopic surgery also can be performed and lead to signiÞcant clinical beneÞt.

Operating on a patient with AIDS entails extra personal risk to members of the surgical team, both from needle sticks and from contact with blood or body secretions by mucous membranes. The risk of nosocomial infection by hepatitis, tuberculosis or other illnesses during surgery has long been recognized. The potential risks to the surgical team can be minimized by wearing extra layers of gloves, using face masks or other devices to shield the mucous membranes from splattering of ßuids, separating needles from suture material and removing them and other sharp instruments from the immediate surgical Þeld, and using laparoscopic techniques when possible.

Chapter 21

Neoplastic Complications of HIV Infection

Paula O'Connor and David T. Scadden

The hallmark of human immunodeÞciency virus (HIV) infection is decreased cellular immunity resulting from the preferential infection and destruction of CD-4 T-cells. This impairment of the immune system decreases the ability of HIV-infected individuals to contain certain viral infections, to respond to tumor antigens or to maintain normal cytokine homeostasis. The neoplasia seen in the setting of HIV infection is a consequence of these abnormalities. KaposiÕs sarcoma (KS), primary effusion lymphoma (PEL), plasmablastic/multicentric CastlemanÕs disease (MCD), non-HodgkinÕs lymphoma (NHL), HodgkinÕs disease (HD), and anogenital carcinomas are all seen with increased frequency in the setting of HIV infection. All but a subset of NHLs are preceded by viral co-infection with KaposiÕs sarcoma herpes virus (KSHV), Epstein-Barr virus (EBV), or human papilloma virus.

In this chapter the pathogenesis, clinical presentation, and treatment of the neoplasias known to arise more frequently in the setting of HIV infection will be reviewed. In addition, we will brießy discuss the complications commonly encountered while treating HIV-infected individuals with chemotherapy and comment upon the concurrent use of HAART during treatment for HIV-associated neoplasia.

KSHV RELATED DISEASE

KaposiÕs Sarcoma

Epidemiology

Initially described in 1872, KaposiÕs sarcoma (KS) was a rare tumor seen in individuals of Mediterranean, eastern European, and sub-Saharan extraction. It was called classic KS when diagnosed in elderly individuals from the Mediterranean and eastern Europe, and endemic KS when diagnosed in individuals from sub-Saharan Africa.

In the 1980s increased rates of KS in young gay men heralded the onset of the AIDS epidemic. At its peak incidence, approximately 20% of patients with AIDS had KS. This epidemic form of KS represented a 73,000 fold increased incidence of KS above that seen in the general population (1,2). KS was seen most frequently in men having sex with men (2). People infected with HIV via blood product contamination or intravenous drug use comprised less than 5% of those with HIV and KS. Promiscuity and oral fecal contact were subsequently identiÞed as risk factors (3), raising the suspicion of an infectious cofactor. In 1995, Moore and Chang detected KSHV, also known as Human Herpes Virus 8 (HHV8), in the lesions of patients with KS using a comparative analysis of the genetic differences between KS lesions and normal skin (2a).

The role played by race and gender in the development of KS is not well understood. KS has consistently been shown to have decreased incidence in women, but early reports of decreased incidence in African American men have not been consistently reproduced (2b).

KS was the most prevalent neoplasm arising in the setting of HIV infection at the peak of the AIDS epidemic. With the advent of highly active anti-retroviral therapies (HAART), KS incidence has declined sharply. This has been conÞrmed by investigators in Australia, Europe, and the U.S. (4Ð6). In some cases the declining incidence of KS antedated the widespread use of HAART. However, the rate of decline accelerated signiÞcantly with its introduction.

Reasons for the decreased incidence of KS prior to the initiation of HAART include earlier detection of HIV infection and a declining incidence of AIDS (7). Public health initiatives to prevent the spread of HIV may perhaps have contributed to the decline by decreasing transmission rates of KSHV. Improved opportunistic infection prophylaxis and treatment may have further contributed to the

Paula OÕConnor: ???.
David T. Scadden: Massachusetts General Hospital, Boston MA 02129.

decline in KS by reducing levels of inßammatory cytokines known to synergize with HIV-1 Tat to promote angiogenesis and KS (8). Other effects of HAART which may be relevant include decreasing the stimulation of KSHV replication by HIV-1 Tat and preserving or restoring immune function necessary to control viral infection (9). In addition, recent animal model experiments have suggested that protease inhibitor anti-HIV medications may directly impair angiogenesis and progression of KS (10).

KS Pathology and Pathogenesis

KS is a multifocal angioproliferative disease. KS lesions consist of endothelial cells lining ectatic vascular spaces surrounded by spindle cells. These spindle cells are considered to be the neoplastic component of the KS lesion. The spindle cells are admixed with an inßammatory inÞltrate and extravasated red blood cells giving the lesions their characteristic red-purple hue.

KSHV has been detected in the endothelial cells and spindle cells of the KS lesion (11). The virus is a complex gamma herpesvirus with genes encoding many cellular protein homologs including bcl-2, interleukin 6 (IL-6), macrophage inßammatory proteins (MIP-I, MIP-II), and cyclin D-1. Like other well known gamma herpesviruses such as Epstein-Barr virus (EBV) and herpesvirus saimiri (HSV), KSHV encodes for gene products that are capable of inducing malignant transformation (12,13) when transfected into cells. Among these is the latent nuclear antigen LANA. LANA has been shown to transform rat Þbroblasts through its interaction with the retinoblastoma susceptibility protein (pRB) (13). The pRB protein plays a signiÞcant role in cellular proliferation, differentiation, and senescence. Other transforming proteins encoded by KSHV include K-1, K-12 (14,15), but it should be remembered that each of these genes has been tested in artiÞcial *in vitro* settings. It is unclear if these gene products contribute to tumor formation *in vivo* or whether chemokine or cytokine homologues affect local microenvironments or whether the constitutively active chemokine receptor encoded by KSHV is able to alter cellular physiology sufÞciently to facilitate oncogenesis.

The ability of KSHV to encode gene products that transform cells, the virusÕ ubiquitous presence in KS lesions of classic, endemic and epidemic type and evidence that KSHV infection precedes tumor transformation, all strongly support a causative role for the virus in KS (16Ð18). The issue of whether KS is a clonal malignancy is more complex. Judde et al demonstrated monoclonal terminal repeats in KS lesions suggesting outgrowth of the tumor from a single clone of KSHV infected cells (19). Others have analyzed the patterns of X-chromosome inactivation similarly demonstrating the clonality of KS cells (20Ð22). However, some studies have suggested polyclonal activation (22) rendering the clonal issue still unresolved.

Immunosuppresion appears to play a central role in the development of KS despite the fact that KS has been described in patients with variable CD-4 cell counts. It generally occurs with advanced immunosuppression, however, and has been described in patients immunosuppressed for reasons other than HIV infection such as organ transplantation (23Ð26). Such tumors are generally quite responsive to immune restoration with rapid regression seen when immunosuppressive drugs are reduced. Similarly, Cattelan and colleagues reported a correlation between tumor response and increased CD-4 count and decreased HIV-viral load (27). As immune restoration occurs in the months following initiation of HAART, the majority but not all patients with KS will have improved tumor control.

Clinical Presentation and Diagnosis

HIV associated KS differs from classic KS in its proclivity to present systemically, involving the skin, the GI tract, and the viscera. Although KS in AIDS patients most commonly presents as erythematous, non-tender, macular, papular lesions involving the skin, it also commonly involves mucosal surfaces of the oropharynx, upper and lower respiratory tract, and gastrointestinal tract and may involve abdominal viscera. KS frequently involves the lymphatics and lymph nodes, in which case patients present with associated edema local and distal to the site of involvement. Edema is commonly found in advanced KS due to the combined heightened permeability of KS vasculature, the release of vascular endothelial growth factor (VEGF) by tumor tissue enhancing permeability of normal vessels and tumor disruption of lymphatic drainage.

At the height of the U.S. AIDS epidemic, KS was among the most frequent presenting signs of HIV infection. While no longer as common, it is not an infrequent indicator of HIV positivity, though not the sole cause of hyperpigmented macules in HIV-infected individuals. The diagnosis of cutaneous KS requires differentiation from other non-blanching skin conditions such as bacillary angiomatosis. Bacillary angiomatatosis is seen with increased frequency in patients with HIV infection and may be differentiated from KS by obtaining a punch biopsy of the skin and staining to exclude Bartonella infection. As this entity is curable with antibiotics, it is clearly important to distinguish it from KS.

The diagnosis of pulmonary, gastrointestinal or visceral KS should be entertained when a patient with HIV infection and a known history of KS presents with unexplained cough, chest pain, hemoptysis, shortness of breath, gastrointestinal bleeding or abdominal pain. It must be noted, however, that patients with KS may present with disease limited to the skin, the viscera, or involving both the skin and the viscera. The presence of disease in one area does not rule out its presence elsewhere.

The gastrointestinal tract is the most common site of extra-cutaneous KS. It most commonly involves the stomach, the small and large bowel (28). It may be detected using endoscopy or barium upper and lower gastrointestinal series. Endoscopy reveals ßat and nodular mucosal lesions while barium studies reveal nodular KS lesions and diffuse wall thickening. CTs may also reveal luminal disease and give information regarding lymphadenopathy, masses, and organ involvement as well. Like mucosal KS, hepatic and splenic KS may occur but are most often asymptomatic and not necessarily a basis for aggressive therapy.

Pulmonary KS is the second most common site of extracutaneous disease and is the most life threatening manifestation of the disease. There are no deÞnitive radiologic criteria for the appearance of pulmonary KS on x-ray or CT scan, however pulmonary KS may appear as a coarse interstitial pattern with thickened bronchovascular bundles or multiple poorly deÞned nodules scattered throughout the lung. Pleural effusions frequently accompany interstitial disease and may be hemorrhagic. Parenchymal lung disease generally does require aggressive management with systemic chemotherapy to avoid signiÞcant respiratory compromise.

Staging

The staging system for KS devised by the AIDS Clinical Trial Group (ACTG) divides KS into good and poor risk categories based upon tumor burden, immune status, and HIV-1 viral load (29,30). Good risk patients are those with KS limited to the skin, lymph nodes, and oropharyngeal palate. Palatal lesions in good risk patients must be ßat. Good risk patients are considered those with a CD-4 count greater than 200 cells/mm^3, no B symptoms (fever, night sweats, $>10\%$ weight loss) and no previous history of opportunistic infections, including thrush. Poor risk patients are those with a large tumor burden, deÞned as bulky oropharyngeal, gastrointestinal, and pulmonary disease. KS lesions with associated edema and ulceration are also placed in the large tumor burden category. CD-4 cell counts less than 200 cells/mm^3, B symptoms, a history of opportunistic infections and other illnesses associated with advanced HIV disease are characteristic of poor risk patients.

Therapy

KS therapy may be local or systemic. The approach is guided by the impact of the tumor on the patient, risk for treatment related toxicity, and immune status. Patients should be questioned about pain, edema, bleeding, respiratory compromise, abdominal pain, difÞculty eating, isolation as a result of visible skin lesions, HIV stage and HIV therapy before deciding upon a treatment plan. Patients with good or poor risk disease who have not initiated anti-retroviral therapy should begin such therapy before embarking on speciÞc KS treatments. HAART, alone, is capable of inducing KS remission in some patients in 8Ð12 weeks (31Ð34). Patients presenting with poor risk disease and impending visceral crisis may initiate cytotoxic therapies, along with HAART, to control their disease more rapidly. These cytotoxic therapies may then be tapered or discontinued once disease control has been established.

Long-term cytotoxic therapies may be considered for those patients presenting with poor risk disease despite effective HAART therapy. When disease control has been established, the cycle length of the therapy may be tailored to maximize quality of life and maintain disease control.

The response of KS lesions to therapy is variable and depends upon the duration and extent of the lesion. Long-standing lesions are frequently large, nodular, and darkly pigmented. They are less likely to resolve completely. Lesions may become ßattened, exhibit central clearing, and decreased edema but frequently maintain some pigmentation because of extravasated red blood cells and hemosiderin staining of the skin. This hyperpigmentation can be expected to gradually fade but the pace of resolution is often measured in months to years.

Local Therapies

Intralesional vinblastine, cryotherapy, laser therapy, and radiotherapy given in single and multi-dose fractions have all been used with varying rates of success to treat localized good risk KS (35Ð37). The beneÞts of these approaches include minimal side effects and a short duration of therapy. Their complications include pain, Þbrosis, ulceration, mucositis, secondary infection and scarring.

Topical 9-cis-retinoic acid (Aliretinoin) has also been approved by the U.S. Food and Drug Administration (FDA) for KS treatment. It is effective when used topically and in some cases when given orally (38). The side effects include headache, dry skin, hyperlipidemia, and pancreatitis when it is given orally. Topical therapy needs to be judiciously applied as local reactions can be substantial.

Interferon-alpha has been used to treat KS locally as well as systemically. The known anti-HIV, anti-angiogenic, anti-proliferative, and pro-immunologic activities of interferon were thought to optimally suit it for treating KS, and it can be effective in producing KS remissions, taking approximately 10 weeks to induce maximal effect. However, ßu-like symptoms, depression, leukopenia and liver function abnormalities may be limiting. In general, interferon should be coupled with HAART and doses as low as 2 million units/tiw have been shown to be active in the setting of combined anti-retroviral and interferon therapy (39).

Systemic Therapies

Chemotherapeutic agents used to treat KS include Paclitaxel, Vinblastine, Vincristine, Etoposide, Bleomycin, Doxorubicin, and Daunorubucin (40–46). Caution must be used in interpreting the response rates of therapeutic trials using these agents. Due to the frequent residual pigmentation, bidimensional tumor measurements often underestimate meaningful response rates in more recent clinical trials. However, other parameters of benefit were sometimes used in older studies tending to inflate response rates, though perhaps these are more closely aligned with patient and clinician estimates of benefit. ABV (Adriamycin, Bleomycin, and Vincristine) combination therapy has a response rate of 50–88% but also has a substantial side effect profile. Nausea, vomiting, peripheral neuropathy, neutropenia and Raynaud's phenomenon are among those side effects that are frequently described. As a consequence investigators have more recently used single agents with good activity but fewer side effects to treat KS.

Liposomal Doxorubicin (20 mg/m2) has induced responses in 46–50% of treated subjects in phase III trials when given at 3 week intervals as compared with a 25% response rate in subjects treated with ABV (47). Liposomal Daunorubicin (40 mg/m2) given at two-week intervals has also been tested against ABV (48). The response rates were equivalent but the toxicity significantly less with the single agent.

Paclitaxel (100 mg/m2) appears to be the most effective single agent regimen for KS, producing response rates of 50–70% when given at two-week intervals (46,49). These responses are seen in naïve subjects as well as those who have been previously treated with liposomal doxorubicin (50). The side effects of paclitaxel and liposomal doxorubicin are typically mild and include mild cytopenias and fatigue. Paclitaxel may also cause peripheral neuropathy, joint aches, and alopecia.

The duration of remission induced by liposomal doxorubicin or paclitaxel is variable ranging from months to years. Patients failing one may be treated with the other with excellent response. The interval of therapy with liposomal doxorubicin or paclitaxel may be tailored to each individual patient. All patients should begin with therapy at two to three week intervals depending upon the agent used. Once disease control is established the interval between courses of therapy may be extended. Chemotherapy may be reduced in frequency based on durability of tumor response once a stable HAART regimen has been established.

Angiogenesis inhibitors such as Thalidomide, IM-862, TNP-470, Col-3, and vascular endothelial growth factor (VEGF) receptor inhibitors have been used to treat KS in phase I and II trials given the vascular nature of the tumor (51–54). They have produced variable response rates and their role in future KS treatment remains to be determined.

The incidence of KS among patients receiving antiviral therapy with ganciclovir or foscarnet is low suggesting a role for anti-viral drugs in the control of KSHV. Ganciclovir, Foscarnet and Cidofovir have been shown to control KSHV *in vitro* (55–58). Cidofovir has also been shown to decrease KSHV cytoviremia, and induce KS remission in scattered anecdotal reports (59–61). The response to antiherpesvirus drugs is generally not substantial enough to merit their routine use for tumor therapy, however.

The decreased incidence of KS in women has led to an investigation of hormonal agents in the control of KS. An associated protein found in certain preparations of human chorionic gonadotropin (HCG) has been shown to induce KS regression (62,63). Once again its utility remains to be determined.

Multicentric Castleman's Disease

KSHV is a lymphotropic virus similar to EBV. KSHV infection has been implicated in the development of multicentric Castleman's disease (MCD) and primary effusion lymphoma, lymphoproliferative disorders seen with increased frequency in patients infected with HIV. As in the case of KS, KSHV transcripts have been detected in tissue samples of MCD, however, the role of KSHV in the development of this disorder has not been well defined.

Epidemiology

Castleman's disease was first described in 1956. It is a rare disorder that is divided into two broad categories, unicentric or localized and multicentric. Unicentric Castleman's occurs in non-HIV-infected individuals, while multicentric Castleman's, the plasmablastic variant, occurs most frequently in the setting of HIV. KSHV has been almost uniformly detected in cases of plasmablastic MCD (64–67).

Pathology and Pathogenesis

Plasmablastic MCD is characterized by preservation of typical lymph node architecture despite a pronounced interfollicular plasma cell infiltrate (11–19). KSHV infected B-cells in the mantle zone express lytic and latent antigens including vIL-6 and LANA (66,68,69). vIL-6 is homologous to hIL-6, which plays a significant role in B-cell proliferation, while LANA has transforming potential.

The mechanisms by which KSHV may induce MCD are not clear, however, expression of the known B cell proliferative factor, vIL-6 produced by KSHV has been consistently noted (69a,69b). Of note, the rhesus rhadinovirus, which is closely related to KSHV and also encodes a vIL-6 homolog, induces an MCD-like syndrome when

inoculated into SIV (simian immunodeficiency) infected macaques (70–72). In addition to virus specific products, however, clinical studies have indicated that active MCD correlates with higher circulating levels of host derived B cell stimulating cytokines such as IL-6 and IL-10 (72a). The relative contribution to B cell proliferative drive of KSHV gene products versus host immune activation is not clear, but multiple stimuli appear to interact in the development of this often devastating complication of HIV.

Judde and his colleagues examined the terminal repeat segments of KS, MCD, and primary effusion lymphoma samples to assess their clonality (19). No clonality was found among the terminal repeats of the MCD samples. This syndrome may represent a polyclonal proliferation in response to KSHV infection of B cells.

Clinical Presentation and Therapy

Multicentric Castleman's disease is characterized by fever, lymphadenopathy, and organomegaly. Diagnosis requires a lymph node biopsy. The clinical course of MCD occurring in the setting of HIV is often aggressive, perhaps more aggressive than that occurring in the non-HIV infected (67,73,74). Durable clinical remissions despite therapy are rare. Up to 25% of patients go on to develop non-Hodgkin's lymphoma (75,76) and concurrent KS is common.

Therapies used to treat MCD include chemo and radiation therapy, antiviral, and anti-CD-20 monoclonal antibodies (74,77,78). Chemotherapy has been utilized most often but anti-CD 20 antibodies appear to have substantial activity in limited anecdotal reports. No reports of combination therapy are available to date.

Primary Effusion Lymphoma

Primary effusion lymphoma (PEL) accounts for $<3\%$ of the non-Hodgkin's lymphomas encountered in the setting of HIV infection (79). It is generally an agonal complication of advanced HIV disease (80). Like KS, it is most often found in HIV positive homosexual and bisexual men. PEL has been described in non-HIV infected individuals. In these cases patients are generally older and immunocompromised (81–83).

PEL cells are characterized by the uniform expression of KSHV and near uniform expression of EBV gene sequences (84–86). The cells exhibit immunoblastic cytology, indeterminate immunophenotype, and B-cell genotype, evidenced by immunoglobulin gene rearrangement. CD-45 and CD-30 are frequently expressed (84,87). MYC rearrangements are absent and BCL-6 mutations have been described (88). Latent KSHV and EBV gene products are capable of inducing transformation. Beyond this little is known about the pathogenesis of PEL. Constitutive activation of NF-kB may play a role in preventing apoptosis of PEL cells, while vIL-6 may promote cell growth (89,90).

Patients with primary effusion lymphoma typically present with pericardial and pleural effusions or new onset ascites with scant lymphadenopathy. There is no staging system. Treatment is palliative. Radiation, modified CHOP, and Liposomal Doxorubicin and Daunorubicin have been utilized with minor success (91–94).

EBV Related Disease

The gammaherpesvirus EBV has been implicated in the development of lymphoid malignancies including HIV-associated Hodgkin's disease (HD), primary CNS lymphoma, systemic AIDS related lymphoma (S-ARL) and PEL. The role of EBV in AIDS associated Burkitt-lymphoma is unclear, but appears to be small. EBV has been implicated in the development of nasopharyngeal carcinoma. This does not occur with increased frequency in the setting of HIV infection.

EBV is a lymphotropic virus that avoids immune detection by establishing latent infection. Differential gene expression during latent infection is associated with the development of different tumors. Latency pattern I is associated with the development of BL and PEL; latency pattern II with the development of HD and nasopharyngeal carcinoma; and latency pattern III with CNS, S-ARL, and post transplant lymphoproliferative disease (PTLD). EBV latent membrane protein 1 (LMP-1) is expressed in latency patterns II and III. The LMP-1 interacts with tumor necrosis factor receptor (TNFR) signaling pathways that activate NF-kB effecting apoptosis and cell growth. LMP-1 has demonstrated transforming potential (95).

The mechanism by which HIV infection promotes the development of EBV lymphoproliferative disease is poorly understood. However, it is clear that virally induced immune activation in the setting of decreased cellular immunity, and viral immune evasion play pivotal roles.

Hodgkin's Disease

Epidemiology and Clinical Presentation

The excess risk for HD in the setting of HIV has been measured at 3–18 times the risk for HIV negative individuals. 80–100% of these are EBV associated (96,97). The predominant histologies are mixed cellularity and lymphocyte depleted. Cases of HIV-associated HD in patients with CD-4 counts <10 and as high as 1300 cells/mm^3 with a median between 120 and 250 cells/mm^3 have been reported (98–101). The risk for HD appears to rise with advancing immunodeficiency. Gender, ethnicity, and intravenous drug use do not appear to alter the risk for HD development (102–104).

HIV-associated HD is typiÞed by advanced stage and the presence of B-symptoms: fever, night sweats, and >10% weight loss. Non-HIV associated HD is characterized by the spread of disease via contiguous lymph-node groups. HIV-associated HD frequently spreads in a non-contiguous pattern and frequently involves extranodal sites (98,101,105,106). Among the sites reported are the tongue, rectum, skin, and lung. The bone marrow is the most frequently observed site of extranodal involvement, occurring in 40Ð50% of patients at presentation.

The advanced stage and extra-nodal presentation of HIV-associated HD may be a reßection of altered HD biology in the setting of immunocompromise but may also be a reßection of late diagnosis. The diagnosis of HD requires differentiation from the persistent generalized lymphadenopathy seen in HIV infection, chronic infection with mycobacteria and fungi, CMV, and non-Hodgkin's lymphoma. Enlarged lymph nodes should be biopsied if they are rapidly growing or unchanged over weeks. It should be remembered that needle aspirates are often non-diagnostic in HD and that excisional biopsy is often required.

The Ann-Arbor staging system is used to stage HIV-associated and non HIV-associated cases of HD.

Therapy

The treatment approach for HIV-infected patients with HD is the same as that for HIV-negative patients. Complete response rates of 45Ð65% have been reported by groups using Adriamycin, Bleomycin, Vinblastine, and Dacarbazine (ABVD), without growth factor support or HAART (100,107). The median survival was 15Ð18 months. No data on response rates with the ABVD regimen since the advent of HAART have been reported. An Italian group using Epirubicin, Bleomycin,Vinblastine ± Prednisone (EBV ± P) with concomitant pneumocystis prophylaxis, AZT or DDI, and growth factor support reported CR rates of 66% with a three year survival rate of 53% (108). This same group has reported the preliminary results of a 20 patient study utilizing the Stanford V regimen in which the CR rate was 80% and the PR rate 15% (109).

Primary CNS Lymphoma

The development of primary CNS lymphoma is an increasingly uncommon and generally lethal complication of advanced AIDS. These lymphomas accounted for up to 15% of all ARL prior to HAART and their incidence was 1,000-fold greater than that seen in the general population. These lymphomas occur in the setting of profound immunosuppression, in patients with CD-4 counts generally less than 50. With the advent of HAART the incidence of primary CNS lymphoma has plummeted (110,111).

These tumors are aggressive, B-cell in origin and EBV related. They express the type III EBV latent gene proÞle of lymphoproliferative disease and are very comparable to post-transplant lymphomas in that regard. Their clinical presentation may be focal or non-focal. Typical symptoms include confusion, headache, seizures, and in some cases cranial neuropathies.

CT and MRI imaging usually reveal multiple ring-enhancing peri-ventricular lesions, however, single lesions have also been described. Attempts to differentiate toxoplasmosis, the most common CNS mass lesion in patients with AIDS, from CNS lymphoma indicate some differences based upon the size and location of the lesion; larger than 2 cm and peri-ventricular favors NHL, extending across the midline occurs only with malignancy. Brain biopsy represents the gold standard for making the diagnosis of primary CNS lymphoma (112). However, lumbar puncture with evidence of EBV DNA using PCR is 100% sensitive and 98% speciÞc for the diagnosis in some studies and is signiÞcantly less invasive (113). Single photon emission computed tomography (SPECT) thallium 201 and positron emission tomography (PET) scanning may also help in making the diagnosis (114,115). Increased uptake is seen with primary CNS lymphoma.

Therapies for primary CNS lymphoma are limited. They include radiation and HAART. Whole brain radiotherapy (30Ð60 Gy) combined with steroids results in response rates of approximately 75%, with a median survival of approximately three months (116). Combination chemotherapy and radiation appears to add only toxicity while high dose methotrexate may offer a reasonable alternative to radiation therapy (117Ð120). HAART has been associated with spontaneous remissions without other systemic or local therapies but is generally used in addition to other therapies (121). Given the universal involvement of EBV in primary CNS lymphoma, a regimen of ganciclovir, azidothymidine (AZT), and IL-2 was developed (122). This regimen appears to have some anti-tumor effect, but the results are preliminary.

Systemic AIDS-Related Lymphoma

The most common systemic ARLs are aggressive B-cell tumors. Immunoblastic, diffuse large cell (DLCL), Burkitt, and Burkitt-like lymphomas occur with relative risks of 650, 110, and 260, respectively (1,2,123). Indolent NHLs may also occur with increased frequency in the setting of HIV, but the magnitude of increase is modest. A relative risk 14-fold greater than that seen in the general population has been reported (1). Risk factors for the development of S-ARL are not completely deÞned. Immunosuppression is among the risk factors as is viral co-infection but their precise roles are not completely clear. 35Ð65% of S-ARLs are EBV related and less than

3% are KSHV related. Median CD-4 counts at diagnosis range from 50–191 cells/mm^3 for immunoblastic and DLCL variants and higher for the Burkitt and Burkitt-like variants (3,124–126).

The impact of HAART on the development of S-ARL is still in the process of being deÞned. S-ARL incidence has been reported to be decreasing as well as to be remaining static (126a,126b). Similarly, the degree of immunosuppression at which S-ARL develops has been reported to be increased, as well as decreased (127–129). These differences likely reßect patterns of access to HAART and other medical care. Overall, the most recent and longest studies have indicated that the overall decline in S-ARL is approximately 50% (129a).

The majority of patients presenting with S-ARL are Caucasian and male. However, the numbers of Black, Latino, and female patients with S-ARL appear to be increasing, likely reßecting changes in the pattern of HIV infection. Differences in the rates of NHL among Caucasians and other ethnic groups may also be a reßection of polymorphisms of the CXCR-4 chemokine receptor, which confers increased risk for NHL and is most often found in Caucasians (130,131).

Pathogenesis and Pathology

HIV promotes the development of NHL, EBV related or unrelated, by impairing immune surveillance, producing chronic antigen stimulation, and dysregulating cytokine expression. This allows for oligoclonal B-cell proliferation during which genetic lesions capable of producing malignant transformation accumulate, resulting in the development of a malignant clone. Among the genetic rearrangements noted in S-ARLs are BCL-6, and c-myc rearrangements. These are found in approximately 33 and 40% of DLCLs, respectively (132–137). C-myc rearrangements have been found in 70–100% of HIV associated Burkitt and Burkitt-like lymphomas (138–140). P53 and Ras mutations have also been reported (135,141).

The histologic features of S-ARL are similar to those of NHL in HIV-uninfected patients. S-ARLS, however, tend to display a greater number of mitotic features consistent with a higher growth fraction and more aggressive natural history (142,143).

Plasmablastic NHL is a rare S-ARL (144). The tumor cells are plasmablasts expressing CD-138. There is weak or no expression of CD-20 and CD-45 (145). Plasmablastic lymphomas typically present in the oral cavity and jaw (146,147).

The majority of S-ARLs are of B-cell origin. However, T-cell ARLs have been described. Demonstration of HIV sequences upstream of the c-fes proto-oncogene suggests a direct role for HIV in the development of a subset of these lymphomas.

Clinical Presentation and Staging

Extranodal disease is a characteristic of S-ARL with 50–60% of patients presenting with disease limited to extra-nodal sites. The most common sites of extranodal disease include the bone marrow, CNS, and GI tract. The small bowel, ileum and rectum are the areas of the GI tract most commonly involved. The presenting symptoms of S-ARL are highly variable given these unusual sites of involvement. B symptoms, fever, night sweats, and weight loss are common, often reßecting a large burden of disease.

Diagnosis of ARL requires documentation of a clonal process utilizing ßow cytometry and/or pathology with immunophenotyping stains and cytogenetic analysis. The initial evaluation of patients suspected to have ARL should include CD-4 count, HIV viral load, notation of previous anti-retroviral therapy and opportunistic infections, uric acid, and LDH, as these factors may inßuence treatment options, reßect prognosis, and risk for complications during therapy. Microbiologic evaluations for *Pneumocystis carinii*, cytomegalovirus, *Toxoplasma gondii*, Mycobacterial disease, and Cryptococcus should be undertaken in patients presenting with B symptoms and CD-4 counts less than 200 cells/mm^3.

Staging for S-ARL is similar to that employed for lymphoma patients without HIV infection. It should include CT imaging of the chest, abdomen and pelvis with contrast in addition to the studies noted above. Head CT or MRI, and lumbar puncture should also be included in the initial evaluation, given the higher risk for CNS involvement in patients with ARL (117).

Therapy

CD-4 count less than 100 cells/mm^3, age over 35, advanced stage (III/IV) and intravenous drug use are among the prognostic indicators identiÞed for poor prognosis prior to the advent HAART (148,149). Subsequent analyses have identiÞed LDH, Karnofsky status, prior AIDS deÞning illness, extranodal disease with extensive bone marrow involvement, and high grade histology as predictors of risk (127). The International Prognostic Index has been validated for use in the setting of HIV (150), though the magnitude of the studies has been limited to date.

For those patients successfully using anti-retroviral therapy, treatment options for ARL are increasing and include dose intensive therapies. HAART has made aggressive therapies previously considered untenable in AIDS, generally more tolerable and the rationale for intensive therapy more reasonable. Prior efforts to minimize the toxicity of anti-tumor therapy due to the generally poor functional status of the patients have largely been supplanted by efforts to maximize the chance for cure of these aggressive, but chemosensitive tumors.

Half-standard dose therapies such as m-BACOD were tested prior to the advent of HAART. They were shown to be active with equivalent tumor outcomes, but have reduced toxicity compared with full dose chemotherapy (151). However, results from other studies using half dose CHOP have raised concern about inferior tumor control (152,153) and current practice is to restrict such dose compromised regimens to those patients with advanced AIDS who are considered HAART failures or unable to tolerate full dose therapy due to concurrent complications.

Outside the setting of end-stage AIDS, full dose regimens such as CHOP have become standard practice with complete response rates documented in the 48–63% range (152–154). Further, recent experience with infusional regimens has suggested that dose delivery may offer promising alternatives. Infusional cyclophosphamide, doxorubicin and etoposide (CDE) over a 96-hour interval was tested under the direction of Sparano and colleagues and was shown to be highly active with a complete response rate of 58%, confirmed at 46% in a follow-up multi-institutional trial (155,156). The U.S. National Cancer Institute (NCI) has tested dose adjusted EPOCH (157,158) and demonstrated durable complete responses in over 75% of patients. The recent improvement in the treatment of aggressive lymphomas by adding rituxan to CHOP has prompted testing of this regimen in ARL in a multi-center phase III trial by the AIDS Malignancy Consortium (AMC), which is nearing completion. Combining rituxan with infusional CDE was well tolerated and resulted in a highly encouraging 86% complete response rate in a preliminary report by Tirelli and Sparano (156).

Second line therapy has always been problematic in S-ARL due to poor tolerability and response rates. However, with the impact of HAART, there is considerably better tolerance and efforts to use more aggressive regimens are again underway. The use of high dose regimens requiring autologous stem cell rescue has been reported to be reasonably tolerated with no difficulty in engraftment (159,160). Non-myeloablative allogeneic transplants are also of considerable interest, but should only be undertaken in the context of clinical trials.

It remains an issue of debate as to whether anti-HIV medication should be continued during the course of cytotoxic chemotherapy. Concurrent anti-retroviral (stavudine, lamivudine and indinavir) in combination with CHOP chemotherapy was tested by the U.S. AMC assessing pharmacokinetic as well as clinical parameters. While no untoward or unexpected toxicities were observed, the clearance of cyclophosphamide was reduced by approximately 50%. In contrast, no alteration in the clearance of doxorubicin or indinavir was noted (160a). A report in which multiple regimens were used documented a higher incidence of hematologic and neurologic toxicity in those receiving HAART along with chemotherapy, which was offset by an improvement in infection and survival rates (154). An alternative approach was adopted by the U.S. NCI where all anti-retrovirals were held during EPOCH chemotherapy. A rise in HIV viral load and decline in CD-4 counts was observed as expected, but both parameters normalized following re-introduction of medications at the end of tumor therapy (161). Weighing the relative tolerance of the anti-virals with the potential for interactions needs to be considered in deciding whether to continue antiretroviral agents; but the anti-HIV medications need to be either stopped or a combination continued, half-measures are to be avoided to prevent the emergence of HIV resistance.

Another therapeutic consideration in the care of patients with S-ARL is whether to use prophylactic CNS therapy to prevent the high incidence of CNS relapse (up to 20%) (117) noted early in the HIV epidemic. Recent data would suggest that in addition to clinical features which have been associated with CNS involvement outside the setting of HIV infection, such as paranasal sinus, bone marrow or testicular involvement, EBV status of the tumor may by important in S-ARL. Cingolani and colleagues documented increased risk for CNS relapse when EBV was present in the primary tumor ($p = 0.003$) (162). These data suggest that CNS prophylaxis with intrathecal chemotherapy may be more selectively applied though no treatment trials have tested this hypothesis.

HPV Related Disease

An increased incidence in genital squamous neoplasia has been documented in HIV-infected individuals since the 1980s (163). Cervical and anal intraepithelial neoplasia (CIN, AIN), presumed to be precursor lesions for invasive squamous cell carcinoma, are the most common manifestations of this disease. However, only invasive cervical carcinoma (ICC) is classified as an AIDS-defining illness, and it is not clear if invasive oral or cervical cancer is increased in the HIV-infected population. Risk factors for the development of squamous neoplasia include immunosuppression (CD-4 < 200), concurrent infection with HPV subtypes 16 and 18, early sexual activity, promiscuity, history of sexually transmitted disease and anal receptive intercourse (164–167).

The magnitude of the problem posed by genital squamous cell neoplasia in the setting of HIV infection is difficult to ascertain. This is well demonstrated by reviewing the rates of CIN and ICC in women dually infected with HIV and HPV. While dually infected women have been shown repeatedly to have a higher incidence of CIN (168,169), whether there is an increased incidence of ICC has been debated. Italian and American linkage analyses have demonstrated increased rates of ICC among HIV-infected women, while studies from Africa and Australia have not (166,170). AIN lesions are reported to occur in 25–45% of HIV-infected homosexual and bisexual men engaging in anal receptive intercourse (171). Progression from low to high-grade dysplasia was documented in 15% of patients observed over 21 months (172).

Despite this an increased incidence of invasive squamous cell carcinoma in men having sex with men has not been convincingly demonstrated.

Expansion of screening programs for genital squamous neoplasia and improved cancer registry documentation of HIV status may help clarify the true extent of this problem. However, whether to institute therapeutic intervention for dysplastic disease, and whether these are truly pre-malignant lesions, remain open areas of debate.

Pathology and Pathogenesis

Cellular disorder, atypia, and the appearance of atypical mitoses are the deÞning characteristics of squamous intra-epithelial lesions (173). Progression of this pattern of cell growth below the basement membrane is described as invasive.

The role of HIV in the development of squamous intraepithelial neoplasia is not well understood. HPV gene products E6 and E7 have demonstrated transforming potential. HIV induced cytokines, growth factors, and proteins like HIV-Tat may alter local cellular immunity, or effect HPV transcription and replication (174,175)

Clinical Presentation and Therapy

Genital squamous neoplasia is typically asymptomatic. Low-grade anal intraepithelial lesions may present as anal condyloma. These may cause discomfort or anal leakage depending upon their size. Invasive squamous disease of the cervix or anus may present with pain or bleeding.

Screening for cervical neoplasia with an annual Papanicolaou (Pap) smear is recommended for HIV-infected women with CD-4 counts >200. Bi-annual exams are recommended for women with CD-4 counts <200. Guidelines for screening the anal canal in men have not been established. Anal pap smears, anoscopy, and anal colposcopy are being used to screen high-risk patients at some medical centers (176,177), though the value of such is unproven at present.

CIN may be treated with ablation or excision using cryotherapy, lasers, cone biopsies and the loop electrosurgical excision procedure. AIN may be treated with excision, imiquimod cream, and observation with biopsy depending upon the size and placement of the lesion (178Ð180). Imiquimod therapy may only be used to treat lesions on the anal verge. CIN and AIN lesions frequently recur in patients with persistent HPV infection so repeat screening and treatment is necessary.

Invasive genital squamous neoplasia should be treated with the same approach used in HIV-negative patients. Combination chemotherapy and radiotherapy may produce bone marrow suppression and radiation induced skin injury, but these may be tolerated with supportive care (181Ð183).

Chemotherapy for AIDS-Associated Malignancy in the Era of HAART

Questions regarding the safety of the co-administration of HAART and chemotherapy have been addressed by several investigators (152,184Ð186). It is clear from these studies, that HAART may be administered safely with at least some regimens of dose intensive chemotherapy. Questions remain, however, regarding the necessity of HAART therapy for maximal tumor control and the timing of HAART initiation in previously drug na•ve or resistant patients.

The magnitude of immunosuppression produced by cytotoxic therapies for HIV-associated malignancies depends upon the underlying malignancy, the pre-existing level of immunosuppression, and the regimen intensity. The greater risk for opportunistic infection in patients undergoing chemotherapy must be weighed against the need for tumor control. HAART may be a way to tip the scales. It may increase the likelihood of achieving complete remission by improving immune function directed against tumor and associated viral antigens, decreasing HIV-associated stimulation of oncogenic viruses, and decreasing the production of inßammatory cytokines, like IL-6, that promote tumor growth and lymphoid stimulation.

HAART is not without risk, however. Zidovudine may cause signiÞcant bone marrow suppression limiting chemotherapeutic options and increasing the risk for opportunistic infection. Protease inhibitors may block the cytochrome P-450 pathway leading to altered metabolism of chemotherapeutic drugs such as cyclophosphamide. Didanosine may potentiate the peripheral neuropathy associated with chemotherapies such as paclitaxel and vincristine. The non-nucleoside reverse transcriptase inhibitor delavirdrine has been associated with severe potentiation of paclitaxol toxicity. In general, the p450 effects of NNRTIs raises concern about particular, unpredictable interactions.

In our institution patients who are taking an effective HAART regimen are encouraged to continue it as long as it is tolerated with the exception of NNRTIs or AZT. Patients who are unable to take their drugs as scheduled because of nausea and vomiting are encouraged to stop their regimen completely rather than compromising dose or schedule of anti-retrovirals to prevent the development of HIV drug resistance. Patients who need to discontinue their HAART regimen have been able to re-establish viral control once their regimen was restarted and this practice is now commonly applied in some centers. HAART na•ve patients are encouraged to begin anti-retroviral therapy after their ability to tolerate chemotherapy has been deÞned to permit clearer discrimination of the source of potential toxic reactions.

AIDS and Other Manifestations of HIV Infection
Fourth Edition, edited by Gary P. Wormser

Chapter 22

Hematologic Manifestations of HIV Infection

John P. Doweiko

The Þrst human retroviruses were discovered in the late 1970s (1). Type one human immunodeÞciency virus (HIV-1), previously known as HTLV-III or lymphadenopathy-associated virus, is a member of the Retroviridae family and the Lentivirus subfamily (2,3). Other members of this subfamily are known to infect other mammalian species. Phylogenetic studies suggest that HIV-1 is a result of cross-transmission from simian viruses, although the exact ancestral point is still unknown (4). HIV-1 has now diversiÞed into at least seven different subspecies (clades). These clades differ in ease and mode of transmission, virulence, and global distribution (4).

HIV-1 infection may have had its origins in the 1940s; it reached epidemic proportions forty years later. Currently, it is estimated that over 1 million people in the United States and over 30 million people world-wide have been infected, making this the greatest lethal epidemic known to man (4,5).

Despite having a relatively simple structure, HIV-1 has a rather complicated mechanism of replication (6). Its genome is encoded within a single strand of RNA that is enclosed within a ÒshellÓ of P-24 protein (7)This is itself contained within a glycoprotein envelope that is studded with the transmembrane P-41 protein to which is attached the GP-120 protein (2,3). The GP-120 glycoprotein is necessary for binding to the CD4 protein of the target cells (8).

HIV-1 is genetically more complex than other members of the Retroviradae family (3). It has a genome of 9.7 Kb in total length, and contains three genes that are characteristic of replicative retroviruses (2,3). The *Gag* gene encodes for the core structural proteins of the virus, the *Pol* gene encodes for the viral enzymes (reverse transcriptase, integrase and protease), and the *Env* gene contains the genetic information for the surface glycoproteins of the virus (8). In addition, the genome of HIV-1 also includes six other genes that are not encountered in other retroviruses and are currently poorly understood (2).

Certain genes of HIV-1 are error-prone, particularly those encoding reverse transcriptase and the envelope proteins. Having this propensity to mutate *in vivo*, progression of the infection within a host is associated with evolution toward a quasi-species composed of viral variants (9Ð11). This allows for extensive genomic variation to develop from a single infecting event.

The CD4 protein is contained on T lymphocytes and cells of the monocyte/macrophage line and is a member of the immunoglobulin superfamily (12). This molecule is in high concentration on T-helper cells and monocytes, designating these cells as the major targets of the infection (13Ð16).Although the CD4 antigen may be the sole high-afÞnity cellular receptor for HIV-1 (13,14), other cell surface proteins act as co-receptors and markedly augment entry into the cell by a factor of at least a ten thousand-fold compared with cell membranes that lack these other proteins (12,17). These other molecules include the chemokine receptors (12). CXCR-4 (fusin) is a co-receptor for strains of HIV-1 that primarily invade T-cell lines. The beta-chemokine receptor CCR5 serves as a co-receptor for strains that infect cells of monocytic lineage (12,17). HIV-1 can also bind to cells by means of other molecules, albeit with much less afÞnity. These alternative receptors include the galactosylcereamide on the cells of the central nervous system, and complement receptors when the virus is part of an immune complex (12).

Other cells also express surface CD4 antigen, rendering them vulnerable to infection by HIV-1 (18). These include Þbroblasts and related cells such as glial cells, and the stromal reticular cells of the bone marrow (13,14). Cells may be infected via routes other than the CD4 antigen (13,14), including galactosylceramide on neurons and enterocytes (12). Entry into cells may also occur via Fc receptors when HIV-1 in bound to antibody within immune complexes (12).

Binding of HIV-1 to the CD4 antigen allows the virus to enter the cell. In addition, other important events that

John P. Doweiko MD: 1 Autumn Street, K-6 Boston, Massachusetts 02215.

result from this binding are inhibition of signal transduction by the T cell CD3 receptor, and secretion of a multitude of cytokines by the infected cell that include interleukin-1B, TNF-alpha, and GM-CSF (12,19).

Some strains of HIV-1 preferentially infect monocytes, while others display selectivity for CD4 lymphocytes (13). This is important to the evolution of the intricate syndrome that results from this viral infection. The major sequellae of HIV-1 infection are degradation of cellular immunity (20). The clinical manifestations of this are the opportunistic infections and neoplasms. The other major result of HIV infection is an ultimately detrimental cytokine response that is deleterious in that it accelerates HIV replication and promotes tissue injury (21–25). During all stages of HIV infection there is dysregulation of cytokines: IL-6, TNF-alpha, Interferon-gamma, and IL-10 tend to be overexpressed, while IL-2, IL-4, and IL-12 are undersecreted (23,26,27). Many of the cytokines that are hyperexpressed result in upregulation of HIV replication (23,28).

The monocyte, as well as the CD4+ lymphocyte, plays an important role in the pathogenesis of HIV infection. Cells of monocytic lineage are central to the complex network of growth factors and cytokines that sustains and regulates the hematopoietic and immune systems (28). In the early phases of infection, monocytotropic strains of HIV-1 predominate over lymphocytotrophic strains (20,29). While HIV assembles almost exclusively on the plasma membrane of CD4 lymphocytes, it can assemble and accumulate within cytoplasmic vacuoles of monocytes and macrophages where it remains hidden from the immune system (16). Infection of cells of the monocyte/ macrophage line is not lethal, making these cells important reservoirs of HIV-1 and vectors for spread of the virus throughout the body (5,24,29). In non-lymphoid tissues, such as the central nervous system, local infection is predominately sustained by cells of monocytic lineage (29,30). Derivatives of the monocyte/ macrophage cell line such as glial cells of the central nervous system may be infected by and harbor the virus (31). Within these cells, the virus may replicate more rapidly than in other tissues (31). Progression of HIV-1 infection is associated with a shift toward more lymphocytotropic variants of the virus (29). This is important to the cellular immune dysfunction that is characteristic of AIDS (24).

One life cycle for HIV is about 1.2 days *in vivo*, with about 0.9 days of this being intracellular and the remainder of time representing the half-life of the virion within the tissues and/or blood (32,33). It was previously thought that after the initial viremia of HIV infection, the virus entered a "latent phase" during which viral replication took place at a very reduced rate. More recent studies have shown that viral replication persists throughout the course of the HIV infection (34,35). During the clinical "latent" phase those infected may be only minimally symptomatic. A large reservoir of HIV-1, however, is sequestered within lymphoid and other tissues wherein viral replication continues (34,36,37), resulting in a ceaseless destruction of the architecture and function of the lymphoid tissues.

HIV-infected persons produce and destroy about 30% of the total body viral burden daily (32,33,38), amounting to billions of viral particles. The clearance of HIV virions is relatively constant during the course of the HIV infection, regardless of the CD4+ lymphocyte counts (25,33). The decline in the CD4+ lymphocyte count that occurs with progression of HIV infection is due to the destructive capacity of HIV-1 for these cells eventually exceeding the replicative capacity of the body (32,33,36,38–40). This results in a progressive deterioration of the cellular immune system (39,40).

Unlike the viral production rate that tends to be fairly constant, there is large variation in the CD4 lymphocyte production rate from patient to patient (25,33). This may explain, in large part, the variations in disease course that occurs among patients. Some of those infected with HIV-1, however, do not succumb to the infection as rapidly as do others (41). In long-term survivors, the viral burden in the plasma and peripheral blood-mononuclear cells is less by several orders of magnitude than in less fortunate patients with similar duration of disease (42,43). These long-term survivors seem to have a vigorous viral-inhibitory CD8 lymphocyte response and a stronger neutralizing antibody response than is typically seen (42). Genetic alterations in the chemokine receptors may also confer some resistance to HIV-1 and promote survival (12).

SPECIFIC CYTOPENIAS IN PATIENTS WITH HIV INFECTION

Infection with HIV-1 is associated with suppression of hematopoiesis (43–46) (Table 22.1). The hematologic perturbations encountered with HIV-1 infection not only have morbidity of their own, but also hinder therapy directed toward the primary viral infection and those toward the secondary infectious and neoplastic complications (47–52). The need to reduce doses or interrupt therapy due to poor hematologic tolerance may cause emergence of drug-resistant organisms, and progression of infections and/or neoplasms (47,48).

Myelosuppressive medications
Autoimmune peripheral destruction
Opportunistic infections involving the marrow
Tumor involvement of the marrow

Anemia

The most common, and well studied, cytopenia associated with HIV-1 infection is anemia. Although anemia occurs less often in the era of HAART than in the past, it remains a signiÞcant clinical problem. The degree of anemia correlates with the stage of HIV-1 infection. Prior to the introduction of HAART, 10Ð20% of people were anemic at the time of presentation, and 70Ð80% eventually become anemic with progression of the infection (49,53). In patients receiving HAART, mild anemia (deÞned as a hemoglobin level of 9Ð11 grams/dL) occurs in about 13% of patients. Severe anemia (hemoglobin levels less than 9 grams/dL) has an overall incidence of about 5% (54,55), particularly in those with advanced HIV infection. In this group, the one-year incidence of anemia was almost 37% in those with an AIDS-deÞning opportunistic infection, about 12% in those with a CD4 count less than 200 and/or a CD4 percentage less than 14, and about 3% in those without clinical or immunologic AIDS (56).

The major cause of anemia in HIV-infected patients is impaired erythropoiesis. The anemia is typically normochromic and normocytic and associated with an inappropriately low reticulocyte count (57). Macrocytosis is unusual, and tends to occur in those treated with zidovudine (57,58). Iron stores are almost always normal or elevated, and there is typically a decrease in serum iron along with a parallel decrease in the total iron binding capacity that is characteristic of the Òanemia of chronic disease.ÓSerum ferritin levels are often increased (57), and these levels tend to parallel the severity and duration of infection with HIV-1 (59Ð61). There may be a positive correlation between iron levels and the replication rate of HIV (62).

While decreases in serum B-12 levels are found in about 20% of HIV-infected patients (62,63,65,66), it is not clear to what extent these low levels contribute to the cytopenias of HIV infection (60,63,67,68). Patients usually do not have other manifestations of B-12 deÞciency, and typically do not improve markedly with parenteral repletion (57,65,66). It has been demonstrated in the non-HIV-infected population, that serum B12 levels may also have poor predictive value (69): Anemia may be absent in patients who are found to be B12 deÞcient using assays that rely on vitamin B12-dependent metabolic pathways (69,70). Macrocytosis may be absent with B-12 deÞciency (70). The low B-12 levels that occur with HIV infection seem to be due to altered serum transport of the vitamin (63,66), but there may be abnormal absorption with advanced HIV infection (63). Considering limited evidence that cobalamins may hinder binding of HIV-1 to the CD4 molecule (65), and the ease and relatively low expense of parenteral administration, this therapy should be considered in an anemic HIV-infected patient with low B-12 serum levels.

While some HIV-infected patients are Coombs positive, this is usually non-speciÞc and not a major contributing factor to the anemia. Sensitive assays show that 2Ð44% of asymptomatic HIV-infected patients are direct Coombs positive, compared with up to 85% of those with AIDS (48,57). This contrasts with about 1% of non-HIV infected blood donors who are Coombs positive (71). While these antibodies may be reactive with speciÞc minor antigens on erythrocytes, most commonly the U and i antigens (48,50,57), they are most commonly due to non-speciÞc binding of anti-phospholipid antibodies or deposition of immune complexes on erythrocytes (48,50,57). Immune hemolysis is very rare (48,51).

Paraproteinemia may occur in upwards of half of HIV-infected patients (57). The peripheral smear may demonstrate rouleau; dimerization or comigration of these proteins during electrophoresis may result in the appearance of a monoclonal protein (57). However, a polyclonal pattern on electrophoresis is more common, and the paraproteinemia does not cause or contribute to the cytopenias seen in HIV-1 infection (57).

Clinical studies have demonstrated that anemia is an independent risk factor for increased morbidity and risk of mortality in HIV-1 infection. In this capacity, anemia is not merely a marker for the degree of severity of the viral infection (72Ð76): The prognostic information provided by the hemoglobin level is independent of the CD4 count, age, history of opportunistic infections, use of prophylaxis of infection, antiretroviral therapy (72), and viral load (77,78). In a study of over 6700 patients, it was demonstrated that a 1 gram/dL decrease in the hemoglobin level was associated with an increase in the hazard ratio for death by 57Ð70% (74,77). Recovery from anemia, either spontaneously or by intervention, is associated with improved survival (54,72,74,79).

Neutropenia

Granulocytopenia tends to occur concomitantly with anemia (60). While 10Ð30% of HIV-infected patients may be neutropenic, this may increase to about three-quarters of those who meet criteria for a diagnosis of AIDS (50,52,60,62). Review of the peripheral smear reveals a variable deÞciency of neutrophils, lymphocytes, and perhaps monocytes; atypical lymphocytes may be seen. Vacuolization of the monocytes is a typical Þnding, and hypolobulation of the neutrophils may occur which may imitate a left shift (60,80).

Impaired myelopoiesis is the major cause of the leukopenia associated with HIV-1 infection (60,81Ð83). Myelotoxic medications should be considered Þrst, as drugs may be the primary cause of granulocytopenia in up to 80% of cases (84). While about a third of patients have antibodies on circulating neutrophils, their presence correlates neither with the incidence nor the severity of the neutropenia (57).

In addition to the direct and indirect effects of HIV on granulocyte numbers during the course of HIV infection,

granulocytes undergo a progressive decline in chemotaxis (85) and oxidative capacities (86–90). Furthermore, there is a progressive acceleration in the rate of apoptosis (86,87). Granulocytes from HIV-infected patients tend to be less pliable than those from controls, making them problematic with respect to microvascular disease or diapedesis into sites of infection (89,90). These qualitative defects in granulocytes tend to improve with protease inhibitor therapy and/or growth factors (G-CSF, GM-CSF) (86).

Thrombocytopenia

While anemia and granulocytopenia tend to occur concomitantly, with a severity that parallels the course of HIV-1 infection, thrombocytopenia can occur independently of other cytopenias and at all stages of HIV infection (49,52,60,91–93). Thrombocytopenia may occur in 30–60% of HIV-infected patients, regardless of the risk group (47,49–51,90,92–95). Of these patients, 16–40% of those with platelet counts below 50,000 may have clinically-significant bleeding (92,95). By itself, however, thrombocytopenia is not a prognostic factor in HIV infection (96,97).

The causes of thrombocytopenia in HIV infection include reduced bone marrow production and immune and non-immune destruction (98). While immune mechanisms and reduced platelet life span may be more important in the early stages of HIV-associated thrombocytopenia, decreased production may be relatively more important in the later stages of disease (98,99).

Mechanism of Platelet Destruction in HIV-Related I.T.P.

The majority of HIV-infected patients have antibodies coating the surface of platelets (100–102). Some of these antibodies are due to non-specific binding of immune complexes (49,103). However, molecular mimicry between the GP-160/120 antigen of HIV-1 and GPIIb/IIIa of platelets may lead to production of more specific antibodies to the platelet surface (100,101,104–107). These antibodies shorten the average platelet life-span by two-thirds (108,109). The presence of antibodies on the surface of the platelets does not, however, correlate well with the platelet count, due to defective reticuloendothelial clearance in HIV-infected patients (110–112). In addition to immune destruction, infections and fevers that occur in patients with HIV infection decrease the life-span of circulating platelets. Splenomegaly that may occur in HIV infection results in some degree of sequestration of platelets. Other causes of non-immune destruction of circulating platelets are hemolytic-uremia syndrome and thrombotic thrombocytopenia purpura that occur more commonly in HIV-infected patients (91,113,114).

Despite stimulated megakaryocytopoiesis that occurs with HIV infection, there is a progressive reduction in the productive capacity of megakaryocytes to counter ongoing peripheral destruction (108,115–118). Megakaryocyte precursors in HIV-1 infected patients demonstrate an increase in apoptosis compared with normal controls and the degree of this has been shown to correlate inversely with the circulating platelet count (93). HIV-1 may directly suppress platelet production in that megakaryocytes are potential targets of infection by the virus (103,117,118), and this may result in quantitative and morphologic abnormalities of megakaryocytes (98). HIV-1 indirectly suppresses platelet production by exposing or altering antigens on the surface of the megakaryocyte that then renders them targets of antiplatelet antibodies (91,100). Compounding this is the dysregulation in cytokines and growth factors that occur during HIV infection that alter platelet production (115,119).

Treatment Modalities for HIV-Associated Thrombocytopenia

There are no well-controlled, prospectively randomized trials of the various treatment options for HIV-associated thrombocytopenia (57) (Table 22.2). Spontaneous remissions may occur in 10–20% of patients (59,120). A sudden elevation in the platelet count, however, may indicate deterioration in the immune system and herald the onset of AIDS (91,120). In those who have a sustained decrease in platelet count, therapy is not always necessary, since the incidence of significant bleeding episodes may be low despite low platelet count (121–123). It is, however, difficult to predict the risk of bleeding based solely upon the platelet count (124).

In those with thrombocytopenia associated with HIV infection, administration of zidovudine may result in elevation of the platelet count in approximately 30% of patients within twelve weeks of initiation of therapy (57,91,92,119,120). Although some studies have shown a dose-response, this has not been demonstrated in others (58). While monotherapy with other nucleoside reverse transcriptase inhibitors has not, as yet, been shown to have this effect (118), small studies have shown that a statistically significant number of patients with HIV-associated thrombocytopenia have a sustained increase in platelet count within a few weeks of starting therapy with HAART (125,126).

Similar to the effects of zidovudine, dapsone may elevate platelet counts in a minority of patients within three weeks of initiating therapy (102). While the mechanism of the effect of zidovudine is not clear, that of dapsone may be due to a reduction in phagocyte-mediated destruction (102).

Corticosteroids will elevate the platelet count in 40–80% of patients with HIV-associated immune thrombocytopenia; long-term remissions, however, occur in only

TABLE 22.2. *Treatment modalities for HIV-associated thrombocytopenia*

Modality	Acute Response Rate (% of patients)	Durable Response Rate (% of patients)
Spontaneous remissions	10–20%	10%
Nucleoside analogs	20–30%	10%
Dapsone	20–30%	10%
Corticosteroids	40–80%	10%
Vincristine	10%	10%
Anabolic steroids	10–30%	10%
High-dose ascorbic acid	Case reports to date	
Interferons	Small and uncontrolled studies	
Anti-D (anti-Rh) antibody	70–80%	10%
Splenectomy	60–90%	60%
Low-dose splenic irradiation	40–60%	40%

10–20% of cases (91). Although chronic, low-dose steroids may be effective in maintaining an acceptable platelet count (111), side effects preclude their use. No controlled trials thus far demonstrate any adverse effects of short-term steroids on HIV infection (111).

Patients who have failed the treatment modalities noted above have been tried on other therapies. Vincristine and anabolic steroids have an overall response rate of only about 10% (127,128). High-dose ascorbate (2–4 grams per day) over several months has also been shown in small studies to increase platelet counts; the mechanism and durability of the response is not entirely clear (91). Interferons, particularly interferon alpha, have been shown in controlled trials to have some efficacy in those with zidovudine-resistant thrombocytopenia (57,129). Small studies have shown an acute response of almost 70% (130); the doses required for this, however, often preclude its use. One potential mechanism by which interferon-alpha restores platelet production may be by increasing levels of interleukin-6 (131), a cytokine with trophic effects on megakaryocytes.

Infusions of gamma globulin offer the potential for a rapid elevation in platelet count with an acute response rate of 70–90% (132,133); the median response duration is on the order of three weeks. Sustained remissions from a single course of such therapy occur in less than 10% of patients (91). A similar acute response rate of 75% is offered by anti-D (Anti-Rh) antibody (134), but sustained remissions from a single administration in less than 10%. As with gamma globulin infusions, re-administration is effective in elevating the platelet counts in over 85% of those who initially responded (91,135–137). Unlike gamma globulin, however, the response may take up to three weeks to occur and there may be some hemolysis; anti-D antibody is not effective in splenectomized patients or in those who are Rh negative (134). Both immune globulin and anti-D antibody may work by increasing production of thrombopoietic cytokines such as IL-6 from cells of the reticuloendothelial system (138). Intravenous gamma globulin and anti-D globulin may also increase the platelet count by saturating complement receptors on the cells of the reticuloendothelial system and, thus, hindering platelet destruction (139).

When other therapies fail, splenectomy needs to be considered. This procedure has an acute response rate of 60–100%, and durable responses occur in at least 40–60% (91). These short and long-term response rates are better than those encountered when splenectomy is used for therapy in classic immune thrombocytopenia (140). No studies to date have demonstrated any detrimental effects of splenectomy on HIV progression (124,141,142). This procedure can, however, result in artificial elevations of the CD4 count due to redistribution of the lymphocyte pool (141). Consequently, splenectomized patients may develop opportunistic infections at higher CD4 counts than otherwise expected (141). A compromise to splenectomy is offered by low-dose splenic irradiation (102,143). Small, uncontrolled studies have demonstrated an acute response rate of 70% with durable responses occurring in about 40% of patients (143). Total doses are about 900–1,000 cGy over a month. Some degree of splenic function is maintained by low-dose radiation (144).

MARROW ABNORMALITIES IN HIV INFECTION

The bone marrow in the majority of patients with HIV infection exhibits morphologic aberrations (145,146) (Table 22.3). The incidence increases with progression of

TABLE 22.3. *Typical features of the bone marrow in HIV infection*

Cellularity:	Increased in 50–60% Normal in 35–40% Hypocellular in 5%
Dysplasia in one or more cell lines occurs in over 70%	
Granulocyte > Erythrocyte > Megakaryocytic	
Lymphoid aggregates occur in 20%	
Fibrosis occurs in 20%	
Less commonly seen:	Eosinophilia Plasma cell infiltrates

HIV infection (62,147). Although common, none of the marrow abnormalities seen with HIV infection, however, are speciÞc for the disease (148,149).

Hypercellularity of the bone marrow is the most common morphologic Þnding encountered in HIV-1 infected patients (150Ð152). This occurs in 50Ð60% of cases and is due to absolute hyperplasia of one or more of the non-lymphoid cell lines (147). There may be mild myeloid hyperplasia, but more often, the myeloid to erythroid ratio tends to remain close to normal (149). Since much of the hypercellularity may not represent effective hematopoiesis, the marrow cellularity correlates neither with the peripheral blood counts nor with the stage of HIV infection (149,152,153). Hypocellularity of the marrow is rare, occurring in less than 5% of cases and is usually a manifestation of advanced HIV infection (47,51,62). In the end-stages of HIV infection, atrophy or necrosis of the marrow may occur (149).

Dysplasia of at least one cell line occurs in over 70% of HIV-infected patients (51,62,117). This is similar to that due to the myelodysplastic syndromes and is largely not distinguishable from the latter on morphologic criteria alone (51,154). Dysplasia of the granulocyte series is the most frequent occurrence, with vacuolization of the granulocyte precursors in the marrow and in the peripheral blood neutrophils (155). Erythrocytic dysplasia is somewhat less common, seen in 50Ð60% of HIV-infected patients, and dysplasia of the megakaryocytes is seen in about one-third of HIV-infected patients (151). In general, the degree and frequency of dysplastic changes in the marrow increase with progression of HIV-1 infection and also with concurrent opportunistic infections (50).

Evidence of defective transfer of iron from the reticuloendothelial system to the maturing erythroid cells is encountered in over 60% of cases (153). Evidence of iron overload may also be encountered.

Less common aberrations include lymphoid aggregates and increased numbers of lymphocytes. This is encountered in about 20% of patients and occurs despite the peripheral lymphopenia that is characteristic of HIV infection (50,80). A similar proportion of those with advanced HIV infection has focal or diffuse increases in reticulin deposition in the marrow (50,62). In general, marrow Þbrosis increases in incidence and severity with progression of HIV-1 infection and with marrow involvement by fungal or mycobacterial infection (57). Other non-speciÞc morphologic changes that may be seen in the marrow include increases in eosinophils and plasma cells, and histiocytic erythrophagocytosis (62,156).

CAUSES OF CYTOPENIAS IN PATIENTS WITH HIV INFECTION

Hematopoiesis is a process that is both constitutive and inducible. Constitutive hematopoiesis is largely under the direction of the colony stimulating factors (157), while inducible hematopoiesis is more within the realm of action of other cytokines and interleukins that modulate hematopoiesis during situations of altered demand (158,159). These cytokines are released from marrow Þbroblasts, endothelial cells, T cells and monocytes as a response to a multitude of stimuli (157,158). The hematologic perturbations that occur in association with HIV infection may be a direct or indirect result of HIV-1 on stem cells and the marrow stromal cells. The alterations in growth factors and cytokines that occur as a result of HIV infection contribute to hematopoietic abnormalities (160). Other factors that merit recognition are opportunistic infections and neoplasms invading the marrow, and myelosuppressive medications.

Altered Hematopoiesis Due to Tumor, Infection, Medications

HIV infection is associated with the development of lymphomas as well as Kaposi's sarcoma and squamous cell carcinomas. The incidences of neoplasms that occur with HIV infection are likely to increase as the infectious complications of AIDS are better controlled. The bone marrow is affected in about one-third of those with AIDS-related lymphomas (161), most commonly, small non-cleaved cell lymphoma (162,163). The extent of replacement of the marrow by these malignant cells does not, however, correlate well with the peripheral blood counts (161). The antineoplastic drugs needed to treat these tumors are myelosuppressive, and the dose reductions that may be needed to preserve hematopoietic function hinder therapy of the tumors.

The medications used to treat HIV infection and the opportunistic infections that occur with AIDS, cause disease-stage and dose-dependent suppression of hematopoiesis (33,57). All of the dideoxynucleoside analogues can inhibit hematopoieis at sufÞciently high doses, with zidovudine being the major offender (164,165). Other myelosuppressive drugs include pentamidine, trimethoprim, sulfonamides, ganciclovir, and pyrimethamine (164). Medications that are not typically associated with decreases in hematopoiesis may cause this effect when given to those with altered hematopoietic potential such as occurs with HIV infection. Furthermore, concurrent administration of myelo-suppressive medications are synergistic in the potential to cause bone marrow suppression.

Several opportunistic infections that result from HIV-induced immunosuppression may cause or contribute to marrow failure. Myco-bacterial infections, particularly *Mycobacterium avium complex* but also disseminated *Mycobacterium tuberculosis* and others, and fungal infections, most common of which are *Cryptococcosis* and *Histoplasmosis*, are capable of widely disseminating throughout the bone marrow and thus may reduce hematopoietic potential. The marrow may reveal a disseminated mycobacterial or fungal infection prior to other

indications of these infections in an HIV-infected host (154,166). Special stains and cultures of the marrow for these organisms may be helpful and may be positive prior to peripheral blood cultures turning positive (154,166, 167). There is, however, not a general consensus on this point in that some studies have shown no difference in the time for blood and simultaneously-obtained bone marrow cultures to become positive (168). Small studies have shown that marrow examination or cultures are positive for mycobacteria and/or fungi in 75–84% of patients who are subsequently found by other diagnostic methods to have these infections (154,166,168). However, with respect to mycobacterial disease, the marrow has histologic evidence of infection in less than 30% of cases (168).

The most common manifestation of these infections within the marrow is diffuse infiltration with loose aggregates and clusters of macrophages (59,169). The ability to detect involvement of the bone marrow by mycobacteria and fungi correlates with the number of macrophages in the marrow (59). Although these cells may organize into granulomas, the tendency to do so lessens with advancing immunosuppression (57). Pseudo-Gaucher cells may also be seen as a manifestation of such infections (170).

Opportunistic infection of the marrow by viruses other than HIV-1 is an important cause of marrow failure. In this regard, *Cytomegalovirus* and *Parvovirus* have special significance. *Hepatitis B* and *C*, however, merit recognition as causes of marrow suppression in an HIV-infected patient (171,172).

Cytomegalovirus may cause suppression of hematopoiesis and may also be associated with autoimmune destruction of blood cells (173). Neutropenia, anemia that may be hemolytic, and thrombocytopenia either alone or in combination can be seen with *Cytomegalovirus* infection (174). This virus can infect bone marrow progenitor cells, rendering them less responsive to colony stimulating factors (173–175). Furthermore, these infected cells may serve as reservoirs of latent *Cytomegalovirus* within the marrow, causing further problems with advancing immunosuppression (173). *Cytomegalovirus* can infect the bone marrow stromal cells, interfering with their hematopoietic supporting functions, largely by decreasing local growth factor production by these cells (173,176,177). Despite the hematologic problems that *Cytomegalovirus* may cause, it does not cause distinctive histologic changes of the marrow, and it is best cultured from the buffy coat of the blood and not from the marrow itself (173).

HIV-infected patients may become infected with *Parvovirus* B-19 which may result in marrow suppression. These patients often do not have the manifestations of Fifth's disease (fevers, rash and arthralgias) that are seen in immunologically normal patients (178). The major hematopoietic target of *Parvovivus* B-19 is the erythroid progenitor (179). This is the only permissive cell of the hematopoietic system for the virus. Morphologically, such an infection results in giant pronormoblasts (178) and erythroblastopenia that can persist, if those infected are unable to make antibodies to the virus (172,179). *Parvovirus* also has an inhibitory effect on myeloid and megakaryocyte progenitors that may result in varying degrees of neutropenia and/or thrombocytopenia (178–180). Immunosuppressed patients may not be able to make specific IgM antibody to *Parvovirus* and this hinders spontaneous recovery from the infection as well as interferes with the usefulness of serology in diagnosis (181). Treatment of *Parvovirus* B-19 infection in those who are unable to make antibodies to this virus infection includes intravenous gamma globulin to reduce serum viral concentrations (178,181). Simultaneous infection with *Parvovirus* B-19 and HIV-1 does not preclude a response to erythropoietin (178).

Human *Herpes Virus-6* is the etiologic agent of another viral exanthem of childhood, roseola. Infection usually occurs in the first three years of life and then establishes latency (182). The primary target of this virus is the CD4 lymphocyte, as well as cells of monocytic lineage (182–184). Immunosuppression may result in loss of latency; subsequent exposure of marrow precursor cells to this virus inhibits their ability to respond to growth factors, and infection of lymphocytes causes further suppression of T cell function (182,183). When HHV-6 suppresses hematopoiesis, it is usually leukocytes that are most affected, followed by platelets and then erythrocytes (184). This virus also enhances immunodeficiency and upregulates HIV-1 replication (184).

Colony Stimulating Factors and HIV Infection

There is a vast network of cytokines composed of over twenty growth factors (185). Important components of this array are the colony stimulating factors that include G-CSF, M-CSF, GM-CSF, IL-3, Stem Cell Factor, and erythropoietin (158,186). These glycoproteins regulate passage of hematopoietic cells into the cell cycle and into the processes of terminal maturation (187). The predominant activity of these cytokines is to suppress apoptosis (188–190).

Major sources of colony stimulating factors are T and B lymphocytes, NK cells, vascular endothelial cells, smooth muscle cells, and fibroblasts (158,159). Many of these cells are targets of infection by HIV-1, and when they are infected, their ability to make growth factors progressively diminishes (160,191). The monocyte, an important primary target for infection by HIV-1, is central to the network of cytokines, interleukins, and growth factors that support and regulate hematopoiesis (159,169,192). While infection of cells of monocytic lineage by HIV-1 enhances their secretion of inflammatory cytokines, it simultaneously diminishes their ability to secrete hematopoietic growth factors (193).

Hematopoietic Growth Factors

Production of G-CSF, GM-CSF, and M-CSF increases during the early phases of HIV infection (45). This may partially explain the hypercellularity of the bone marrow that is often seen at this stage of HIV infection (160). This is largely due to the effects of low concentrations of IL-1 and other inßammatory cytokines, such as interferon-gamma and tumor necrosis factor-alpha, on cells within the bone marrow that produce these growth factors (160,194,195).

As HIV infection advances, however, levels of these inßammatory cytokines progress beyond levels that stimulate hematopoiesis to levels that inhibit it (160,193). Furthermore, with advancing HIV infection, the increasing levels of inßammatory cytokines that occur alter receptors on target cells to make them less responsive to growth factors (194Ð198). Other cytokines that inhibit hematopoiesis, such as transforming growth factor-beta (TGF-beta) are produced in increasing amounts with advancing HIV infection (160,191).

A major stimulus to the production of these negative regulators of hematopoiesis is products of HIV itself. The *Tat* protein is released from infected monocytes and lymphocytes and is taken up by other cells and stimulates them to release proinßammatory cytokines that include TNF-alpha, IL-1-alpha, IL-1-beta, and IFN-gamma (199Ð203). HIV-1 *Nef* protein also may be released from infected cells and induces IL-6 production and release by peripheral blood lymphocytes (204).

The pharmacokinetics of growth factors that are administered to cytopenic patients depend upon the dose, amount of glycosylation, and the route of administration. Cytokines may have effects in combination that are not seen with each alone (160,185). Exogenous administration of growth factors offers the potential of ameliorating some of the adverse effects of HIV infection on hematopoiesis. Prescribing growth factors permits the administration of myelosuppressive medications without dose reduction or interruption of therapy (48). With the exception of erythropoietin, the potential uses of growth factors have been investigated in uncontrolled studies only (205).

Granulocyte Colony-Stimulating Factor (G-CSF)

G-CSF is produced by activated monocytes, stimulated endothelial cells, and Þbroblasts. Exogenous administration of G-CSF results in a sustained, dose-dependent rise in circulating neutrophil counts (81,157). In HIV-infected patients on a stable HAART regimen, G-CSF may also increase the concentration of CD4+ and CD8+ lymphocytes as well as NK cells (206). High doses may result in modest elevations of monocytes (157,207). The relative and absolute elevation in neutrophil count is due to an increase in the number of divisions of neutrophil precursors in the marrow, and a decrease in their maturation time (208). *In vitro*, G-CSF augments neutrophil functions such as chemotaxis and phagocytosis, migration of granulocytes into sites of infection, and the oxidative functions of these cells (209,210).

Granulocyte-Monocyte Colony-Stimulating Factor (GM-CSF)

GM-CSF is produced primarily by stimulated Þbroblasts and endothelial cells, but also by T cells. Administration of this growth factor, as with G-CSF, results in a dose-dependent elevation in neutrophils and monocytes. The kinetic basis of the elevation in neutrophils differs from that of G-CSF: GM-CSF prolongs the circulating half-life of these cells rather than decreasing the production time as does G-CSF (157,211). Unlike, G-CSF, however, it also results in a signiÞcant elevation in eosinophils and monocytes (212,213). GM-CSF has been shown to augment the phagocytic activity of monocytes and macrophages in those infected with HIV-1 (214).

GM-CSF and G-CSF have different effects on HIV-infected cells (81,186,215). While G-CSF does not seem to alter HIV replication in cells that are targets for the growth factor, GM-CSF can stimulate HIV replication *in vitro* in infected cells of monocytic lineage (212Ð217). Moreover, activation of monocytes by HIV infection induces them to produce GM-CSF and to stimulate T cells, endothelial cells, and Þbroblasts to produce this growth factor, and this in turn augments HIV replication in the monocytes (158,159). When GM-CSF is administered in conjunction with zidovudine, the result is enhanced antiviral effects due to an increase in the concentration of the active drug within monocytes (212,213,216,218). Thus far, this effect has been shown only for zidovudine, and because of this GM-CSF may be administered concomitantly with zidovudine in HIV-infected patients (172).

Erythropoietin

The majority of HIV-infected patients with anemia have adequate erythropoietic capacity but are unable to augment this during times of demand due in large part to relatively inadequate erythropoietin levels (57). Inappropriately low endogenous levels (< 500 mU/cc) of serum erythropoietin are seen in 75% of AIDS patients regardless of the medications they are receiving (48,160,219). Proinßammatory cytokines not only decrease erythropoietin production, but also alter the sensitivity of erythroid precursors to this growth factor (160,194,220,221). One study has demonstrated that over 20% of HIV-infected patients, particularly those with higher endogenous erythropoietin levels, have autoantibodies to erythropoietin (222).

Administration of erythropoietin may reverse the suppression of erythropoiesis that occurs in response to

proinßammatory cytokines (194,223,224). In placebo-controlled trials, exogenous administration of erythropoietin increased the hematocrit and improved the quality of life for patients with AIDS (219,223). Elevation in erythrocyte counts was dose-dependent (47,48). Initial concerns about stem-cell exhaustion or lineage diversion did not occur (48). Erythropoietin neither promoted nor prevented HIV replication (48,215).

Despite these promising results, not all patients respond to administration of this growth factor. The beneÞts are principally seen in those with baseline erythropoietin levels of less than 500 mU/cc (48). About 25% of patients on zidovudine will not have a signiÞcant elevation in hematocrit with concurrent administration of erythropoietin (48).

Administration of erythropoietin offers an alternative to transfusions, the latter having potential morbidity. Transfusions may be immunosuppressive (225,226), having been shown to cause decreases in the ratio of CD4 to CD8 lymphocytes, and reductions in natural killer cell number (227). Transfusions may enhance HIV replication (228,229), perhaps accounting for the observation that the time to progression to AIDS is shorter in those who are transfused (227,228). Furthermore, transfusions risk exposure to new blood-borne infectious agents (48), and there is a risk of alloimmunization transfusion reactions despite the immunodeÞciency induced by HIV-1 infection (48,149).

Stem Cell Factor (SCF, Kit-Ligand)

S-CSF is a multipotential growth factor that is produced by marrow stromal cells (200). It acts on cells of myeloid, lymphoid, and mast cell lineage (230). For optimal stimulatory effects, it acts in synergy with other, more lineage-restricted, colony stimulating factors (230–232).

Levels of endogenous stem cell factor decrease as HIV infection advances, and these levels directly correlate with overall survival (232). Reduction of these levels may be due to progressively defective function of the stromal cells that make stem cell factor (232). When administered to HIV-infected patients, S-CSF increases hematopoiesis in a dose-dependent fashion and does not alter HIV expression (233).

Interleukin-3

This growth factor is produced by activated T cells and has direct effects on granulocytes, monocytes, and mast cells, and indirect stimulatory activities on erythroid production and T lymphocytes (234). Administration results in a dose-dependent increase in circulating granulocytes, erythrocytes, and platelets (234).

The loss of T cells that is characteristic of advancing HIV infection results in reductions in endogenous IL-3 levels (235–237). This may contribute to the myelosuppression associated with advancing HIV infection (218). Suboptimal concentrations of IL-3 may act in synergy with other growth factors to counter the myelosuppression that occurs with HIV-1 infection. The mechanism involves preventing the apoptosis of hematopoietic progenitor cells that occurs in the presence of HIV and in the absence of growth factors (190).

While some have found IL-3 to potentiate HIV expression in monocytes *in vitro*, others have found no consistent effects on viral activity (238). Like GM-CSF, it may augment the antiviral effects of zidovudine by elevating the intracellular levels of the active form of this antiretroviral drug (14,148,218,239).

Bone Marrow Progenitor Cells in HIV Infection

Results of studies on HIV infection of bone marrow progenitor cells have been conßicting (147). While there are data indicating progenitor cells to be targets of HIV infection (60,119), others have revealed that CD34+ bone marrow progenitor cells are infrequently infected with the virus (240–246). Some investigations have shown that progenitor cell numbers in the marrow and peripheral blood (152,247,248) are decreased in HIV infection (51,66,146), while others have found no signiÞcant differences in the numbers of these cells in HIV-infected patients when compared with normal patients (242,245, 249,250).

Reconciliation of these ostensibly conßicting results comes about when consideration is given to several factors. Studies on the effects of HIV-1 on hematopoietic progenitor cells need to consider the different strains of virus that are known to occur and evolve with advancing infection. Monocytotropic strains of HIV-1 may be more prone to alter hematopoiesis than are lymphocytotropic strains (249,251). There are also differences in the cytopathic capacity of different strains of HIV-1 (243,245), with some strains known to impair hematopoiesis in a dose-dependent manner (243,252–254).

It is difÞcult to obtain highly puriÞed populations of CD34 cells from bone marrow (246). When this impediment is overcome, however, it becomes apparent that only a minority of CD34+ progenitor cells are also positive for CD4 and therefore only a relatively unimportant number of progenitor cells are major targets for HIV-1 (244,255–258). Direct infection of hematopoietic cells by HIV-1 does not seem to make a major contribution to the hematopoietic defect that occurs with HIV-1 infection (190,201,249,259,260).

The presence or absence of accessory cells within marrow cultures is also important to the myelosuppression that occurs *in vitro* in the presence of HIV-1. T cells, monocytes, adipocytes, Þbroblasts and vascular endothelial cells are important components of the bone marrow stroma and inßuence hematopoiesis by production of

growth factors (160,191). These cells, particularly the stromal cells of monocytic lineage, are targets for HIV and may serve as reservoirs of virus within the bone marrow (192,261). When infected with HIV-1, these cells are less able to make growth factors (60,67,193). As the major function of growth factors may be to prevent apoptosis, the deficiency in local production permits marrow progenitor cells to undergo this process (249). Furthermore, these cells may produce inhibitors of hematopoiesis such as TGF-beta, platelet factor 4, interferons, and tumor necrosis factor-alpha (239,262–264). *In vitro* depletion of marrow cultures of these cells increases hematopoiesis (259,261, 265).

Progenitor cells of HIV-1-infected patients may be impaired without productive infection by HIV-1 (249). Protein products of HIV-1 can directly inhibit marrow progenitor cells, and this effect does not depend upon the presence of active virus (146,266). The GP-120 and GP-160 envelope proteins of HIV-1 have been shown to cause a dose-dependent decrease in viable CD34+ cell counts by a process that stimulates apoptosis in these hematopoietic cells (190,257,267). Preincubation of HIV-1 with neutralizing anti-gp-120 antibody prevents the apoptosis that occurs in hematopoietic cells when envelope gp-120 interacts with the low levels of CD4 antigen present on these cells (190,249). However, prevention of apoptosis does not occur if HIV-1 or recombinant gp-120 treatment of hematopoietic cells is followed rather than precedes by the addition of gp-120 antibody (249). This implicates the engagement of CD4 antigen present in low levels on progenitor cells as a trigger to programmed cell death thus depleting the hematopoietic reserve (249,258). Anti-CD4 and anti-GP-120 antibodies themselves also may induce apoptosis in hematopoietic cells (265,268). The mechanism that permits anti-CD4 antibodies to do this may be via altering protein kinase C activity and intracellular calcium levels (210,266).

Indirectly, GP-120 can suppress hematopoiesis by inducing other cells to produce cytokines that inhibit hematopoiesis such as tumor necrosis factor-alpha (259,269). Protein products of the *Tat* and *Nef* genes cause suppression of hematopoiesis either directly (211), or indirectly by causing other marrow stromal cells to produce inhibitors of hematopoiesis such as TGF-beta and TNF-alpha (259,269,270).

Another product of HIV-1, the Vrp protein, also plays a role in suppression of hematopoiesis (271). This 96 amino acid protein is important to the efficiency of infection of mononuclear phagocytic cells by HIV-1. It activates these cells and in so doing increases HIV replication. Activation of these cells also promotes premature phagocytosis of hematopoietic cells (271).

Other factors need to be recognized when one looks at studies that investigate the effects of HIV-1 on bone marrow progenitor cells. At least with respect to megakyarocytes, HIV-1 infection induces alterations in surface antigens that renders them potential targets of antiplatelet and anti-HIV-1 antibodies (115,119). Anti-retroviral drugs may influence the results of experiments on the presence of HIV-1 in marrow progenitors (245,272). Protease inhibitors have been shown to decrease apoptosis in bone marrow cells by a mechanism that seems to be independent of their effects on HIV replication (273).

Taken all together, the data indicate that the effects of HIV-1 on the marrow progenitor cells are largely indirect rather than a result of direct infection of these cells. The summation of these indirect effects on hematopoietic cells is a reduction in the potential of the progenitor cells to differentiate and proliferate (253,254).

Other Cytokines and Interleukins

Interleukin-1

Interleukin-1 is one of the primary mediators of the acute phase response (274). This cytokine is produced largely by cells of monocytic lineage (274–276), but is also produced by dendritic cells, B and T lymphocytes, NK cells, fibroblasts, and vascular endothelial cells (1). Interleukin-1 causes fever and anorexia, and contributes to a catabolic state (275). With respect to hematopoiesis, it induces secretion of colony stimulating factors by accessory cells in the marrow, particularly G-CSF, M-CSF, and GM-CSF (158,277), and also IL-6 (158,274). In this way, it enhances hematopoiesis (124,223). Prolonged secretion of interleukin-1, however, induces secretion of tumor necrosis factor-alpha and other inflammatory cytokines that suppress hematopoietic activity (263,274,277). *In vivo* and *in vitro*, levels of interleukin-1 tend to increase with progression of HIV-1 infection (275,278).

Interleukin-2

Interleukin-2 is a primary growth factor for T cells (158,159) and secondarily stimulates proliferation and differentiation of B cells (186). Interleukin-1 and TNF-alpha are the major stimuli for production of IL-2 by T cells, and these cytokines also increase IL-2 receptor numbers and binding capacity on the T cell membrane (158,159,186).

Interleukin-2 can indirectly decrease hematopoiesis by its ability to induce synthesis of interferon gamma by other cells (158). More importantly, production of IL-2 during the chronic inflammatory state of HIV infection augments replication of HIV-1 in infected cells (279,280). In this way, production of this cytokine directly upregulates HIV-1 production, and indirectly contributes to the suppression of hematopoiesis that is characteristic of advancing HIV-1 infection.

Interleukin-6

HIV infection is associated with increased production of IL-6 primarily by monocytes (143). This may occur as a

result of the interaction of GP-160 antigen with the CD4 receptors of these cells (131,193,280). IL-6 may also be produced by stimulated B cells, T cells, and Þbroblasts (158,231,277). Circulating neutrophils and eosinophils as well as vascular endothelial cells have been shown to produce this cytokine in the presence of HIV-1 (281,282). HIV-1 Tat protein has been shown to directly and indirectly upregulate IL-6 expression (270).

Interleukin-6 can act in synergy with IL-3 to enhance hematopoiesis (158,283Ð285). In this regard the elevated levels of IL-6 that occur with advancing HIV-1 infection (264,278) would be expected to upregulate hematopoiesis (131,193). This cytokine, however, also induces hepatocytes to produce acute phase proteins (131), primarily IL-1, and this directly and indirectly down-regulates hematopoietic potential (231,254,286). Furthermore, IL-6 can upregulate HIV-1 production by infected cells (256,279), and may cause T cell proliferation thereby expanding the pool of HIV-infected cells (231).

Interferons

The interferons are a family of cytokines that are produced by leukocytes (interferon-alpha), Þbroblasts (interferon-beta), and cells of lymphocyte and monocytic lineage (interferon-gamma) (25). The latter may be produced by cytotoxic T lymphocytes upon contact with target cells that present HIV antigens (25).

Serum interferon levels tend to increase with progression of HIV infection (241,287,288). Interferons in general, and INF-alpha in particular, inhibit marrow progenitor cells (288Ð290). This effect may be mediated by inducing secretion of other cytokines such as TNF-alpha, and IL-1 from marrow monocytes and T cells (263,277,291).

Interferon gamma has been shown to upregulate chemokine receptors, particularly CXCR-4, on bone marrow progenitor cells (292). This molecule is the co-receptor for strains of HIV that primarily infect T cells, strains that tend to occur later in the course of HIV infection. The CXCR-4 molecule is also present on maturing megakaryocytes and platelets (292,293), thus providing a potential explanation for the decrease in platelet production that occurs late in HIV infection.

Tumor Necrosis Factor

Tumor necrosis factor-alpha (cachectin) is produced by stimulated monocytes and macrophages (148,159,277), T lymphocytes (25), stimulated B cells (294) and vascular endothelial cells (276). Although it is not produced constitutively by HIV-infected cells, it can be produced in response to diverse stimuli concurrent with HIV infection (275,276,295). The Tat protein of HIV-1 may activate TNF-alpha genes *in vitro* (196,278). Cytotoxic T lymphocytes are capable of producing TNF-alpha upon contact with target cells presenting HIV-1 antigens (25), and monocytes and macrophages are capable of producing TNF-alpha after contact with GP-120 (30,259). This does not require the presence of live virus (259).

TNF-alpha levels are elevated in the sera of HIV-infected patients (259,275,278,296), and rise progressively with the disease. *In vitro*, TNF-alpha can maintain HIV expression in chronically infected cells (277,297,298). TNF-alpha is, therefore, important to the autocrine and paracrine regulation of HIV infection (211).

TNF-alpha can act as both a positive and negative regulator of hematopoiesis (259,276,299). TNF-alpha has indirect suppressive effects on hematopoiesis by inducing the production of IL-1 by monocytes that, in turn, suppress hematopoiesis (158,263). It can alter the production of growth factors by marrow stromal cells as well as modulate the expression of cell surface receptors for growth factors on cells that are targets of HIV infection (158,259,274,276,299).

The concentration of TNF-alpha is important to the quantitative effect on hematopoiesis (299,300): Low concentrations stimulate IL-3 and GM-CSF-induced colony formation, but high levels inhibit the actions of these growth factors (158,263). TNF-alpha also has differential effects upon various hematopoietic cell lines: The same concentration of TNF-alpha that stimulates growth of committed granulocyte and monocyte progenitor cells inhibits erythroid growth (300). There are at least two receptors for TNF-alpha, a 55 kD and a 75 kD receptor, and these seem to use different signaling pathways and result in different effects on hematopoiesis. While the inhibitory effects of TNF-alpha on progenitor cells involves p55 and p75, the p55 receptor alone mediates the stimulatory effects on progenitors (299,300).

Transforming Growth Factor-Beta (TGF-beta)

Transforming growth factor-beta is a stimulatory agent for some cell lines, Þbroblasts in particular, but is a potent inhibitor of hematopoietic proliferation (262,301,302). It has a reversible, suppressive effect on marrow progenitors (262). It acts on early cells in hematopoiesis in a multipotential and non-lineage speciÞc fashion (262). Its mechanism of action may be via down regulation of cell surface C-kit expression and IL-1 receptors (301).

Levels of TGF-beta increase progressively as infection with HIV-1 advances (302). The *Tat* protein of HIV-1 upregulates production of this cytokine in a direct and indirect manner (270). Moreover, TGF-beta is capable of inducing its own synthesis (302).

In addition to its effects on hematopoiesis, TGF-beta is a potent endogenous immunosuppressive factor (302). It down-regulates activity of B cells, T cells, monocytes and macrophages (302). Its overall effect is to augment the immunosuppression and hematosuppression characteristic of HIV-1 infection (302Ð304). Moreover, TGF-beta enhances HIV-1 expression in infected cells (305).

THE HEMATOPOIETIC MICROENVIRONMENT AND HIV INFECTION

The bone marrow stroma consists of cellular and acellular components that provide a structural framework organizing hematopoiesis into a non-random distribution that is conÞned to the bone marrow (306Ð308). The cellular component of the bone marrow stroma consists of endothelial cells, Þbroblasts, macrophages, adipocytes, and reticular adventitial cells (309). Adhesion events between hematopoietic cells, the stromal cells, and the extracellular matrix are important to the regulation of hematopoiesis (310,311). In addition to providing sites of attachment for hematopoietic cells, the marrow stromal cells produce growth factors and cytokines that regulate proximately hematopoiesis (306,308,310Ð312).

The cytokines that are released in response to infection with HIV-1, particularly IL-1 and TNF-alpha, alter the adhesion molecules on the marrow stromal cells (313). Alterations in the attachment events between marrow stromal cells and hematopoietic cells (313) may result in suppression of hematopoiesis (311).

HIV-1 infection of accessory cells within the marrow adversely alters hematopoiesis (309,314,315). Monocytes and lymphocytes within the marrow are important cellular components of the bone marrow stroma, and regulate hematopoiesis by their capacity to produce locally growth factors, particularly GM-CSF and IL-3 (316). During the early phases of infection by HIV-1, lymphocytes and monocytes within the bone marrow may increase production of these growth factors; this may partially explain the marrow hypercellularity commonly seen during this stage of HIV infection (147,316).

As the viral infection progresses, however, lymphocytes and monocytes within the marrow begin to produce increasing levels of IL-1 and IL-2 (263,277,316) that not only decrease hematopoietic potential (263,274,277), but also up-regulate HIV replication within these and other cells (148,263,276,277). As noted above, these cells may also serve as a reservoir for HIV within the bone marrow (317,318).

Non-hematopoietic cells within the bone marrow are also important to the structure and function of the bone marrow microenvironment. A major component of the stroma is the reticulum cell (Þbroblast). This accounts for 60Ð70% of the volume of the marrow framework (235). The marrow reticulum cell is a target of HIV infection (261,319,320). When infected with HIV-1, these cells are less able to support hematopoiesis (317,318,320,321) due to impaired ability to secrete growth factors (322). Moreover, HIV-infected marrow stromal cells may also secrete factors that inhibit hematopoiesis (201,246). Medications used to treat HIV infection, such as zidovudine, have the potential to inhibit the growth and development of these stromal cells in addition to that of the hematopoietic cells themselves (272).

The endothelial cells that line the marrow sinusoids are also important to the structure of the marrow (309). These cells are essential to the homing of circulating hematopoietic cells and, in addition, regulate migration of marrow cells into the circulation. They also secrete growth factors. These cells are targets for HIV-1 (281,322), and tend to be infected early during the course of infection (309). When infected by HIV-1, they undergo alterations in surface receptors, and their ability to secrete growth factors is hindered, thus adversely altering their ability to support hematopoiesis (309). In addition, these cells may serve as reservoirs of HIV-1 within the bone marrow (322).

COAGULATION ABNORMALITIES IN HIV INFECTION

Clotting disorders are not uncommon issues encountered with HIV infection (323,324). The most common of these are due to antiphospholipid antibodies. This class of proteins may bind to cardiolipin, anionic phospholipids (the ÒlupusanticoagulantsÓ), and beta-2-glycoprotein I. The latter is a phospholipid binding protein that inhibits coagulation and platelet aggregation (325Ð327). All of these antibodies occur as a result of the abnormal immune responses characteristic of HIV infection. These antibodies are found in 20Ð66% of HIV-infected patients (328Ð333). Titers tend to increase with active opportunistic infections (333).

The antiphospholipid antibodies were once thought to be clinically relevant leading to thromboembolic phenomena (325) both arterial and venous (334). However, the risk of thromboembolic events associated with antiphospholipid antibodies in HIV-positive patients may be less than that encountered in the HIV-seronegative population due to a lower incidence of antibodies to beta-2-glycoprotein I in the HIV-positive population (326,327). Antibodies to this protein may be central to the pathophysiology of the antiphospholipid antibody syndrome (326,327).

Thromboembolic events may also occur as a result of reduced levels of active protein S (324,335Ð338). This peptide is the cofactor for Protein C, acting to localize active Protein C to the phospholipid surface. Mean total and free protein S levels are signiÞcantly lower in HIV-infected patients with or without thromboses than in healthy male controls (324,336,337). The levels of free and total protein S correlate with CD4 counts(339,340). Protein S binds to C4b-binding protein, and increases in C4b-binding protein with the chronic inßammatory state encountered with HIV infection results in greater binding of Protein S, so less is available to prevent aberrant thrombotic events (337). Another mechanism that may contribute to lower levels of active Protein S in HIV-infected patients is the presence of anti-Protein S antibodies in these patients (341). These antibodies bind Protein S, thus decreasing the unbound and active forms of the protein (338).

Heparin cofactor II, a thrombin inhibitor, is lower in HIV-infected individuals than in healthy controls (342). The levels of this anti-thrombotic molecule are decreased further in those with advanced HIV infection (342).

Several of the opportunistic viral infections that result from the immunosuppression induced by HIV-1 may cause or contribute to the pro-thrombotic state characteristic of HIV infection. Quiescent endothelial cells have control mechanisms that restrict expression of pro-coagulant phospholipids to areas of vascular injury (343,344). *Cytomegalovirus* and *Herpes simplex* types 1 and 2 can convert vascular endothelial cells from a non-coagulative to a pro-coagulative phenotype (343–345). The mechanism of this seems to be alterations in surface phospholipids to forms that are active in the coagulation system (343,344).

Increases in levels of antigenic von Willebrand factor, a marker of endothelial injury (109), correlate with CD4 lymphocyte counts. Decreases in plasminogen activator inhibitor levels also occur in those infected with HIV-1 (338) and may contribute toward a prothrombotic state. Other abnormalities in coagulation that may occur with HIV infection include isolated deficiencies in prothrombin levels (344), and abnormal platelet aggregation (343,344). Acquired circulating anticoagulants with anti-factor V activity also have been reported, as well as deficiencies in heparin cofactor II (333,346). The hypo-albuminemia that occurs with advancing HIV infection may cause fibrin polymerization and fibrinolytic defects (323,347).

Thrombotic thrombocytopenia purpura (TTP)-hemolytic uremia syndrome (HUS) has been reported to occur more frequently among patients with HIV infection (347,348). Although the exact etiology of this consumptive coagulopathy is unknown, therapy with plasma exchange has been shown to be effective as therapy (349).

Chapter 23

Cardiac Manifestations in Human Immunode ciency V irus Infection

William H. Frishman, Aysha Arshad and Ajay Bansal

Over 40 million people worldwide are infected with human immunodeÞciency virus (HIV). As the AIDS epidemic spreads, it is clear that cardiovascular problems associated with this infection are going to become more prominent (1,2). Cardiac disease in HIV-infected patients may be multifactorial, caused by infectious or neoplastic complications or their therapies, any of the established causes of cardiac disease in other patient populations, and perhaps HIV infection of the myocardium itself. Knowledge of the relative frequency of each form of heart disease in HIV-infected patients is currently evolving.

Appreciation of cardiovascular dysfunction in HIV infection dates back to a necropsy study in 1982 which described cardiac involvement in a patient with AIDS and Kaposiõ sarcoma (3). Subsequently, cardiac involvement in patients with HIV infection has been described in multiple autopsy (4Ð17) and echocardiographic series (18Ð25). However, the exact prevalence of cardiac involvement in HIV-infected patients is uncertain.

Important clinical syndromes described in patients with HIV infection that involve the heart include cardiac tamponade resulting from pericardial effusion or hemorrhage, dilated cardiomyopathy, other forms of myocardial failure, myocarditis, refractory ventricular tachyarrhythmias and/or sudden death, and systemic thromboembolic disease caused by infectious and non-infectious thrombotic endocarditis, left ventricular aneurysm, myocardial infarction coincidental with the use of the protease inhibitors, and sudden infant death syndrome (26Ð28) (Table 23.1). In one large autopsy series from Europe, cardiac disease was the cause of death in 9.1% of patients dying from HIV infection (29).

The prevalence of cardiac involvement in patients with HIV infection, as demonstrated by echocardiographic examination, has been shown to be much greater than that seen in autopsy series, especially in critically ill hospitalized patients (30). As demonstrated by Blanc et al. in a prospective echocardiographic study of HIV patients admitted to an intensive care unit, few patients presented with clinical evidence of cardiac disease (5/68), but echocardiographic abnormalities were identiÞed in 55 of 68 patients (81%) (22). Herskowitz et al., in their echocardiographic study, showed that patients with CD4 counts $< 100\ mm^3$ had higher rates of left ventricular dysfunction (31) than those with higher CD4 counts. According to Barbaro et al., who examined 952 asymptomatic patients with HIV infection during a mean follow-up period of 60 ± 5.3 months, an echocardiographic diagnosis of dilated cardiomyopathy was made in 8% of patients, with a higher incidence seen in those patients with CD4 counts $< 400\ mm^3$ and in those who received therapy with zidovudine (18). Often the clinical manifestations of cardiac disease may be obscured by the systemic manifestations of HIV infection. Risk factors for myocardial disease other than HIV infection (systemic hypertension, coronary artery disease, alcoholism, intravenous drug use) may also be present (25,32Ð38).

MYOCARDIAL DISEASE

Opportunistic bacterial, fungal, protozoal and viral infections, possible direct HIV infection, non-speciÞc myocarditis and neoplasia can involve the myocardium in HIV-infected patients with advanced immunodeÞciency

TABLE 23.1. *Cardiac conditions associated with human immunodeÞciency virus infection*

MYOCARDIAL DISEASE

Opportunistic Infections
- Bacterial: Mycobacterium tuberculosis
  Mycobacterium avium complex
- Fungal: Cryptococcus neoformans
  Aspergillus fumigatus
  Candida albicans
  Histoplasma capsulatum
  Coccidioides immitis
- Protozoan: Toxoplasma gondii
  Pneumocystis carinii
- Viral: Cytomegalovirus
  Herpes simplex
  Coxsackie B virus

Direct HIV Infection
Lymphocytic Myocarditis
Non-In ammatory Myocardial Necrosis: Microvascular spasm
Catecholamine excess
Nutritional De ciency
Hypoxic Injury
Toxic Lesions: Anti-HIV drugs
Drugs used for opportunistic infections or malignancies
Arteriopathy
Cardiomegaly & Cardiomyopathy:
- Right ventricular hypertrophy or dilation with pulmonary hypertension resulting from:
  - pulmonary infections
  - pulmonary emboli
  - plexogenic pulmonary arteriopathy related to HIV infection
- Biventricular dilation (congestive cardiomyopathy)

Neoplasia: Kaposi's sarcoma
Lymphoma

ENDOCARDIAL DISEASE

Marantic endocarditis (non-bacterial thrombotic endocarditis)
Healed bacterial endocarditis
Infective endocarditis: bacterial
fungal

PERICARDIAL DISEASE
Infectious
- Bacterial: Myobacteria (M. tuberculosis, M. avium complex, M. kansasii)
  Nocardia
- Viral: Herpes simplex
  HIV
  Coxsackie
- Fungal: Histoplasma
  Cryptococcus

Non-infectious: Uremia

Neoplastic: Kaposi's sarcoma
Lymphoma

Fibrinous Pericarditis
Idiopathic

Reproduced from Arshad A, Bansal A, Patel RC: Cardiac complications of human immunode ciency virus infection. Diagnostic and therapeutic considerations. *Heart Disease* 2000;2:133–145.

(Table 23.1). The complete etiologic spectrum of myocarditis has not yet been delineated. In an autopsy study, Kaul and associates (39) described myocarditis in 46% of patients with HIV infection. In 80% of these patients no speciÞc microorganism was found, whereas in the remaining 20%, one or more opportunistic pathogens was present.

In the aforementioned study by Barbaro et al. (18), all patients found to have echocardiographic evidence for a dilated cardiomyopathy, underwent endomyocardial biopsy. A histologic diagnosis of myocarditis was made in 83% (63/76) of these patients. Inßammatory inÞltrates were predominantly composed of CD3 and CD8 lymphocytes. Some of the patients with evidence for HIV in cardiac tissue were also co-infected with Coxsackie virus group B, cytomegalovirus (CMV), or Epstein-Barr virus (EBV) (18).

Myocardial involvement in HIV infection has been classiÞed into the following categories: infectious or lymphocytic myocarditis; non-inßammatory myocardial necrosis; dilated cardiomyopathy; and inÞltrative myocardial disease caused by neoplasia such as KaposiÕs sarcoma or high grade lymphoma (40).

Bacterial, Fungal and Protozoan Opportunistic Infections

The number of reported opportunistic infections in HIV-infected patients involving the heart continues to grow (Table 23.1) (37). Multiple simultaneous infections may also occur (41,42). Common pathogens include *Toxoplasma gondii*, *Mycobacterium tuberculosis* and *Cryptococcus neoformans*.

Opportunistic infections, neoplasia and other pathologic conditions which occur in patients with HIV infection often have been explained in terms of deÞcient immune surveillance that stems from a reduced number of T helper (CD4) lymphocytes. However, in studies by Himelman et al. (24) and Akhras et al. (25), there was lack of a quantitative difference in the number of CD4 cells in HIV-infected patients with and without cardiomyopathy or myocarditis. In contrast, other studies have demonstrated that the degree of immunosuppression, as evidenced by a decreased CD4 lymphocyte count, correlated strongly with echocardiographic evidence of myocardial dysfunction (31,43). However, cardiomyopathy may occur before advanced immunodeÞciency develops (CD4 $< 200\ mm^3$) (18).

Reactivation of infection is the proposed explanation for many of the HIV-associated opportunistic infections (44,45) including infections caused by *P. carinii*, *T. gondii*, *H. capsulatum*, *C. neoformans*, *M. tuberculosis* and *M. avium-intracellulare*. Myocardial involvement, when present, is usually not extensive and often occurs in the absence of signiÞcant histologic damage by these organisms. Often the myocardium is an incidental site of infection. *T. gondii* and *M. tuberculosis*, however, are two pathogens with an apparent tropism for the myocardium or pericardium (45). Cardiac toxoplasmosis was diagnosed at necropsy in 12% of AIDS cases in an autopsy study by Hofman et al. (46). In this study, myocardial lesions were generally asymptomatic and were not discovered until necropsy. Myocarditis is not a common Þnding with *M. tuberculosis* (47). More common is the Þnding of pericardial involvement as part of widely disseminated tuberculosis.

Viral Myocarditis

The histologic Þnding of mononuclear inßammatory inÞltrates in myocardial tissue suggests a viral cause for myocarditis, although this could also reßect an autoimmune process. Viral agents, such as CMV, Herpes simplex, Coxsackie, as well as HIV itself, are seriously considered as etiologic agents. Intranuclear inclusions characteristic of CMV infection have been reported in the myocardium of some patients (14,48,49). Other studies have demonstrated CMV antigen and CMV immediate early gene expression within myocytes from HIV-infected patients with cardiomyopathy (50,51), suggesting non-permissive infection of myocytes without classical intranuclear inclusions. Myocyte infection may be necessary to trigger cellular and humoral-mediated cardiac injury. Because it is well known that CMV infections can cause tissue necrosis without associated inßammatory changes, it is still possible that CMV or other viruses, including HIV, are the responsible agents in patients with HIV infection in whom myocardial necrosis without inßammation is seen (48). Coxsackie B virus has also been associated with myocarditis in patients with AIDS (52). EBV is another opportunistic pathogen which can be reactivated to cause disease in immunosuppressed patients. Chronic B-cell stimulation mediated by EBV in the absence of modulation by functional T helper lymphocytes may be an etiologic factor in the development of cardiac lymphomas (53).

HIV Myocarditis

Hypothetically, HIV may damage myocytes either by direct infection with ultimate cytolysis or by Ònnocent bystander destructionÓ as proposed by Ho and coworkers (54) in their explanation for the presence of neuroglial cell damage in HIV infection-associated subacute encephalitis. Autocrine and paracrine factors, lymphokines, or other enzymes released by HIV-infected lymphoreticular cells may be involved in disease pathogenesis by mechanisms other than immunosuppression (54). HIV has been documented in cardiac tissue by culture (7), southern blot (55), *in situ* hybridization (56,57), and polymerase chain reaction (58). Because there is no direct correlation with

any histopathologic Þnding or clinical heart muscle disease (56), it is difÞcult to make a direct link between the presence of HIV in the myocardium and the induction of myocarditis. In one study (18), HIV nucleic acid sequences were detected by in situ hybridization in 76% of patients with dilated cardiomyopathy and 57% of patients with a histologic diagnosis of myocarditis, which would suggest that there is a pathogenetic relationship between HIV and myocarditis or dilated cardiomyopathy. However, in most cases, the myocytes with a positive hybridization signal were sparse and were not surrounded by inßammatory cells.

Flomenbaum et al., in an autopsy study, described large numbers of multi-lamellated membrane bodies predominantly associated with the mitochondria of myocytes (55), and it is believed that this membranopathy may be an HIV infection-speciÞc abnormality related to the development of heart muscle disease. Cotton (59) reported on the observation that large amounts of HIV proteins rather than the whole virus can be found bound to muscle Þbers in heart muscle. Other investigators, using different methods, also found HIV viral proteins in the human heart (5,55Ð58). These studies suggest that the cardiac myocyte is at least an induced target for HIV. However, a direct link between the presence of HIV in the myocardium and the induction of myocarditis has not been established.

Autoimmunity and the Heart

Various cytokines and hormones may play an important role in HIV-related cardiac dysfunction; these include endothelin (ET-1), tumor necrosis factor alpha (TNFα), atrial natriuretic factor (ANF) and nitric oxide (NO), substances which may be deleterious to cardiac myocytes (60Ð62).

Recent studies suggest that inducible NO synthases (iNOS) and TNFα can inßuence the clinical course of cardiomyopathy in patients with AIDS (63,64). Endomyocardial biopsy specimens from 82 HIV-infected patients with dilated cardiomyopathy were compared with biopsy material from 80 patients with idiopathic dilated cardiomyopathy and were processed for determination of immunostaining intensity of TNFα and iNOS and for virological examination. Staining intensity was greater in patients with AIDS cardiomyopathy than in the other group and correlated inversely with the CD4 count (64). These data suggest that cytokine-mediated cell signalling plays an important role in AIDS cardiomyopathy.

Acierno (47) suggested that myocardial damage could relate to hypersensitivity resulting from uncontrolled hypergammaglobulinemia from altered T cell function. HIV-infected patients show high concentrations of immune complexes in their sera, but the relationship of this Þnding to direct myocardial damage still needs to be determined.

Herskowitz and other investigators (65Ð69) have proposed an autoimmune mechanism for HIV-related myocardial disease, similar to that described with anti-myosin antibodies. They postulate that an HIV gene alters the cell surface of the muscle Þber, eliciting a progressive autoimmune reaction. A series of experiments have revealed the presence of circulating cardiac autoantibodies to a variety of antigens in patients with cardiomyopathy without HIV infection and in a majority of patients with cardiomyopathy and HIV infection. Patients who are HIV-infected without cardiomyopathy do not demonstrate these autoantibodies. Immunohisto-chemical, immunopathological and serological studies in humans with HIV infection and cardiomyopathy have shown that the majority of inßammatory cells are CD8 positive and express abnormally large amounts of Class 1 and 2 histocompatibility markers, interleukin-1 and other cytokines, which may contribute to the induction of heart speciÞc autoimmunity (65,69a).

Non-Inßammatory Myocardial Necrosis

It is common to Þnd areas of myocardial necrosis in patients dying of AIDS without associated inßammation. Necrosis of myocytes may be brought about by the long-term stresses that HIV- infected patients are subjected to as a result of their disease, mediated by excessive catecholamine stimulation (70). Microvascular spasm causing transient and focal or widespread ischemia and necrosis has been implicated as another pathogenic mechanism (71), especially for the development of congestive cardiomyopathy (72). Microvascular spasm may also be an aggravating factor in HIV infection-associated myocarditis (47).

Vascular Lesions (Arteriopathy)

Several types of arterial vascular lesions have been described in patients with HIV infection. These include an arteriopathy with and without aneurysmal formation, a ÞbrocalciÞc lesion, and endothelial proliferation in association with Kaposiõ sarcoma with episodes of coronary artery thrombosis (73Ð76).

Joshi and coworkers (74) reported the occurrence of arteriopathy in children with HIV infection. Two types of lesions were described: inßammatory and ÞbrocalciÞc. Inßammatory lesions consisted of a vasculitis or perivasculitis in the brain and myocardium. FibrocalciÞc lesions consisted of intimal Þbrosis with fragmentation of elastic tissues, Þbrosis and calciÞcation of the media with variable luminal narrowing. This has been observed in many organs, including the heart and has involved small and medium-sized arteries. In one case, three aneurysms of the proximal right coronary artery were seen in association with intraluminal thrombosis and myocardial infarction. The left coronary artery had similar ÞbrocalciÞc lesions but of lesser severity and without aneurysmal

formation. None of the lesions showed evidence of inflammation or necrosis of vessel walls (74). The pathogenesis of fibrocalcific arteriopathy is unclear. Based on its clinicopathologic and immunologic features, it appears to be distinctive and separate from Kawasaki's disease and idiopathic arterial calcification of infancy (73–76). Causative factors that have been suggested include: (1) HIV itself; (2) persistent and unchallenged antigenic stimulation; and, (3) endogenous or exogenous elastases (77). These observations in children suggest the possibility that an arteriopathy will be seen with increasing frequency and severity as longer survival rates of children with HIV infection are achieved (74,77).

In an autopsy series of HIV-infected adults, Paton et al. described the presence of major eccentric atherosclerotic lesions involving the coronary vessels with significant luminal obstruction (78). The mean age of subjects in this series was 27 years, and no detectable risk factors for coronary artery disease were found other than tobacco smoking at moderate levels.

Mild aortic root dilation was recently observed in children from 2 to 9 years of age with vertically transmitted HIV infection (79). The aortic root size was not significantly associated with markers for stress modulated growth, however, aortic root dilation was associated with left ventricular dilation, increased viral load, and lower CD4 counts.

Autonomic Dysfunction

Neild et al. studied heart rate variability as a marker of cardiovascular autonomic tone and found it to be reduced in HIV-infected patients (80). All components of heart rate variability were reduced in patients with AIDS ($p < 0.0001$) when compared with controls. Therefore, HIV may be associated with global autonomic dysfunction which is not related to heart disease (80).

Drug-Induced Myocarditis or Vasculitis

A number of drugs used in the treatment of HIV infection and its infectious or neoplastic complications have been associated with a variety of heart problems. Some have been shown to induce structural changes in the heart and blood vessels with resultant dysfunction. Others have direct toxic effects, manifesting as acute or chronic myocarditis.

Pentamidine has been associated with severe ventricular arrhythmias including torsades de pointes (10). When used intravenously it can also cause orthostatic hypotension, especially if infused too quickly (81). Trimethoprim-sulfamethoxazole has also been associated with torsade de pointes (82), as well as hypokalemia through its action on renal tubules. Neither of these drugs, which are used to treat *P. carinii* pneumonia, have been described to cause myocarditis or congestive heart failure in patients with or without HIV infection (83,84). Amphotericin B, used in severe fungal infections, has been reported to cause arrhythmia, hypotension, hypertension, electrolyte disturbances (notably hypokalemia and hypomagnesemia), and cardiac arrest.

Cocaine abuse has been associated with myocarditis and dilated cardiomyopathy (85–88). Whether intravenous drug use is an additional risk factor for myocarditis or myocardial dysfunction among patients with HIV infection is still uncertain (33,89). Cho et al. (33) observed that the prevalence of idiopathic myocarditis and dilated cardiomyopathy was significantly higher in a group of HIV-infected patients who had intravenous drug use as their primary risk factor, as compared to male homosexuality, a finding confirmed by our own clinical experience. Turnicky et al. (35) concluded in their study that intravenous drug use is an independent risk factor for myocardial diseases.

Chemotherapy used for treatment of Kaposi's sarcoma in patients with HIV infection includes vincristine, vinblastine, doxorubicin and α-interferon. Cardiomyopathy is a well-recognized complication of doxorubicin (90,91). Hypertension and unexpected myocardial infarction have been reported with vinblastine (47). Adverse cardiovascular effects of α-interferon are hypotension, hypertension and tachycardia (91–94). Three patients, after prolonged and high-dose therapy with α-interferon, developed dilated cardiomyopathy with profound myocardial dysfunction which improved after cessation of therapy (95).

Investigators demonstrated that zidovudine could induce myocardial and skeletal muscle mitochondrial changes (96–98) related to zidovudine-induced inhibition of mitochondrial DNA replication. Zidovudine and didanosine, two reverse transcriptase inhibitors, have been proposed as both deterrents to and inducers of cardiomyopathy (99,100). Lipschultz et al. (101), however, compared 24 HIV-infected children receiving zidovudine with untreated HIV-infected children, and did not find a decrease in myocardial contractility associated with use of the drug. Lipschutz et al. recently studied a larger group of infants born to HIV-infected women from birth to five years of age with echocardiographic studies every four to six months. They found that zidovudine was not associated with acute or chronic abnormalities in left ventricular structure or function in infants exposed to the drug in the perinatal period. No child over the age of 10 months had depressed fractional shortening (102).

Lipodystrophy and vascular complications can occur during treatment with protease inhibitors (103–109). Initial case reports have described the development of lipid abnormalities and vascular events that were closely related to the initiation of protease inhibitor therapy. It was suggested that the important risk factors for atherosclerosis and atherothrombosis be characterized in order to establish which patients might be at risk for vascular

events on protease inhibitors (106). In a recent review on hyperlipidemia associated with protease inhibitor use, it was suggested that lipid abnormalities generally consist of elevated triglycerides and total cholesterol levels, with reduced HDL cholesterol levels. The pathophysiological mechanism is unknown, but a recent hypothesis is that the catalytic region of HIV-1 protease has a 60% homology to regions within 2 proteins that regulate lipid metabolism: cytoplasmic retinoic acid-binding protein-1 and LDL receptor-related protein. Inhibition of these proteins by protease inhibitors may result in abnormalities in lipid metabolism leading to hyperlipidemia, fat redistribution and insulin resistance (104,107). The clinical signiÞcance of these abnormalities in terms of risk of coronary events, however, has not been established. Coplan et al. conducted a cross protocol analysis of randomized phase 3 clinical trials sponsored by the pharmaceutical industry that examined treatment with the protease inhibitors, indinavir, nelÞnavir, ritonavir and saquinavir (110). A total of 7668 subjects were randomized to treatment with nucleoside analogues plus a protease inhibitor and 3318 to treatment with nucleoside analogues only. Rates of myocardial infarction did not differ between the subjects receiving protease inhibitors compared with control subjects, and the rates were similar to those reported in population-based epidemiological studies of the general population. The mean age of the patients in these trials was 37 years and mean follow up time was one year (110). Observational data from Kaiser Permanente also failed to show an increased incidence of coronary events in patients receiving protease inhibitors (111).

Use of anabolic steroids has increased in patients with the wasting syndrome of AIDS. Physicians need to be alerted to the possibility of toxicity from this treatment including a risk of myocardial infarction (112).

Nutritional DeÞciency

The terminal stages of HIV infection often involve signiÞcant cachexia and nutritional problems such as selenium and vitamin B deÞciencies, which can cause myocardial dysfunction (113,114). Kavanaugh-McHugh et al. (113) documented that selenium deÞciency is common in malnourished pediatric AIDS patients. Selenium supplementation in this subgroup of AIDS patients has been shown to improve cardiac function (113). Vitamin B1 deÞciency in sick patients may be a cause of cardiomyopathy. However, Acierno (47) feels that at most, it would be a secondary factor. In an autopsy study, Lewis described concurrent cardiac atrophy in subjects who were seriously wasted (115). Umana et al. found that the left ventricular mass index was signiÞcantly higher and left ventricular fractional shortening signiÞcantly lower in HIV-infected patients with recent substantial weight loss compared to normal healthy controls (116). A recent study by Martinez-Garcia et al. demonstrated that HIV-infected patients had a reduced left ventricular mass index with diastolic abnormalities (117).

Clinical Implications of Myocarditis

Many cardiac syndromes have been described in patients with HIV infection, some of which may be progressive and disabling or fatal. Clinical manifestations of myocarditis can include chest pain, dyspnea, fatigue, peripheral edema, dizziness and syncope, although the majority of patients are asymptomatic (40).

Successful therapy for *T. gondii* myocarditis has been reported (118). Therefore, there should be a low threshold for considering this diagnosis in toxoplasma seropositive HIV-infected patients with advanced immunodeÞciency who develop heart failure suddenly (41).

Levy and colleagues (119) made an antemortem diagnosis of myocarditis by endomyocardial biopsy in two patients with known cardiac dysfunction. After treatment with azathioprine and prednisone, a repeat myocardial biopsy showed resolution of the myocardial inÞltrate in one patient who remained asymptomatic without medication during 15 months of follow up. Similar observations were made by Kaul et al. (39). However, there is a report of spontaneous regression of cardiomyopathy in a patient (120). In addition, the Myocarditis Treatment Trial did not support the routine treatment of non-HIV-infected patients with myocarditis with immunosuppressive therapy (121). In patients with heart failure and myocarditis, digoxin should be used with caution because there is an increased sensitivity to the drug. At present, there is no standard methodology for diagnosing myocarditis. Myocardial biopsy may be diagnostically helpful, but has limited sensitivity due to non-diffuse involvement. The presence of speciÞc classes of ventricular ectopic beats may represent a simple and sensitive EV6 marker of HIV-related myocarditis. These beats correlate signiÞcantly with abnormalities in systolic and diastolic echocardiographic parameters (19). Cardiac nuclear scans, such as the gallium 67 scan, the technetium 99 pyrophosphate scan, and the antimyosin antibody scan, are currently used to evaluate patients suspected to have myocarditis. A positive scan is supportive but not diagnostic of the disease. The gallium 67 scan has a limited sensitivity of 36%, with an excellent speciÞcity of 98% (122). The indium 111 antimyosin antibody scan has a sensitivity of 83% and a speciÞcity of 53% (123,124).

CARDIOMEGALY AND CARDIOMYOPATHY

Right ventricular hypertrophy and dysfunction are common Þndings in autopsy series of HIV-infected patients. The most probable cause is pulmonary hypertension related to hypoxia (125), secondary to recurrent pulmonary infections with *P. carinii* or other interstitial lung diseases (47,115). Reports have suggested a possible

association between HIV infection and primary pulmonary hypertension (37,126–130). Mette et al. (127) reported three HIV-infected homosexual men with primary pulmonary hypertension independent of drug use and pulmonary disease. The condition did not appear to be due to direct infection of the pulmonary vasculature by HIV, but to an autoimmune process. Possible etiologies of pulmonary hypertension and cor pulmonale in HIV-infected patients appear diverse, and may include recurrent viral, bacterial, parasitic or fungal pulmonary infections; HIV related interstitial pneumonitis and fibrosis; necrotizing angiotis secondary to intravenous drug use; and thromboembolic events. In a recent review of 131 HIV-infected patients with pulmonary hypertension (131), the interval between diagnosis of HIV infection and diagnosis of pulmonary hypertension was 33 months. Sixty-six patients died during a median follow up period of 8 months, and it was concluded that 82% of the cases were related solely to HIV infection. The appearance of unexplained cardiopulmonary symptoms in HIV-infected patients should suggest pulmonary hypertension (131). In a case series of 56 HIV-infected patients, 7.1% of patients had pulmonary hypertension not related to other well known associated conditions (132). Despite low HIV RNA viral loads and an efficacious antiretroviral drug regimen, pulmonary hypertension worsened. Antiretroviral therapy seems not to prevent or reduce the RV pressure gradient in pulmonary hypertension. It may be that in individuals with an immunogenetic predisposition, high levels of secretion of cytokines and endothelin-1 stimulated by a trigger other than HIV may be at work (132). Aguilar et al. (133) studied six patients with severe pulmonary hypertension associated with HIV infection and treated them with continuous intravenous epoprostenol infusions. This treatment resulted in rapid decreases in both mean pulmonary artery pressure and pulmonary vascular resistance and an increase in cardiac output with similar hemodynamic improvements when these patients were restudied at one year.

Congestive dilated biventricular cardiomyopathy is increasingly being recognized as an important manifestation of HIV infection. Both Cohen et al. (7) and Anderson and Virmani (26) reported the association between HIV infection and dilated cardiomyopathy in clinicopathologic studies. Subsequently, both Himelman et al. (24) and DeCastro et al. (21) documented dilated cardiomyopathy with echocardiography in a large series of patients with HIV infection. The most common echocardiographic findings in their series (21,24) and that of Hecht et al. (23) were impaired left ventricular fractional shortening and left ventricular dilation. It is estimated from echocardiographic studies that cardiomyopathy may be present in up to 30–40% of patients (7,9,23,24,41,43). Herskowitz et al. (31) reported on the prevalence and incidence of left ventricular dysfunction in a large cohort of patients with known HIV infection using two-dimensional echocardiography. They described a 14.5% prevalence of hypokinesis and an incidence of 18% per year, most of which occurred in patients who had low CD4 counts. A subgroup of these patients developed symptomatic heart failure. Similarly, DeCastro and associates (134), in a prospective study showed that about 10% of patients with AIDS developed acute global left ventricular dysfunction.

The pathogenesis of cardiomyopathy still remains uncertain. Shannon et al. (135) studied simian AIDS-associated dilated cardiomyopathy in Rhesus macaques, and found that left ventricular ejection fraction was significantly depressed in those chronically infected with pathogenic SIV compared with those infected with non-pathogenic SIV. Furthermore two-thirds of macaques that succumbed to simian AIDS had myocardial pathology which included lymphocytic myocarditis, coronary arteriopathy and complete vessel occlusion and associated myocardial infarction and necrosis (135). A primary culture of a subpopulation of human fetal cardiac myocytes could not be infected with wild type HIV1, suggesting that direct infection of cardiac muscle fibers is not the cause of HIV heart disease (136). The presence of other viruses, i.e. EBV, CMV or Coxsackie, in certain of the biopsies done by Barbaro et al. (18) suggests a role for these viruses in the pathogenesis of myocarditis. Bowles et al. used polymerase chain reaction to demonstrate that 42% of HIV-infected patients with myocardial inflammation had CMV and adenoviruses besides HIV in their hearts (137). However, some patients with adenovirus had congestive heart failure but no myocarditis, an observation that raises doubt regarding the possible role of adenoviruses as an etiological agent.

Myocarditis has been suggested as the cause for cardiomyopathy (5,134,138–140). However, many reports describing dilated cardiomyopathy do not describe myocarditis at autopsy (115). It has been postulated that in these patients, the active myocarditis had already resolved or that the altered immune response masked the presence of myocardial infection with opportunistic viruses or HIV.

Gross pathologic findings in patients with cardiomyopathy include increased heart weight, biventricular or four chamber dilation, and a pale-appearing myocardium (7,15). On microscopic examination, these cases have shown evidence of both hypertrophy in focal areas and focal areas of atrophy with diffuse loss of myofibrillar elements and vacuolization of the atrophic myocytes (7,15). Focal areas of inflammatory infiltrate have been seen containing lymphocytes, histiocytes, and occasional plasma cells in the myocardial interstitium (115). Electron microscopic studies have revealed loss of myofibrils, lipid deposition, and an increase in the number of mitochondria.

Clinical Implications of Cardiomyopathy

In the early years of the HIV epidemic, clinical cardiac disease was rarely described. However, more recent

studies have described patients with symptomatic cardiac dysfunction. The onset of congestive heart failure often heralds the preterminal stage of the disease (25).

The underlying cause of heart failure has prognostic value in patients with unexplained cardiomyopathy. Patients with cardiomyopathy due to HIV infection may have a worse prognosis compared with other patients with cardiomyopathy. In a recent study by Felker et al. (141), patients with HIV cardiomyopathy had a worse survival over a 4.4 year follow-up period compared to patients with idiopathic cardiomyopathy (adjusted hazards ratio for death was 5.86 with the 95% conÞdence interval, 3.92 to 8.77) (141).

In another study the median survival was 101 days in HIV-infected patients with cardiomyopathy as compared with 472 days in HIV-infected patients with normal hearts who were at a similar stage of disease (142). A longitudinal prospective study of HIV-infected infants and children found that left ventricular fractional shortening determined by echocardiography was a signiÞcant independent predictor of overall mortality, even after adjustment for age, CD4 cell count, and progressive neurologic disease, demonstrating the clinical importance of cardiac function in the outcome of HIV-infected patients (143). The degree of left ventricular dysfunction correlated with the extent of immune dysfunction at baseline but not over time, suggesting that the CD4 count may not be a useful surrogate marker of HIV associated left ventricular dysfunction. Another study in children also showed that depressed left ventricular function correlated with CD4 counts at baseline but not longitudinally (144). The same study showed that development of encephalopathy correlated well with decreased fractional shortening of myocardial muscle Þbers. Hornberger et al. found that vertically transmitted HIV infection may be associated with reduced left ventricular size but no alteration in cardiac function in the fetus in utero (145).

Dyspnea is one of the most common symptoms of HIV infection and because of the high prevalence of pulmonary disease, it is presumed to be secondary to it. However, with the increasing prevalence of cardiac dysfunction, myocardial disease has to be considered in the evaluation of patients, especially when dyspnea is out of proportion to underlying pulmonary disease. Chest x-rays are relatively insensitive for detecting cardiac dysfunction, but they may show evidence of cardiomegaly. EKG Þndings are usually non-speciÞc. Hsai and coworkers (146) found that late potentials on signal-averaged electrocardiograms performed on HIV-infected patients were both common and intermittent, but were not related to contractile abnormalities. Echocardiography shows cardiac abnormalities in excess of 30% of patients in some studies (22), often segmental abnormalities at the level of the interventricular septum (21). Barbaro and co-workers found an early impairment of systolic and diastolic function in asymptomatic HIV-infected patients (CD4 □600) (20). In their multicenter echocardiographic and echo-doppler study, 1236 asymptomatic New York Heart Association class I HIV-infected patients were compared to 1230 healthy subjects. An analysis of the echocardiographic data revealed a reduction of 19.7% in ejection fraction, an increase of 55.7% in wall motion score, a reduction of 34.6% in the E/A ratio and an increase of 19.7% in the isovolumetric relaxation time in HIV-infected subjects compared with healthy controls. Echocardiographic alterations were observed in 57.2% of HIV-infected subjects and in 13.7% of control subjects (20).

Although the etiology of cardiomyopathy is most often unclear, treatment of congestive heart failure is the same as for patients without HIV infection. Treatment for opportunistic infections and neoplasia may need to be altered. Intravenous treatment should be given in lower volumes, and cardiotoxic drugs, such as doxorubicin and daunorubicin, should be avoided (33).

NEOPLASIA OF THE HEART

Kaposiõ sarcoma and malignant lymphoma affecting the heart have been described in patients with HIV infection (16,147). Kaposiõ sarcoma is, by far, the most common malignancy affecting the heart.

Kaposiõ Sarcoma

Kaposiõ sarcoma is a neoplasm which possibly arises from endothelial cells. Heart involvement in Kaposiõ sarcoma is usually part of a widely disseminated process. In 1983, Autran et al. (3) Þrst described Kaposiõ sarcoma involving cardiac tissue in HIV-infected patients. Kaposiõ sarcoma originates in the visceral or parietal pericardium, and less frequently in the myocardium (148). Rarely are both the pericardium and myocardium involved together. Kaposiõ sarcoma may also involve the adventitia of the coronary arteries and involvement of the great vessels has also been reported (148). Various groups have reported its predilection for the epicardium and subepicardial fat (148,149). At autopsy, the prevalence of cardiac Kaposiõ sarcoma in HIV-infected patients with other evidence of Kaposiõ sarcoma was reported by Cammarosano and Lewis (148) to be 4 out of 21 (20%) and by Silver et al. (16) to be 5 out of 18 (28%). A few cases of fatal cardiac tamponade in patients with epicardial Kaposiõ sarcoma have been reported (150,151), and one patient presented with pericardial constriction (39). A common observation in all studies was the paucity of clinical cardiac dysfunction even in cases with extensive myocardial involvement.

Malignant Lymphoma

Malignant lymphoma involving the heart, although infrequent, has been described in HIV-infected patients.

Most of these non-Hodgkin lymphomas are high grade with Burkitt-like cells (small and non-cleaved), reticulum cell sarcomas, or large cell immunoblastic sarcomas (16,152). In the majority of cases they appear to originate from B cells, with most of them displaying a monoclonal pattern of immunoglobulin staining. In some cases the EBV genome was shown in the proliferating cells (152). Extranodal sites of lymphoma are common in HIV-infected patients, and involvement of the heart can occur as part of this disseminated process (16,97,147,153–155).

Despite their rarity in general (156), primary cardiac lymphoma has been reported in HIV-infected patients (157–159), and many theories have been put forward for their pathogenesis (160,161): (1) chronic antigenic stimulation; (2) impaired immune surveillance; (3) reactivation of latent oncogenic herpes group viruses; (4) impaired immunoregulation; (5) carcinogenic effects of immunosuppressive, cytotoxic or other drugs; (6) genetic susceptibility; and (7) interleukin-6 production (161).

Lymphomas involving the heart are characterized by one of two different pathologic patterns: diffuse infiltration that imparts a pale appearance to the heart; or involvement of the epicardium, myocardium and endocardium in the form of focal circumscribed nodules (156,157).

Clinical manifestations of lymphomatous involvement of the heart may include cardiomegaly, pericardial effusion, congestive heart failure, or progressive heart block (157,159). Sudden death is a rare event (159), and over one-half of the patients have no clinical evidence of cardiac dysfunction. Gallium-67 and blood pool isotope studies can aid in the diagnosis (162,163). Echocardiographic and EKG studies demonstrate non-specific findings. The outcome is usually poor, and the optimal approach to therapy is still not known (164).

ENDOCARDIAL DISEASE

Marantic Endocarditis

The most common endocardial lesion seen with HIV infection is non-bacterial thrombotic endocarditis, also known as marantic endocarditis (148,165,166). Any of the valves can be involved, but left-sided lesions are the most common. Marantic endocarditis is also associated with chronic wasting disease, malignancies and hypercoagulable states (148,165,166). In a study of HIV-infected patients with marantic endocarditis (148), vegetations were friable and systemic embolization occurred. The diagnosis of marantic endocarditis is very difficult to make before death, even with the help of echocardiography (167).

Bacterial Endocarditis

Infective endocarditis is infrequent in AIDS, despite the fact that intravenous drug use is an important risk factor for HIV infection (39). The most common organism causing bacterial endocarditis in HIV-infected intravenous drug users is *Staphylococcus aureus* (>75%) (168).

One study reported no significant difference in hospital mortality among patients with endocarditis whether or not they were HIV positive or negative. However, the investigators did note a higher frequency of left ventricular dysfunction in the HIV-infected group (169). Bacterial endocarditis may be more virulent in immunocompromised hosts as compared with normal hosts (11).

Fungal Endocarditis

Henochowicz and colleagues (170) described one patient with HIV infection who had *Aspergillus* endocarditis diagnosed at autopsy. The patient did not have a cardiac murmur, nor a positive blood culture for *Aspergillus fumigatus* or any evidence of cardiac dysfunction. At autopsy, pulmonary aspergillosis, myocardial abscesses and cerebral emboli were found. *Cryptococcus* and *Candida* fungal endocarditis have also occurred in AIDS patients, particularly among intravenous drug users. In patients with fungemia, signs of systemic or cerebral embolism may indicate the presence of endocarditis (40).

PERICARDIAL DISEASE

Pericardial disease is a frequent cardiovascular manifestation of HIV infection and is often associated with a shortened survival (171). The prevalence of a demonstrable effusion based on echocardiography varies from 10–59% (26,39,115,134,172) and the development of an effusion suggests endstage HIV disease (171). The spectrum of pericardial disease in different reports ranges from asymptomatic effusions detected by echocardiography to fatal tamponade and constrictive pericardial disease. In 15 autopsy and echocardiographic series involving 1139 patients with HIV infection, the average prevalence of pericardial disease was 21% (173). Pericarditis is usually non-specific in origin and can occur with or without pericardial effusion (174). Levy et al. found no difference in the prevalence of pericardial effusion between HIV-infected patients with and without AIDS (119). Initial symptoms and signs are frequently subtle, but may include chest discomfort and findings of tamponade and hypotension (39). Low pressure tamponade is a phenomenon that is sometimes seen in AIDS patients who are severely dehydrated and cachectic; the severe volume depletion may cause reduced right ventricular filling pressures, and even a minimal pericardial effusion may cause a hemodynamically significant tamponade (173). In this setting, jugular venous distention or pulsus paradoxus may be absent (175). Most cases of pericardial effusions are asymptomatic and without an identifiable cause. However, in those that are symptomatic, about two-thirds

are caused by an infection or neoplasm. Etiology includes Kaposi's sarcoma and various microorganisms such as *M. tuberculosis* (8), *M. avium-complex* (176), *Cryptococcus neoformans* (177), Herpes simplex (178), *Nocardia asteroides* (179) and pyogenic bacteria such as *Staphylococcus aureus* (Table 23.1). In 66 published cases of cardiac tamponade in patients with HIV infection, 26% were caused by tuberculosis, 17% were pyogenic, and 8% were caused by atypical mycobacteria. Lymphoma and Kaposi's sarcoma each accounted for 5% of these effusions. Less frequent causes of tamponade were *C. neoformans*, CMV and *M. kansasii* (173). The cause of asymptomatic effusions often remains uncertain. Culture of pericardial fluid in these cases is usually unrevealing. Some pericardial effusions are attributable to viral pericarditis, uremia or congestive heart failure in patients with HIV-associated cardiomyopathy. Echocardiographic evaluation has proven to be an excellent diagnostic tool in detecting and monitoring pericardial effusion (21,24,39,172).

Small asymptomatic pericardial effusions in patients with HIV infection do not require diagnostic evaluation, and may be followed with serial echocardiography; however, symptomatic pericardial effusions should be investigated to find a potentially treatable infection or neoplasm (173). Non-steroidal anti-inflammatory drugs may be helpful therapeutically, but corticosteroids should generally be avoided because concurrent infections may be exacerbated by steroid therapy.

The value of pericardial fluid analysis in HIV-associated pericardial effusions is controversial with diagnostic yields ranging from 0 to 100% (150,172,180–182). HIV infection is the most common underlying disease in recent retrospective and prospective reports of patients undergoing pericardiocentesis in urban settings (172,182,183). Reynolds et al. (182) have suggested that mycobacterial disease is a common etiology for large HIV infection-related pericardial effusions. HIV-infected patients from the inner city who have pulmonary infiltrates and fever are at risk for tuberculosis as the cause of pericardial effusion (184). Based on available evidence, the diagnostic use of pericardiocentesis in this population remains questionable. However, the procedure can provide unexpected diagnostic information and often demonstrates a total lack of concordance between infections in other organ systems and that in the pericardium (172).

Pericardiocentesis may not only be diagnostic, but also therapeutic in the case of tamponade. Pericardial biopsy may increase the diagnostic yield. An open drainage procedure usually done by the subxiphoid approach may be necessary for large pericardial effusions. Open drainage is required for pyogenic pericardial effusions (173).

THERAPEUTIC IMPLICATIONS

Since cardiac complications in HIV infection are often clinically non-apparent or subtle initially, periodic screening of these patients with both an EKG and echocardiogram is probably worthwhile, specifically in the subgroups of patients with a low CD4 count (< 400 mm^3) or in those patients receiving therapy with zidovudine. Because of the concern that patients receiving highly active antiretroviral therapy may develop a higher incidence of vascular complications and lipid abnormalities, risk factors for atherosclerosis should be evaluated before starting treatment with these drugs. Care should be given to proper nutrition of the HIV-infected patient because there is evidence that nutritional deficiency can initiate or aggravate a cardiomyopathic condition. Patients who have acute myocarditis should be treated when an arrhythmia develops or when there is evidence of myocardial dysfunction. Drugs used to manage congestive heart failure may include digoxin, diuretics, angiotensin converting enzyme inhibitors, angiotensin II receptor blockers, or beta-adrenergic blockers.

Patients with treatable infections of the myocardium, heart valves, and pericardium should receive the appropriate antimicrobial regimens. The appearance of unexplained cardiopulmonary symptoms in a patient with HIV infection should stimulate prompt evaluation of left and right ventricular function and the possibility of pulmonary hypertension should be investigated. The development of pulmonary hypertension portends a poor clinical outcome. Continuous infusion of intravenous epoprostenol has shown hemodynamic benefit in a small case series (184a).

Treatment of AIDS-related neoplasms of the pericardium or myocardium should be based on providing symptomatic relief. If cancer chemotherapy is being used, those agents that can cause myocardial depression should be avoided.

CONCLUSION

HIV infection is responsible for significant morbidity and mortality worldwide (185), and cardiac disease is increasingly being recognized as a complication of HIV infection. Cardiac diseases in HIV infection include myocarditis, myocardial necrosis, cardiomyopathy, arteriopathy, endocarditis, pericarditis, pericardial effusion, and neoplasm. These conditions are often not detected by clinical examination, and current knowledge is based almost exclusively on echocardiographic and autopsy studies which have detected abnormalities in over 30% of patients. AIDS is providing a clinical venue for gaining insights into the pathogenesis of rare cardiac diseases such as lymphocytic myocarditis, Kaposi's sarcoma involving the heart and dilated cardiomyopathy. In the future, observational and clinical trials may yield more information on the impact of treatment on these conditions and will be necessary for obtaining data concerning the mechanisms of myocardial damage in AIDS.

The cause and pathogenesis of myocarditis, cardiomyopathy and pericardial disease remain unresolved in

most situations. Opportunistic infections, vasculitis, hypoxia, an autoimmune process, catecholamine excess, adverse effects of medication (e.g. zidovudine) and nutritional deficiencies have been suggested as possible causes. There is now some evidence to suggest that HIV infection itself may be an important cause of myopericardial disease. In more than 80% of patients, no specific cause for myocarditis has been found.

Once myocardial failure develops, it has a poor prognosis despite the observation that patients often respond to traditional heart failure therapies. Pericardial involvement is frequent, often asymptomatic, and usually manifested as an idiopathic pericardial effusion, although neoplasms and opportunistic infections may also be seen. The value of pericardial fluid analysis is controversial. Endocardial involvement is most likely related to marantic endocarditis, however, bacterial endocarditis may also complicate the course of patients who are intravenous drug users. Infection with HIV does not appear to make patients more susceptible to bacterial endocarditis. Physicians should be alert to the high frequency of cardiac involvement in patients with HIV infection which might impact on the treatment and supportive care that these individuals require.

Chapter 24

Renal Manifestations of HIV Infection

Jonathan A. Winston, Paul E. Klotman and Mary Klotman

HIV-1 related diseases of the kidney encompass a spectrum of disorders and a diversity of clinical syndromes. They are often multifactoral in etiology, but a few very speciÞc diseases are known to be direct consequences of HIV-1 infection in the kidney. The others appear to be renal manifestations of systemic complications of HIV-1 infection or are related to drug therapy. A useful approach to the diagnosis of kidney diseases in general is to distinguish between the syndrome of acute renal failure (ARF) and chronic renal insufÞciency. The former is commonly encountered in the hospital setting, caused by combinations of tissue hypoperfusion, systemic infection, and/or the use of nephrotoxic drugs. Chronic renal insufÞciency is more commonly encountered in the outpatient setting, and can be due to one of many speciÞc disease entities. A clear separation of diseases into these two categories is not completely appropriate, however, because several diseases that are considered chronic in nature, such as HIV-associated nephropathy (HIVAN) and immune-complex glomerulonephritis, may present as the syndrome of acute renal failure. The physician must also consider the stage of the underlying HIV-1 infection, the presence of concomitant illnesses, current medications, the rate of fall in glomerular Þltration rate (GFR), abnormalities in urinary sediment, and urinary protein excretion.

Jonathan A. Winston MD: Clinical Associate Professor of Medicine, Division of Nephrology, Mount Sinai School of Medicine, New York.

Paul E. Klotman MD: Murray M. Rosenberg Professor of Medicine, Chairman, Department of Medicine, Chief, Division of Nephrology, Mount Sinai School of Medicine, New York.

Mary Klotman MD: Professor of Medicine and Associate Professor of Microbiology, Chief, Division of Infectious Diseases, Mount Sinai School of Medicine, New York.

ACUTE RENAL FAILURE

Acute renal failure (ARF) is a syndrome deÞned as an abrupt, detectable fall in GFR in an individual with otherwise stable kidney function. The causes of ARF found in the setting of HIV-1 infection are listed in Table 24.1.

Ischemic Acute Renal Failure

Ischemic acute renal failure from sepsis or hypotension induces acute renal failure usually as a result of acute tubule necrosis (ATN). The endothelium of the glomerular microcirculation and the renal tubular epithelial cells are most susceptible to ischemic injury. The functional abnormalities that result from this insult include a reduction in glomerular Þltration rate (GFR) and defects in urinary concentrating ability.

Under physiologic conditions, the kidney responds to hypotension or renal vasoconstriction by conserving salt and water. Urea is reabsorbed more efÞciently and the increase in blood urea nitrogen that occurs is referred to as prerenal azotemia. Daily urinary volume falls to as low as 500 ml/day, urinary sodium concentration falls below 10 meq/l, and urinary osmolality approaches 800 mosm/l. After ischemic injury, however, daily urinary volume may fall, may stay the same or can increase. Thus, the volume of urine unless the patient is anuric (urine volume $<$ 500 ml/day) is a poor index of renal function.

A much better index of renal function in distinguishing ischemic vs. prerenal azotemia in the setting of oliguria is the analysis of concentrating functions of the kidney. In prerenal conditions such as hypotension or sepsis, the kidney concentrates the urine and avidly resorbs sodium. Urine speciÞc gravity increases well above the plasma level of 1.010 and urine Na concentration falls to $<$ 5 meq/l. In the setting of renal injury, however, urinary speciÞc gravity rarely exceeds 1.010, and the urinary Na

TABLE 24.1. *Common causes of acute renal failure in HIV-1 infection*

Cause of ARF	Pathophysiology	Clinical presentation and diagnostic clues
Ischemic ARF (also known as acute tubule necrosis (ATN))	Hypoperfusion induces ischemic injury in renal endothelial and tubule cells.	Often accompanies a systemic in ammatory response syndrome. Clinical picture is marked by oliguria with defective Na and H_2O reabsorption (urinary speci c gravity (SG) □1.010 and urine Na concentration (U_{NA}) > 20 meq/l). Pigmented urinary casts observed on microscopic examination of urine.
Prerenal azotemia	Hypoperfusion reduces GFR by lowering effective glomerular ltration pressure. There is no ischemic cell injury.	Develops with severe intravascular volume depletion or low cardiac output. Oliguria is present but urinary Na and H_2O reabsorption are preserved (urinary SG > 1.018 and U_{NA} < 20 meq/l.) Urine sediment is normal.
Hepatorenal syndrome	Seen with chronic liver disease, advanced liver failure and portal hypertension. Marked abnormalities in arterial hemodynamics and vasoactive hormone production.	Recognized by progressive oliguric renal failure associated with chronic and acute liver disease. Chemical composition of the urine is similar to prerenal azotemia (SG > 1.018, U_{NA} < 10 meq/l), but does not improve with intravenous uids.
Drug induced Nephrotoxicity		
Aminoglycosides	Selectively transported into proximal tubule cells where drug accumulates in high concentration.	Nephrotoxicity is dose-dependent, daily urinary volumes exceed 500 ml (non-oliguric ARF) and is reversible.
Amphotericin B	Direct tubule epithelial membrane injury associated with acute reductions in GFR due to reduced renal blood ow .	Dose dependent nephrotoxicity characterized by renal tubule dysfunction including acidosis, hypokalemia and hypomagnesemia.
Acyclovir	Drug is secreted into tubule lumen where solubility may be exceeded. ARF is due to intratubule obstruction and perhaps direct tubule toxicity.	Urinary sediment is characterized by needle-shaped crystals, hematuria and pyuria.
Foscarnet	Electrolyte disorders suggest direct tubule toxicity.	ARF often accompanied by hypercalcemia, hypomagnesemia and hypokalemia.
Cidofovir	Direct toxicity on tubule cell, drug is eliminated by the kidney and secreted by proximal tubule cells.	Incidence of ARF is decreased with co-administration of probenecid
Pentamidine	Mechanism of toxicity is unknown. Drug is concentrated in the kidney but not eliminated by the kidney.	Non-oliguric acute renal failure develops after 7–10 days of therapy. Non-speci c urinary ndings include microscopic hematuria and pyuria.
Drug-induced interstitial nephritis	Methicillin,* rifampin, trimethoprim-sulfamethoxazole and other sulfonamides, NSAIDS, phenytoin	Methicillin* associated allergic interstitial nephritis can present with eosinophilia, eosinophiluria, fever and skin rash. Other drugs may induce interstitial nephritis without other allergic components.
Crystalluria	Indinavir, sulfadiazine, acyclovir	Indinavir is associated with needle-shaped, fan or rectangular crystals. Sulfadiazine with “shocks of wheat”- appearing crystals and acyclovir with needle-shaped crystals that are birefringent under polarized light.
Myoglobin-induced (rhabdomyolysis)	Multifactorial pathophysiology in which nephrotoxic potential is accentuated in the setting of hypovolemia and/or renal vasoconstriction.	Myoglobinuria develops as a direct effect of HIV-1 infection, especially in the acute retroviral syndrome. Also associated with cocaine use and drug treatment of dyslipidemia. CPK levels usually > 10,000 U/L.
Glomerular and vascular disease.	HIVAN, glomerulonephritis secondary to hepatitis C, post-infectious glomerulonephritis, lupus nephritis, microangiopathic hemolytic anemia.	As a group, these disorders are distinguished by either heavy proteinuria (HIVAN) or hematuria with red blood cells casts (acute glomerulonephritis). Certain diseases, such as HIVAN and glomerulonephritis, more commonly present as chronic renal failure syndromes.

* Methicillin is no longer in clinical usage.

concentration is usually >20 meq/l. With ATN, cellular elements also appear in the urinary sediment. Numerous necrotic, pigmented (muddy-brown) tubule epithelial cells or casts are usually easy to observe. The chemical indices and the characteristic urinary sediment conÞrm the diagnosis of ischemic acute renal failure in the proper clinical setting. Once ischemic injury has been established, the usual course is a one to four week period of oliguria and reduced GFR. Morbidity is quite high during this period from sepsis and ßuid and electrolyte disorders and early aggressive dialysis reduces the complication rate of ATN. Treatment during this time is focused on correction of underlying hemodynamic abnormalities, on establishment of proper dietary intake of calories and protein to minimize tissue catabolism, and on management of ßuid and electrolyte disorders, particularly hyponatremia, hyperkalemia, and metabolic acidosis. Hemodialysis should be initiated as soon as the diagnosis is clear and the blood urea nitrogen concentration (BUN) approaches 80 mg/dl to prevent complications of uremia. Recent studies indicate that more frequent dialysis in critically ill patients with ARF is associated with better outcomes (1).

Prerenal Azotemia

Prerenal azotemia is a syndrome in which effective Þltration pressure in the glomerular microcirculation is reduced because of reduced renal blood ßow, but the hypoperfusion is not severe enough to induce ischemic cell injury. The hepatorenal syndrome is one of the more classic examples of this hemodynamic condition. As a consequence, GFR is reduced but the tubule response to hypoperfusion is physiologic. Patients are oliguric, but the urine speciÞc gravity exceeds 1.020 and urinary Na concentration is <5Ð10 meq/l. The fractional excretion of Na or FE_{Na} is particularly useful in this setting; it is measured as the ratio of Na to creatinine clearance.

$$\begin{aligned} \%\, FE_{Na} &= (U_{Na}V/P_{Na})/(U_{Cr}V/P_{Cr}) \times 100 \\ &= (U_{Na}/P_{Na})/(U_{Cr}/P_{Cr}) \times 100 \\ &= (U_{Na} \times P_{Cr})/(U_{Cr} \times P_{Na}) \times 100 \end{aligned}$$

In acute renal failure the FE_{Na} is >5% and in prerenal azotemia the FE_{Na} is <1%

A disproportionate rise in blood urea nitrogen concentration compared to creatinine concentration is also a suggestive feature of prerenal azotemia. The rate of urea resorption is urine ßow-dependent, the greater the ßow, the lower the rate of urea uptake. Under normal conditions, the ratio of their respective plasma concentrations approaches 10:1. In low urine ßow conditions such as hypotension or sepsis, the ratio increases, often to greater than 20:1. The BUN/creatinine ratio should only be used as an ancillary clue because non-renal factors often seen in HIV-infected patients, such as nutritional status, liver disease, steroid use and gastrointestinal bleeding alter plasma BUN levels. The diagnosis of either ischemic ARF or prerenal azotemia is almost always made on clinical grounds combined with urinalysis and an analysis of serum and urine electrolytes. A biopsy is rarely, if ever, necessary.

Treatment of prerenal azotemia is aimed at restoring renal hemodynamics to normal as quickly and effectively as possible. In cases of intravascular volume depletion this is easily accomplished with intravenous ßuids. In patients with low cardiac output, early sepsis and third space accumulation of volume due to liver disease, therapeutic options to correct the hemodynamic abnormalities are usually focused on the underlying condition rather than the kidney.

Hepatorenal Syndrome

Advanced liver disease as seen in HIV-infected patients co-infected with hepatitis C or B can lead to acute renal failure which is particularly difÞcult to manage. In cirrhosis, total peripheral vascular resistance is low, mean arterial blood pressure is low and vascular resistance in non-splanchnic vascular beds, including the renal vascular bed, is increased. Clinical conditions that aggravate this underlying renal hypoperfusion, such as diuretic use, large volume paracentesis, GI bleeding or spontaneous bacterial peritonitis, often result in acute renal failure. Prerenal azotemia, ischemic renal failure and nephrotoxic renal injuries are all relatively common in cirrhotic patients as well. Non-steroidal anti-inßammatory drugs commonly cause ARF in patients with liver disease. These agents reduce renal production of prostanoids with vasodilating effects, particularly PGE_2. This leads to unopposed vasoconstriction in the renal vascular bed and a reduced GFR.

The hepatorenal syndrome is a unique form of acute renal failure that occurs in the setting of advanced chronic liver disease with liver failure and portal hypertension. It is similar to prerenal azotemia with low urinary volume, low urinary Na concentration (<10 meq/l) and normal urinary sediment. Unlike prerenal azotemia, however, there is no improvement following a challenge with I.V. ßuids. The hepatorenal syndrome is clinically conÞrmed when infection, nephrotoxic renal injury, ischemic injury and prerenal azotemia have been excluded. It is not restricted to patients with chronic liver disease, and can develop in more acute forms of liver disease, such as in alcoholic hepatitis and acute liver failure (2).

Drug-Related Renal Disease

Nephrotoxicity

Acute renal failure is a well-recognized complication of radiocontrast dyes as well as a number of drugs frequently given to HIV-infected patients (Table 24.1). In general,

when these drugs are used all attempts should be made to limit simultaneous exposure to other nephrotoxic drugs and to optimize the patient's fluid and electolyte status.

Aminoglycosides

Aminoglycosides are selectively filtered then efficiently resorbed into proximal tubule cells where they reach a high concentration and trigger an injury cascade. Toxicity is dose-dependent and renal failure usually occurs 5–10 days after initiation of therapy. It is typically non-oliguric and, in most cases, it reverses with cessation of the drug, although recovery may take weeks to months. Hypokalemia and hypomagnesemia are common, and indicate proximal tubule dysfunction. Potential for toxicity can be minimized by appropriate adjustment of maintenance dosing relative to renal function. Following drug trough levels is the best index for appropriate dosing. Once daily dosing has been shown to be efficacious in most settings and is associated with lower toxicity. As with all nephrotoxic agents, it is important to correct any underlying volume and electrolyte disorders and to avoid the concomitant administration of other nephrotoxic drugs (3,4).

Amphotericin B

Amphotericin B does not accumulate in the kidney but is associated with a dose-related reduction in GFR in most patients by altering renal blood flow. Amphotericin binds to membranes along the renal tubule and causes potassium and magnesium wasting and a distal renal acidosis. Minor elevations of serum creatinine in the range of 2 to 3 mg/dl are common and not an indication to discontinue therapy. Lipid-complexed formulations of amphotericin result in lower renal concentrations, are less nephrotoxic and a reasonable alternative in the setting of altered renal function.

Miscellaneous

Many antivirals are associated with renal toxicity. Nephrotoxicity from acyclovir has been attributed to intratubule obstruction caused by precipitation of the drug, but direct tubule toxicity may occur in the absence of drug crystals. The nucleotide analogue, cidofovir, accumulates in proximal tubule cells where it induces injury. Preadministration of saline and the co-administration of probenecid may lessen toxicity. Reversible renal toxicity is commonly associated with foscarnet therapy and can present as ATN. Appropriate dose adjustments in the setting of renal insufficiency as well as adequate prehydration help minimize nephrotoxicity (5). Nephrotoxicity with or without hyperkalemia appears to be a more frequent complication of pentamidine therapy in AIDS patients than in other patient populations (6). The nucleotide analogue, adefovir was originally developed as an antiretroviral agent. However, at the doses tested in clinical trials (120 mg/day and 60 mg/day), the drug was associated with nephrotoxicity manifested as a Fanconi's syndrome (7). At significantly lower doses (10 mg/day), adefovir appears to be an effective agent against hepatitis B in HIV-infected patients without the associated toxicity (8).

Acute Interstitial Nephritis

Acute interstitial nephritis (AIN) can be associated with a number of drugs often used in the setting of HIV infection. Allergic interstitial nephritis is common with the β-lactam antibiotics; the prototype for the disease is due to methicillin. The disease is rarely seen with the initial use of the drug, but it can occur at almost any other point in the therapeutic course and is not dose-related. Although classically methicillin-associated AIN is associated with fever, skin rash, eosinophilia and eosinophiluria, all elements of the clinical syndrome may not be present. The more commonly used drugs in the setting of HIV infection that might be associated with AIN include trimethoprim-sulfamethoxazole, cephalosporins, phenytoin and rifampin.

A plasmacytic interstitial nephritis has been described in HIV-1 infection that is not clearly related to drug ingestion. The etiology remains unknown, it can be diagnosed only by renal biopsy and responds to steroids.

Rhabdomyolysis and Crystalluria

Two renal syndromes associated with drug ingestion have become more frequently recognized in the setting of HIV, rhabdomyolysis and crystalluria. The higher frequency of rhabdomyolysis is most likely due to the use of statins in the setting of protease inhibitor-induced hyperlipidemia (9). Statins and protease inhibitors (PI) may share a common metabolic pathway (CYP3A4) and their combination may result in high tissue drug levels. Rhabdomyolysis has also been reported with newer agents that are metabolized via alternate pathways (10). The diagnosis should be considered when creatinine phosphokinase (CPK) levels exceed 10,000 IU. Treatment for renal disease secondary to rhabdomyolysis requires discontinuation of the offending drug, increasing urinary flow and increasing the solubility of myoglobin by alkalinization of the urine. This is accomplished by infusing intravenous solutions containing bicarbonate in an attempt to increase urinary ph to levels greater than 7. Rhabdomyolysis may also occur as a direct result of HIV-1 infection, in association with zidovudine or trimethoprim-sulfamethoxazole, and complicating trauma, convulsions, or cocaine use.

Drug induced crystalluria has been reported in 20–40% of patients receiving the protease inhibitor indinavir (11–13). Dehydration secondary to vomiting, diarrhea or poor intake are predisposing factors. Crystalluria may be asymptomatic or associated with dysuria, colic, obstructive uropathy or even a chronic renal insufficiency syndrome due to interstitial fibrosis (14). The urine is characterized by leukocyturia, with needle-shaped, fan or rectangular-shaped crystals by light microscopy. Oral hydration prior to drug ingestion should reduce intratubule concentrations of the drug. Indinavir may be safely continued in the face of asymptomatic disease or even colic, but should be discontinued in patients with chronic renal impairment whose creatinine approaches 2 mg%. Sulfadiazine can also produce crystalluria (15), recognized as "shocks of wheat" under light microscopy. This syndrome usually presents as acute renal failure and should be treated with bicarbonate-containing IV fluids to increase urinary flow and the solubility of sulfadiazine crystals.

Glomerular Diseases

Glomerular diseases, including HIVAN, acute glomerulonephritis and the hemolytic-uremic syndrome, can present as acute renal failure in HIV-infected patients. They can be distinguished from drug-induced disease or ischemic renal failure by the urinary sediment, which is marked by proteinuria and varying degrees of hematuria and red blood cell casts. Acute glomerulonephritis is often due to immune complexes; the more common causes are post-infectious and cryoglobinuric renal disease associated with hepatitis C. Idiopathic renal vasculitis has been described, as has lupus nephritis and IgA nephropathy induced by idiotypic antibodies to HIV-1 envelope proteins. When the clinical picture suggests acute glomerular disease, an evaluation for circulating immune complexes is warranted, but a kidney biopsy is required to make a precise diagnosis and guide therapy. The hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura have been associated with ARF in the setting of HIV infection. The underlying cause is unknown, but several investigators are studying the direct effects of the virus in the pathogenesis. Plasmapheresis is the treatment of choice.

CHRONIC RENAL INSUFFICIENCY

Several glomerular and tubulointerstitial diseases can present as a more chronic disease (Table 24.2).

HIVAN

Epidemiology

The most common cause of chronic renal disease associated with HIV-1 infection is HIVAN. The disease occurs almost exclusively in Blacks, not only from North America, but also in from Europe and Asia (16–18). When Blacks comprise a large proportion of the population under study, as in reports from New York, Washington, D.C., Miami, and the African or Afro-Caribbean communities of Paris and London, HIVAN is the predominant cause of renal disease (16–18). In the United States, HIVAN has become the third leading cause of ESRD in Blacks between the ages of 20 and 64 years old, more common than lupus nephritis, polycystic disease or primary glomerulonephritis (19). When reports of kidney disease in HIV-1 infected subjects come from predominantly Caucasian populations, however, HIVAN is not as frequent a cause of chronic kidney disease (20–23). Because the population of patients at risk for HIVAN continues to expand disproportionately in those living with AIDS, a growth in the number of HIV-infected patients with end stage renal disease is foreseeable in the future (26).

Clinical Presentation

The reported presentation of HIVAN is usually in patients with CD4+ cell counts below 200, however, this may not represent the full spectrum of the disease due to a bias introduced by methods of case identification (24). More recently, HIVAN has been reported in patients with higher CD4+ counts and even during primary HIV infection (25).

HIVAN is defined morphologically as focal segmental glomerulosclerosis with collapse of the glomerular capillary tuft, glomerulosclerosis, and microcystic tubulointerstitial disease (27,28) (Fig. 24.1). Visceral epithelial cell abnormalities include podocyte hypertrophy and hyperplasia. Special stains demonstrate increased markers of proliferation in podocytes as well as loss of markers of differentiation. The important clinical characteristics include the presence of heavy proteinuria, often in the nephrotic-range, the absence of edema or hypertension, and varying degrees of renal insufficiency. Ultrasound evaluation usually reveals enlarged, echogenic kidneys in contrast to most forms of chronic kidney diseases, which are associated with small, shrunken kidneys. The predictive value of these clinical characteristics has not been rigorously tested, and numerous reports suggest that the clinical impression is not always supported by the biopsy findings (29–31). A kidney biopsy is needed to determine the cause of kidney disease in most cases of HIV-associated chronic kidney disease. The clinical course in most patients with HIVAN is marked by rapid progression to ESRD within weeks-to-months, with some recent suggestion of a slowing in the rate of progression since the HAART era. HAART may have reduced the mortality of HIV-infected patients on dialysis as well. Prior to the introduction of HAART, the prognosis of HIV-infected patients on dialysis was very poor with a

TABLE 24.2. *Common causes of chronic renal disease in HIV-1 Infection (Adapted from ref (70))*

Glomerular Disease	Clinical Features
HIVAN	Morphologically de ned by focal segmental glomerulosclerosis with microcystic tubulointerstitial disease. Manifested by proteinuria, absence of an active urinary sediment, absence of hypertension and enlarged kidneys. HIV infection in renal epithelial cells.
Membranoproliferative glomerulonephritis	Associated with hepatitis C infection with or without cryoglobulinemia as well as hepatitis B. Often presents as an acute nephritic syndrome (hypertension, hematuria, red cell casts and azotemia). Hypocomplimentemia is found in approximately 50% of cases. A more subacute form can be clinically indistinguishable from HIVAN.
Minimal Change Disease	Nephrotic syndrome (proteinuria, edema and hypertension), biopsy is required for diagnosis.
Membranous Nephropathy	Nephrotic syndrome, can be secondary to hepatitis B, hepatitis C, lupus nephritis or lymphoma.
Systemic Lupus Erythematosis	Clinical presentation as acute nephritis or nephrotic syndrome. Several cases described in association with HIV-1 infection, but no direct link between these two diseases has been established.
Amyloidosis	Nephrotic syndrome and enlarged kidneys, progressive renal failure, also known as “skin popper’s” amyloid (AAamyloid), associated with injection drug use.
HIV Thrombotic Microangiopathies (Hemolytic Uremic Syndrome and Thrombotic thrombocytopenic Purpura)	Microangiopathic hemolytic anemia, thrombocytopenia and elevated LDH. More common in children.
IgA Nephropathy	Chronic presentation with hypertension and hematuria, however, several cases reported with acute nephritis, IgA anti-HIV idiotypic antibodies.
Focal Necrotizing glomerulonephritis	Necrotizing vasculitis with systemic features (polyarteritis nodosum), reported in HIV-1 infection but no direct link between these two diseases.
Post-infectious glomerulonephritis	Prototype is post streptococcal glomerulonephritis, but may arise as a complication of other bacterial infections.
Tubulointerstitial Diseases	May be idiopathic but consider drug-induced causes; non-speci c urinary ndings, absence of hypertension.

mortality rate of 50% at one year. More recent data from the U.S. Renal Data Service suggests that mortality at one year has declined to 30% (32).

Pathogenesis

Our understanding of the pathogenesis of HIVAN has advanced considerably over the past decade. Transgenic mice expressing a gag/pol deletion mutant of the cloned HIV-1 provirus pNL4Đ3 manifest a renal disease that is indistinguishable from that observed in HIVAN in man. Three lines of transgenic mice with different sites of integration all manifested HIVAN, suggesting a direct role for HIV in the pathogenesis of this disease (33Đ35).

Kidney disease develops when kidneys from transgenic mice are transplanted into normal littermates, whereas normal kidneys transplanted into a transgenic host do not develop the disease demonstrating that in the murine model, expression in kidney is required for HIVAN to develop (36). Renal tubule and glomerular epithelial cells in the murine model as well as in humans with HIVAN express histochemical markers characteristic of an immature phenotype (37,38) along with markers for proliferation and apoptosis (36,39). These data identify the podocytes and renal tubule epithelium as the major targets for HIVAN pathogenesis.

Similar to the murine model, renal epithelial cells appear to be the primary site of pathogenesis and are the cells infected by HIV in man. Proviral DNA has been detected in microdissected glomeruli (40). *In situ* hybridization studies have detected viral mRNA in podocytes, tubule epithelial cells and inÞltrating mononuclear cells (36) (Fig. 24.2). These data provide evidence in man that HIVAN is associated with HIV infection of tubule and glomerular epithelial cells. The mechanisms of viral entry remain unclear. Tubule cells can be infected *in vitro* using co-culture techniques and they have been shown to express low levels of CD4 and chemokine receptors (41). By in

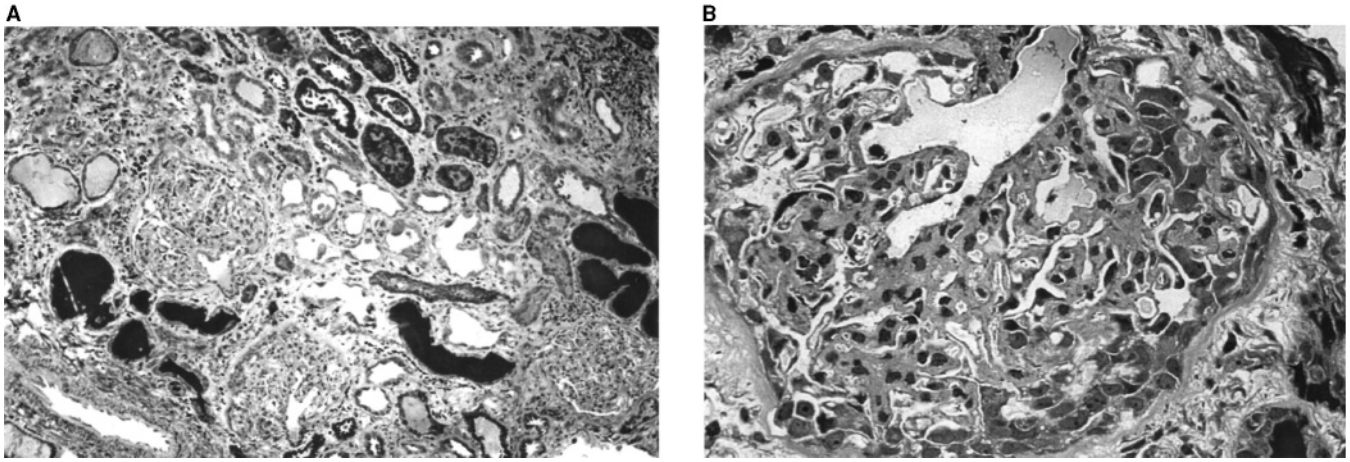

FIG. 24.1. Kidney biopsy of a patient with HIVAN. Panel A and B are low and high power views, respectively. Panel A shows one of three glomeruli with collapsing sclerosis and marked podocyte hyperplasia. The tubules are separated by edema, mild brosis, and patchy interstitial in ammatory in ltrates. Many proximal tubules show degenerative changes and there are focal tubular microcysts containing large casts (Trichrome stain, × 125). Panel B shows a glomerulus with segmental collapse of the glomerular tuft and hyperplasia of the overlying podocytes (Trichrome stain, × 400).

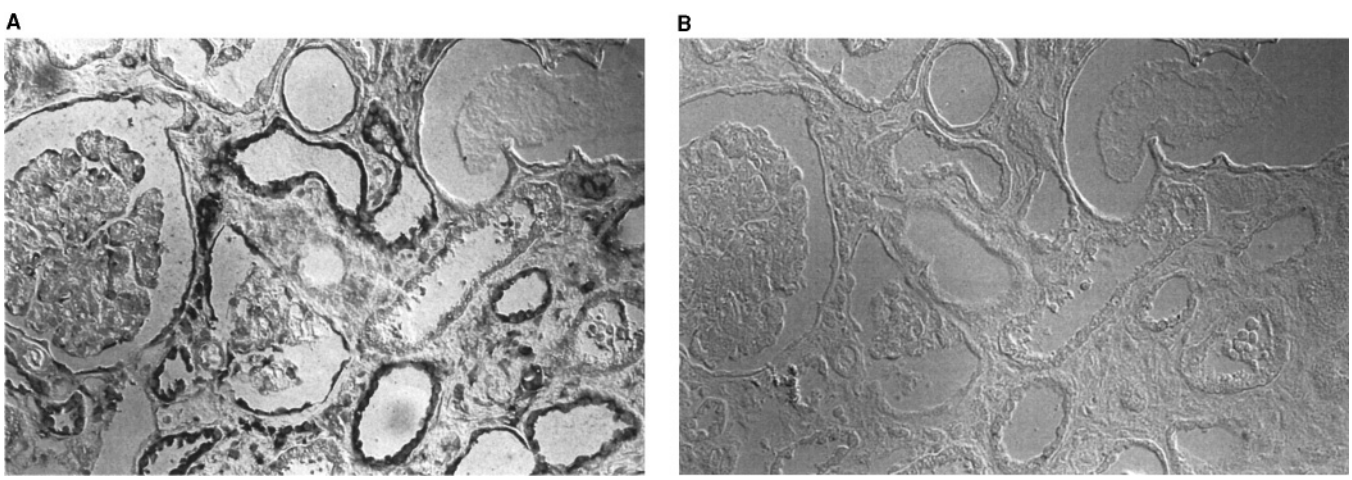

FIG. 24.2. IV RNA *in situ* hybridization of kidney biopsy of a patient with HIVAN. Utilizing an antisense probe generated from the *gag* region, panel A demonstrate the presence of HIV-1 RNA in tubular cells and podocytes as well as in interstitial in ammatory cells. A control sense probe showed no staining of the pretreatment biopsy (Panel B) (Panels A and B, × 50).

situ hybridization techniques, infection of tubules can be shown to be a rare event but once a tubule is infected, most of the cells in the tubule are positive for HIV mRNA (42). Thus, the infection rate of renal cells appears low but once infected, HIV-1 efÞciently moves from cell to cell down the nephron.

Increasing anecdotal evidence supports HAART as the appropriate therapeutic strategy for HIVAN. A recent study (25) presented a patient who developed HIVAN during an acute retroviral syndrome. Prior to initiation of HAART, the patient had nephrotic-range proteinuria and a reduced GFR. HAART reduced plasma viral load to non-detectable levels, and normalized the GFR and urinary protein excretion rate. Kidney biopsies before and after 3 months of therapy demonstrated resolution of the collapsing GN and improved renal function. Viral mRNA in kidney epithelium, however, was detectable both before and after therapy. These observations suggest that while there are clinical and morphological responses to HAART, the kidney is a persistent reservoir for HIV-1 (25).

Therapy

Three classes of drugs have been used to treat HIVAN; steroids, angiotensin converting enzyme inhibitors and antiretrovirals. Most therapeutic reports were in the era prior to HAART when mortality in AIDS was extremely high. Furthermore, the observational nature of the studies and lack of appropriate control groups raises concerns about the ability to extrapolate from the results.

Steroids

Several case reports and small series have described beneficial effect of prednisone for HIVAN (43–46). The largest trial tested the effects of prednisone in 19 patients (47) with HIVAN and found a brief improvement in GFR and/or urinary protein excretion. At the end of the first year, however, only two patients had survived without progressing to end stage renal disease. Another study described an experience using prednisone, 60 mg for one month followed by an eight week taper. Most patients were not treated with HAART (48), and were selected according to individual physicianÕs standards. Kidney function stabilized or improved in steroid-treated patients compared with the untreated group. In contrast to the previous study, treated patients in this study did not experience a greater risk of opportunistic infections, however, this risk may outweigh the benefits of steroids in the absence of HAART.

Angiotensin-Converting Enzyme (ACE) Inhibitors

Ace inhibitors have demonstrated efficacy in preventing progressive kidney failure in other diseases and have been studied in HIVAN (49,50). Their mechanism(s) of action, although still unclear, are ascribed to reducing hydrostatic pressure in the glomerular capillary, altering glomerular basement membrane permeability, or reducing the renal generation of cytokines, such as TGFβ. Similar to the experience with steroids, however, studies of ACE inhibitors were performed prior to the widespread use of antiretrovirals and lacked randomized controls.

Antiretrovirals

Several studies suggest an association between antiviral therapy and a slower progression to ESRD (49,51,52), even prior to the introduction of HAART. In the HAART era, patients with kidney disease have experienced improved survival, as have most patients with AIDS, but there have been no prospective randomized trials to determine the efficacy of HAART for HIVAN. By looking at the end-stage renal disease population as a group, however, some conclusions can be inferred. Since the introduction of HAART, the number of cases of ESRD due to HIVAN has stabilized despite an increase in the pool of patients living with AIDS (26). This indicates that the incidence of HIVAN has fallen, or that the rate of progression to kidney failure has decreased. Retrospective reports indicate that the use of protease inhibitors is associated with a slower progression of HIVAN (53). Two reports demonstrate improvement in kidney structure and function in individual patients with HIVAN treated early in the course of their kidney disease with HAART (25,54). These cases are important because the dramatic effect of treatment was observed when therapy was begun in drug naïve patients almost immediately after the onset of nephropathy. In most clinical situations, HIVAN is diagnosed later in the clinical course at a time when therapy may be less effective. It remains to be tested whether early detection of kidney disease, and initiation of aggressive antiviral therapy along with addition of agents such as ACE inhibitors can further improve overall renal survival.

Other Causes of Chronic Renal Insufficiency

Membranoproliferative Glomerulonephritis

Membranoproliferative glomerulonephritis is characterized by thickening of the glomerular basement membrane, proliferation of mesangial cells, and an influx of mononuclear inflammatory cells. This disease is often the result of immune-complexes and is seen with hepatitis C (HCV) and hepatitis B (HBV) infection (55). Immune complex disease associated with HCV co-infection is the most important cause of MPGN in the setting of HIV-1 infection (56). The presence of cryoglobulins in MPGN is almost exclusively associated with HCV infection. The prevalence of proteinuria has recently been estimated as high 30% in HIV-1 infection (57), and a positive test for hepatitis C antibody increases the risk of kidney disease. It remains to be determined whether the proteinuria is specific for HCV co-infection or whether these are early cases of HIVAN.

The presentation of MPGN as a complication of HCV infection includes nephrotic-range proteinuria, gross or microscopic hematuria, hypocomplementemia and cryoglobulinemia. Renal biopsy findings demonstrate an immune complex glomerulonephritis. Like HIVAN, hepatitis C-associated renal diseases in the setting of HIV progresses rapidly to ESRD, especially in injection drug users. Although the presence of hypertension and cryoglobulins may suggest MPGN rather than HIVAN, a biopsy is often required to distinguish the two entities (56).

Treatment for HCV-induced glomerulonephritis has not been systematically studied in the presence or absence of HIV infection. Prior to identification of HCV, many of these cases were classified as mixed-essential cryoglobulinemia and treated with steroids and plasmapheresis. Antiviral therapy with interferon alpha and ribavirin are considered standards of care for hepatitis C-infected patients, but the role of combination therapy in immune-complex nephritis remains to be established.

Miscellaneous

Several cases of IgA nephropathy associated with immune complexes containing HIV proteins and glomerulonephritis have been described (58,59). Appropriate therapy for this form of immune complex disease remains

uncertain. Both membranous nephropathy and polyarteritis nodosa are known but rare complications of hepatitis C and B infection. Biopsy surveys of HIV-infected patients with chronic renal insufficiency have also revealed findings consistent with diabetes, amyloidosis as well as a lupus-like nephritis. Steroids and alkylating agents are often used to treat lupus nephritis, and reports suggest that this therapy can be reasonably well tolerated in selected HIV seropositive patients (60,61).

Clinical Approach

The clinical approach to patients with chronic renal insufficiency due to HIV infection should not be different from patients who are seronegative. The physician should attempt to make a precise diagnosis by standard tests and by renal biopsy when necessary. The presence of proteinuria and hematuria, particularly with red blood cell casts in the urinary sediment, indicates glomerulonephritis. Serologic tests for circulating immune complexes, complement levels and cryoglobulins should be performed as should hepatitis B and C serologies. While heavy proteinuria in patients who are black or Hispanic may suggest the diagnosis of HIVAN, a biopsy is still required to distinguish the diagnosis of HIVAN from other causes of glomerular disease.

Complications as a result of kidney biopsies are rare (62). Transient microscopic hematuria, with or without computerized tomographic evidence of a hematoma, occurs in the majority of patients although this is rarely associated with clinical morbidity. Transient gross hematuria occurs in 3–10% of cases, requiring transfusions in 0.1–0.3%. Surgery or angiography with embolization of the bleeding vessel has been required in 0.1–0.4% of cases. The latter procedure avoids nephrectomy, estimated to occur in 0.06% of patients.

There are special treatment considerations for patients with chronic renal insufficiency in general. Lipid disorders, secondary hyperparathyroidism and hypertension should be treated early and aggressively. If GFR falls, the therapeutic focus should include preparation for renal replacement therapy. Proper planning for hemodialysis, peritoneal dialysis or kidney transplantation should be made well in advance of uremic symptoms. In those patients who are likely to start hemodialysis, an AV fistula should be created months before an anticipated start date.

In light of the therapeutic success of antiretroviral therapy for the underlying disease, kidney transplantation is an option in selected patients with safety and efficacy currently under study (63). The criteria for considering renal transplantation should include evidence of well controlled HIV infection with sustained undetectable plasma HIV RNA and CD4 cells >200/ul. The long-term prognosis of patients with HIV infection on dialysis is determined by the stage of AIDS (30,64), and these patients should be aggressively treated with HAART. Survival on dialysis is improving and should continue to do so with newer antiviral drug therapies (65,66).

Although data for clearance of some of the antiretrovirals in the setting of renal insufficiency or hemodialysis is incomplete, every attempt should be made to dose for maximal antiviral effects and minimal toxicity. As a class, the nucleoside analogue reverse transcriptase inhibitors (NRTIs) are cleared by the kidney and require dose adjustments to avoid toxicity, while the protease inhibitors are metabolized by the liver and do not generally require dose adjustment. The non-nucleoside reverse transcriptase inhibitors (NNRTIs) are primarily metabolized by the liver as well and therefore dose adjustments are not recommended. In the setting of hemodialysis, NRTIs and NNRTI dosing is recommended after dialysis (67–69).

Chapter 25

Skin Manifestations of HIV Infection

Miguel Sanchez and Alvin E. Friedman-Kien

The impact of skin disease on the lives of HIV-infected men and women cannot be measured by either financial costs or mortality rates. Early in the AIDS epidemic, HIV-infected men identified Kaposi's sarcoma, as the most dreaded manifestation of their disease, a visible stigma that elicited social prejudice and produced disfigurement unconcealable by even the most opaque available camouflage cosmetics. Even today, despite advances in treatment, the mere suspicion of the "gay cancer" provokes dread in patients who develop the typical violaceous skin lesions. Cutaneous diseases may herald deterioration of immunity, cause intolerable symptoms, heighten isolation, and promote depression. Not only can a skin disease be the initial presentation of the underlying HIV infection, but it may remain a major health problem during the patient's life (1). Disseminated opportunistic infections may present with skin lesions, which permit more expeditious diagnosis of these life-threatening illnesses (2).

With advancing immunosuppression, the prevalence of mucocutaneous diseases requiring treatment becomes nearly universal (3). In a review of medical records of 684 HIV-infected patients insured by the Harvard Community Health Plan, 79% of 540 patients had one or more dermatologic diagnoses, for a total of 2,281 diagnoses, including 188 cutaneous reactions to drugs and 43 hospitalizations for cellulitis (4).

A prospective study of 912 HIV-infected patients followed for 42 months confirmed previous reports that xerosis and seborrheic dermatitis are the most common skin findings. These manifestations as well as dermatophytic infections, common warts and condyloma accuminata are also seen early, although the cases are usually not as severe as in later more advanced HIV disease (5). The prevalences of acne vulgaris and eosinophilic folliculitis peak in mid-stage disease (5). On the other hand, chronic ulcerative herpes simplex infection, herpes zoster, oral candidiasis, molluscum contagiosum, and oral hairy leukoplakia are associated with late-stage disease when immunity is profoundly impaired (5). As patients become increasingly immunocompromised, these diseases tend to become more aggressive, appear more atypical, and respond less readily to treatment.

Widespread use of highly active antiretroviral therapy has not only effectively reduced morbidity and motality rates among HIV-infected persons but has also altered the development and course of many skin diseases (6,7). On the other hand, new dermatologic diseases, some of which are disfiguring and even potentially lethal, continue to be described (7).

Primary HIV Infection

Between 40% to 89% of newly infected cases develop a symptomatic acute retroviral syndrome as early as five days and up to six weeks after HIV contact. The syndrome is associated with high titer HIV replication in blood coupled with a vigorous immunologic response to the virus, and resolves as the plasma level of HIV RNA declines (8). Although initially the acute syndrome was described as a mononucleosis-like illness associated with fever, pharyngitis, and cervical adenopathy, larger studies indicate that this presentation occurs in only 15.6% of patients (9). Symptoms may persist less than 14 days but in a study of 218 cases, the mean duration of acute primary infection was 25.1 days (median, 20.0 days) (9). Rarely, patients may continue to experience symptoms for up to 10 weeks. There appear to be no differences in the duration or type of symptoms according to gender, age, and risk factors (9). The more common symptoms are fever (77–96%), fatigue (70–92%), weight loss (70%), adenopathy (40–70%), pharyngitis (50–70%), fatigue

Miguel Sanchez: Associate Professor of Dermatology, NYU School of Medicine.
Alvin E. Friedman-Kien: Professor of Dermatology and Microbiology, NYU School of Medicine.

(65%), skin eruption (40–80%), myalgia (50–70%), headache (32–70%), nausea (30–60%), nightsweats (40–50%), and aseptic meningitis-like syndrome (9–24%) (8–9). Arthralgias, photophobia, nausea, and abdominal cramps are also common. Mucocutaneous ulcerations can involve the buccal mucosa, gingiva or palate (10–20%), genitals (5–15%), and esophagus or anus (10). Oral thrush was reported in 12% of patients from an early, small study and was associated with early development of opportunistic infections (10).

A skin eruption, usually involving the trunk, occurs in approximately half of persons with symptomatic acute HIV-1 infection. Although often described as morbilliform or maculopapular, the lesions are often discrete, faint, erythematous, 5 to 10 mm, oval macules papules on the chest and upper back, and sometimes the palms and soles (11) (Fig. 25.1). In some cases, papules, vesicles or papulopustules are the predominant lesions and the eruption has been reported to resemble roseola, syphilis, rubella, typhus, pityriasis rosea, drug hypersensitivity, and acne. In persons with darkly pigmented skin, the lesions are more difficult to detect. Histopathological examination shows a mononuclear-cell infiltrate of the superficial dermal vessels, consisting mainly of CD_4 T-lymphocytes, and focal lymphocytic vasculitis (8).

The diagnosis of acute HIV infection is confirmed by detection of serum HIV antigenemia (HIV-RNA) in the absence of HIV antibodies. The course of HIV infection correlates with the HIV-RNA level, which usually stabilizes approximately six months after exposure to the virus. High viral loads ($>10{,}000$ copies) correlate with higher risk for accelerated immune deterioration. Low viral loads (less than 200 copies) are associated with disease stability and a favorable course, and intermediate titers (between 200 and 10,000 copies) with gradual but progressive disease.

A similar syndrome associated with a dramatic rebound in plasma HIV-RNA (the Retroviral Rebound Syndrome) has been reported in patients who have ceased suppressive antiretroviral therapy (12). One case developed an erythematous, generalized, macular eruption, which became papular and pruritic. Neither pharyngitis nor lymphadenopathy was present (12).

FIG. 25.1. Faintly erythematous, oval, non-scaly patches on the chest of a man with primary HIV infection eruption.

NONINFECTIOUS DISEASES

Seborrheic Dermatitis

In contrast to the 2% to 5% incidence in the general population, seborrheic dermatitis has been detected in 21%, 32% and 46% of HIV-infected persons from various studies, and as high as 83% of severely immunocompromised patients with AIDS (3,13a–13e). This condition is more common and becomes more severe when the CD_4 T-cell count drops below 200 cells/mm^3 and improves or resolves with effective treatment of HIV infection. Patients commonly complain of "dry skin" on the face. The eruption consists of discrete or diffuse, pink patches or plaques. White to yellow oily-looking scales and occasionally crusting may be present on the surface of the lesions (Fig. 25.2). The eruption develops in body regions rich in sebaceous follicles, such as the scalp, eyebrows, nasolabial folds, retroauricular folds, external ears, beard area, and less commonly in the axillae, groin and V-shaped areas of the chest (13). Occasionally, seborrhea is pruritic, and the plaques may become lichenified from rubbing. The severity ranges from scalp flaking to exfoliative erythroderma. Seborrheic dermatitis may be so severe and extensive that it resembles and is sometimes clinically

FIG. 25.2. In seborrheic dermatitis, pink-red patches and papules with yellow-white scales are typically present along the nasolabial fold, eyebrows, mustache, beard and forehead.

confused with psoriasis. The pathogenesis remains unelucidated, although an overgrowth of the yeast, *Pityrosporum ovale*, or an exaggerated inßammatory response with cytokine activation in affected areas has been suggested (13f). One study correlated heavy skin colonization with *P. ovale* to speciÞc depressed cellular immunity. In these patients, after exposure to *P. ovale* antigen, peripheral blood mononuclear cells did not proliferate and also produced less interleukin-2 and interferon-gamma but more interleukin-10 (14). One report concluded that the pathogenesis did not depend on the density of *P. ovale* on the skin but rather on the presence of a speciÞc subtype, which was found in 78% of AIDS patients with seborrheic dermatitis (15).

Scalp disease is treated with shampoos containing selenium sulÞde, ketoconazole, zinc pyrithione, sulfur, salicylic acid, or coal tar and also with intermittent courses of topical corticosteroids. Solutions, gels, oils and foams are better-accepted vehicles on densely hairy areas. Some cases respond to calcipotriene lotion. In other body areas, corticosteroid creams or lotions (low-potency on the face and intertriginous areas and mid-potency on the rest of the body) are highly effective. Occasionally, mid-potency corticosteroids are also needed on the face but prolonged use of these agents leads to facial atrophy, acne, and telangiectasias. Pimecrolimus cream and tacrolimus ointment are usually effective without propensity to cutaneous atrophy. Topical imidazole creams, such as ketoconazole, produce resolution of the eruption in approximately 25% of cases but may be used prophylactically. There are reports of marked improvement following treatment with systemic anti-yeast agents, such as ßuconazole, but seborrheic dermatitis can appear even when the patient is being treated with antifungals. Recalcitrant cases often respond to ultraviolet B phototherapy.

Psoriasis

The incidence of psoriasis in HIV-infected persons is between 1% and 2% (16), which is similar to the general population, although prevalences as high as 5% have been reported (17). The disease may develop at any point during the course of HIV infection, but with advancing immunodeÞciency, the lesions become different, more extensive and more therapeutically unresponsive. In approximately one-third of patients, the development of psoriasis precedes HIV-infection but the appearance and extent of the eruption often changes following the marked decline in a patientÕs immune function. In contrast to the well-demarcated, erythematous plaques covered with micaceous, adherent silvery scaling characteristic of classic psoriasis, the lesions seen in HIV-infected individuals tend to be ßatter, larger, more irregular, more widespread, potentially pruritic and are covered with Þner scale and occasionally crusting (Fig. 25.3) (18). Often, the eruption is polymorphous with plaques, guttate papules and pustules simultaneously present in any affected area. Instead of the typical elbows and knees distribution, the face, scalp, intertriginous areas, genitals, palms and soles are often involved (19). In fact, although not pathognomonic, the appearance of a severe form of ÒinverseÓ psoriasis in individuals at risk for HIV infection should prompt consideration of HIV testing. Nail changes, such as onycholysis, nail pitting and subungual hyperkeratosis, are common. The eruption can progress rapidly to generalized exfoliative erythroderma. In fact, psoriasis is the most common cause of erythroderma in HIV-infected persons, although in these cases, histopathological evaluation is necessary to exclude cutaneous T-cell lymphoma, drug eruption, contact dermatitis, atopic dermatitis, or exuberant seborrheic dermatitis. Psoriatic arthritis, present in only 1% of HIV-seronegative cases of psoriasis, has been reported in up to 10% of HIV-infected psoriatics.

FIG. 25.3. Numerous small erythematous, thin plaques with adherent silvery scale and crusting con uent into a larger geographic plaque on the abdomen of a man with HIV-associated psoriasis.

In contrast to the 0.06% incidence of ReitersÕsyndrome in the general population, this disease has been reported in as many as 6Ð10% of HIV-infected patients, depending on the adherence to the diagnostic criteria (20). In some studies that found high prevalences, several patients were missing the classic triad of arthritis (usually sacroileitis), urethritis, and conjunctivitis. Instead, these patients had incomplete syndromes with arthritis, skin manifestations (pustular psoriasis, balanitis circinata, keratoderma blenorrhagicum, dactilytis, nail dystrophy) and occasionally other noncutaneous associated signs (Fig. 25.4) (21). HLA-B27 has been detected in as many as 70% of HIV-infected patients with ReiterÕs syndrome (22).

FIG. 25.4. Hyperkeratotic plaques within which crusted papules are present. The plaques are surrounded by an erythematous border with papules and pustules. This is the typical appearance of plantar keratoderma blenorrhagica associated with Reiter's syndrome.

Psoriasis in immunocompromised HIV-infected persons is usually more recalcitrant to traditional treatment regimens. Topical corticosteroids, calcipotriene, pancrolimus, and tazarotene may not sufficiently control the disease so that narrow band or conventional UVB phototherapy, Psoralen and UVA photochemotherapy (PUVA) or oral acitretin are often needed. Despite earlier concerns about safety, phototherapy has been found not to exert a deleterious effect on the course of HIV infection (23) or to increase viral loads significantly (24). Methotrexate and cyclosporine are reserved for severe cases unresponsive to other treatments. These systemic drugs are usually effective and temporarily well-tolerated without a high incidence of complications (17). Although some cases of Reiter's syndrome may respond to acitretin, cyclooxygenase inhibiting non-steroidal anti-inflammatory drugs or etanercept, methotrexate remains the treatment of choice for severe cases. The efficacy of antiretroviral agents in the treatment of HIV-associated psoriasis became evident years ago after high doses of zidovudine were demonstrated to improve psoriasis even in HIV-seronegative patients with, unfortunately, intolerable side effects (25). Although not studied, combinations of other antiretroviral agents appear to be effective either through a direct effect on psoriasis or by improving immunity and reducing HIV viral load. In fact, HIV-associated psoriasis has become less common in patients effectively treated with antiretroviral therapies (26).

Xeroderma

Even before the availability of antiretroviral protease inhibitors, xeroderma ranging from dry skin to severe ichthyosis developed in 23–30% of HIV-infected individuals, and in almost all end-stage, malnourished AIDS patients. Because xeroderma can develop in some patients in the absence of profound immunosuppression, it has been suggested that skin dryness can be caused by direct retroviral effects. Xerodermic skin is diffusely dry and flaky. Ichthyotic skin consists of adherent polygonal, fish-like scales. These changes are most apparent on the lower extremities. Acquired ichthyosis has been correlated with severe helper T-cell depletion, increasing age, and concomitant infection with HTLV-II (27). However, the etiology of such dry skin changes is likely to be multifactorial. Malnutrition, malabsorption, genetic predisposition, antilipidemic drugs, dry climate, and even some antiretroviral agents can cause dry skin. Among the protease inhibitors, indinavir, especially, seems to predispose to xeroderma (28). Some patients treated with protease inhibitors have also developed a desquamative cheilitis and paronychia xeroderma (28). While changes in skin lipids probably occur during the course and treatment of HIV infection, environmental factors and prolonged bathing increases xerosis. Nutritional evaluation may be indicated. Treatment consists of short-duration showers and avoidance of harsh cleansers as well as frequent applications of moisturizers containing alpha-hydroxy acids (lactic acid, glycolic acid), urea, or phospholipids.

Cutaneous Adverse Drug Reactions

Early in the AIDS epidemic, it was recognized that the prevalence of cutaneous eruptions caused by hypersensitivity to drugs was significantly higher in HIV-infected patients than in the general population (29). In one study 27% of 684 patients developed drug eruptions (30). The drugs with the highest rate of cutaneous allergic reactions (per 1,000 courses) included trimethoprim-sulfamethoxazole (22%), sulfadiazine (29%), trimethoprim-dapsone (23%), and aminopenicillins (14%) (30). The majority of drug eruptions are maculopapular or morbilliform.

Cutaneous hypersensitivity eruptions have been reported in 40% of patients on amoxicillin-clavulanic acid, 33% of patients treated for Toxoplasma encephalitis with intravenous clindamycin, 38% of patients treated for aphthous ulcers with thalidomide, and 10% of patients on antituberculous medications (30).

In some studies, 50% to 60% of patients on standard doses of trimethoprim-sulfamethoxazole, the most commonly prescribed prophylaxis and treatment of *Pneumocystis carinii* pneumonia (PCP), developed cutaneous hypersensitivity to the drug (31). The incidence of these reactions is increased in patients with less than

200 CD_4 T-lymphocytes/mm^3, but decreases in late-stage disease when the CD_4 T-lymphocyte counts drop below 25 cells/mm^3. Notably, Black patients in this country or abroad appear to have diminished predisposition to sulfa drug hypersensitivity (30). The eruption, which can be accompanied by fever, appears to involve the activation of mast cells by immunoglobulin E (IgE) but may also be caused by acetylation phenotype and accumulation of a toxic hydroxylamine sulfonamide metabolite which diminish stores of glutathione.

In most patients who develop drug allergy eruptions, widespread pink to bright red macules and papules appear on the trunk, extremities and occasionally the face and mucous membranes (Fig. 25.5). The drug eruption typically appears eight to twelve days after initiation of therapy and reaches its pinnacle of intensity one to two days later. Even with continuation of the drug, the reaction may resolve within three to Þve days. However, it may persist for weeks or require discontinuation of the drug due to severity. Although recurrence of the eruption may not follow rechallenge, readministration of the drug requires careful monitoring for potential anaphylaxis. Gradual dose escalation is also associated with signiÞcantly fewer adverse drug reactions (32). Antihistamines and oral corticosteroids can help to prevent the reaction. Desensitization is indicated when there are no alternatives to trimethoprim-sulfamethoxazole. Although several desensitization protocols have been published, the most extensively studied regimen was developed by Conant and colleagues (33,33a). It consists of increasing dilutions of an oral suspension containing 40 mg of trimethoprim and 200 mg of sulfamethoxazole in 5 mL. A 1:100,0000 dilution is administered on day one followed by dilutions of 1:100,000 (day 2), 1:10,000 (day 3), 1:1,000 (day 4) 1:100 (day 5), 1:10 (day 6), 1:1 (day 7), 1 cc of standard suspension (day 8) and 1 DS tablet (day 9 and thereafter) (33). The regimen has been reported to be successful in up to 83% of studied patients with no fatalities.

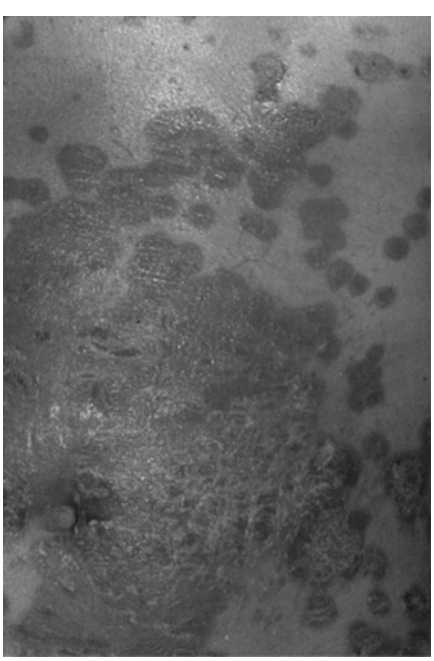

FIG. 25.5. Erythematous, blanching macules and patches with a few papules producing an exanthematous eruption due to hypersensitivity to trimethroprim-sulfamethoxazole.

Other treatments for PCP also have high rates of cutaneous drug reaction. Approximately 20% of patients treated with parenteral pentamidine develop morbilliform or urticarial eruptions (31). Dapsone can also cause morbilliform and scarlatiniform eruptions, as well as the potentially fatal sulfone syndrome which includes exfoliative dermatitis, fever, hepatic necrosis, lymphadenopathy and hemolytic anemia (30).

Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are severe reactions characterized by acute vesicles, bullae and epidermal detachment on the skin and mucous membranes due to necrosis of the epidermis (Fig. 25.6). In SJS, the total extent of skin detachment is less than 10%, whereas in TEN epidermal detachment is found over more than 30% of the body surface area (34). The incidence of toxic epidermal necrolysis in HIV infection is approximately 1.08 per one thousand patients per year, 500 times the rate in the general population. Previously, most cases were caused by sulfonamides in Western countries and thiacetazone in Africa, although other medications, including aminopenicillins, cephalosporins, clindamycin, quinolones, barbiturate, phenytoin and imidazole antifungals have been implicated. However, in a recent review, 83% of SJS/TEN reactions were caused by nevirapine (29). The reaction began 10Ð240 days (median 12 days) after the introduction of nevirapine even though most patients were still taking the recommended initial daily dose of 200 mg (34).

Although with currently prescribed doses, the prevalence of drug eruptions is lower, 1% of patients treated

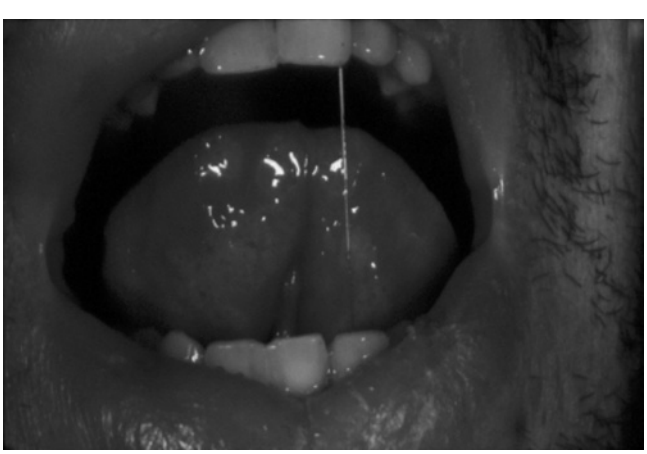

FIG. 25.6. Diffuse erythema and edema of the lips and tongue in a man with Stevens-Johnson syndrome. Well demarcated circular and irregular erosions are present on the undersurface of the tongue.

with zidovudine at high doses require discontinuation of the drug due to severe exanthematous eruptions. Lichenoid eruptions with planar polygonal pink papules on the body and whitish reticulated plaques in the oral mucosa resembling lichen planus, as well as acral and periarticular reticulate erythema that simulates dermatomyositis have also been reported. Zidovudine can cause hyperpigmentation of the nails, skin and mucous membranes. The most common manifestation is the development of pigmented striated nail bands (34a).

Foscarnet has induced painful 1 to 5 cm ulcerations of the urethral meatus, glans penis and scrotum in some individuals receiving high doses due to irritation from the concentrated urine. These ulcers resolve with discontinuation of treatment or dilution of concentrated urine through increased hydration. Foscarnet may also produce a generalized eruption. Rifampin may cause a drug rash that can rapidly progress to erythroderma.

Relatively few serious drug reactions occur from administration of protease inhibitors. However, indinavir has been associated with a number of mucocutaneous manifestations, including in one report, cheilitis (57.1%), diffuse cutaneous dryness and pruritus (40%), asteatotic dermatitis (11.9%), scalp deßuvium (11.9%), fairer, thinner, shedding body hair (7%), digital pyogenic granulomas (5.9%) and severe alopecia (1.2%) (35). Recurrent paronychia, usually of the Þrst toes, and Þssures of the lips have also been reported (36). Although the prevalences may be lower than in this study, all of these effects are, indeed, encountered in clinical practice with the use of indinavir and to a lesser extent other protease inhibitors. Fixed drug eruptions to saquinavir are uncommon.

A case of acute generalized exanthematous pustulosis (AGEP) induced by combination therapy with zidovudine, lamivudine, and a protease inhibitor in the setting of HIV prophylactic treatment in an HIV-seronegative man was reported (37). AGEP is characterized by an acute maculopapular eruption accompanied by skin edema and nonfollicular sterile pustules, and eventual widespread epidermal exfoliation. Fever is invariably higher than 38 degrees C. Purpuric lesions may be present. Most cases are induced by drugs, particularly by beta-lactams and other antibiotics. Cutaneous patch tests are useful when the patient is being treated with multiple medications, and implicate a particular drug in approximately half of the cases.

Some non-nucleoside reverse transcriptase inhibitors have a high incidence of cutaneous reactions. A skin eruption is the most common adverse effect of nevirapine and delavirdine (Fig. 25.7); the incidence is similar with both of these compounds, but lower with efavirenz.

A syndrome consisting of Òdrug rash with eosinophilia and systemic symptomsÓ (DRESS), also called hypersensitive syndrome (HSS), has been associated with the use of navirapine and less often with carbamazepine, sulfonamides, calcium channel blockers, allopurinol, ranitidine, thalidomide, and zalcitabine (38). The onset is usually between two to six weeks after receiving the Þrst dose. The Þrst signs are fever and a maculopapular eruption followed by lymphadenopathy, arthritis, myalgias, visceral manifestations (potentially fulminant hepatitis), hyperleukocytosis, and eosinophilia. The eruption responds well to treatment with topical corticosteroids, but systemic corticosteroids are recommended for internal organ involvement (38).

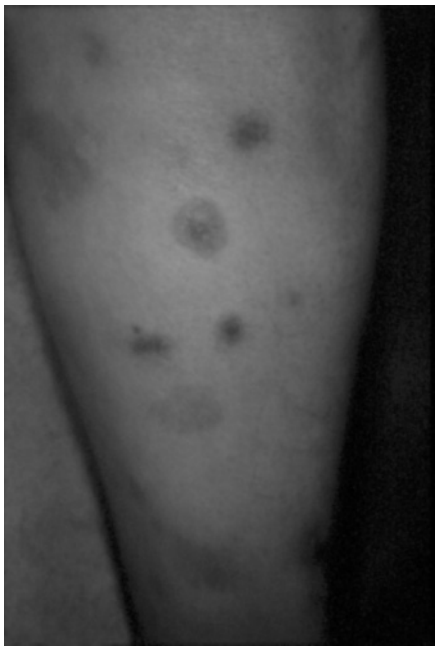

FIG. 25.7. Targetoid erythematous plaques with bullous and necrotic centers caused by hypersensitivity reaction to nevirapine.

Several skin toxic reactions have been reported during administration of liposomal encapsulated doxorubicin for the treatment of AIDS-related KaposiÕs sarcoma. Palmar-plantar erythrodysesthesia syndrome, also known as toxic acral erythema, develops in as many as a third of patients treated with high doses and short schedules. Painful erythema of the palms, soles, and Þngers progresses to diffuse violaceous erythema and edema with or without formation of vesicules or bullae, and eventually to desquamation. Other cutaneous complications include stomatitis, an intertriginous dermatitis, and a scaly erythematous accentuation of the hair follicles (39).

Fat Redistribution Syndrome

In recent years, shortly after the introduction of antiretroviral therapy with protease inhibitors the development of lipoatrophy, lipohypertrophy, or both in localized areas, frequently in association with dyslipidemia and disturbances in glucose homeostasis, was recognized. The largest prevalence surveys found that lipodystrophy was present in 49Ð53% of patients, almost exclusively in patients receiving antiretroviral therapy (40). The severity

FIG. 25.8. Abnormal lipodystrophic deposition of adipose tissue on the abdomen, cervical area and breasts accompanied by thinning skin over upper extremities resulting in prominence of veins and muscles.

and prevalence of lipodystrophy is higher in patients treated with protease inhibitors, suggesting that these agents accelerate changes of fat redistribution. However, lipodystrophy has also been observed in patients treated with regimens without protease inhibitors, and in a few cases receiving no antiretroviral therapy at all. Notably non-nucleoside reverse transcriptase inhibitors do not appear to promote the development of lipodystrophy. Potential contributing factors include prolonged antiretroviral therapy, long duration of HIV infection, high viral load, genetic predisposition, and increasing age.

Accumulation of fat in the abdomen resulting in increased abdominal girth is the most common manifestation and occurs in 76% of affected men and in 93% of affected women (Fig. 25.8). Women with body changes may be more likely to experience increases in breast size and overall weight gain than men (41). Accumulation of fat also causes enlargement of the dorsocervical fat pad (buffalo hump) and lipomas. In 69% of women, increased fat in breast tissue is present and gynecomastia is common in men. Fat depletion in the arms and legs resulting in prominent cutaneous veins is observed in 67% of men and 59% of women (40). Other changes associated with subcutaneous fat depletion result in sunken facial cheeks and loss of shape in the buttocks (Fig. 25.9).

Dyslipidemia becomes more prevalent with advancing lipodystrophic changes, and includes increased serum levels of triglycerides, total cholesterol and low density lipoprotein (LDL) cholesterol, accompanied by decreased levels of high density lipoprotein (HDL) cholesterol (42). Between 15% and 30% of HIV-infected patients have dyslipidemia, about 1% of patients treated with protease inhibitors develop insulin resistant diabetes, and 47% have impaired glucose tolerance (40). Because of the disÞguring changes, patients may be reluctant to initiate or continue antiretroviral therapy.

Treatment with 3-hydroxy-3-methylglutaryl-CoA reductase inhibitors (atorvastatin, cerivastatin, ßuvastatin, lovastatin, pravastatin, and simvastatin) reduce both triglycerides and cholesterol (40). Fibrates (cloÞbrate, fenoÞbrate, gemÞbrozil) are helpful in reducing triglycerides alone. Metformin reduces serum triglycerides and may diminish deposition of fat. Rosiglitazone and pioglitazone increase insulin sensitivity by increasing glucose transport and adipogenesis. Diets consisting of moderate amounts of fat and substitution of omega-3 and omega-6 fatty acids for saturated fatty acids may reduce lipogenesis and decrease insulin resistance. Exercise programs consisting of resistance training with an aerobic component can reduce abdominal adiposity.

Patients who are switched from HIV protease inhibitor therapy to antiretroviral combinations that include NNRTI agents may have improvement in their lipid proÞles and less intra-abdominal fat (43). Testosterone supplementation may improve abdominal obesity in men. Growth hormone reduces fat buildup around the waist, breasts, and back of the neck. Although it has no effect on wasting, growth hormone may make the loss of fat less noticeable in the legs and arms by promoting muscle growth. Growth hormone improves lipid proÞles but also increases fasting glucose and insulin levels (43). Breast reduction effectively corrects breast enlargement. Liposuction effectively and permanently removes fat cells and has provided

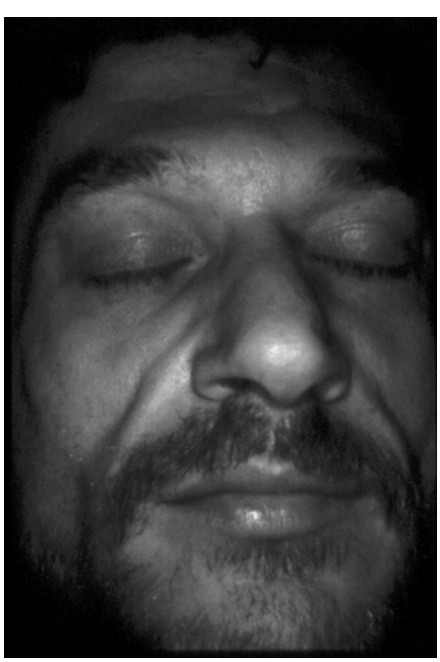

FIG. 25.9. Loss of facial fat resulting in sunken cheeks and depression of nasolabial folds.

cosmetic correction of dorsocervical fat pads. Subcutaneous fat can be suctioned from the abdomen resulting in a more tapered waistline although the presence of peritoneal fat may maintain a protuberant abdomen. Fat implants can temporarily restore a normal appearance to the face and hands. Injections of human collagen (Fascian), hyaluronic acid (Restylane, Perlane), and silicon (Silikon) improve the appearance of lipoatrophic facial changes. Implantation of devices made of expanded polytetraßuoroethylene (Gortex) can improve the appearance of the nasolabial fold furrows. In preliminary studies a polymer of polyactic acid (New-Fill) injected into the deep layers of the skin, where it produces collagen formation, has been shown to improve and correct the subcutaneous depressions in fat depleted regions of the face (43a).

Photosensitivity Disorders

A number of ultraviolet light-induced pathologic changes in the skin of individuals with HIV infection have been reported. Photosensitivity from medications, such as sulfonamides and nonsteroidal antiinßammatory agents, may lead to erythema even after brief exposure to sunlight (44). Chronic actinic dermatitis, a photodistributed, pruritic, eczematous dermatitis with licheniÞed, hyperpigmented plaques on the face, hands, neck, V-area of the chest and arms, has been described in several patients (Fig. 25.10) (45). Hypopigmentaion and hyperpigmentaion secondary to excoriations further contributes to the disÞguring appearance. The reaction persists for months to years. Although affected patients have CD_4 T-cell counts below 200 cells/mm^3, in several cases photosensitivity was the presenting disorder leading to the diagnosis of HIV infection (5). HIV-associated chronic actinic dermatitis predominantly affects patients with very dark skin (type VI). All studied patients have had heightened sensitivity to ultraviolet B light, most to ultraviolet A light, and a rare few to visible light. Treatment consists of avoidance of sunlight and photoallergens, strict sun protection with broad-coverage sunblocks, application of topical corticosteroids to affected areas, oral antihistamines, antimalarials and for the most challenging cases thalidomide (46).

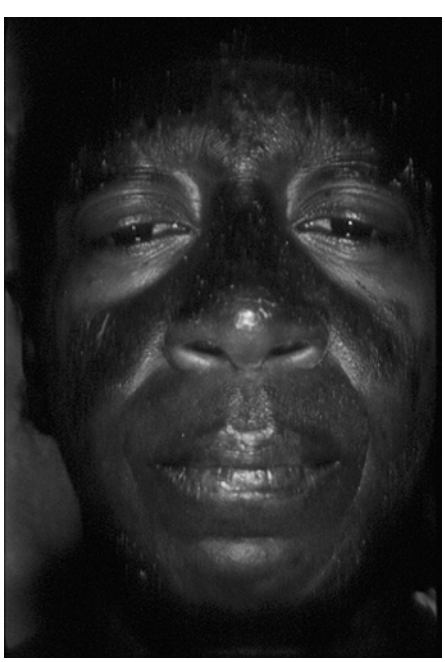

FIG. 25.10. Marked facial hyperpigmentation over sun-exposed areas due to chronic actinic dermatosis.

The occurrence of porphyria cutanea tarda (PCT) has been rarely reported in HIV-infected patients. As in immunocompetent HIV-seronegative patients, vesicles, crusted ulcers, milia, sclerotic skin, and dyspigmentation develops on sun-exposed areas, particularly the face and dorsa of the hands (47). Hypertrichosis and hyperpigmentaion are often present on the malar areas of the face and the dorsa of the hands. Most of the cases have been intravenous drug addicts who were also co-infected with hepatitis C (HCV) or hepatitis B (HBV). Patients may develop the disease at any stage of HIV-infection, but invariably there is hepatic dysfunction. Circulating and urinary uroporphyrin and coproporphyrin levels are elevated. Repeated phlebotomy is the treatment of choice, however antimalarials (hydroxychloroquine, 25 to 200 mg weekly) or erythropoietin are instead prescribed for anemic patients.

Aphthous Ulcers

Although the incidence of aphthous ulcers, also known as canker sores, is similar in HIV-infected and HIV-seronegative persons, immunocompromised HIV-infected individuals with CD_4 T-lymphocyte counts below 100 cells/mm^3 are predisposed to the development of major, recurrent, multiple, slow healing or persistent, symptomatic ulcers (48). The lesions are often preceded by a pricking or burning sensation from 24 to 48 hours before their appearance. The ulcers are characteristically round or oval, crateriform, have a grayish yellow base and are surrounded by an erythematous halo (Fig. 25.11). One or more lesions erupt on the ventral, lateral or underside surface of the tongue, the buccal mucosa, the ßoor of the mouth, or the soft and hard palate. Dysphagia may be severe. Large ulcers may heal with extensive scarring. Herpetiform aphthae erupt in clusters of small 10 to 100 ulcers which coalesce to form large areas of ulceration. These clusters account for 7Ð10% of recurrent lesions (48).

Mixtures of nystatin oral suspension, diphenhydramine elixir, tetracycline suspension, liquid antacids and lidocaine gel are compounded and prescribed for relief of pain. In cases not improved with swish-and-swallow doses of tetracycline suspension, applications of clobetasol or betamethasone gel, covering the ulcer surface with

FIG. 25.11. Discrete, well-circumscribed, round apthous ulcer with typical gray slough covering ulcer base.

amlexanox oral paste, ingestion of colchicine and intralesional injections of 5% triamcinolone acetonide solution, or oral corticosteroids may be effective. Approximately 90% of HIV-infected patients with aphthous ulcers of the mouth and oropharynx treated with thalidomide have at least a partial healing of their ulcers (49). In one study, 55% of aphthous ulcers completely healed and 34% partially resolved, as compared to 7% and 18%, respectively, in the placebo group (48).

Granuloma Annulare

Granuloma annulare is a chronic eruption that presents clinically as granulomatous, inÞltrated papules, plaques, or nodules. The disease may occur more commonly in the setting of HIV infection (50). The lesions can be localized, perforating, generalized, erythematous, or subcutaneous. The lesions often form elevated rings with clear centers, hence the name granuloma annulare.

Although the name of the disease implies the lesions are annular, the more frequent lesions in HIV-infected persons are asymptomatic, discrete, skin colored, smooth, inÞltrated papules (Fig. 25.12). In 60% of patients the disease is generalized. The predominant location is the upper extremities, followed by the trunk. Oral mucosa lesions are rare. Some cases are exacerbated by ultraviolet B light. Potential treatments include PUVA, UVA-1; oral, intralesional or topical corticosteroids; systemic retinoids, antimalarials, potassium iodide and cyclosporine.

Vasculitis

Leukocytoclastic (hypersensitivity, necrotizing, hypocomplementemic, immune complex) vasculitis is characterized by the presence of nonblanching purple papules that may become conßuent, forming plaques (51). These lesions, commonly referred to as Òpalpable purpura,Óare gravity dependent and present most often on the lower extremities, although they may erupt on the forearms or any body area. Early lesions usually consist of petechiae, which become conßuent resulting in larger purpuric patches, and occasionally urticarial papules. Late lesions can be pustules, ulcers, and necrotic bullae. Abnormal laboratory tests include elevated erythrocyte sedimentation rates and decreased total complement levels as well as enzyme elevations if systemic organs are affected. Other diseases, including idiopathic thrombocytopenic purpura, drug-induced thrombocytopenia, and septicemia may produce similar purpura. However, the clinical Þndings are usually characteristic, and the histopathologic presence of Þbrin within the walls of small and medium-sized blood vessels as well as neutrophilic debris conÞrm the diagnosis. Leukocytoclastic vasculitis is more common in patients co-infected with HIV and hepatitis B or C. Adverse drug toxicity, connective tissue diseases, cryoglobulinemia and infectious diseases, especially streptococcal infection, must be excluded as potential causes.

Several cases of erythema elevatum diutinun, a chronic variant of leukocytoclastic vasculitis, have been reported (52). The lesions begin as purpuric macules, papules, and plaques which can evolve into indurated erythematous plaques and eventually into nodules. Areas of predilection are the dorsa of the hands, ankles, pretibial regions, knees, and skin overlying other joints. Other types of vasculitis, especially polyarteritis nodosa and microscopic polyangiitis have been reportedly associated with HIV infection (52a-d).

FIG. 25.12. In ltrated plaques and papules with crusted umbilications due to perforating granuloma annulare are present along the metacarpal-phalangeal joints of the hand. In this form of the disease, the characteristic annular lesions are not usually present.

Hair Abnormalities

AIDS patients often develop premature thinning of scalp as well as body hair. Lengthening, softening and discoloration of the scalp hair has been noted in Black patients. Straightening of curly hair has also been reported, as well as curliness of straight hair associated with lipodystrophy during treatment with the protease inhibitor, indinavir. Patients on indinavir may also complain about scalp hair loss due to shedding, as well as fairer and thinner body hair. Scalp hair loss has also been reported during treatment with zidovudine and in association with high viral loads. Febrile illnesses not uncommonly result in diffuse hair loss due to telogen effluvium. During late disease, when nutritional deficiencies are common, the hair may become lusterless, dull, and eventually a diffuse downy alopecia may develop (53). Premature canities (graying) and alopecia areata are rare. Trichomegaly (elongation) of the eyelashes is an interesting finding in some HIV-infected persons (Fig. 25.13).

Nail Disorders

In one study nail changes were present in 67.7% of HIV-infected patients. Clubbing (5.8%), transverse lines (7.1%), onychoschizia (7.1%), leukonychia (14.3%) and longitudinal melanonychia (14.8%) were the most frequent noninfectious abnormalities observed (54).

Most of the nail changes seen in HIV-infected patients are not specific and some have been discussed in other sections of this chapter. "Blue nails" are common in patients treated with zidovudine (AZT), although rare cases of dyschromic nails not associated with zidovudine treatment have been reported (54a). Blue to brown-black longitudinal streaks, transverse bands, diffuse pigmentation or of the nail plates develop in some patients, usually four to eight weeks after initiation of therapy with zidovudine. The "yellow nail syndrome" has been observed in patients with lymphedema and hypoxia. Malnourished patients often have thin, brittle nail plates. Transverse linear depressions of the nail plates, Beau's lines, may develop after a serious opportunistic infection. Muehrcke's lines, transverse white streaks, develop in patients with hypoalbuminemia. All white (Terry's nails) develop in association with hepatic disease and half-white and half-pink nails occur in renal disease. Protease inhibitors, especially indinavir, can cause painful paronychia of one or more toes, usually the first, which may recur even after partial nail avulsion.

HIV-Associated Pruritus

Pruritus is a common symptom of scabies, cutaneous drug hypersensitivity, eosinophilic pustular folliculitis, insect bites and many other skin eruptions. Itching in the absence of primary skin lesions and only excoriations and lichenification, should instigate an evaluation for underlying biliary disease, chronic renal failure, lymphoproliferative disorders, and intestinal parasites. There are cases in which no specific cause is evident and the pruritus is then attributed to HIV infection. However, many cases labeled as HIV-induced pruritus result from xerosis worsened by climactic effects, such as low humidity. In HIV-associated pruritus, only secondary changes, such as excoriations and lichenification are present (Fig. 25.14). The itching usually improves during treatment with emollients containing menthol, camphor, phenol, pramoxine or lidocaine; topical doxepin; capsaicin cream/gel; oral H1 and H2 antihistamines; or ultraviolet B phototherapy. Chronic cases may progress to prurigo nodularis, thick, hyperkeratotic nodular plaques, which may require more

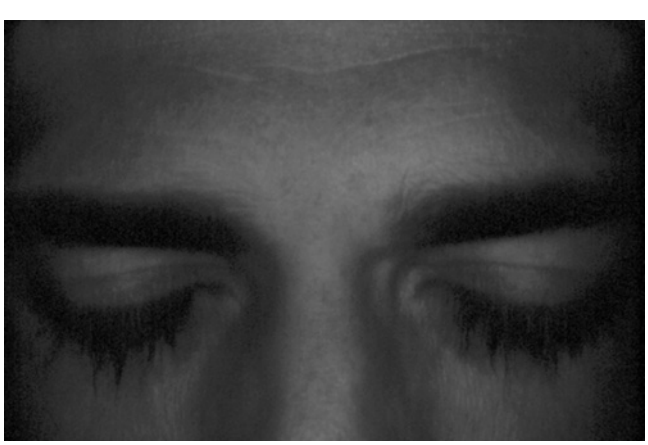

FIG. 25.13. Elongated eyelashes due to stimulated growth during treatment with indinavir.

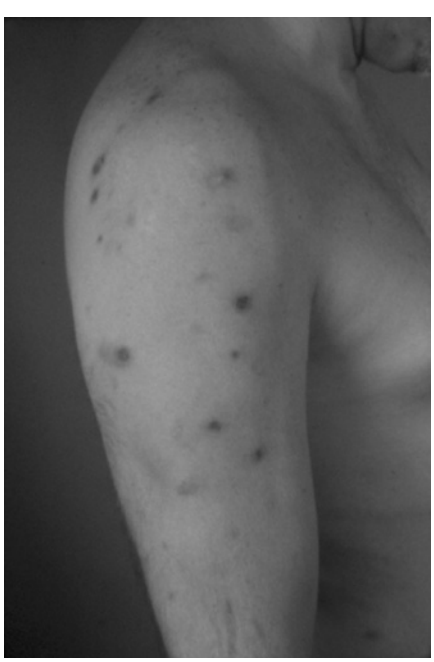

FIG. 25.14. Scattered excoriations in the absence of primary lesions due to HIV-associated pruritus.

aggressive treatments, such as intralesional corticosteroid injections and oral thalidomide.

Pruritic Papular Eruptions

There are a number of pruritic eruptions associated with HIV-infection. Pruritic papular eruption represents an umbrella term for several papular and papulopustular cutaneous eruptions with similar clinical and histologic features and therapeutic response. The causes include arthropod bites; hypersensitivity-induced recall reaction to previous insect bites (papular urticaria); or early lesions of eosinophilic folliculitis which do not yet show histologically the characteristic folliculocentric inÞltrate of eosinophils. Typically, there are pink urticarial papules, each of which resembles an insect bite.

Eosinophilic Pustular Folliculitis (EPF)

This eruption occurs in 5% to 9% of HIV-infected persons with CD_4 lymphocyte counts lower than 250 cells/mm^3, who are not being treated with effective antiretroviral therapy (55). Flares are more common in patients with CD_4 lymphocyte counts between 50 and 100 cells/mm^3. The prevalence of EPF declined sharply after the introduction of highly active antiretroviral therapy. However, in some cases onset has occurred shortly after initiation of antiretrovirals, possibly as a result of sudden immune restoration. Serum IgE levels and peripheral eosinophil counts are usually elevated.

Clinically, 2Ð3 mm follicular, erythematous, urticarial papules and papulopustules, which can be intensely pruritic, erupt on the forehead, face, shoulders, trunk, upper arms, and neck (Fig. 25.15). Often, there is a single vesicle or pustule on the surface of each papule. As a result of scratching, no intact lesions may be present and only potentially disÞguring excoriations and licheniÞcation from rubbing may be apparent. Other body sites can also be affected but the eruption is only rarely generalized. A well-developed, intact lesion is necessary for a histopathologic diagnosis. Alternately, the expressed contents of a pustule can be treated with a Wright stain and examined for a predominance of eosinophils. The etiology remains unknown. The Demodex folliculorum mite has been implicated as a possible cause through induction of an immune response that induces eosinophilia and Ig-E antibodies that bind to mast cells and Langerhans cells. In addition, chemokines and cytokines associated with a Th-2 predominant immune response are important in the pathogenesis (55).

FIG. 25.15. The typical eruption of eosinophilic folliculitis consists of pink and skin colored accuminate papules and papulopustules that resemble arthropod bites.

Milder cases may respond to medium to superhigh potency topical corticosteroids and H_1 antihistamines, such as hydrozyzine. Topical or systemic antibiotics are only beneÞcial if a bacterial folliculitis is concomitantly present, which is occasionally the case. Systemic corticosteroids provide prompt relief, but are not recommended for chronic use. The most consistently efÞcacious therapeutic modality is ultraviolet B phototherapy (56). This previously maligned treatment has been clearly shown not to activate latent HIV infection to any signiÞcant degree (23). Treatment with either isotretinoin (20Ð40 mg daily) (57) or itraconazole (200Ð400 mg daily) (58) is usually more effective than metronidazole (250 mg three times daily for three weeks) (59), dapsone (100 mg daily), or daily applications of permethrin (60).

ARTHROPOD INFESTATION

Insect Bite Reactions

The reaction to bites of ßeas, mites, mosquitoes and other insects may be exaggerated, producing more extensive, exhuberant and symptomatic lesions (61). In these patients, large pruritic, weeping, urticarial papules may erupt on the skin, especially on the extremities. Occasionally, vesicles also appear (61).

The location of the lesions may help to determine the responsible arthropod. Flea bites occur predominantly on the legs, bedbug bites often involve the trunk and extremities and mites and mosquitoes are usually limited to exposed areas. Treatment consists of identiÞcation and avoidance of the offending arthopod, application of insect repellents, topical corticosteroids, oral antihistamines, doxepin cream or topical mentholated lotions.

Demodicidosis, caused by Demodex mites, causes an eruption that may resemble rosacea, acne or miliaria. The eruption consists of numerous tiny papules and papulospustules on the face and occasionally also the neck, scalp, shoulders and presternal area. These mites usually respond to treatment with antiscabicidal agents.

Scabies

In HIV-infected persons, the presentation of infestation with the Sarcoptes scabiei hominis mite may be either typical or exaggerated, and may be crusted and hyperkeratotic (62).

The typical lesions of classic scabies are tiny, intensely pruritic, often excoriated, pink papules (often along a path) and serpiginous or linear burrows. Lesions are frequently found along the Þngers, ßexor aspects of the wrists, antecubital fossae, axillae, umbilicus, buttocks, feet, genitalia and breast areola. The diagnosis of scabies is not routinely an easy one, as only excoriations may be present on examination, the presentation may be variable, and mites are not consistently seen in skin scrapings. Therefore, a high degree of suspicion is warranted in any patient with intense, persistent, unexplained itching. Permethrin 5% cream or gamma benzene hexachloride (lindane) 1% lotion are effective treatments when applied to the whole body from the neck downwards overnight and repeated in one week. All clothing worn during several weeks prior to the diagnosis of scabies, and linens, such as towels and bed sheets, must be carefully laundered.

When immunity is impaired, the clinical picture is exaggerated with generalized scaly papules and extensive excoriations. In these cases, longer duration of treatment is often required and lindane is avoided due to concern about neurotoxicity from absorption through non-intact skin (62a).

Hyperkeratotic (Norwegian) scabies, a fulminant and highly infectious form, occurs in profoundly immunocompromised persons (63). Crusted, hyperkeratotic psoriasiform plaques develop in any part of the body, but especially on the hands, feet, scalp and body folds (Fig. 25.16). Marked periungual and subungual hyperkeratosis can be present in both Þnger and toenails. Weeping Þssures often appear within the plaques. Notably, pruritus may be mild or absent altogether. Hyperkeratotic scabies is highly contagious. It has been estimated that as many as 3,500 mites can be shed into the environment from a single patient every day. This form of scabies may be clinically misdiagnosed as psoriasis, although on skin biopsy or even a simple skin scraping many mites are found, easily establishing the diagnosis. Rarely, Norwegian scabies may present with only thickly crusted localized plaques or nodules on the feet, hands and scalp. The treatment of choice is ivermectin 200 mcg per kg (63). The dose is usually readministered two or three times one week apart. The advantage of concomitant use of topical antiscabiecidal agents is speculative, although it is common practice. Topical scabiecidal agents can be used but more frequent applications are necessary. Salicylic acid 5% ointment should also be prescribed to exfoliate the thickened epidermal scales and facilitate penetration of other topically applied medications.

FIG. 25.16. Diffuse erythema, hyperkeratosis, crusting, excoriations and ssures caused by Norwegian scabies.

BACTERIAL INFECTIONS

Cutaneous Pyoderma

The most common bacterial pathogen cultured from infected skin lesions is *Staphylococcus aureus*. Depending on closeness of inspection and the degree of immunosuppression of the studied patients, *S. aureus* skin infections may be found in 71% of HIV-infected persons (64) and skin bacterial infection may be present in 83% of autopsies (65). Nasal colonization with *S. aureus* has been reported in as many as half of HIV-infected patients (66). Abscesses, furuncles, carbuncles, cellulitis, polymyositis and necrotizing fasciitis occur more commonly in HIV-infected patients with CD_4 T lymphocyte counts below 250 cells/mm^3, and often require aggressive surgical drainage or debridement and intravenous antibiotics (Fig. 25.17). *S. aureus* folliculitis is the most common bacterial pyoderma.

Typically, erythematous follicular and perifollicular pustules are scattered on the trunk and extremities, but lesions may arise on the skin of any body area (Fig. 25.18). When pruritus is present, there may be extensive excoriations and large abrasions with few intact pustules. In intertriginous areas, the eruption may resemble Candidiasis. Atypical Staphylococcal folliculitis in the groin, axilla, or scalp with violaceous crusted plaques up to 10 cm in diameter and superÞcial pustules, has been reported. Botryomycosis appears as crusted, suppurative, verrucous papules or erythematous nodular abscesses, which exude granules composed of clumps of bacteria (66a). The characteristic lesions of ecthyma are chronic, necrotic, deeply seated ulceration. Streptococcal axillary lymphadenitis usually presents as bilateral, painful, tender, swollen lymph nodes. There are reports of nonmenstrual toxic shock syndrome, associated with infected wounds and tampons or packing contaminated by toxigenic strains of *S. aureus*, in immunosuppressed patients (67). Patients with this syndrome present with fever, conjunctivitis, diffuse cutaneous erythema with subsequent desquamation, hypotension and shock. A similar eruption, known as

FIG. 25.17. Numerous furuncles, pustules and erosions on the beard area extending to the neck caused by infection with *Morganella morganii*, an uncommon skin pathogen. Abscesses and ulcers were also present on the chest and throughout the back.

the ÒToxic Strep SyndromeÓ caused by exotoxin-producing strains of *Streptococcus pyogenes* has also been reported. Chronic diffuse dermatitis in patients with *S. aureus* infection has been associated with elevated serum IgE levels and eosinophilia.

Haemophilus inßuenzae cellulitis is common in infants, may also occur on the head and neck of adults, has an aggressive course, and may become disseminated or progressively involve deep structures.

Cultures are imperative as skin infections may be caused by a large variety of bacteria, including unusual species, such as *Rhodococcus equi*, which has been cultured from abscesses. *Corynebacterium diphtheriae* may cause bullous lesions that ulcerate and become covered with a grayish pseudomembrane.

Bacillary Angiomatosis

Bacillary angiomatosis is caused by *Bartonella henselae* and, less often by *Bartonella quintana* (68). Epidemiologic evidence has associated infection with *B. henselae* with exposure to ßea-infested cats and infection with *B. quintana* with contact with the human body louse (69).

The most common skin lesions are pyogenic granuloma-like, Þrm, friable, dome-shaped, non-blanching purple to dusky red angiomatous papules and nodules, 0.5 to 10 cm, which may track linearly along veins in the extremities (Fig. 25.19) (70). The lesions may erupt anywhere in the body in numbers ranging from a few to hundreds but usually spare the oral mucosa, and the palms and soles. However, lesions have been reported in the lips, tongue and cervix.

Other lesions include violaceous nodules resembling Kaposiõs sarcoma, lichenoid violaceous plaques and subcutaneous nodules (71). Hyperpigmented indurated

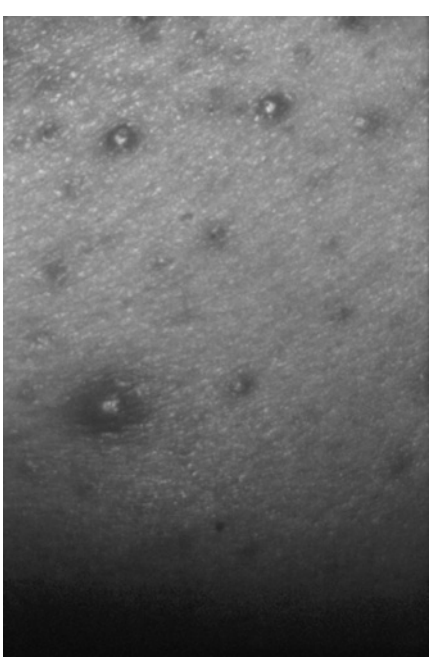

FIG. 25.18. Bacterial folliculitis consisting of follicular pustules with erythematous borders is usually caused by *Staphylococcus aureus*.

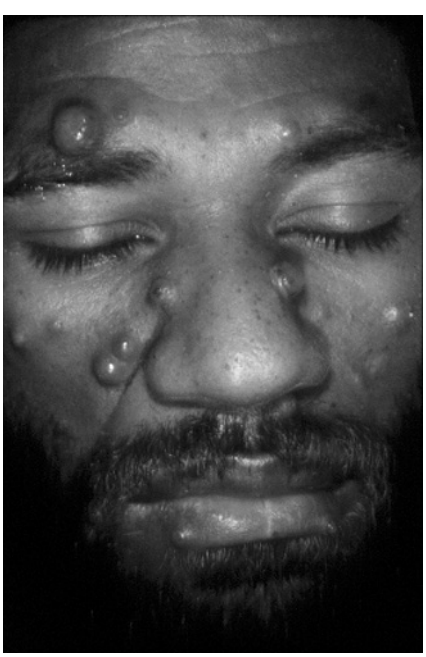

FIG. 25.19. Bright red, exophytic, dome-shaped papules and nodules on the face of a man with bacillary angiomatosis.

ovoid, hyperkeratotic plaques have been described in some dark-skinned patients.

Although skin involvement is the usual presentation, other organs may be affected. Patients may develop fever, chills and weight loss due to Bartonella bacteremia, even in the absence of skin lesions. Peliosis hepatis results from vascular lesions in the liver which typically result in highly elevated alkaline phosphatase levels but normal or only mildly elevated transaminases. Osteomyelitis is characterized by the presence of painful osteolytic lesions usually in the long bones, often beneath soft tissue masses or cellulitic plaques (71). Lymphadenopathy and hepatitis are signiÞcantly more frequent in cases infected with *B. henselae*, while osteomyelitis and central nervous system involvement are more common in *B. quintana*-infected patients. Involvement of the gastrointestinal tract, spleen, lymph nodes, respiratory system, central nervous system, bone marrow, and endocardium is possible (68). In contrast to *B. quintana*, *B. henselae* infection is more often associated with diarrhea.

Histopathologic examination of affected tissue shows vascular proliferation of capillary-sized blood vessels lined with protuberant, cuboidal or polygonal endothelial cells. A dermal mixed inßammatory cell inÞltrate contains numerous neutrophils. In hematoxylin and eosin stained tissue, the pleomorphic bacteria appear as granular or Þbrillary amorphic eosinophilic clumps in close proximity to vascular channels but are best visualized with silver stains (Fig. 25.20) (71). In cases when no bacteria can be identiÞed under light microscopy, electron microscopy demonstrates the characteristic trilaminar cell-walled bacilli (71).

The small, curved, gram-negative rods can be cultured in 5% carbon dioxide with high humidity on freshly poured agar containing 5% deÞbrinated rabbit blood, but growth requires 20Ð40 days (71). However, the diagnosis can be readily conÞrmed with a PCR-enzyme immunoassay (71).

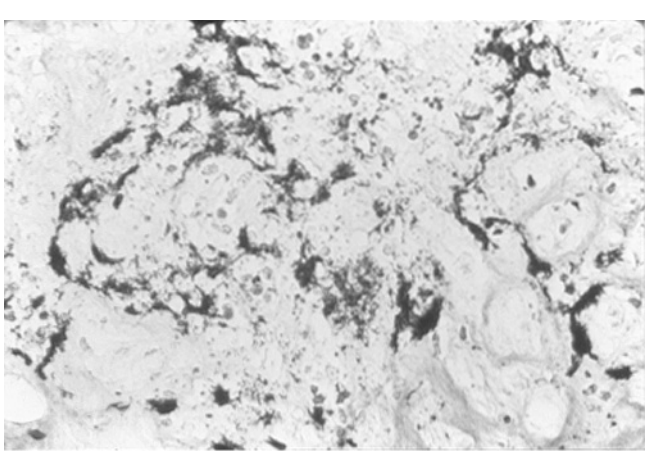

FIG. 25.20. Impregnated silver (Steiner) stain showing irregular clumps of Bartonella bacteria in a lesion of bacillary angiomatosis.

Erythromycin (500 mg orally four times daily) results in dramatic improvement in the skin lesions within one week, and resolution within one month. Intravenous erythromycin is recommended for systemic infections. Although insufÞcient data are available for recommendation, other macrolides such as azithromycin and clarithromycin also appear to be effective. Doxycycline 100 mg twice daily is an alternative treatment. An eight-week course of antibiotics is recommended for isolated cutaneous disease. Relapses are treated with an additional 16-week course. Hepatitis and osteomyelitis require longer treatment courses and possibly even lifelong suppressive antibiotic therapy.

Mycobacterial Infections

Although infection with *M. avium intracellulare* (MAC) rarely involves the skin, Þrm papules and nodules, skin ulcers, perianal erosions, and cellulitis have been described in patients with mycobacteremia (72). The occasional incidental presence of this organism in skin biopsies of other lesions is not surprising considering that 20% to 40% of profoundly immunosuppressed HIV-infected patients not receiving antimycobacterial prophylaxis developed systemic MAC infection (73).

On the other hand, skin lesions are the most common manifestation of infection with *M. haemophilum*. The lesions are erythematous granulomatous papules, exophytic or subcutaneous nodules, and abscesses that drain spontaneously and ulcerate (Fig. 25.21) (74). Lymphadenitis, usually of the submandibular and cervical nodes, and central venous catheter tunnel infections may occur. Infection of bones, joints, lymphatics and lung is common (74). This organism is fastidious and requires supplementation of iron or heme to the culture media which must be incubated at 30Ð32¡C. The infection can be treated with antibiotics to which the microorganism is susceptible, such as minocycline, clarithromycin, ciproßoxacin, clofazimine, isoniazid, rifampin, ethambutol amikacin,

FIG. 25.21. One of several ulcerated nodules in a patient with disseminated *Mycobacterium haemophilum* infection.

streptomycin, and pyrazinamide. Infection with *M. marinum*, *M. kansasii*, *M. ulcerans* and other mycobacteria have been described and cause lesions that are similar to those found in HIV-seronegative individuals. In contrast to tuberculosis, numerous bacilli are readily visible in biopsied, acid fast-stained tissue of lesions caused by atypical mycobacteria (Fig. 25.22).

The skin is rarely involved in *M. tuberculosis* infection. The more common cutaneous presentations are abscesses and scrofuloderma. Lupus vulgaris, which is the most common presentation in HIV-seronegative persons with adequate immunity, is infrequently seen. Miliary tuberculosis is notably uncommon (75). The typical lesions of scrofuloderma are irregular, purulent ulcers and sinuses with a granulation base overlying lymph nodes, and occasionally infected bones or joints.

Although it was suspected that HIV-induced immunosuppression would propel a shift towards the multibacillary (lepromatous) spectrum in patients co-infected with *M. leprae*, studies have failed to document a difference in disease spectrum between HIV-infected and HIV-seronegative Hansen's disease patients. However, in one study 22% of co-infected patients developed new lesions during treatment, suggesting that the disease is less responsive to standard therapeutic regimens.

Syphilis

Numerous studies have demonstrated that syphilis is more common in HIV-infected than in HIV-seronegative persons, however this higher prevalence may be attributable to the increased risk for syphilis in certain groups at risk of acquiring HIV infection (76). It has been stated that the signs and symptoms of primary and secondary syphilis may be more exaggerated and that the course may progress more rapidly towards the tertiary stage. However, prospective studies have shown that the appearance of lesions and the course of disease is not different in the vast majority of HIV-infected patients compared with HIV-seronegative patients (76). The appearance of primary chancres is typical, although patients with primary syphilis present more frequently with multiple ulcers, and chancres may persist more often into the secondary stage (76). The course of secondary syphilis is usually unchanged, although rapidly progressive disease and unusual manifestations have been rarely reported (76). Nodular and noduloulcerative lesions are more common, but most of these cases have no constitutional symptoms associated with malignant syphilis. Although most cases of early syphilis in HIV-infected patients respond to conventional doses of penicillin, serologically defined treatment failures are more common, and for this reason close evaluation after therapy is mandatory. Reactivation of previously thought to be adequately treated latent syphilis has been reported, although many of these patients have serofast titers without clinical manifestations. Clinical relapses, usually with neurosyphilis, occurred in 1% of patients in a prospective study and more frequently in retrospective studies (77). Rarely, patients experience multiple relapses. The prevalence of neurosyphilis is higher in patients coinfected with both syphilis and HIV, and progression to the symptomatic forms of neurosyphilis is accelerated. Uncontrolled production of antibodies may produce extremely elevated titers and a higher rate of biologic false-positive nontreponemal serologic tests. Conversely, an occasional patient may have a nonreactive nontreponemal test during early syphilis, and the sensitivity of treponemal tests appears to be slightly lower in patients treated for past syphilis. Treatment consists of a single injection of benzathine penicillin G, 2.4 million units for primary, secondary or early latent syphilis, and three injections one week apart for late latent or syphilis of indeterminate duration. CSF examination is recommended for patients with early syphilis in the presence of neurologic signs or symptoms, syphilis of indeterminate or more than one year duration, and tertiary disease.

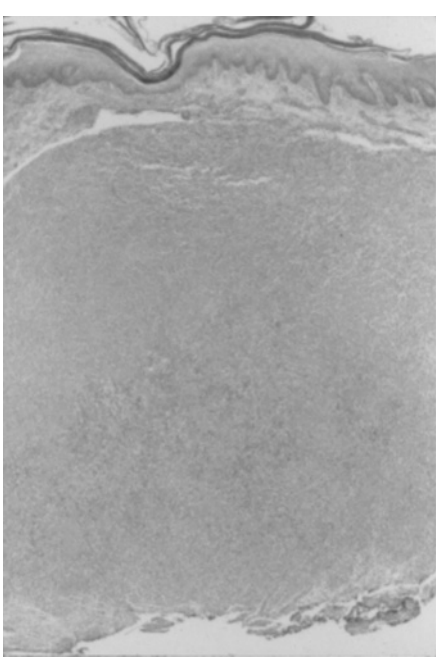

FIG. 25.22. Numerous acid fast bacilli present in the dermal in ltrate are characteristic of infection with atypical mycobacteria.

FUNGAL INFECTIONS

Candidiasis

Oropharyngeal candidiasis (thrush) due to Candida species, usually *Candida albicans*, is the most common opportunistic mucosal infection seen in HIV-infected persons. *C. tropicalis*, *C. parapsilosis*, *C. krusei*, and *C. glabrata* tend to cause infection in patients with advanced HIV infection. Previous to the introduction of highly

aggressive antiretroviral therapy, oropharyngeal candidiasis was found in 7–48% of HIV-infected persons and as many as 93% of profoundly immunocompromised patients (78). The development of "thrush" is an important early marker of progressive immunodeficiency, which implies immune deterioration with progression to symptomatic disease independent of CD_4 counts. Approximately 75% of patients have at least one episode of thrush at some point in the course of HIV infection. In about a third of these, the disease is recurrent and the severity worsens with advancing immunosuppression (79). Candidal esophagitis affects 20–40% of all HIV-infected persons. Mucocutaneous candidal infection is rare with CD_4 T-lymphocyte counts above 500 cells/mm^3 but frequent with counts below 100, and therapeutically challenging when counts drop below 50 cells/mm^3. During treatment with HAART, the prevalence of oropharyngeal candidiasis was reduced from 31% at baseline to 1% at 48 weeks in one study (78). However, the prevalence of oral candidiasis in these patients increases when viral load counts rise above 30,000 copies/ml (80,81).

Oropharyngeal candidiasis is asymptomatic in many patients, but those with inflammation and erosions experience burning pain and altered taste sensation. Dysphagia is more often a symptom of esophagitis. Pseudomembranous candidiasis, the acute and most common form of oral candidiasis, presents with soft, creamy white to yellowish plaques that can be easily scraped off with a tongue depressor, leaving erythematous, eroded, or ulcerated bases, which may be tender and bleed easily. In chronic hyperplastic candidiasis, asymptomatic white plaques or papules that are adherent and unscrapable are most commonly present along the laterodorsal surfaces of the tongue (Fig. 25.23). Chronic atrophic (erythematous) candidiasis appears as an occasionally symptomatic, red patch or velvet textured plaque, usually on the hard palate but also on the dorsal tongue and other mucosal surfaces.

The diagnosis of candidiasis is confirmed by the detection of Candida species in 10% potassium hydroxide preparation or culture. More than 90% of patients have clinical resolution of physical findings and symptoms within seven days of initiation of treatment. Effective agents include fluconazole (100 mg daily), itraconazole (100–200 mg daily), ketoconazole (200 mg daily), or clotrimazole troches (10 mg 4–5 times daily) for 7 to 14 days for thrush or 14 to 21 days for esophageal disease. Azole resistant cases that do not respond to itraconazole or high doses of fluconazole (400–800 mg daily) are treated with amphotericin B suspension (100–500 mg swish and swallow four times daily), or an intravenous amphotericin B preparation. Routine primary prophylaxis is not recommended because of the effectiveness of therapy for acute disease, the low mortality associated with mucosal candidiasis, the potential for resistant Candida strains to develop, the possibility of drug interactions, and the cost of prophylaxis. However, chronic suppression therapy may be required in cases with recurrent episodes.

FIG. 25.23. Candida albicans infection (thrush) consisting of creamy white plaques on the dorsal surface of the tongue.

In angular cheilitis due to Candida, either unilateral or bilateral cracking, fissuring, and redness develop at the oral commissures. Candidiasis of glabrous skin is common especially in intertriginous areas, such as the groin, axillae, inframmamary folds, and gluteal cleft (82). In these areas, erythematous, moist, scaly patches and papules become confluent into plaques which are surrounded by tiny satellite reddish papulopustules. In the anal area, pruritus ani is the chief symptom. Vulvovaginal candidiasis is a poorly tolerated complication that develops in 30 to 40% of HIV-infected women. In some women, the infection is chronic and intractable. HIV-infection should be suspected in non-diabetic men with recurrent candidal balanitis. In infants with congenital HIV infection, candidal diaper rashes are more recurrent and severe (82a). Disseminated candidiasis is rare in HIV-infected individuals.

Dermatophytosis

The prevalence and severity of superficial fungal infections increase proportionally with the severity of HIV-induced immunosuppression. These infections are more widespread, more recurrent, require more prolonged treatment and may have atypical appearances. The typical lesions are annular (ringworm) papules and plaques (Fig. 25.24), but scaly planar plaques may be misdiagnosed as psoriasiform or eczematous dermatitis. Several cases of

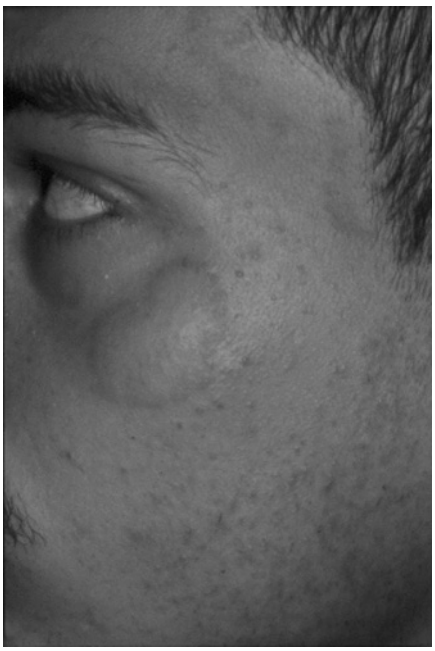

FIG. 25.24. Tinea faciei with erythematous annular lesions covered by ne scaling on the face caused by *Trichophyton rubrum*.

tinea capitis, including kerion formation which is uncommon in adults, have been reported, mainly in women (83).

Onychomycosis

Compared to the general population, HIV-infected persons have an increased susceptibility to onychomycosis. In general, fungal nail infections are more rapidly progressive, involve more nails, respond less favorably to antifungal therapies, and have higher rates of post-treatment relapse. In a prospective study of nails, onychomycosis was the main nail disease and was present in 30.3% of patients as compared with 12.6% of controls (54). *Trichophyton rubrum* was present in 48% of the onychomycoses cases and unusual Candida species were also recovered from some abnormal nails. Multiple fungi were frequently cultured in a single patient. The mean CD_4 T-lymphocyte count was lower in patients with onychomycosis and the frequency of onychomycosis increased with advanced immunosuppression.

Any form of onychomycosis, including distal subungual onychomycosis, proximal subungual onychomycosis and total dystrophic onychomycosis may be present. However, white superÞcial onychomycosis is the most common form of onychomycosis in HIV-immunocompromised patients, and is usually caused by *Trichophyton rubrum*, rather than *T. mentagrophytes*, the fungus usually implicated in most nail infections of this type (84). The fungus invades the dorsal portion of the nail plate. A superÞcial, white, powdery discoloration appears in the dorsal nail plate (Fig. 25.25). As the disease

FIG. 25.25. White proximal onychomycosis.

progresses, the coloration merges and spreads. The discolored nail plate becomes rough, soft, and friable. Candida species can invade the nail plate or nail bed directly or infect the nail folds, hyponychium, or nail bed after the nail unit is exposed to trauma, moisture, or contact irritants. Candidal paronychia is characterized by erythema and edema of the proximal and lateral nail folds. *S. aureus* paronychia is associated with greater tenderness, increased rubor, and ßuctuance with purulent discharge. Candidal onychomycosis presents with onycholysis, or brittle, thickened and opaque nail plates.

Cryptococcosis

Without effective antiretroviral therapy, between 6% and 13% of all AIDS patients develop *Cryptococcus neoformans* infection, usually meningitis (85). Approximately 5.9Ð15% of patients with disseminated cryptococcosis manifest skin lesions, the most common of which are skin-colored or pink, umbilicated papules and nodules, many with central hemorrhagic crusts (85). These lesions resemble molluscum contagiosum but there is no central keratotic plug and the surface of the lesions is less smooth (Fig. 25.26). The lesions are most frequently present on the face and neck followed by the trunk and extremities. There could be a single or dozens of lesions. Crater-like ulcers with raised edges resemble basal cell carcinoma (86). Purple nodules and plaques appear similar to Kaposi's sarcoma (85). Cases with cutaneous pustules, abscesses, vegetating plaques, cellulitic areas, panniculitis and palpable purpura are less common (85,86). Rarely, the lesions are scattered erythematous crusted plaques that can be confused with eczema (85). Encapsulated budding yeast forms can be demonstrated in curetted skin scrapings crushed on a glass slide and stained with Giemsa stain or India ink. A skin biopsy specimen stained with PAS, hematoxylin and eosin, or methanamine silver readily shows the organisms. A culture of tissue provides conÞrmation. The treatment of choice is ßuconazole.

FIG. 25.26. Disseminated cryptococcosis with whitish-pink papules which become centrally eroded, resembling molluscum contagiosum.

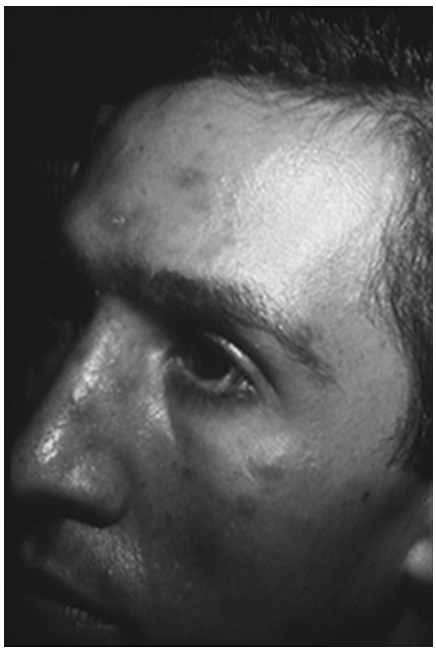

FIG. 25.27. Acneiform erythematous papules and pustules some of which become necrotic due to histoplasmosis.

Itraconazole is also effective. Intravenous amphotericin B with ßuconazole or 5-ßucytosine is given to patients with cryptococcal meningitis or life-threatening infection. Prophylactic treatment has been continued indeÞnitely since over half of cases relapse after discontinuation of antifungals. However, recent reports indicate that discontinuation of prophylaxis may be safe in patients who have responded to HAART with increases in the CD_4 cell count to greater than 100 cells/mm^3 (87).

Histoplasmosis

Disseminated infection with *Histoplasma capsulatum* develops in 4.7% of HIV-infected patients living in endemic areas, especially those who have a history of exposure to chicken coops, serologic evidence of previous infection, and CD_4 T-lymphocyte counts below 150 cells/mm^3. In about 11% (10Ð20%) of systemic cases, mucocutaneous lesions are present. In one study of 32 AIDS patients from South America with disseminated infection, two-thirds presented with mucocutaneous lesionsÑ six exclusively with oral lesions, six only with facial lesions and nine with both orofacial lesions 88. The most common cutaneous presentation is an eruption of scattered erythematous granulomatous papules or pustules that become necrotic on the face, extremities and trunk (Fig. 25.27) (89). However, caseating nodules, ulcers, vegetating plaques, condyloma-like granulomatous papules, intranasal masses, panniculitis and acneiforn, rosacea-like, folliculitis-like and maculopapular eruptions have also been described. Verrucous papules and ulcers are the common oral lesions (88).

Penicilliosis

Infection with the dimorphic fungus *Penicillium marneffei* is the third most common opportunistic infection among HIV-infected persons residing in Southeast Asia and southern China (90). Cases are seen in this country among immigrants or travelers returning from endemic areas. The exact route of infection, although unknown, is assumed to involve inhalation of conidia. The fungus proliferates in macrophages. Patients are profoundly immunosuppressed with CD_4 T-lymphocyte counts below 50 cells/mm^3. The typical presentation consists of fever, anemia, weight loss, lymphadenopathy, hepatomegaly, gastrointestinal symptoms and in 60% of cases cough and dyspnea due to pulmonary inÞltrates (90). In as many as 75% of cases, the skin is involved. Typically, there are one or more umbilicated skin colored or pink papules, usually on the face, pinnae, arms and upper trunk (Figs. 25.28, 25.29). Small genital ulcers measure between 0.5 to 3.0 cm. Shiny oral papules and erosions or shallow ulcers covered with whitish yellow, necrotic sloughing may erupt on the palate, gingiva, labial mucosa, tongue, and oropharynx. A diagnosis can be presumptively established with a positive serologic test and conÞrmed by identiÞcation of the fungus on skin biopsy or culture from blood or other organs. Itraconazole (200 mg) is administered for mild to moderate infection. The treatment of choice in patients with shock or respiratory failure is amphotericin B (0.6 to 1 mg/kg daily). Because relapses are common,

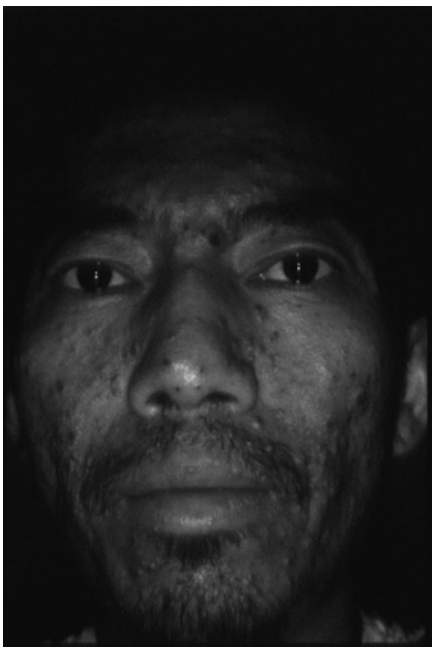

FIG. 25.28. Disseminated penicilliosis with erythematous, umbilicated, skin colored papules of various sizes.

long-term suppressive therapy with itraconazole is recommended.

Coccidioidomycosis

Reactive cutaneous manifestations of acute pulmonary infection with *Coccidioides immitis* include erythema multiforme, erythema nodosum and scarlatiform toxic erythema (91). Chronic primary cutaneous coccidioidomycosis infection consists of erythematous papules, which often ulcerate and become vascular warty granulomatous nodules, usually on the face and neck (92). Disseminated coccidioidomycosis infection is not common and only

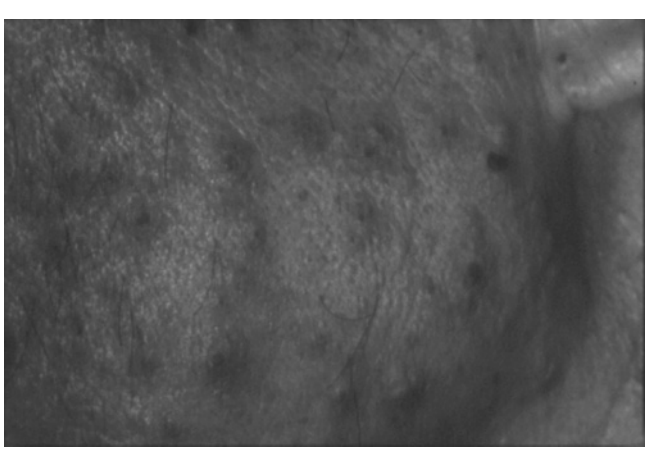

FIG. 25.29. Close up of small, discrete, brownish pink, ulcerating papules on the face of a man with disseminated *Penicillium marnefÞ* infection.

5Ð10% of cases develop skin lesions (91). Verrucous plaques or granulomatous papules may erupt on the face (92). Other lesions are not speciÞc and include pustules, nodules, subcutaneous abscesses, ulcers, sinuses and scars.

Sporotrichosis

Lymphocutaneous infection with the dimorphic fungus, *Sporothrix schenckii*, is usually contracted in North America through traumatic puncture or scratches during outdoor activities, such as rose bush gardening (93). A tender inÞltrated erythematous papule forms at the inoculation site and progressively becomes a pustule and then an ulcerated nodule with ragged undermined borders. In approximately, two to three weeks new subcutaneous nodules may erupt in a linear pattern along the draining lymphatic vessels.

Patients with Þxed cutaneous sporotrichosis usually live in endemic areas and have a high degree of immunity. In Þxed cutaneous infection, pyodermatous erosions or inÞltrated and crusted plaques are localized to one area, most commonly the hand or face. Both forms have been reported in HIV-infected patients (94).

Immunocompromised patients with severe CD_4 T-lymphocyte depletion develop either disseminated cutaneous infection with large, tender, erythematous nodules that ulcerate, or multifocal systemic infection with widespread, purple, crusted ulcerated plaques, often associated with polyarticular arthritis (94). Disseminated osteoarticular sporotrichosis may masquerade as gout.

Sporotrichosis localized to skin and subcutaneous tissues is readily treated with itraconazole, ßuconazole or supersaturated potassium iodide. However, management of osteoarticular and other localized visceral and disseminated forms of sporotrichosis is challenging. Eradication of the organism may not be possible, but clinical resolution can be attained and is subsequently maintained with suppressive antifungal therapy (93).

OTHER OPPORTUNISTIC INFECTIONS

Pneumocystosis

Dissemination of *Pneumocystis carinii* to the skin is rare, but has been reported in some cases receiving pulmonary prophylaxis with aerosolized pentamidine or dapsone (95). Cutaneous pneumocystosis has variable clinical presentations, the most common of which are discrete, friable, erythematous papules or small nodules on the ear canals or the nares (Fig. 25.30) (95). Other lesions have included molluscum contagiosum-like papules on the head and neck, bluish cellulitic plaques in the sternum, polypoid masses in the ears, Þrm hyperpigmented axillary nodules, deep abscesses, and a gangrenous foot (95).

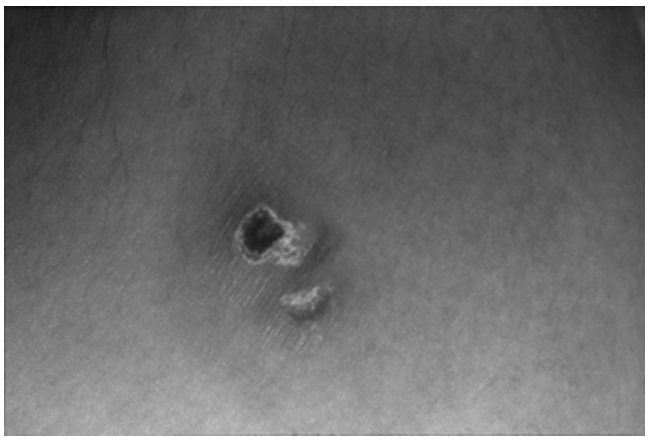

FIG. 25.30. Two ulcerated erythematous papules, one covered with black crust on the face of a patient with disseminated *Pneumocystis carinii* infection.

Amebiasis

Systemic infection with Acanthamoeba or Leptomyxida spread from intestinal infection, usually presents with slowly progressive, invariably fatal granulomatous encephalitis. Skin involvement was present in approximately 75% of reported patients and may be the only manifestation of disseminated disease (96). Notably cutaneous infection may precede other manifestations by weeks or months. Skin lesions include pustules, pruritic and painful erythematous inÞltrated papulonodules, and subcutaneous, occasionally draining, ßuctuant nodules. The usual location is the skin of the extremities and face (96). These lesions often ulcerate forming deep or shallow crusted ulcers, which range in size from 0.5 to 5.0 cm (Fig. 25.31). Ulcer and sinus Þstulas are often present on the hard palate. Histopathologic examination shows a neutrophilic lobular and septal panniculitis with trophozoites. The prognosis is dismal. Various combinations of drugs have been effective in isolated cases. An aggressive multidrug regimen with intravenous pentamidine, oral sulfadiazine, ßuconazole, and ßucytosine, has been advocated as the most promising treatment for disseminated acanthamebiasis (96).

VIRAL INFECTIONS

Human Papilloma Virus Infection

More than 100 types of human papillomavirus (HPV), a DNA virus that can affect the mucocutaneous surface of any body area, have been classiÞed (97). Cutaneous warts account for 2.9Ð27% of all skin diseases in HIV-infected persons. In immunocompromised patients, cutaneous warts tend to be multiple, can grow unusually large, spread over wide areas, and respond less favorably to conventional therapy (Fig. 25.32) (97). Palmoplantar warts may

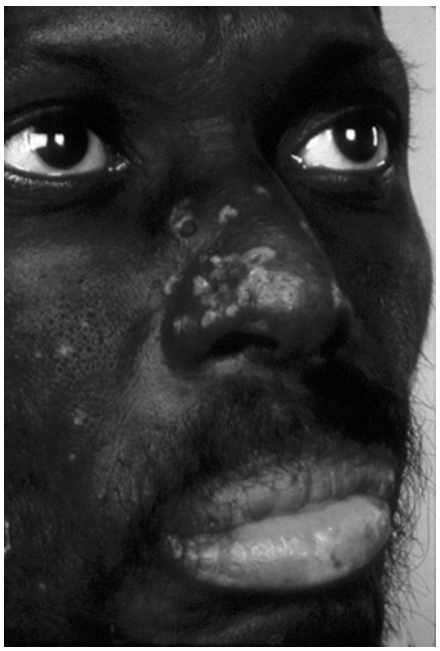

FIG. 25.31. Prothecosis consisting of small erythematous vesicles and papules that ulcerate and scar on the central face and lips.

be so numerous as to become conßuent into keratodermatous plaques (Fig. 25.33). Flat warts may erupt and become conßuent into plaques on the upper extremities, face, and trunk. In such cases type 5 and type 8 HPV, which are associated with epidermodysplasia verruciformis, have been recovered (98).

The prevalence of oral warts has remained at 1 to 4%, a frequency apparently unaltered by the development of new antiretroviral therapies. HPV, most commonly types 7, 13 and 32, can be recovered in clinically normal oral mucosa in up to 60% of HIV-infected individuals versus one-third of the general population. The most common clinical presentation is multiple ßat warts with stippled surfaces on

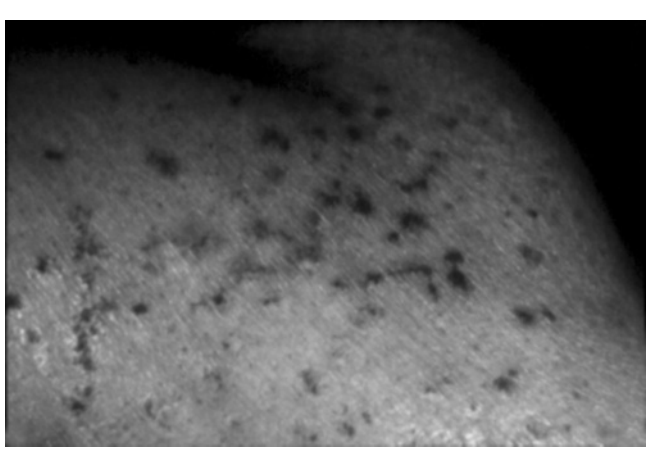

FIG. 25.32. Pigmented, disseminated verrucae plana. Linear arrangement of warts in some areas re ect koebnerization.

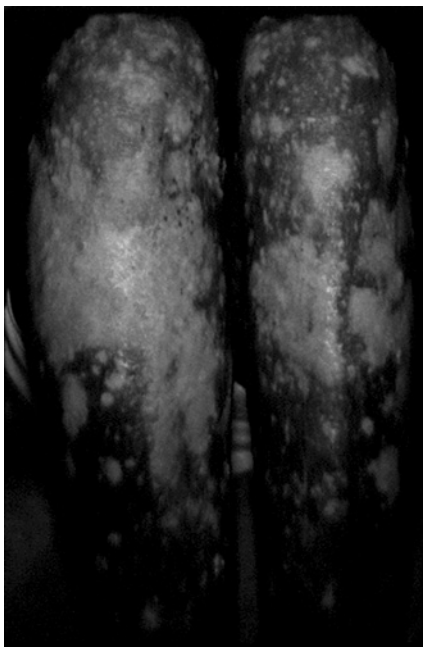

FIG. 25.33. HPV infection with numerous at warts confluent into psoriasiform plaques on the anterior legs. Some lesions had progressed to squamous cell carcinoma.

FIG. 25.35. Exophytic, convoluted, rm erythematous nodular invasive anal squamous cell carcinoma.

the lips, labial commissures, buccal mucosa, and tongue (99). Anogenital warts are common, and with increasing immunosuppression become extensive, relapse frequently after treatment, and have higher rates of dysplastic changes (Fig. 25.34). There is evidence that the prevalences of both oral and anogenital warts are increased in patients treated with HAART (99,100).

The prevalence of anal HPV infection is as high as 93% in HIV-infected compared to 23% in HIV-uninfected homosexual or bisexual men (101). In San Francisco 196/269 (73%) of HIV-infected gay men were infected with multiple HPV types, with type 16 being the most common type (101). These statistics are alarming in view of the high incidence of anal cancer in HIV-infected homosexual and bisexual men (at least 70 cases/100,000 persons) in comparison to the general population (0.8/100,000 persons) (101a,101b). The risk of invasive anal cancer was calculated to be 34-fold higher in long-term HIV survivors (Fig. 25.35). HIV-infected men and women have higher rates of high-grade squamous intraepithelial lesions than the otherwise healthy HIV-seronegative population. Some investigators have recommended screening all HIV-infected patients with anal cytologic smears regularly, evaluating abnormal cytology with colposcopic guided biopsies, and obliterating high grade dysplastic lesions (102,103).

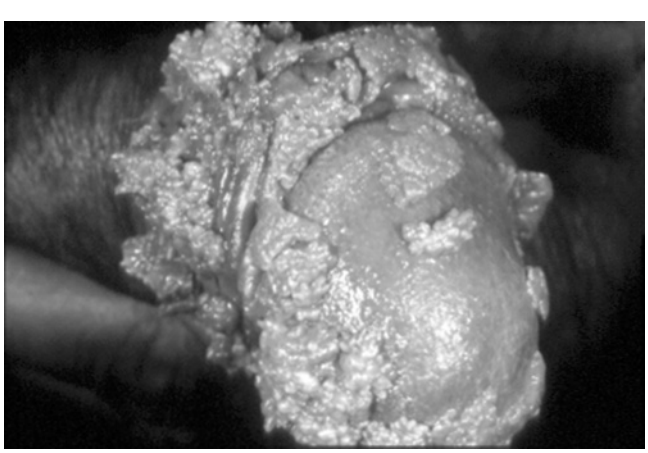

FIG. 25.34. Extensive number of condylomata accuminata on the penile glans and distal shaft.

Cell-mediated immunity is considered to be a critical factor in the regression of warts, and there is an inverse association between CD_4 T-lymphocyte counts and the presence of warts. Indeed, cases of previously treatment unresponsive warts that resolved after initiating effective antiretroviral therapy have been reported (**ref ???**). However, in other patients, cutaneous warts have persisted despite a striking increase in the CD_4 T-lymphocyte counts. It was recently suggested that in patients with a nadir CD_4 cell count below 120 cells/mm^3, or a mean CD_4 cell count below 135 cells/mm^3, at the start of aggressive antiretroviral therapy, cutaneous warts will persist despite a rise in CD_4 T-lymphocyte counts (100).

Common treatments include cryotherapy, electrocautery, CO_2 laser ablation, pulse dye laser treatments, excision, intralesional bleomycin, cantharidin, and imiquimod (97,104). Anogenital lesions can also be treated with podophyllotoxin, trichloroacetic acid, intralesional or intramuscular injections of alpha interferon, and cidofovir (97,105). The use of acitretin at a dose of 25 mg twice

daily has been found to be beneficial in promoting the resolution of even large HPV-related warts, although the lesions return upon discontinuation of this treatment (105a).

Molluscum Contagiosum

Molluscum contagiosum is caused by the largest known human Poxvirus, which replicates in the cytoplasm of infected keratinocytes. Identification of these basophilic intracytoplasmic inclusion bodies in cytological preparations (Molluscum preps) treated with Giemsa stain confirms the diagnosis (106). The usual incubation period ranges form two to seven weeks but data from HIV-infected cases strongly suggest that the virus may remain latent in the skin for years. The virus is usually transmitted from skin to skin contact with a person with active lesions, as well as through contaminated inanimate objects, such as towels and gymnasium equipment. Self-inoculation by picking, rubbing and shaving spreads the infection.

In immunocompetent persons the infection is self-limited with each lesion resolving spontaneously in approximately two to three months, however, in immunocompromised individuals the disease is frequently progressive with increasing number of lesions which persist, disseminate, and grow larger in size (107). The prevalence of molluscum contagiosum in HIV-infected persons ranges between 5% and 18% (107). Infection is common in persons with CD_4 counts below 100 cells/mm^3. Smooth, round, dome-shaped, umbilicated, gray-white, pink or flesh-colored papules erupt as scattered individual lesions or as grouped, often symmetrical, crops (Fig. 25.36). A firm, gray-white core can be expressed from the lesions. The lesions are usually 2–5 mm in size but may grow to 3 cm (giant molluscum). More than one hundred lesions may be present and these may become confluent into cobblestone plaques. When the infection is sexually transmitted the lesions are found in the anogenital and pubic areas, the perineum, upper thighs and lower abdomen. However, in the HIV-infected host, the face, neck, shoulders and upper back are the most commonly affected areas. The presence of molluscum lesions on the eyelids is not uncommon in AIDS patients and has been suggested to be, without supporting evidence, pathognomonic of HIV infection.

Several small reports have documented resolution of molluscum contagiosum five to six months after initiation of highly active antiretroviral therapy. Destructive treatments include curettage, electrodessication, cryotherapy with liquid nitrogen, applications of trichloroacetic acid (50–90%), podophyllin (25–50%), podophyllotoxin, or cantharidin, excision, carbon dioxide laser ablation and pulse dye laser treatments 108. Tretinoin (0.025–1%) cream or gel and 5-fluorouracil, 5% or 1%, are less successful at eradicating lesions than retarding their growth and preventing formation of new ones. Imiquimod used three times a week and even daily has been effective in several cases. Cidofovir 3% in Dermovase successfully cleared some cases which had been recalcitrant to other treatments (109).

Oral Hairy Leukoplakia

The prevalence of oral hairy leukoplakia (OHL) may be as high as 25% in HIV-infected individuals. CD_4 T-lymphocyte counts are below 200 cells/mm^3 in most cases, but may be as high as 500 cells/mm^3. In one study 48% of patients developed AIDS within 16 months of onset of OHL, and 83% within 31 months (110). The lesions usually involute during treatment with effective antiretroviral therapy (111).

Grayish-white, corrugated, shaggy rug-like, verrucous plaques are located continuously or discontinuously along the lateral margins of the tongue (Fig. 25.37). These

FIG. 25.36. Typical lesions of mim contagiosum consisting of skin-colored, dome-shaped umbilicated papules with central opening (umbilication) from which exudes keratotic material.

FIG. 25.37. Macerated, gray-white, planar papules confluent into linear corrugated plaques along the side of the tongue are the characteristic lesions of oral hairy leukoplakia.

glossal lesions may extend to the ventral and dorsal surfaces of the tongue. When present in the oral mucosa, gingiva or palate, the lesions are ßat without hairy projections, strongly resembling oral candidiasis. However, the surface cannot be removed by scraping.

The cause is believed to be reactivation of Epstein-Barr virus infection (EBV) (110). Multiple EBV strains can be detected in the lesions. The lesions may disappear spontaneously, presumably when cytotoxic T lymphocyte responses to Epstein-Barr virus are mounted, but may recur.

Although oral hairy leukoplakia is usually asymptomatic, some patients may seek treatment due to mild pain, uncomfortable sensation, taste alteration or unacceptable appearance. Oral acyclovir at high doses has been reported to achieve resolution within two weeks (112). Alternatively, daily application of tretinoin gel, cryotherapy or weekly application of trichloroacetic acid or podophyllin resin have also improved or resolved the lesions. Surgical excision is reserved for painful lesions, which are resistant to other therapeutic modalities (112).

Herpes Simplex Virus

As in the general population, in HIV-infected persons anogenital herpes is the second most common sexually transmitted disease seen (HPV infection is the most common one). A 60Ð80% seroprevalence of HSV-2 infection has been found among HIV-infected homosexual or bisexual men (113). In a study from England, herpetic genital ulcers were found in 43% and 38% of HIV-infected heterosexual women and men respectively (Fig. 25.38). As with other genitoulcerative diseases, especially primary syphilitic chancres, herpetic genital ulcers appear to facilitate the transmission of HIV due to the impaired epidermal barrier and the high density of HIV present in the CD_4 cells in the inßammatory inÞltrate of the ulcerations. Cervical shedding of HSV-DNA is detected in approximately 17% of HIV and HSV-1 or -2 co-infected women by cervical swab samples (114).

Herpetic lesions in HIV-infected patients are caused by reactivation of the latent virus. Although mucocutaneous lesions may appear in any region of the body, the most common sites are the genital, perianal area (Fig. 25.39), lips, oral cavity, and perilabial area (Fig. 25.40). Chronic ulcerations have appeared on the scalp, ears, feet and other unlikely body areas. Necrotic herpetic whitlow has caused destruction of the tip of the digit of some patients. The typical manifestation of herpes simplex is small clusters, each consisting of grouped vesicles on an erythematous base. The vesicles rupture and become small shallow crusted ulcers, which almost always heal without scarring within one to two weeks even in the absence of treatment. The diagnosis of herpes simplex infection can be conÞrmed with Tzanck preparations of a blister roof or the active edge of an ulcer in chronic cases, or by viral culturing or skin biopsy and monoclonal antibody staining of tissue.

As immune deÞciency progresses, clinical reactivation becomes more frequent. Severely immunocompromised patients with CD_4 counts below 100 cells/mm^3 develop erosive, persistent, hypertrophic plaques or ulcers which gradually expand, become progressively destructive, shed virus persistently, and do not heal unless treatment is instituted (2).

Oral acyclovir at a dose of 400 mg three to Þve times a day is usually effective. Intravenous acyclovir at a dose of 5 mg/kg every eight hours, is the treatment of choice for widespread or disseminated lesions. Valacyclovir (500 mg

FIG. 25.39. Super cial, weeping, erythematous ulceration with well-de ned but active borders on the anal-perianal area extending towards the sacral and perineal regions caused by herpes simplex.

FIG. 25.40. Herpes simplex ulcerations surrounded by erythema and covered with serosanguinous crust on the chin and inner lip.

twice daily) and famciclovir (250 mg twice daily) are also useful in suppressing symptomatic and asymptomatic HSV shedding and recurrences. HSV-2 shedding is decreased 81%, and the frequency of genital signs and symptoms is decreased 65% in patients treated with suppressive doses of famciclovir (115). Thrombotic microangiopathy was reported in immunocompromised patients treated with 8 g of valacyclovir intravenously daily, but this complication does not occur at lower doses of this medication. Resistance to acyclovir, caused by mutations in the viral thymidine kinase or DNA polymerase genes, is found in 6.4% of HSV cases. Resistant strains are more common in patients who receive therapeutic rather than prophylactic antiviral therapy, but may also be found in patients who have never been treated with acyclovir. These cases usually respond to treatment with intravenous foscarnet, cidofovir or vidarabine. Treatment with intravenous foscarnet at a dose of 40 mg/kg every eight hours, should be initiated within 10 days of the onset of the eruption in patients suspected to have acyclovir-resistant herpes simplex infection and should be continued for at least 10 days or until all lesions are completely healed (116). Daily application of cidofovir 1% and 3% gel for at least Þve days has been effective in improving and resolving cases of thymidine kinase inhibitor-resistant herpes (117). A similar preparation can be made by compounding cidofovir solution in a cream vehicle such as Dermovase. The lesions of resistant HSV infection may heal with application of topical foscarnet 2.4% twice daily (118).

Several studies have documented a stimulation of HIV replication following acute or reactivated herpes simplex infection. Because of possible accelerated progression to AIDS in the presence of HSV, some experts recommend suppressive doses of acyclovir to individuals who have frequently recurrent herpes outbreaks. Although HSV outbreaks may be less frequent and less severe in patients taking highly active antiretroviral therapy, these patients continue to have clinical disease and asymptomatic viral shedding.

Herpes Zoster

Herpes zoster infection (shingles) is a reactivation of the varicella zoster virus (VZV), which was dormant in the dorsal root ganglia following the initial episode of varicella (119). The infection is seven times more common in HIV-infected persons and tends to be more widespread, severe and prone to dissemination (120). It may be the harbinger of an underlying HIV infection (119).

Most patients experience localized tingling, burning pain or itching, two to three days prior to the appearance of lesions. The eruption consists of grouped erythematous macules and papules progressing Þrst to vesicles (12 to 24 hours) then pustules (three to four days) and Þnally crusted erosions (seven to ten days) arising in a characteristically unilateral, linear, dermatomal (zosteriform) distribution (Fig. 25.41). Pain can be intense and has been described as throbbing, aching, or sharp and burning like Òelectric jabs.Ó In immunocompromised patients hematogenous dissemination may result in involvement of multiple

FIG. 25.41. Grouped blisters on erythematous patches linearly distributed along a skin dermatome typical of herpes zoster infection.

dermatomes, and potentially fatal systemic disease, including encephalitis, hepatitis, or pneumonitis. Cutaneous dissemination is deÞned as more than twenty vesicles outside the primary and immediately adjacent dermatomes.

The appearance of lesions on the nose (Hutchinson's sign) indicates involvement of the nasociliary branch of the ophthalmic nerve and requires evaluation for conjunctivitis, keratitis, corneal ulceration, iridocyclitis, and glaucoma. Involvement of the geniculate ganglion is associated with peripheral facial nerve weakness and deafness (Ramsay Hunt syndrome).

Treatment should be started early with famciclovir (500 mg three times daily), valacyclovir (1,000 mg three times daily) or acyclovir (800 mg Þve times daily). Disseminated infection is treated with intravenous acyclovir 10 mg/kg or 500 mg/m^2 every eight hours. Acyclovir resistant cases are more prevalent in the immnocompromised host and are treated with foscarnet, 60 mg/kg q 8 h infused slowly over at least 1 h (116). Studies indicate that these antivirals diminish scarring and reduce the risk of dissemination (121). One study showed that epidural administration of bupivacaine and methylprednisolone was signiÞcantly more effective in preventing neuralgia at 12 months than intravenous acyclovir followed by high dose prednisolone (122).

Postherpetic neuralgia, a common complication, is treated with applications of topical lidocaine patch or capsaicin, intralesional corticosteroids, nerve blocks, and oral analgesics, opioids, tricyclic antidepressants, carbamazepine or gabapentin.

Cytomegalovirus (CMV)

Between 75Ð100% of HIV-infected patients are infected with CMV and active CMV infection occurs in 20% of those with CD_4 counts below 100 cells/mm^3. While the skin is not commonly involved, mucocutaneous lesions may develop even in the absence of other manifestations, such as chorioretinitis, esophagitis, and enterocolitis. Still, the presence of CMV lesions on the skin usually indicates concomitant generalized infection.

The most common lesions are ulcers and erosive erythematous papules localized on the perianal, genital, perigenital areas or oral cavity, usually as part of polymicrobial infections, particularly herpes simplex and varicella-zoster virus. In these areas, the ulcers are usually round or oval, small, and have erythematous, weeping bases, occasionally with exhuberant granulation tissue (Fig. 25.47). However, the manifestations of CMV infection are protean and include large painful ulcerations, erosive vesiculobullous lesions, or chronic, asymptomatic or pruritic hyperkeratotic papules and plaques resembling prurigo nodularis on the extremities. The diagnosis is established with skin biopsy. Many inclusion bodies which stain immunohistologically with anticytomegalovirus antibodies, are present around dermal blood vessels. On electron microscopy, many viral particles are found in the areas with inclusion bodies. Treatment consists of intravenous ganciclovir, valganciclovir, cidofovir or foscarnet.

MALIGNANT NEOPLASMS

Kaposi's Sarcoma

Up until 1981, almost all cases of Kaposi's sarcoma in the United States were of the "classic" type, which affected elderly men and women of Eastern European and Mediterranean ancestry in a ratio of twelve males to one female (123). In general, these patients developed few slowly-growing lesions on their lower extremities and the disease had a rather indolent course. The most common complication was venous stasis and lymphedema of the involved lower extremities; visceral involvement occurred in approximately 10% of patients. A fulminant form of Kaposi's sarcoma seen in young, previously healthy homosexual men with rapidly progressive mucocutaneous and visceral lesions was Þrst recognized in 1981. That observation heralded the AIDS epidemic. Remarkably, few cases of Kaposi's sarcoma have been seen in non-gay HIV-infected individuals who contracted HIV infection through intravenous drug use, heterosexual sexual intercourse, or blood transfusions.

Patients with AIDS-related Kaposi's sarcoma present with mucocutaneous lesions consisting of pink, violaceous or deep purple, usually nontender patches, plaques, exophytic nodules and subcutaneous nodules, often with symmetrical distribution (Figs. 25.42, 25.43). Although

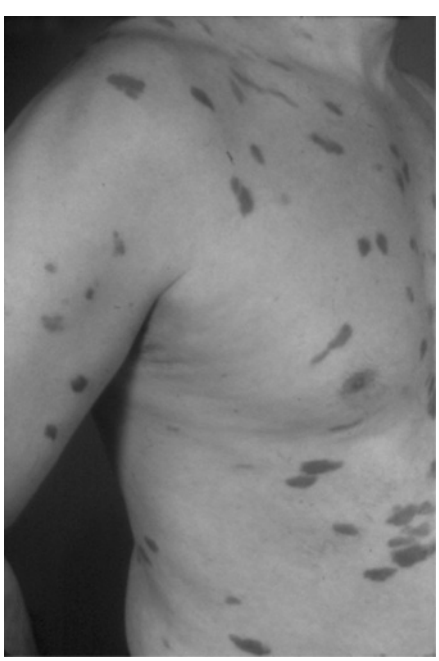

FIG. 25.42. Typical Kaposi's sarcoma violaceous papules and plaques oriented along skin lines of the trunk, neck and upper extremity.

FIG. 25.43. Purple in ltrated oval plaques and a large dis guring nodule on the nose of a man with Kaposi's sarcoma.

early patches can blanch after direct pressure, the lesions soon become non-blanchable (124). In patients with dark skin, the tumors are hyperpigmented (Fig. 25.44). The most commonly affected areas are the head (tip of nose, periorbital area, ears, scalp), trunk, penis, legs, palms, soles, and oral mucosa (Fig. 25.45) (125). Approximately

FIG. 25.44. In persons with dark skin shades Kaposi's sarcoma plaques and nodules are often dark-brown and may lack a violaceous hue.

FIG. 25.45. Brightly red nodule of Kaposi's sarcoma in l-trating the gingiva.

80% of patients eventually develop visceral involvement in the gastrointestinal tract (75%), lymph nodes (30%), pulmonary, liver, urogenital tract, kidney and other organs. The course is progressive and disseminated with systemic involvement. In this country, approximately 95% of all the cases of this epidemic type of Kaposiõ sarcoma have been diagnosed in homosexual or bisexual men. However, in Central Africa AIDS-related Kaposiõ sarcoma is commonly seen in heterosexual men, women and children with HIV infection. In contrast, in Southeast Asian countries, such as Thailand, Kaposiõ sarcoma is extremely rare, even in HIV-infected gay men.

Kaposiõ sarcoma was the presenting manifestation in 40% of gay men with AIDS from New York and California in 1981. In the early years of the AIDS epidemic, approximately 26% of all HIV-infected homosexual men but only 3% of heterosexual intravenous drug users developed Kaposiõ sarcoma at some point during the course of their illness (125). Following widespread treatment with highly active antiretroviral therapy, the adjusted incidence declined from 15.2 in 1992 through 1996 to 4.9 in 1997 through 1999. However, Kaposiõ sarcoma remains the most common AIDS-associated malignant neoplasm in the world (124). Even during its peak prevalence, patients usually died from other opportunistic infections rather than from the effects of Kaposiõ sarcoma. The exception was patients with pleuropulmonary Kaposiõ sarcoma, who without treatment died in an average of six months.

Epidemiological evidence strongly suggests that a novel virus discovered in 1994 known as the Kaposiõ sarcoma-associated herpesvirus (KSHV) or Human Herpesvirus-8 (HHV-8), causes Kaposiõ sarcoma (126). Fragments of this virus have been detected by PCR in more than 95% of Kaposiõ sarcoma lesions. Furthermore, serum antibodies are detectable in 70Ð90% of all patients and almost 100% of immunocompetent patients with Kaposiõ sarcoma

FIG. 25.46. Dark-purple in ltrated plaques resulting in marked facial dis gurement. Note a bright red dome-shaped Kaposi's sarcoma nodule resembling bacillary angiomatosis.

(127). The virus is recoverable from blood, saliva and semen (128).

Due to intense dread of disÞgurement and social discrimination associated with the readily noticeable lesion of KaposiÕs sarcoma, treatment is sought by many HIV-infected patients, even when the nature of the disease is not life-threatening (Fig. 25.46).

The type of treatment depends on the location, size, and extent of the tumors. Intralesional vinblastine or localized cryotherapy using liquid nitrogen are effective for small, superÞcial mucocutaneous lesions. An overall response rate of 87% has been reported in thin tumors treated with cryosurgery for a variable duration of thaw time depending on the depth of the lesion. Usually there is signiÞcant cosmetic improvement, but the treatment may not eradicate neoplastic cells in the deep reticular dermis, resulting in a high rate of recurrences. A dose of 0.1mg/cm^2 of vinblastine is injected into each tumor. The overall response rate in appropriately selected lesions is 70%, however partial regression rather than complete resolution is more common. Side effects with both of these treatment modalities include mild to severe local inßammation, ulceration, pain, and pigmentation. Application of 0.1% Alitretinoin gel (9-cis-retinoic acid, Panretin) to the tumors for four to eight weeks results in a 34% overall response rate in patch stage lesions (129). Dermal irritation is common but generally mild to moderate in severity.

FIG. 25.47. Well-demarcated circular, discrete ulcerations with raised borders and necrotic slough secondary to cytomegalovirus infection.

Although KaposiÕs sarcoma lesions are very responsive to radiotherapy, this treatment is avoided due to concern about chronic radiation dermatitits now that the lifetime of patients with AIDS has been extended by more effective antiretroviral treatment combinations (130). Radiotherapy is especially discouraged in the oral mucosa where it can cause painful residual mucositis. Surgical excision is practical when one or few lesions are present. There was an overall response of 91% (complete response rate, 80%) in 36 patients with tumors of the feet treated with a fractionation schedule of three fractions a week at 3.5 Gy per fraction to a total dose of 21.0 Gy.

Systemic chemotherapy is used to treat extensive or symptomatic visceral involvement and widespread, disÞguring or disabling mucocutaneous disease. Regression and resolution of both cutaneous lesions and visceral tumors follows initiation of effective antiretroviral therapy.

Either liposomal encapsulated doxorubicin (Doxil) at a dose of 20 mg/m^2, liposomal daunorubicin (DaunoXome) at a dose of 40 mg/m^2, or paclitaxel (Taxol) at a dose of 100 mg/m^2 every two weeks or 135 mg/m^2 every three weeks, are more effective and less toxic than previous chemotherapeutic regimens, which included combinations of adriamycin, bleomycin and vincristine (ÒABVÓ) (131,132). The most common adverse effect of liposomal doxorubicin is neutropenia. Liposomal doxorubicin achieves responses in up to 59% of treated cases. Even in previously refractory cases, paclitaxel achieves objective response rates of 59Ð71%, which persist for a median duration of approximately 10 months (132,133).

Recombinant interferon alfa-2a and interferon alfa-2b result in a 40% objective response rate in patients with epidemic KS with CD_4 lymphocyte counts above 200 cells/mm^3, with lower response rates in more immunosuppressed patients (134). Compared to chemotherapy, the response is indolent. Interferon-alfa in doses of 1 to 18 million units may be given in combination with aggressive antiretroviral therapy. However, the side effects of interferon have reduced the use of this drug in favor of Doxil.

One study suggested that low does (1 million units daily) and moderate dose (10 million units daily) interferon produce similar response rates when each is combined with antiretroviral agents.

OTHER NEOPLASMS

Epidermal skin cancer

Both extra-anogenital squamous cell carcinomas (SCC) and basal cell carcinomas (BCC) appear to be more prevalent and more aggressive in HIV-infected persons (Fig. 25.48). Risk factors include fair skin, actinic damage, and immunosuppression. As patients live longer with AIDS, the number of HIV-infected cases with ultraviolet radiation-induced skin epidermal skin cancer is expected to increase. Some HIV-infected patients develop multiple and occasionally synchronous basal cell carcinomas (Fig. 25.49) (135). The typical appearance of basal cell carcinoma is a dome-shaped pearly papule or nodule with a tendency toward slow enlargement and central ulceration. Telangiectasias are common. SuperÞcial spreading basal cell carcinoma, a variant that is common in HIV-infected persons with multiple tumors, appears as an erythematous patch with thin pearly borders.

Squamous cell carcinomas have a variety of morphologies, but usually an erythematous, scaly patch or plaque, or an ulcer are the most common lesions. In contrast to the usual appearance of these tumors on sun-exposed areas, especially the face, SCC arises more commonly on the scalp while BCC occurs more commonly on the trunk.

Although it is common practice to treat basal cell carcinomas with electrodessication and curettage or surgical excision, the recurrence rate with these modalities in HIV-infected persons is 5.4% for tumors followed for more than 12 months (135). The rate of recurrence for squamous cell carcinomas after curettage and electrodessication is 20% (135). Therefore, MohsÕmicrographic surgery is the treatment of choice for these neoplasms. Photodynamic therapy using tin ethyl etiopurpurin has been used successfully in cases of multifocal basal cell carcinomas. Experience with topical treatments, such as imiquimod and 5-ßuorouracil, is limited.

FIG. 25.48. Unusually aggressive and rapidly growing basal cell carcinoma invading nose and eyes.

FIG. 25.49. Multiple super cial spreading basal cell carcinomas on the lower extremities.

Melanoma

Although epidemiologic conÞrmation is lacking, the incidence of malignant melanoma appears to be increased in HIV-infected persons. Available data suggest that the prognosis is graver for HIV-infected men than for immunocompetent HIV-seronegative men for melanomas with similar thickness, especially for tumors thicker than 3 mm (135). Cases with multiple melanomas have been reported. In one series of twelve cases of melanoma, six patients presented with metastatic disease (135). The mean age of the HIV-infected men at the time of diagnosis is 35.6 years. The number of CD_4 T-lymphocyte correlates inversely with melanoma thickness and prognosis (135).

Cutaneous Lymphoma

In HIV-infected patients, cutaneous lymphomas are more aggressive, are usually diagnosed at a more advanced stage, respond less favorably to therapy and more frequently involve extranodal sites. Although most lymphomas are of the B-cell type, cutaneous T-cell lymphoma

(CTCL) has also been reported. In one large recent survey of nine HIV-infected patients, seven had B-cell lymphomas, one had an HTLV-I-positive CD4+ T-cell lymphoma, and one patient infected with HIV-2 had a CD4+ T-cell lymphoma that was HTLV negative (136).

On the skin, the typical presentation of B-cell lymphomas is one or more discrete ulcers, nodules or ulcerated plaques or nodules (Fig. 25.50). In some cases, the immunohistologic pattern suggest a T-cell proliferation, and the correct diagnosis is only established after gene rearrangement studies demonstrate a clonal B-cell population.

HIV-infected patients with cutaneous T-cell lymphomas have a dismal prognosis, because intact immunity is an essential factor in preventing progression of the disease. In late stages of lymphoma, profound T-cell deficits compound those resulting from AIDS to increase the patient's susceptibility to opportunistic infections, the most common direct cause of death from both diseases. The clinical findings range from skin colored, dry-looking patches with fine scale, to plaques, to nodules, to exfoliative erythroderma (138). The lesions may be pruritic.

Some patients with inflammatory diseases manifest erythematous plaques and even erythroderma with lymphadenopathy, and have been misdiagnosed as CD8+, suppressor cutaneous T-cell lymphomas (137). In advanced HIV infection with CD_4 lymphopenia, inflammatory processes may be result in a massive cutaneous influx of CD8+ T-lymphocytes which result in histopathologic patterns which mimic those of cutaneous T-cell lymphoma. However, Southern blot and polymerase-chain-reaction (PCR) studies show that these lymphocyte aggregations have polyclonal patterns. Despite the benign nature of the infiltrate, the prognosis in these patients is poor.

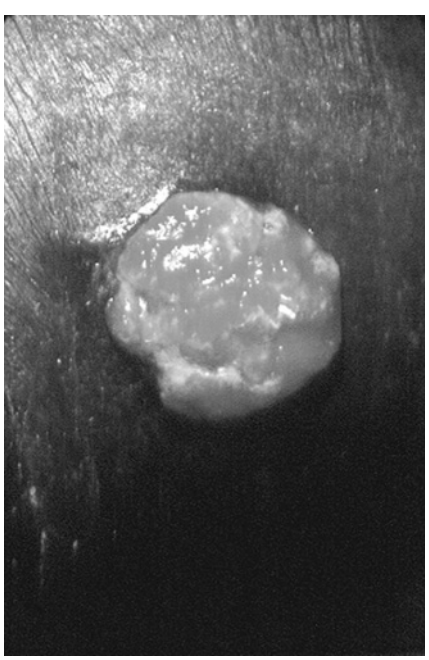

FIG. 25.50. B-cell lympoma presenting as an exophytic ulcerated nodule with exuberant granulation tissue.

Chapter 26

Ophthalmologic Aspects of HIV Infection

Daniel A. Johnson and Douglas A. Jabs

Ever since the original description of eye changes by Holland et al. (1) in 1982, it has become evident that ocular manifestations are often seen in patients with the acquired immunodeficiency syndrome (AIDS). Such conditions are generally classified into five areas: (1) a non-infectious microangiopathy, most often seen in the retina, and sometimes called "AIDS retinopathy;" (2) opportunistic ocular infections, particularly cytomegalovirus (CMV) retinitis; (3) conjunctival, eyelid, or orbital involvement by those neoplasms seen in patients with AIDS (e.g. Kaposi's sarcoma and lymphoma); (4) neuro-ophthalmic lesions; and (5) drug-induced manifestations (Table 26.1). The retinal microangiopathy is the most frequent ocular manifestation, and CMV retinitis is the most frequent opportunistic intraocular infection. Recent advances in the treatment of human immunodeficiency virus (HIV) infection, specifically the development of highly active antiretroviral therapy (HAART) (2–5), have altered the frequency and management of opportunistic ocular infections (6–8). HAART has been shown to increase CD4+ T-cell counts (3,5,9,10), decrease HIV viral load, (5,9) and increase survival (6,8,9,11,12). Even though HAART has decreased the incidence of opportunistic infections in the developed world, ocular complications of AIDS continue to occur, albeit at a decreased rate.

AIDS RETINOPATHY

"AIDS retinopathy," also known as "HIV retinopathy" "noninfectious HIV retinopathy" or "HIV-related retinal microangiopathy syndrome," has been the most frequent form of ocular involvement reported in patients with AIDS. Multiple series (1,13–30) from the pre-HAART era have reported an abnormal eye exam in 35% to 100% of patients with AIDS. In the Johns Hopkins series of 754 patients with AIDS from the pre-HAART era (31), retinopathy was present in 51% of the patients. It generally is asymptomatic and there is no indication for treatment (29,32).

Ophthalmoscopic features of HIV retinopathy include cotton wool spots, intraretinal hemorrhages, and less frequently, perivascular sheathing. Cotton wool spots are microinfarcts of the nerve fiber layer of the retina caused by ischemic disruption of axonal transport. Axonal swelling occurs which produces these characteristic white, opaque lesions. Cotton wool spots (Fig. 26.1) are the most common feature of HIV retinopathy and in the pre-HAART era were reported in 22–92% of patients with

TABLE 26.1. *Ocular complications of aids in the pre-Haart era (modified from jabs)*

HIV Retinopathy	50%
Cotton Wool Spots	46%
Intraretinal Hemorrhages	10%
Opportunistic Infections	
Cytomegalovirus retinitis	37%
Toxoplasmic retinitis	1%
Varicella Zoster retinitis	< 1%
Pneumocystis carinii choroiditis	< 1%
Fungal retinitis or endophthalmitis	< 1%
Infectious keratitis	< 1%
Kaposi's sarcoma	
Conjunctival	1%
Cutaneous lid	2%
Orbital Lymphoma	< 1%
Neuro-ophthalmic lesions	6%
Drug-induced manifestations	unknown

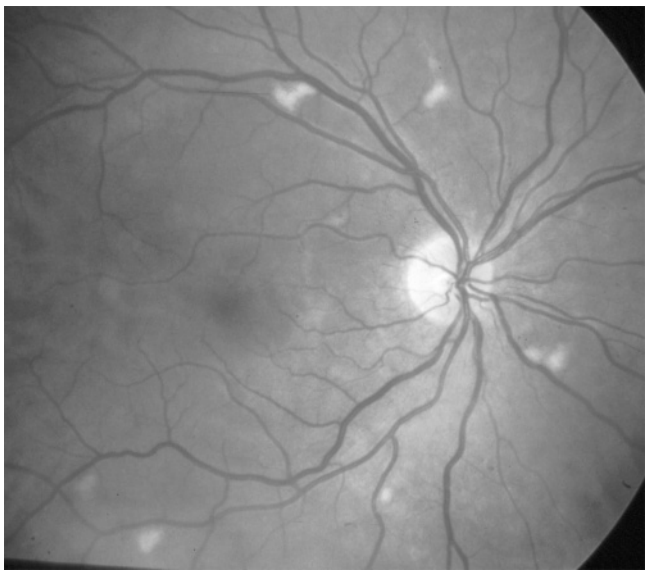

FIG. 26.1. AIDS retinopathy (cotton wool spots).

AIDS, with most series reporting that over 50% of patients were affected (14,16,18–21,23,26,27,30). Intraretinal hemorrhages were less frequent and were reported in 0–54% of patients, with most series reporting their presence in less than 20% of patients. In the Johns Hopkins series (31), cotton wool spots were present in 46% of patients and intraretinal hemorrhages in 10% of patients. Perivascular sheathing without an infectious retinitis has been reported (14,26) but is uncommon in the United States. Most often, perivascular sheathing is seen in association with CMV retinitis or other infections (26,33). Perivascular sheathing has been reported to occur in 15% of African patients with AIDS and 60% of African children with AIDS-related complex (ARC) (22,25). The reasons for the regional difference in perivascular sheathing are unclear.

Fluorescein angiographic and autopsy studies of AIDS retinopathy in the pre-HAART era showed evidence of a widespread microangiopathy. The ßuorescein angiographic study by Newsome et al. (19) found microaneurysms, telangiectatic vessels, and other microangiopathic changes in all twelve patients studied. A single case report (34) described signiÞcant visual loss associated with angiographic macular ischemia. The autopsy series of Pepose et al. (21) found evidence of a retinal microangiopathy in 89% of cases. Histologic Þndings in the retina in this and other series include loss of pericytes, microaneurysm formation, thickened vascular walls with deposition of periodic acid-schiff-positive material, and lumenal narrowing (19–21). Ultrastructural studies have shown swelling of the endothelial cells, occlusion of the vascular lumina, and thickening of the vascular basal lamina (35). These vascular lesions result in the microinfarcts that produce cotton wool spots.

Although retinopathy is common in patients with AIDS, it is uncommon in patients with asymptomatic HIV infection. In the Johns Hopkins experience from the pre-HAART era (31), retinopathy was present in 50% of patients with AIDS, 34% of patients with earlier but symptomatic HIV infection (formerly known as AIDS-related complex), and 3% of patients with asymptomatic HIV infection. It was not identiÞed in a cohort of non-HIV-infected homosexual men (26).

Retinopathy is more common in patients with lower CD4+ T cell counts (27). In the series of Spaide et al. (36), 93% of patients with cotton wool spots had CD4+ T cell counts less than 200 cells/µL. In the series of Kupperman et al. (28), 45% of patients with CD4+ T cell counts less than 50 cells/µL had HIV retinopathy. The mean CD4+ T cell counts in patients with cotton wool spots in these two series were 36 cells/µL and 31 cells/µL, respectively. Freeman et al. (27) also reported that patients with HIV infection and retinopathy have lower CD4+ T cell counts than do patients without retinopathy. These results suggest that the frequency of the retinopathy parallels the decline in the immune system.

In addition to the association of AIDS retinopathy with HIV stage and lower CD4+ T cell counts, other risk factors have been identiÞed, such as concurrent infections and method of HIV exposure. In one report (31), concurrent *Mycobacterium avium* complex infection was associated with the presence of HIV retinopathy with an odds ratio of 1.67. Age, race, sex, other opportunistic infection and concurrent neoplasia were not associated (31). In the series of Spaide et al. (36), cotton wool spots were more common in the group which acquired HIV through sexual contact compared to that group which acquired it through injection drug use (24% vs. 13%) despite similar CD4+ T cell counts.

Pathogenesis

The pathogenesis of AIDS microangiopathy is unknown and is likely to be multifactorial. Three hypotheses have been proposed: (1) immune complex disease; (2) infection of the retinal vascular endothelium; and (3) rheologic abnormalities.

The earliest hypothesis for the etiology of the microangiopathy was Type III hypersensitivity. Holland et al. (14) noted circulating immune complexes in 10 of 12 patients studied, and Gupta and Licorice (37) in 6 of 10 patients with AIDS and 8 of 10 patients with earlier but symptomatic HIV infection. Engstrom et al. (38) were unable to conÞrm this association, although they did report an association between circulating immune complexes and the conjunctival microvasculopathy present in some patients with HIV infection. Pepose et al. (21) demonstrated immunoglobulin deposition within arterial walls, and others (37,39) have reported that AIDS is characterized by polyclonal B cell activation and

hypergammaglobulinemia. Diseases such as collagen vascular diseases, which also have polyclonal B cell activation and circulating immune complexes, have an indistinguishable microangiopathy (19). Therefore, immune complex disease seems a plausible mechanism, although whether it is present in all cases is uncertain.

Direct infection of the retinal vascular endothelium by HIV or other pathogens has also been suggested as a cause of AIDS retinopathy but the evidence is conßicting. This hypothesis contends that the microbial insult to the vascular endothelium or the subsequent cascade of immunologic events results in the development of a vascular occlusion and cotton wool spot formation. HIV itself has been suggested to infect retinal blood vessels. Pomerantz et al. (35) have cultured HIV from the retina of patients with AIDS and have localized HIV proteins to the retinal vascular endothelial cells using immunohistochemical techniques. Shuman et al. (24) have reported electron micrographic evidence of HIV infection of the retina. Since the central nervous system is commonly affected by HIV (40Ð42), demonstration of HIV infection in the retina is not surprising. Conversely, Faber et al. (43) were unable to Þnd multinucleated giant cells in trypsin digests of autopsy retinas or immunohistochemical evidence of HIV-1 p24 antigen at sites of cotton wool spots. Gonzalez et al. were unable to Þnd an association between HIV DNA and cotton wool spots. Thus, direct involvement of HIV with cotton wool spot formation is debatable.

The evidence supporting infections other than HIV as being linked directly to cotton wool spot formation is similarly contradictory. Although Kwok et al. (45) reported one case of *Pneumocystis carinii* infection possibly causing cotton wool spots, multiple other studies have demonstrated no associated opportunistic organisms (19Ð21,26,43). *Pneumocystis carinii* infection has not been associated with cotton wool spots in any of the large autopsy series of eyes of patients with AIDS. Faber et al. (43) were unable to identify histologic evidence of CMV, *Toxoplasma gondii*, fungal infection, or *Pneumocystis carinii* in their autopsy series. More recently, however, CMV DNAÑ but not HIV DNAÑ was identiÞed in 90% of cotton wool spots in patients without CMV retinitis (46). That some patients with CMV retinitis never develop cotton wool spots may argue against viral pathogenicity (46). It has been suggested (46) that the vascular disruption at the site of the cotton wool spot merely facilitates entrance into the eye of the hematogenously spread CMV.

Lastly, systemic rheologic abnormalities have been suggested to be associated with AIDS retinopathy. Abnormal blood ßow has been identiÞed in patients with HIV (38,47,48). Engstrom et al. (38) found conjunctival changes consisting of blood column sludging, alterations in blood ßow, capillary dilatation, microaneurysms, and irregular vascular caliber. These changes, as well as cotton wool spots, were found to be associated with increased Þbrinogen levels. Some of these changes were found associated with anemia. It has been suggested that Þbrinogen, which is a large molecule, might induce red blood cell aggregation and sludging thus producing vascular damage. The vascular damage in the setting of anemia may then lead to ischemia and cotton wool spot formation. An increased frequency HIV retinopathy in patients coinfected with hepatitis C virus (HCV) has been attributed to increased serum viscosity and immunoglobulin deposition resulting from the hypergammaglobulinemia of HCV (30). The relative contributions of immune complex disease, direct infection, and blood ßow abnormalities to the development of HIV retinopathy remain to be determined.

OPPORTUNISTIC OCULAR INFECTIONS

Multiple opportunistic infections have been documented to infect the eye of patients with AIDS (Table 26.1). The most common of these is CMV retinitis, but other opportunistic ocular infections include herpes zoster ophthalmicus, *Pneumocystis carinii* choroiditis, varicella zoster retinitis, toxoplasmic retinitis, and fungal chorioretinitis. Multiple infectious agents can coinfect the same eye (31,49Ð52). The correct diagnosis and treatment may have life-saving beneÞts. In one autopsy series (51), 8% of patients with AIDS studied had an infectious choroiditis. Eighty-three percent of the patients with infectious choroiditis died due to dissemination of the same organism identiÞed in the choroid, yet only 27% of the patients had the diagnosis made before death (51).

Cytomegalovirus Retinitis

Cytomegalovirus is a ubiquitous herpes family virus of the Betaherpesvirus subfamily (53). Its four structural elements include an outer glycoprotein-containing envelope, an amorphous matrix (tegument), a nucleocapsid, and an internal core with linear double-stranded DNA (46,53). Approximately 50% of the general population have antibodies to CMV, suggesting previous exposure (53,54), while nearly 100% of homosexual men have antibodies to CMV (46,55). Transmission of CMV occurs by direct contact, and humans are believed to be the only reservoir for human CMV (53). Generally, CMV exists in a latent state; however, when the patientÕs immune system declines, CMV can reactivate. It is thought that CMV is hematogenously disseminated to the retina, invades the retinal cells, and establishes a productive infection. The autopsy series of Rao et al. (56) identiÞed the retinal vascular endothelial cells as the initial target of CMV infection in eyes with a clinical diagnosis of CMV retinitis. Over 90% of patients with AIDS and CMV retinitis will have positive cultures for CMV from a nonocular source, such as the blood or urine (57).

Epidemiology

CMV retinitis is the most common intraocular infection in patients with AIDS (26) and the most common end organ disease in CMV infection (58–60). In a multicenter observational cohort of 1,002 patients with CD4+ T cell counts less than 250 cells/μL, AIDS or earlier but symptomatic HIV infection, CMV retinitis developed in 85% of the 109 patients who developed CMV end organ disease (59). In the study by Hoover et al. (61), CMV end organ disease increased in incidence from 25–45% with the advent of routine prophylaxis for *Pneumocystis carinii* pneumonia (PCP) which has delayed the onset of AIDS defining illnesses in patients with HIV infection. Risk factors for the development of CMV retinitis include white race (31), sexual transmission (31,36), *Mycobacterium avium* complex infection (31), extraocular CMV disease (31), AIDS retinopathy (31), high HIV viral load (46), high CMV viral load (46), lack of protease inhibitor-containing anti-retroviral regimen (46), and low CD4+ T cell counts (36,60,62). Hoover et al. (60) reported that the incidence of CMV retinitis in the four years following a decline in CD4+ T-cell counts to less than 100 cells/μL was 25%. Pertel et al. (62) showed that at 27 months the incidence of CMV retinitis was 42% for patients with CD4+ counts less than 50 cells/μL, 26% for patients with CD4+ counts between 50 and 100 cells/μL and 15% for patients with CD4+ from 101–250 cells/μL. Approximately one-third of patients will present with bilateral ocular involvement and of those patients who present with unilateral disease, 60% will ultimately develop bilateral disease unless treated (57).

Estimates of the frequency of CMV retinitis in patients with AIDS from the pre-HAART era have varied from 6–38% (14–20,26,28,36,57,60,63) with higher estimates coming from surveys of inpatients and autopsy series (21,64). The variability in these estimates is probably due to a variety of factors, including differences in the patient populations studied, underdetection in non-ophthalmic series, referral bias in ophthalmic series, and the limitations of retrospective data analysis. Lower CMV retinitis incidences in more recent series have been attributed to the widespread use of HAART (2,8,65,66). Recognizing the potential for ascertainment bias, Jabs (57) estimated a minimum frequency of 11% among all patients with AIDS seen at the Johns Hopkins Hospital prior to the routine use of HAART (2). The reported frequency at that time among patients seen in the AIDS Ophthalmology Clinic at the same institution was 37% (31).

Estimates of the frequency of CMV retinitis since the advent of HAART are much lower than in the pre-HAART era. A 60–75% reduction in the incidence of new cases has been reported (67). At the Johns Hopkins hospital alone, the frequency of CMV retinitis has declined by over 50% (2). The University of California, Davis, similarly has reported a profound reduction in cases of CMV retinitis (65,68). This reduction has been mirrored internationally as well (66). In the series of Varani et al. (66), from Northern Italy, the frequencies of CMV retinitis, CMV visceral disease, and CMV reactivation in 1995 prior to the widespread introduction of HAART were 5.8%, 12.4%, and 38% respectively. Following the introduction of HAART in 1998, these incidences uniformly decreased to $< 1\%$, 1.5%, and 0% respectively (66).

The decline in the frequency of CMV retinitis following the use of HAART (11) has been attributed to the recovery of immunity to CMV load due to HAART-induced immune reconstitution (6). In the series of Deayton et al. (6), patients with preexisting CMV viremia identified by PCR, but without documented CMV-related end organ disease, were followed after initiation of HAART. All 16 patients became CMV PCR negative in a median time of 13.5 weeks (range 5–40) (6). Fourteen remained CMV PCR negative during a median follow-up of 21 months, and no patient developed CMV retinitis (6). In the report by Varani et al. (66), the frequency of a positive CMV antigenemia assay, an assay that quantitates the expression of CMV lower matrix phosphoprotein pp65, in patients with AIDS, declined from 25.9% in 1995 to 2.4% in 1998 following the widespread use of HAART.

Although it initially was suggested that CMV retinitis was a preterminal event (14), it has been recognized that CMV retinitis may occur at any time during the course of AIDS (57,69,70). The median interval from the diagnosis of AIDS to that of CMV retinitis in the pre-HAART era varied from 9–14 months, with ranges of 0 to 81 months (31,62,70). With the advent of the 1993 revised definition of AIDS by the Centers for Disease Control, which includes patients with CD4+ counts less than 200 cells/μL (71), almost all patients will have AIDS before the diagnosis of CMV retinitis.

CMV retinitis is associated with profound immunodeficiency (20,72), and prior to widespread use of HAART, very low CD4+ T-cell counts were characteristic of patients with CMV retinitis. Several series have reported mean CD4+ T-cell counts of less than 25 cells/μL (20,28,31,36,72). In the pre-HAART era, rare cases of CMV retinitis with CD4+ T cell counts greater than 200 cells/μL, existed (73), however, these cases have become less rare (4,74). Prior to widespread use of HAART, only 4% of patients with newly diagnosed CMV retinitis had CD4+ T-cell counts greater than 100 cells/μL compared to 14% following HAART acceptance (46).

CMV infection itself may potentiate the degree of immunosuppression in HIV-infected patients with CMV end organ disease. CMV has been shown to be a cofactor in HIV-I infection *in vitro*, possibly mediated through tumor necrosis factor alpha (75). Bilateral CMV retinitis has been associated with HIV encephalitis (43). Furthermore, patients with CMV retinitis have been shown to have a more rapid decline in their CD4+ T cell counts than patients without CMV retinitis (62).

Since CMV retinitis is associated with profound immunodeficiency, survival after the diagnosis of CMV

retinitis historically had been brief, in the range of six to thirty months (31,57,60,70,76–81) in the pre-HAART era. Survival had been shown to differ based on some regimens utilized for CMV retinitis (79,82), but not on other regimens (83). In one large prospective trial, a positive blood or urine culture at the time of diagnosis of CMV retinitis decreased median survival by five to seven months (84). Quantitative CMV PCR also has been shown to be predictive of mortality (85). With the advent of HAART, the potential for more significant longevity has been achieved.

Diagnosis and Natural History

Symptoms

The symptoms associated with CMV retinitis may be minimal or nonexistent. In one series of 62 patients who underwent routine ophthalmologic screening (86), 10% were found to have previously undiagnosed CMV retinitis. The CMV retinitis in almost half of these patients was bilateral and in more than half of the patients it was immediately sight threatening. None of the 14 patients identified with CMV retinitis in a medical HIV clinic were symptomatic, and almost 30% of these patients were found to have macular lesions (28). Eleven percent of the patients with CMV retinitis in the series of Pertel et al. (62) were asymptomatic.

One reason for the lack of symptoms is that the retinitis may start peripherally and spread circumferentially around the fovea thus sparing central vision until late in the course of the disease (87). Peripheral retinal lesions are typically larger than more posteriorly located lesions since they are less symptomatic (88). Another reason for a lack of patient symptoms is that patients often do not monitor the vision in each eye separately. Of the patients that are symptomatic, the complaints include a vague sense of blurred vision, floaters, photopsia (flashing lights), and constriction in the peripheral vision. For posteriorly located lesions, patients may complain of scotomata or a loss of vision. Because patients with advanced disease can be asymptomatic, routine screening of patients at high risk through dilated ophthalmoscopy is recommended.

Screening

Although large fluctuations in a patient's CD4+ T cell count have been identified (89), the CD4+ T cell count has been used as the basis for routine screening recommendations (2,62,67,86,90–93). In the series of Pertel et al. (62), the mean time from the first CD4+ count less than 50 cells/μL to the diagnosis of CMV retinitis was 13.1 months (range 0–40). It has been recommended that that dilated ophthalmoscopy be performed every four months for patients with CD4+ T cell counts less than 50 cells/μL, every six months for patients with CD4+ T cell counts between 50 and 100 cells/μL, and yearly for patients with CD4+ T cell counts greater than 100 cells/μL (2). The cost effectiveness of this approach, however, has never been validated. Patients with any symptoms potentially attributable to CMV should be seen by an ophthalmologist as soon as possible.

The utility of CD4+ T cell count-based screening recommendations has been influenced by the use of HAART since there is a time lag before protective immunity has been restored (2,4,7,29,94,95). A few cases of have been described in which CMV retinitis developed in the setting of CD4+ T-cell counts > 100 cells/μL early in the course of HAART (74). This incomplete immune reconstitution despite elevated CD4+ T-cell counts has been attributed to the preferential expansion of memory CD4+ T-cells compared to naïve CD4+ T-cells in patients who have had very low CD4+ T-cell counts (46). The naïve CD4+ T cells are thought to expand later in the course of immune reconstitution (46). Lymphocyte proliferative responses to recall antigens have been shown not to increase *in vitro* during the first year of antiretroviral therapy (9), and one patient with recurrent CMV retinitis with a CD4+ T cell count >200 cells/μL on HAART did not have a CMV-specific lymphocyte proliferation response despite having responses to other antigens (96). Thus, some patients who have lost CMV-specific clones may not be able to generate a significant immune response to CMV or other "new" antigens until later in the course of immune recovery. As a result of this HAART effect, a lag of several months may be required for a patient to develop the level of immune function predicted by their CD4+ T-cell count, and a single CD4+ T-cell count measurement in the early phase of immune reconstitution should be interpreted with caution.

Certain laboratory tests have been helpful in stratification of patients at risk for developing end organ disease from cytomegalovirus and may ultimately facilitate directed examinations or primary prophylaxis. Current investigations suggest that plasma CMV DNA (92,93), quantitative CMV PCR on plasma or white blood cells (85,93), quantitative hybrid capture (93), and CMV antigen (p. 65) (92,93) testing may predict the development of CMV-related end organ disease. Shinkai et al. (97) reported prospectively that qualitative PCR had a sensitivity, specificity, positive predictive value, and negative predictive value of 89%, 75%, 58%, and 94% respectively in identifying patients with CMV-related end organ disease. Quantitative PCR (QC-PCR) in the same study had a sensitivity, specificity, positive predictive value, and negative predictive value of 73%, 90%, 73%, and 90% respectively. Retinitis accounted for 73% of the end organ disease in this study; however, routine dilated eye examinations were not a part of the protocol suggesting that retinitis may have been underdiagnosed.

Other investigations similarly have shown a potential benefit of CMV PCR testing and have linked testing to

screening recommendations (93,98). In the Roche oral ganciclovir prophylaxis study (93), the risk of CMV retinitis was directly proportional to the baseline quantitative CMV viral load (93). The 12 month risks of CMV retinitis for patients with baseline CMV viral loads (in copies/ml) of zero, less than 2,500, 2,500–50,000, and 50,000–100,000 were 14%, 22%, 50%, and 75% respectively (93). Unfortunately, the sensitivity of this method has allowed detection of CMV in many patients who do not develop end organ disease (99). Furthermore, up to 25% of patients at the time of diagnosis of CMV retinitis may have negative PCR studies (93), and with the marked decrease in CMV retinitis due to HAART, such laboratory screening typically is not performed.

Blood and urine cultures also have been investigated regarding their ability to identify patients at risk for CMV-related end organ disease. In the prospective Cytomegalovirus Retinitis and Viral Resistance Study (CRVR) (84), patients who developed positive blood, urine, or blood and urine cultures at follow up had increased risk of CMV retinitis developing in the contralateral eye with odds ratios of 6.5, 6.4, and 5.7 respectively. Positive blood and urine cultures, and lower CD8+ T-cell counts in a separate large prospective trial (100) were associated with progressive retinitis despite therapy in previously untreated patients. The sensitivity, speciÞcity, positive predictive value, and negative predictive value of urine cultures were reported by Shinkai et al. (97) to be 85%, 29%, 31%, and 83% respectively, whereas the corresponding values for blood leukocyte cultures were 38%, 74%, 69%, and 81% respectively. Thus, although correlation with disease exists, the predictive value of blood and urine cultures is considered too low to be used as a basis for routine screening (58).

Other methods studied for their usefulness to predict those at highest risk of CMV end organ disease include CMV immune reactivity (53), conjunctival swabs for CMV (101), laser ßare photometry (102), and entoptic perimetry (103). None of these methods to date has supplanted CD4+ T-cell count based screening recommendations for the evaluation of asymptomatic HIV-infected patients for CMV retinitis.

Clinical Appearance

The diagnosis of CMV retinitis usually can be made by ophthalmoscopy by an experienced observer. The most characteristic feature of CMV retinitis is a yellowish-white area of retinal necrosis with a granular border that extends into the surrounding retina. Although CMV retinitis often has been described as hemorrhagic, hemorrhages may or may not be present. Lesions that have extensive necrosis and hemorrhage are often described as ÒfulminantÓ whereas those without hemorrhage are sometimes described as ÒgranularÓ or ÒindolentÓ (Fig. 26.2). Lesion location may be a factor in lesion appearance. In one large series (104), 51% of the lesions were considered fulminant, 45% granular, and 4% indeterminate. In that series, two-thirds of the fulminant lesions involved zone 1 (deÞned as the area within two disc diameters of the foveal center or one disc diameter of the optic nerve). Conversely, only 36% of granular lesions had zone 1 involvement. There was no difference in the rate of spread of the two lesion types (87,104); however, granular lesions have been associated with better visual acuity, presumably due to this lower frequency of macular involvement (104).

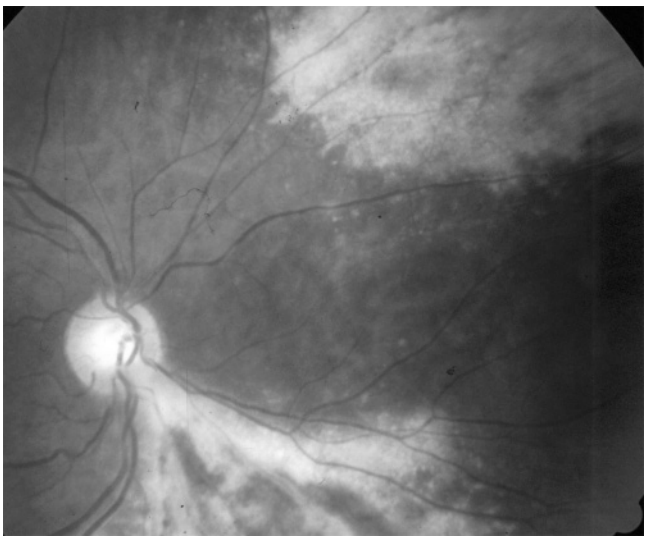

FIG. 26.2. CMV retinitis in a patient with AIDS. Note the granular (non-hemorrhagic) and fulminant (hemorrhagic) areas.

At times, CMV retinitis can be associated with mild anterior uveitis (90,105,106), elevated laser ßare photometry measurements (102), Þne refractile stellate corneal endothelial deposits (105), retinal periphlebitis (33), papillitis (64), disc neovascularization (107), exudative maculopathy (108), large vessel occlusion (108), and bilateral serous retinal detachments (109). Occasionally, a very early and small lesion of CMV retinitis may be difÞcult to distinguish from a cotton wool spot; however, follow up examination generally reveals the diagnosis since CMV retinitis will progress and enlarge over time, whereas a cotton wool spot will resolve. Rarely, CMV has been identiÞed as a cause of a necrotizing retinitis with vasculitis and vitreous inßammation indistinguishable from the acute retinal necrosis syndrome (110,111). The diagnosis in this and other atypical presentations of CMV retinitis can be conÞrmed through PCR studies of intraocular ßuid samples (99,110,111).

Natural History

Untreated CMV retinitis is a progressive and potentially blinding disease (57). Natural history series of CMV retinitis report progression of the disease in virtually 100% of patients (57,112). The borders of the infection harbor active CMV, and the retinitis characteristically spreads from the periphery of the process outward, reminiscent of a brush-fire, and such lesions are often referred to as "brush-fire" lesions. In the series by Holland et al. (87), 17 patients with untreated retinitis had mean border advancement of 24.4 μm/day (range 0–164 μm/day).

Clinical trials often evaluate a drug's efficacy by its ability to slow this advancement of the retinitis, generally measured as time-to-progression. Time-to-progression is the time for the retinitis to move a specified distance, and the definition of progression in several large series has been the movement of the border of retinitis by 750 μm over a span of 750 μm or the development of new lesions (79,80,104,113–116). Untreated patients typically are shown to have progression identified in 15 to 21 days when photographs are evaluated by a reading center (80,115,116). Time to progression as assessed by clinical examination is typically longer for treatment groups than that assessed by fundus photography reading centers (83,117).

Areas of retina previously infected with CMV show total destruction of the retinal architecture and replacement by a thin gliotic scar (21). Often there is hyperpigmentation of the scarred lesion or areas of atrophic retina with holes. Lipid and calcium may be deposited as well (119). Some areas of retinitis exhibit a "persistent white edge" (120) that does not advance but can be mistaken for active retinitis unless compared with prior photographs. Histopathology of one eye with a "persistent white edge" revealed necrotic, devitalized, nonviable cells without evidence of superinfection (120). The clinical picture of treated CMV retinitis where only an atrophic and gliotic scar can be detected and there is no evidence of an active process, is often called a "complete response" or "remission." (Fig. 26.3).

Effect of HAART

HAART has modified the clinical manifestations of CMV retinitis in some patients (4,7,29). Excessive inflammation and atypical features of CMV retinitis, previously described in patients with CMV disease from iatrogenic immunosuppression (121), have now become less rare in patients with HIV on HAART (4,7,8,29,74,122,123). In the series of Deayton et al. (8), of patients with CMV retinitis, 5% developed vitreitis and 4% developed cystoid macular edema (CME) following institution of HAART (8). Neither the vitreitis nor the CME in this series was related to anti-CMV treatment, CD4+ T-cell count, or HIV viral load (8). Bilateral optic disc neovascularization occurred in 2.4% of patients in the series of Curi et al. (122) as well as in at least one additional case report (123). These features were rarely identified in HIV-infected patients before the widespread use of HAART.

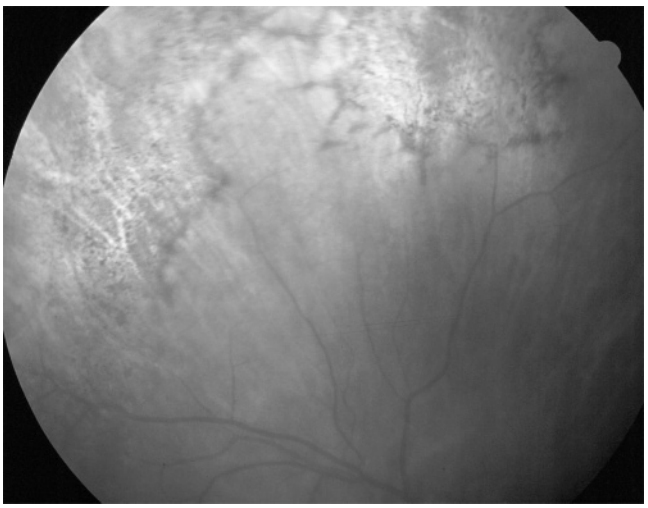

FIG. 26.3. CMV retinitis following successful treatment in a patient with AIDS.

Treatment

The goal of treatment of CMV retinitis is to arrest the progression of the disease, prevent further spread of infection in the eye, and maximize visual function. Treatment of CMV retinitis is generally performed in a two-step fashion. Initially a high dose of an anti-CMV drug is given to control the infection (induction therapy), and subsequently long-term lower dose therapy is given to prevent relapse (maintenance therapy). The phenomenon of relapse when an antibiotic is discontinued was characteristic of patients with AIDS in the pre-HAART era and of patients who do not have immune reconstitution from HAART. This phenomenon occurred in other infections such as *Pneumocystis carinii* pneumonia, cryptococcal meningitis, and *Toxoplasma gondii* encephalitis. Because relapse of CMV retinitis was frequently seen when induction therapy was discontinued, maintenance therapy became used early in the AIDS epidemic. Since maintenance therapy must be continued indefinitely unless there is immune reconstitution, placement of a permanent indwelling central venous catheter often is necessary for patients treated with intravenous therapy. Monitoring clinical response with high quality fundus photographs is important in order to recognize subtle progression of the retinitis (83,117,118).

Prior to HAART, cases of resolution of CMV retinitis without specific treatment for CMV were reported, but

were rare. Two case reports describe the resolution of CMV retinitis after the initiation of zidovudine (also known as azidothymidine or AZT) therapy in patients with AIDS (57,124). Since widespread application of HAART to patients with HIV disease, the frequency of arrested CMV retinitis in the absence of speciÞc CMV therapy has increased (4,68,92,125,126) and has led to recommendations regarding the cessation of anti-CMV maintenance therapy once immune reconstitution has occurred (92) (below). The efÞcacies of some treatments appear to have improved when given with HAART (74).

Intravenous Medication

Ganciclovir

The Þrst drug approved by the Food and Drug Administration (FDA) for the treatment of CMV retinitis in immunocompromised patients, ganciclovir, is still used. Ganciclovir (Cytovene, Roche Bioscience) was previously known as 9-(1,3-dihydroxy-2-proproxymethyl) guanine or DHPG. It is a nucleoside analog, which is taken up by the infected cell, phosphorylated by a viral phosphotransferase, and inhibits viral DNA replication through its effect on viral DNA polymerase (127,128). Autopsy studies of patients treated with ganciclovir have demonstrated the presence of viral DNA at the border of the lesion but the absence of a productive infection and the absence of intact virions (129).

Induction therapy with ganciclovir consists of 5 mg/kg every 12 hours intravenously for 14 to 21 days (10 mg/kg/day). There have been no reported differences between the 14 and 21-day induction courses. The dosing schedule recommended for maintenance ganciclovir is 5 mg/kg/day intravenously once daily (35 mg/kg/week), although 6 mg/kg/day, Þve of seven days (30 mg/kg/week), has been used in the past. Lower doses of maintenance and every other day dosing schedules were associated with unacceptably high rates of early relapse. Because ganciclovir is excreted in the urine, the dose must be adjusted for renal function.

Multiple series have reported the efÞcacy of ganciclovir for the treatment of CMV retinitis. Response rates have ranged from 80% to 100% (57,63,76,77,130ÐI135). Sixty to 80% of patients will achieve quiescence of the infection while on therapy (57,63,76,77,130ÐI135). In patients treated with ganciclovir, the median time to quiescence is 21 to 38 days (57,77). Prior to the use of maintenance therapy, patients given only induction ganciclovir often achieved quiescence of retinitis at one month after starting therapy only to subsequently suffer relapse of the active retinitis (130). This lag between the institution of therapy for CMV retinitis and the resolution of the ophthalmoscopic evidence of active disease represents the time required for areas of necrotic retinitis to resolve and leave a scar.

The most frequent side effect reported for ganciclovir is reversible granulocytopenia. Other side effects include thrombocytopenia, poorly characterized neurologic side effects, and abnormal liver function tests. Approximately one-third of patients receiving ganciclovir will experience granulocytopenia at sometime during the course of their disease (57,114) with an event rate of 1.30 per person-year at risk (79). The fall in the absolute neutrophil count (ANC) often occurs during or just after the completion of induction therapy with 46% of the events occurring within the Þrst month of treatment (114). Historically, physicians treating patients with ganciclovir needed temporarily to discontinue ganciclovir if the ANC fell below 500 cells/µL. Colony stimulating agents now available such as granulocyte colony stimulating factor (G-CSF, Þlgrastim) or granulocyte-macrophage colony stimulating factor (GM-CSF, sargramostim), however, have allowed ganciclovir therapy to continue by boosting the white blood cell count above this dose limiting cutoff. Before the widespread use of these agents, 16% of patients treated with ganciclovir were unable to tolerate the drug because of recurrent granulocytopenia. A later series reported that only 6.5% of patients treated with ganciclovir needed to change therapy due to this side effect (114). Thrombocytopenia occurs in approximately 10% of patients, and may also limit the dose tolerated. Other side effects rarely lead to discontinuation of therapy. Since an indwelling catheter is often placed, line-related complications occur (136,137). Thorne et al. (137) reported a rate of catheter complications of 1.2 complications per person-year or 0.33 complications per 100 catheter-days (137). In this series, mortality from the Þrst complication was 5.8%, 40% of patients required catheter removal, and 87% of these required a new catheter (137). The use of subdermal port catheters and current injection drug use increased the risk of catheter infections (137).

Two mechanisms of CMV resistance to ganciclovir have been identiÞed *in vitro*. The Þrst involves structural changes to the viral UL97 gene that encodes a viral phosphotransferase (53,138,139). Multiple mutations have been identiÞed (139). As a result, the ganciclovir, once taken up by the infected cell, is not activated through the initial phosphorylation. Point mutations and deletions have been identiÞed; however, CMV strains with more than one mutation in the UL97 gene were not more resistant than those strains with only one mutation (138). Resistant mutants with wild type UL97 genes have been identiÞed which led to the suggestion of an additional mechanism of resistance (138). This second mechanism has been related to changes in the *pol* gene coding for the viral DNA polymerase (gene UL54) (53,127,139). The identiÞed *pol* point mutation encodes a structurally altered DNA polymerase with decreased ganciclovir binding afÞnity (127). Consequently, the ganciclovir is activated through phosphorylation but cannot affect viral replication. As with UL97 mutations, multiple UL54 mutations have been identiÞed (139). Mutants with resistance from both mechanisms have been identiÞed *in vitro* (140,141). Smith et al. (141) characterized these mutants with resistance

from both mechanisms as high-level, and reported that they were associated with prior prolonged ganciclovir therapy.

The frequency of *in vivo* ganciclovir resistance has been characterized, and although low at time of diagnosis, it increases with duration of therapy (142). In the prospective series of Jabs et al. (143,144), 0.9% and 2.7% of baseline blood and urine culture isolates, respectively, showed ganciclovir resistance. After nine months of therapy for patients treated initially with ganciclovir, the frequency of blood or urine isolate resistance increased to 27.5%. In this series, the development of resistance correlated with the development of CMV retinitis in the contralateral eyes of patients initially affected unilaterally (143,144).

Foscarnet

The second drug reported to be effective against CMV retinitis is foscarnet (Foscavir, Astra Phramaceuticals) (128). Foscarnet, also known as trisodium phosphonoformate hexahydrate, is a pyrophosphate analog which, like ganciclovir, inhibits DNA polymerase in infected cells. Foscarnet is also used in a two-step fashion with the initial induction dose being 90 mg/kg/day every 12 hours (or 60 mg/kg/day every eight hours) for two weeks and the maintenance dose being 90–120 mg/kg/day. Some researchers have used three week induction courses (116); however, there have been no reports directly comparing the duration of induction therapy.

Preliminary studies have demonstrated a similar response rate with foscarnet as with ganciclovir, with 80–100% of patients showing some response to the drug (145–147). In a dose ranging study of patients with previously untreated CMV retinitis, Jacobson et al. (82) found that the median time to retinitis progression for patients treated with 180 mg/kg/day divided every eight hours for two weeks followed by maintenance of 90 mg/kg/day was 56 days by clinical exam and 31 days when evaluated by the more sensitive masked fundus photograph reading center. Higher dose maintenance was more effective in delaying relapse (82,148), but there was a trend toward a higher creatinine level and a higher incidence of proteinuria (82). In the randomized controlled clinical trial by Palestine et al. (116), mean time to progression was 13.3 weeks (93 days) by masked fundus photograph reading center for patients treated with 180 mg/kg/day divided every eight hours for three weeks followed by 90 mg/kg/day maintenance compared to 3.2 weeks (22 days) for patients in the treatment deferred control group.

In contrast to ganciclovir, foscarnet is not significantly bone marrow toxic. Its primary toxicities are renal and metabolic, which occur in 13% of patients (82,114,116, 149). In the series by Jacobson et al. (82), 9% of 54 patients were unable to tolerate maintenance foscarnet due to these adverse events. Nephrotoxicity is usually reversible (116). In a large prospective series with close monitoring, frequent dose changes based on renal function, and concomitant hydration, the incidence was only 13% at six months (114). Despite its renal toxicity, foscarnet has been used in a patient with renal failure (150).

The metabolic side effects of foscarnet include abnormalities of calcium, phosphorus, and magnesium. Often, supplementation will be required for hypocalcemia or hypomagnesemia. Paresthesias related to temporary metabolic aberrations are not uncommon. Infusion related nausea has been reported in 26–50% of patients (114,116). Uncommon side effects include oral and genital ulcerations (114,151–154), which generally resolve within two weeks of discontinuation of the foscarnet. Hygeine has been implicated as a factor in the genital ulcers since foscarnet is excreted in the urine and many of the affected patients were uncircumcised, however, the explanation of the oral ulcerations is less clear (153). Seizures, previously thought to be associated with foscarnet therapy, occurred at the same frequency in patients on ganciclovir or foscarnet in one large comparative trial (114); hence, seizures appear to be unassociated with foscarnet therapy.

Despite low baseline foscarnet resistance (142,155), resistance increases with treatment duration (155,156). In one large prospective study, blood and urine culture foscarnet-resistant CMV strains increased from 2.4% and 0.8% respectively at baseline to 22% and 3% respectively at six months with foscarnet therapy (157). As with ganciclovir, *in vitro* foscarnet resistance has been linked to *pol* gene mutations (158); however, a single *pol* mutation does not necessarily confer resistance to both drugs (127). Resistance to foscarnet and to both foscarnet and ganciclovir has been identified in clinical isolates (119,156,159, 160). One foscarnet resistant isolate was from a patient who had never been exposed to foscarnet (156). Dunn et al. (156) found that continued treatment with either foscarnet or ganciclovir was associated with an increase in the IC50 for that drug.

The relative efficacy and safety of ganciclovir and foscarnet were evaluated in the multicenter randomized Foscarnet-Ganciclovir Cytomegalovirus Retinitis Trial (FGCRT) (79,104,113,114), which showed no difference in median time to progression of the CMV retinitis. The FGCRT and other studies (80,82,149,161) identified a survival benefit in patients treated with foscarnet, which was attributed to inhibition of HIV-1 replication *in vitro* (162,163), as well as a synergistic (162) or additive (163) effect against HIV-1 reverse transcriptase when used with zidovudine. Unlike the combination of foscarnet and zidovudine which has been shown to be beneficial, ganciclovir has been shown to reduce the antiretroviral effect of zidovudine when HIV p24 antigen production, reverse transcriptase activity, and infectious viral yield were used as measures of HIV replication (164). Currently, the survival difference of foscarnet and ganciclovir

may be less important due to the increased number of available antiretroviral medications, their application via HAART, and the diminished concern regarding HIV resistance to zidovudine monotherapy.

Although survival was increased for patients randomized to treatment with foscarnet, treatments were changed in 36% of patients assigned to foscarnet and 11% of patients assigned to ganciclovir (79,104), indicating that foscarnet was not as well tolerated as ganciclovir. The rates of hypocalcemia, hypomagnesemia, hypophosphatemia, hypokalemia, nephrotoxicity, genital lesions, infusion related nausea, and infusion time were higher with foscarnet (114). The incidence of neutropenia was expectedly higher in the ganciclovir group (114). The incidence of catheter related infections (79), anemia (114), opportunistic infections (79), hospitalization (79), extraocular CMV (114), and seizures (114) were not signiÞcantly different between the two groups. In the era of HAART, the modest survival beneÞt of foscarnet therapy appears to have little signiÞcance.

Cidofovir (HPMPC)

In addition to ganciclovir and foscarnet, cidofovir or (S)-1-(3-hydroxy-2-(phosphonylmethoxy)propyl)cytosine has obtained FDA approval for the treatment of CMV retinitis. It is a long-acting nucleotide analogue, which does not require a viral-encoded phosphotransferase for its initial phosphorylation to cidofovir diphosphate (HPMPCpp), the active metabolite (165Ð167). Its target, like that of ganciclovir and foscarnet, is viral DNA polymerase (140), and altered DNA polymerase via *pol* gene mutation is one method of resistance to this agent (53,127,140,168,169). Mutations to DNA polymerase capable of causing ganciclovir resistance may show resistance to cidofovir (141,166,168). Prior ganciclovir and cidofovir use have been associated with resistance formation (141,170). As with ganciclovir and foscarnet, resistance increases with duration of drug exposure (157). In one large prospective study, 4.1% and 6.6% of baseline blood and urine cultures contained cidofovir resistant CMV strains respectively, but after six months of therapy, 29% of blood or urine cultures contained resistant organisms (155).

One advantage of cidofovir over ganciclovir and foscarnet is its long duration of effect which abrogates the need for, and risks of, chronic indwelling catheters (137,160,171). This long duration of effect has been attributed to the long intracellular half-lives of two of its metabolites, cidofovir diphosphate (17Ð65 hours) and cidofovir phosphate-choline (87 hours) (46,166,171). In a phase I/II study of patients with asymptomatic CMV excretion, negative semen cultures persisted for 37 days after the last dose of cidofovir (167). Human studies evaluating the effect of cidofovir on asymptomatic viral shedding showed efÞcacy at doses of greater than 3.0 mg/kg/week (167) or 5.0 mg/kg/week (165). Several studies have shown efÞcacy for both untreated and previously treated CMV retinitis (166).

The multicenter Phase II/III HPMPC Peripheral Cytomegalovirus Retinitis Trial (HPCRT) (81,83) which compared low dose (3 mg/kg) and high dose (5 mg/kg) intravenous maintenance injections to no treatment (deferred group) for previously untreated peripheral CMV retinitis showed that both doses were effective in delaying time to progression of retinitis. Each treatment group received the same induction dose of 5 mg/kg once weekly for two weeks, then the individual maintenance therapy doses every two weeks (83). The median time to progression in the low dose group was 64 days versus 21 days in the deferred group (83). The median time to progression in the high dose group was not reached but was 20 days in its corresponding deferral group (83). Although the median time to progression was longer in the high dose group compared to the low dose group, the study was not designed to compare the two dosing regimens, so such a conclusion could not be made (83). There was no difference in mortality among the three groups.

The multicenter controlled trial of cidofovir for previously treated relapsing CMV retinitis of Lalezari et al. (172), in which patients were randomized to receive induction cidofovir 5 mg/kg weekly for two weeks, then either 3 mg/kg or 5 mg/kg maintenance therapy every two weeks, showed a median time to progression (as determined by masked fundus photo reading center) of 49 days for the 3 mg/kg group. The second group did not reach the median time to progression (172). The relative risk for progression in the 3 mg/kg group was 3.05 compared to the high dose maintenance group (172). The Kaplan-Meier survival estimate for this series in 1996 was 4.9 to 5.9 months (172).

Dose and schedule dependent nephrotoxicity is the principal side effect as the drug is concentrated by active transport into the proximal convoluted tubule (92,128,167) and typically becomes evident Þrst as proteinuria and then as an elevated serum creatinine level (128). Reported frequencies of proteinuria and elevated creatinine are 39% and 24% respectively (172). Prior treatment with foscarnet has been shown to be a risk factor for cidofovir-induced nephrotoxicity (172), and death from cidofovir-associated renal failure (in two patients with additional nephrotoxic drugs) has been reported (173). In the HPCRT (81,83), proteinuria occurred at rates of 2.6, 2.8, and 6.8 per person-year for the deferred, low dose (3mg/kg), and high dose (5 mg/kg) groups respectively suggesting a dose relationship. For patients with adequate follow-up to assess toxicity resolution, 80Ð90% had subsequent normalization of renal function (81). One case report describes a patient who developed nephrogenic diabetes insipidus without signiÞcant preceding change in creatinine or proteinuria (174). Other side effects of cidofovir include nausea (13Ð48%), fever (14Ð35%), alopecia

(16–18%), myalgia (16%), neutropenia (13.7–25%), headache (11%), cutaneous hypersensitivity (7.8%), anemia (2%), peripheral neuropathy, Fanconi syndrome, cardiomyopathy, and erythroderma (128,165–167,172,173,175).

The ocular side effects of intravenous cidofovir are potentially sight-threatening. The two most concerning are hypotony and anterior uveitis. Both have been reported in patients taking intravenous cidofovir for non-ocular CMV infections (176). Hypotony has been reported to occur in approximately 10% of patients in some series (92,128,172,177); however, in the HPCRT (83), there was no difference in frequency of hypotony between the low dose, high dose, and deferred treatment arms. This HPCRT result has been attributed to low patient numbers (83) and concurrent use of probenecid, which has been shown to reduce this toxicity (178).

The frequency of anterior uveitis following intravenous cidofovir has been reported to occur in 12–42% of patients (81,92,128,172,173,177,179–182) at a rate 0.2 per person-year (81). It typically occurs in the week following the cidofovir infusion and between four and 10 weeks following induction therapy (177,179–181). Patients complain of pain, redness, and photophobia. Features of the anterior uveitis include hypopyon (20%) (179), non-granulomatous keratic precipitates (12%), posterior synechiae (50–60%) (177,179,180), iris transillumination defects (50%) (177), and corneal edema (20%) (179).

Uveitis associated with cidofovir use is related to the immune status of the patient. In the series of Ambati et al. (179), which reported an anterior uveitis frequency of 59%, stepwise linear regression suggested that one-third of cases were related to immune reconstitution as evidenced by a more significant increase in CD4+ T-cell counts in patients with anterior uveitis compared to those without anterior uveitis. All patients in this series received probenecid prophylaxis. Since 25% of the patients with unilateral CMV retinitis developed anterior uveitis bilaterally, CMV retinitis itself was not a pathogenetic requirement (179). Berenguer et al. (173) similarly found an association between immune reconstitution with HAART and iritis development since, in their series of 51 patients, median CD4+ T-cell counts were three times higher in the 41% of patients who developed iritis than in those patients without iritis. Age, sex, HIV risk factors, retinitis severity, and renal insufficiency were not associated with iritis development in this series (173), although an association with renal dysfunction was suggested in one small case series (181). In the HPCRT (81), the relative risk of developing uveitis associated with cidofovir use was 6.9 if protease inhibitors were used concomitantly; however, nearly one-half of the cases of cidofovir uveitis occurred in patients not receiving a protease inhibitor. Bainbridge et al. (177) however, found no association of anterior uveitis following intravenous cidofovir with HAART, rifabutin use, or absolute CD4+ T-cell count. Thus, while some studies are contradictory, it appears that immune reconstitution may increase the rate of development of inflammation associated with cidofovir use.

Probenecid, a benzoic acid derivative with a sulfa moiety, has been used competitively to block cidofovir concentration in the proximal convoluted tubule in an attempt to minimize toxicity (53,92,165,167); however, probenecid allergy is not uncommon (167) and more than half of patients treated with this drug will develop side effects (46). Probenecid reactions of nausea and constitutional symptoms occur in 43% of patients and are treatment-limiting in some patients (172). Other reactions include fever, hypotension, and angioedema (81). In the HPCRT (81,83), probenecid reactions occurred at a rate of 0.7 per person-year, and in the 3mg/kg/dose maintenance group, the median time to discontinuing therapy due to side effects increased from 7.4 months to 16.3 months when probenecid intolerance was excluded. In spite of these side effects, use of cidofovir along with probenecid, hydration, and careful monitoring for proteinuria (92,167), may be a viable alternative to the currently available intravenous preparations.

Oral Preparations

The first oral anti-CMV agent, which has received FDA approval for maintenance therapy and primary prophylaxis of CMV end organ disease, is ganciclovir. The bioavailability of oral ganciclovir of 2.6–8.8% is poor (128,183,184); however, bioavailability is enhanced by food (183,185). Pharmacokinetic studies by Anderson et al. have shown that oral ganciclovir at doses of 500 mg six times a day or 1,000 mg three times a day provided area under the time-concentration curves equivalent to 70% of that provided by an intravenous regimen of 5 mg/kg/day. The peak ganciclovir concentration in serum by oral administration was 16% of the peak IV concentration; however, the steady state concentration by the oral route was higher than that obtained by IV for 12 hours of the day (183). Since the serum concentrations approximate the IC50 for CMV, the exacerbation of drug resistance is a concern, although there has been no increased incidence of drug resistance in patients treated with oral ganciclovir when compared with intravenous ganciclovir according to one report (186).

The efficacy of oral ganciclovir maintenance was compared to intravenous ganciclovir maintenance in several trials (187–189). In a study by Drew et al. (187) which randomized patients to oral ganciclovir (500 mg six times a day) or intravenous ganciclovir (5 mg/kg/day), following three weeks of intravenous ganciclovir (5 mg/kg every 12 hours for two weeks then 5 mg/kg/day for one week), found no significant difference in the time to progression of retinitis by masked fundus photograph reading center. The mean time to progression by masked fundus photograph reading center was 62 days for intravenous ganciclovir and 57 days for oral ganciclovir.

By unmasked clinician examination, however, there was a signiÞcant difference favoring intravenous ganciclovir: 96 days versus 68 days, respectively (187). Physician bias was invoked to explain the difference between the masked reading center and clinical examination discrepancies.

Other studies have similarly supported the efÞcacy of oral ganciclovir (184,188,189); however, when all studies are collectively evaluated, there is a suggestion that oral ganciclovir may be slightly less effective than intravenous ganciclovir for maintenance therapy and the recommendation has been made to avoid oral ganciclovir for induction monotherapy for any patient or for maintenance monotherapy for a patient with immediately sight-threatening disease (92,128).

The relative side effects of the oral and intravenous preparations generally favor the use of oral ganciclovir. The incidences of neutropenia (187Ð190), fever (189), sepsis (46,188Ð190), anemia (187,190), and catheter-associated problems (187,188,190) were higher in patients treated with intravenous ganciclovir compared to oral ganciclovir. The incidence of rash was higher in patients treated with oral compared to intravenous ganciclovir (188), and there are conßicting reports regarding the relative incidence of gastrointestinal problems between the two routes of administration (187Ð189). Survival does not seem to be affected by the different treatment modalities (187).

A second oral agent approved by the FDA for CMV infections is valganciclovir (46,85,93,128,191,192). Valganciclovir, or L-Valine, 2-((2-amino-1,6-dihydro-6-oxo-9H-purin-9-yl)methoxy)-3-hydroxypropyl ester monohydride, is an L-valyl ester prodrug of ganciclovir which is rapidly converted by hepatic and intestinal esterases into ganciclovir. Like ganciclovir, valganciclovir requires dose adjustment for patients with renal impairment. In a randomized, open-label, controlled study of patients with AIDS and newly diagnosed CMV retinitis, valganciclovir (900 mg bid induction for 21 days followed by 900 mg qd maintenance) was comparable to intravenous ganciclovir. Although no clinical data directly compare oral valganciclovir (900 mg qd) to intravenous ganciclovir (5 mg/kg/day) as maintenance therapy, pharmacologic data suggest equivalency. Side effects of valganciclovir include gastrointestinal complaints, pyrexia, neutropenia, anemia, and insomnia.

Local Therapy

Given the morbidity associated with central venous catheters (103,136,137,193Ð195), there has been an effort to develop local treatment of CMV (196). At least one case report documents successful control of bilateral CMV retinitis using local therapy alone for over three years (197). The principal disadvantage of local therapy is the absence of systemic protection against CMV disease (196,198,199). Contralateral retinitis develops in 50% of previously uninvolved contralateral eyes in patients with unilateral disease treated locally at six months (115). Visceral CMV disease occurs in 27Ð31% of patients treated locally at six months (115,200). Local therapy for unilateral disease in combination with oral ganciclovir or valganciclovir for systemic prophylaxis may be an attractive approach.

Early attempts at local therapy have utilized intraocular injections of ganciclovir (197,201Ð205) and/or foscarnet (206). Both require six injections for induction over two to three weeks (202,203,206) or until the retinitis is inactive (204), then weekly injections for maintenance. The 0.1 ml injections generally are given via a trans-pars plana approach 4 mm from the limbus with a 30-gauge needle on a tuberculin (1 cc) syringe (202,206). Ganciclovir doses of 200 μg to 2,000 μg have been well tolerated (202Ð205) as have foscarnet doses of up to 2,400 μg (206). Velez et al. (207) report the successful use of combined high-dose ganciclovir and foscarnet at doses of up to 3.0 mg and 2.4 mg, respectively, twice a week for a patient with resistant CMV retinitis. The efÞcacy of both drugs given intravitreally has been reported to be similar to that of the intravenous preparations (202,204Ð206). Since multiple injections are required, it is not surprising that complications of local therapy have included endophthalmitis (202,203,205), retinal detachment (203,204), vitreous hemorrhage (204), optic atrophy (204), keratitis (204), and subconjunctival hemorrhage (202). Administering topical povidone iodide (206) before the injection or performing the injections in an operating room (204) may decrease the risk of endophthalmitis, but cannot eliminate it completely.

Methods to increase the length of action of locally injected drugs or using longer acting preparations may increase the acceptance by patients and physicians. Loading biodegradable 50:50 poly(DL-lactide-co-glycolide) microspheres with ganciclovir and injecting them intravitreally has shown some promise in a rabbit model of CMV retinitis, vitreitis, and optic neuritis (208); however, it is not yet available for human use.

The long duration of action of cidofovir may Þll this need since less frequent injections are required (171). Kirsch et al. (209) in a phase I/II un-masked, uncontrolled, case series reported that the median time to progression after a single 20 μg injection of cidofovir was 64 days. Typically, dosing regimens of 20 μg every Þve to six weeks are administered (46). In the non-randomized series of Taskintuna et al. (210) of patients with previously treated and untreated CMV retinitis, a dose of 10 μg was shown to be less effective than a dose of 20 μg and possibly associated with the development of drug resistance.

The ocular side effects of intravitreal injections of cidofovir can be sight-threatening. Kirsch et al. (209) found that a 20 μg intravitreal dose was well tolerated but that a 100 μg dose was associated irreversible visual loss, due to cidofovir toxicity (uveitis and hypotony). Doses of

10 μg have been shown to cause fewer side effects; however, as noted earlier, they are less effective (210).

Like intravenous cidofovir, intravitreal cidofovir has been associated with iritis and hypotony (178,200). In the prospective series by Chavez-de la Paz et al. (178) in which 46 eyes received 130 injections of cidofovir at a dose of 20 μg, the frequency of anterior uveitis after the first injection was 26%. The anterior uveitis typically occurred between five and 12 days after the injection, was symptomatic, nongranulomatous and at times associated with posterior synechiae formation, miosis, perilimbal flush, and hypotony (178). Iritis occurring in one eye increased the likelihood of iritis in the second eye when treated by injection (178). Taskintuna et al. (200) in his series of 115 eyes that received 296 injections of cidofovir (20 μg) with probenecid prophylaxis, reported a frequency of nongranulomatous anterior uveitis of 32%. Posterior synechiae, cataracts, and retinal detachment developed in 19%, 11%, and 6% of eyes respectively (200).

Hypotony can be equally sight-threatening. Taskintuna et al. (200), reported that transient hypotony occurred in 14% of eyes and chronic hypotony in 1% of eyes. The risk of chronic hypotony with permanent visual loss was increased in eyes in which the fellow eye had transient hypotony, which led to the recommendation of waiting at least two weeks between injections in the two eyes (200). The frequency of chronic hypotony with visual loss in the series of Banker et al. (211) was similarly 1%.

The hypotony and intraocular inflammation associated with intravitreal cidofovir use has been attributed to ciliary body toxicity. Aqueous fluorophotometry has shown a reduction in aqueous humor flow rate following intravitreal cidofovir injections (211). *In vivo* ultrasound biomicroscopy of eyes with severe hypotony following intravitreal injections of cidofovir has identified ciliary body atrophy (211). Histopathology of human eyes that have received multiple injections of intravitreal cidofovir (cumulative doses of 40–60 μg) has shown mild to moderate atrophy of the nonpigmented ciliary epithelium (200). Electron microscopy of these same eyes showed vacuolization of the nonpigmented ciliary epithelium (200). Histopathology of the retina, choroid, and remainder of the ciliary body showed no abnormalities (200). Concurrent HAART has been suggested to increase cidofovir toxicity either by increasing circulating cidofovir levels or by increasing the number of circulating pro-inflammatory CD4+ T cells (212). Probenecid prophylaxis has reduced the frequency of anterior uveitis from 71% to 18%, presumably by reducing cidofovir absorption into the ciliary body (178). Pretreatment with topical steroids (prednisolone acetate 1% q.i.d.) and cycloplegics does not alter the frequency of hypotony or uveitis (178). The routine use of intravitreous injections of cidofovir is neither recommended nor approved (196).

Encapsulating cidofovir in phospholipid liposomes prior to intravitreal injection in rabbit eyes has shown antiviral efficacy and allowed the injection of higher doses of cidofovir without the toxic effects (213). The liposome acts as a sustained release depot similar to the ganciclovir microspheres (214) mentioned earlier. A single injection of liposome-encapsulated cidofovir provided protection against an intraocular HSV-1 challenge for 240 days in this model (213). Akula et al. (215) reported one patient in whom liposome encapsulated ganciclovir halted progression of retinitis for four months. Additional studies will be required to further delineate the utility and side effects of this treatment.

Fomiversen sodium (Vitravene, formerly ISIS 2922, Isis Pharmaceuticals, Inc., Carlsbad CA, and CIBA Vision Ophthalmics, Atlanta, GA) was approved by the FDA for the local treatment of CMV retinitis in patients with AIDS in August 1998 (53,91,216–218). The first "antisense" drug approved for clinical use, Fomiversen is an oligonucleotide which binds to the "sense" strand of messenger RNA (mRNA) for CMV immediate early genes UL36 and UL37, thus inhibiting translation and subsequent protein formation (53,216,217). The fomiversen-mRNA complex is then degraded by RNAse H liberating a degraded mRNA strand and an unaltered fomiversen oligonucleotide which can then bind to another strand of mRNA (216). DNA replication in human CMV can be inhibited by 99% with use of this agent (53). The recommended intravitreal dose is 330 mcg on day 1 and 15 for induction followed by monthly maintenance injections (216). Fomiversen requires storage between 2 and 25 degrees Celsius and protection from light (216). Activity against ganciclovir-, foscarnet-, and cidofovir-resistant CMV strains has been identified (53).

Phase III trials of fomiversen showed median time to progression of 71–80 days compared to 13 days in the deferred treatment group (216,217). Side effects included temporary elevations in intraocular pressure and intraocular inflammation (46,216). As a result of the inflammatory potential of fomiversen, it should not be used in patients treated with cidofovir in the prior two to four weeks (216). Other side effects include peripheral retinopathy and a reversible, non-visually significant "Bull's eye"-type maculopathy (218). No systemic side effects have been observed (217).

The longest-acting form of local therapy is the sustained-release ganciclovir intraocular implant (Vitrasert) which was approved by the FDA for use against CMV retinitis in March 1996 (196). The implanted device is 5–6 mm long, 4 mm wide and 3.5 mm high (219). It is composed of a 4.5–6.4 mg pellet of ganciclovir coated on all sides but one by impermeable ethylene vinyl acetate then completely recoated with permeable polyvinyl alcohol (196,220,221). Intraocular implantation occurs in an operating room and involves placement of the device through a pars plana incision with the pellet facing the lens to facilitate observation (221). Its benefit compared to other local therapies is the ability to deliver ganciclovir steadily for prolonged periods of time. Calculated release rates from explanted devices range from 1.40 to 1.89 μg/

hour (115,221) which are constant until 90% of the drug has been released (220). Mean vitreous concentrations range from 4.1 to 8.37 μg/ml (115,221) which are well above the IC50 for many CMV isolates and higher than that obtained following intravenous administration (128). The duration of delivery is approximately Þve to eight months (222) and the device can be replaced as needed (223) typically every six to eight months (2,92,103,128, 196,197).

Clinical studies have shown efÞcacy of the ganciclovir implant against CMV retinitis (115,221,223). In the study by Martin et al. (115), in which patients with newly diagnosed peripheral retinitis were randomized to deferred treatment or immediate treatment with a device, the median time to progression by masked fundus photograph reading center was 15 days for the deferred group and 226 days for the device group. Progressive retinitis generally occurs with the implant is empty, resulting in low or nondetectable vitreous concentrations of ganciclovir (115,223). In the randomized controlled trial of Musch et al. (199), patients were treated with either a ganciclovir implant with a release rate of 1 microgram per hour, an implant with a release rate of 2 micrograms per hour, or intravenous ganciclovir. The median times to progression of retinitis were 221 days, 191 days, and 71 days respectively for each of the groups. The risk of progression was 2.8 times higher for patients treated with intravenous ganciclovir than for patients treated with the implants. In the randomized controlled trial of Martin et al. (198), patients received either a ganciclovir implant plus oral ganciclovir (4.5 mg/day), a ganciclovir implant plus placebo, or intravenous ganciclovir monotherapy. Retinitis progression was delayed in patients who received the implant plus oral ganciclovir compared to the implant plus placebo.

The implant may be less effective in relapsed disease than in primary disease (92,103,224). In the review of Roth et al. (224), in which 54 patients with active, previously treated, sight-threatening, CMV retinitis and poor venous access or prior failure of intravenous ganciclovir and foscarnet, were given a ganciclovir implant, a positive initial response was seen in 67.4% of patients. The median time to progression in eyes with a positive initial response was 8.0 months in the group with poor intravenous access versus 2.0 months in the group that previously had failed intravenous ganciclovir and foscarnet (224). The relative risk of early implant failure was 6.1 for each additional six month period of treatment with ganciclovir (224). In the series of Marx et al. (225), of the 91 eyes of 70 patients with recurrent CMV retinitis that were treated with the ganciclovir implant, a positive initial response occurred in 76% of eyes. The median time to progression in eyes with a positive initial response was seven months (225). Some, but not all, investigators recommend intravitreal injections of high dose ganciclovir (2mg) prior to placement of the ganciclovir implant in eyes with refractory disease (two relapses in a 10 week period despite two induction/ maintenance cycles) to determine efÞcacy (92).

A prospective randomized multicenter clinical trial, the Ganciclovir Cidofovir Cytomegalovirus Retinitis Trial (GCCRT) (74), compared the ganciclovir implant combined with oral ganciclovir (1 gram tid) to parenteral cidofovir (5 mg/kg weekly for two weeks, followed by 5 mg/kg every two weeks) in patients with AIDS and newly diagnosed or recurrent CMV retinitis. There was no signiÞcant difference in rate of retinitis progression (0.67 versus 0.71 per person-year), rate of visual loss (0.78 versus 0.47 per person-year), and mortality (0.41 versus 0.49 per person-year) between the ganciclovir and cidofovir groups (74). There was a higher rate of visual Þeld loss in the patients treated with the ganciclovir implant which was attributed to the implant blocking a portion of the visual Þeld (74). Quality of life questionnaire indices such as mental health score, and energy score, favored cidofovir use (74). Side effect proÞles of each of the treatments were different, as expected.

The ganciclovir implant is well tolerated. Histopathologic studies in a rabbit model and in autopsy human eyes have shown no signiÞcant inßammatory effect (219Ð221). Implantation of uncoated ganciclovir pellets into rabbit eyes showed no ophthalmoscopically evident toxicity; however, there were some changes by electrophysiologic testing (220).

As with any surgical procedure, complications occur. Posterior segment complications such as retinal detachment, vitreous hemorrhage, endophthalmitis, cystoid macular edema, and epiretinal membrane have been reported in 12% of patients and are often associated with permanent visual loss (226). Reported frequencies of retinal detachment are variable (115,223); however, in the large prospective series of Kempen et al. (227), there was no increased risk of retinal detachment following placement of a ganciclovir implant compared to systemic therapy with ganciclovir, foscarnet, or cidofovir, a Þnding which has been attributed to better control of the intraocular CMV. Cases of separation of the ganciclovir pellet from the suspension strut during removal have been reported and recommendations regarding the technique of implant removal have been made (228). Other complications include transient astigmatism, corneal dellen, hypotony, and temporary decrease in visual acuity (92,115,128,221,223,224).

Investigational Therapy

Additional agents have been evaluated for the treatment of CMV disease including MSL-109, benzimidazole riboside derivatives, and others; however, the low incidence of CMV disease due to HAART has hindered these investigations. MSL-109 (Protein Design Laboratories, Inc, Mountainview, CA) is a human IgG1-κ class monoclonal antibody directed against the CMV gH glycoprotein

with *in vitro* neutralizing activity against CMV (46,53,229–237). Although a phase I/II investigation suggested a therapeutic benefit of MSL-109 (53), a larger phase II/III trial (229) showed that there was no difference between MSL-109 and placebo with respect to rates of retinitis progression, visual acuity outcomes, and quality of life indices (229).

Two benzimidazole riboside compounds have been investigated as therapy for CMV infection (53,99,128, 238). Derivatives of 5,6-dichloro-1-b-D-ribofuranosyl benzimidazole (DRB), 2-bromo-DRB (BDCRB) and 1263W94 inhibit CMV replication via mechanisms unlike ganciclovir, foscarnet, and cidofovir (238). As a result, cross resistance is not a concern (238). BDCRB is thought to inhibit viral DNA maturation by interacting with the products of genes UL89 (possible terminase) and UL56; however, it is rapidly inactivated thus making its clinical application difficult (238).

The second benzimidazole compound, 1236W94, also inhibits viral DNA synthesis, but by an as yet uncharacterized mechanism, which is distinct even from that of BDCRB (238). 1236W94 shows activity against ganciclovir, foscarnet, cidofovir, and BDCRB-resistant mutants (238). It has very good oral bioavailability, limited metabolism, and an adequate half-life (238). It does not require phosphorylation for activity, is eliminated by biliary excretion, and its albumin binding is readily reversible (238). Phase 1 trials (238) in healthy and HIV infected volunteers have shown that it is well tolerated with altered taste being the most common but not dose-limiting side effect. Efficacy studies on asymptomatic CMV shedding in urine and semen in patients with HIV are under way (238).

Relapsed Retinitis

Although many agents have been shown to be effective against CMV retinitis, if anti-CMV therapy is interrupted for a sufficiently prolonged period of time, relapse is essentially universal. Active, immature, replicative intermediates of human CMV have been shown to persist in retinal glial cells despite treatment (239). Whether the human retina is a normal site of viral latency is unclear (239). The time to relapse among patients who have had ganciclovir discontinued is approximately three to four weeks (57,135). In addition, despite the use of maintenance therapy, CMV will often relapse while on maintenance, a phenomenon sometimes called "breakthrough" retinitis (79,104,113,114). Given enough time nearly all patients on systemic therapy will experience recurrent retinitis. Although relapse of retinitis while on maintenance therapy may occasionally be fulminant, it often appears to be a slow "smoldering" intermittent movement of the border, suggesting a partial effect of the maintenance drug.

Relapsed retinitis has been attributed to both progressive immunosuppression from AIDS (92), less intraocular drug penetration due to progressive arterial occlusion with advancing CMV disease (196), and drug resistance (119). The efficacy of the ganciclovir implant when compared to intravenous ganciclovir supports the belief that reduced drug penetration may account for some treatment failures (161,224).

The ability to predict which patients are likely to develop a relapse of their retinitis may allow for a change in therapy to prevent the progressive loss of visual function that occurs with each reactivation. This ability would be especially beneficial for patients with peripapillary or perifoveal lesions whose visual function would not tolerate a relapse. Viral culture sensitivities have provided mixed results in terms of predicting those patients at risk for recurrent CMV retinitis since viral strains identified by blood and urine cultures may not be the same as those responsible for ocular disease (156,229). In addition, the identification of CMV viremia and viruria by culture is not always possible despite active retinitis (58,119,240). One alternative to viral culture that has been investigated is polymerase chain reaction (PCR) detection of CMV DNA from blood (139,144,241,242). None of these methods to date has proven sufficiently reliable for general use.

Treatment of Relapsed Retinitis

The treatment of relapsed or resistant retinitis has included continued monotherapy with the same or different agent (119,120,128,149,156,159) and combination therapy with different agents or different routes of administration (119,128,240,243–245). The Cytomegalovirus Retinitis Retreatment Trial (CRRT) was a multicenter randomized clinical trial which enrolled 279 patients with persistently active or relapsed retinitis to treatment with either foscarnet (90 mg/kg every 12 hours for two weeks then 120 mg/kg/day high dose maintenance), ganciclovir (5 mg/kg every 12 hours for two weeks followed by 10 mg/kg/day high dose maintenance), or ganciclovir and foscarnet (same induction doses as above but 5 mg/kg/day maintenance with ganciclovir and 90 mg/kg/day maintenance with foscarnet) (240). Median time to progression was 1.3 months for the foscarnet group, 2.0 months for the ganciclovir group, and 4.3 months for the combination group when determined by masked fundus photographic reading center. Changing treatment from one monotherapy drug to the other at randomization made no difference in outcome suggesting that there was no benefit in switching treatment as opposed to re-induction with the same medication for early relapses. Treatment impact on a quality of life questionnaire (246) was more negatively affected in the combination group than in either monotherapy group, which was probably related to the increased infusion time. There was no significant difference in morbidity or mortality among the three groups. Although this combination therapy generally no longer is used, the principle of

combination therapy for relapsed CMV disease such as foscarnet plus the ganciclovir implant has been used.

Primary Prophylaxis

Three studies have evaluated the safety and efficacy of selected antiviral agents for the prevention of CMV retinitis (46,192). A multicenter, randomized, double-blind study by the AIDS Clinical Trial Group and the Glaxo Wellcome International CMV Prophylaxis Study Group (53,192), compared valacyclovir 8 g/day with acyclovir 3.2 or 0.8 g/day for prevention of CMV end organ disease. Baseline and semi-annual dilated eye exams were performed. The study was terminated early due to a significant albeit, unexplained, early mortality increase in patients treated with valacyclovir (192). Despite the early termination, valacyclovir was shown to reduce the frequency of CMV end organ disease by 33% (192). CMV retinitis accounted for 79.3% of CMV-related end organ disease and occurred in 9.75% of patients treated with valacyclovir compared to 13.5% of patients treated with acyclovir (192). Oral ganciclovir (1,000mg po tid) was evaluated in two randomized, double-masked, placebo-controlled trials (53). The Roche Bioscience/ Syntex Study 1654 included HIV positive patients with CD4+ T-cell counts less than 100/μL and an AIDS defining opportunistic infection or patients with a CD4+ T-cell count less than 50/μL with positive CMV serology (53). Dilated eye exams were performed at baseline and every two months (53). A 49% reduction in the frequency of CMV retinitis from 39% in the placebo group to 18% in the treatment group was found which was not restricted to patients in the lower CD4+ T-cell group (53). The prophylactic benefit of oral ganciclovir was related to baseline CMV viral load with no benefit identified if the baseline viral load was greater than 50,000 copies/ml (93). The Community Programs for Clinical Research on AIDS (CPCRA) study (Trial 023) included HIV-infected patients with CD4+ T-cell counts less than 100/μL, and positive CMV serology, but no evidence of CMV disease (53). No reduction in the frequency of CMV retinitis was identified in the treatment group (relative risk, oral ganciclovir versus placebo, 0.92); however, patients in the study did not undergo routine dilated eye exams which suggests that the true incidence of retinitis may not have been identified (53). These conflicting results, combined with drug expense, and the low incidence of CMV retinitis in the HAART era have limited the use of primary prophylaxis for CMV retinitis.

Discontinuation of Anti-Cytomegalovirus Therapy While on HAART

The renewed ability of some HAART-reconstituted immune systems to control CMV retinitis effectively and the publication of several case series where anti-CMV agents were successfully discontinued without relapse in patients with immune reconstitution has led to the development of recommendations for when discontinuation of anti-CMV maintenance therapy may be appropriate (4,7,92,247–249). In a review of 41 patients with CMV retinitis and immune reconstitution following HAART, Curi et al. (122) found no CMV retinitis reactivation following discontinuation of maintenance anti-CMV therapy with a mean follow up of 20 months. In the series of Macdonald et al. (249), of 22 patients with immune reconstitution following HAART who discontinued anti-CMV therapy, only three developed recurrent CMV retinitis during the median follow up of 72 weeks. The three patients who had reactivation of the CMV retinitis had simultaneous failures of HAART with CD4+ T-cell count declines to less than 50 cells/μL. Reed et al. (126) and Whitcup (250) similarly found that CMV reactivation in patients on HAART was associated with HAART failure. In the series of Jabs et al. (248) in which 15 patients with CMV retinitis and immune reconstitution following HAART were monitored off maintenance CMV therapy, no CMV relapses were identified during the median follow-up of eight months. Median CD4+ T-cell nadir before stopping HAART was 20 cells/μL and at time of discontinuing CMV maintenance therapy it was 297 cells/μL (248). As a result, some patients who have had immune reconstitution may safely have maintenance anti-CMV therapy discontinued.

The recommendations for discontinuing anti-CMV therapy typically are based on the CD4+ T-cell count, or change in the CD4+ T-cell count, in combination with a time factor (248–250). Absolute CD4+ T cell count alone may not be reliable as previously discussed since it is the existence of memory CD4+ T-cell clones directed against specific antigens that more directly identifies the disease-specific immune reconstitution (251). The U.S. Public Health Service recommends that cessation of maintenance anti-CMV therapy (95) be considered only for patients with an increase in CD4+ T-cell counts to greater than 100–150 cells/μL for three to six months on HAART while other factors such as duration of CD4+ T-cell count rise, location of retinitis, vision in contralateral eye, and ability to continue regular ophthalmologic monitoring are considered as well.

Retinal Detachments

Retinal detachments are a substantial cause of ocular morbidity in patients with CMV retinitis. The prevalence of retinal detachments at the time of diagnosis of CMV retinitis is 3.4–6% (104,252). In one report, the median time from the diagnosis of CMV retinitis to retinal detachment was 10.6 months (31); however, detachment may occur at any time following the diagnosis of CMV retinitis. In retrospective series done prior to the widespread use of HAART, the cumulative probabilities of

retinal detachment at six and 12 months from the diagnosis of CMV retinitis were 11–23% and 24–57% respectively (31,225,252,253). In the prospective FGCRT, the cumulative probability of retinal detachment in at least one eye at six months was 27–28% (104), and in a series of patients with recurrent CMV retinitis treated with the ganciclovir implant, the six month risk of retinal detachment was 23% (225). The rate of retinal detachments in two large prospective trials was 0.28 per person-year (81,192). Of patients with a retinal detachment in one eye, 28–46% develop detachments in the contralateral eye (31,254). As a result, retinal detachment is a common complication of CMV retinitis.

Since the widespread use of HAART, a 60% reduction in the rate of retinal detachments has been reported (227). This reduction has been attributed to improved control of CMV replication by the patient's immune system, increased inflammation producing stronger retinal-retinal pigment epithelial adhesion in areas of retinitis, and/or alterations in the course of posterior vitreous detachments in patients with CMV retinitis on HAART (227).

Risk factors for the development of retinal detachments include peripheral retinitis, extent of retinitis, and the presence of detachment in the contralateral eye (252). The presence of active retinitis may (252), or may not (253) be associated with an increased risk. Freeman et al. (252) reported that the relative risk of retinal detachment in an eye with active retinitis and more than 25% retinal involvement in zones 2 and 3 was over 20 times that of an eye with no activity and less than 5% retinal involvement in zones 2 and 3. Treatment of the CMV retinitis delays development of the retinal detachment (253), and treatment with a ganciclovir implant, despite requiring intraocular surgery, does not increase the rate of retinal detachment when compared to systemic therapy (227).

Retinal detachments associated with CMV retinitis are difficult to repair, but the prognosis for eyes with unrepaired detachments is poor (253,254). The causative retinal breaks are identified at the location of the normal and atrophic retinal areas in 66% of eyes, although the retinal breaks are not identified in 15% of eyes (254). Prophylactic laser has been suggested for small or peripheral detachments. The detachments often progress despite this treatment but the treatment may delay the need for more invasive surgery. Since the median survival following retinal detachment was from 7.6 to 9 months in the pre-HAART era (253,255), with 25% of patients living longer than two years (254), and given the high incidence of contralateral CMV retinitis or retinal detachments, the surgical repair of CMV-associated detachments is indicated.

In the pre-HAART era, the surgical management of retinal detachments associated with CMV retinitis typically required the use of silicone oil, which provided a better tamponade of the areas of necrosis, atrophy, and frequently developing proliferative vitreoretinopathy than did gas (253,254). Retinal reattachment using silicone oil could be accomplished in 70–100% of eyes (254,256,257). Visual acuities of eyes with retinal detachments treated with silicone oil initially had been poor with only 20% of patients achieving ambulatory visual acuity (253); however, as surgical technique and CMV therapy improved, 75–86% of patients could achieve ambulatory visual acuity postoperatively (256,257).

In the HAART era, with the improved control of CMV retinitis, the increased life expectancy of patients, and the corneal complications of silicone oil, attempts to repair CMV-related detachments without the use of silicone oil have been investigated (258). In the study of Canzano et al. (258), retinal reattachment was achieved in 83% and macular reattachment in 100% of six eyes following pars plana vitrectomy, peeling of the posterior hyaloid, laser photocoagulation, scleral buckle placement and intraocular gas tamponade without the use of silicone oil. Mean postoperative visual acuity was 20/40 at a mean follow up of 12 months (258). Thus, improved anti-retroviral and anticytomegaloviral control may allow for improved surgical outcome.

Cataract formation has been one complication of retinal detachment repair, and in the setting of increased longevity due to HAART, surgical repair is indicated. Capsular fibrosis, hyphema, and lens calculation errors have been reported following cataract surgery following CMV related retinal detachment repair (157). Lens power errors have been attributed to differing indices of refraction between silicone oil and vitreous and the attendant alteration of the refractive effect of the back surface of the intraocular lens due to its juxtaposition with the silicone oil (157). Use of convexplano intraocular lenses and modifications of the intraocular lens power formulas have improved postoperative refractive predictability (157).

Immune Recovery Uveitis

Patients with immune reconstitution following HAART have been reported to develop more significant intraocular inflammation, especially vitreous inflammation, than patients prior to HAART (7,8,29,46,259,260). This immune recovery uveitis (IRU), also known as immune recovery vitreitis (IRV), is a potential cause of vision loss in patients with AIDS and CMV retinitis (261). There is as yet no standard definition of immune recovery uveitis with definition variations related to severity of inflammation, loss of vision, symptomatology, level of CMV retinitis activity, and antiretroviral therapy (261).

Immune recovery uveitis is caused by a latent response to intraocular CMV infection in patients who respond to HAART (250,260,262). It does not occur in HAART non-responders or in eyes without a history of CMV retinitis (250,260,262,263). The CMV retinitis does not need to be active to precipitate the inflammation (264). In the series of Zegans et al. (260), vitreous inflammation occurred only in eyes with active or inactive CMV retinitis and not

in contralateral eyes of patients with unilateral CMV disease. In that series, CMV retinitis did not recur following resolution of the inßammation (260) suggesting that the inßammation had some anti-CMV activity. Nussenblatt and Lane (251) suggested that the intraocular inßammation occurs when the expansion of speciÞc CMV CD4+ T cell clones reaches a level at which an inßammatory response can be generated but at which viral protein production continues. The inßammatory response then diminishes once viral protein production ceases. The level of intraocular inßammation may be related to the aggressiveness of anticytomegalovirus therapy, (261) since the less active the infection, the smaller the antigenic load stimulating the immune response. The breakdown of the blood-ocular barrier by the CMV retinitis may facilitate the development of inßammation by allowing migration of inßammatory cells into the eye (263) or by allowing CMV antigen to exit the eye and contact the lymphoid organs (250).

Immune recovery uveitis is common and may occur from one month to several years following the onset of HAART (259,262,263). In the series of Karavellas et al. (262), 63% of 30 patients who responded to HAART developed symptomatic vitreitis with an incidence rate of 0.83/person-years. There were no signiÞcant differences in frequency whether patients with pro-inßammatory cidofovir use were included or not included (262). In the series of Nguyen et al. (265), six (18%) of 33 HAART responders developed IRU with an incidence rate of 0.109/person-year. The Longitudinal Studies of the Ocular Complications of AIDS (LSOCA) (67) reported a frequency of IRU of 15.5% among prevalent cases of CMV retinitis. The cause of the variability of these frequency estimates is uncertain but appears to be due to variable deÞnitions of immune recovery.

Ocular morbidity associated with immune recovery uveitis is high. In the series of Robinson et al. (263) 50% of patients developed a visual acuity of 20/40 or worse in at least one eye and 12% had a visual acuity of less than 20/800 in one eye. Anterior segment complications include cataracts, chronic anterior uveitis, posterior synechiae, and intraocular lens deposits (250,263,266). Severe and/or prolonged intraocular inßammation following cataract surgery in eyes with immune recovery uveitis has been reported prompting the recommendation of aggressive perioperative corticosteroid use (266). Posterior segment complications include proliferative vitreoretinopathy (266), spontaneous vitreous hemorrhage (266), papillitis (250,262,263), optic disc neovascularization (265), vitreomacular traction syndrome (259), cystoid macular edema (250,262,263,265), and epiretinal membrane formation (250,262,263,265,266).

The treatment of IRU often requires topical, regional, and/or oral corticosteroids (46,260). Clinical improvement typically occurs within six weeks of onset. It may resolve without treatment (260), or may develop a chronic course (266). Response rates to treatment are approximately 50%.

Other Opportunistic Infections of the Posterior Segment

Necrotizing Herpetic Retinopathy

Infection of the retina with the varicella-zoster virus has been described (18,267–280). It is the second most common infectious retinitis after CMV at tertiary referral centers (29,268,278), accounting for 4% of ophthalmologic cases in one series (278). The frequency among 1,163 HIV-infected patients at Johns Hopkins was 0.6% (31). Two variants of necrotizing herpetic retinopathy have been identiÞed, acute retinal necrosis (ARN) syndrome, and progressive outer retinal necrosis (268–279).

Acute retinal necrosis is characterized by prominent anterior chamber reaction, marked vitreitis, occlusive retinal and chorodial vasculitis, and full thickness retinal necrosis (273,281). The lesions usually begin peripherally and extend rapidly and circumferentially (273). Pain, optic atrophy and scleritis may be associated (273), and retinal detachment is common (281). Affected patients may have a history of cutaneous herpes zoster occurring either simultaneously with the retinitis or several months before (29,280). The ARN syndrome may occur in both immunologically normal and immune compromised patients and in patients with AIDS it may occur at any level of CD4+ T cell counts.

ARN can be managed successfully with intravenous acyclovir at a dose of 500 mg/M^2 every eight hours for 10 to 14 days (282), and, in patients with AIDS, is followed by long-term suppression with oral acyclovir. Palay et al. (283) reported that treatment with acyclovir reduces the risk of bilateral involvement in immunocompetent patients. Monitoring renal function in patients taking intravenous acyclovir is recommended given the rare complication of acyclovir-induced acute renal failure, which has been attributed to acyclovir crystallization in the collecting ducts and to acute tubular necrosis (284). Luu et al. (285) reported successful management of ARN with adjunctive intravitreal injections of ganciclovir and/or foscarnet in three immunocompetent patients with retinitis refractory to systemic therapy. Ramsay et al. (286) caution that immune recovery alone with HAART may be insufÞcient to control ARN in patients with HIV.

Although VZV is likely the most common cause of clinically deÞned ARN, PCR studies have identiÞed CMV, HSV1, and HSV2 as pathogens as well (29,110,111,287,288). In a retrospective series of 28 cases, Ganatra et al. (111) found that ARN in a patient younger than 25 years more commonly is associated with HSV2 whereas in a patient older than 25, the underlying etiology is likely HZV or HSV1. Prior or concurrent central nervous system involvement in a patient with ARN suggests HSV as a

cause of the inßammation: HSV1 if the patient had encephalitis and HSV2 if the patient had meningitis (111). Some investigators have noted that vascular involvement by HSV1 is typically arteriolar with widespread occlusive disease, whereas the vascular involvement seen with HSV2 is venular and associated with an exudative retinal detachment (287). Whether these clinical differences hold for larger numbers of involved cases remains to be determined.

Unlike ARN, eyes with the progressive outer retinal necrosis variant have much less clinical inßammation. The differential appearance of the two variants of necrotizing herpetic retinopathy is thought related to differences in the degree of immune deÞciency among those at risk (271). Patients with progressive outer retinal necrosis generally have profound immune deÞciency (CD4+ T-cell counts < 50 cells/μL), whereas patients with ARN are often healthier (268,278,288), or even immunologically normal. In the series of Engstrom et al. (268), the median CD4+ T cell count of 38 patients with progressive outer retinal necrosis was 21 cells/μL with only one patient having a CD4+ T cell count greater than 100 cells/μL. As with ARN, patients with progressive outer retinal necrosis often, but not always, have a history of active or antecedent cutaneous herpes zoster (268,271,278).

Progressive outer retinal necrosis is characterized by rapidly progressive multifocal retinal opaciÞcation associated with little or no inßammation (268,270,271,273). Although the patients may present while the process is unilateral, approximately two-thirds will develop bilateral disease (271,277,278). The retinitis often begins in the posterior pole and can involve the optic nerve and vessels (268,270,271). Previously involved retina may have a Òcracked mudÓ appearance due to clearing of necrotic material and edema from around the vessels. Although the diagnosis often can be made on clinical appearance alone, retinal biopsy may be necessary (268,270,271,278).

Numerous medications have been used for the treatment of progressive outer retinal necrosis including acyclovir, ganciclovir (intravenous and intravitreal), vidarabine, foscarnet, and sorivudine alone, and in varying combinations, with inconsistent results (268,271,272,276–279, 289,290). There have been no controlled trials comparing these treatment regimens. Intravenous acyclovir alone usually is not effective. Some authors avoid acyclovir monotherapy given the identiÞcation of acyclovir-resistant varicella zoster virus mutants and that many patients with progressive outer retinal necrosis have had prior acyclovir exposure (268,279). We have had success with combination foscarnet (90 mg/kg twice a day IV induction for two weeks followed by 120 mg/kg/day IV maintenance) and acyclovir (500 mg/M^2 every eight hours IV induction followed by 800mg Þve times a day orally); however, the combination of foscarnet with valacyclovir may reduce the intravenous requirements without sacriÞcing therapeutic efÞcacy. It is unclear whether discontinuation of maintenance therapy may be an option for patients who respond to HAART.

Despite treatment, eyes with progressive outer retinal necrosis often do not do well visually. In one series, 67% of 61 eyes lost light perception within four weeks of diagnosis (268). Treatment did not prevent second eye involvement. Retinal detachment occurs in approximately 70% of involved eyes (268,278). Prophylactic laser photocoagulation has not been shown to be effective at preventing retinal detachments (268,279), possibly due to the posterior location of many of the lesions, although it may preserve vision for several weeks and has been recommended by some investigators (289).

Ocular Toxoplasmosis

Disease due to ocular infection by the protozoan *Toxoplasma gondii* in the pre-HAART era occurred in Western countries in up to 3% of patients with HIV infection (31,278,291). One autopsy series of patients with AIDS reported a frequency of 6% (52). The incidence declined due to widespread use of trimethoprim-sulfamethoxazole prophylaxis for *Pneumocystis carinii* pneumonia and HAART. Seventy-six to 100% of patients with HIV and ocular toxoplasmosis will have AIDS (31,291); the rest will have earlier stages of HIV infection. Correct diagnosis is important due to the high incidence of concurrent central nervous system (CNS) toxoplasmosis. Twenty-nine to 56% of patients with ocular toxoplasmosis have associated CNS toxoplasmosis (31,291), and in one study, the relative risk of CNS disease for patients with ocular involvement was 20 (31). Thus, the diagnosis of ocular toxoplasmosis should prompt neuroimaging in HIV-infected patients (291).

Unlike immunocompetent patients who generally develop ocular toxoplasmosis from reactivation of congenitally acquired infection, patients with HIV may develop ocular toxoplamosis as a primary infection or as a metastatic focus from another source (291–294). Only 4% of HIV patients with toxoplasmic retinitis in one series had retinal scars suggesting local reactivation, and 12% had positive IgM titers suggesting primary infection (291).

The appearance of ocular toxoplasmosis in patients with AIDS is protean, from a pauci- or unifocal homogeneous yellow-white, full-thickness, necrotizing retinitis with ßuffy borders, sheathing and an occasional hemorrhage (51,291,295,296) to a multifocal, Òmiliary Ódeep retinitis. The disease is predominantly unilateral although it can be bilateral (291). Vitreitis and anterior uveitis are common (291), but unlike ocular toxoplasmosis in immunocompetent patients not universal. The presence of signiÞcant vitreitis, anterior uveitis and the lack of granular borders can help to distinguish ocular toxoplasmosis from CMV retinitis, with which it may occasionally be confused (31,295). Patients with ocular toxoplasmosis historically

had higher CD4+ T cell counts than patients with CMV retinitis, typically over 100 cells/μL. Both CMV and toxoplasmosis can coexist in the same eye (31,51,291). The absence of serum antibodies to *Toxoplasma gondii* make the diagnosis of ocular toxoplasmosis unlikely, but their presence does not conÞrm the diagnosis due to the high incidence of these antibodies in the general population (291,295).

Most lesions respond to standard anti-toxoplasma treatment within six weeks (291). Induction regimens have included pyrimethamine, sulfadiazine, and clindamycin (31,291,295,297). Atovaquone, a lipophilic hydroxynaphthoquinone, which selectively inhibits mitochondrial electron transport in protozoa, has shown beneÞt in patients intolerant of standard treatment (296,298), but can be associated with a non-visually signiÞcant vortex keratopathy (299). Unlike ocular toxoplasmosis in immunocompetent patients, systemic steroids are not needed in patients with HIV and ocular toxoplasmosis (297). As with other infections in patients with HIV, unless there is immune reconstitution, long-term maintenance therapy generally is required to prevent relapse of the disease. The best maintenance therapy for ocular toxoplasmosis in patients with AIDS currently is unknown, but any of the antibiotics effective against toxoplasmosis may be tried. In one retrospective series, the 24-month relapse rate was 0.18Ð0.20 for patients maintained on pyrimethamine and either sulfadiazine or clindamycin (291). We have successfully maintained patients on pyrimethamine and sulfadiazine or clindamycin alone (31).

Intraocular Cryptococcal Infection

Intraocular infection with *Cryptococcus neoformans* is rare, and in the pre-HAART era, occurred in less than 1% of patients with AIDS (31), 2.5% of patients with systemic cryptococcosis (300), and 6.25% of patients with cryptococcal meningitis (301). Autopsy series have reported higher frequencies (22,51). The primary site of cryptococcal infection is the lung; however, hematogenous dissemination to the eye can occur (300). Case studies have identiÞed cryptococcal lesions of the choroid which clinically appear deep, hypopigmented or yellow-white and range from 1/5 to 1 disc diameter in size (300,301). They can be unifocal or multifocal and bilateral (51,301,302) and generally are distinguishable from *Pneumocystis carinii* choroiditis; however, they may be difÞcult to distinguish from other infectious choroiditides. A less commonly identiÞed clinical appearance is that of a ÒcloudyÓ choroiditis in which the choroidal lesions are larger, more blotchy, and have the appearance of clouds (303). Histopathologically, the lesions involve the choriocapillaris and inner choroidal vessels (51). One clinicopathologic study described a cryptococcal iris mass with anterior uveitis and trabecular inÞltration (302). Treatment of cryptococcal infection usually requires amphotericin B, ßuconazole, or itraconazole. Choroidal granulomata have been shown to decrease in size and fade with adequate treatment (300,301). Late pigmentation can occur (300).

Other Fungal Infections

Several fungal pathogens have been identiÞed clinically and in autopsy series. One autopsy series has identiÞed isolated cases of choroidal infection with Candida sp., *Histoplasma capsulatum*, and *Aspergillus fumigatus* (51); however, these infections rarely are identiÞed clinically. Candida has been identiÞed in the choriocapillaris in a multifocal distribution with several organisms extending through Bruch's membrane (51). Candida retinitis and/or endophthalmitis has been reported clinically in patients with AIDS but the frequency in the pre-HAART era was less than 1% (16). *Histoplasma capsulatum* has been identiÞed in scleral vessels (304), the optic nerve (305), choroidal vessels (51,304,305), all layers of the retina (305), the ciliary body (305), trabecular meshwork, and Schlemm's canal (304). Case reports of disseminated bilateral chorioretinitis due to *Histoplasma capsulatum* do exist but are rare (26,305,306). The chorioretinal lesions have been described as creamy-white 1/6Ð1/4 disc diameter in size with distinct borders and occasionally tan halos (305). Some may have surrounding hemorrhage (305). Glasgow et al. (195) reported a case of bilateral endogenous endophthalmitis from *Fusarium*.

Bacterial Infections

Syphilis

Syphilis is the most common intraocular bacterial infection in patients with HIV infection (29,307Ð310). Ocular involvement can occur in patients at any stage of HIV infection (290) and can be the Þrst manifestation of HIV disease (311). Ophthalmic disease associated with syphilis was the presenting sign of HIV in four of the nine patients in the series of McLeish et al. (310); however the true frequency is likely signiÞcantly lower. Conventional syphilis staging is unrewarding in patients with ocular syphilis (312).

All parts of the eye can be affected by *Treponema pallidum*. Anterior segment involvement can include episcleritis (311), scleritis (311), interstitial keratitis (311), granulomatous or non-granulomatous keratic precipitates (311,312), and iridocyclitis (310). Elevated intraocular pressure on presentation occurs in only 4% of eyes (312). Posterior segment complications include vitreitis (isolated or in association with other intraocular inßammation) (311,313), chorioretinitis (313), sectoral retinochoroiditis (312), retinitis (310), serous retinal detachments (311,312), neuroretinitis (310), acute retinal necrosis

(313), retinal vasculitis (313), posterior placoid retinitis (313), and pseudoretinitis pigmentosa (313). Neuro-ophthalmic manifestations include papillitis (310), optic perineuritis (310), papillary light-near dissociation (311), and retrobulbar optic neuritis (310).

Controversy exists regarding the indication for lumbar puncture in patients with ocular syphilis (312); however, we recommend lumbar puncture since, if positive, a post-treatment lumbar puncture can be used to conÞrm therapeutic success (311). In the series of McLeish et al. (310), six of nine patients had neurosyphilis, and when the authors added their cases to other published reports, 15 of 19 patients with ocular syphilis had CNS involvement.

Syphilis in association with HIV coinfection may cause signiÞcant morbidity (214,314). In addition, serologic testing may be unreliable (310,315). Haas et al. (315) reported that the sensitivity of the treponemal tests (FTA and MHA-TP) dropped from 93% in patients with asymptomatic HIV infection to 62% in patients with symptomatic HIV infection. In BrowningÕs (312) series of nine patients with HIV and ocular syphilis, the range of RPR titers was 1:1 to 1:2,048 with a median titer of 1:128. Fourteen per cent of patients in BrowningÕs series (312) had a negative non-treponemal study, and up to 75% of patients with ocular syphilis have been reported to have a negative venereal disease research laboratory (VDRL) study (312). Despite the limitations of conventional treponemal and non-treponemal tests, they are likely the most commonly used method for screening. Polymerase chain reaction (PCR) studies are not widely available and require intraocular specimens to make an ocular diagnosis.

Ocular syphilis associated with HIV coinfection generally is treated with 12Ð24 million units of aqueous penicillin daily for 10Ð14 days (310,314). Less aggressive regimens are ineffective (312); and primary treatment failures can occur even with this regimen (313). In the series of Ormerod et al. (313) neurosyphilis dose treatment failures were managed with a second course of the IV penicillin followed by three weekly intramuscular injections of benzathine penicillin. Other agents have been used in patients with penicillin allergies such as tetracycline, erythromycin, and chloramphenicol; however, desensitization with penicillin followed by neurosyphilis level dosing should be considered (310,312).

Miscellaneous Bacterial Infections

Like *T. pallidum*, other bacteria can infect the eye, typically as a result of hematogenous spread in the setting of systemic infections (316). One case documents endogenous *Staphylococcus aureus* endophthalmitis from bacteremia from the intravenous catheter used to administer ganciclovir for CMV retinitis (136). Metastatic choroidal abscesses from *Staphylococcus aureus* have been reported in a patient with AIDS who succumbed to severe bilateral polymicrobial infectious pneumonitis (317). Mycobacterial infection of the choroid with *M. avium* complex or *M. tuberculosis* has been demonstrated at autopsy (22,26,50Ð52). One case report describes a white non-tuberculous choroidal granuloma with an associated exudative retinal detachment and iridocyclitis that responded to clofazimine, ciproßoxacin, ethambutol and amikacin (52). Unusual bacterial retinitis has been reported in two patients with AIDS (318). The bacteria were identiÞed morphologically on an endoretinal biopsy specimen but not in culture and responded to tetracycline therapy. Overall, these infections are rare, occurring in less than 1% of patients with HIV in the pre-HAART era (31).

Pneumocystis carinii Choroiditis

Choroidal infection with the unicellular *Pneumocystis carinii* is uncommon, occurring in less than 1% of patients with AIDS (31) in the pre-HAART era but accounting for 22% of infectious choroidopathies identiÞed in one autopsy series (51). First described by Rao et al. in 1989 (319), several additional series subsequently have been reported (319Ð322). Most, but not all, patients with *Pneumocystis carinii* choroiditis have a history of *Pneumocystis carinii* pneumonia (PCP) (31,321). Eighty-six percent of patients with *Pneumocystis carinii* choroiditis in one series had received aerosolized pentamidine for PCP prophylaxis (321). *Pneumocystis carinii* choroiditis may be the initial or only sign of disseminated *Pneumocystis carinii* infection (320).

Clinically, the lesions are 1/3 to 2 disc diameters in size, creamy-white, round or oval, and located at the level of the choroid (Fig. 26.4) (319Ð321). They are usually multifocal and bilateral, although they can be unilateral and unifocal (321,322). They are usually found in the posterior pole or midperiphery but not anterior to the equator (321). Some

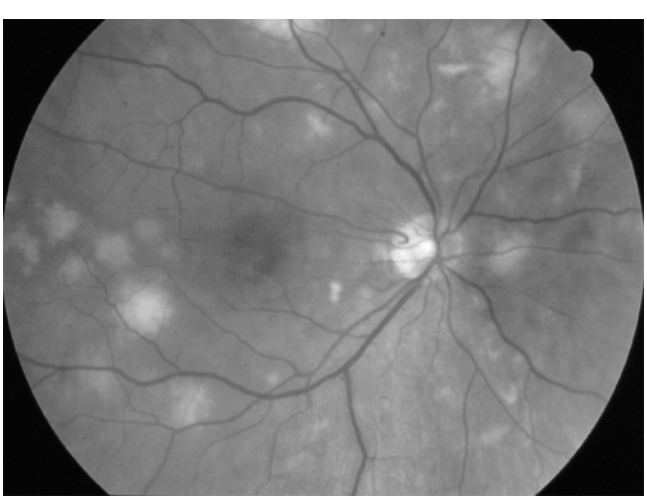

FIG. 26.4. Pneumocystis choroiditis in a patient with AIDS.

can become confluent and appear multilobulated (319). The retinal pigment epithelium is normal although it can be mottled or appear granular if the lesion is large (319). There is no associated vitreitis. The lesions are generally asymptomatic (319,321), although patients may complain of blurry vision (320). Pathologically, an eosinophilic, amorphic, acellular, foamy infiltrate is identified in the inner choroid and choriocapillaris (51,319,321). Organisms can be identified with electron microscopy (319). *Pneumocystis carinii* choroiditis often responds to systemic trimethoprim/sulfamethoxazole, pentamidine, or dapsone, alone or in combination (320–322). Atovaquone has been used for pulmonary pneumocystosis, however, its role for the management of ocular involvement remains to be determined (299). Lifelong maintenance historically has been needed to prevent recurrence, however, with the advent of HAART, such continued treatment may not be needed. It has been recommended that maintenance therapy be continued at least until the patient's CD4+ T-cell count has been higher than 200 cells/μL for at least three to six months (95).

Other Ocular Infections

Herpes zoster ophthalmicus

Herpes zoster ophthalmicus (HZO), a vesiculobullous dermatitis caused by varicella-zoster virus, was reported to occur in approximately 3% of patients with AIDS and 4% of patients with earlier stages of HIV infection in the United States in the pre-HAART era (31). The process typically involves the distribution of the ophthalmic branch of the trigeminal nerve alone; however, in patients with HIV infection, up to 29% can have involvement of multiple dermatomes simultaneously (323). Zoster *sine herpete* in which there is no observable dermatomal involvement, has been reported (323,324).

Ocular complications occur in 49% of patients with HZO and HIV infection and can involve all portions of the eye (31). Corneal involvement can be either epithelial or stromal and occurs in approximately 20% of patients with HIV and HZO (323). The stromal keratitis can be disciform, non-disciform, or manifest as avascular stromal infiltrates (323). An uncommon but particularly painful chronic infectious pseudodendritic epithelial keratitis is characterized by elevated, gray, pleomorphic pseudodendritiform lesions distributed over the corneal, limbal, and conjunctival epithelium which stain intensely with rose bengal but only moderately with fluorescein (323,324). In the series of 16 patients reported by Chern et al. (324), the interval between onset of herpes zoster and keratitis ranged from 0 days to 6 years. Most of the patients had a history of herpes zoster ophthalmicus; however, two patients had thoracic zoster alone, two had no history of a rash, and one had primary varicella infection. The diagnosis of chronic infectious pseudodendritic keratitis can be made by culture, direct fluorescent antibody testing, or polymerase chain reaction (324). The latter two methods have been reported to be more sensitive (324). Antiviral agents are usually effective against the process. Intravenous foscarnet has been used successfully to control the chronic infectious pseudodendritic keratitis; however, discontinuation of therapy was associated with relapse (323). For patients with chronic infectious pseudodendritic keratitis, pain is a prominent feature and pain management is typically the most important issue. Other complications of HZO include blepharitis, conjunctivitis, ischemic optic neuropathy, encephalitis, and a post-infectious, chronic pain syndrome, post-herpetic neuralgia (29,325).

In the series by Margolis et al. (323), mild or no ocular involvement was seen in 31% of 48 patients HIV infection and HZO. Ocular involvement in the remaining patients took the form of iritis (50%), stromal keratitis (35%), conjunctivitis (21%), elevated intraocular pressure (6%), chronic infectious pseudodentritic keratitis (4%), necrotizing retinitis (4%), post-herpetic neuralgia (4%), scleritis (2%), and eyelid scarring (2%). Four percent of patients in the series developed central nervous system involvement (323). A relationship between CD4+ T-cell count and specific ocular complications has not been identified (323).

In appropriate populations, HZO in a young man may be a marker for HIV infection (326–328), even without other manifestations of HIV. In immunocompetent patients, HZO can be treated successfully with oral acyclovir (329). The dose most commonly used is 800 mg five times daily. In immunocompromised patients, the initial treatment is often with intravenous acyclovir at a dosage of 500 mg/M^2 every eight hours followed by oral maintenance therapy of 800 mg three to five times per day (29). This form of therapy decreases the incidence of ocular side effects.

Alternative agents for HZO include valacyclovir and famciclovir, which have the advantage of less frequent dosing (330). Valacyclovir, a L-valine ester of acyclovir, has been shown to have excellent oral bioavailability and similar efficacy to acyclovir with respect to ocular complications of keratitis, uveitis, and episcleritis, time to lesion healing, and pain for patients with HZO (331). Famciclovir (Famvir) is an oral prodrug of penciclovir, a nucleoside deoxygaunosine analog, with excellent bioavailability (332). The bioavailability of penciclovir (following oral administration of famciclovir) is 77% compared to the oral bioavailability of acyclovir of 10–20% (332). Following phosphorylation by viral and cellular thymidine kinases, penciclovir triphosphate inhibits viral DNA synthesis (332). Penciclovir is eliminated in the urine, requires dose adjustment for patients with renal disease, and has an excellent safety profile. Side effects include headache (similar frequency as placebo), abdominal discomfort, elevated serum lipase, and hyperbilirubinemia, however, there have been no cases of thrombotic

thrombocytopenic purpura (TTP) or hemolytic uremic syndrome (HUS) as has been a concern with valacyclovir at doses of 2 grams qid, much greater than the 1 gram tid dose used for HZO. The use of intravenous foscarnet for induction and maintenance may be considered in patients that do not respond to acyclovir or famciclovir.

Infections of the Anterior Segment

Other ocular infections reported in patients with AIDS include infectious keratitis (29,333,334), microsporidial keratoconjunctivitis (335–338), and molluscum contagiosum (339,340).

Bacterial, viral, and fungal corneal infections have been reported in HIV-infected patients, and although for most pathogens the infection rates among patients with and without HIV infection appear similar, patients with HIV infection may have more severe involvement (341). The frequency of Herpes simplex virus keratitis has not been shown to be more common in HIV-infected patients than the general population; however, when it does occur, it may be atypical, more severe, and take longer to heal (325,341).

Microsporidial keratoconjunctivitis is caused by ubiquitous eukaryotic obligate intracellular protozoa of several species of the Microspora phylum (337,338,342–345). Of the five genera, Nosema and Encephalitizoon are the only two known to cause ocular disease, specifically *Encephalitizoon hellum*, *Encephalitizoon cuniculi*, *Nosema corneum*, and *Nosema ocularum* (337,338,342–345). The mode of infection is unclear, however, direct inoculation such as from trauma or poor hygiene has been suggested (345).

In patients with HIV, the microsporidial ocular appearance is characterized by a fine to coarse corneal punctate epitheliopathy with associated conjunctival hyperemia and papillary conjunctivitis and is usually caused by *Encephalitizoon* species (345). Superficial stromal infiltrates and conjunctival fluorescein staining are inconsistent findings. In contrast, immunocompetent patients typically develop ulcerative keratitis with deep stromal involvement usually in association with *Nosema corneum* (341,345). Symptomatically, patients report foreign body sensation, dryness, epiphora, photophobia, and decreased vision.

Although it is difficult to culture microsporidia, the diagnosis can be made by identifying the intra-cellular, oval, organisms with Gram (positive), Giemsa (341,346), periodic acid-Schiff (345), Grocott-methenamine silver (345), acid-fast (345), and Weber modified trichrome stains (344), and confocal microscopy (343). Speciation can be accomplished by transmission electron microscopy (345) or immunocytochemistry (341,342,344). Microsporidial infection also can occur in the lungs, sinuses, urogenital, renal, and gastrointestinal tracts as well as in bone (341,342). Agents with activity against this parasite include fumagillin, itraconazole, and propamidine isethionate (341–344). An oral benzimidazole, albendazole, has shown inconsistent efficacy (341,342,344–346). Martins et al. (347) reported one case of microsporidial keratoconjunctivitis in a patient with HIV that was effectively managed with HAART consisting of indinavir, lamivudine, and stavudine but no specific anti-microsporidial agents. Penetrating keratoplasty was curative in at least one immunocompetent patient with deep stromal involvement following the failure of medical therapy (345).

Molluscum contagiosum, a highly infectious pox virus, is capable of producing multiple small umbilicated lesions on skin and mucous membranes. It occurs on the eyelids of up to 5% of patients with HIV (29,341,348). The process is more severe in patients with HIV infection, but unlike in immunocompetent patients, it typically does not produce a follicular conjunctivitis or superficial keratitis when involving the eyelid (29). Cryotherapy, curettage, excision, incision, and topical chemotherapy are therapeutic (29,341).

Cryptococcus neoformans has been described in one case report by Coccia et al. (349) as a cause of an eyelid nodule in a patient on HAART. Surgical excision of this papular lesion allowed histologic identification of the encapsulated saprophytic yeast (349). Waddell et al. (350) described a case of a 6×10 mm conjunctival mass mimicking a squamous cell carcinoma which similarly was identified histopathologically as caused by *Cryptococcus neoformans* (350). In this patient, the conjunctival mass led to the subsequent identification of systemic cryptococcosis.

OCULAR NEOPLASMS

Kaposi's sarcoma is a vascularized tumor of skin and mucous membranes possibly associated with human herpesvirus 8 (29,341). In the pre-HAART era, ocular involvement was reported in 2% of patients with AIDS. Of patients with AIDS and Kaposi's sarcoma, 15–22% (26,351) had ocular involvement. Either the eyelids or the conjunctiva may be involved. The lesions are typically painless and may mimic a subconjunctival hemorrhage or chalazion (29). Dugel et al. (352) have correlated the histological and clinical appearances of these lesions. They identified a continuum of features from thin dilated vascular channels with flat endothelial cells to densely packed spindle cells depending on the size, shape and duration of the lesion.

Conjunctival Kaposi's sarcoma (Fig. 26.5) usually does not require treatment. The lesions are slowly growing, do not invade the eye and often do not compromise vision. When removal is necessary, small, early lesions of the conjunctiva do well with surgical excision with a clear margin of 1–2 mm (353). Larger, older lesions of the conjunctiva often recur with simple excision (353). Eyelid involvement by Kaposi's sarcoma may require therapy if it causes functional problems with the eyelid. Some lesions of the eyelid can be treated with cryotherapy; however,

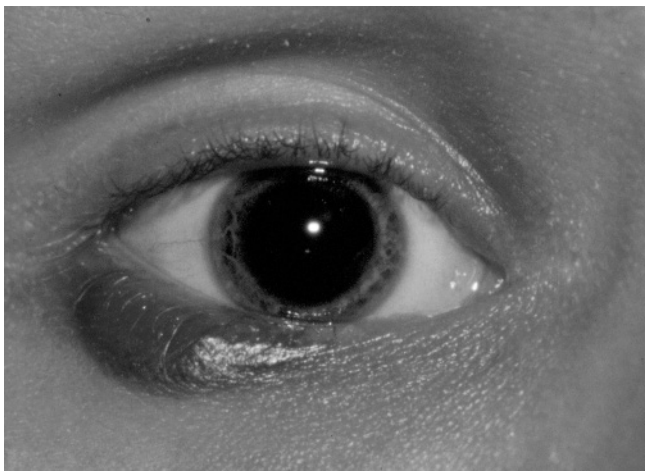

FIG. 26.5. Kaposi's sarcoma of the lower eyelid in a patient with AIDS.

others may require radiation therapy (341,353). Intralesional vinblastine (29) or interferon alpha (341) may prove a viable option for conjunctival and lid involvement. Systemic or extensive disease may require chemotherapy with doxorubicin hydrochloride, bleomycin sulfate, and vinblastine sulfate alone or in combination (351). Local therapy should be deferred for patients undergoing chemotherapy for systemic involvement until the response of the ocular adnexal lesions is known (351,353). HAART alone has been reported to produce spontaneous and sustained remission of Kaposi's sarcoma (341).

In patients with HIV infection, high grade lymphoma is an AIDS defining disorder (354). Orbital involvement by lymphoma has been reported (26,355), but even in the pre-HAART era it occurred in less than 1% of patients with AIDS (26). Intraocular malignant large cell lymphoma (356,357), primary eyelid, and conjunctival non-Hodgkins lymphoma (341) also have been reported, but are uncommon. Other neoplastic lesions identified in patients with HIV include squamous cell carcinoma, conjunctival intraepithelial neoplasia, and basal cell carcinoma (341).

NEURO-OPHTHALMIC LESIONS

In the pre-HAART era, neuro-ophthalmic lesions were reported in 6–8% of patients with AIDS (26,31). These lesions included cranial nerve palsies, papilledema, optic neuropathy, hemianopsias, and cortical blindness (26,291,300,310,358–365). The most common etiology for neuro-ophthalmic lesions was cryptococcal meningitis, accounting for 54% of the neuro-ophthalmic lesions reported in one series (26,31,300). Of patients with AIDS and cryptococcal meningitis, 25% had neuro-ophthalmic lesions on careful ophthalmologic examination (31). Papilledema occurred in 31% of patients with cryptococcal meningitis (300). Disc elevation without hemorrhage, focal blurring of the disc margin or loss of the cup are the rule in 84% of patients with cryptococcal meningitis and papilledema according to Kestelyn et al. (300). Visual loss from cryptococcal meningitis occurs in 1–9% of patients (300,365). This loss may occur from direct invasion of the optic nerve by *C. neoformans*, elevated intracranial pressure, or adhesive arachnoiditis (365).

Other causes of neuro-ophthalmic lesions in patients with HIV include herpes zoster ophthalmicus, toxoplasmosis, syphilis, viral encephalitis (29,364), other opportunistic infections, progressive multifocal leukoencephalopathy associated with JC polyomavirus, and CNS lymphoma. *Histoplasma capsulatum* was cultured from the optic nerve sheath of a patient with optic neuritis (366).

HIV may be responsible for some cases of optic neuritis or optic neuropathy. Case reports of optic neuropathies in the setting of HIV infection but without other identified cause have been described by Sweeney et al. (367) and Newman and Lessell (368). Tenhula et al. (369) found that optic nerves from patients with AIDS but no associated ocular opportunistic infections have 42% fewer axons than those from age matched controls without AIDS. Quiceno et al. (370) found that patients with AIDS and no ocular opportunistic infections had deficits in Farnsworth-Munsell 100-hue color vision testing and in contrast sensitivity compared to controls without AIDS. In addition, Plummer et al. (371) found that patients with HIV have an increased frequency of localized visual field defects and an increased mean defect on perimetry compared to age-matched healthy controls. Whether these findings are related to the cumulative effect of nerve fiber layer infarcts from AIDS retinopathy or due to a direct effect of HIV on the optic nerve or CNS is unknown (369,370). Subtle ocular motility defects also can be detected in patients with AIDS by eye movement recordings using infrared oculography (360,361). These defects include slowed saccades, fixational instability, and abnormal pursuit and appear to be more directly related to HIV infection than to opportunistic ocular or neurological infections. They may correlate with the severity of the AIDS-dementia complex.

DRUG RELATED OCULAR EFFECTS

Several drugs used to treat HIV and its complications have been associated with adverse ocular effects. Clofazimine, an iminophenazine dye with antimicrobial activity used to treat *M. avium* complex infection, has been associated with pigmented corneal verticillata and in one case a bull's eye maculopathy (372). Dideoxyinosine (didanosine), a purine nucleoside analogue used to treat HIV-1, was reported to cause well-circumscribed areas of RPE atrophy in three of 43 children in one study (373). No such toxicity has been reported in adults treated with this agent. Intravenous and intravitreous cidofovir has been associated with hypotony and intraocular inflammation

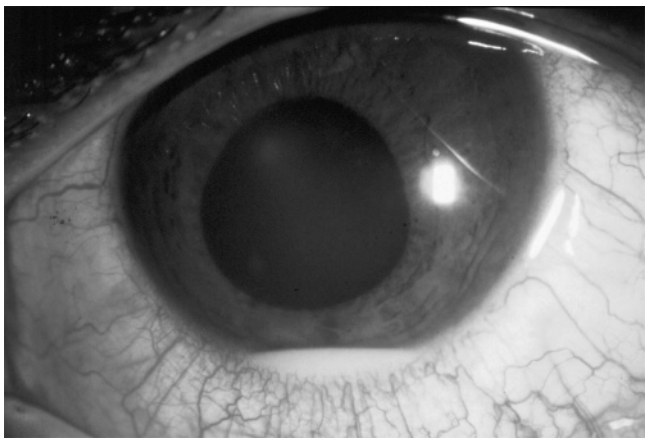

FIG. 26.6. Hypopyon secondary to rifabutin use in a patient with AIDS.

(29,212). Ganciclovir and acyclovir have been reported to be associated with the development of a corneal epitheliopathy due to the accumulation of lipid vacuoles and lipid containing inclusions in the corneal and conjunctival epithelial cytoplasm in two patients (374). Whether one, both, or the combination of these two agent(s) is responsible is unclear; however, dose reduction or discontinuation of the agents has led to resolution of the process. Atovaquone used in the treatment of Toxoplasmosis and *Pneumocystis carinii* pneumonitis has been associated with subepithelial corneal deposits and vortex keratopathy which may or may not affect vision (29,298,299,341). Rifabutin, an antimycobacterial agent, has been linked to the development of fulminant anterior uveitis which can mimic infectious endophthalmitis (Fig. 26.6) (375–381). Two of nine subjects in one study who developed a symmetric polyarthralgia/polyarthritis syndrome while taking 1,800 mg/day or more of rifabutin also developed acute anterior uveitis (379). Twenty-three of 59 patients randomized to receive rifabutin 600 mg/day, clarithromycin 1,000 mg twice a day and ethambutol 15 mg/kg/day for treatment of MAC infection as part of the MAC Study Group of the Canadian HIV Trials Network developed iridocyclitis (380). The process can be unilateral or bilateral with 55–100% of patients presenting with a hypopyon (375,378). The use of concurrent ßuconazole and/or clarithromycin has been suggested as a factor in the onset of this condition due to the inhibition of the hepatic microsomal cytochrome P-450 system by these agents which has the pharmacokinetic effect of raising serum levels of rifabutin (375,378,381). Reports of rifabutin-associated uveitis occurring in patients with iatrogenic immunosuppression and in patients with no immunosuppression suggests that HIV infection is not a prerequisite for this drug-related complication (381,382). Dose reduction, drug discontinuation, with or without topical steroids often is effective. Drugs associated with ocular toxicity used in non-immunosuppressed patients, such as ethambutol, are likely to have similar toxicity proÞles in patients with HIV infection.

MISCELLANOUS OCULAR INVOLVEMENT

HIV has been isolated from the tears (383,384), conjunctiva (383,384), cornea (385–387), aqueous and vitreous of patients with HIV infection (388–392). As such, all potential material for corneal transplantation is screened for the presence of HIV infection, and all infected material not transplanted. Whether viable virus can be aerosolized during laser corneal refractive surgery is under investigation. Hagen et al. (393) were unable to infect tissue culture plates from the plume generated following excimer laser photoablation of a culture plate infected with pseudorabies virus, a porcine herpesvirus similar to HIV, and suggested that photoablation of HIV infected human corneas during photorefractive keratectomy (PRK) and laser *in situ* keratomileusis (LASIK) is unlikely to pose a health hazard to the surgeon. Nonetheless, HIV infection is considered a contraindication to laser eye surgery by at least one laser manufacturer. Due to the potential presence of HIV in tears, it is recommended that ophthalmologists performing eye exams utilize appropriate universal precautions (394).

HIV-associated keratoconjunctivitis sicca has been reported to occur in 10–20% of patients with HIV infection (29,341). Potential causes include direct involvement of HIV with the lacrimal gland, accessory lacrimal glands, or conjunctiva, abnormal blink reßex due to encephalopathy or ocular surface tumors, abnormal tear composition, and drug-related side effects (29,341). Treatment with artiÞcial tear drops or ointments, punctual occlusion, and management of contributing eyelid abnormalities is appropriate.

Anterior uveitis has been identiÞed in HIV-infected patients with intraocular infections such as cytomegalovirus, varicella-zoster, *Toxoplasma gondii*, *Treponema pallidum*, bacterial, and fungal infections (29,106). One autopsy report identiÞed cytomegalic and acute inßammatory cells in the iris stroma of a patient with HIV suggesting that CMV can cause a direct infectious anterior uveitis (106). As discussed previously, some patients taking rifabutin or cidofovir develop intraocular inßammation (29). Cases of HIV-associated uveitis, which responded to treatment with zidovudine have been reported (389,392), however, this process appears to be an infrequent occurrence, and was not related to immune recovery uveitis since they did not involve HAART, immune reconstitution, or CMV retinitis. Cases of immune uveitis associated with systemic conditions such as ReiterÕs syndrome may be more common in patients with HIV infection (29,341).

Levinson et al. (395) described an inßammatory syndrome consisting of multifocal retinal inÞltrates, and mild

anterior chamber and vitreous cellular reaction in 50 eyes of 26 patients with HIV infection, none of whom received HAART. Clinical or angiographic retinal vascular sheathing and keratic precipitates were inconsistent findings. The retinal lesions were irregular, poorly-demarcated, gray-white or yellow, less than 200 μm in diameter, and located in the midperipheral or anterior retina. The lesions remained stable in size or slowly enlarged over a period of months and were felt to respond to zidovudine but not acyclovir or ganciclovir. Infectious causes of multifocal retinitis were excluded, however, HIV was cultured from the vitreous of one patient. Whether this syndrome is caused by direct HIV infection, an associated autoimmune phenomenon, or some other cause remains to be determined. Profound immunosuppression was not a prerequisite for this relatively benign condition since the median CD4+ T-cell count among affected patients was 272 cells per μL with a maximum count of greater than 2,000 cells per μL in one patient.

Cases of other uncommon ocular complications have been reported in patients with HIV infection, but whether these complications were of higher frequency than in the general population remains to be determined (341, 396–398).

Chapter 27

General Pathology of HIV Infection

James L. Finley, Vijay V. Joshi and Nancy L. Smith

Since the initial cases of what was subsequently labeled as acquired immunodeÞciency syndrome (AIDS) (1,2), pathologic diagnosis of the major indicator diseases, opportunistic infections and neoplastic disorders according to the Centers for Disease Control (CDC) deÞnition of AIDS (3), has played a major role in recognition of the syndrome. In addition to diagnosis of known lesions, new or previously undescribed lesions were also recognized in biopsy material from AIDS patients (e.g. pulmonary lymphoid lesions in children with AIDS, bacillary angiomatosis of skin). Similarly, autopsy studies on fatal cases of AIDS extended the clinical spectrum by demonstrating involvement of clinically unsuspected organs by opportunistic infections and neoplastic disorders. Familiarity with the clinical spectrum of AIDS and dissemination of information regarding its various clinicopathologic Þndings had reached a plateau with respect to new or unsuspected pathologic observations about the infectious and neoplastic complications of AIDS. With longer patient survival due to effective antiretroviral drug treatment, in conjunction with prophylactic and supportive therapies, a variety of processes have been identiÞed for which the pathogenesis is obscure, though clearly associated with human immunodeÞciency virus (HIV) infection (i.e. nephropathy, cardiomyopathy, arteriopathy, etc.). We are also seeing examples of tissue damage associated with toxic reactions to different drugs, with diagnostic and therapeutic procedures, and with the chronic debilitating disease process of AIDS. Thus, pathologic lesions seen in patients with AIDS are broadly classiÞed into three major categories (4): (1) primary lesions directly due to HIV infection itself (lymphoreticular system and brain); (2) associated lesions due to direct or indirect sequelae of HIV infection (opportunistic infections due to defective cell-mediated immunity, iatrogenic lesions, lesions associated with chronic debilitation disease); and (3) lesions of undetermined pathogenesis (cardiomyopathy, nephropathy, arteriopathy, etc.). Finally, it is recognized that many lesions are the result of more than one pathogenic mechanism and are modiÞed by attempts to inßuence the disease process with chemotherapy or immunotherapy.

Most pathology reviews of this subject have employed either an organ systems approach or have concentrated on speciÞc infections and neoplasms. As the pathology of diseases associated with AIDS represents a broad spectrum of lesions affecting virtually all tissues and organs, we have endeavored to integrate both approaches to avoid redundancy and stress important clinicopathologic correlations.

The Þrst sections in this chapter address the diagnosis of AIDS-related opportunistic infections in cytology and biopsy material by use of both conventional and more recently described immunologic and molecular methods. This is followed by an overview of common neoplasms and some of the poorly understood complications of the disease. Pathology of the nervous system and skeletal muscle in HIV infection, which is described in a separate chapter, is excluded. The pathology of AIDS in children emphasizes characteristic lesions of this age group and highlights important similarities and differences as compared with adults. The chapter concludes with a discussion of the risks of nosocomial transmission of HIV and recommendations to laboratory personnel on procedures to prevent mucosal and parenteral exposure to infectious agents.

GENERAL ASPECTS OF THE PATHOLOGY OF AIDS

Because of the profound deÞciency in cell-mediated immunity, the pathologic lesions related to infections in AIDS patients have certain unusual features. The lesions tend to be larger than usual (e.g. molluscum contagiosum of skin); the inßammatory reaction is minimal or absent

James L. Finley: AfÞliation
Vijay V. Joshi: AfÞliation
Nancy L. Smith: AfÞliation

(e.g. cryptococcosis); granuloma formation is indistinct or absent (e.g. *Mycobacterium avium-intracellulare* (MAI) infection); lesions contain large numbers of organisms (e.g. MAI); infection with two or more organisms may involve the same site (e.g. *Pneumocystis carinii*, cryptococcal and cytomegalovirus (CMV) pneumonitis); necrotizing lesions may be present (e.g. CMV lesions in gastrointestinal tract or adrenal glands); and wide dissemination of organisms (e.g. *Pneumocystis carinii* infection) may occur. Concerning neoplastic lesions, malignant lymphomas are usually of high grade and occur more frequently in extranodal sites. Similarly, HIV-related Kaposi's sarcoma is clinically distinct from the endemic form and often shows wide cutaneous dissemination, early visceral spread, and incomplete brief response to therapy.

DIAGNOSIS OF AIDS-RELATED OPPORTUNISTIC INFECTIONS

Opportunistic infections are the most common initial manifestations of AIDS, and the etiologic diagnosis of these infections is generally made through examination of tissue biopsies or through cytologic techniques. Many of these organisms either cannot be cultured (e.g. *Pneumocystis carinii*) or require several days for positive culture results. Therefore, morphologic identiÞcation of the etiologic agents of infections is of prime importance in these patients. Besides the routine histologic procedures, immunologic and molecular biologic methods can be used as ancillary diagnostic techniques.

Cytologic Specimens and Techniques for Diagnosis of Infectious Diseases

The rapidity with which a diagnosis can be rendered is one of the major strengths of cytologic techniques. Respiratory specimens (bronchial washings, brushings, transtracheal aspirates, and bronchoalveolar lavage), Þne-needle aspiration biopsies, cerebrospinal ßuid, effusions, and gastrointestinal brushings are the principle sources of material for diagnostic cytologic studies in these patients. The more common respiratory cytopreparatory methods include the Saccomanno technique, cytocentrifugation, thin-layer, and membrane Þltration. Most specimens are received in the Þxed state due to their infectious nature, but fresh material gives laboratory personnel greater ßexibility if ancillary techniques, such as immunocytochemistry or molecular diagnostic methods, are to be employed. From cerebrospinal ßuid and effusions, slides are prepared from cytocentrifuged material or membrane preparations. For gastrointestinal brushings, direct smears are usually employed. Attention to the precautions outlined later in this chapter make the cytopreparatory techniques safe.

Fine-needle aspiration biopsy (FNAB) has assumed an important role in the diagnosis of opportunistic infections and neoplasms in AIDS patients. Aspiration biopsy of superÞcial lesions is easily performed using a 22 or 25-gauge needle attached to a 20-ml syringe. Percutaneous FNAB of deep lesions is generally performed by a radiologist using a 22-gauge Chiba needle employing ultrasound, computerized tomography (CT), or ßuoroscopic guidance. Smears are prepared by spreading the material over a small area with another slide (similar to the preparation of a bone marrow aspirate) and some are air-dried and some are alcohol-Þxed. The rapid staining and interpretation of air-dried smears using a modiÞed Wright-Giemsa stain (Diff-Quick, Baxter, Healthcare Corp.) determines the adequacy of a specimen and can often provide prompt information to clinicians, in addition to identifying those cases requiring more material for ancillary studies such as immunohistochemistry, culture, electron microscopy, and ßow cytometry. FNAB is also an excellent source of material for bacterial, fungal, or viral cultures. Alcohol-Þxed smears are stained by a modiÞed Papanicolaou technique.

From the sources described above, a variety of special stains are selectively employed to detect microbiologic organisms. These include Gomoris methenamine silver (GMS) for fungi, Nocardia, and *Pneumocystis carinii*, periodic acid-Schiff (PAS) for fungi; mucicarmine to demonstrate the capsule of cryptococcus; modiÞed Ziehl-Neelsen, Fite or Kinyoun for mycobacteria; Brown-Brenn and Brown-Hoff for bacteria; Giemsa for certain protozoans; and Dieterle for Legionella. Calcoßuor white, a nonspeciÞc ßuorochrome with afÞnity for chitin and cellulose, has been used to delineate fungal elements and cysts of acanthamoeba in clinical specimens (5,6). While not widely utilized, ßuorescence microscopy performed on Papanicolaou-stained material can identify several genera of fungi such as Aspergillus, Blastomyces, Histoplasma, Cryptococcus, and Coccidioides that demonstrate autoßuorescence (7). The choice of Þxed or unÞxed material employed for immunocytochemistry, immunoßuorescence, and DNA probe studies for microbiologic organisms must be tailored to the particular antibody or probe.

Surgical Biopsy Specimens

The most common surgical biopsy specimens for diagnosis of infections and neoplasms in AIDS patients are those from lung, lymph nodes, alimentary tract, skin, liver, bone marrow, and brain. The proper handling of this material is dependent on the disease process suspected. Frozen section examination plays a pivotal role by allowing the pathologist to triage the specimen for appropriate diagnostic studies in a timely and cost-effective manner similar to that provided by an immediate examination of an FNAB specimen. Recognition of an infectious process in a frozen section of lung or lymph node would prompt submitting tissue for appropriate

microbiologic cultures, molecular biology studies, and preparing touch imprints or frozen sections for histochemical stains. If a neoplastic process were suggested, routine light microscopy could be supplemented with immunocytochemical studies, cytogenetics, and ßow cytometry.

Immunologic and Molecular Biologic Procedures in the Diagnosis of Infectious Agents

When traditional methods fail to establish an unequivocal diagnosis, newer immunologic and molecular biologic procedures may improve recovery rates and detect fastidious organisms. These include immunoperoxidase and immunoßuorescence methods, RNA/DNA hybridization, and molecular diagnostic techniques. Commercially available polyclonal and monoclonal antibodies can be used to detect a variety of antigens and infectious agents including many fungi, viruses, bacteria, and protozoa (8). DNA/RNA hybridization techniques identify speciÞc microbial DNA or RNA sequences in tissue sections, smears, or culture specimens (9). Commercially available probes useful in AIDS include those to Epstein-Barr virus, cytomegalovirus, mycobacteria, Legionella, Campylobacter, herpes simplex virus, and HIV (8Ð14). Polymerase chain reaction results in the rapid replication of target DNA sequences providing dramatic improvement in sensitivity. Because of the extreme sensitivity of this technique, control studies are essential and specimen/reagent contamination must be meticulously avoided. A wide variety of infectious agents, including mycobacteria, cytomegalovirus, Epstein-Barr virus, *Pneumocystis carinii* and HIV have been detected using this method (15Ð19). A case of HIV infection occurring in 1959 was identiÞed by using this technique in the DNA extracted from paraffin blocks of autopsy tissues in a 25-year-old sailor (20).

IMPORTANT OPPORTUNISTIC INFECTIONS IN AIDS PATIENTS

Parasitic Infections

Pneumocystis carinii

Pneumocystis carinii (PC) pneumonia is an important indicator of severe immunodeÞciency due to HIV infection and is a criterion for the diagnosis of AIDS as deÞned by the Centers for Disease Control (CDC) (3). Since 1987, there has been a signiÞcant decrease in the incidence of PC pneumonia as an initial AIDS-deÞning diagnosis among HIV-infected homosexual men, which is most likely due to increasing use of chemoprophylaxis for PC prior to the onset of AIDS (21). Despite the decreased frequency of PC infections in these patients, it does remain a common cause of death in AIDS (22). While PC infections are most commonly conÞned to the lungs, an increasing number of patients with extrapulmonary spread, including widely disseminated disease, are being reported (23Ð27). Resistance to sulfonamide therapy has been detected in some cases of PC infection. Mutations in dihydropteroate synthetase genes of PC have been identiÞed which are responsible for this sulfonamide resistance. These mutations may develop following exposure to sulfa drugs and have been found to be a poor prognostic factor in PC pneumonia (28).

Although traditionally classiÞed as a sporozoan protozoal parasite, recent molecular biological and ultrastructral studies have demonstrated that PC is more closely related to fungi than to protozoa (26). There is homology of mitchondrial DNA and ribosomal RNA in PC and fungi, and a gene found exclusively in fungi, translation elongation factor 3 gene, has also been demonstrated in PC (29). The organismÕs natural reservoir and life cycle are poorly understood. Current studies support four stages in the life cycle: precyst, cyst, sporozoites within cysts, and freestanding trophozoites (30,31). The cyst, presumed to be the proliferative form, contains up to eight small, nucleated structures termed sporozoites. After rupture of the cyst wall, sporozoites are released and mature into trophozoites, the vegetative form. Large trophozoites develop into precysts, which undergo further maturation to cysts containing sporozoites.

PC has been recovered from a large number of animal species as well as humans (32). Serologic investigations in humans imply that many infections are acquired early in childhood (33) and disease develops through reactivation of latent infection. Alternatively, de novo infections probably also occur and transmission is by the aerosol route (34,35).

Diagnosis

Pulmonary specimens including induced sputum, bronchial washings and brushings, bronchoalveolar lavage, FNAB, transtracheal aspirate, transbronchial biopsy, and open lung biopsy are used for diagnosis. However, with the recognition of disseminated pneumocystosis, FNAB and surgical biopsies of tissues from a variety of sites are also employed. In our experience and from a number of studies, bronchoalveolar lavage has shown the greatest sensitivity in the diagnosis of lung infections when compared with other noninvasive methods. Bedrossian (36), in reviewing 17 studies comparing various techniques, reported yields of 83% for transbronchial biopsy, 82% for bronchoalveolar lavage, and 53% for washing and brushing cytology. When bronchoalveolar lavage is combined with other methods such as bronchial washings and brushings, diagnostic yields approach 100%. Open lung biopsy and transbronchial biopsy remain the gold standard but are rarely necessary to secure a diagnosis. Spontaneous and induced sputum yield the worst results as compared with other methods. CT-guided FNAB is usually reserved

for focal or cavitary lung lesions (37) but may also have a role in the evaluation of pediatric patients (38).

Staining Methods

While the Grocott or GMS stains are the most commonly used methods, Gram-Weigert, PAS and toluidine blue also detect the cyst wall. Sporozoites and trophozoites are best demonstrated with Diff-Quick, cresyl violet, Giemsa, May-Grunwald-Giemsa, PAS, and Wright-Giemsa stains (39–41). The cyst wall stains can be used to evaluate tissue sections, imprints, and cytology specimens, whereas the trophozoite/sporozoite stains are applicable only on imprints and cytology specimens. We utilize the GMS stain with a microwave modiÞcation and have found this to be the single best method as it can be rapidly performed and has the advantage of staining other pathogens such as fungi, bacteria, and the cytoplasmic inclusions of cytomegalovirus (42). With this stain, cyst forms are spherical, crescentic, or cup-shaped and measure 5–7 μm in diameter. Single or paired capsule dots correspond to the internal capsular thickening seen ultrastructurally. Ghali et al. (43) have shown ßuorescence of the cysts in Papanicolaou-stained material when it is examined under UV light.

Other methodologies for detection of PC in cytology specimens and tissue biopsies include immunoßuorescence and immunoperoxidase techniques (44–46). Genomic DNA fragments of PC have been used as probes in the Southern blot technique and ribosomal RNA sequences employed as probes for in situ hybridization (47,48). PCR appears to be a speciÞc and sensitive method for detection of PC in HIV-infected patients (19). While antibody and probe techniques have been shown to be speciÞc, demonstrating little or no cross reactivity with common fungi, bacteria, or parasites, they offer few advantages over traditional staining methods.

Histopathologic Features

As compared with sporadic and endemic forms, AIDS-associated PC lung infections generally show less interstitial widening and lymphoplasmacytic inÞltrate and more atypical features (49). The pattern of reaction also differs from that described in animal models in which cortisone and low protein diet are used for immunosuppression (50). The characteristic and speciÞc feature is a foamy refractile intra-alveolar exudate in which variable numbers of organisms are demonstrated with the cyst wall stains (Fig. 27.1). This is accompanied not infrequently by nonspeciÞc features including diffuse alveolar damage with hyaline membrane formation, hyperplasia and atypia of type II pneumocytes, and sparse septal inßammation. Less common manifestations include epithelioid granulomas, giant cell formation, necrotizing bronchopneumonia,

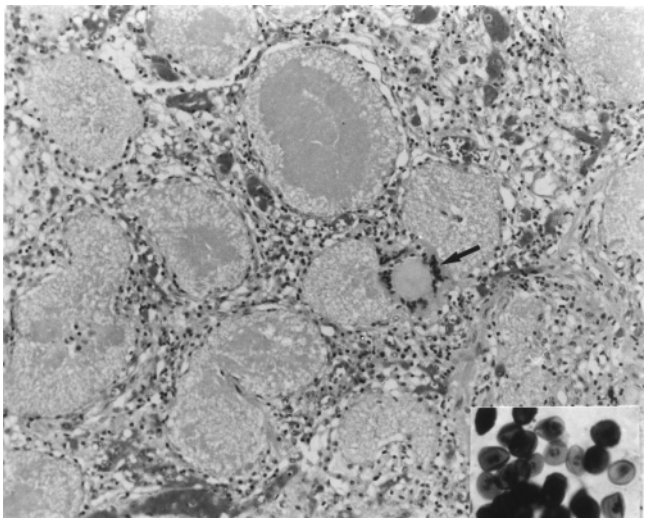

FIG. 27.1. *Pneumocystis carinii* pneumonitis characterized by foamy alveolar exudate and mild interstitial mononuclear cell in ltrate. Giant cell reaction (arrow) is an unusual feature (hematoxylin and eosin, × 100). Inset: GMS stain demonstrating cup-shaped and spherical cysts with dot-like or double comma-shaped capsule thickenings (Gomori's methenamine silver, × 1,000).

interstitial Þbrosis, a desquamative interstitial pneumonitis like pneumonia, pneumothorax with pleural spread of PC, and cavitary lesions showing central necrosis (37, 51–59). In a study of 123 lung biopsies from 76 AIDS patients with PC pneumonitis, Travis et al. (51) additionally noted (in a small percentage of patients) parenchymal cysts, interstitial microcalciÞcations, vasculitis, and vascular permeation by PC; the latter Þnding was also described by Liu et al. (54) and was suggested as a possible mechanism for dissemination. The characteristic alveolar inÞltrate was not present in 19% of PC-positive biopsies, emphasizing the importance of performing special stains in the absence of typical features (51). Concomitant polymicrobial infections with a variety of viruses, fungi, and bacteria are common. The cysts of PC are cleared slowly in patients treated for acute PC pneumonia, with cysts still detectable in sputum of 76% of patients three weeks after diagnosis (at the time of completion of therapy), and cysts detectable in 24% of patients 6 weeks after diagnosis (60).

Extrapulmonary Spread

An increasing number of extrapulmonary infections, including widely disseminated disease, are being reported (23–27,61). In a study by Telzak et al. (24), 2.5% of patients with AIDS showed evidence of extrapulmonary PC infection. There is an increasing incidence of extrapulmonary PC (21,62). The most common extrapulmonary site of spread is the lymph node; however, involvement of bone marrow, spleen, liver, GI tract, pancreas, palate, pericardium, thymus, central nervous system, ear and eye

have also been reported. These patterns suggest lymphatic and hematogenous spread, but the risk factors for dissemination are not well understood. Rarely, patients with AIDS may present with extrapulmonary disease without a documented lung infection (24, 63). Sites of involvement in this setting have included spleen, thyroid, external auditory canal, middle ear, and skin. The histopathology of extrapulmonary PC infections is generally similar to that described in typical pulmonary disease. Frothy eosinophilic exudates containing numerous cysts and trophozoites are usually associated with necrosis and scant inßammatory inÞltrates.

Toxoplasma gondii

Transmission of *Toxoplasma gondii* (TG) to humans occurs primarily by ingesting oocysts from cat feces or by eating meat that contains tissue cysts (64). When the oocysts are ingested by secondary hosts (possibly all mammals), the organisms excyst, cross the bowel wall, and invade cells of many organs. Before immunity develops, they divide rapidly, giving rise to tachyzoites in a pseudocyst that eventually Þlls the cell, ruptures it, and enters contiguous cells. In chronic and latent infections, bradyzoites develop slowly and form within true cysts.

Toxoplasmosis is the most common opportunistic infection of the central nervous system in AIDS. Toxoplasmosis is the presenting/index AIDS diagnosis in up to 51% of HIV-infected patients (65). The overall incidence of clinical toxoplasmosis among AIDS patients with neurological disease is about 30% and it is particularly common in Haitian patients with AIDS (66). Toxoplasmosis appears to represent reactivation of latent infection rather than primary infection, as serologic studies have shown detectable toxoplasma IgG antibodies in patients several months prior to development of clinical disease (67).

Chorioretinitis is an infrequent manifestation, but may appear associated with or independent of encephalitis (68). Extraneural toxoplasmosis has been reported in the heart, lungs, testis, and skin of AIDS patients with concurrent central nervous system (CNS) disease (69Ð72). In autopsy studies, the organisms have been detected in many other organs, including stomach, adrenals, skeletal muscle, and pancreas, but infections in these sites are usually of little clinical signiÞcance (73,74).

Diagnosis and Histopathology

The primary method of diagnosing toxoplasmosis is by demonstrating the tachyzoites and cysts in clinical specimens including ßuids, smears, and tissue biopsies. While serologic studies are considered reliable in the normal host, in an immunocompromised individual they play a limited role in establishing the diagnosis of acute infection. Even with severe toxoplasmosis, it is unusual for AIDS patients to demonstrate positive IgM titers or appropriate four-fold increases in IgG titers (73). However, the absence of antibodies against TG is strong evidence against a diagnosis of toxoplasmosis (75). Methods to detect TG antigens (dot-blot and enzyme-linked immunosorbent assay (ELISA)) are under investigation and may prove more reliable than antibody tests (76,77). TG antigen can be detected by PCR in specimens such as CSF (65). TG can also be detected in peripheral blood specimens using indirect immunoßuorescence in cell culture systems (78).

TG visualized in ßuids, tissue imprints, and histologic sections show the characteristic crescentic or oval tachyzoites, pseudocysts, and true cysts. In Giemsa or Wright-stained material, the tachyzoite cytoplasm stains blue and the eccentric nucleus appears dark red. The organisms are small, measuring 3Ð4 μm in length and 1Ð2 μm in width. They are generally broader at the end containing the nucleus. Cysts are variable in size, measuring up to 40 μm in diameter and contain numerous tightly aggregated bradyzoites surrounded by a thin eosinophilic membrane that is weakly positive with silver and PAS stains (Fig. 27.2). Organisms may be more easily demonstrated with a commercially available immunohistochemical stain for TG (79). The lack of a kinetoplast and the presence of a distinct nucleus differentiate TG from Leishmania and *Trypanosoma cruzi* (80).

The gross and microscopic pathology of TG infection, which is described in another chapter devoted to the central nervous system pathology of HIV infection, will be brießy reviewed here since TG can produce lesions outside the CNS. In the brain, the principle microscopic features are a diffuse meningoencephalitis or a focal necrotizing encephalitis with associated arteritis and thrombosis (81, 82). Tachyzoites and cysts can be demonstrated in brain tissue surrounding areas of necrosis although organisms may not be seen in over 50% of cases.

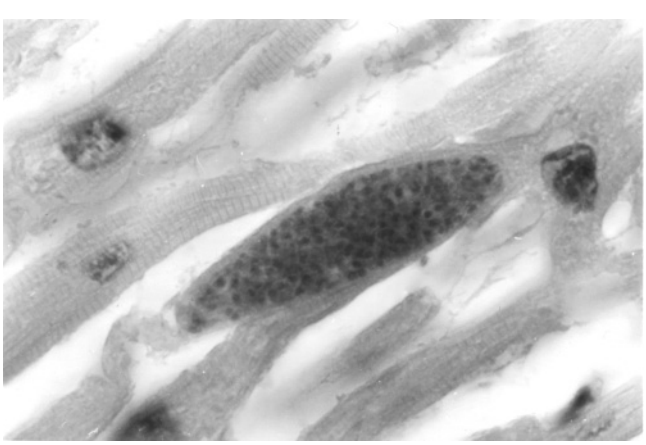

FIG. 27.2. Chronic myocardial infection with *Toxoplasma gondii*. Elongated cyst contains numerous tightly aggregated bradyzoites unassociated with in ammation (hematoxylin and eosin, × 200).

Ocular toxoplasmosis often produces a granulomatous inßammatory reaction of the retina and choroid, which is in part related to a hypersensitivity reaction. There may be retinal necrosis with hemorrhage and vascular thrombosis. The parasites may be numerous or difÞcult to demonstrate (83).

Toxoplasma pneumonitis shows a variable histology often consisting of an interstitial and intra-alveolar inÞltration by mononuclear cells of a focal or diffuse nature. Abundant tachyzoites are usually demonstrable (69).

Involvement of many other organs such as heart, liver, adrenal gland, and stomach has been documented in AIDS patients with these lesions usually showing focal necrosis and variable numbers of organisms and inßammatory cells (73,74). Rarely, tachyzoites can be found in peripheral blood smears (Figs. 27.3aÐc).

Cryptosporidia and Other Protozoa

Cryptosporidium, a sporozoan parasite taxonomically related to Toxoplasma, Isospora, and Plasmodium species, has become recognized as a common cause of enteritis in the immunocompromised host (84Ð89). The life cycle of Cryptosporidium is similar to other coccidia in that asexual and sexual stages lead to production of oocysts that are released into the gastrointestinal tract and discharged in the feces. The organism gains access to humans through inhalation or ingestion and thus can be sexually transmitted through the oral-fecal route (90,91). As the oocysts are resistant to most common disinfectants, strict hand washing and enteric precautions are necessary to prevent nosocomial transmission.

In the United States, cryptosporidia infects approximately 5% of HIV-infected men (92). Cryptosporidia is found in the stool of 10Ð20% of patients with AIDS associated diarrhea (93), while in African patients with enteropathic AIDS, they are implicated in up to 48% of cases (94). These infections can involve the entire gastrointestinal tract from esophagus to rectum (84,95). Less common sites of infection include gallbladder, pancreas, biliary and pancreatic ducts, and respiratory tract (87,88,96,97). The biliary and pulmonary forms have been

described almost exclusively in the immunocompromised host.

Diagnosis of cryptosporidiosis is usually based on fecal examination or small intestinal biopsy, but in our experience, the parasite can also be recognized in cytology preparations of small intestinal aspirates or brushings (98) (Fig. 27.4). The organisms are readily detected in the stool by a Kinyoun modiÞed acid-fast stain in which 4Ð5 μm bright red oocysts are present in background fecal material (99,100). The acid-fastness allows differentiation from yeast (100). As oocyst excretion can be sporadic, multiple stool examinations are sometimes necessary. In infections shedding low numbers of organisms, concentrating techniques such as SheatherÕs sucrose or zinc sulfate ßotation improve rates of detection. A speciÞc and sensitive direct immunoßuorescence method has been described and can be used on smears and parafÞn-embedded tissue sections (101).

In small intestinal mucosal biopsies, histologic changes do not correlate well with the degree of infection or clinical symptoms. Small intestinal villi exhibit mild atrophy and a nonspeciÞc increase in lamina propria chronic inßammation. The diagnostic feature in hematoxylin and eosin-stained sections is the presence of basophilic organisms located along the brush border or within parasitophorous vacuoles (86) (Fig. 27.5). Organisms are best demonstrated with the Giemsa or Gram stains and are inconsistently positive with the Kinyoun acid-fast stain in tissue sections (86,102). Cryptosporidia are differentiated from Isospora by their smaller size and location along the brush border.

Cryptosporidial infections of the gallbladder and extrahepatic biliary tree are observed in up to 10% of AIDS patients and present as acalculous and rarely gangrenous cholecystitis (87). The gallbladder shows luminal exudates and ulceration, and as in other sites, the organisms are visible lining the mucosa. Liver biopsies reveal pericholangitis and organisms attached to the epithelium of large bile ducts (97). Respiratory tract infections are less well characterized and probably result from aspiration of gastroduodenal material. Cryptosporidia are demonstrated lining bronchiolar epithelium associated with mild chronic inßammation (88). About one-third of patients with cryptosporidiosis have other gastrointestinal pathogens including herpes, Candida, cytomegalovirus, Mycobacterium, Giardia, *Entamoeba histolytica*, Shigella, and Salmonella (103).

Isospora belli, a protozoan related to the Cryptosporidium species, is an uncommon pathogen in AIDS patients in the United States only being found in approximately 2% of patients with AIDS-related diarrhea (93). *Isospora belli* is found in approximately 10% of patients with AIDS and diarrhea in Brazil, and in 12% of such patients in Zaire and Haiti (93). Clinical manifestations closely resemble those of cryptosporidial infection, most commonly chronic or relapsing enteritis (104,105). Diagnosis is made by demonstrating oocysts in stool or duodenal aspirates with the Kinyoun acid-fast or auramine-rhodamine stains (113, 114). Concentration methods similar to those described for Cryptosporidium enhance recovery and identiÞcation (104). In small intestinal mucosal biopsies, the organisms are seen in an intracellular location within clear vacuoles (106). Giemsa and PAS stains with diastase pretreatment enhance the ability to identify the organism (107). In gastrointestinal infection, Isospora may disseminate to regional lymph nodes and rarely to extraintestinal lymph nodes (lymphadenopathic isosporiasis) (104,107).

Only a limited number of human microsporidial infections have been recognized in AIDS patients, usually associated with gastrointestinal involvement or sinonasal

disease (108Ð112). The predominant clinical manifestations of these infections are weight loss, chronic diarrhea, or refractory sinusitis (110). Microspordia are found in 6Ð50% of patients with chronic diarrhea and AIDS (93). Small intestinal biopsy is currently the best method to demonstrate the organisms (111). They appear as small refractile bodies in a supranuclear location in epithelial cells of the villi. While difficult to visualize in hematoxylin and eosin-stained sections, some species are variably gram and Giemsa-positive and acid-fast (113,114). Electron microscopy has been used diagnostically and ultrastructural characteristics allow species identification (108,112). These organisms have also been reported to infect other tissues including liver, peritoneum, and skeletal muscle (109).

Other protozoan parasites including Leishmania, *Giardia lamblia*, *Blastocystis hominis*, and *Cyclospora cayetanensis* have also been infrequently reported to cause enteric infections in AIDS (115Ð118).

Fungal Infections

Fungal infections have been recognized as important AIDS-related opportunistic infections dating from early clinical reports. Initially, mucosal candidiasis and cryptococcosis were identified as the most prominent AIDS-related opportunistic pathogens while histoplasmosis and coccidioidomycosis were recognized much less frequently. While this trend still holds true today, in certain endemic locations, histoplasmosis and coccidioidomycosis are now being diagnosed with increasing frequency. Other fungi reported less commonly in these patients include Aspergillus, Sporothrix, Alternaria, Zygomycetes, and the superficial/deep dermatophytes.

Detection

Fungal serologic tests, with the exception of cryptococcal antigen testing and histoplasma antigen testing, are generally not useful in making a specific diagnosis of fungal infections, and culture methods may require extended periods of time, so direct microscopic examination of clinical specimens plays an important role in the management of AIDS patients providing prompt and useful information to clinicians.

In our laboratory, cytology preparations from fluids, smears, or FNAB are initially stained with the Papanicolaou technique and a modified Wright-Giemsa (Diff-Quick) stain. We have found the GMS and PAS stains in combination with Calcofluor-white to be the best general purpose fungal stains. In the microbiology laboratory, prompt handling of freshly collected specimens and use of a battery of enriched culture media with and without antibiotics are essential for recovering pathogenic fungi. Table **27.1???** outlines the characteristic morphologic features of fungi seen in clinical specimens discussed in this section.

Candida

Candida is a genus of yeast that is a well-recognized cause of mucocutaneous and invasive disease in patients with AIDS. Oral and esophageal candidiasis, the most common fungal infections in HIV-infected patients, are often the first indications of advancing immune dysfunction (119,120).

Oral candidiasis occurs as four distinct clinical variants: (1) pseudomembranous; (2) erythematous; (3) hyperplastic; and (4) angular cheilitis (121,122). The pseudomembranous type is the most frequent variant and presents as small yellow patches often on the tongue and buccal mucosa. Scrapings of these lesions contain epithelial cells mixed with necrotic debris, inflammatory exudates, and fungi consisting of yeast and pseudohyphae (Fig. 27.6).

Gastrointestinal candidiasis most frequently involves the esophagus but is also commonly seen in the stomach and to a lesser extent the small and large intestine (123). In AIDS patients, esophageal candidiasis almost always coexists with oral candidiasis (124). The clinical diagnosis is made by esophagoscopy, in which the characteristic white patches overlay inflamed mucosa. Endoscopic biopsy demonstrates yeast and pseudohyphae within the epithelium. Positive culture alone from biopsy specimens is not definitive evidence of infection (because the microorganism is part of the normal oral flora).

While oral and esophageal candidiasis is extremely common in patients with AIDS, systemic Candida infections are less frequently encountered. Recently, however, because of the more widespread use of indwelling catheters and parenteral hyperalimentation, increasing

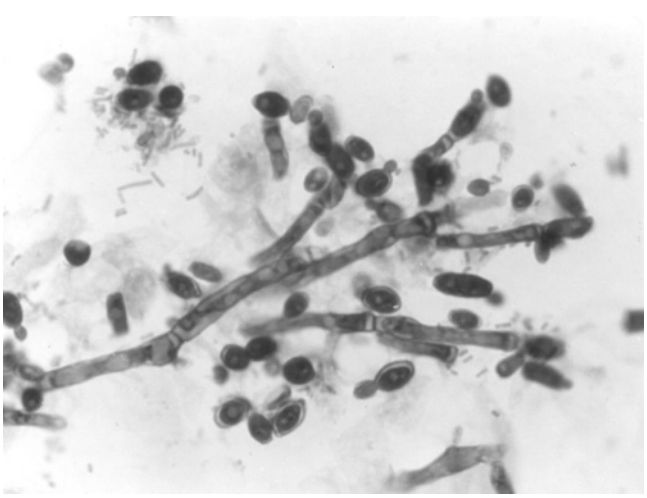

FIG. 27.6. Candida in esophageal brushing. Pseudohyphae and budding yeast differentiate this from other fungi (Papanicolaou, × 400).

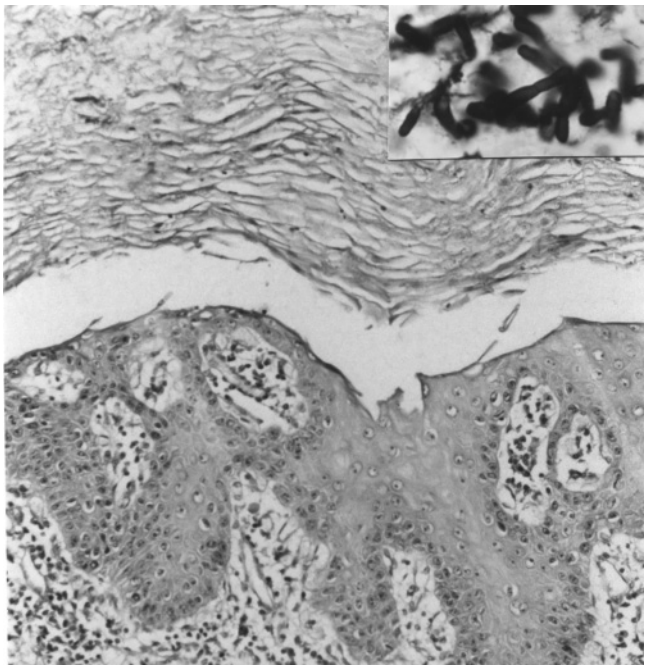

FIG. 27.7. Candida esophagitis, hyperplastic type. Hyperkeratotic layer above epithelium contains numerous yeast and pseudohyphae (hematoxylin and eosin, × 200). Inset: GMS stain demonstrating pseudohyphae and budding yeast (Gomori's methenamine silver, × 400).

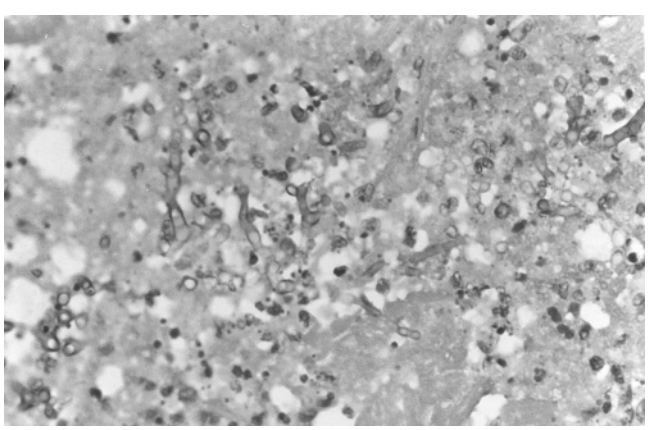

FIG. 27.8. Necrotizing candida pneumonitis. Pseudohyphae admixed with brin and in ammatory cells in destroyed lung parenchyma (hematoxylin and eosin, × 250).

numbers of reports of candidemia have appeared. Depending upon the cause and mechanism of entry, candidemia may spontaneously resolve, or the patient may succumb to overwhelming sepsis or develop visceral candidiasis. Widespread visceral dissemination usually involves the central nervous system, kidneys, heart, bone, skin, and lung (Fig. 27.8) (125–128). Unusual cutaneous presentations of mixed infections include coexistent Candida within lesions of molluscum contagiosum and Candida with herpes simplex (129).

Cryptococcus

Cryptococcosis is the fourth most common infection in AIDS patients after *Pneumocystis carinii*, cytomegalovirus, and mycobacterial disease (130). This life-threatening opportunistic infection is observed in between 5% and 10% of AIDS patients in the United States and has three major clinical presentations of disease: CNS, pulmonary, and disseminated infection (131,132). As many as 10–20% of patients with cryptococcosis have cutaneous involvement (papules, pustules, nodules, in ltrative plaques, ulcers, bullae, and cellulitis) as a component of disseminated disease, although there are reports of isolated cutaneous infection in the absence of systemic involvement (133). The vesicular and ulcerative forms may be mistaken for a herpetic infection or pyoderma gangrenosum, respectively, while the umbilicated papules may resemble molluscum contagiosum (134,135). Rarely, cutaneous lesions can clinically mimic Kaposi's sarcoma (136). Disseminated infections frequently involve lung, lymph node, adrenal gland, skin, and kidney (137,138). Unusual manifestations of systemic infections include myocarditis, massive peripheral and mediastinal lymphadenopathy mimicking malignant lymphoma, isolated pleural effusion, and biliary tract obstruction secondary to cryptococcal lymphadenitis (139–142). Simultaneous infections with other opportunistic organisms including *Pneumocystis carinii* in the lung and Toxoplasma in the brain have been found in up to 13% of cases (131,138,143). Cryptococcus has also been reported within lesions of Kaposi's sarcoma (144).

Diagnosis

The diagnosis of cryptococcosis requires isolation of the organism from body uids, biopsy demonstration of the encapsulated yeast, or detection of the polysaccharide capsular antigen in serum or cerebrospinal uid (CSF).

In cytology specimens such as CSF, bronchial washings and lavage, and joint uid, the diagnosis is made by identifying the 4–6 μm in diameter yeast with doubly refractile cell walls, a distinctly outlined capsule, and narrow based budding. Organisms are highlighted by the PAS or methenamine silver stains. The mucicarmine stain, speci c for the mucopolysaccharide capsule, and the characteristic variability in size, distinguish cryptococcus from other fungi.

The India ink method, in which nigrosin or India ink is added to CSF (or other body uid) and examined by light microscopy, is a commonly used technique to detect Cryptococcus. While the method is simple, the test suffers from poor sensitivity and requires strict attention to criteria for identi cation, as encapsulated forms of *Klebsiella pneumoniae*, Rhodotorula, Candida, and Prototheca can be confused with Cryptococcus. It is preferable to utilize routine cytologic stains supplemented by methenamine silver, PAS, and Mayer's mucicarmine stains to

establish the diagnosis. Although not unique to AIDS patients, recent reports have suggested that poorly encapsulated or capsule-deÞcient strains may be more commonly isolated from AIDS patients (145,146). Capsule-deÞcient strains can be presumptively identiÞed by demonstrating a melanin-like substance in the cell wall with a Fontana-Masson stain (147).

The reaction to cryptococcus in the skin has been classiÞed as gelatinous or granulomatous, but both reaction patterns may be seen in the same lesion. The gelatinous type shows numerous organisms surrounded by abundant capsular polysaccharide and little inßammation (Fig. 27.9). The granulomatous lesion shows fewer Cryptococci, predominantly in an intracellular location with greater inßammation consisting primarily of lymphocytes, histiocytes, and occasional giant cell (148).

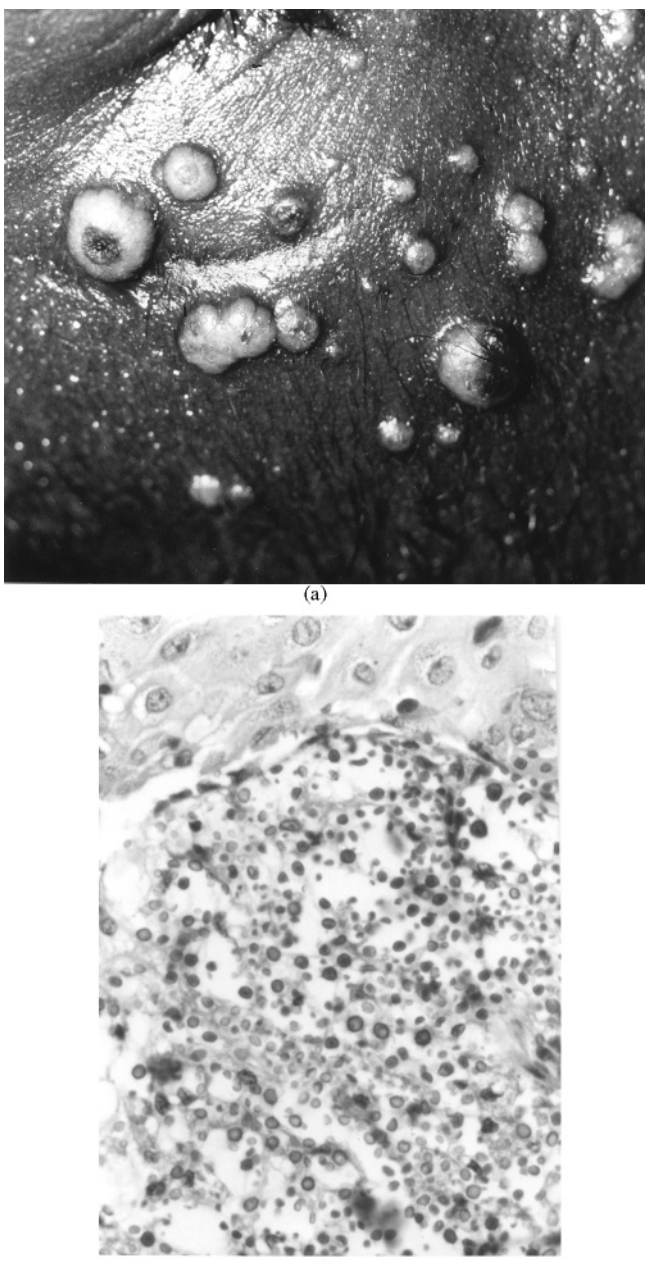

FIG. 27.9. a: Cryptococcus of skin: Multiple umbilicated nodules involving the face. b: Skin biopsy demonstrating gelatinous dermal reaction. Numerous organisms surrounded by abundant capsular material with a paucity of in ammation (PAS, × 250).

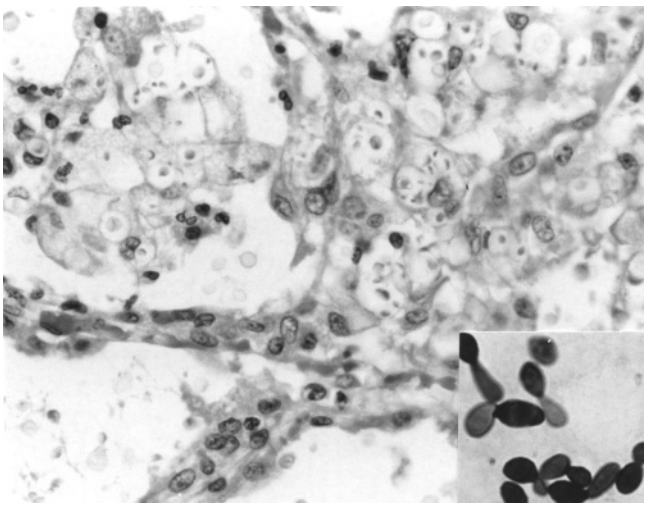

FIG. 27.10. *Cryptococcus neoformans* in lung. Organisms within alveoli and interstitium demonstrate characteristic variability in size, surrounding clear zones occupied by mucopolysaccharide material and narrow based budding (inset) (hematoxylin and eosin, × 250). Inset: (Gomori's methenamine silver, × 1,000).

In transbronchial lung biopsies, a variety of histopathologic abnormalities can be seen. Most commonly, fungi are present in an interstitial location with minimal accompanying inßammatory inÞltrate (Fig. 27.10). There may also be alveolar invasion and rarely vascular invasion (138). The organisms often coexist with other pathogens including Pneumocystis and cytomegalovirus.

Infections by Cryptococcus have been demonstrated in a variety of other sites, particularly lymph node, bone marrow, adrenal gland, and kidney. The inßammatory response to infection can be quite variable, ranging from absent to ßorid. As Cryptococcus elaborates no known exotoxins, tissue necrosis is minimal and inßammatory reactions are usually sparse. Occasionally, some inßammatory cells of mixed types accompany the proliferating organisms, but well-formed granulomas are generally not present (137,149).

Endemic MycosesÑHistoplasmosis and Coccidiodomycosis

The endemic mycoses are designated as such because of their characteristic geographic ranges. While these pathogens can produce disease in normal individuals, they generally do not cause progressive disseminated infections in hosts with intact cellular immunity. However, patients with AIDS who live in or have traveled from endemic

areas are at an increased risk for disseminated multisystem disease. Major organisms in this group include *Histoplasma capsulatum*, *Coccidioides immitis*, and *Blastomyces dermatitidis*.

Histoplasma Capsulatum

Histoplasma capsulatum, a dimorphic fungus, exists in soil contaminated by bird feces. The major endemic area is the central United States and most normal persons living in that region show skin test evidence of past infection (150,151). Reactivation of latent infection and newly acquired primary infection are both important modes of acquiring disease in immunocompromised patients. As expected, the frequency of histoplasmosis in AIDS patients shows marked geographic variability. In highly endemic regions, *H. capsulatum* has been reported in up to 27% of AIDS patients, while in some autopsy series from nonendemic areas, the infection is documented very rarely (152,153). The clinical manifestations, including high fever, maculopapular rash or necrotic papules, hepatomegaly, splenomegaly, lymphadenopathy, anemia, and pulmonary inÞltrates, reßect a disseminated process.

Diagnosis

The diagnosis is made by the identiÞcation or culture of the fungus in clinical specimens and tissue biopsies and by urine Histoplasma antigen detection assays (154). Because of the disseminated nature of infection in AIDS patients, a variety of specimens including bone marrow, blood, respiratory specimens (lavage, washings, and bronchial biopsy), CSF, lymph node, and skin can be diagnostically useful (Figs 27.11 and 27.12). Culture of bone marrow specimens is highly sensitive, but because of the organismÕs slow growth, up to six weeks may be required for identiÞcation (155). Positive cultures from peripheral blood have been reported in about 40% of published cases in AIDS patients, with the lysis centrifugation technique being the most sensitive method to detect the organism (152,155Ð157). Yeast will be identiÞed occasionally in Wright-stained buffy coat smears and in up to 46% of peripheral blood smears (158,159).

Biopsy of focal sites of disease such as skin, lymph nodes, or liver will reveal the typical 2Ð5 μm oval to round budding yeast in clusters within histiocytes. Special stains including methenamine silver or PAS are usually necessary to visualize the organisms because of their small size. Bone marrow biopsy is particularly useful and positive in most cases of disseminated disease. Four patterns of involvement are recognized in marrow biopsies: (1) no evidence of infection (positive culture without morphologic abnormality); (2) discrete granulomas; (3) lymphohistiocytic aggregates; and (4) diffuse macrophage inÞltration. Organisms are found within and outside of macrophages. Other common Þndings reported, which are probably unrelated to infection with this organism, include megaloblastoid erythropoiesis and dysplastic myeloid and megakaryocytic maturation (160).

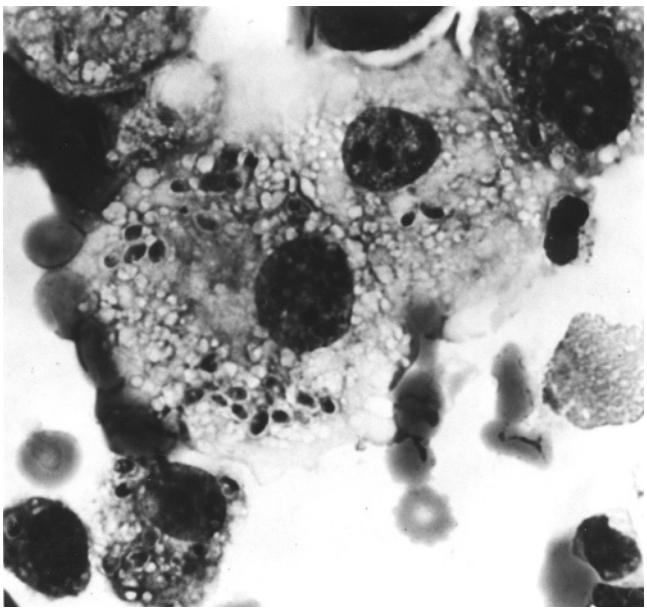

FIG. 27.11. *Histoplasma capsulatum* in bronchial washing. Small oval to round yeast are primarily within macrophages. Narrow based budding, intracellular location, and absence of cup-shaped organisms differentiates this from *Pneumocystis carinii* (Papanicolaou, × 1,000).

Coccidioides Immitis

Coccidioidomycosis, a systemic mycosis endemic to arid regions of North and South America, is becoming recognized as a signiÞcant cause of morbidity and mortality in AIDS patients, particularly in endemic regions (161). Symptomatic disease may occur from reactivation of latent infection or by progressive primary infection (162). The immunocompromised host is prone to develop severe pulmonary and widely disseminated disease (163).

Diagnosis

The diagnosis of coccidioidomycosis is made by serologic methods, skin testing, microbiologic culture, and identiÞcation of the endosporulating spherules in body ßuids or tissue biopsies. The most effective method for diagnosis is evaluation of respiratory tract specimens (bronchial washings, bronchoalveolar lavage, and transbronchial biopsy) using culture and special stains including GrocottÕs or GMS and PAS. In tissue sections, *C. immitis* is identiÞed as large spherules measuring 30Ð60 μm in diameter containing endospores 2Ð5 μm in diameter. Because of the large spherule size, they are often visualized in routine hematoxylin and eosin-stained sections. Hyphal forms consisting of barrel shaped

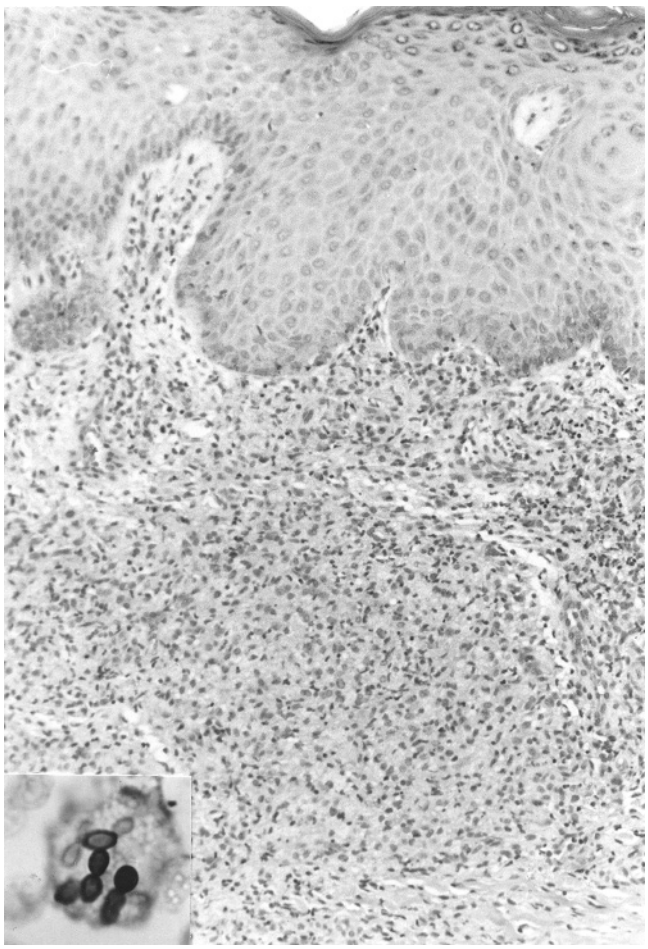

FIG. 27.12. Cutaneous histoplasmosis. Dermal infiltrate of histiocytes and poorly formed granulomas containing numerous yeast in an intracellular location (inset) (hematoxylin and eosin, × 200). Inset: (Gomori's methenamine silver, × 400).

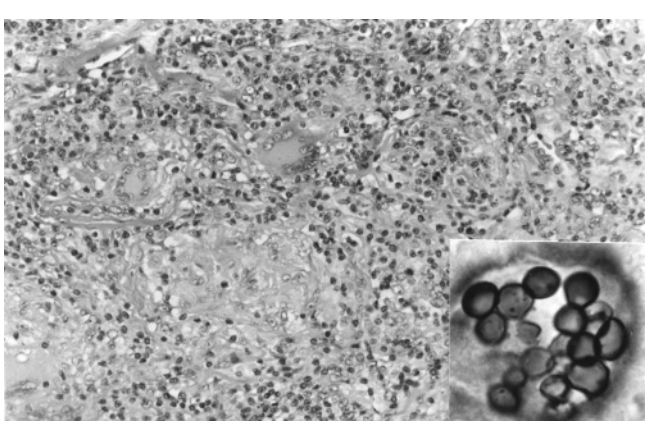

FIG. 27.13. Lung biopsy with *Coccidioides immitis*. Diffuse granulomatous reaction with giant cells. Inset: Endosporulating spherule diagnostic for *C. immitis* (hematoxylin and eosin, × 100). Inset: (Gomori's methenamine silver, × 400).

arthroconidia are also seen in more than 50% of pathologic specimens (164). The inflammatory response to the organism in lung biopsies usually consists of poorly formed granulomas and lymphohistiocytic aggregates with few multinucleated giant cells (Fig. 27.13). Older lesions may show areas of organizing pneumonitis. AIDS patients show greater numbers of spherules compared with non-AIDS patients, and the fungus often coexists with other opportunistic pathogens including *Pneumocystis carinii*, cytomegalovirus, and MAI (163). In keeping with the disseminated nature of the infection, organisms have also been cultured or identified histologically in lymph node, liver, spleen, bone marrow, kidney, skin, and blood (161,163,165–167).

Other Fungi

While considerably less common than Candida, Cryptococcus, Histoplasma, and Coccidioides, a variety of other fungi have infrequently been described in AIDS patients. These include *Sporothrix schenckii* (168,169), Aspergillus (170,171), Alternaria (172), and *Blastomyces dermatitidis* (173).

Bacterial Infections

Tuberculous and Nontuberculous Mycobacteria

Up to 50% of AIDS patients will develop a mycobacterial infection at some stage of their disease (174). The pathogenicity of mycobacteria is modulated by the host's immune response to determine the type and extent of infection (175). About 10% of isolates are *Mycobacterium tuberculosis* (MTB) and the remaining are nontuberculous mycobacteria (NTM), which include MAI, *M. kansasii*, and *M. scrofulaceum* (176). Infections with other mycobacteria, especially *M. gordonae*, *M. xenopi*, and *M. fortuitum*, are also being recognized with increasing frequency (177–178).

As environmental saprophytes, nontuberculous mycobacteria gain access through the aerosol route or by ingestion of food or water and may temporarily colonize the nasopharynx or intestinal mucosa (179). In immunodeficient individuals, once established, these opportunistic pathogens can extensively disseminate and proliferate to enormous numbers before causing overt disease (gastrointestinal, pulmonary, soft tissue, and systemic lesions are seen in these infections) (180). NTM infections may be clinically silent, the diagnosis being made incidentally in a lymph node biopsy, in endoscopic biopsy of gastrointestinal tract, or at autopsy. When clinical manifestations occur they may be nonspecific (fever, weight loss, anorexia, abdominal pain, etc.). A case of disseminated *M. bovis* infection following bacillin Calmette-Guérin (BCG) vaccination highlights the importance of not using live

vaccines in individuals with HIV infection (181). MTB among patients with AIDS is seen most frequently in those groups with historically high rates of infection (intravenous drug users, Haitians, Hispanics, and blacks) and tends to occur early in the course of HIV infection, often in a disseminated extrapulmonary form (182).

Histopathologic Diagnosis

Although microbiologic culture is required for precise species identiÞcation, rapid diagnosis of mycobacterial infections rests on morphologic demonstration of the organisms in cytologic preparations and tissue sections. Gastrointestinal tract, lymph node, lung, liver, and bone marrow are the most common biopsy specimens. The cellular response to the organisms is variable and includes well or poorly formed granulomas, lymphohistiocytic reactions, histoid pattern, and paucity of immune response.

MAI Infections

Disseminated MAI infection is the most common bacterial infection in AIDS patients (183). In endoscopic biopsies of the small intestine, MAI infections show villous atrophy with diffuse inÞltration of the lamina propria by foamy or granular histiocytes (Fig. 27.14). Necrosis is unusual, and granulomas are generally not present or are poorly formed. Acid-fast bacilli (AFB) stains demonstrating the abundant beaded magenta rods within these histiocytes differentiate this lesion from Whipple's disease, which can have similar clinical and histologic features, and from intestinal *Rhodococcus equi* infection (184,185). Focal involvement of gastric or colonic mucosa may be overlooked, and special stains are appropriate even in the absence of an obvious inÞltrate.

Lymph node involvement with NTM can take several forms. The cortex and part of the medulla are replaced by sheets of histiocytes containing many organisms. Granulomas, necrosis, Þbrosis, and calciÞcation are usually absent. An unusual spindle cell proliferation, described by Wood and similar to the histoid reaction of lepromatous leprosy, may suggest a connective tissue tumor or Kaposi's sarcoma, but special stains demonstrate abundant bacilli within the spindle cells (186) (Fig. 27.15).

In the lungs, NTM infections manifest minimal tissue response. In the interstitium, rare clusters of histiocytes containing numerous organisms associated with minimal chronic inßammation are often the only evidence of infection. Special stains may demonstrate abundant organisms throughout the interstitium in the absence of reaction.

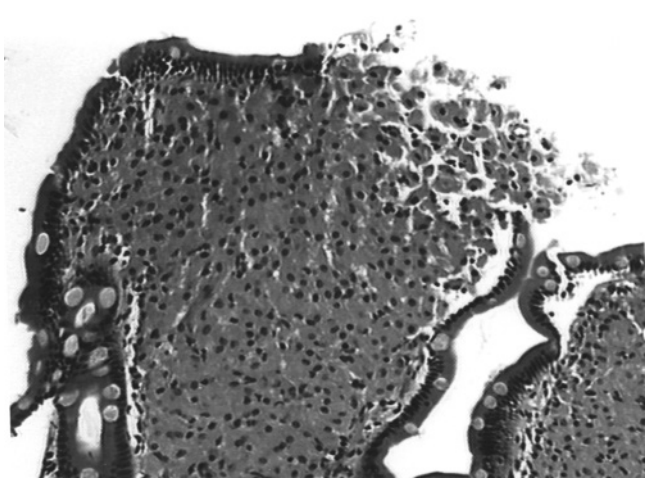

FIG. 27.14. MAI enteritis. Small intestinal biopsy demonstrating blunting and expansion of villi with a histiocytic in Itrate in the lamina propria. An acid fast stain showed large numbers of acid-fast bacilli within the histiocytes. The differential diagnosis includes Whipple's disease and infection by *Rhodococcus equi* (hematoxylin and eosin, × 200).

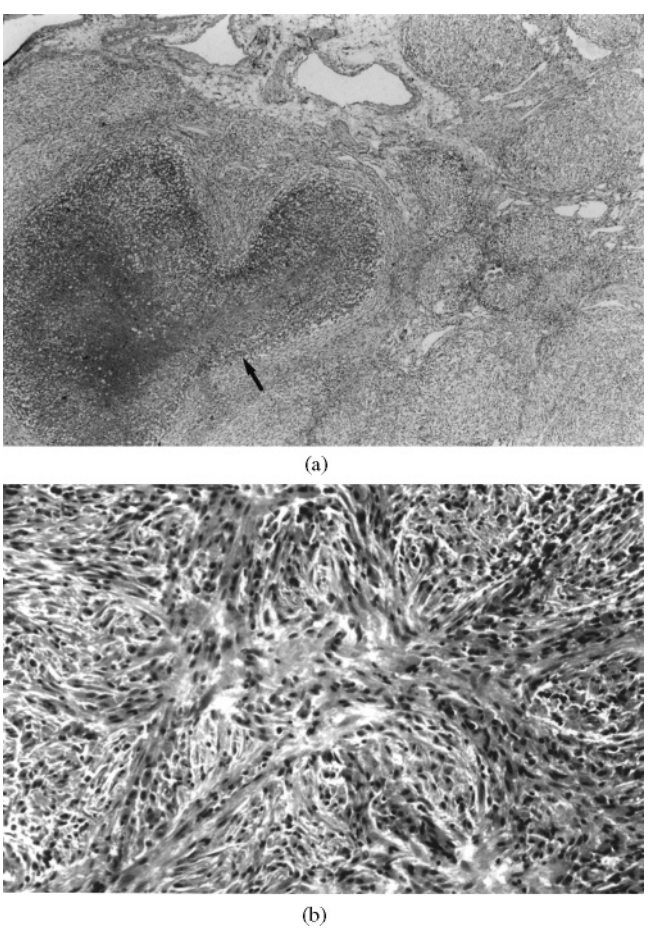

FIG. 27.15. Necrotizing lymphadenitis and "histoid" reaction. a: Atypical MAI infection of lymphoid tissue. Culture proven MAI infection demonstrating unusual feature of zonal necrosis (arrow) (hematoxylin and eosin, × 25). b: Histoid reaction with spindle-shaped histiocytes arranged in interlacing fascicles. Ziehl-Neelsen stain showed acid-fast bacilli within spindle cells (hematoxylin and eosin, × 250).

Hepatic involvement of MAI is seen in about 70% of liver biopsies in patients with systemic MAI infection and has been reported in up to as many as 83% of those patients coming to autopsy (187–188). The histologic appearance can be deceptively bland, ranging from widely dispersed histiocytes to focal granuloma-like collections lacking necrosis and giant cells. AFB stains show numerous organisms within histiocytes and rarely within Kupffer cells (189). Occasionally organisms are cultured from biopsies demonstrating no tissue reaction (190).

Bone marrow involvement by mycobacteria manifests as lymphohistiocytic aggregates and poorly formed granulomas that tend to be very small and focal in distribution. AFB stains demonstrate organisms within granulomas and also within more widely dispersed histiocytes (191). As formic acid decalciÞcation may interfere with AFB stains, EDTA decalciÞcation solutions are recommended since it is desirable to perform acid-fast stains routinely on bone marrow biopsies from HIV-infected patients (192).

The ßuorescent stain auramine-rhodamine can be used on cytology preparations and adapted to tissue sections to facilitate demonstration of mycobacteria. This method requires less time to screen the slides as it can be read at lower magniÞcation and has been shown to be about twice as sensitive as the Ziehl-Neelsen stain in demonstrating AFB in lymph node biopsies (193). Several methods of rapid mycobacterial culture and identiÞcation are now commercially available, with the BACTEC system being employed by many laboratories. Ribosomal RNA probes for the identiÞcation of MTB and MAI provide rapid results and are now the gold standard. Methods such as PCR for the direct identiÞcation of mycobacteria in clinical specimens are being developed, but are not yet appropriate for routine clinical diagnosis (194).

MTB Infections

HIV-associated MTB infections of any site generally present a more variable tissue response, ranging from well-formed granulomas to loose clusters of histiocytes with lesser numbers of organisms than are seen in NTM infections. However, in our experience, MTB infections in AIDS patients cannot be reliably distinguished from MAI infections solely on the basis of morphologic features such as necrosis, type of inßammatory response, presence of granulomas, or numbers of organisms. In the lungs, miliary patterns are common and typical necrotizing cavitary lesions infrequent (195). Some cases of pulmonary MTB infection in AIDS patients show abscess formation with numerous neutrophils, necrosis and few or no epithelioid histiocytes (196). Dual pulmonary infections with MTB and MAI have been reported (197). Involvement of other organs shows similar histologic features.

In summary, the tissue reactions to mycobacterial infections are varied and depend on factors such as the inherent virulence of the particular mycobacterial species, degree of immunodeÞciency when the infection occurs, the length of time the lesion is present prior to biopsy, and the inßuence of concomitant or prior chemotherapeutic agents. Because of this variability and differences in the response and treatment of NTM and MTB, stains to demonstrate the bacteria should always be supplemented with methods to culture the organisms and determine chemotherapeutic sensitivities.

Other Bacteria

Infections with a variety of bacteria such as *Streptococcus pneumoniae*, *Haemophilus inßuenzae*, *Staphylococcus aureus*, *Neisseria meningitides*, *Pseudomonas aeruginosa*, Salmonella, Shigella, Campylobacter, and *Treponema pallidum* are important causes of morbidity and mortality in HIV-infected children and adults (198–214). The multiplicity of immunologic defects of cellular and humoral types predisposes these patients to persistent infections and bacteremia (215). In addition, chemotherapeutic and antineoplastic agents used to treat opportunistic infections and neoplasms may cause neutropenia, further compromising the immune status. These infections often show atypical presentations including infections with more than one organism and a high relapse rate despite appropriate antibiotic therapy. Infections with *Streptococcus pneumoniae* and *Haemophilus inßuenzae* are particularly frequent in children with AIDS and the latter organism is responsible for about 10% of pneumonias in adult AIDS patients (198,202–203). Bacterial pneumonia is a very common pulmonary Þnding in AIDS patients at autopsy, with most cases caused by *Pseudomonas aeruginosa*, *Staphylococcus aureus* or *Klebsiella pneumoniae* (216). Important enteric pathogens in HIV-infected patients include Salmonella, Campylobacter, and Shigella. Salmonellosis may present initially as acute gastroenteritis or less commonly as bacteremia. The infections often have a severe clinical course with bacteremia in up to 45% of AIDS patients and show a tendency to relapse despite antibiotic therapy (200–201,203). Cultures of blood and stool usually conÞrm the diagnosis, but Salmonella may be recovered from many sources including brain, bone marrow, urine, and spleen. Campylobacter species have been recognized as important pathogens in the general population as well as in homosexual men and immunocompromised patients. Most infections in AIDS patients are associated with gastroenteritis while bacteremia and cholecystitis are infrequently reported (208,209). *Shigella ßexneri* is the most common species isolated from AIDS patients with Shigella gastroenteritis (205–207). Bacteremia is infrequently seen and diagnosis is principally made by culture of stool.

A number of studies have suggested that HIV infection may be associated with rapid progression of secondary

syphilis or tertiary neurosyphilis, even following appropriate antibiotic therapy (210,211). Unusual clinical presentations, atypical serologic responses after appropriate treatment and false-negative serologic tests, make the diagnosis of syphilis in HIV-infected patients difficult (212,214,217). Darkfield examination or direct fluorescent antibody staining of scrapings or exudates from suspicious primary lesions will help to establish the diagnosis even with negative rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL) serologic studies. Silver stains such as the Steiner or Warthin-Starry can be performed on tissue biopsies but in the author's experience are difficult to interpret (218). Overall, the diagnosis of syphilis can be problematic in HIV-infected patients, and many clinicians will presumptively treat patients for early syphilis and closely monitor serial serologic tests to detect a delayed antibody response.

Bacterial infections are seen more commonly at autopsy than in biopsy specimens. Few pathologic studies, however, describe the microscopic features of pure bacterial enteric infections uncomplicated by the more common pathogens seen in AIDS patients. In typical enteric infections by most of these organisms, the initial phase is an invasion of the epithelium with propagation of the bacteria in epithelial cells followed by entry into the lamina propria. The subsequent reaction is acute and pyogenic with superficial mucosal necrosis and pseudomembrane formation beginning as a focal process and in severe infections becoming confluent. Organisms can be demonstrated within epithelial cells, lamina propria, and adherent membranes by Gram, Giemsa, and silver stains. Microbiologic culture will confirm the species of the enteropathic bacteria. This typical reaction pattern is modified by the host's ability to mount an immunologic response based on the degree of immune suppression. Dissemination to other organs will result in necrotizing lesions associated with scan inflammatory infiltrates and an abundance of organisms, particularly in neutropenic patients.

Viral Infections

Cytomegalovirus

Cytomegalovirus (CMV) is a common opportunistic pathogen found in cytology and biopsy specimens from AIDS patients surpassed in frequency only by Pneumocystis and MAI (219,220). Nearly all AIDS patients have serologic evidence of prior exposure, suggesting these infections almost always represent reactivation and dissemination of latent virus (221).

The gastrointestinal tract is a common site of CMV infection in AIDS. Colitis is the most frequent clinical presentation of enteric disease and these lesions appear as focal or diffuse areas of ulceration and hemorrhage commonly involving the more distal colon (219). Multiple biopsies are usually required to establish a diagnosis. A CMV-related occlusive vasculitis which may be complicated by intestinal perforation, has also been described (222). Esophageal involvement results in ulceration predominantly involving the distal portion (223). In the stomach, CMV appears as a nonspecific gastritis with focal ulceration or as a submucosal mass (224). Other alimentary tract sites less commonly involved include the duodenum, pancreas, biliary tree, and gallbladder (225). In patients with AIDS, CMV pneumonitis is not a well-characterized syndrome and is frequently found to coexist with other opportunistic pulmonary pathogens, especially *Pneumocystis carinii* (226). The histopathologic findings reported in lung biopsies or autopsy tissues from AIDS patients with CMV pneumonitis range from focal and mild interstitial pneumonitis to severe diffuse alveolar damage with necrosis. Infections in a variety of other organs including brain, lymph nodes, skin, endocrine organs (especially adrenal gland), genitourinary system, liver, and heart have also been described (227,228).

Diagnosis

The most widely utilized method of diagnosing active CMV infection is by demonstrating the characteristic inclusion bodies in biopsies or cytology specimens. The significance of a positive CMV culture in the absence of clinical or pathologic evidence of tissue injury or viral cytopathic effects, remains unclear. The identification of infection based on the presence of cytopathic changes, while specific, is a relatively insensitive technique. The diagnostic accuracy in biopsy material can be enhanced by immunohistochemical stains for CMV early and late antigens and in situ hybridization for CMV nucleic acids (229,230). Recently the polymerase chain reaction has been used to demonstrate CMV DNA in clinical specimens and paraffin-embedded tissues. However, the presence of CMV DNA does not necessarily indicate active disease as the virus is latent in a very high proportion of the HIV-infected population (231).

Cells actively infected by CMV show characteristic cytologic changes including cellular and nuclear enlargement, acidophilic intranuclear inclusions, and granular basophilic cytoplasmic inclusions (Fig. 27.16a). Gomori's methenamine silver and PAS stain the viral glycoproteins of the cytoplasmic inclusions because of their high carbohydrate content (42). Mesenchymal cells, especially endothelium, are preferentially involved, while epithelial cell involvement is seen less frequently (Fig. 27.16b). CMV infections display wide variability in the degree of associated inflammation, necrosis, and tissue damage, which ranges from focal and mild to extensive with organ

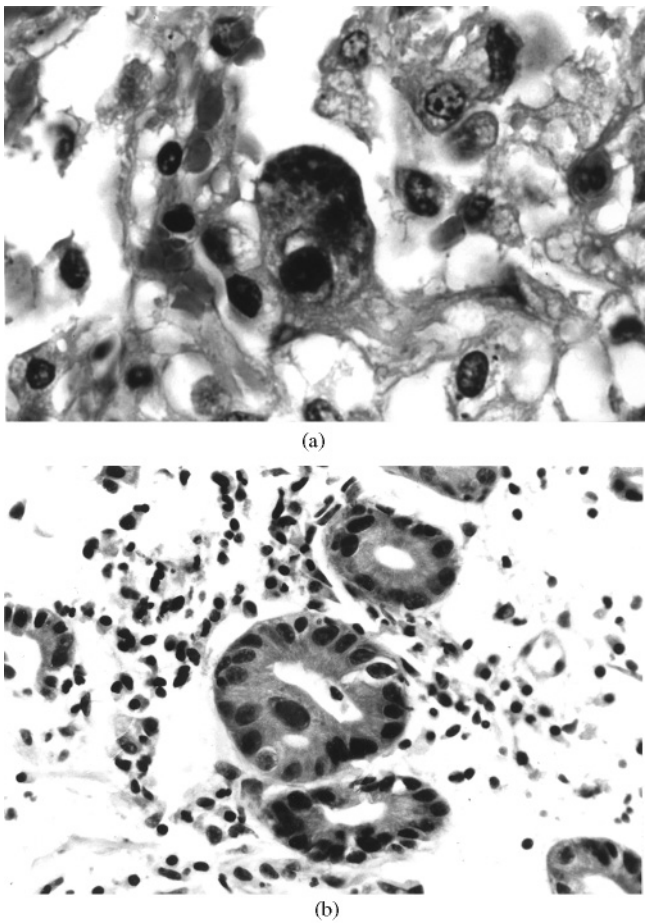

FIG. 27.16. Cytomegalovirus pneumonitis and gastritis. a: Pneumocytes showing cytomegaly and large intranuclear inclusions (hematoxylin and eosin, × 250). b: Gastric biopsy with cytomegalic inclusion in epithelial cell (hematoxylin and eosin, × 100).

perforation (232). Rarely, CMV vasculitis is associated with severe infections (233).

Herpes Simplex and Varicella-Zoster

Primary infections with herpes simplex virus (HSV) are unusual in adults with AIDS because of the high rates of previous infection. However, these patients are prone to severe recurrent infections, which show delayed healing, prolonged virus shedding, and frequent relapses (234,235). HSV produces oral, labial, genital, and anal lesions, retinal infections/necrosis (236), esophagitis, pneumonitis, and encephalitis, while the lesions of varicella-zoster (HZ) occur in a dermatomal distribution or show extensive cutaneous dissemination (237). During recurrences, patients may develop visceral disease (238). In most studies from western countries, cases reported in association with HIV infection usually have disease progression to AIDS prior to the onset of disseminated HZ infection (235). In African patients, HZ is highly predictive of HIV infection; in one study 91% of African patients with HZ were HIV-seropositive (239).

Diagnosis

Serologic tests for herpes antibody are rarely useful in AIDS patients because antibody formation occurs late in primary infection and is usually unchanged during recurrent infection. DeÞnitive diagnosis requires demonstrating viral cytopathic effects in cytology specimens or surgical biopsies, culturing the virus from tissues, or detecting viral antigens. Cultures of fresh vesicles show high recovery rates whereas specimens from crusted lesions are usually negative. Biopsy specimens or swabs from vesicles are inoculated onto tissue monolayers capable of supporting virus growth. Viral cytopathic changes or staining of the monolayer with speciÞc monoclonal antibodies permit rapid identiÞcation usually within four to Þve days (240).

Cytologic preparations from scrapings of fresh vesicles provide a rapid and inexpensive method to identify virally infected cells but are a relatively insensitive technique and cannot differentiate HSV types 1 and 2 from varicella-zoster infections. This procedure (Tzanck preparation) consists of unrooÞng a fresh vesicle and gently scraping the base of the lesion. The scrapings are transferred to a glass slide and stained with any of the routine cytologic methods (usually Wright-Giemsa or Papanicolaou). Typical viral cytopathic changes include nuclear enlargement and multinucleation with nuclear molding. The nuclear features consist of a diffuse homogenization giving the chromatin a Òground glassÓ appearance (Fig. 27.17). Alternatively, nuclei may contain prominent eosinophilic inclusions surrounded by a clear halo and prominent nuclear membrane.

Tissue biopsies of skin or mucosal lesions show vesicle formation or ulceration with dermal or submucosal necrosis and inßammation. The virally transformed cells

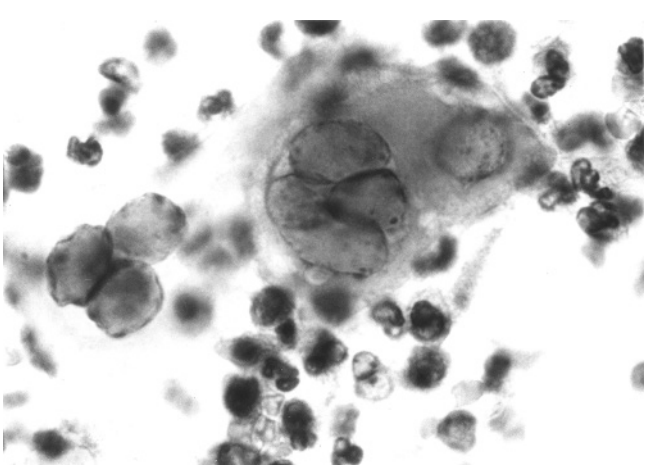

FIG. 27.17. Tzanck preparation demonstrating characteristic viral changes of herpes infection. Epithelial cells show multinucleation, nuclear molding, and “ground glass” nuclear chromatin (Diff-Quik, × 400).

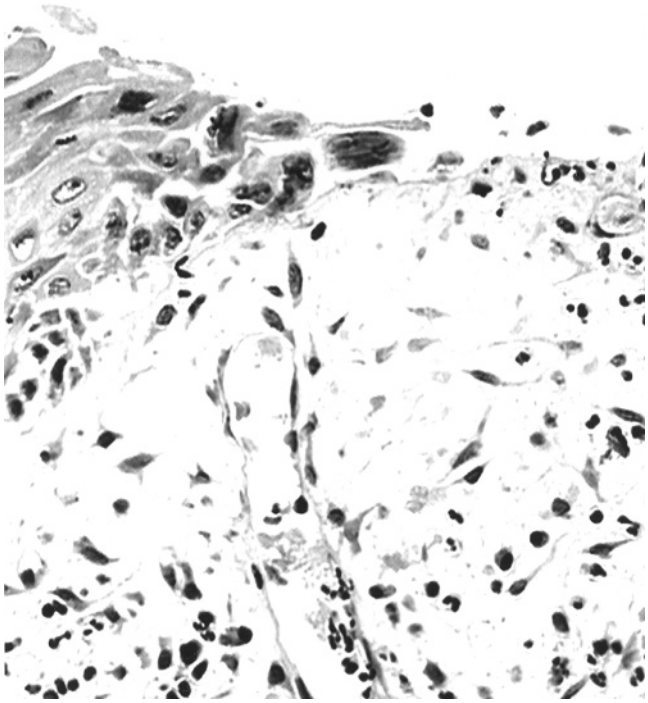

FIG. 27.18. Persistent herpes skin infection. Focus of ulceration with acantholysis and multinucleated giant cells (hematoxylin and eosin, × 200).

described previously are frequently seen at the margins of the ulcer (Fig. 27.18). In contrast to CMV, HSV preferentially infects squamous epithelial cells, whereas CMV shows a propensity for mesenchymal and endothelial cells. HSV-infected cells do not show marked cytomegaly or produce the intracytoplasmic inclusions seen in CMV-infected cells. The diagnosis in smears and in tissue sections can be conÞrmed by immunoperoxidase methods to identify viral proteins or by in situ hybridization techniques that demonstrate HSV DNA (241,242).

Herpes simplex and varicella-zoster viral pneumonitis are often antedated by oral or labial lesions. Histologically, this type of viral pneumonitis usually produces parenchymal necrosis, lymphohistiocytic inßammatory inÞltrates, multinucleated giant cells, and intranuclear inclusions. There may be associated necrotizing tracheobronchitis. Evidence of disseminated herpetic infections can be detected in many visceral organs and lymph nodes. Biopsies from these sites show necrotizing changes with scattered virally transformed cells.

Other Viruses

A number of other viral infections have been described in patients with AIDS. Epstein-Barr virus (EBV), another member of the herpes virus group, is endemic in humans and serologic studies show it to be a frequent latent infection in AIDS patients. There is considerable evidence associating EBV with malignancies including lymphoma and nasopharyngeal carcinoma (243Ð245). Oral hairy leukoplakia, a benign papillomatous epithelial proliferation usually involving the tongue or buccal mucosa and described predominantly in AIDS patients, has been shown to contain EBV DNA sequences in most cases (246). It has been theorized that oral hairy leukoplakia is due to reactivation of latent lingual infection with EBV (247). Some children with AIDS develop a lymphocytic interstitial pneumonitis also shown to contain EBV capsid antigen and viral DNA (244). Infections with this virus can be demonstrated using DNA probes and serologic techniques (244,248,249). Histopathologic features of acute EBV infections of lymph nodes show characteristic but nonspeciÞc hyperplastic patterns and are sometimes confused with Hodgkin's disease (250).

Other viral diseases described in AIDS or AIDS-related complex include the pox virus associated with molluscum contagiosum and human papillomavirus associated with verruca vulgaris and cervical/vaginal neoplasia (251,252). Molluscum contagiosum may be generalized and severe in patients with AIDS and can clinically mimic cutaneous cryptococcosis (135). Lesions of condyloma accuminata may be large and extensive in patients with AIDS, and one study has suggested a high prevalence of cervical and vaginal cytologic abnormalities of squamous epithelium in HIV-infected women (252). Progressive multifocal leukoencephalopathy caused by a papovavirus is described in a separate chapter.

NEOPLASMS ASSOCIATED WITH HIV

Kaposi's Sarcoma

Kaposi's sarcoma (KS), the most common neoplasm occurring in association with AIDS, has been recognized clinically in up to 25% of patients at some point during their illness and had been reported in between 50% and 95% of AIDS patients at autopsy (171,253,254). Epidemiologic studies have shown the highest prevalence to be in white male homosexuals with AIDS (255). Since the advent of antiretroviral therapy, the incidence of KS has declined precipitously in North America and Europe, but not in third world countries where this therapy is largely unavailable (256).

AIDS-associated KS differs from the classical form seen in elderly individuals of Mediterranean or Jewish extraction in the sites of involvement (arms, oral cavity, trunk, and face rather than of lower extremities) and appearance (multicentric pink to violet patches, inÞltrated plaques, or small angiomatoid nodules in contrast to purple macules, papules, or nodules). Although these characteristics enable a clinical diagnosis to be made, a biopsy diagnosis, particularly of early lesions, is recommended. Most AIDS patients with KS have cutaneous and

visceral involvement, but between 5% and 29% show visceral involvement in the absence of cutaneous lesions (257,258). In autopsy studies, many organs have been reported to be involved; however, lymph nodes, gastrointestinal tract, and lung are the most frequent sites of extracutaneous disease (171,257,256). Most patients with KS die as a result of opportunistic infections and only rarely as a direct consequence of this tumor (257,259).
