Preface

In 1981, when AIDS was Þrst recognized, cases were rare and the disease was regarded mostly as a curiosity. By the mid-1980s, the etiologic agent, HIV, had been discovered and partially characterized, allowing the enormity of the pandemic to begin to be appreciated. It became accepted that HIV infection was a chronic illness whose natural history may span more than a decade, with symptoms arising transiently within the Þrst two months for some patients, and during the last few years of life for almost all patients. The most common method of transmission is sexual, with populations who have traditionally been at greater risk for sexually transmitted diseases disproportionately affected. Because of this, it affects a much younger population than do most other chronic diseases.

In the early 1980s, management was relegated to the diagnosis and treatment of the late opportunistic infections. With the discovery and development of antiretroviral therapies, the clinical approach has changed dramatically. HIV-infected persons are now placed under medical supervision as soon as they are diagnosed, with or without symptoms. Equipped with an expanding array of diagnostic tests (e.g. T-cell subsets, HIV viral load testing, HIV resistance testing, *Pneumocystis carinii* direct ßuorescent assays) and an even wider variety of new antiretroviral drugs (reverse transcriptase inhibitors, protease inhibitors, and others), the health care practitioner has more to offer these patients than ever before. Objective reductions in mortality and improvements in quality of life have resulted, which are truly remarkable achievements. However, chronic antiretroviral therapy has posed new challenges in managing drug toxicity, adherence and prevention of the emergence of drug resistance.

The purpose of this book is to chronicle the emerging story of HIV infection and to describe its diverse manifestations and consequences. It is hoped that the Fourth Edition of *AIDS and Other Manifestations of HIV Infection* will provide a comprehensive overview of the biologic properties of the etiologic viral agent, its clinicopathological manifestations, the epidemiology of its infection, and present and future therapeutic and preventive options. Particular importance is given to providing a rigorous scientiÞc foundation as a basis for understanding the pathobiology of HIV.

Chapters have been extensively revised in accordance with the rapidly expanding knowledge base, and are well referenced. The section on clinical manifestations has been expanded in the Fourth Edition and now includes new chapters on the: cardiovascular, renal, and dermatologic manifestations of HIV infection. In-depth discussions of particular clinical issues are principally done on a system-by-system basis for the major systems involved. New chapters have also been added to the Fourth Edition on molecular diagnostic techniques (to the Etiologic Agent Section), the role of host genetic variation in HIV infection and its manifestations (to the Immunology of HIV Infection Section), discovery and development of new HIV medicines, analysis of HIV dynamics using mathematical models, toxicities of antiretroviral therapy, HIV drug susceptibility testing, practical therapeutics, the global impact of HIV and AIDS (to the Treatment and Prevention Section), reßecting the increasing importance of these topics as a basis for improving the care of HIV-infected patients worldwide.

It is my hope and intention that the Fourth Edition of *AIDS and Other Manifestations of HIV Infection* will provide a reference source for essential information needed by members of the healthcare and scientiÞc community, and that it will enable healthcare workers to render the highest level of care possible to their patients.

Chapter 1

The Epidemiology of HIV and AIDS

Patricia L. Fleming

The emergence and dissemination of a new infectious disease agent worldwide within the span of two decades at the end of the twentieth century has presented unprecedented medical, social, and political challenges. The human immunodeÞciency virus (HIV) and the syndrome of opportunistic illnesses that characterize late-stage HIV disease, known as the acquired immunodeÞciency syndrome (AIDS), have claimed over 20 million lives worldwide and the Joint United Nations Program on AIDS (UNAIDS) estimates that there were more than 40 million HIV-infected persons living worldwide in 2001 (1). In the United States (U.S.), the Centers for Disease Control and Prevention (CDC) estimates that there were 850,000Ð950,000 prevalent cases of HIV/AIDS in 2000 (2). More than 467,000 deaths of persons with AIDS have occurred since the epidemic was Þrst recognized in 1981 (3Ð5). Despite recent successes in treating HIV that have increased survival and substantially decreased death rates (6,7), HIV remains a devastating illness, without cure, that mainly affects young adults. Its social and economic tolls threaten to destabilize some countries in the developing world and it continues to be a costly and controversial disease in the U.S.

Understanding the epidemiology of HIV provides an important foundation for clinicians in recognizing risk behaviors associated with clinical manifestations suggestive of HIV infection in their patients, and encouraging acceptance of HIV testing, adoption of risk-reduction strategies to prevent further transmission, and treatment to prevent opportunistic illnesses and delay disease progression. At the start of the third decade of the HIV pandemic, and following the terrorism of September 11, 2001 and the subsequent bio-terrorism, the government and the public have a heightened awareness of the crucial role of public health preparedness in assuring well-being.

Patricia L. Fleming: Division of HIV/AIDS Prevention, National Center for HIV/STD/TB Prevention, CDC, 1600 Clifton Rd. NE, Atlanta, GA 30333. E-mail: pßeming@cdc.gov

Disease surveillance, prevention and control are in the headlines. Health care providers have a renewed appreciation of their responsibility to report cases of notiÞable diseases to public health authorities. This chapter reviews the historical context of the epidemic, summarizes the global epidemic, presents HIV/AIDS surveillance data to characterize affected populations, describes trends in the incidence and prevalence of HIV and AIDS, describes clinical manifestations and the impact of treatment, and identiÞes emerging issues that challenge the ability to prevent and control HIV.

BACKGROUND AND CONTEXT

The HIV pandemic is arguably the most compelling public health crisis of the post-World War II generation. In the post-World War II era, infectious diseases were on the wane. Common bacterial infections were readily treated with available antibiotics; ubiquitous childhood diseases (e.g. polio, measles, mumps) were preventable with vaccination; even the scourge of smallpox was eradicated worldwide. The epidemiology and clinical management of chronic diseases such as heart disease and cancers and an emerging interest in environmental health were ascendant public health priorities.

In 1981, with the Þrst reports of what came to be called AIDS, a new awareness of the threat of emerging infectious diseases arose. Within two years, the epidemiologic evidence suggested that a new infectious agent was responsible for cases of unusual opportunistic illnesses, indicative of severe immunosuppression. The pattern of AIDS case reports suggested that this disease agent was likely transmitted through sexual contact (homosexual and heterosexual), sharing of drug injecting paraphernalia, contamination of the blood supply, and perinatally from mother to child (8Ð13). By 1983, a new retrovirus was isolated from AIDS patients and identiÞed as the causative agent (14,15) An antibody test was developed that enabled diagnosing HIV infection early in the disease course and

permitted screening of the blood supply (16). By March of 1985, universal screening of the blood supply, coupled with voluntary donor deferral and heat-treatment of blood components, had virtually eliminated new HIV infections through transfusions or the receipt of blood products by hemophiliacs. During the Þrst decade, the U.S. government and all state and territorial health departments began to conduct AIDS case surveillance to monitor the outcome of HIV infection and its impact on the population. Anonymous serologic surveys of the prevalence of HIV antibodies in some populations were implemented using blood routinely collected for other purposes in a large number of hospitals and clinics serving high-risk clients in diverse geographic settings, and in selected accessible populations such as military applicants and women giving birth. These surveys revealed that HIV was more widespread and more prevalent than AIDS case data suggested (17).

Many warning signs of the potential for the emergence or re-emergence of great pandemics caused by infectious agents were accumulating during the latter half of the twentieth century: increasing population pressures, migration and urbanization, political or social upheaval, and especially in western countries, the sexual revolution and drug-culture. Emerging from obscure African origins, HIV was introduced into susceptible populations in North America and western Europe and spread rapidly during the latter part of the 1970s and early 1980s. In the western countries, its spread was most rapid among homosexual men and drug-injectors. The epidemic had spread worldwide by the late 1980s. In Africa, the epidemic was termed ÒPattern IIÓ, i.e. heterosexually-acquired HIV predominated, as opposed to the homosexual and drug injecting associated epidemics in North America and Western Europe (i.e. ÒPattern IÓ). In Asia, Latin America and the Caribbean, heterosexual and drug-use associated transmission led to rapid spread and recently, a drug-use associated epidemic has emerged in eastern European nations (18,19).

Despite the warning signs of fertile ground for an infectious disease epidemic, HIV continues to confound medical and public health practitioners worldwide. As yet, there is no cure, and no vaccine. The ability to mount effective prevention and control efforts is complicated by social taboos, fear and prejudice. In the U.S., because HIV is spread principally through sex and sharing of drug-injection paraphernalia, and disproportionately affects racial/ethnic minority populations and homosexual men, discussions of HIV prevention inevitably touch on sensitive cultural topics. There is not one standard or paradigm for providers or communities to adopt in communicating behavioral risk reduction messages or implementing programs to promote HIV prevention. Yet, HIV remains eminently preventable through behavior change.

The complexity of the virus itself, its mechanism of action, and its effects on the immune system have stimulated giant leaps forward in research in basic science, immunology, and virology. This knowledge has rapidly advanced HIV clinical management and inßuenced medical practice far beyond HIV. The epidemic has also changed how affected communities inßuence government. New coalitions of communities, government, academics, and private industry have mobilized funding, deÞned research priorities, stimulated a growing pipeline of drugs for treatment, revised rules for eligibility for services and beneÞts, and communicated effective strategies for HIV prevention and control.

GLOBAL EPIDEMIOLOGY

UNAIDS estimates that approximately Þve million persons were newly infected with HIV during 2001 and about three million deaths were attributed to AIDS worldwide (1). Many countries, particularly some in Africa, Asia and eastern Europe are now experiencing rapid spread of HIV (20). Because of the long incubation period from infection to end-stage disease, about 10 years in the absence of treatment, these countries are still in relatively early stages of the epidemic with the peak of HIV-related morbidity and mortality yet to come. As the world goes through a period of rapid HIV spread with a large gap between the number of new cases and the number of deaths of prevalent cases, HIV prevalence worldwide is expected to escalate for the foreseeable future.

Sub-Saharan Africa accounts for over 70% of prevalent cases of HIV worldwide (Fig. 1.1). Political, cultural and economic barriers to HIV prevention and control are likely to combine to assure a decade or more of human misery in this region of the world. Already, many countries in Africa have experienced large numbers of AIDS deaths among adults in their prime years of productivity with resultant decreases in life expectancies and negative economic impact. The epidemic is believed to be transmitted principally through heterosexual contact with a large proportion of the infections in women, high rates of HIV among infants, and a growing number of orphaned children.

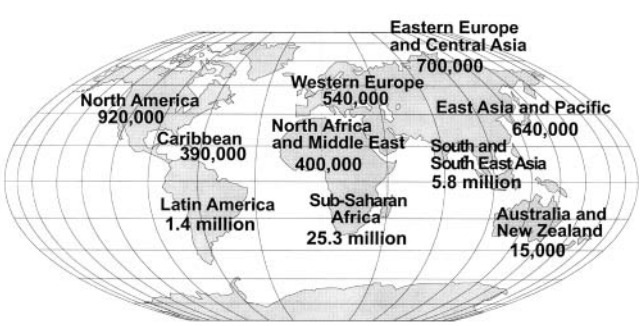

FIG. 1.1. Number of living adults and children estimated to be infected with HIV and AIDS – worldwide, 2000. Source: Joint United Nations Program on AIDS.

Other geographic areas have not yet been as severely affected (Fig. 1.2). In Latin America and the Caribbean, the epidemiologic pattern is more similar to that in the U.S., i.e. a mixed population infected by sex between men and between men and women as well as through needle-sharing among drug-users. Resources invested in HIV prevention and treatment have shown some successes in some Latin American countries. In contrast, in resource poor India, China, and other countries in southern and eastern Asia, there are rapidly emerging epidemics (1,19,20). In many of these countries, there is the potential for explosive sexual spread through populations that have high background rates of sexually transmitted diseases. Some Asian countries with entrenched drug cultures experienced the emergence of the epidemic among drug-injectors. If the epidemic continues to grow rapidly in this heavily populated region of the world, the human toll will be devastating. In addition to sexual, perinatal and drug-use associated transmission, inadequate screening for HIV antibodies and contamination of the blood supply contribute to the epidemic in many developing countries. Despite hopeful advances in short-course therapy during labor and delivery to prevent mother-to-child transmission, logistical, economic and policy barriers challenge efforts to reduce mother-to-child transmission in many developing countries. Finally, breastfeeding continues to pose a transmission risk in developing countries (21).

The U.S. rate of 14.9 reported AIDS cases per 100,000 population in 2001 is by far the highest in the industrialized world; the rates in adult (13 years) men and women, respectively, were 28.1 and 9.1 (5). In 1993, when the U.S. expanded the AIDS case deÞnition to include laboratory-initiated reporting of a measure of severe immunosuppression, European countries elected not to adopt the immunologic criterion and only adopted the added clinical conditions. Thus, trends in AIDS incidence in Europe and the U.S. are not directly comparable after 1992. Nevertheless, the marked disparity between U.S. rates and those among the western European countries highlights the severity of the epidemic in the U.S. Among the European countries with the highest numbers of cumulative AIDS cases through 2000 are Spain (59,466), France (53,095) and Italy (47,503) compared to 774,467 cases reported in the U.S. through 2000 (18,22). For cases diagnosed in 2000, the western European countries with the highest AIDS incidence rates per 100,000 were: Portugal 10.4; Spain 6.3; Italy 3.2; Switzerland 2.8; France 2.6; Luxemburg 2.4; Greece 1.2; United Kingdom 1.1 (18). These countries have complex and variable epidemics in that drug-use associated HIV predominates in some, while sexual transmission among men predominates in others. The epidemic curves have been similar to the U.S., with a rapid increase in infections in the early to mid-1980s, a peak in AIDS incidence in the early l990s, and dramatic declines in AIDS incidence and deaths during 1996 and 1997 following the introduction of highly active anti-retroviral treatment (HAART) including protease inhibitors. Many of the developed countries are implementing HIV case reporting and studies of HIV incidence to supplement their AIDS surveillance data. Evidence suggests that there is a resurgence of sexually transmitted diseases including gonorrhea and syphilis among men who have sex with men which may presage new increases in HIV infection rates in western Europe and the U.S. (23Ð25).

In contrast, the emerging epidemics in the eastern European countries have largely been concentrated in injecting-drug users. The highest AIDS incidence rates per 100,000 population were reported from Romania (2.5) and Ukraine (1.2) (18). However, these countries do not yet have well established HIV/AIDS surveillance systems, and the recency of the HIV epidemic has not yet resulted in a large proportion of infected persons having AIDS.

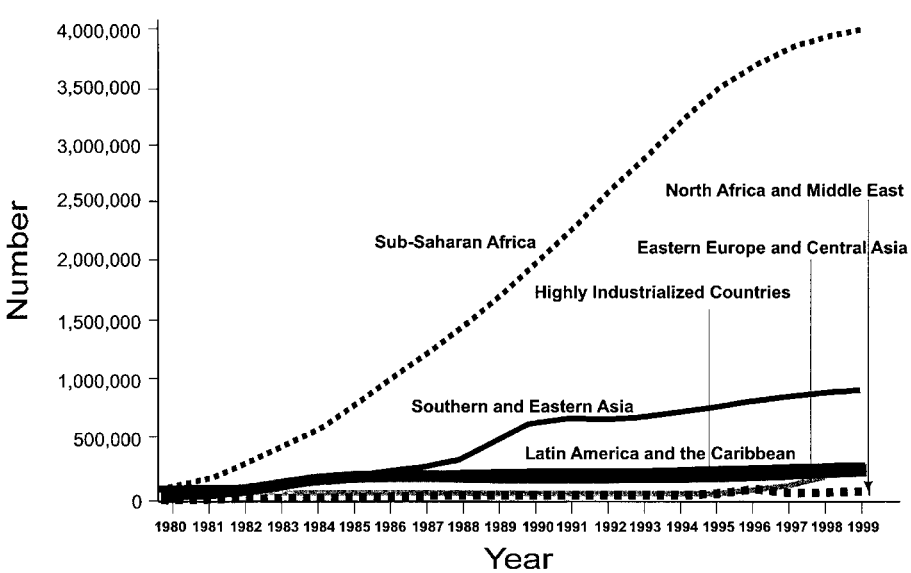

FIG. 1.2. Estimated number of new HIV infections, by region and year—worldwide, 1980–1999. Source: Joint United Nations Program on AIDS.

Efforts to prevent spread from drug injectors to their heterosexual partners are essential in this region.

In the U.S., recent attention to the economic threat and destabilizing political potential from the HIV epidemic has resulted in mobilizing resources to provide assistance. U.S. government agencies are working in collaboration with the ministries of health in African and Asian countries to build capacity for epidemic surveillance, deliver short-course treatments in labor and delivery for perinatal prevention, provide training to improve clinical management of HIV infection, and conduct behavioral surveillance and research to improve efforts in primary HIV prevention. A consortium of U.S. government and academic institutions is engaged in clinical trials of treatment interventions that can be delivered in the context of developing world infrastructure. However, perhaps the most important effort of all, i.e. vaccine research and development, has yet to yield a highly effÞcacious vaccine. This elusive prevention tool is most critical to stemming the further spread of HIV. Regardless of any future success in developing vaccines or in bringing new drugs to market, the current burden of 40 million HIV-infected persons worldwide marks a disease toll of historic proportions.

HIV/AIDS EPIDEMIOLOGY IN THE UNITED STATES

Case DeÞnition and ClassiÞcation System

Case DeÞnition

Following the initial reports of *Pneumocystis carinii* pneumonia (PCP) and KaposiÕs sarcoma (KS) among young homosexual men in Los Angeles and New York (3,4), a working case deÞnition was established to identify other cases of unusual opportunistic illnesses or malignancies that were previously known to occur principally in persons with immunosuppressive disorders. Health care providers were alerted to report cases of unusual opportunistic illness, termed AIDS, in previously healthy persons to local health authorities. The earliest AIDS data collection forms included conditions such as cytomegalovirus infection, toxoplasmosis of the central nervous system, and gastrointestinal candidiasis (excluding oral thrush) in addition to PCP and KS. Data on non-speciÞc signs and symptoms thought to be attributable to the opportunistic illnesses were collected such as skin lesions, lymphadenopathy, fever, diarrhea, oral thrush, weight loss. In 1982, history of ÒIV drug usageÓ and history of blood transfusion were collected but sexual behaviors were not. By 1983, the AIDS case report form was revised to include: a more extensive list of opportunistic illnesses (e.g. tuberculosis, nocardiosis); conditions or symptoms associated with but not speciÞc for AIDS such as amebiasis, disseminated herpes zoster, persistent bone marrow dysfunction, arthralgialmyalgia; conditions preceding or coexisting with AIDS such as HodgkinÕs disease, chronic hepatitis, chronic renal failure, insulin-dependent diabetes mellitus; and an extensive social and risk history including drug use and sexual orientation. The epidemiologic characteristics of persons with the new syndrome were consistent with sexual transmission or spread by a blood-borne agent. They were inconsistent with air-, food-, water-borne or insect vector transmission. Thus, even prior to the identiÞcation of HIV as the etiologic agent, disease surveillance and case investigations had made clear that this new condition was transmitted via sex between men or between men and women, through receipt of contaminated blood via needle-sharing among drug-users, or transfusion of blood or blood products, and perinatally from mother to child (3,4,8Ð13).

With the isolation of HIV and the availability of a serologic antibody test, it was feasible to revise the case deÞnition to include laboratory test results indicative of HIV infection and to restrict the clinical conditions indicative of AIDS to those that were highly speciÞc to immunosuppression in the absence of any other cause. Thus, the 1985 AIDS case deÞnition thus included opportunistic clinical conditions deÞnitively diagnosed based on culture, biopsy or radiologic evidence (e.g. PCP deÞnitively diagnosed) and conditions requiring additional laboratory evidence indicative of HIV infection (26). Because the epidemic initially was detected among homosexual men, as the epidemic spread into racial/ethnic minority communities, including drug-users and their (mostly female) heterosexual partners, there were concerns that the AIDS case deÞnition disproportionately captured clinical manifestations common in white gay men. In 1987, the AIDS case deÞnition was expanded to include additional conditions (e.g. wasting, dementia) that were more characteristic of injecting drug-users, and presumptive diagnoses of opportunistic illnesses in the presence of serologic evidence of HIV infection (e.g, PCP presumptively diagnosed). The 1987 AIDS case deÞnition for adults and adolescents (13 years old) included 23 opportunistic conditions and that for children, 24 conditions (27). In 1993, the AIDS case deÞnition for adults was expanded to include three additional clinical conditions and laboratory evidence of severe immunosuppression in persons with documented evidence of HIV infection, i.e. invasive cervical cancer, pulmonary tuberculosis, recurrent pneumonia, and <200 CD4 T-lymphocytes per microliter of blood (28,29). The addition of the immunologic criterion reßected the widespread use of this laboratory measure in clinical practice to monitor disease progression. These changes effectively deÞned the onset of AIDS approximately 18 to 24 months earlier in the clinical course than the previous deÞnition and necessitated the use of statistical adjustments to monitor temporal trends in AIDS incidence (30). The pediatric case deÞnition was not changed in 1993.

Beginning in 1985, several states initiated reporting of HIV cases in addition to AIDS cases. Although proponents of HIV case reporting argued for expansion of the AIDS

TABLE 1.1. *2000 revised surveillance case deÞnition for HIV infection (35)*

This revised de nition of HIV infection, which applies to any HIV (e.g. HIV-1 or HIV-2),is intended for public health surveillance only. It incorporates the reporting criteria for HIV infection and AIDS into a single case de nition. The revised criteria for HIV infection update the de nition of HIV infection implemented in 1993 (29); the revised HIV criteria apply to AIDSde ning conditions for adults (29) and children (27,37) which require laboratory evidence of HIV. This de nition is **not** presented as a guide to clinical diagnosis or for other uses (27,29).

I. In adults, adolescents, or children aged greater than or equal to 18 months,[a] a reportable case of HIV infection must meet at least one of the following criteria:

Laboratory Criteria

- Positive result on a screening test for HIV antibody (e.g. repeatedly reactive enzyme immunoassay), followed by a positive result on a con rmatory (sensitive and more speci c) test for HIV antibody (e.g. Western blot or immuno uorescence antibody test)

or

- Positive result or report of a detectable quantity on any of the following HIV virologic (non-antibody) tests: HIV nucleic acid (DNA or RNA) detection (e.g. DNA polymerase chain reaction (PCR) or plasma HIV-1 RNA[b]; HIV p24 antigen test, including neutralization assay; HIV isolation (viral culture)

OR

Clinical or Other Criteria (if the above laboratory criteria are not met)

- Diagnosis of HIV infection, based on the laboratory criteria above, that is documented in a medical record by a physician

or

- Conditions that meet criteria included in the case de nition for AIDS[cd] (27,29,37)

II. In a child aged less than 18 months, a reportable case of HIV infection must meet at least one of the following criteria:

Laboratory Criteria

De nitive

- Positive results on two separate specimens (excluding cord blood) using one or more of the following HIV virologic (nonantibody) tests: HIV nucleic acid (DNA or RNA) detection; HIV p24 antigen test, including neutralization assay, in a child greater than or equal to 1 month of age; HIV isolation (viral culture)

or

Presumptive

A child who does not meet the criteria for de nitive HIV infection but who has:

- Positive results on only one specimen (excluding cord blood) using the above HIV virologic tests and no subsequent negative HIV virologic or negative HIV antibody tests

OR

Clinical or Other Criteria (if the above deÞnitive or presumptive laboratory criteria are not met)

- Diagnosis of HIV infection, based on the laboratory criteria above, that is documented in a medical record by a physician

or

- Conditions that meet criteria included in the 1987 pediatric surveillance case de nition for AIDS[d] (27,37)

III. A child aged less than 18 months born to an HIV-infected mother will be categorized for surveillance purposes as "not infected with HIV" if the child does not meet the criteria for HIV infection but meets the following criteria:

Laboratory Criteria

De nitive

- At least two negative HIV antibody tests from separate specimens obtained at greater than or equal to 6 months of age

or

- At least two negative HIV virologic tests[e] from separate specimens, both of which were performed at greater than or equal to 1 month of age and one of which was performed at greater than or equal to 4 months of age

AND

NO other laboratory or clinical evidence of HIV infection (i.e. has not had any positive virologic tests, if performed, and has not had an AIDS-de ning condition)

or

Presumptive

A child who does not meet the above criteria for de nitive "not infected" status but who has:

- One negative EIA HIV antibody test performed at greater than or equal to 6 months of age and NO positive HIV virologic tests, if performed

or

- One negative HIV virologic test[e] performed at greater than or equal to 4 months of age and NO positive HIV virologic tests, if performed

or

- One positive HIV virologic test with at least two subsequent negative virologic tests,[e] at least one of which is at greater than or equal to 4 months of age; or negative HIV antibody test results, at least one of which is at greater than or equal to 6 months of age

TABLE 1.1. *Continued*

AND

NO other laboratory or clinical evidence of HIV infection (i.e. has not had any positive virologic tests, if performed, and has not had an AIDS-de ning condition)

OR

Clinical or Other Criteria (if the above de nitive or presumptive laboratory criteria are not met)

- Determined by a physician to be "not infected", and a physician has noted the results of the preceding HIV diagnostic tests in the medical record

AND

NO other laboratory or clinical evidence of HIV infection (i.e. has not had any positive virologic tests, if performed, and has not had an AIDS-de ning condition)

IV. A child aged less than 18 months born to an HIV-infected mother will be categorized as having perinatal exposure to HIV infection if the child does not meet the criteria for HIV infection (II) or the criteria for "not infected with HIV" (III).

[a] Children aged greater than or equal to 18 months but less than 13 years are categorized as "not infected with HIV" if they meet the criteria in **III**.

[b] In adults, adolescents, and children infected by other than perinatal exposure, plasma viral RNA nucleic acid tests should NOT be used in lieu of licensed HIV screening tests (e.g. repeatedly reactive enzyme immunoassay). In addition, a negative (i.e. undetectable) plasma HIV-1 RNA test result does not rule out the diagnosis of HIV infection.

[c] AIDS-de ning conditions for adults and adolescents 13 years and older include the following conditions (27,29) Candidiasis of bronchi, trachea, or lungs; Candidiasis, esophageal; Carcinoma, invasive cervical;* CD4 T-lymphocyte count < 200 cells/microliter or percent < 14;* Coccidioidomycosis, disseminated or extrapulmonary;* Cryptococcosis, extrapulmonary; Cryptosporidiosis, chronic intestinal; Cytomegalovirus disease (other than in liver, spleen or nodes); Cytomegaloviris retinitis;* HIV encephalopathy;* Herpes simplex: chronic or bronchitis, esophagitis or pneumonitis; Histoplasmosis, disseminated or extrapulmonary,* Isosporiasis, chronic intestinal;* Kaposi's sarcoma; Lymphoma, Burkitt's;* Lymphoma, immunoblastic;* Lymphoma primary in brain;* *Mycobacterium avium complex* or *M. kansasii*, disseminated or extrapulmonary, *M. tuberculosis*, pulmonary,* *M. tuberculosis*, disseminated or extrapulmonary;* Mycobacterium of other species, disseminated or extrapulmonary;* *Pneumocystis carinii* pneumonia, Pneumonia, recurrent;* Progressive multifocal leukoencephalopathy; Salmonella septicemia, recurrent;* Toxoplasmosis of brain: Wasting syndrome due to HIV.*

* Conditions that are AIDS-de ning in the presence of laboratory evidence for HIV infection (35); other listed conditions require diagnosis by de nitive methods if laboratory tests for HIV were not performed or gave inconclusive results and the patient had no other cause of immunode ciency.

[d] AIDS-de ning conditions for children less than 13 years old include the conditions listed above and: Bacterial infections, multiple or recurrent (including Salmonella septicemia)* and Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia (27,37); but they **exclude** the conditions above that were added to the adult/adolescent case de nition in 1993: invasive cervical carcinoma, extrapulmonary), *M. tuberculosis*, recurrent pneumonia, and CD4 T-lymphocyte count < 200 cells/microliter or percent < 14.

* See asterisk under footnote c above.

[e] HIV nucleic acid (DNA or RNA) detection tests are the virologic methods of choice to exclude infection in children aged less than 18 months. Although HIV culture can be used for this purpose, it is more complex and expensive to perform and is less well standardized than nucleic acid detection tests. The use of p24 antigen testing to exclude infection in children aged less than 18 months is not recommended because of its lack of sensitivity.

An original paper copy of the document containing this de nition (35) can be obtained from the Superintendent of Documents, U.S. Government Printing Of ce (GPO), Washington, D.C. 20402–9371; telephone (202)512–1800 Contact GPO for current prices.

case de nition to include all persons infected with HIV in 1993 [or even earlier], it was not until the dramatic declines in AIDS cases and deaths which occurred following the introduction of HAART that a national debate earnestly addressed the need to monitor infected persons at all stages of disease (31–34). As of January 1, 2000, CDC implemented a revised integrated HIV and AIDS case de nition for adults and children that recognizes one disease with multiple stages and incorporates current laboratory measures of HIV for adults and children (Table 1.1). This de nition was published together with CDC recommendations for nationwide HIV case surveillance (35).

Classi cation System

As the AIDS case de nition was revised to incorporate advances in clinical, diagnostic and laboratory practices, it was also necessary to revise the HIV disease classi cation systems. The current classi cation system for adults and adolescents was introduced in 1993 (29). It incorporates stage of disease as measured by symptoms, and stage of immunosuppression as measured by CD4 count. A 9-cell grid is organized into three clinical stages (asymptomatic or acute HIV infection, symptomatic, AIDS-de ning conditions) and three immunologic categories (CD4 □ 500 cells per microliter of blood, 200–499, and < 200). For infants and children < 13 years old, a 12-cell classi cation system was introduced in 1994 (36,37). The immunologic criteria for children are divided into three age-speci c categories characterized as none, moderate, or severe immunosuppression. The clinical categories are none, mild, moderate, or severe symptoms.

HIV/AIDS Surveillance Methods

Case Reporting and Seroprevalence Surveys

The HIV/AIDS surveillance system represents the collective efforts of health department staff at county, city

and state/territorial levels, physicians, nurses and other health care providers, affected communities and the CDC to develop and maintain an accurate, timely, representative, and conÞdential system of reporting information about those who are affected by the epidemic. When the Þrst cases of AIDS were detected, the surveillance system only identiÞed severe morbidity, which we now understand represents only the end-stage of HIV disease. Thus, as the epidemiology of HIV was revealed and as laboratory advances enabled improved testing and diagnostics, it became possible to expand reporting criteria to include asymptomatic and mildly symptomatic stages of disease.

AIDS is a notiÞable disease in all states and territories, meaning that each jurisdiction has legal requirements that health care providers notify health authorities when a person is diagnosed as having AIDS. In implementing laws, rules, or regulations requiring disease reporting, states enact legal requirements for conÞdentiality of the surveillance data and penalties for inappropriate use or disclosure (38). AIDS cases are reported to local health departments by health care providers, facilities and laboratories using a standard case report form and case deÞnition. These reports are forwarded to state or territorial health departments for aggregation and dissemination of summary data. In addition to passive reporting by providers, health departments conduct active surveillance by visiting facilities and soliciting case reports, completing case report forms to reduce the burden on providers, providing training and feedback to reporting sources, and monitoring completeness of case reporting. At the state level, the data are used to track changes in the local epidemic and identify emerging populations at risk. States then forward data to CDC which is responsible for analysis and dissemination of the national data (Fig. 1.3). The national database is protected under a federal assurance of conÞdentiality which prohibits the release of HIV/AIDS surveillance data for non-public health purposes. The CDCÕs database does not contain individual patient or physician identifying data and is only linked to identifying data maintained at the state or territorial level by state-assigned numbers and codes. In cases requiring follow up investigation to identify potential new or unusual modes of HIV transmission, CDC scientists must work in collaboration with local health authorities.

Following the availability of the HIV antibody test, efforts to monitor HIV in the population were focused on large-scale anonymous unlinked serologic surveys. CDC and states invested surveillance resources in establishing a network of seroprevalence surveys (39). Populations targeted for seroprevalence surveys were those thought to be at high-risk, such as drug-users entering treatment and clients of sexually-transmitted disease clinics. In addition, accessible populations such as military service applicants, or those in which HIV testing was required such as Job Corps entrants, were sources of epidemiologic data on the extent of HIV in the population. While these data were useful to estimate the prevalence of HIV in selected populations in the U.S., they were able to collect only limited demographic and other epidemiologic data. Only one serologic survey, the survey of childbearing women which anonymously tested blood specimens routinely collected from newborns for other health purposes, provided population-based estimates of HIV prevalence.

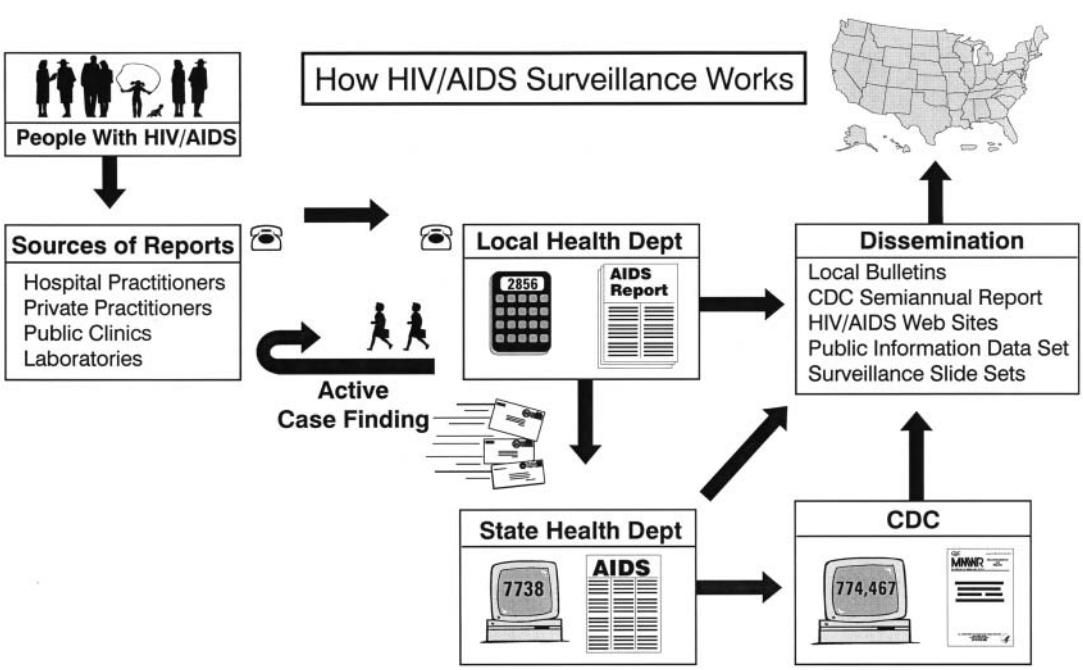

FIG. 1.3. Core HIV/AIDS surveillance information ow. Source: CDC, Division of HIV/AIDS Prevention.

From this survey, the prevalence of HIV in women delivering liveborn infants in the U.S. was derived (40,41). Implemented in the late 1980s, after HIV incidence had already peaked in the U.S., the serologic surveys tracked relatively stable seroprevalence levels in most of the target populations through the mid-1990s (42). Most national seroprevalence surveys were discontinued in the mid-1990s. Although some states continue these surveys, it is now challenging to interpret whether changes in seroprevalence represent increasing or decreasing HIV incidence or increasing survival of persons with HIV who are on HAART.

During the late-1980s, in response to the growing epidemic, Congress allocated resources to improve and standardize AIDS surveillance. CDC and state and territorial health departments responded by improving the quality, completeness and timeliness of AIDS case reporting (43,45). As a result of the high quality and comparability of the data across jurisdictions, during the 1990s, the AIDS surveillance data became the basis for allocating nearly $2 billion in federal resources for patient care and treatment to states and hard-hit cities. The epidemiologic characteristics of AIDS cases also became an important basis for allocating resources for HIV prevention.

However, with the advent of HAART, by the mid-1990s, AIDS surveillance data were clearly inadequate to represent the extent of the epidemic in the U.S. Together with the discontinuation of the seroprevalence surveys, the national HIV/AIDS surveillance program was in jeopardy. Because resources for prevention and care are tied to surveillance data, broad political, public health and community efforts combined to support an expansion of surveillance crtieria to include all persons with HIV, regardless of stage of disease. These efforts led to the 2000 integrated HIV and AIDS case definition for adults and children and the recommendation that all states implement HIV case reporting in addition to AIDS (35).

While case reports are extremely valuable for monitoring the number and characteristics (e.g. sex, racial-ethnic group, age group, mode of HIV transmission, geographic distribution, clinical status and CD4 count or viral load at diagnosis of HIV or AIDS) of persons who are known to be infected with HIV or to have progressed to AIDS, they do not represent undiagnosed HIV-infected persons or those tested anonymously. Thus, epidemiologists use case surveillance data in conjunction with data from other sources including seroprevalence surveys in selected populations, studies of HIV incidence, death certificates, service databases such as test results from publicly funded counseling and testing sites, and behavioral surveys (7,46–52).

Prior to 1993, AIDS surveillance data reliably estimated trends in HIV incidence and the cumulative number of HIV infections by the application of statistical back-calculation models which estimated that HIV incidence peaked at over 100,000 infections annually in the mid-1980s and declined to between approximately 40,000 to 60,000 infections annually in the early 1990s (53–55). However, during the l990s, this method became unuseable because of changes to the AIDS case definition and the impact of HAART on AIDS incidence. It has since been necessary to estimate HIV incidence indirectly by synthesizing data from multiple sources; CDC has estimated that HIV incidence remained relatively stable, at approximately 40,000 annual infections, during the mid- and late-nineties (35,47). Technical developments have enabled estimating recent seroconversions, within a window period of about 130 days, from blood samples of persons newly testing HIV positive (56). Because direct measures of HIV incidence in the population are crucial to efficient targeting of prevention resources, detecting new trends in populations at risk, and monitoring the effectiveness of prevention programs, HIV incidence monitoring in conjunction with HIV/AIDS case reporting are current priority surveillance strategies.

Adjustments to Surveillance Data

The process of case reporting involves a time lag from when a laboratory or clinical diagnosis is confirmed until a report is forwarded in turn to local, state, and federal levels. Case reports in a given time period are useful to monitor the performance of the reporting system. However, in order to monitor trends in AIDS incidence in the population, the data are statistically adjusted to account for reporting delays. The adjusted data do not represent counts of persons with AIDS, rather they represent estimates of AIDS incidence taking into account variations in reporting delays by demographic and geographic variables. Nearly all cases are reported to CDC within a year of diagnosis, thus, estimates for the most recent quarter-years are subject to the greatest adjustment (5,57).

Similarly, there are lags in obtaining complete data on mode of HIV transmission. These data are important to understanding epidemiologic patterns, detecting emerging communities at risk, and guiding prevention program priorities. However, unless a patient divulges risk behaviors, or providers elicit and record a thorough behavioral risk history, cases often are reported without any behavioral data. The number and proportion of such cases has steadily increased reflecting the increased volume of cases reported after the 1993 definition change, increased reliance on laboratory reporting, and the growth of the heterosexual epidemic wherein patients may not have primary HIV risk behaviors (58). With the adoption of laboratory-initiated HIV case reporting, behavioral data are usually lacking until a patient is obtaining on-going medical care and health departments conduct a labor intensive follow up review of medical records, or interview the provider or the patient. To address the lack of behavioral risk data on a large proportion of cases, CDC and states are implementing a variety of more efficient

strategies including follow up studies on a sample of cases and estimating the distribution of behavioral risks using statistical models based on behavioral surveys (59). In addition, for persons who were infected heterosexually, who may not have a partner with a primary risk or recognize their partnersÕ risks, efforts are underway to develop a standardized deÞnition of high-risk heterosexual sex so that states will classify persons with multiple sex partners or a history of sexually transmitted diseases in a consistent way. Finally, standardized statistical methods are applied at the national level to estimate the true risk distribution by adjusting for unreported risk information using historical patterns of reclassiÞcation after follow up investigations of persons initially reported without risk (60).

HIV/AIDS Surveillance Data

Through December 31, 2001, state and territorial health departments have reported 816,149 persons with AIDS to the CDC; 81.6% were adult and adolescent men, 17.3% women, and 1.1% infants and children (5). Although the annual number of reported AIDS cases declined dramatically in the latter half of the 1990s coincident with the widespread use of HAART, the number of reported AIDS cases has remained stubbornly over 40,000 cases per year. During 2001, 43,158 AIDS cases were reported to CDC (5). Through December 31, 2001, deaths of persons with AIDS numbered 467,910, or 57.3% of cumulative reported AIDS cases. In addition, 174,026 reports of persons diagnosed with HIV (without an AIDS diagnosis), of whom 3,923 (2.3%) were infants and children, have been received from 39 areas that have implemented conÞdential (i.e. reporting by patient name) HIV infection case surveillance. These latter reports are not necessarily reßective of the characteristics of all persons diagnosed with HIV in the U.S. However, additional data will become available in future from the remaining geographic areas which have either implemented HIV case reporting using a patient code, or a hybrid name-to-code system, or are expected imminently to implement HIV reporting (61). Ultimately, the national HIV/AIDS case reporting system should include data on all persons known as having HIV or AIDS in the U.S.

Demographic Characteristics

From statistical models based on the distribution of ages at AIDS incidence in the absence of treatment, it has been estimated that the vast majority of new HIV infections occur among adults < 30 years old, with as many as half of all infections occurring in those under 25 (55,62). These young ages represent the highest risk of acquiring or transmitting HIV because rates of partner change and of sexually transmitted infections that potentiate HIV spread are highest in young adult age groups (63). Following infection, a small proportion of individuals progress rapidly to AIDS (64). However, the majority of AIDS cases are diagnosed in their mid-thirties, consistent with models of the natural history of HIV which estimate the median incubation period from infection to AIDS-deÞning opportunistic illnesses to be about 10 years (Fig. 1.4).

Although the epidemic in the U.S. has disproportionately affected men since the beginning, the proportion of adult AIDS cases reported annually that are female has increased steadily from less than 10% during the 1980s to 26% in 2001 (Fig. 1.5) (5). As the heterosexual epidemic has grown in the U.S., CDC has estimated that at least one-quarter of new HIV infections are now occurring in women (CDC, unpublished data). The proportion of reported HIV cases that are female was 32% in 2001 reßecting the characteristics of the epidemic in the HIV reporting states, which under-represent states in which the epidemic has predominantly affected men who have sex with men (MSM) and injecting drug-users (IDU).

The proportion of AIDS cases that are racial/ethnic minorities (including blacks, Hispanics, American Indians/

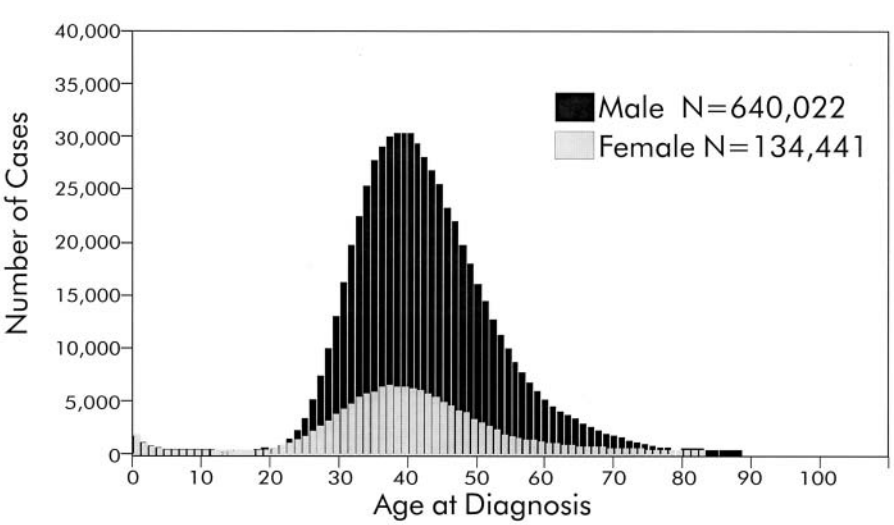

FIG. 1.4. AIDS cases by age and sex, reported 1981–2000, United States. Source: CDC, Division of HIV/AIDS Prevention.

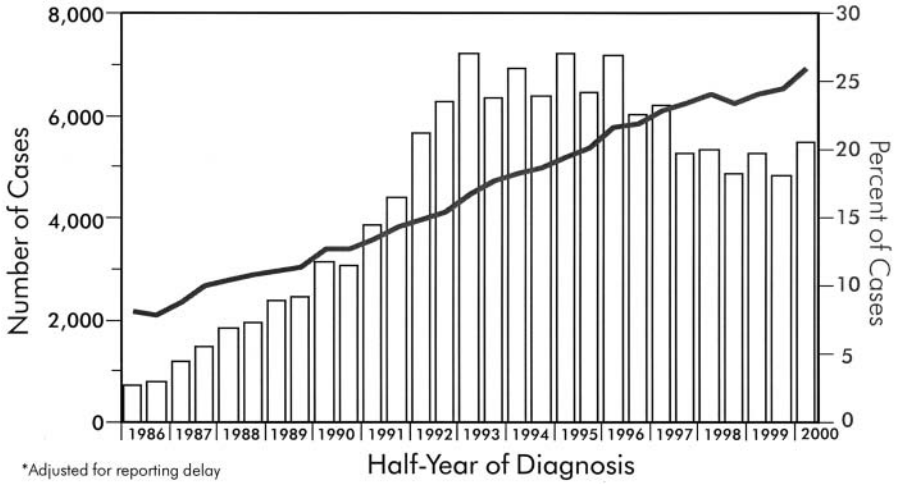

FIG. 1.5. IDS incidence in women (bars—left scale) and percentage of total AIDS cases (line—right scale), January 1986–June 2000, United States. Source: CDC, Division of HIV/AIDS Prevention.

Alaska Natives, and Asians/PaciÞc Islanders) has also increased steadily over time (Fig. 1.6). Of the 42,983 adults reported with AIDS in 2001, 69% were racial/ethnic minorities. Among women with AIDS, the proportion is even higher, 82% in 2001. The disproportionate impact of the drug-use associated epidemic on racial/ethnic minorities, including drug-injectors and their heterosexual partners, is reßected in rates that are many times higher than those in whites. Among adult men, the rates of reported AIDS cases per 100,000 males in 2001 were: whites 13.7; blacks 109.2; Hispanics 43.3; Asian/PaciÞc Islander 8.6; American Indian/Alaska Native 18.8. For adult women, the rates were 2.4, 47.8, 12.9, 1.5, and 4.9, respectively (5).

AIDS cases have been reported from every state, however, among men, the epidemic is concentrated mainly on the east and west coast, in large urban areas with the highest concentrations of MSM. Among IDU, both male and female, the epidemic has largely affected urban centers along the east coast. HIV-infected heterosexual partners of drug-users tend also to reside in east coast states. Thus, for men, states with the highest reported AIDS rates per 100,000 in 2001 are bicoastal, whereas for women, the highest rates are mainly on the east coast (Figs. 1.7 and 1.8, respectively). While the number of AIDS cases reported from smaller urban and rural areas has increased as HIV was disseminated throughout the nation, the proportionate distribution of cases by urbanicity has remained remarkably stable (Fig. 1.9). The rate of reported AIDS cases in 2001 was 2 times higher in metropolitan areas with populations greater than 500,000 population (19.0) than in those with $<$500,000 (9.5) and 3.3 times higher than in non-metropolitan areas (5.8). Even within the most densely populated metropolitan areas, the central counties are more heavily affected than the outlying counties with a rate of 20.4 versus 4.9 (5).

Trends by Mode of HIV Transmission

The dynamics of HIV transmission are quite complex at both the individual and population levels. The risk of

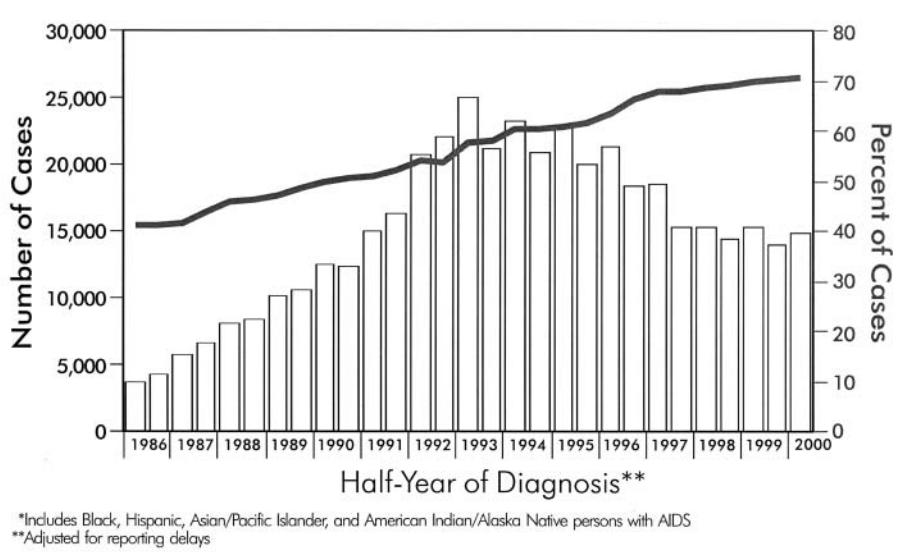

FIG. 1.6. AIDS incidence in racial/ethnic minorities (bars—left scale) and percentage of total AIDS cases (line—right scale), January 1986–June 2000, United States. Source: CDC, Division of HIV/AIDS Prevention.

contracting HIV varies by mode of exposure to the virus (65Ð75). Numerous published studies have quantiÞed HIV transmission risks; some of these studies are summarized in Table 1.2. At the individual level, factors that determine the risk of infection include the per contact risk of becoming infected if exposed, the probability that a partner of unknown status may be infected which is determined by the prevalence of HIV in that population, and the frequency of practicing the risky behavior. Numerous individual factors may mitigate the risk including genetic factors, the use of microbicides or barrier protection. Others may potentiate infection, for example, the presence of ulcerative sexually-transmitted infections or traumatic sex. The stage of disease of the infected contact and whether treatment has reduced levels of circulating virus may also affect the risk of transmission (76). For clinicians counseling patients about HIV prevention, it is important to understand that the epidemiologic

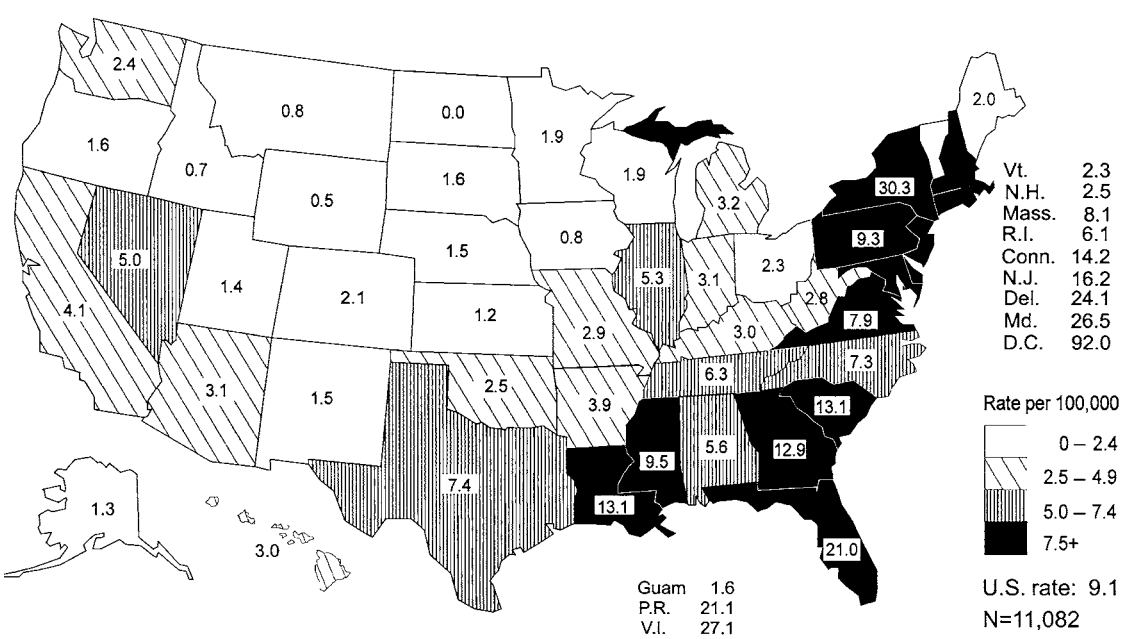

FIG. 1.8. Female adult/adolescent annual AIDS rates per 100,000 population for cases reported in 2001, United States. Source: CDC, Division of HIV/AIDS Prevention.

risks summarized in Table 1.2 represent population probabilities and are not necessarily applicable at the individual level. That is, because any single exposure may result in infection, individuals need to avoid high risk behavior to prevent transmitting or acquiring HIV.

The early burst of HIV in the U.S. population occurred when the virus was introduced into susceptible populations with high rates of behaviors conducive to viral spread. The Þrst reports of AIDS in homosexual men in 1981 suggested that this population was at the vanguard of the Þrst wave of HIV transmission in the U.S. In retrospect, these early cases represented only a small proportion of men who were infected during the late 1970s and progressed relatively rapidly to AIDS. As HIV spread, AIDS appeared in IDU, recipients of blood and blood products, and infants born to drug-injecting women. A second wave of susceptibles was infected through heterosexual spread of HIV from drug-users to their male or female partners or from bisexual men to their female partners. Thus, a number of factors facilitated rapid spread of HIV during the 1980s: the existence of bridge populations (e.g. men who engage in sex with other men and inject drugs through sharing of paraphernalia represented a bridge for spread of the epidemic from the MSM community as did bisexual men), geographic mobility of at-risk and infected populations, high rates of risky sex and drug-using behaviors, and a large size demographic cohort in their twenties and thirties when the virus was introduced, i.e. the generation born between 1946 and 1964 known as the Òbaby boomÓthat was in the ages of peak sex and drug-using behavioral risks.

Exposure to contaminated blood poses a high risk of infection but that varies by the route of blood exposure. Early in the HIV epidemic, highly efÞcient transmission occurred to transfusion recipients of blood donated by HIV-infected persons. Hemophiliacs who had multiple

TABLE 1.2. *Reported estimates of per-contact HIV transmission risk from selected studies*

Risk category	Probability of transmission	Source[a]
Recipients of HIV + transfusions	89.5%	Donegan, 1990
Mother-to-child transmission		Connor, 1994
Without zidovudine	25%	
With zidovudine	8%	
MSM, overall[b]	0.01–5.1%	Vittinghoff, 1999
IDU (Connecticut)	0.67%	Kaplan, 1992
Heterosexual, overall[b]	0.03–0.23%	Downs, 1996; Peterman, 1988
Needlestick	0.13–0.70%	Henderson, 1990

[b] Included within the range are estimates for unprotected insertive and receptive anal, oral, or vaginal intercourse.
MSM = Men who have Sex with Men.

exposures to contaminated blood products through receipt of clotting factors also experienced high rates of HIV infection. In recent years, more sensitive HIV viral detection tests have enabled the identiÞcation of blood donated during the Òwindow periodÓ following infection but prior to developing antibodies. Thus, the risk of infection through receipt of blood has been virtually eliminated (77). Sharing of syringes and other drug-injecting equipment can expose multiple users to contaminated blood and the repetitive nature of exposures in drug-addicted populations assured high probabilities of infection in this population. High rates of transmission occurred in large cities in the northeast and the drug-associated epidemic remains concentrated in urban areas along the east coast with high rates also in Puerto Rico. Occupational transmission through exposure to HIV-infected blood has occurred much less frequently, and has been principally through needlesticks (78). The risk of infection per exposure is inßuenced by the size of the needle bore and the depth of the wound. Recently, this risk has been reduced through post-exposure prophylactic antiretroviral therapy (79).

Epidemiologic studies suggest that unprotected receptive anal intercourse is among the most efÞcient modes of sexual transmission. Sexual transmission by vaginal, anal, or oral routes is facilitated by high risk behaviors including multiple partners and anonymous sex, ulcerative sexually transmitted diseases, and the use of non-injecting drugs or alcohol which are associated with lower rates of condom use. With rising background HIV prevalence rates in the population, high prevalence of risky sexual behaviors, and high STD rates, rapid spread of HIV occurred in MSM populations in the early epi-centers in the northeast and on the west coast as the virus spread geographically through the susceptible population. With each successive cohort of young men who come of age, prevalence in the population will be determined in part by the prevalence of risky behaviors and the mixing of populations across age groups. Heterosexual transmission from male or female (mostly male) injecting drug-users to their male or female (mostly female) sex partners triggered the epidemic of heterosexually-acquired HIV. While the act of receptive anal intercourse does not necessarily pose a differential risk by sex per contact with an infected partner, the role of unprotected anal intercourse has apparently played a greater role in the MSM epidemic than in the heterosexual epidemic because of differences in the prevalence of this behavior in MSM versus heterosexual populations in the U.S. and because the prevalence of HIV is higher among MSM than among the general heterosexual population. Vaginal intercourse is thought to be relatively less efÞcient for female-to-male transmission than for male-to-female. However, as with transmission among MSM and IDU, rates of heterosexual transmission are affected by background prevalence in the population, prevalence of risky sex (multiple partners, anonymous sex, unprotected sex), sexual mixing patterns and sexually transmitted diseases. Sorting out the role of prostitution in the heterosexual epidemic in the U.S. has been challenging in that many commercial sex workers are also drug-injecting women who may have multiple routes of acquiring and transmitting HIV.

Transmission vertically from mother to child occurs at a rate of about 25% (80). In 1994, results of clinical trials were published indicating that maternal zidovudine (ZDV) treatment prenatally and intra-partum, together with post-partum treatment of the neonate resulted in a reduced rate of transmission to about 8% (80) Subsequent recommendations for ZDV to reduce perinatal transmission coupled with universal counseling and voluntary HIV testing of pregnant women have dramatically reduced the incidence of perinatally-acquired HIV in the U.S. (81Ð83). Currently, the transmission rates have been reduced to as low as 2% or less with the addition of maternal antiretroviral treatment during pregnancy for maternal health, improved obstetrical practices including Caesarian-section and rapid testing in labor and delivery, and the emergence of effective short-course interventions in labor and delivery for women who have little or no prenatal care (84Ð87).

Other categories of transmission risks have been reported but they occur much less frequently in the population and they involve unusual sexual behaviors or exposures to blood or body ßuids. For example, there have been reports of sexual transmission to very young children, deliberate self-inoculations, exposure to concentrated virus in laboratory settings, and other unusual exposures to blood (60,88,89). Conversely there have been no credible reports of transmission by bites between children, mosquito bites, or other common potential routes of exposure. The results of standard investigations of potential cases of unusual transmission have reassured the public that there are no reported risks from sources other than blood and sexual exposure (60,90). Providers should alert health departments to any cases of potential unusual routes of transmission so that they may investigate in collaboration with the CDC and issue revised prevention guidelines if appropriate.

Hierarchical Risk ClassiÞcation

To monitor trends in the population by mode of transmission, the HIV/AIDS case report form collects data on multiple modes of exposure. However, in order to summarize data for persons reported as having multiple risks, CDC adopted a hierarchical risk classiÞcation system. For any individual who has multiple risks, it is difÞcult to determine with certainty which exposure mode accounted for the infection (5). Fourteen percent of 807,075 AIDS cases reported through December, 2001 were reported with two or more transmission modes, 76% with one, and 10% with no risks reported (5). Thus, the hierarchy classiÞes persons having multiple modes as

most likely infected by the one listed highest in the hierarchy. One exception is the category of MSM who are also IDU. Because both modes represent high risk of exposure to HIV, men with both are classiÞed as such rather than presuming that one is more likely than the other to be the source of the HIV infection. The hierarchy of modes of HIV exposure for adults/adolescents is: MSM, IDU, MSM and IDU, hemophilia/coagulation disorder, heterosexual contact with a person with HIV/AIDS or with a person who has a primary risk (e.g. bisexual male, IDU), receipt of blood or blood products or tissue (5). The distribution of transmission modes for men and women with AIDS who were diagnosed during 2000 is shown in Fig. 1.10.

Men who have Sex with Men (MSM)

MSM have always accounted for the largest proportion of AIDS cases. MSM accounted for 40% of the estimated 41,311 adults diagnosed with AIDS during 2001 (Table 1.3) (5). Cohort studies, begun in 1983 in cities hit early by the MSM epidemic, stored baseline sera from volunteers. Later, after the antibody test was available, these specimens revealed seroprevalence rates as high as over 40% (91). These studies, plus statistical models of AIDS incidence, suggest that the epidemic in gay men spread very rapidly early in the l 980s and that HIV incidence had peaked by the mid-1980s (53Ð55). AIDS incidence peaked approximately 10 years later in MSM, in the early 1990s, in association with the expansion of the AIDS case deÞnition. Dramatic declines in AIDS and deaths occurred during 1996Ðl998, attributed in part to the introduction of HAART and in part to the expected declines reßecting the epidemic curve (Fig. 1.11). Trends in AIDS incidence have stabilized during l999 through 2001. However, characteristics of MSM with AIDS have shifted, with racial/ethnic minority MSM representing an increasing proportion of AIDS cases (Fig. 1.12) (92). While the shift to minority MSM may in part reßect differentials in access to care and treatment, reports of resurgent STD incidence and of high HIV seroconversion rates among MSM in several cities, particularly among racial minorities, have resulted in a new focus on prevention needs of all MSM (46,93).

At the end of 2000, nearly 338,000 persons were living with HIV/AIDS of whom 45% were MSM. AIDS prevalence by risk group for men is shown in Fig. 1.13. Although most seroprevalence surveys have been discontinued, the data available from 1993 through 1997 highlight the high HIV prevalence rates among black MSM in STD clinics, compared to Hispanics and whites (Fig. 1.14).

Injecting Drug Users (IDU)

The epidemic in drug-using populations has been disproportionately concentrated among racial/ethnic minorities, especially black and Hispanic men and women on the east coast. Seroprevalence surveys have documented large differentials in HIV prevalence among IDU entering drug treatment in cities on the east coast versus the west coast (Fig. 1.15). HIV incidence peaked among IDUs in the mid-1980s (53,54). As the high HIV prevalence in minority drug injectors contributed to the heterosexual spread of HIV, heterosexually acquired infections began to account for an increasing proportion of AIDS cases in minority women and men. The age at initiation of drug-injecting generally lags several years behind initiation of non-injecting drug use as well as

behind age at initiation of high-risk sexual activity. Trends in HIV seroprevalence among IDU entering drug treatment centers by age group (Fig. 1.16) and sex (Fig. 1.17) illustrate the highest rates in older cohorts and the similarity in rates for men and women. IDU accounted for about 27% of 338,000 persons living with HIV/AIDS as of 2000 and 26% of persons diagnosed with AIDS in 2001 (Table 1.3). Declines in AIDS cases and deaths were observed during 1996 and 1997, although the rate of decline was not as great as for MSM (Fig. 1.11).

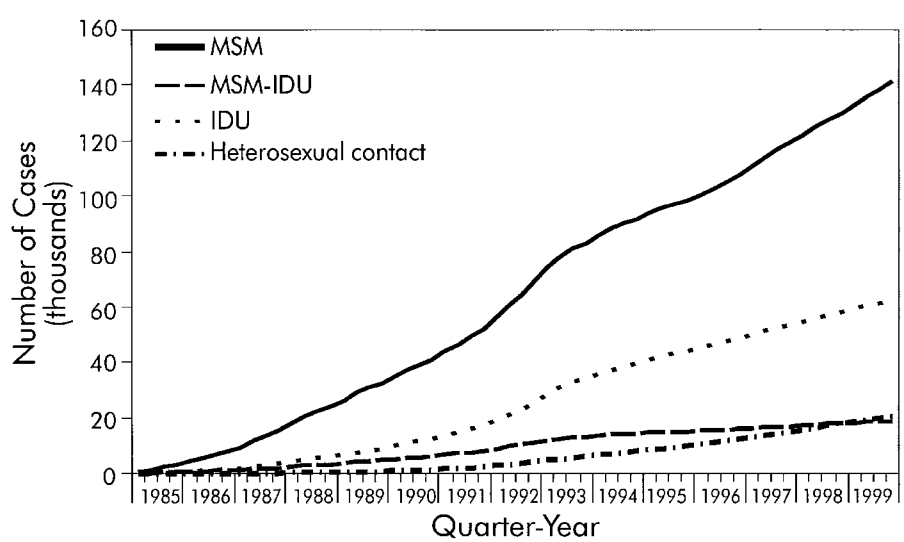
Heterosexually-Acquired Infections

The extent of the heterosexual epidemic in the U.S. has met with controversy. Some claim that the risk of heterosexual transmission is overstated in order to alarm the public and garner attention and resources to a disease that has not affected mainstream America (94). Others claim that the extent of the heterosexual epidemic has not been recognized and that prevention resources are not being appropriately targeted (95). Classifying infected persons by a behavioral risk when they are not members of a primary risk group (i.e. MSM, IDU, infected transfusion



*Adjusted for reporting delays and unreported risk

recipient, hemophiliac) is complicated. Obviously, for sexually active infected persons for whom one can deÞnitively rule out any exposure since 1978 through needle-sharing, male-male sex, or history of transfusion prior to 1985, they most likely were infected heterosexually (barring rare modes and infrequent occupational exposures). However, CDC has deÞned heterosexual-contact cases based on evidence that one or more sex partners is in a primary risk group or is *known* to have tested positive or to have AIDS. Most case reports are completed by infection control practitioners or health department staff from abstraction of medical records and heterosexual risk factors may not be documented unless the provider inquired about the risk behaviors or infection status of current and prior partners. Many bisexual men and drug-injectors may conceal their primary risk behavior such that heterosexual partners may not know or recognize their partnerÕs risk (96). Prevalence in the general heterosexual population is low, and heterosexual sex is a highly prevalent behavior, thus, heterosexual sex per se is not classiÞed as a risky behavior. Early in the epidemic, many partners had not been tested or had not progressed to clinical illness such that a partnerÕs antibody status was likely unknown. Among heterosexuals, identifying high risk sexual behaviors such that an infected person can be classiÞed as having heterosexually-acquired HIV, has been the subject of several studies (59,96). These studies have found that with detailed case investigation, one or more sex partners having primary risks or positive HIV test results can generally be identiÞed. However, there is an

important group that denies behavioral risk factors and cannot identify partners having a primary behavioral risk or partners known to be HIV-infected. Such persons probably acquired HIV through secondary heterosexual transmission (i.e. transmitted sexually from persons who themselves were infected through high-risk heterosexual contact). A number of factors may be associated with the growth of a secondary heterosexual epidemic. Among the racial/ethnic minorities disproportionately affected by the IDU epidemic, high rates of non-injection drug use, notably crack cocaine, are also associated with large numbers of partners, anonymous sex, exchange of sex for drugs or money and high rates of sexually transmitted diseases (49,96Ð98). Whether the prevalence of HIV in a sub-population, speciÞcally racial/ethnic minority groups in the U.S., can achieve high enough levels to be self-sustaining and become endemic against a backdrop of high prevalence of risky heterosexual behaviors is a major epidemiologic question in the U.S. Prevention interventions targeted to heterosexual men and women who engage in high risk behaviors are needed to forestall this scenario.

Among prevalent AIDS cases at the end of 2000, 19% were heterosexual-contact cases. Women account for the majority of heterosexual-contact AIDS cases (Table 1.3); the distribution of prevalent AIDS cases by risk exposure is shown for women in Fig. 1.18. Despite overall declines in AIDS incidence in other major risk groups, slight increases have been reported in the number of heterosexual AIDS cases in the last few years and they accounted for

about 28% of incident AIDS cases during 2001 (Figure 1.11) (Table 1.3). Whether this represents increases in new HIV infections in recent years in this population, or lack of access to testing and treatment, cannot be determined from the available data. However, there is some evidence of increases in new HIV cases in some states among cohorts of young women who are most likely to be recently infected (99). On the other hand, HIV prevalence among young men and women entering the Job Corps, and among military applicants suggest that prevalence in young, mostly heterosexual populations may be stable or decreasing (Figs. 1.19 and 1.20, respectively). Data from HIV reporting states showed stable numbers of new HIV diagnoses among young adults during 1994 to 2001 suggesting that HIV incidence in the youngest age groups is likely to have been fairly stable in these states in recent years (Fig. 1.21).

Perinatally-Acquired Infections

The perinatal AIDS epidemic peaked at above 900 cases in 1992, and declined more than 80% through 1999 (Fig. 1.22). The declines in AIDS have been inßuenced by the introduction of prophylaxis against AIDS-deÞning opportunistic illnesses including PCP, HAART for children which is maintaining infected children longer AIDS-free, but mostly, the use of ZDV and other antiretroviral therapy for pregnant women which reduced the number of infected children born each year (100Ð104). Reductions in HIV transmission rates from 25% to $<2\%$ have been reported in a number of sources (84,85,104). Thus, the pool of children at risk of AIDS has dropped dramatically. Recently, CDC estimated that 280Ð370 HIV-infected children were born in 2000, representing a signiÞcant decline from the estimated peak of 1,760 HIV infected

children born during 1991 (105). These declines reßect the successful implementation of public health guidelines for universal offering of voluntary testing to pregnant women, ZDV and other antiretroviral treatments which have reduced transmission rates, and improved obstetrical practices for HIV-infected women. To further reduce the number of infected children born each year, programmatic efforts are centered on outreach to high-risk women to promote access to prenatal care, testing and treatment.

HIV/AIDS Prevalence in the U.S.

Following the peak of infections in the mid-1980s, the prevalence of AIDS began to rise gradually as infected persons progressed inexorably to AIDS. However, prior to HAART, survival following an AIDS diagnosis was poor with most persons dying within two years (6). With the HAART-associated increases in survival of AIDS patients on treatment (Fig. 1.23), death rates with HIV as the

underlying cause have declined. Among adults 25Ð44, it was the leading cause of death from 1993 through 1995 and dropped to the Þfth cause in 1998 (Fig. 1.24). As survival of persons with HIV/AIDS has improved, deaths due to HIV infection decreased and the proportions of deaths of persons with HIV/AIDS that were caused by other conditions increased (7). The prevalence of AIDS has steadily increased as deaths declined more rapidly than AIDS incidence (Fig. 1.25). If survival gains continue, and infections are not reduced, overall HIV prevalence (including AIDS) can be expected to rise. During 1998 through 2000, the number of deaths annually was less than half the estimated number of persons newly infected, as well as less than half of the number of new AIDS cases. If these patterns continue, HIV prevalence will rise, and the proportion of infected persons who are AIDS-free will rise. Factors that can change the current dynamics include: a rise or decline in annual infections from the estimated

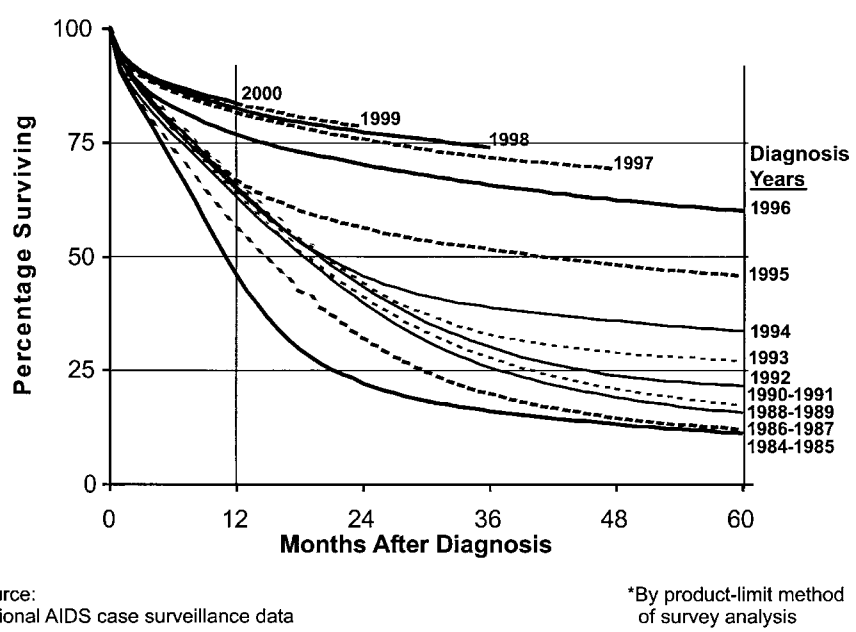

FIG. 1.23. Cumulative proportion of AIDS patients surviving, by months after diagnosis of the first AIDS-defining opportunistic illness, for different years of diagnosis of the opportunistic illness. Source: CDC, Division of HIV/AIDS Prevention.

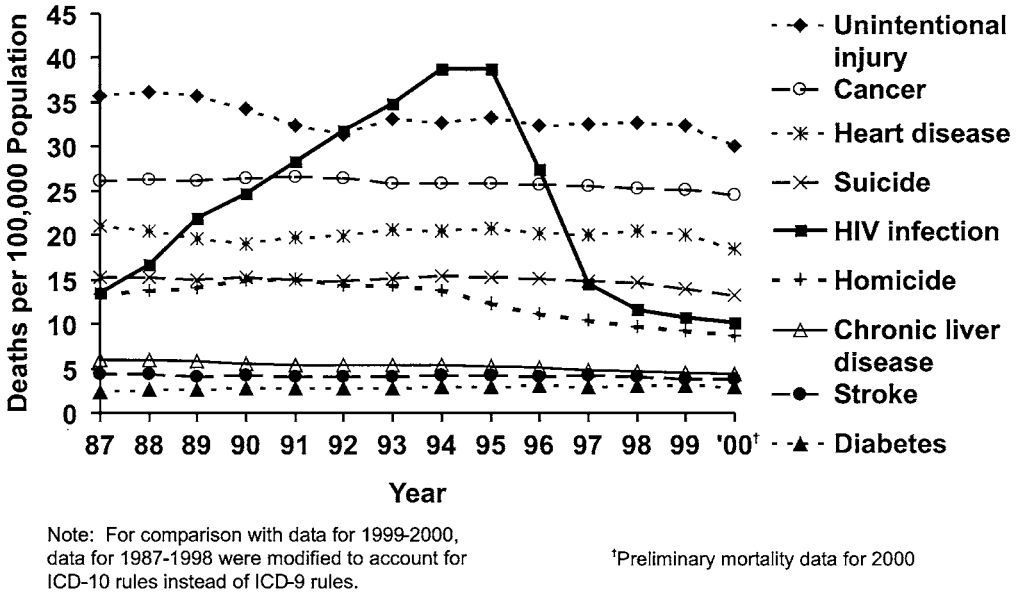

FIG. 1.24. Trends in annual rates of death from leading causes of death among persons 25–44 years old, 1987–2000, United States. Source: CDC, National Center for Health Statistics.

stable rate of approximately 40,000 per year during the l990s; a rise in deaths due to the emergence of treatment resistant viral strains, aging of the infected cohort with competing causes of mortality, serious or life-threatening side effects of treatment, declines in offering or accepting timely HIV testing, or decreases in access to treatment; a further decline in deaths due to improved therapies, and better access to early testing and treatment. As of 2000, CDC estimates that there have been from 1.3 to 1.4 million cumulative HIV infections: approximately 450,000 cumulative deaths and an estimated three-fourths of the 850,000Ð950,000 persons living with HIV/AIDS had been diagnosed with HIV/AIDS (2).

Clinical Manifestations and Impact of Treatment

The clinical course of HIV is characterized by an acute viral illness following infection, an incubation period of

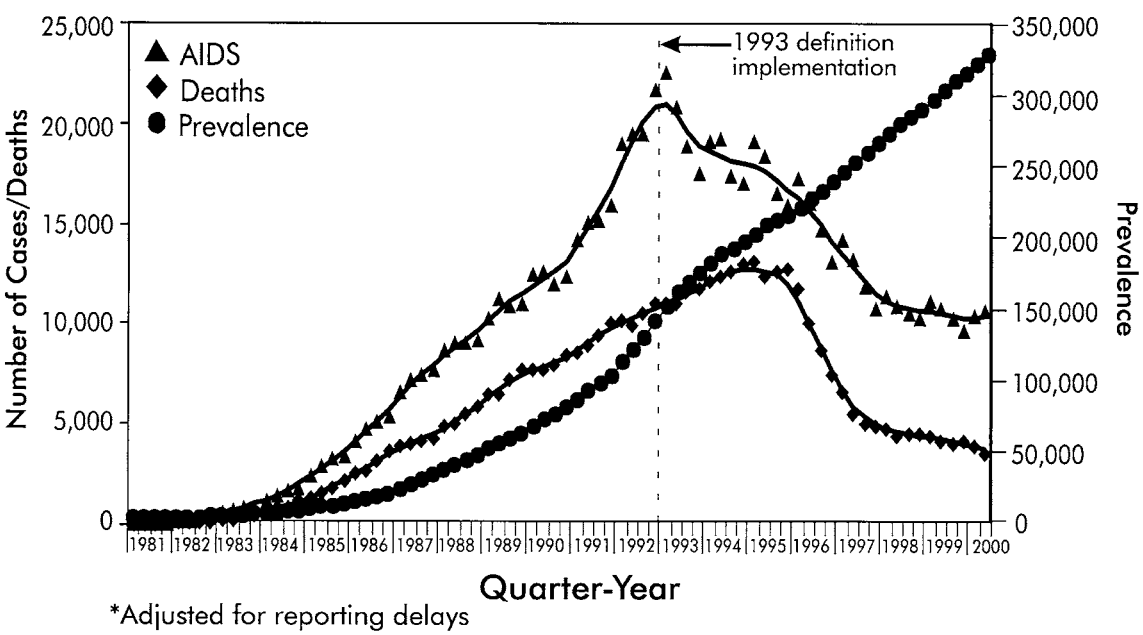

FIG. 1.25. Estimated AIDS incidence, deaths, and prevalence, by quarter year of diagnosis/death, 1981–June 2000, United States. Source: CDC, Division of HIV/AIDS Prevention.

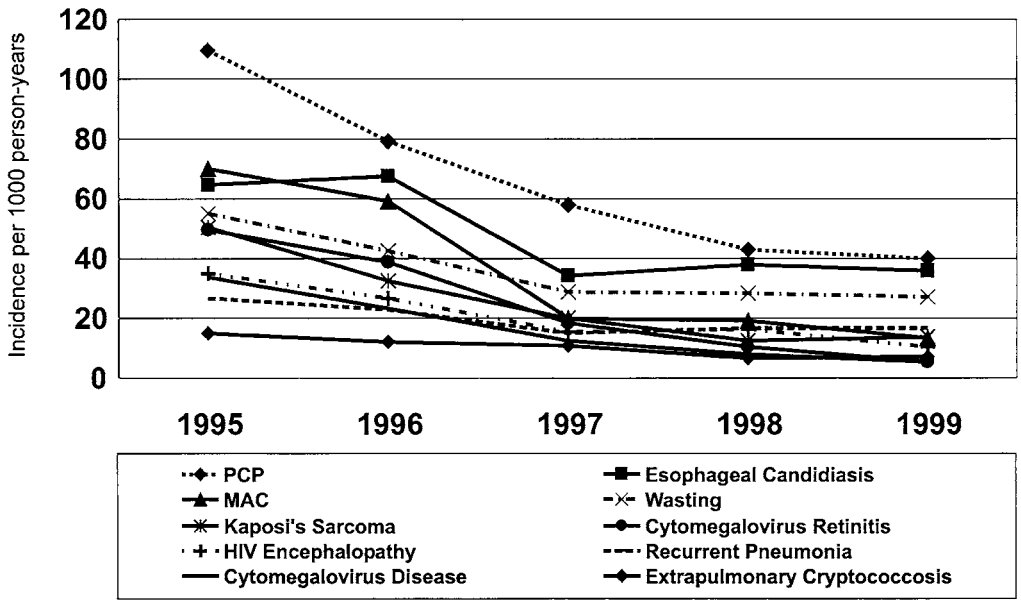

FIG. 1.26. Annual trends in the 10 most common incident opportunistic illnesses, Adult/adolescent Spectrum of Disease (ASD) project, 1995–1999. Source: CDC, Division of HIV/AIDS Prevention.

variable duration which may be marked by no or mild nonspeciÞc clinical symptoms during which viral load increases and the CD4 count decreases, severe immunosuppression which is associated with the onset of AIDS-deÞning conditions, and death. Because the AIDS epidemic was Þrst recognized based on the appearance of unusual clinical symptoms in previously healthy young men, early surveillance efforts concentrated on describing the spectrum of illnesses that were associated with HIV-induced immunosuppression. AIDS cases were reported based on the occurrence of an initial AIDS-deÞning condition such that AIDS incidence reliably tracked trends in the initial AIDS OIs. However, with the inclusion of the immunologic criterion in the 1993 case deÞnition, AIDS surveillance data no longer reliably tracked speciÞc AIDS-related clinical conditions. Instead, large cohorts or multi-site surveillance projects are relied on to track trends in the incidence and prevalence of speciÞc HIV-related conditions in the HIV-infected population, and to examine the impact of treatment on the occurrence of opportunistic illnesses. One such project, the Adult/Adolescent Spectrum of Disease Project, has conducted reviews of medical records of persons with HIV or AIDS every six months until death or loss to follow up since 1990 in over 100 clinical facilities in 11 geographic areas. In 1995, the last year before the widespread use of HAART, among persons having one or more AIDS-deÞning conditions, the most frequently occurring initial opportunistic illnesses were *Pnemocystis carinii* pneumonia (35%), esophageal candidiasis (14%), Kaposiõ sarcoma (13%), wasting syndrome (7%), and *Mycobacterium avium* complex (7%) (106). Pulmonary tuberculosis, which was added to the AIDS case deÞnition in 1993 to reßect the intersection of the TB and AIDS epidemics, occurred in 4% of persons with AIDS. The incidence per 1,000 person years of observation of any AIDS-deÞning condition was 269 in 1995; by 1996 and 1997, incidence had decreased to 215 and 148, respectively. This trend was directly associated with increased proportions of subjects who were prescribed triple combination antiretroviral therapy containing a protease inhibitor. The declines in the incidence of the most commonly occurring opportunistic illnesses were greatest from 1995 through 1998 followed by a stabilizing trend, similar to that observed in national AIDS surveillance data (107) (Fig. 1.26). The beneÞcial impact of antiretroviral therapy in preventing or delaying the onset of severe AIDS-deÞning illnesses is reßected in improved AIDS-free survival times and in decreased risk of mortality among patients with AIDS (6,107Ð109).

Acute primary HIV infection is associated with a rapid rise is plasma viremia. Although there are no large-scale population-based studies from which estimates can be derived, in small studies, more than half of newly infected persons experience an acute retroviral syndrome (ARS). This illness is characterized as ßu-like and is marked by fever, lymphadenopathythy, rash, and myalgia. Onset occurs within a few weeks of infection and the syndrome generally resolves with two weeks (110,111). Many persons with ARS who seek care may not be offered HIV testing, therefore, it is important that clinicians be alert to a history of HIV risk behaviors in persons presenting with such symptoms. Timely HIV diagnosis may improve opportunities to prevent further HIV spread as infectiousness may be high during this stage; as well, early identiÞcation of HIV offers the best options for clinical management and treatment consistent with current guidelines (102,112,113). Following ARS, seroconversion occurs as antibody levels begin to rise and nearly all HIV-

infected persons have detectable antibody 6 months after infection (114). Recent testing technology can distinguish between positive antibody tests of long duration and those in the window period of seroconversion, thus identifying incident HIV infections among all persons with positive antibody tests (56).

Progressive immune dysfunction follows infection but only a small proportion of infected persons develop AIDS OIs within the Þrst few years (64). The proportion progressing to AIDS increases with time and is estimated to follow a normal distribution with a median incubation period of approximately 10 years. Regular monitoring of CD4 counts and viral load are crucial tools for detecting progressive disease in advance of the appearance of severe clinical symptoms. However, as most persons living with HIV now have been diagnosed, and as opportunities to receive treatment increase, AIDS cases increasingly represent persons who were not diagnosed previously or those for whom treatment regimens may be failing due to resistance or adherence problems. Recent reports of side effects of long-term treatment with protease inhibitors suggest that the spectrum of clinical conditions occurring in persons with HIV may be much changed in the treatment era compared to the natural history era (7,115,116).

The rapid evolution of the treatment armamentarium has led to on-going updates of treatment recommendations via the internet to provide clinicians with up-to-date recommendations. Published guidelines for HIV treatment for adults/adolescents (113), children (103), and pregnant women (104) are routinely reviewed and updated based on the strength of evidence ranging from clinical trials to observational studies. They are disseminated widely and rapidly Òon-lineÓ http://www:hivatis.org/trtg;dlns.html #Adult or http://www: hivatis.ors/trtsdlns.html#Pediatric

EMERGING ISSUES

The third decade of the HIV pandemic looms ahead with innumerable challenges. Advances in prevention science and a growing number of treatment regimens have raised new research, surveillance and programmatic issues (117,118). Behavioral risk reduction has been achieved in many at-risk populations, notably safer sex and injecting practices among MSM and IDUõ, respectively, but as people with HIV are diagnosed earlier and survive longer on treatment, sustaining safer sex and drug-using behaviors among infected persons will require ongoing programs to reduce further transmission. Reports of on-going risky sexual behaviors among infected persons emphasize the need for research studies to identify effective interventions, programs to support risk reduction, and monitoring of behavioral risk factors (119). Behavioral surveillance efforts in at-risk and infected populations have lagged disease surveillance efforts. Rapid clinical advances have been accompanied by reports of side effects of treatment as well as the threat of transmitting drug-resistant viral strains (116,120). Efforts to develop effective treatments with less complex dosing and fewer side effects are needed to promote adherence and decrease the risk of developing drug-resistance. The intersection of disease prevention and control comes in efforts to develop new rapid testing technologies to promote testing acceptance and knowledge of infection status, referrals to care and treatment for positive persons, and surveillance efforts to implement a nationwide HIV reporting system with the capacity to characterize incident infections and use these data to target prevention resources to the highest risk communities (121Ð124). Increasingly, surveillance data are relied on for prevention and treatment services planning, evaluation, and resource allocation. Ultimately, Þelding an effective vaccine may offer the best hope of HIV prevention and control worldwide.

The public health surveillance system for HIV/AIDS is widely recognized as among the best disease surveillance systems in the world. As the need for accurate, timely, and high quality data on persons with HIV/AIDS continues to grow in response to the growing array of prevention and treatment programs, expanded support for and commitment to public health surveillance will be required by all levels of government, health care providers and affected communities. As one of the costliest epidemics in human history, the HIV epidemic will no doubt ultimately be contained. The cost of that containment in human lives will be determined by political, social and economic forces that will either enable or thwart the delivery of effective and compassionate prevention and control measures worldwide.

Chapter 2

Epidemiology of Pediatric HIV Infection

Susan M. King, Mary Lou Lindegren and Martha F. Rogers

The Þrst cases of the acquired immunodeÞciency syndrome (AIDS) in children were reported to the Centers for Disease Control and Prevention (CDC) in 1982. Since that time nearly 9,000 cases of AIDS in children aged less than 13 years and over 5,000 deaths in children under 15 years have been reported (1). Perinatal transmission of the human immunodeÞciency virus (HIV) accounts for 91% of the pediatric AIDS cases and almost all new HIV infections in children (1). Based on data from the National Survey of Childbearing Women, conducted during 1989Ð1995, the CDC estimates that approximately 6,000 to 7,000 infants are born each year to human immunodeÞciency virus (HIV)-infected women in the United States (2). Considerable advances in the understanding of the pathogenesis, diagnosis, treatment, monitoring, and prevention of HIV infection in children have changed the epidemiology of pediatric HIV infection in United States.

EPIDEMIOLOGY IN CHILDREN

In the United States, 8908 (1.2%) of the 774,467 cases of AIDS reported to the CDC as of December 2000, occurred in children aged under 13 years and another 4061 cases occurred in adolescents aged 15 to 19 years. Children in the United States have acquired HIV infection primarily through two routes: perinatally (mother-to-child) and by transfusion of blood or blood products (Table 2.1). In most developed countries, transmission of HIV through blood products virtually ended in 1985, when universal screening of blood donations for HIV antibody began (3,4). Trends in pediatric AIDS cases therefore reßect predominantly trends in perinatally acquired cases. The number of perinatal AIDS cases reported each year continued to increase through 1992, leveling off in 1993 and declining dramatically throughout the late 90s (5) (Fig. 2.1). From 1993 to 2000, an 81% decline in perinatal AIDS was observed, largely attributable to the widespread implementation of recommendations for zidovudine (AZT) therapy to HIV-infected pregnant women; combination antiretroviral therapy for the womanÕ9 own care and obstetrical interventions such as scheduled cesarean delivery. Some of the decline is also attributable to improved treatments that delay the onset of AIDS-deÞning illness for HIV-infected children, such as prophylaxis for *Pneumocystis carinii* pneumonia (PCP), a common AIDS-deÞning condition.

The demographic characteristics of children acquiring HIV through these various routes differ markedly. Characteristics of children with perinatally acquired AIDS parallel those of women with HIV infection and AIDS in the United States (Fig. 2.2). The HIV epidemic among women is concentrated in the Northeast and in the South, especially in New York, Florida, Texas, California and New Jersey. Black and Hispanic women are disproportionately affected by the HIV epidemic, with the rates of AIDS for females reported in 2000 being highest in black, non-Hispanic at 45.9 per 100,000, followed by Hispanic at 13.8 per 100,000 compared with white, non-Hispanic at 7.9 per 100,000 (1). In the United States, most of these children are from large eastern urban areas (Table 2.2), and they are largely of minority race and ethnicity (Table 2.3). The male-to-female ratio in these children is 1:1, indicating that mothers transmit equally to male and female infants. Mothers of these children have most commonly acquired HIV infection through injecting drug use (39%) or heterosexual transmission (36%) (Table 2.1).

Susan M. King, MD: Visiting Scientist, Surveillance Branch, Division of HIV/AIDS Prevention, Centers for Disease Control and Prevention.

Mary Lou Lindegren, MD: Surveillance Branch, Division of HIV/AIDS Prevention, Centers for Disease Control and Prevention.

Martha F. Rogers, MD: Associate Director for Science, Division of HIV/AIDS Prevention, Centers for Disease Control and Prevention.

(Dr. Rogers is currently employed by the Center for Child Well-Being, Task Force for Child Survival and Development.

TABLE 2.1. *Reported estimates of per-contact HIV transmission risk from selected studies*

Exposure category	2000 Number	%	Cumulative 1982–2000 Number	%
Perinatally acquired (by mother's risk factor	177	90	8133	91
Intravenous drug user	40		3172	
Heterosexual contact	79		2969	
Transfusion recipient	2		153	
Risk unknown	56		1839	
Transfusion acquired	2	1	382	4
Hemophilia	1	1	237	3
Other/unknown	16	8	156 *	2
Total	196	100	8908	100

* Includes 26 children with sexual abuse as risk factor.

In the United States, since the implementation of heat treatment for clotting factors in 1984 and nationwide screening of blood donors in 1985, in conjunction with self-deferral of blood-donations from high-risk individuals, the incidence of HIV infection attributable to HIV transmission through blood and blood products has been virtually eliminated (6,7). As of December 2000, only two children in the United States developed AIDS following the receipt of blood screening negative for HIV antibody at the time of donation, after which the donor seroconverted (1). Children infected by transfusion account for 4% and children with hemophilia or other clotting disorders for 3% of cumulative pediatric AIDS cases (1). Most children with transfusion-acquired AIDS were transfused in infancy because of perinatal problems; the demographics of these cases reßect characteristics of children with increased perinatal morbidity (7,8). The racial distribution of children infected from blood products is more reßective of the United States population. The male-to-female ratio differs between these groups (Table 2.3). This is consistent with the Þnding in a study of blood-transfusion practices, that male infants are more likely to receive transfusions than females (9) and that blood products are used for clotting disorders, such as hemophilia, which are most

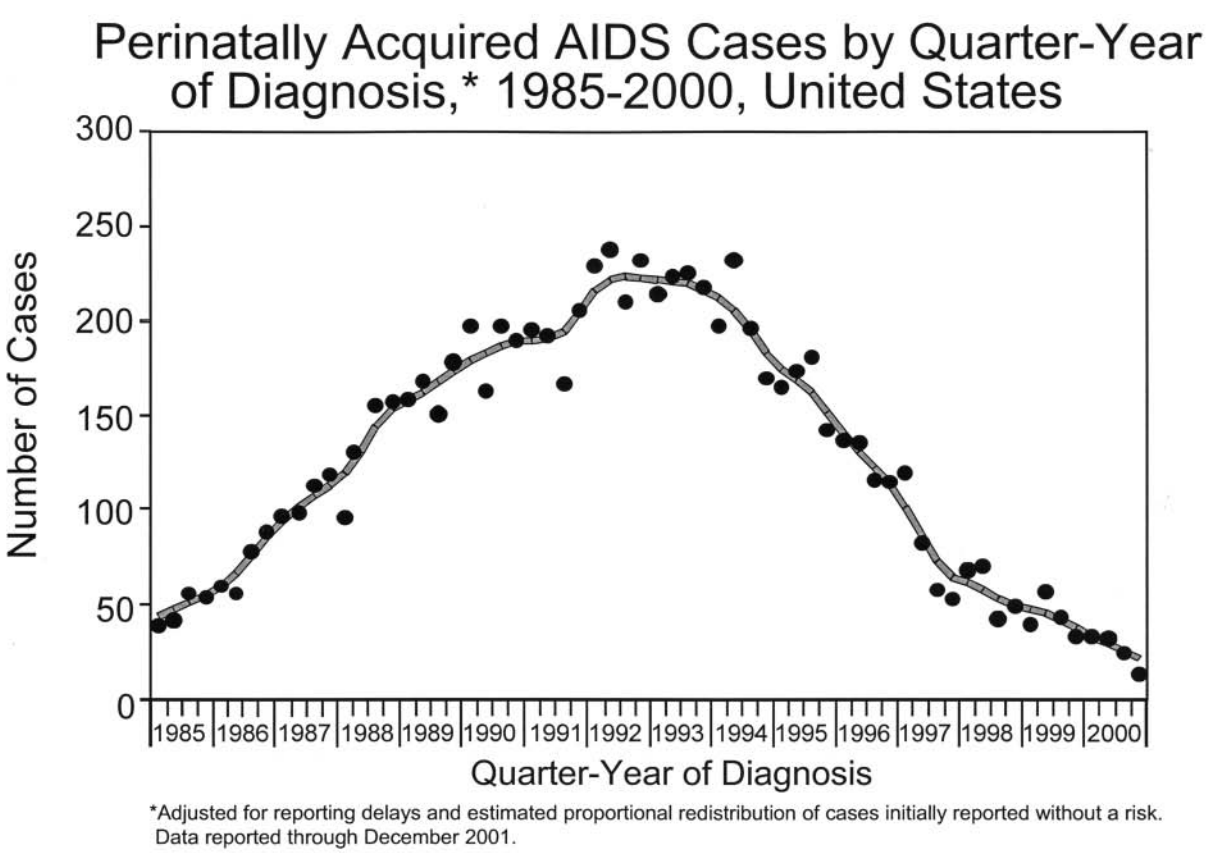

FIG. 2.1. Perinatally acquired AIDS cases by quarter-year of diagnosis, 1985–2000, United States.

commonly sex-linked genetic disorders. Nearly all patients with transfusion-associated AIDS received their contaminated transfusion in or before 1985 and thus are now adolescents and young adults. Similarly patients with hemophilia, diagnosed with AIDS as children are now largely young adults.

With the implementation of routine testing for HIV in pregnancy, recommended since 1995, most HIV-exposed babies should be identiÞed before birth. However, infants born to women who have not been tested for HIV, may be Þrst recognized when they present with symptoms. Untreated, 50% of HIV-infected children will develop serious HIV-associated illness by 5 years of age and will have an AIDS deÞning illness by 6.6 years (10). As of December 2000, 180 adolescents who acquired HIV perinatally were not diagnosed with AIDS until 13 years of age or older and are counted as adolescent or adult cases (1).

It was estimated, using data from the Pediatric Spectrum of Disease Project (PSD) and the CDC HIV/AIDS surveillance databases, that in 1999 in the United States there were 10,000 children and youth living with HIV of whom 2400 were adolescents (11). Improvement in survival of children with HIV/AIDS is largely due to two factors: the use of combination antiretroviral therapy and prevention of PCP. Without antiretroviral therapy, a bimodal progression pattern has been reported in children infected by perinatal transmission. About 10% to 20% of infected infants developed rapidly progressive disease and died within the Þrst few years of life (10,12). In the remaining children however, the disease advanced more slowly and they survived well beyond school age with a course similar to that seen in adults (10,12). The annual number of deaths from pediatric AIDS has declined each year from 586 in 1994 to 107 in 1999 (1). Initially the effect of antiretroviral therapy on survival in children with AIDS was limited (4,13). But with current antiretroviral therapy, survival has improved by about 70% and the annual mortality rate decreased from 5.3% to 0.7% (14,15). In the early 1990s the most common cause of death was pneumocystosis, accounting for about 25% of deaths, but by 1998, it accounted for only 6.2 to 8.8% of deaths (16).

The incidence of AIDS in children has also been reduced by these two factors: the use of combination antiretroviral therapy and prevention of PCP. PCP was also the most common AIDS deÞning condition (ADC) in children and infants pre-1995, accounting for about one-third of ADCs. Since 1996, the proportion of ADCs due to PCP has fallen to about 25% (17). This change in

incidence of PCP occurred after implementation of guidelines to start PCP prophylaxis for all infants born to mothers with HIV-infection and to discontinue when the infant is conÞrmed to be not-infected (18).

The successes of antiretroviral therapy and prevention of opportunistic infections, such as PCP, has led to HIV infection becoming more of a chronic illness than a rapidly fatal one. This means that many more infected infants and children will be living to be adolescents and adults. This brings with it additional issues for care of adolescents with HIV, such as acceptance of complex treatment regimens and the potential toxicity of long term drug therapy, as well as the many psychosocial issues for adolescents with a chronic illness, especially one that is transmissible.

MODES OF TRANSMISSION IN CHILDREN

Perinatal Transmission

Prospective studies of mother-to-infant transmission in both developed and developing countries found transmission rates of 13% to 40% (19–22). Transmission rates in developed countries, such as the United States, are generally lower, between 15% and 25%, whereas rates in developing countries, such as those in Africa, are generally higher between 25% and 40% (23). Differences in transmission rates from study to study reßect differences in factors that affect the likelihood of mother-to-infant transmission in the populations under study.

Mother-infant transmission of HIV can occur during pregnancy (*in utero*), during labor and delivery (intrapartum); and through breast-feeding (postpartum). *In utero* transmission has been demonstrated by identiÞcation of the virus in fetal tissue and amniotic ßuid (24–26). Increasing evidence indicates that most perinatally infected infants acquire their infection close to or during labor and delivery (intrapartum period). Among infants who are not breast-fed, the proportion of infections occurring *in utero* is estimated to be approximately 25–40% and 60–75% intrapartum (27,28). The absolute risk for *in utero* transmission is estimated to be approximately 5–6%, and for intrapartum 13 –18% (29,30).

A large body of literature has described risk factors associated with perinatal HIV transmission. The pathogenic basis for transmission is affected by a number of factors, some of which are not fully understood. A number of studies have shown that maternal viral load is a critical determinant of perinatal HIV transmission (31–33). Other factors associated with an increased risk of transmission include low maternal CD4 counts, advanced maternal illness, vaginal delivery, premature delivery, and longer duration of rupture of membranes (22,27,29,34–38). There is also evidence to suggest that mother-child discordance of HLA and HLA supertypes is associated with decreased risk of HIV transmission (39,40). There is less conclusive evidence that the following factors affect perinatal HIV transmission: viral genotype or phenotype, viral strain diversity, chorioamnionitis, sexually transmitted infections, fetal scalp electrodes, and maternal factors such as, illicit drug use, cigarette smoking, anemia, nutritional status (27,31).

Evidence for HIV transmission through breast milk was Þrst documented in case reports of mothers who were infected subsequent to giving birth and transmitted HIV to their breast-fed infants (41–43). HIV has been isolated from breast milk (44,45). In addition, studies of mothers who were infected during or before pregnancy showed an increase in the maternal-infant transmission rate among those who breast-fed compared with those who did not. A meta-analysis of six studies indicated an additional risk of about 14% (46). In a randomized trial of the effect of formula feeding versus breast feeding on perinatal HIV transmission, the frequency of breast milk transmission of HIV was 16.2% (47). Factors affecting HIV transmission from breast milk are currently a topic of research in order to determine strategies to reduce perinatal HIV transmission in the developing world. It appears that most HIV transmission occurs during the early weeks to months of breast-feeding, estimated as 66% in the Þrst 6-weeks of life, or 0.7% per month in the Þrst six months, 0.3% per month from 12 to 18 months and 0.2% per month from 18 to 24 months (48). In one study, from South Africa, it was found that HIV transmission was lower in those infants exclusively breast-fed compared to those with mixed breastfeeding (hazard ratio (HR) = 0.56) (49). Further studies are needed to conÞrm this observation. Other factors associated with postnatal HIV transmission are maternal nipple lesions, mastitis, maternal CD4 count, maternal seroconversion during breast-feeding and infant oral thrush (50).

Transfusion-Associated Transmission

Transfusion of blood or blood components from an HIV-infected donor is a highly efÞcient mode of transmission. More than 90% of persons receiving an HIV-seropositive unit of blood acquire the infection (51,52). Both cellular and plasma components of whole blood have transmitted HIV infection. Immunoglobulin preparations including Rh factor have not transmitted HIV because the fractionation process used to prepare these products effectively removes HIV by partitioning and inactivation (53).

The CDC has estimated that between 1978 and 1985, about 12,000 transfusion recipients in the United States who survived their underlying disease acquired transfusion-associated HIV infection (54). Persons receiving multiple transfusions between 1978 and 1985 were at greater risk. For this period, HIV seroprevalence rates of 4% to 8% were detected in leukemic (54), hemodialysis (55), and other patients receiving multiple transfusions (56). In the cumulative data reported to CDC as of December 31, 2000, of the children less than 13 years of age diagnosed with AIDS, 382 cases (4%) had transfusion acquired infection (1).

Since donor screening was implemented in March 1985, two pediatric cases of AIDS following infection acquired from blood that was screened as HIV negative have been reported to the CDC as of December 31, 2000 (1). With donor screening using questionnaires and laboratory tests for HIV antibodies and p24 antigen, the chances of HIV transmission from a unit of blood have been reduced to between 1 in 450,000 and 1 in 660,000 (4). In 1999, U.S. Blood Banks implemented Nucleic Acid AmpliÞcation Testing (NAT) of all donated units of blood; this has further reduced the risk of an HIV-infected unit of blood being transfused to about one in two to three million (57).

HIV Infection from Blood Products

Historically, both Factor VIII and IX concentrates have transmitted HIV (53). In the United States up to 80% of persons with hemophilia receiving large-pool, non-heat-treated factor products from plasma donated before HIV screening, were infected with HIV. More severe hemophilia and greater factor usage have been associated with a greater risk of HIV infection. Persons with hemophilia treated exclusively with cryoprecipitate appear to have had a lower risk of exposure to HIV and subsequent infection (58). In the cumulative data reported to CDC as of December 31, 2000, of the children less than 13 years diagnosed with AIDS, 237 cases (3%) were reported among children with hemophilia (1).

Sexual transmission from HIV-infected men with hemophilia to their female sex partners, with subsequent perinatal transmission to their infants, has also occurred in some of these families. About 10% to 20% of the long-term female sex partners of HIV-infected men with hemophilia have acquired HIV infection through heterosexual contact (59). As of December 31, 2000, the CDC has received reports of 101 children with AIDS whose mothers acquired HIV infection from men who had received contaminated blood or blood-products (26 of whom had hemophilia) (60).

Other Routes of Transmission

Sexual transmission of HIV infection is the most common route of transmission among adolescents and adults but is not a commonly reported risk for infection among children in the United States. However, several cases of sexual transmission of HIV by sexual abuse have been reported among children in the United States (61–63). In 1998, using population-based HIV and AIDS surveillance, 26 children were identified who were sexually abused by an abuser with confirmed ($N=17$) or suspected ($N=9$) HIV infection (63). Although this number is small, since it is likely a minimum estimate, it indicates that HIV transmission from sexual abuse is a public health problem.

Transmission of HIV also has occurred through transplantation of bone, kidney, liver, heart, pancreas, and possibly skin (64). HIV infection acquired through artificial insemination also has been reported (65,66). The U.S. Public Health Service (USPHS) recommends that all tissue and organ allograft donors as well as blood and semen donors be evaluated for risks associated with HIV infection and tested for HIV infection (60). To date no pediatric cases, in which the transplanted organ was identified as the source of HIV infections, have been reported to CDC.

Early in the AIDS epidemic, concern was raised about transmission of HIV through casual contact in settings such as schools, day-care facilities, and families; however, evidence indicates that transmission in these settings is extremely rare or non-existent. No cases of transmission within the school or day-care setting have been reported. In at least 18 studies of more than 1300 household contacts of HIV-infected persons, transmission within households has not been found despite close personal contact and sharing of items likely to be soiled with blood and body secretions of the infected family member (67,68). Rare cases of transmission within household settings have been reported (69,70). One instance of transmission between two children living in the same household, documented by molecular epidemiology, was reportedly due to unrecognized blood contact between the children during bleeding episodes (70). Another instance of apparent transmission between two siblings was not well documented, as molecular techniques were not available at the time of occurrence (71). Two instances of transmission between brothers who were receiving intravenous infusion of factor products at home also have been reported (72,73). Transmission in both instances was most likely due to blood contact with infected blood. Four other cases involving unprotected exposure to blood or blood-containing fluids while providing home nursing care also have been reported (69). These cases, although quite rare, highlight the need for precautions to minimize skin, mucous membrane and percutaneous contact with blood in households and other settings, especially when health care is being provided.

Biting has received much attention as a possible mode of HIV transmission, but there is little evidence that biting transmits HIV (67). In a study of the family members of children with transfusion-associated HIV infection, nine HIV-infected children bit their contacts, and seven contacts bit an HIV-infected child. There was no evidence of infection in the contacts (74). Similarly, no evidence of infection was found in 30 health care workers bitten and scratched by a brain-damaged adult with HIV infection (75) or in a woman who was bitten severely while attending an HIV-infected patient who was having a seizure (76). Further, four children bitten several times by an HIV-infected child over a 2-week period were seronegative 6 months after the incident (77). Transmission involving biting has been suspected in six cases (67,71,78–82). In only one case was the biter a child. This case, however, is lacking in evidence to confirm this route of transmission because of lack of availability of molecular technology at that time (71). In the other cases, the bites were by adults and were severe with blood exchange.

The CDC and the American Academy of Pediatrics (AAP), as well as a number of state health and education departments, have recommended that most children with HIV infection be allowed to attend school and day care (83,84) and that these children should not be excluded from these settings solely on the basis of their HIV infection. Persons caring for children should be trained in, and adhere to proper infection-control technique (85). It

should be kept in mind, however, that the vast majority of HIV-infected persons do not transmit the virus except by the well-recognized routes, most commonly, sexual contact, sharing of contaminated needles, and mother-to-child transmission.

PREVENTION OF HIV INFECTION IN CHILDREN

The 1994 Pediatric AIDS Clinical Trials Group (PACTG) protocol 076 demonstrated that AZT therapy administered to selected HIV-infected pregnant women and their newborn infants reduced the rate of perinatal HIV transmission from 25% to 8% and was the Þrst major prevention breakthrough in the HIV epidemic (86). In 1994, the USPHS published guidelines for the use of AZT to reduce perinatal HIV transmission (87), and in 1995 the USPHS published guidelines for universal, routine HIV counseling and voluntary testing of pregnant women (88). These guidelines are updated regularly (89,90). Updated guidelines reßect the data extending the efÞcacy of AZT to all HIV-infected women, including those with advanced disease and prior AZT therapy and data on obstetrical interventions such as scheduled cesarean delivery. The guidelines also address issues about new standard treatment regimens for adults in the context of pregnancy (89). Data from additional clinical trials and observational studies have found transmission rates as low as 5% with AZT alone (91,92). In the late 1990s, highly active combination antiretroviral therapy became available that could decrease viral load below the level of quantitation and is now standard treatment of HIV-infected individuals including pregnant women (89). In several observational studies, the perinatal HIV transmission rate has been found to be lower with maternal combination therapy than with AZT monotherapy, that is, in the range of 1Ð3% (93,94). In a meta-analysis of observational studies, maternal viral load below 1,000 copies per ml at the time of delivery was found to be associated with a risk of perinatal transmission of 1% (95).

Consistent with the evidence that most fetal and newborn HIV infections are acquired near or during delivery, recent clinical trials have shown that abbreviated antiretroviral regimens focused on the peripartum period are also effective in decreasing the risk of perinatal transmission (93,96). A short course of AZT, administered late in pregnancy and intrapartum decreased the perinatal HIV transmission rate by 50% in the non-breast-feeding cohort of women in Thailand (97) and by 37% in a breast-feeding cohort of women in West Africa at 3 months and 26% at 24 months (98). A study in breast-feeding women in Uganda demonstrated that a single oral dose of nevirapine administered to the women at the onset of labor followed by a single oral dose administered to the infant decreased the risk of HIV infection by 41% compared with a very short AZT regimen. This difference remained through 18 months of life (99,100). In another African trial, a short course of AZT and lamivudine (3TC) was compared to placebo in breast-feeding women. This intervention of antenatal AZT + 3TC followed by 1 week postpartum AZT + 3TC to both mother and baby reduced the risk of infant infection by 63% at 6 weeks (to 5.9% transmission). However at 18 months, the transmission rate was 14.9% in the AZT + 3TC study arm compared to 22.2% placebo arm and conÞdence intervals overlapped. In other words, the efÞcacy of the AZT + 3TC regimen was no longer statistically signiÞcant at 18 months of age in this breast-feeding population (101,102).

Use of postpartum antiretroviral prophylaxis alone has not been evaluated in a randomised clinical trial. In an observational study in New York, administration of AZT for six weeks to newborns was associated with a signiÞcant decrease in transmission if the drug was initiated within 24 hours of birth (103). However, in another observational study from North Carolina, administration of AZT only to the newborn was not associated with a decrease in the risk of HIV transmission (92).

Obstetrical interventions have the potential to decrease perinatal transmission. Both a metanalysis of observational studies and a randomised clinical trial indicated that the perinatal transmission rate is lower for women delivered by elective Cesarean delivery compared to those delivered vaginally (35,36). The American College of Obstetricians and Gynecologists (ACOG) recommends that HIV-infected women with an HIV viral load of 1,000 copies per ml or greater be counseled regarding the potential beneÞt of scheduled cesarean delivery (104). They also state that data are insufÞcient to demonstrate a beneÞt for women with HIV viral load $< 1{,}000$ copies per ml. Other obstetrical interventions such as those to decrease the duration of rupture of membranes would potentially also contribute to decreasing HIV transmission (34). Vaginal lavage intrapartum has been proposed as an intervention to reduce perinatal HIV transmission. So far, a safe and effective cleansing agent has not been found (105,106).

The use of HIV vaccines in the perinatal period and later in infancy to protect against breast feeding transmission of HIV is theoretically appealing if an effective and immunogenic product could be developed. Studies using passive antibody have so far been inconclusive (107). Phase 1 studies of perinatal HIV vaccine candidates are currently underway (108,109). A model of peripartum antiretrovirals paired with an infant HIV vaccine series is a promising approach which requires further study for use in developing countries where many HIV-infected women breastfeed into the second year.

The American College of Obstetricians and Gynecologists, AAP and USPHS have all made recommendations, for universal, routine prenatal HIV education and HIV testing (90,110). Women who are identiÞed as HIV-infected need to be counseled on ways to prevent

transmission to their infant, including treatment of maternal disease (using combinations of antiretroviral agents as needed), use of AZT prophylaxis, elective cesarean delivery and avoidance of breast-feeding. Despite widespread implementation of these guidelines, perinatal HIV infection has not been eliminated, about 300 new cases of perinatally acquired HIV are estimated to occur each year in the United States. The major barrier to prevention is that some women do not receive adequate prenatal care. Compared with the general population, HIV-infected women are much less likely to receive prenatal care. In one report, overall 2% of pregnant women but 15% of HIV-infected women did not receive prenatal care (111). If perinatal HIV infection is to be eliminated then approaches must be developed to address the needs of women who receive little or no prenatal care. Approaches to reaching these women and to increase voluntary counseling and testing, include provider social marketing, community outreach, case management and provider training.

INTERNATIONAL PERSPECTIVE

HIV infection has become a worldwide pandemic, The World Health Organization (WHO) estimates that 40 million people, of whom 2.7 million are children (< 15 years) are living with HIV/AIDS (112). In 2001, 800,000 children worldwide became infected with HIV and 580,000 children died of AIDS. At least 1,700 new perinatal HIV infections occur each day with a rate of more than one infection every minute. The largest numbers of infected children live in sub-Saharan African countries. Because the virus is spread primarily through sexual contact, devastating potential exists for the spread of infection to sexually active women and for transmission of the virus from these women to their children.

Two patterns of pediatric HIV infection now exist, one in the industrialized countries, such as the United States, Canada and European countries, and another in resource-poor countries. In the industrialized countries, there are effective programs for prevention of perinatal HIV infections (113,114). In contrast, in resource poor countries, there is a perinatal HIV epidemic and HIV/AIDS has become one of the leading causes of death in children. Affordable and acceptable approaches to HIV counselling and testing in pregnancy, peripartum antiretroviral prophylaxis and reduction of transmission from breast-feeding in resource-poor settings are urgently needed (115).

CONCLUSIONS

In the United States, the epidemiology of pediatric HIV infection has changed dramatically over the past decade. The incidence of pediatric HIV infection has fallen because transfusion-acquired infection has been virtually eliminated and perinatal infections dramatically reduced. However, the epidemic among young women and adolescents, who become infected through sexual transmission and drug use, continues. Clearly, prevention of HIV infection in young women would prevent perinatal HIV transmission. However, much progress has been made in reducing perinatal HIV transmission. For further decreases in perinatal HIV transmission, health care providers must increase the uptake of prenatal care and HIV testing among all pregnant women including late presenting women whose HIV status is unknown at delivery.

For children infected with HIV, the current management of HIV infection has markedly improved their survival. Many children, both infected and uninfected, will outlive their HIV-infected parents and the death of their parents may leave them orphaned. It is estimated that by the end of 2000, about 80,000 children and adolescents in the United States will be orphaned by parental death caused by HIV infection (116,117). Health care providers now must find ways to provide complex care to children in families frequently from disadvantaged backgrounds and in which one or both parents may also be chronically ill or deceased.

With the improvement in survival, the focus of care for the HIV-infected child has changed from acute to chronic care and from infants to children of all ages including adolescents. The drugs currently available are however not a panacea. For optimal viral suppression at least 90% adherence to therapy is required and for many, sustaining that level of adherence is difficult. In addition, the drug regimens may be complex and expensive and drug toxicity and resistance become an increasing problem with prolonged therapy. Those caring for children with HIV infection continue to be challenged to find the best approach to provide comprehensive medical and psychosocial management for children with this complex disease.

Chapter 3

The Genetic Diversity and Global Molecular Epidemiology of HIV

Dale J. Hu, Danuta Pieniazek, Timothy D. Mastro

The human immunodeÞciency virus (HIV) and its most severe clinical manifestation, the acquired immunodeÞciency syndrome (AIDS), have produced a pandemic of unprecedented proportions. By the end of the year 2001, the Joint United Nations Programme on HIV/AIDS (UNAIDS) estimated that there were over 40 million persons infected and living with HIV worldwide (1). Despite the rapid ascertainment of the diseaseÕs epidemiology, the discovery of the etiologic agent itself and ways to prevent its spread, and the development of diagnostic tests and antiretroviral therapies, it is clear that HIV will continue to be a global problem well into the 21st century. Nevertheless, continuing advances in molecular biology, immunology, and epidemiology have contributed greatly to the understanding of HIV. This chapter will summarize the global molecular epidemiology of HIV including an overview of its genetic diversity and related implications.

GENETIC DIVERSITY OF HIV

Human immunodeÞciency virus is a primate retrovirus of the Lentivirinae family, a group that shares the ability to infect their host chronically, and progressively damage the hostÕs immune system. Genetic variation of HIV is extremely high as a consequence of the rapid turnover of HIV virions (2). Individuals infected with HIV maintain a substantial viral burden during the entire course of infection (3,4). Related strains share genetic similarity, as expressed by the sequence of component nucleotides, and methods have been developed to infer the phylogenetic relationships among different strains (5Ð7). Two viral types have been characterized in humans: HIV type 1 (HIV-1) and HIV type 2 (HIV-2). Both of these viruses most likely originated as cross-species (zoonotic) transmissions from two non-human primate reservoirs, namely chimpanzees (*Pan troglodytes troglodytes*) and sooty mangabeys (*Cercocebus atys*), respectively (8Ð10). The initial epicenters of HIV-1 and HIV-2 infection appear to have been in Central Africa and West Africa, respectively. In contrast to HIV-1, which has spread extensively around the world, HIV-2 is still primarily found in persons from West Africa (11,12).

Based on viral genetic sequences, HIV-1 isolates have been classiÞed into a number of subtypes (alternatively termed clades or genotypes) (Fig. 3.1). These subtypes, designated by letters A, B, C, D, F, G, H, J, and K, constitute the major group of HIV-1 or group M (13,14). Phylogenetic analyses of viral sequences from numerous HIV-1 isolates worldwide have revealed two additional groups of viruses, namely groups O (outlier) and N (non-M, non-O) (Fig. 3.1). The vast majority of HIV-1 strains identiÞed worldwide, which is responsible for the global pandemic, belong to group M. Besides the various subtypes within group M, more detailed analyses have revealed additional complexities in the classiÞcation of strains (15). For example, some subtypes are further subdivided into sub-subtypes (16). Other strains can only be classiÞed within a group but fail to cluster with known subtypes (17).

Distinguishing among HIV variants is further complicated by the potential for coinfection (18Ð20) and genetic recombination between distinct viral strains (21Ð23). Recombination was initially detected when phylogenetic analyses of full genome sequences collected from different regions of the world, documented that some HIV genomes consisted of mosaic structures with two or more different

Dale J. Hu and Timothy D. Mastro: HIV Vaccine Section, Epidemology Branch, Division of HIV/AIDS Prevention, CDC Mailstop E-45, Atlanta, GA 30333.
Danuta Pieniazek: Retrovirus Disease Branch, Division of AIDS, STD and TB Laboratory Research, CDC Mailstop G-19, Atlanta, GA 30333.

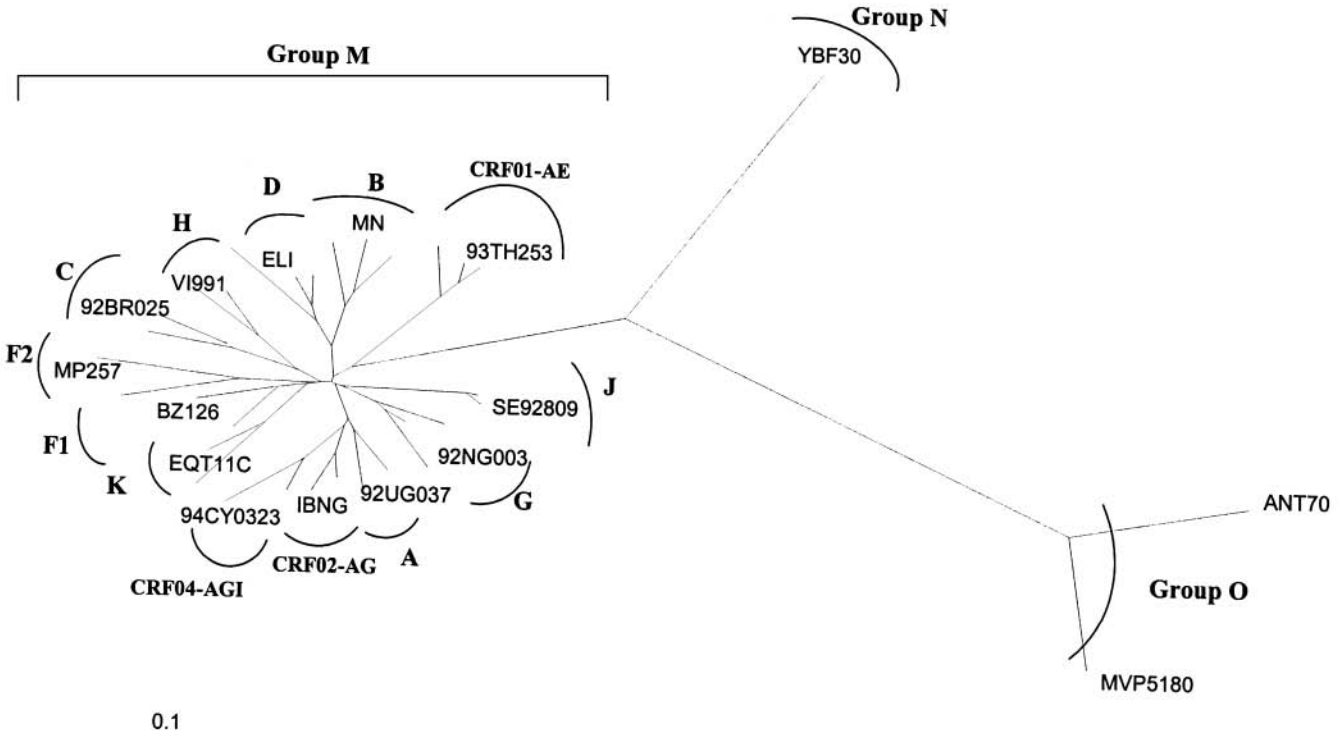

FIG. 3.1. Simpli ed phylogenetic tree of HIV-1 presents the relationship among group M. group N, and group O. Group M comprise nine basic subtypes A, B, C, D, F (F1 and F2), G, H, J, K, and three CRFs (CRF01-AE, CRF02-AG, CRF04-AGI). The *env* gp41 sequences were used for construction of the tree by the neighbor joining method with the Kimura two-parameter algorithm. The distance scale represents 10% divergence.

viral subtypes (22,24–26). Recent data indicate that co-infection between different subtypes of HIV-1 is more common than previously thought, especially in regions where a number of different HIV strains circulate (18,19,27). Recently, intersubtype HIV-1 superinfection has been documented in two individuals where the immune responses elicited by the primary infecting viral strain did not protect against subsequent reinfection with viral strains at a different subtype (27a). Dual infection and recombination between divergent HIV-1 strains of group M and group O have been documented (28,29).

As with HIV-1, a mosaic HIV-2 genome was reported, indicating that coinfection with genetically divergent strains and recombination can occur in HIV-2-infected individuals (8,30). While dual infections with HIV-1 and HIV-2 have been reported, no recombination between these viruses has been found (20,31).

Many recombinant viruses appear to be unique in that they have been found only in isolated individuals without evidence of epidemic spread. However, a few recombinant viruses have been designated as "circulating recombinant forms" (CRF) and account for a signi cant amount of HIV-1 transmission in some areas (15,17). For example, CRF01-AE represented strains that were initially described as subtype E based on *env* sequences but were later determined to be recombinants of subtypes A and E (26). Several CRFs have been reported from diverse regions around the world (32–37). Ongoing research aims to elucidate the biologic and epidemiologic signi cance of coinfection and recombination on HIV genetic diversity (14).

In the early 1990s, divergent strains of HIV-1 were reported and provisionally categorized as group O (38,39). The public health signi cance of these divergent strains was originally highlighted by reports that some strains were not reliably detected by many of the antibody screening tests then in use (40,41). However, unlike HIV-1 group M, which has spread globally, group O has had limited geographic dissemination. Outside West Central Africa (Cameroon, Gabon, and Equatorial Guinea) group O viruses have been found sporadically in other parts of the world including Western Europe and the United States in individuals of West Central African origin or among those with African contacts (42–44). HIV-1 group N was rst reported in 1998 and is so far represented by only a few viral isolates from Cameroonian patients (45).

HIV-2 was rst identi ed in West Africa and there is evidence that such viruses were present in this geographic region as early as the 1960s (11,46). As with HIV-1, HIV-2 has also been classi ed into several subtypes (A–G), although based on a much smaller number of sequenced isolates (8,30,47).

Although nucleotide sequences have been determined from thousands of HIV isolates, this is much less than the

tens of millions of HIV-infected persons in the world and not necessarily representative of the actual distribution of HIV strains. International collaborative efforts have been expanded to collect, characterize, and classify systematically HIV isolates from around the world (14). Figure 3.2 illustrates geographically where the HIV-1 subtypes and HIV-2 have principally been recognized (14). Based on available data, the greatest diversity of HIV strains has been found in sub-Saharan Africa. In contrast, most HIV isolates reported from Europe and the Americas are subtype B. However, multiple independent introductions of various HIV strains into different regions of the world have increased the complexity of the epidemiologic picture.

GLOBAL MOLECULAR EPIDEMIOLOGY

The pandemic of HIV/AIDS reßects many coexisting subepidemics in different regions and populations (14,48,49). As described in the chapter entitled Global Impact of HIV, there are many important epidemiologic, sociodemographic, behavioral, and biologic factors that contribute to the differential spread of HIV.

The vast majority of HIV infections in the world is transmitted sexually, most often through heterosexual intercourse (48). Notable exceptions occur, particularly among certain populations in industrialized countries in North America, Europe, and the PaciÞc Basin, where transmission has predominantly occurred through male-to-male sexual contact and injecting drug use. The areas characterized by these latter transmission modes have typically had a predominance of HIV-1 subtype B, though not all areas with subtype B predominance have featured these transmission modes, whereas the other subtypes appear to predominate in most of the areas where heterosexual transmission prevails (14).

In regions such as sub-Saharan Africa and some Caribbean and Latin American countries where transmission occurred primarily via heterosexual intercourse, the highest rates of HIV-1 infection have been among female commercial sex workers or prostitutes, their male sexual contacts, and young adults in urban areas. This pattern has occurred in some areas where subtype B has predominated, but to a greater extent has been associated with subtypes other than B, notably A, C, D, and CRF01-AE (previously referred to as subtype E) (14). Based on known distributions of the major subtypes, it has been estimated that subtype C represents the largest number of HIV-1 infections worldwide (who.int/emc-hiv/global_reprt/index.html).

In contrast to the wide dispersion of HIV-1 group M subtypes, the distribution of the more divergent HIV-1 group N and O strains, as well as HIV-2, remains more geographically limited (11,12,39,41,50). Given the wide diversity of HIV-1 and HIV-2 subtypes recognized from non-systematic sampling, both a wider distribution of recognized strains and the existence of yet more divergent variants seem likely. The potential for difÞcult-to-detect divergent HIV strains to enter human populations remains a public health concern.

MOLECULAR EPIDEMIOLOGY BY REGION

Africa

Africa has been the region most severely affected by the HIV/AIDS epidemic. The high prevalence of HIV in many parts in Africa, the wide distribution of HIV-1 and HIV-2 subtypes (Fig. 3.2), and the genetic variation within subtypes, suggest that HIV has been on that continent for a relatively long time compared with other regions (14,51,52). However, extensive demographic changes with shifts from rural to urban areas and numerous population displacements from migrant labor and civil disturbances over recent decades, may have facilitated the spread of HIV in many areas.

Heterosexual HIV transmission is the major mode of spread among adults, with very little transmission recognized from male-to-male sexual exposure or injection drug use. A number of explanations have been proposed for the relative efÞciency of heterosexual transmission and the rapid spread of HIV-1 in sub-Saharan Africa. HIV-1 infection in Africa has been associated with increased numbers of heterosexual partners, a history of prostitution among women, and sexual contact with prostitutes among men (53Ð55). The role of STDs in augmenting transmission of HIV-1 has received considerable attention (56). A number of sexually transmitted infections, especially genital ulcer disease, have been associated with HIV-1 infection in both men and women in various studies (57,58). In addition, lack of circumcision appears to be a risk factor for HIV infection, either independently or perhaps due to an association between genital ulcer disease and an intact foreskin (59Ð61). HIV-1 subtypes other than B (relatively little subtype B has been recognized in Africa) have been suggested as contributing to the heterosexually-transmitted epidemics in Africa (and Asia) based on ecologic patterns of infection, but documentation that the non-B subtypes are actually transmitted more readily by this route than subtype B is lacking (62,63).

As noted previously, the distribution of HIV-2 infection as well as the more divergent HIV-1 groups N and O strains appears to be limited geographically primarily to West Africa (11,12) and Central Africa, particularly Cameroon (39,41,50), respectively. Retrospective serologic studies indicate that persons from a number of West African countries were infected with HIV-2 as early as the 1960s (46). Nevertheless, in most areas, the prevalence of HIV-2 remains low and does not appear to be increasing over time, in contrast to the continued rise in rates for HIV-1 in the same areas.

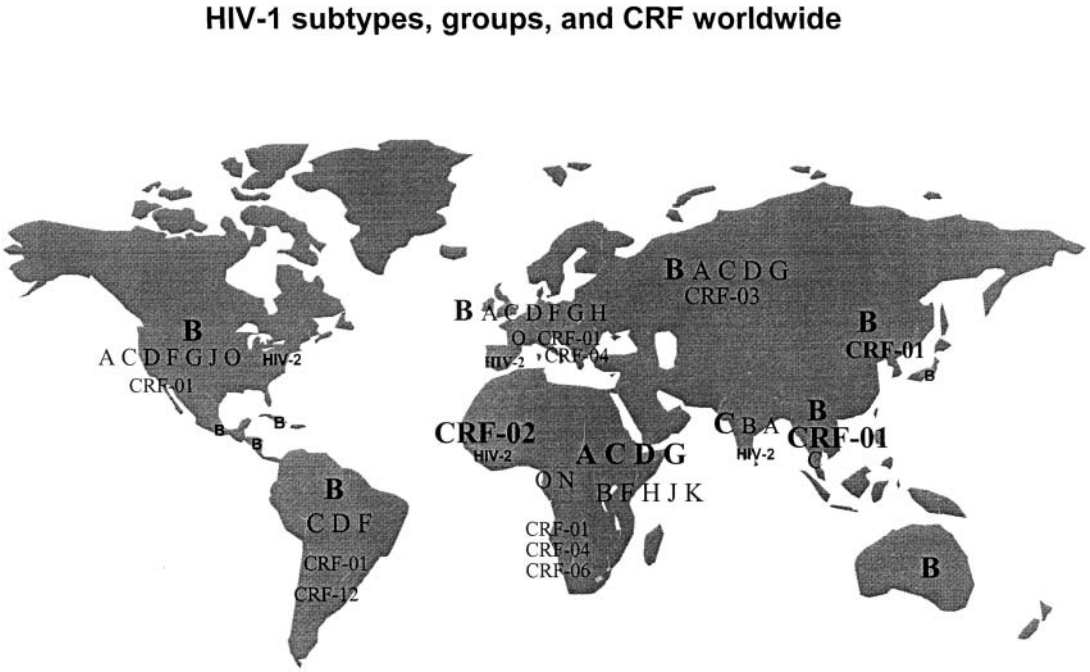

FIG. 3.2. Distribution of HIV-1 group M (subtypes A, B, C, D, F, G, H, J, and K), groups N and O, and circulating recombinant forms (CRF) throughout the world. Letters in bold represent major prevalent strains in speci c geographic regions, This map is not an exhaustive list of all reported strains and does not include reports of single cases nor recently imported cases.

Americas

Since the Þrst recognition of AIDS in 1981 in the United States (64), HIV-1 infection spread rapidly in this region in the early 1980s, primarily associated with male-to-male sexual exposure and injecting drug use, and subsequently by heterosexual transmission (65,66). As in North America, most Latin American and Caribbean countries experienced rapid spread of HIV-1 among homosexual and bisexual men early in the epidemic (66). However, the proportion of reported AIDS cases resulting from heterosexual transmission has increased dramatically since the early 1980s in most Latin American countries and heterosexual transmission appears now to be the predominant route of transmission in a number of countries (66).

The resulting geographic distribution of AIDS cases is far from homogenous either among or within countries. The great diversity of the countries and populations in the region has led to substantial variations in the patterns and rates of HIV-1 infection and AIDS. In most countries, HIV-1 infection has been concentrated in urban areas (67). Smaller numbers of persons with HIV-2 infection have been reported from the Americas, notably in the United States and Brazil, without evidence to date of local epidemic spread (12). While the vast majority of previously characterized isolates in the Americas have been HIV-1 subtype B, the occasional presence of HIV-2 (12,68,69) and other HIV-1 subtypes (70Ð73), indicates that multiple introductions of HIV have occurred and probably continue to occur.

Europe and the Former Soviet Republics

As in North America, groups predominantly affected early in the epidemic, especially in northern Europe, were homosexual and bisexual men and IDUs. However, transmission patterns vary widely within the region (48). In contrast, heterosexual IDUs account for the majority of AIDS cases in southern European countries. In addition to the HIV patterns resulting from local transmision, several western European countries have had appreciable numbers of persons with of HIV infection who came from or were infected in developing countries, especially in Africa. The HIV strains involved extend well beyond the well-characterized subtype B of Europe and North America and include non-B HIV-1 subtypes and HIV-2 (14,74,75). Thus far, wider spread of these strains, including those HIV-1 subtypes associated with the primarily heterosexually spread epidemics in Africa, has not been recognized beyond the imported cases themselves and their direct contacts.

In Eastern Europe and the former Soviet republics, HIV-1 has emerged as a major public health problem in recent years. Earlier in the epidemic, outbreak investigations of nosocomial HIV-1 transmission in Romania and the former Soviet Union demonstrated the potential for localized epidemics resulting from unscreened transfusions or the improper use of needles and syringes to administer multiple therapeutic injections (76Ð78). Following major political and economic changes in Eastern Europe and the former Soviet Union, massive social upheaval from economic difÞculties and ethnic and

religious conßicts have created circumstances which have facilitated the spread of HIV-1 and other sexually transmitted infections as well as infectious diseases like tuberculosis (34,79Ð81).

Asia and the PaciÞc

It appears that extensive spread of HIV-1 did not begin until the late 1980s in the worldÕ most populous region and that reported numbers of HIV and AIDS do not adequately reßect the dramatic increases of HIV-1 in many Asian countries such as India and China, which each have populations larger than all of Africa (1,48).

The HIV epidemic in Thailand, clearly documented by excellent surveillance, illustrated the potential for rapid HIV-1 transmission in Asia. Extensive HIV transmission began around 1988 with rapid increases in HIV-1 seroprevalence among IDUs, as evidenced by the prevalence among persons attending drug treatment centers in Bangkok increasing from 1% to approximately 40% by the end of 1988 (82). The second phase of the epidemic, which was later shown by molecular epidemiological studies to be distinct from the Þrst (83Ð85), occurred primarily among persons at heterosexual risk (82,86). High incidence resulted in marked increases in HIV-1 prevalence and the female commercial sex industry was quickly recognized as being a major source of transmission (87). The increased infectiousness that occurs in the primary phase of HIV infection and the large number of clients served by prostitutes, compounded by prevalent sexually transmitted diseases, are likely to have contributed greatly to extensive transmission and the rapidly expanding HIV epidemic (88). The many men who were infected by sexual contact with prostitutes transmitted HIV in turn to their other female sex partners (89Ð91) resulting in a subsequent increase in maternal-infant HIV transmission (92).

The dramatic epidemic documented in Thailand illustrates the potential for HIV transmission in other Asian countries through both sexual and drug-related spread. Molecular epidemiological studies have been useful in showing the association between population movements and the introduction of different HIV strains (82,93). Cross-border opiate traffÞc between countries in the region and drug use involving the sharing of injection equipment pose a substantial risk for HIV-1 transmission (94,95). Studies in China have documented the rapid spread of HIV-1 among injecting heroin users in the southwestern provinces bordering Southeast Asia (96,97). Since the mid-1990s, HIV has spread extensively beyond the initial risk groups and regions (98,99)[1].

In India, sharp increases in HIV seroprevalence have been noted, especially among female prostitutes and patients attending STD clinics in some urban areas (100,101). Even by 1995, it was estimated that over 1.7 million Indians were infected with HIV-1 (48). The problem was further compounded by the potential for HIV transmission via transfused blood since professional blood donors provide over half the blood for Indian hospitals (102,103). Due to the high HIV seroprevalence among some groups of blood donors and the resultant HIV risk, India has expanded blood screening programs in a number of cities. While most HIV detected in India has been type 1, smaller numbers of persons with HIV-2 infection have also been reported (12).

Implications of HIV Genetic Diversity

HIV genetic diversity impacts a number of important areas. For example, there are important questions on epidemiologic transmission patterns as well as the intriguing possibility that genetic and phenotypic differences in HIV affect transmissibility, pathogenicity, and responses to therapy and vaccines. In addition, genetic recombination of different strains or subtypes during co-infection may allow for the formation of viral hybrids with altered pathogenic or transmissibility properties.

Diagnostics, Virus Detection, and Screening Strategies

The high genetic variation of HIV has important implications for the sensitivity and speciÞcity of diagnostic tests. The isolation of HIV-1 in 1983 and the development of an antibody test soon thereafter were major breakthroughs. However, the subsequent identiÞcation of HIV-2 required signiÞcant modiÞcation of diagnostic tests. Somewhat analogous to the discovery of HIV-2 has been the characterization of the highly divergent HIV-1 group O and group N strains. Reports that infections with these viral strains were not well detected by commonly used HIV screening tests in Europe and North America have raised concerns about test sensitivity for blood transfusion safety as well as for individual diagnosis (40,41). Although earlier development and evaluation of different diagnostic tests were based primarily on subtype B strains from North America and Europe, more recent tests, including rapid tests, are much more sensitive in detecting divergent strains like group O as well as group M subtypes other than subtype B (104). Similarly, recent versions of assays to quantitate viral load have improved sensitivities to the major HIV-1 subtypes compared with earlier assays which were primarily based on subtype B sequences (105,106). In addition to antibody tests and viral load assays for screening and diagnosis, new serologic testing strategies to detect recent infection and to estimate incidence have also demonstrated different performance characteristics depending on subtype (107).

Active surveillance for and characterization of the prevailing HIV strains are essential to validate the sensitivity of HIV tests in clinical practice and research use. This surveillance may well be particularly challenging

because infections with as yet unrecognized highly divergent strains may be difficult to detect using available diagnostic tests.

Transmission and Transmissibility

As outlined earlier, molecular epidemiology has helped to elucidate the epidemiologic and historical aspects of transmission at the community (108), national (78,109),and international levels (110,111). As mentioned earlier, molecular characterization documented the recent, independent introductions of different HIV subtypes in a number of countries (72,83,112,113).

Once identified, genotypic differences among isolates can be used to evaluate community transmission patterns and epidemiologic linkage among cases (108,114). A well-known molecular investigation of HIV transmission involved the case of an HIV-infected dentist who apparently transmitted the virus to six of his patients (115–117). Nucleotide sequence analysis showing strong similarities between the viral strains from the dentist and those of his patients, was a powerful tool in identifying the epidemiologic link among these individuals. Subsequent investigations have used this approach to either support or refute other putative cases of transmission (118–121).

In addition to the well-recognized sociodemographic and behavioral factors, it has been hypothesized that virologic strain differences in transmissibility may play a role in the spread and therefore in the epidemiologic patterns of HIV infection (63,122). Studies concerning HIV-1 and HIV-2 have provided the clearest evidence of differences in transmissibility of viral strains. Although HIV-2 shares the same modes of transmission as HIV-1 (123), prospective cohort studies have shown less efficient rates of sexual transmission (124,125) and substantially lower mother-to-infant transmission rates for HIV-2 than HIV-1 (123,126).

There is also preliminary evidence from mother-infant pairs suggesting selective transmission of certain maternal HIV-1 variants (127,128) and suggestive evidence for differential transmissibility of two different subtypes through sexual contact (129). More detailed prospective studies with controls for potentially confounding factors are needed to more fully examine strain-specific differences in transmissibility.

Clinical Manifestations

Although the clinical and immunologic manifestations of HIV infection are addressed in other chapters of this book, it is important to realize that the wide spectrum of clinical conditions described in North America does not necessarily reflect the typical clinical picture of HIV disease in other parts of the world (130). Relatively little information is available on the natural history of HIV infection in many parts of the world, including the chronological order and the stages of immune deficiency at which different opportunistic diseases occur. It has been hypothesized that HIV infection may progress more rapidly among persons in developing than in industrialized countries (131). However, an apparently poor outcome may reflect initial diagnosis of HIV/AIDS late in the course of infection, lack of access to medical care, or death from prevalent opportunistic infections such as tuberculosis that occur relatively early in the course of HIV infection, rather than any appreciable differences in the rate of decline of immunologic function (131–133).

Although various biological, including host immunological, factors may hasten HIV pathogenesis and disease progression, studies do not suggest significant differences in natural history of HIV-1 infection by sex or racial/ethnic group (134–136). However, there is *in vitro* evidence that different strains may vary in pathogenic potential. For instance, HIV isolates vary in their cellular host range and tropism (137,138), and some studies have shown that these properties are associated with specific viral genetic and phenotypic changes (139–143). Additional evidence suggesting that pathogenicity is viral strain specific comes from small studies of persons with transfusion-acquired HIV infection, in which the rate of disease progression in recipients correlated with the rate of progression in the corresponding donors (144,145). While much of the research on clinical progression has involved North American and European subtype B viruses, work has expanded in recent years to characterize the biological properties of other HIV subtypes (63,146–149).

Studies from West Africa show that persons with advanced HIV-2 infection have clinical manifestations similar to those among persons with HIV-1 infection (150,151). However, the rate of immunologic deterioration and disease progression resulting from HIV-2 infection appears to be appreciably slower than that from HIV-1 or HIV-1/HIV-2 dual infection (151–157) Although little is known about intratype differences in pathogenesis, there are a few reports suggesting the possibility that disease progression may be faster for certain HIV-1 or HIV-2 subtypes (8,63,148,149,158). However, since disease progression and natural history are also influenced by non-viral factors, prospective studies are needed to assess accurately the pathogenic effects of different HIV subtypes (63).

Viral Resistance to Therapy

Given the high genetic variation of HIV, drug-resistant strains are present even in the absence of therapy. When therapy is initiated, selection begins for these drug-resistant strains (159–161) and replacement of previously sensitive variants can occur rapidly (162). As with many other aspects of HIV characterization, efforts are increasing to describe resistance mutations among strains other

than HIV-1 subtype B from the Americas and Europe (163,164). Since drug-resistant strains of HIV can be effectively transmitted, resulting in "primary" resistance in the newly infected person (118,165–167), it has become necessary to conduct surveillance for drug-resistant HIV strains, as is done for gonorrhea, tuberculosis, and malaria.

Vaccines

As with early diagnostic tests for HIV-1, initial vaccine candidates were primarily based on subtype B (168). However, the expanding knowledge of HIV genetic diversity coupled with the urgent need to develop vaccines for subtypes other than B in developing countries where the majority of infections occur has led to a number of new vaccine candidates which are described elsewhere in this book (Progress in the development and testing of HIV vaccines).

To the extent that vaccine efficacy is strain- or subtype-specific, the ability to evaluate them in areas of highest HIV incidence, where multiple HIV strains may be present, and the later applicability of the vaccine may pose considerable challenges. Currently, it is unclear to what extent the various HIV-1 subtypes or clades represent different immunotypes for host humoral and cellular responses (168). Ongoing assessment of vaccine candidates will clearly depend on continued surveillance and characterization of viral variants as well as detailed evaluation of host immune responses to these strains.

CONCLUSION

As the HIV/AIDS pandemic enters the twenty-first century, the pace of HIV transmission is increasing in sizeable parts of the world. Epidemiologic data suggest that for many parts of the world, especially in developing countries, there will be continued high rates of transmission and increases in HIV/AIDS. Large parts of Africa have already been devastated by the epidemic, and the coming years will bring an increased burden of AIDS-related death. As the Americas, Europe, and Africa began to come to terms with AIDS in the 1980s and early 1990s, Asia, with over three billion people, will be the new arena for HIV infection in the next millenium. In many countries, AIDS is or will likely become the leading cause of death in adults and one of the leading causes of infant and child mortality. The resulting socioeconomic consequences for communities will be considerable.

As understanding of the significance of HIV genetic diversity increases, knowledge of the frequency and distribution of different strains will play an important role in a timely and effective response to the HIV pandemic. At present, data regarding HIV subtypes are mostly limited to studies conducted for purposes other than surveillance. The expansion of epidemiologic surveillance for different strains of HIV and attempts to collect representative specimens from different populations will provide useful information to the public health community on the danger of emerging infectious agents such as HIV (14). Strong public and political support is necessary to rally the resources to monitor global HIV strain diversity for surveillance, prevention and vaccine development activities. In an age of rapid population movements and extensive interactions between communities, the challenge of HIV underscores the importance of well-coordinated clinical, laboratory, and epidemiologic efforts to stop its spread.

Chapter 4

Introduction to Retroviruses

Stephen P. Goff

Human immunodeficiency virus type 1 (HIV-1), the causative agent of acquired immune deficiency (AIDS), is a lentivirus, a member of a subfamily of retroviruses with complex regulation of viral gene expression and replication. HIV-1 is an unusual retrovirus. Whereas most retroviruses are relatively benign and rarely kill the infected cell, HIV-1 is cytopathic and cytotoxic, and high levels of viral gene expression often result in the death of the infected cell and even neighboring cells. The mechanisms of cell killing and the basis for the remarkable pathogenicity of the virus remain to be elucidated. But unusual as it is, HIV-1 is still a retrovirus, and as such its life cycle is similar to that of the simple retroviruses. This chapter will review the fundamentals of retrovirus structure and replication and so provide the basic context in which to understand the biology of this agent. The most broadly conserved aspects of the life cycle will be the focus.

The retrovirus family is a large and diverse group of viruses found in all vertebrates. These viruses replicate through an extraordinary and unique life cycle, differentiating them sharply from other viruses. The virion particles generally contain a genomic RNA, but upon entry into the host cell, this RNA is reverse transcribed into a DNA form of the genome that is integrated into the host chromosomal DNA. The integrated form of the viral DNA, the provirus, then serves as the template for the formation of viral RNAs and proteins that assemble progeny virions. These features of life cycleÑespecially the re verse ßow of genetic information from RNA to DNA, and the establishment of the DNA in an integrated form in the host genomeÑare the deÞning hallmarks of the retro viruses. This life cycle also accounts for many of their diverse biological activities. Creation of proviral DNA confers on the viruses a powerful ability to maintain persistent infection in the face of the host immune response; and to enter the germ line, permitting vertical transmission of virus.

TAXONOMY

The genera of the retroviruses have recently been formalized and given new names by the International Committee on Taxonomy of Viruses. While older classiÞcation schemes utilized morphological criteria, more modern systems use genome organization as deÞning criteria. The alpharetroviruses, betaretroviruses, and gammaretroviruses are considered Òsimple Ó retroviruses, while the deltaretroviruses, epsilonretroviruses, lentiviruses and spumaviruses are considered Òcomplex Ó. The simple viruses encode only the Gag, Pro, Pol, and Env gene products; the complex viruses encode these same gene products but also an array of small regulatory proteins with a range of functions. The properties of the viruses belonging to each of these genera are summarized brießy below. Representative members of each genus are listed here (Table 4.1).

VIRION STRUCTURE

Retrovirus virions are initially assembled and released from infected cells as immature particles containing unprocessed Gag and Gag-Pol precursors of the proteins that eventually make up the mature virus. The immature virion morphology is spherical, with a characteristic electron-lucent center. The virions have been described as a Òprotein vesicle Ó, to suggest some ßuidity in the interactions between the individual Gag proteins that make up the particle. Upon maturation, the precursor proteins are cleaved, and the structure and morphology of the virion changes drastically (1). The mature retrovirus particle is a spherical structure, roughly 100 nm in

TABLE 4.1. *Retrovirus genera*

New name	Examples	Morphology
Alpharetrovirus	Avian leukosis virus (ALV) Rous sarcoma virus (RSV)	C-type
Betaretrovirus	Mouse mammary tumor virus (MMTV) Mason-P zer monkey virus (MPMV) Jaagsiekte sheep retrovirus (JSRV)	B, D-type
Gammaretrovirus	Murine leukemia viruses (MuLV) Feline leukemia virus (FeLV) Gibbon ape leukemia virus (GaLV) Reticuloendotheliosis virus (RevT)	C-type
Deltaretrovirus	Human T-cell lymphotropic virus (HTLV)–1,–2 Bovine leukemia virus (BLV) Simian T-cell lymphotropic virus (STLV)–1,–2,–3	—
Epsilonretrovirus	Walleye dermal sarcoma virus Walleye epidermal hyperplasia virus 1	—
Lentivirus	Human immunode ciency virus type 1 (HIV -1) Human immunode ciency virus type 2 Simian Immunode ciency viruses (SIV) Equine infectious encephalitis virus (EIAV) Feline immunode ciency virus (FIV) Caprine arthritis encephalitis virus (CAEV) Visna/maedi virus	rod/cone core
Spumavirus	Human foamy virus (HFV)	immature

diameter. The size of the virions in a given preparation is not highly homogeneous but rather varies over a fairly wide range, suggesting that a discrete, highly ordered structure may not exist. After processing of the Gag precursor during virion maturation, the CA protein collapses to form a more ordered paracrystalline core, and in the case of HIV-1 the conical core is probably a well-deÞned structure (2). But even after maturation the overall diameter of the virion is heterogeneous and suggestive of considerable disorder. The virions exhibit a buoyant density in sucrose in the range of 1.16Ð1.18 g/ml. The sedimentation rate of the particles is typically about 600 **S**. The virions are sensitive to heat, detergent, and formaldehyde.

Virion Proteins

The stoichiometry of the various viral gene products in the virion are not very Þrmly established, but estimates suggest that about 1,500 to perhaps 2,000 Gag precursors are present per particle. After processing, all cleavage products are thought to be retained, suggesting equimolar presence of these proteins in the mature virions. Levels of the Pol proteins are typically about one-tenth to one-twentieth of the Gag proteins, corresponding to about 100 to 200 molecules per virion. The levels of the Env proteins are quite variable among the viruses. For the simple retroviruses such as the murine leukemia viruses, the levels of Env are close to that of Gag; perhaps 1200 monomers, or 400 trimers, are present per virion. For the lentiviruses the levels of Env per virion are much lower, possibly as low as ten trimers per virion.

Nomenclature

The cleavage of Gag, Pol and Env precursors forms the products in the mature infectious virions. These proteins are named by convention by a two-letter code: MA for matrix or membrane-associated protein; CA for capsid; NC for nucleocapsid; PR for protease; DU for dUTPase; RT for reverse transcriptase; IN for integrase; SU for surface protein; and TM for transmembrane protein (3). The localization of these proteins in the mature virion is not known with great precision, but a highly schematic version of the generic retrovirion can be drawn (Fig. 4.1).

Arrangment of Virion Components

The genomic RNA is highly condensed in the virion by its association with the nucleocapsid protein, NC. The complex is contained within a protein core largely composed of the capsid protein CA, another Gag gene product. The shape of the core is different among the various retroviral genera, and indeed is a distinguishing feature of the genera. In most of the viruses the core is roughly spherical, but in some cases can be either conical or cylindrical. In all the viruses the core is surrounded by a roughly spherical shell consisting of MA, which in turn is surrounded by the lipid bilayer of the virion envelope. The virion membrane contains the envelope glycoprotein, with the TM subunit present as a single-pass transmembrane protein anchor, and the SU subunit as an entirely extravirion protein bound to TM. The envelope proteins for those viruses examined closely have been found to reside in the membrane as trimers.

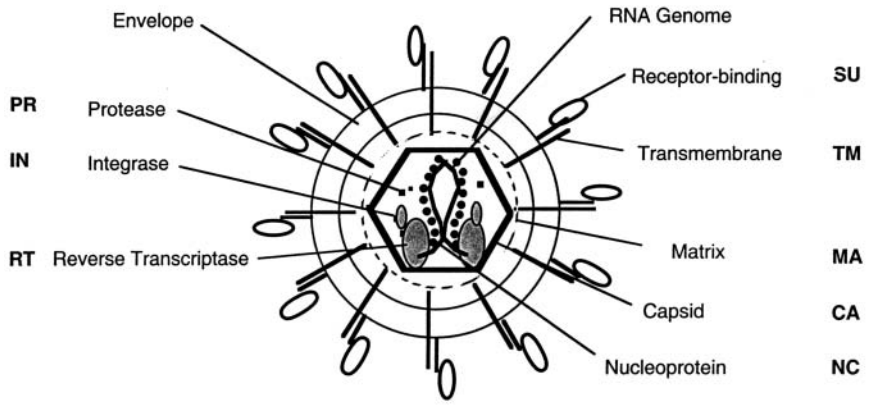

FIG. 4.1. Generalized retrovirion structure and components. A highly schematic view of the arrangement of viral gene products within the virion particle. The two-letter nomenclature for each protein is indicated. From (486) courtesy of Lippincott, Williams and Wilkins.

OVERVIEW OF THE LIFE CYCLE

The retroviruses replicate through a complex life cycle. A short summary of the steps of the cycle is as follows (a schematic view is shown in Fig. 4.2):

- ¥ Binding of the virion particle to the receptor and fusion of the viral and cell membranes
- ¥ Internalization of the virion core and uncoating to allow access of deoxyribonucleotides
- ¥ Reverse transcription of the RNA genome to form double-stranded linear DNA in the cytoplasm
- ¥ Transport of the pre-integration complex (PIC) to the nucleus and import into the nucleus
- ¥ Integration of the linear DNA into the cellular genome to form the provirus

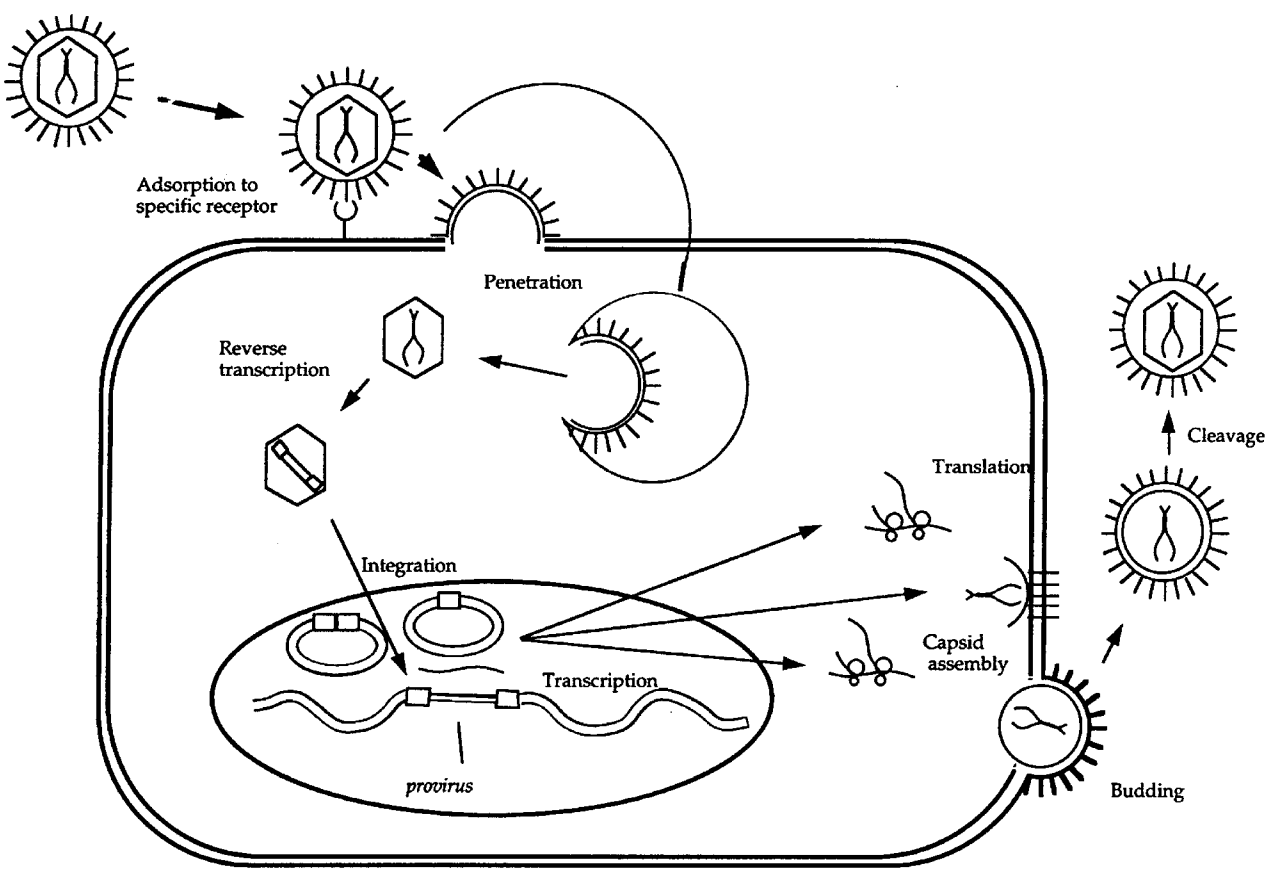

FIG. 4.2. A schematic view of the retrovirus life cycle. The major steps in the replication of a typical retrovirus are indicated, including those in the early phase of the life cycle, extending from the infecting virion (top left) to the formation of the integrated provirus, and those in the late phase of the life cycle, extending from the provirus to the formation of mature progeny virus (right). From (486) courtesy of Lippincott, Williams and Wilkins.

- Transcription of the provirus by RNA Polymerase II to form viral genomic RNA and mRNAs
- Splicing and nuclear export of the RNAs
- Translation of the RNAs to form precursor proteins
- Assembly of the virion particle and packaging of the viral RNA genome
- Budding and release of the virions
- Proteolytic processing of the precursors and maturation of the virions to create an infectious progeny virus.

We will consider each of these steps in detail in the rest of this chapter.

THE VIRUS RECEPTORS

To enter a cell and initiate infection, all retroviruses require an interaction between a cell surface molecule Ða receptor Ðand the envelope protein on the virion surface. The interactions are complex, involving an initial binding, drastic conformational changes in the envelope protein, an induced fusion of the viral and cellular membranes, and the internalization of the virion core into the cytoplasm. The SU subunit of Env is thought to make the major initial contacts with receptor, and the TM subunit is thought to be most important for membrane fusion. The reorganization of the two lipid bilayersÑ one on the virion and one on the cellÑ to join them and evert the core into the cell is a remarkable process. The details of these complex processes are not understood for any retrovirus, and the whole Env protein is likely to be involved in efÞcient entry. However, there is a great deal of information about the identity and structures of the receptors used by various retroviruses. It is apparent that these viruses utilize an extraordinarily diverse set of cell surface molecules as receptors (see (4,5) for reviews).

The Þrst receptor identiÞed for any retrovirus was the CD4 molecule, established as essential for infection by HIV-1 (6Ð8). Soluble forms of CD4 can bind to virions and inhibit infection; in some strains of virus, CD4 induces release or shedding of the SU subunit from the virion. However, other strains are quite resistant to inhibition by soluble CD4. CD4 is an important surface protein on T cells, and with few exceptions serves to deÞne the helper subset of T cells. CD4 is also expressed at signiÞcant levels on dendritic cells, macrophages, and on certain cells in the brain, which may be related to astrocytes rather than cells of neural origin. The limited distribution of expression of CD4 accounts well for the tropism of HIV-1, largely restricted to helper T cells and macrophages. There may be other routes of entry utilized at lower efÞciency: antibody to virus, for example, can promote virus entry into cells by the Fc receptor (9).

Early work established, however, that although CD4 was sufÞcient to mediate virus binding to a cell surface, it was not sufÞcient to mediate virus infection and entry. For example, rodent cells and other cells of non-primate origin could not be successfully infected by HIV-1 even if they were engineered to express human CD4. Searches for genes that would render such cells sensitive to virus infection ultimately led to the identiÞcation of various members of the chemokine receptor family, notably CCR5 and CXCR4, as coreceptors that were needed to mediate the post-binding step of membrane fusion and virus entry (10Ð13). The regions of the human coreceptors that are needed for virus entry have been identiÞed (13Ð16), though, surprisingly, some HIV-1 isolates can utilize the murine CXCR4 (17). Antibodies to the coreceptor as well as the natural ligand for these molecules, the chemokines themselves, can block virus entry. Variants of SIV and HIV-1 have been identiÞed that are CD4-independent, needing only a chemokine receptor for infection; these viruses suggest that the chemokine receptors might have been the primary receptor for a primordial virus. A further proof of the importance of the chemokine receptor is the existence of a mutant allele of the gene encoding CCR5 in the human population, a 32-bp deletion, that confers dramatic virus resistance to homozygous individuals (18Ð20).

REVERSE TRANSCRIPTION

The reverse transcription of the viral RNA genome into a double-stranded DNA form is the deÞning hallmark of the retroviruses, and the step from which these viruses derive their name. The course of reverse transcription is complex and highly ordered, involving the initiation of DNA synthesis at precise positions, and translocations of DNA intermediates that result in duplication of sequence blocks in the Þnal product (for reviews see (21,22)). The major steps in the reaction are relatively well-established, largely through the analysis of reactions carried out *in vitro* in puriÞed virion particles (the so-called Òendogenous reactionÓ).

Reverse transcription normally begins soon after entry of the virion core into the cytoplasm of the infected cell. The reaction takes place in a large complex, roughly resembling the virion core, and containing Gag proteins including NC, RT, IN, and the viral RNA (23). The signal that triggers the onset of DNA synthesis is not known, though it may be as simple as the exposure of the viral core to the relatively high levels of deoxyribonucleotides present in the cytoplasm. This notion is consistent with the observation that simply stripping or permeabilizing the virion membrane with detergents in the presence of deoxyribonucleotides is sufÞcient to induce DNA synthesis. This may also be at least part of the explanation for the difÞculty HIV has in completing reverse transcription and infection in quiescent cells (24). In some cells, notably cells arrested by starvation, triphosphate levels may be low and limiting for reverse transcriptase, so that addition of exogenous nucleosides can stimulate viral DNA synthesis (25).

It has been recently appreciated that DNA synthesis can be initiated "prematurely" during virion assembly and release, such that virion preparations can be shown to contain small amounts of the early DNA intermediates, such as minus strand strong stop DNA (26–29). In most cases the levels of these DNAs are very low, indicating that only a very small minority of the virion particles have carried out any significant synthesis. However, some circumstances affecting the rate of production and release of virions may enhance this synthesis (30). In addition, in some particular retroviruses, notably the spumaviruses, substantial DNA synthesis may occur during assembly such that the major form of the genome found in mature virions is a partially or even completely reverse transcribed DNA molecule (31,32). These viruses thus resemble the hepadnaviruses more closely than the conventional retroviruses in the relative timing of assembly and reverse transcription.

Steps in Reverse Transcription of the Retroviral Genome

The course of reverse transcription is complex. The reaction can be broken down into a series of discrete steps (21), as presented in Fig. 4.3.

- Formation of minus strand strong stop DNA.
  The process of reverse transcription is initiated from the paired 3′ OH of a primer tRNA annealed to the viral RNA genome at a complementary sequence termed the primer binding site (pbs). DNA is first synthesized from this primer, using the plus strand RNA genome as template, to form minus strand DNA sequences. Synthesis occurs toward the 5′ end of the RNA to generate U5 and R sequences. The intermediate formed in this step is termed minus strand strong stop DNA. The primer tRNA remains attached to its 5′ end.
- First translocation.
  The next step involves the translocation, or "jump," of the strong stop DNA from the 5′ to the 3′ end of the genome. This translocation requires the degradation of those 5′ RNA sequences that were placed in RNA:DNA hybrid form by the formation of strong stop DNA. The degradation is mediated by the RNase H activity of RT; mutants with altered RNase H activity do not mediate the translocation (33,34). This step exposes the single stranded DNA and facilitates its annealing to the R sequences at the 3′ end of the genome. Normally a full-length strong stop DNA, synthesized by copying to the 5′ cap of the RNA, performs the translocation (35), though incomplete molecules can jump at low efficiency. Specific sequences or structures in or near the R region are required for efficient jumping (36,37). The NC protein may facilitate the transfer step. Although there have been reports that jumping is always in *trans*, from one RNA template to the other RNA in the virion, the best evidence is that minus strand strong stop jumping goes randomly to either RNA (38).
- Long minus strand DNA synthesis.
  The annealing of minus strand strong stop DNA recreates a suitable primer-template structure for DNA synthesis, and RT can now continue to elongate the minus strand strong stop DNA to form long minus strand products. Synthesis ends in the vicinity of the pbs. As the genome enters RNA:DNA hybrid form, the RNA becomes susceptible to RNase H action and is degraded.
- Initiation of plus strand DNA synthesis.
  The primer for plus strand synthesis is created by the digestion of the genomic RNA by RNase H. A particular short purine-rich sequence near the 3′ end of the genome, the polypurine tract or ppt, is relatively resistant to the activity of RNase H. The oligonucleotide remains hybridized to the minus strand DNA and serves as the primer for synthesis of the plus strand DNA, using

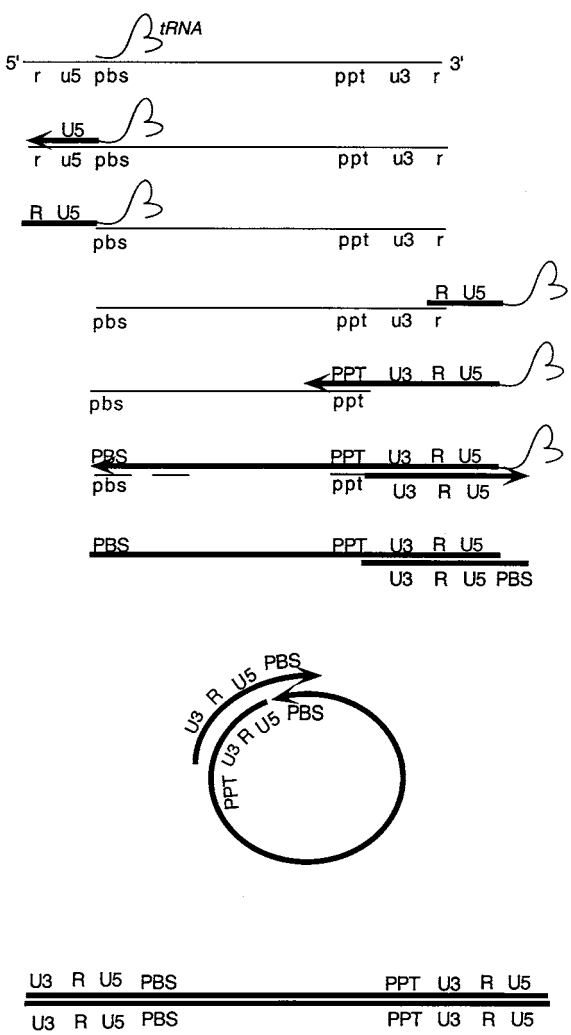

FIG. 4.3. The reverse transcription of the retroviral genome. Thin lines represent RNA; thick lines represent DNA. See text for details. Drawing courtesy of A. Telesnitsky. From (486) courtesy of Lippincott, Williams and Wilkins.

the minus strand DNA as template. Sequences upstream of the polypurine tract, an AT-rich region called the T-box, are also important for proper priming (39,40). The primer, once it has served to initiate DNA synthesis, is quickly removed from the DNA, presumably by RNase H action. Synthesis proceeds toward the 5′ end of the minus strand, Þrst copying the U3, R, and U5 sequences, and then extending to copy a portion of the primer tRNA still present at its 5′ end. Elongation stops at a modiÞed base normally found at position 19 of the tRNA. The resulting intermediate is termed plus strand strong stop DNA.

In some viruses, secondary plus strand initiation sites are used. There may be multiple RNA primers generated from the RNA genome by the nuclease action of RNase H that can initiate DNA synthesis at dispersed heterogeneous sites. In the case of the lentiviruses and spumaviruses, a second copy of the ppt sequence near the center of the genome is used at high efÞciency, and is important for proper completion of reverse transcription (41).

¥ Removal of tRNA

In the next step, the primer tRNA at the 5′ end of the minus strand DNA is removed by RNase H. Its removal may occur in two stages: with an initial cleavage near the RNA-DNA junction, and a second one within the tRNA. The cleavage need not occur exactly at the RNA-DNA junction, and a single ribonucleotide base (A) is normally left on the 5′ terminus of the minus strand (42Ð45) without affecting subsequent processes. The sequence of bases near the junction can signiÞcantly modulate the cleavage by RNase H (46). Recent experiments indicate that the post-transcriptional modiÞcations present in the natural tRNA may be important for proper recognition by RT and for plus strand strong stop translocation (47).

¥ The second translocation

The removal of the tRNA exposes the 3′ end of the plus strand strong stop DNA to permit its pairing with the 3′ end of the minus strand DNA. The sequences anneal via the shared pbs sequences. This annealing forms a circular intermediate, with both 3′ termini in a suitable structure for elongation.

¥ Completion of both strands

Both strands are now elongated. The Þnal extension of the minus strand DNA is coupled to displacement of the plus strand strong stop DNA from the 5′ end of the minus strand; as minus strand elongation occurs, the plus strand strong stop is peeled away and transferred to the 3′ end of the minus strand. At the end of this elongation, the circle is opened up into a linear DNA. The plus strands are all extended, and displacement synthesis may occur to remove short DNAs and make longer plus strand DNAs (48). Any internally primed plus strand DNAs may be prevented from participating in strong stop translocation simply by kinetics; the normal plus strand strong stop DNA may simply form Þrst, and elongation to transfer it to the minus strand may occur before it could be displaced by any plus strand elongation (49). Finally, the plus strand strong stop DNA is extended to complete the plus strand.

When multiple plus strand initiation events occur, the completed plus strand will consist of adjacent fragments and so contain nicks or discontinuities. Displacement synthesis by an upstream fragment can slowly displace downstream RNAs and DNAs, leading to longer plus strands (48). However, some nicks or gaps may persist in the Þnal double stranded product. These breaks may be at heterogeneous positions, though strong sites of plus strand initiation, such as the one at the central ppt of lentiviruses, can lead to speciÞc sites for such discontinuities. Sequences near the central ppt of the lentiviruses cause termination of synthesis during elongation from upstream primers, and thus ensuring the maintenance of a discontinuity at this site (50). This site retains a partially displaced sequence or overlap of a few nucleotidesÑ 99 nt in the case of HIV-1. The structure has been shown to persist even to the time of integration of the DNA into the cell. Host DNA repair processes ultimately correct all such discontinuities.

Biochemistry and Structure of Reverse Transcriptase

The enzyme that mediates the complex series of events outlined above is reverse transcriptase, one of the most famous of the viral polymerases (51); for review, see (52). All RTs contain two separate activities present in two separate domains: a DNA polymerase able to incorporate deoxyribonucleotides on either an RNA or a DNA template, and an RNase H activity able to degrade RNA only in duplex form. These two activities are responsible for the various steps of reverse transcription. Two distinct domains of the enzyme contain these two activities: an aminoterminal domain contains the DNA polymerase, and a carboxyterminal domain contains the RNase H activity (53). While isolated domains can be shown to exhibit either one of the two activities separately, an intact enzyme is required for full activity and speciÞcity. However, the two functions can be provided by two mutant RT molecules so long as they are co-incorporated into a single virion (54).

DNA Polymerase

The DNA polymerase activity is similar to that of all host and viral polymerases in requiring a primer, which can be either RNA or DNA, and a template, which can also be either RNA or DNA. RTs incorporate dXTPs to a growing 3′OH end with release of PPi, and require divalent cations, usually Mg^{++}. The primer must contain a 3′OH end that is paired with the template. RTs are relatively slow DNA polymerases, under standard conditions only incorporating 1Ð100 nucleotides per second,

depending on the template. Further, they exhibit poor processivity, and tend to release primer-template frequently *in vitro*. Secondary structures in RNA templates can strongly enhance the pausing of RT and its tendency to release from the template (55). The enzyme also exhibits low Þdelity, and though the values of the error rate vary widely with the primer (56), template (57,58) and type of assay, the misincorporation rate of most RTs under physiological conditions is on the order of 10^{-4} errors per base incorporated. This rate suggests that during replication there would be approximately one mutation per genome per reverse transcription cycle. Indeed, the mutation rate observed *in vivo* is roughly consistent with this high error rate (59Ð63), though Þdelity *in vivo* may be somewhat better than *in vitro* (64). Drug-resistant variants that do not incorporate chain-terminating analogues are often found to exhibit higher Þdelity, perhaps because they require a more precise Þt for the correct incoming triphosphate to allow for discrimination against the analogue. A wide range of types of mutations are created by RT errors, and both the type and the frequency of appearance of each type of mutation exhibit a complex dependence on sequences and structures in the template (65Ð67).

RTs do not generally exhibit a proofreading nuclease activity (68), and misincorporated bases are not removed efÞciently by most RTs as they are by host DNA polymerases. Very recently, however, mutants of the HIV-1 RT resistant to AZT have been shown to exhibit an enhanced ability to remove the incorporated AZT moiety at the 3′ end through a pyrophosphorolysis reaction (69). Thus, it is possible for RT to remove some such analogues and rescue a terminated chain for continued elongation.

RNase H

The RNase H activity of RT is an endonuclease that releases oligonucleotides with a 3′OH and a 5′PO4. This property allows the products of RNase H action to serve as primers for initiation of DNA synthesis by the DNA polymerase function of RT. There is an obligate requirement that the RNA be in duplex form, normally an RNA-DNA hybrid. However, retroviral RTs are also able to degrade RNA-RNA duplexes (70,71), an activity termed RNaseH* (72). The RNase H enzyme is capable of acting on the RNA of a template in concert with the polymerase as it moves along a nucleic acid, and as it does so its active site is located about 17Ð18 bp behind the growing 3′ end (73). RNase H can also act independently of polymerization.

Crystal Structures

The three-dimensional structure of a number of RTs have been determined by X-ray crystallographic studies. Structures of the unliganded HIV-1 RT (74,75), RT bound to non-nucleoside RT inhibitors (76Ð79), RT bound to an RNA pseudoknot inhibitor (80), and an RT bound to a duplex oligonucleotide (81Ð84), as well as the isolated RNase H domain (85), have all been reported. The two subunits are folded quite differently so that the overall structure is highly asymmetric. The structure of the p66 is similar to that of a right hand, with Þngers, palm, and thumb domains all named on the basis of their position in the structure. The nucleic acid lies in the grip of the hand, held by the Þngers and thumb. The YXDD motif present at the active site for the DNA polymerase lies at the base of the palm. The RNase H domain is attached to the hand at the wrist. The p51 subunit, while made up of the same domains as the aminoterminal part of p66, is folded differently and lies under the hand, not making direct contact with the nucleic acid and so not thought to participate in chemistry. The structure of p66 with and without a liganded nucleic acid is quite different, with the thumb domain ßexing to allow substrate binding. Theoretical considerations suggest the thumb may move during elongation (86). A structure of the Þngers and palm subdomain of the Moloney MuLV RT at very high resolution (87) has also been determined.

Inhibitors

RT is a major target of antiviral drugs useful in the treatment of retroviral diseases such as AIDS. All such drugs used to date are inhibitors of the DNA polymerase activity of RT, and fall into two classes: nucleoside analogue inhibitors (chain terminators), and non-nucleoside RT inhibitors (NNRTIs). The nucleoside analogues are typically precursors, and need to be activated by phosphorylation to the triphosphate form. These are then incorporated by RT into the growing chain, and serve to block further elongation. Examples include AZT, ddC, ddI, d4T, and 3TC. The NNRTIs are a group of compounds that are structurally diverse, but nevertheless interact with a common binding pocket in RT to prevent its normal activity (88). There are indications that the binding may inhibit the enyzmeÕs ßexibility. For both classes of inhibitors, monotherapy with a single drug selects for drug-resistant variants that quickly predominate in the virus population, and for each drug, a pattern of mutations has been identiÞed that serves to indicate the appearance of drug resistance (89). In many cases these mutations alter the binding site for the nucleoside or NNRTI such that the drug cannot bind and so cannot inhibit the enzyme. In the case of AZT, however, the mutations do not prevent the binding and incorporation of AZTTP into the growing chain, but rather seem to activate a reverse reaction in which the AZT nucleotide is removed from the chain, subsequently permitting normal elongation (69). Combination therapy, typically involving the simultaneous treatment with three different drugs, can suppress virus

replication to such an extent that variants resistant to all the drugs do not appear, at least for months or years.

RECOMBINATION

The process of reverse transcription could in principle take place using a single template RNA molecule. In fact, however, retrovirions contain two copies of the RNA genome copackaged into one particle, and the course of reverse transcription typically makes use of both RNAs (90,91). Recombination occurs between homologous sequences in the two RNAs (92,93), and it happens normally at surprisingly high frequencies, perhaps once per replication event per genome on average (94). Normally the two RNAs in a virion are identical, so that homologous recombination events are invisible and without consequence. When the two RNAs are distinct, however, as when they derive from two viruses or viral strains, the result is a very high frequency of recombination between them among the resulting proviral DNAs. Thus, physical markers and genetic markers recombine rapidly whenever the two genomes are copackaged into one virion and so are coextant during a single round of reverse transcription.

INTEGRATION OF THE PROVIRAL DNA

Integration of the linear retroviral DNA, like reverse transcription, is a crucial feature of the retroviral life cycle. Integration is required for efficient replication of most retroviruses; mutants that are unable to integrate do not establish a spreading infection. The orderly and efficient integration of viral DNA is also unique to the retroviruses. Further, the establishment of the integrated provirus is responsible for much of retroviral biology. It accounts for the ability of the viruses to persist in the infected cell; for their ability to enter permanently the germ line; and for the mutagenic and oncogenic activities of the leukemia viruses. Once the provirus is established, the DNA is permanently incorporated into the genome of the infected cell. There is no mechanism by which it can be efficiently eliminated. At very low frequencies, homologous recombination between the two LTRs can delete most of the provirus, but even here a single (ôsoloõ) LTR remains (95).

Entry into the Nucleus

A key step that must take place before integration can occur is entry of the viral DNA into the nucleus. The mechanisms of nuclear entry are largely unknown, but there are probably at least two distinct routes used by different retroviruses. The simple retroviruses show a profound requirement for passage through mitosis for successful establishment of the integrated provirus (96–99), and the block in non-dividing cells is at or close to the step of nuclear entry. Tests of the state of the viral DNA in non-dividing cells are consistent with the notion that the preintegration complex must await the breakdown of the nuclear membrane in order to have access to the cellular DNA. Infection of non-dividing cells results in the accumulation of linear double stranded DNA in the cytoplasm, and no further signs of infection. The viral DNA will persist in the cell for some time, and if the cell is stimulated to undergo division, the viral DNA will integrate and infection will proceed. However, the DNA loses its capacity to become activated in this way fairly rapidly (97,100). The restriction is quantitatively very significant, and it profoundly limits the utility of simple retroviral vectors for gene therapy.

In contrast, lentiviruses and spumaviruses are able to infect successfully non-dividing cells, and thus there must be an active transport of viral DNA through an intact nuclear membrane (101–104). This capability has made lentiviruses very attractive as gene delivery vectors for gene therapy applications. The molecular basis for this capability is a subject of great controversy. The lentiviral MA and Vpr proteins have been argued as essential for the infection of non-dividing cells (105–108), and the phosphorylation of MA has been argued as necessary to promote dissociation from the membrane and allow nuclear import (109–112). These findings have not been universally confirmed (113–115), however, and the role of MA in these steps is uncertain. Similarly, it has been shown that the Vpr protein is present in the preintegration complex, and can bind to nucleoporin components that may mediate nuclear import. However, here too universal support for this model has not been forthcoming. A triple stranded DNA structure, termed a DNA structure, formed by reverse transcriptase at the second internal copy of the polypurine tract have also been suggested as important for infection of non-dividing cells (116). Another attractive model is that the IN protein might be involved in the nuclear import of the complex. IN itself contains nuclear localization signals (107, 117), and these can function to target ectopically expressed IN to the nucleus, but it is not clear whether this is related to preintegration complex nuclear import or nuclear retention. The foamy viruses may have a distinctive route of nuclear entry involving microtubular transport and centrisomal association, but the mechanism is not well understood (104).

Biochemistry of Integration

The actual integration of the viral DNA into a target is mediated *in vivo* by the viral integrase protein, IN (118–120), which is brought into the cell inside the virion, and acts to insert the linear DNA into the host chromosome. Some of IN functions have been studied by analysis of viral DNA formed *in vivo* (121). Most of our

understanding of IN function, however, has been obtained through analysis of *in vitro* integration reactions, Þrst using complexes extracted from infected cells (122, 123), and later using recombinant IN protein. The reaction proceeds in two steps: 3′ end processing and strand transfer. A schematic view of these reactions is shown in Fig. 4.4.

3′ End Processing

In the Þrst step, the two terminal nucleotides at the 3′ ends of the blunt-ended linear DNA are removed by the integrase to produce recessed 3′ ends and correspondingly protruding 5′ ends. This cleavage occurs endonucleolytically at a highly conserved CA sequence, and releases a dinucleotide. For most viruses the terminal sequence is such that a TT dinucleotide is released, though this rule has exceptions. The ends do not remain covalently bound to protein, and the energy of the hydrolyzed phosphodiester bond is not retained.

Strand Transfer

In the second step, the 3′ OH ends created by processing are used in a strand transfer reaction to attack the phosphodiester bonds of the target DNA (123). The attack occurs by an Sn2-type reaction, with inversion of the phosphorus center as detected with chiral labelling of the phosphate (124). The formation of the new phosphodiester bond between the viral end and the host DNA displaces one of the phosphodiester bonds in the host DNA, leaving a nick. The protruding 5′ end of the viral DNA is not joined to the host DNA by IN. The reaction is a direct transesteriÞcation, and so no ATP or other energy source is

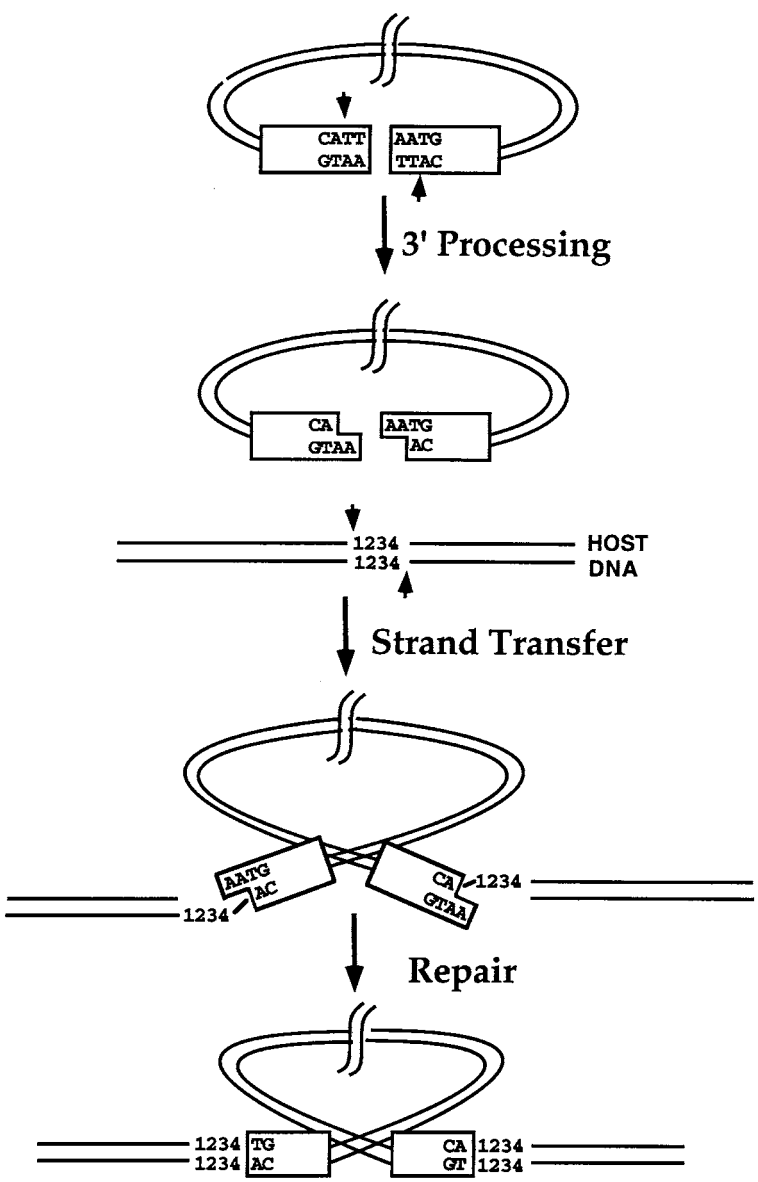

FIG. 4.4. Steps in the integration of the viral DNA. The full-length linear DNA (top) is processed by the viral integrase by the endonucleolytic removal of dinucleotides at the 3′ termini. The resulting DNA is then used in a strand transfer reaction in which the 3′ OH ends make staggered breaks in the two strands of the target site DNA. The resulting gapped intermediate is presumably repaired by host enzymes. From (486) courtesy of Lippincott, Williams and Wilkins.

required. Mutational studies strongly suggest that the two activitiesÑ processing and joiningÑ utilize the same active site residues. In fact the two steps involve similar chemistry: 3′ end processing is an attack on DNA by a hydroxyl residue of water, while joining is an attack on DNA by a 3′ hydroxyl residue of another DNA. It should be noted that other hydroxyl residues can participate; alcohols such as glycerol can be utilized (125), and the 3′ OH of a DNA can even attack a phosphodiester bond on the same DNA, forming a cyclic product (124).

Disintegration

The IN protein exhibits a third enzymatic activity *in vitro*: a reversal of the integration reaction known as disintegration (126). This activity releases DNA from a branched structure and seals the nick at the site of the branch. The signiÞcance of the activity *in vivo* is uncertain.

Target Site Duplication

In a wild-type virus, when the two ends are joined to the two strands of the target DNA, the two sites of attack are staggered by a few base pairs. After the joining, the resulting structure contains short gaps in the host DNA and unpaired bases from each 5′ end of the viral DNA. The 5′ ends of the viral DNA are not joined to host DNA by any known activities of IN. However, the 5′ ends are very quickly repaired *in vivo*, almost as quickly as the initial integration reaction (127). These discontinuities are presumed to be repaired by the host repair enzymes, though it is possible that the viral RT or IN could participate. Indeed, the IN protein has been suggested to manifest a DNA polymerase activity that might Þll in the gaps. The processing and Þlling in the gaps creates a short duplication of sequence that was present only once at the target site; these duplications ßank the integrated provirus. The number of bases duplicated is characteristic of each virus. Thus, the murine and feline viruses cause a 4 bp duplication; HIV-1 causes a 5 bp duplication; and the avian viruses cause a 6 bp duplication.

Viral *att* Sites

The sequences at the termini of the viral DNA, the *att* sites, are recognized by the viral IN protein and are important for end processing and joining (128Ð131). These terminal sequences are imperfect inverted repeats. The most conserved residues are a CA dinucleotide pair that lies near the 3′ terminus and determines the site of 3′ processing. While these bases are absolutely conserved among all the retroviruses, and among many transposable elements, small changes can be tolerated, and mutants can utilize TA or CG relatively well (132). Sequences upstream from the CA for perhaps 10Ð12 bp are needed for efÞcient integration, but these sequences are different for different viruses, with no indication of broadly conserved sequence motifs. Since the two termini of any given virus are somewhat different, they usually show differential efÞciency of utilization in various assays (133). The fact that two distinct ends are bound together in a complex may be important for the concerted integration of these ends into the target (134).

The sequence-speciÞc binding to the att site is probably performed by the core domain of IN (135). The non-speciÞc DNA binding activity of IN has made it difÞcult to detect sequence-speciÞc binding to these regions, though under some conditions preferential binding to the authentic sequences can be demonstrated (136). A demonstration that an IN mutation can compensate for a mutation in the DNA termini provides good evidence for the delicate interaction between IN and the DNA termini (137).

Structure of the Integrase

The IN protein consists of three distinct domains: an N-terminal region containing an HHCC zinc-Þnger motif; a central catalytic core containing the so-called D,D-35-E motif; and a less well-conserved C-terminal region. The IN protein is a multimer: it readily dimerizes, and at high concentration forms tetramers as well. All three regions may be involved in the multimerization of IN (138) and in DNA binding (139,140). Many of the residues important for enzymatic activities have been identiÞed by mutagenesis. The most crucial residues for catalysis are the acidic amino acids in the D,D-35-E motif, a highly conserved array of three residues in the core region of many integrases and transposases (141). Mutants indicate that both the N and C-terminus are also important for function. Surprisingly, pairs of IN mutants with alterations in different regions of the molecule can complement to restore normal function (142,143). The separate N-terminal domain can even complement a non-overlapping fragment, suggesting that these domains can still coassemble into a functional oligomeric complex (144).

The structures of the HIV-1 and avian virus IN cores have been determined by X-ray crystallography (145Ð148), revealing a compact dimer with similarity to prokaryotic recombination enzymes and RNase H (149). The structures of the N- and C-terminal domains have been determined by NMR (150Ð153). The structures can be partially merged into a complete molecule (154), but the models do not yet provide a clear picture of the binding sites for viral or host DNAs or the mechanism of the reaction. Indeed, the likely active sites are not located at positions in the dimeric molecule that could mediate concerted integration of two termini into a single target DNA. Crosslinking studies have helped the development of some models for the interaction of IN with DNA (155).

The avian IN is phosphorylated at a carboxyterminal serine (156), but the signiÞcance of this modiÞcation is not clear.

Preintegration Complex

IN does not normally act alone, and a large complex of proteins and nucleic acid is responsible for mediating the formation of the provirus *in vivo* (23,157,158). The nature and components of the preintegration complex (PIC), or intasome, are not known in any detail for either the simple or the complex viruses. The PIC of the simple viruses seems to contain CA, RT, and IN, but other viral proteins may be present (23). Many of these proteins probably stay with the DNA even after entry into the nucleus (159). The PICs of the complex viruses do not contain detectable CA, but rather contain MA, NC, Vpr, RT and IN (160). Thus, the PICs of these viruses may be very different, consistent with their very distinctive ability to infect non-dividing cells. Normal PICs apparently contain a large structure covering the two ends of the DNA, and perhaps holding them in proximity. The formation of this structure, detected as a footprint in a modiÞed nuclease sensitivity assay (161), requires both IN and the correct sequences at the termini of the DNA (162).

Structure of the Provirus

An important aspect of retroviral integration that distinguishes the process from non-viral or other viral mechanisms of DNA integration is the fact that the insertions create a consistent provirus structure. The integrated provirus is collinear with the product of reverse transcription, and consists of a 5′ LTR, the intervening viral sequences, and a 3′ LTR, inserted cleanly into host sequences. The joints between host and viral DNA are always at the same sites, very near the edges of the viral LTRs. As compared to the unintegrated linear DNA there is a loss of a small number of base pairs, usually two, from each terminus of the viral DNA; and there is a duplication of a small number of base pairs of host DNA initially present once at the site of insertion that ßank the provirus. The number of base pairs duplicated is characteristic of each virus, and ranges from 4 to 6 bp.

EXPRESSION OF VIRAL RNAS

Integration of the provirus signals a dramatic change in the life style of the retrovirus; it marks the end of the early phase of the life cycle and the beginning of the late phase. The early phase is driven by viral enzymes performing abnormal events such as reverse transcription and DNA integration, while the late phase is mediated by host enzymes performing such relatively normal processes as transcription and translation. This late phase of gene expression may begin immediately with the synthesis of viral RNAs and proteins, and the assembly of progeny virions (see Fig. 4.5 for an overview). For many viruses, the transcriptional promoters that drive this expression are constitutively active and cause the production of virions in a relatively unregulated way. In other viruses the activity of the promoter may be regulated, either by viral or host factors. We will review the basic phenomenology of proviral gene expression, and mention brießy the regulation exhibited by the complex retroviruses.

Initiation of Transcription

The efÞciency of initiation of transcription at the 5′ LTR is the major determinant of the levels of viral RNA formed in the cell. The promoter in the LTR is typically a very potent one, and the levels of viral RNA are often constitutively high. However, the cell type, the physiological state, and the integration site (163,164) can all result in substantial variation in the efÞciency of transcription. In some viruses, the promoter is not constitutively active but depends on the activity of speciÞc transcription factors such as the glucocorticoid receptors.

Positive Regulatory Elements in U3

The transcriptional elements in the U3 region of the simple viruses contain both core promoter sequences and enhancers. The core promoters contain a TATA box, bound by TFIIB, a CCAAT box, bound by CEBP (165), and sometimes an initiator sequence near the U3-R border. The U3 regions of even closely related retroviruses are very diverse, and can evolve rapidly during viral replication. The enhancers are similar to those found in many host promoters in containing multiple short sequence motifs, arranged in very close packing; often there are tandemly repeated copies of some of these motifs. These short sequences are the binding sites for a large number of host factors that regulate transcription (e.g. see (166)). Different cells and cell types will make use of distinct arrays of these factors to mediate transcription from a given viral LTR (167Ð170). The factors are not simply additive but may interact in complex ways on particular viral sequences.

Trans-Acting Viral Regulatory Factors

The complex retroviruses encode an array of small regulatory proteins that can activate transcription from the viral LTR in *trans*. Examples of these transactivators include the HTLV-1 Tax protein (171) and the HIV-1 Tat protein (172). The Tax protein acts in concert with a complex of host proteins, the activating transcription

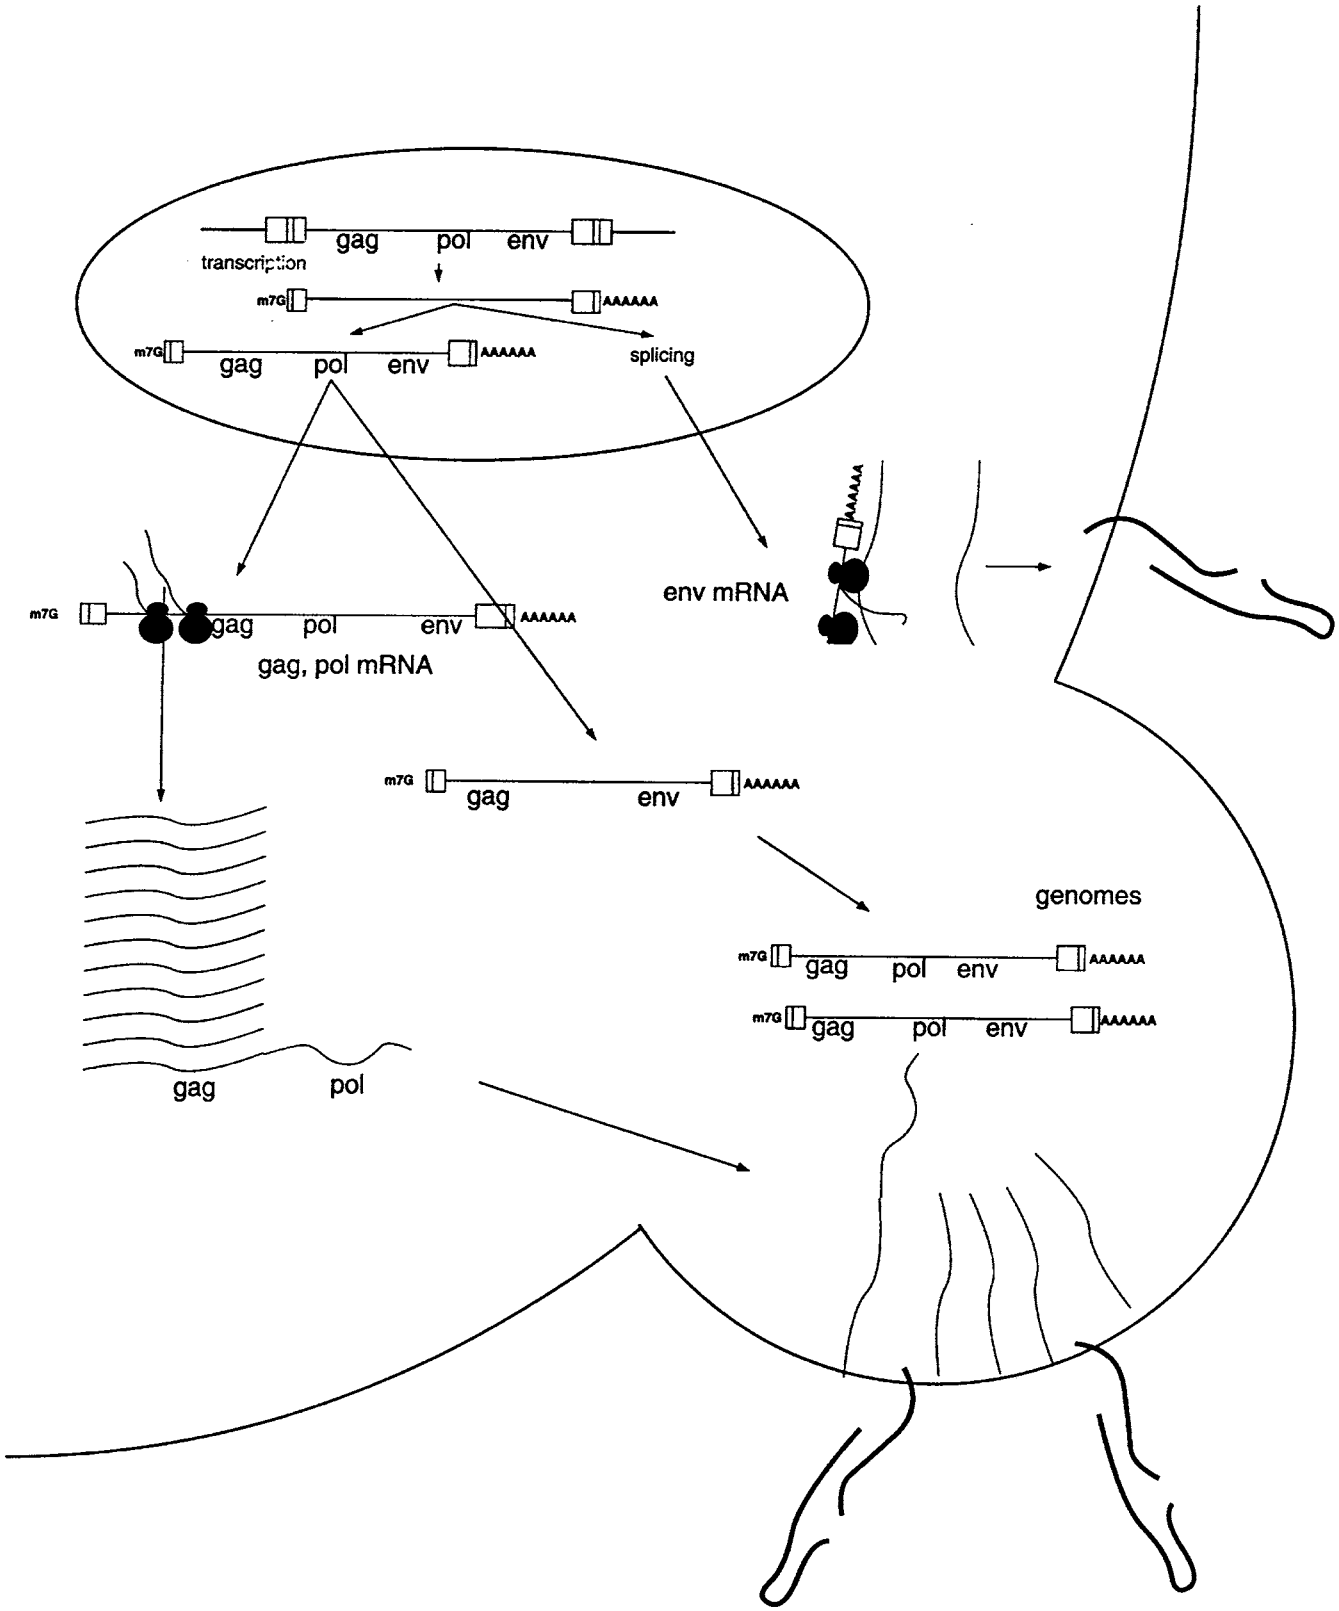

FIG. 4.5. The late stages of the retroviral life cycle. The integrated provirus is used as the template (top) for the expression of viral RNAs. A subset of the transcripts are spliced, and the unspliced and spliced mRNAs are exported to the cytoplasm. The unspliced RNA is used to make Gag and Gag-Pol proteins and also serves as the genome; spliced mRNA is used to make Env proteins. The proteins and RNA associate under the membrane to form the budding progeny virion. From (486) courtesy of Lippincott, Williams and Wilkins.

factor/CRE-binding protein (ATF/CREB), and binds to three cAMP response elements in the viral LTR. Tax thus sets up a positive feedback loop that results in high levels of viral transcripts. The Tat protein is unusual among transcriptional activators in that it binds to a structure in the 5′ end of nascent viral RNA (173, 174), rather than to DNA. Tat binds to a bulged hairpin structure, the TAR element, and recruits a pair of host proteins, cyclinT/cdk9, to the RNA. These proteins enhance the ability of RNA polymerase to elongate beyond the LTR and down the genome with high processivity, probably by phosphorylation of the C-terminal repeat domain (CTD) of the polymerase. Again, the result is a strong positive feedback loop that results in high levels of viral RNA.

RNA Processing

The full-length transcript of the retroviral genome is directed into several pathways. A portion of the transcripts is exported directly from the nucleus and serves as the genome to be packaged into the progeny virion particle, assembling either at the plasma membrane or in the cytoplasm. Another portion with identical structure is also exported and used for translation to form the Gag and Gag-Pol polyproteins. It is not yet clear if these two subsets are truly distinct, whether there can be interchange between the pools, or whether there is a single pool of such molecules used for both purposes. It has been proposed that the translated mRNAs are selectively packaged in cis (175). A third portion is spliced to yield subgenomic mRNAs. For the simple retroviruses, there is a single spliced mRNA encoding the Env glycoprotein. For the complex viruses, there can be multiple alternatively spliced mRNAs, encoding both Env and an array of auxiliary proteins (176,177).

The splicing and subsequent export from the nucleus of only a portion of an initially transcribed RNA is an extraordinary process; normally splicing goes to completion, and only then is the mRNA exported. The export of a precursor mRNA is prevented until splicing is complete. At least three aspects of the retroviral genome may promote the export of unspliced mRNAs. First, the splice sites of the viral RNA may have quite poor overall efficiency of utilization by the splicing machinery in the cell (178). Indeed, the sequences at the splice donor and acceptor regions are often poor matches to the consensus sequences for splice sites, and mutations that make the sites better matches increase splicing and are actually deleterious to virus replication (179,180). These mutations can be suppressed by secondary mutations that reduce splicing efficiency. The overall folding of the RNA may affect the efficiency of splicing, and thus sequences at some distance, as in the *gag* gene, may modulate splicing (181,182).

Secondly, studies of ASLV have identified specific sequences that act as negative regulators of splicing (NRS) through their interaction with host factors (183–186). These elements can be important for the expression of transduced genes in some viruses (187). Similar signals may exist in other viruses; mutations in the Gag region of MuLV can affect RNA processing in complex ways (188).

In addition, unspliced mRNAs contain cis-acting elements that promote the export of the RNA out of the nucleus, the so-called constitutive export elements (CTEs) (189). These sequences are located near the 3′ end of the genomic RNA of MPMV (190), between *env* and the LTR, and possibly in similar regions of ASLV (191). CTE function of the MuLVs may be present in the Gag region (192), or possibly in the R region of the LTR (193). The CTE is recognized by one or more host proteins that assemble a complex onto the RNA to mediate its export, though which proteins are most important is controversial (194–196). In the complex viruses, RNA export is regulated through complex interactions of both trans-acting proteins, the Rex or Rev gene products, and cis-acting sites, the RRE elements that promote RNA export and the CRS elements that prevent it (197–206). A key aspect of this process is the recruitment of Crm1, a cellular nuclear export factor, to the RNA. The Rev/RRE pathways of export are probably distinct from those used by the CTEs, because the two are differentially sensitive to a competitive block acting through Crm1 (207,208).

TRANSLATION AND PROTEIN PROCESSING

All retroviral genomes, at a minimum, contain open reading frames designated the *gag*, *pro*, *pol*, and *env* genes. These genes are expressed by complex mechanisms to form precursor proteins, which are then processed during and after virion assembly to form the mature, infectious virus particle. The expression of the various proteins as large precursors that are subsequently cleaved provides several advantages: it allows for many proteins to be made from one ORF; it ensures that the proteins are made at proper ratios; and it allows for many proteins to be targeted to the virion during assembly as a single entity. The *gag, pro*, and *pol* genes are expressed in a complex way from the full-length unspliced mRNA. The arrangement of these genes, and especially the way *pro* is expressed, are different in different viruses.

Gag Gene Expression

The *gag* gene is present at the 5′ proximal position on all retroviral genomes. A full-length mRNA, identical in sequence to the genomic RNA, is translated in the cytoplasm to form a Gag precursor protein, in the 50–80 kDa range. Translation begins with an AUG initiator codon and proceeds to a terminator codon at the 3′ end of the ORF. The viral RNA typically contains a relatively long 5′

untranslated region, and it has been uncertain whether ribosomes could scan from the 5′ cap to the start codon for Gag translation. These 5′ RNA sequences are predicted to contain stable secondary structures that would inhibit scanning. Furthermore, the long 5′ UTRs often contain AUG codons in contexts that are favorable for translation, that are not in frame with the *gag* ORF, and presumably would inhibit successful translation of Gag (209). Recent experiments suggest that for the MuLVs, an internal ribosome entry site (IRES) is present near the start of the *gag* ORF and is used to initiate translation in a cap-independent mechanism (210,211). Thus, at least in these viruses, ribosomes can bind directly near the *gag* gene and do not need to scan the mRNA. However, other viruses such as HIV-1, may not use such sequences (212).

The major Gag product is often modified by the addition of myristic acid, a relatively rare 14-carbon fatty acid, to the penultimate aminoterminal residue, a glycine (213). The addition is mediated by a myristyl CoA transferase that cotranslationally transfers myristate from a myristyl CoA donor to the amino group of the glycine residue, forming an amide bond. The fatty acid is important for the membrane localization and binding of the Gag precursor, increasing the hydrophobicity of the aminoterminal domain. Mutant Gags in which the glycine is altered are not modified, and these Gags do not associate with membrane properly and do not aggregate to form virions (214–216). It should be noted that although myristate is important, it is not sufficient for membrane targeting; hydrophobic residues in the MA domain are also required. Furthermore, basic residues further downstream in the MA of some viruses form a patch of positive charge that may interact with negatively charged phospholipids in the membrane.

An aminoterminal myristate is not found on the Gags of BIV, EIAV, visna, or ASLV. For the avian retroviruses, the aminoterminus is not myristylated but rather acetylated. The Gag protein of these viruses is apparently sufficiently hydrophobic to be targeted to the membrane without the fatty acid in avian cells, though, curiously, not in mammalian cells. Alteration of the avian Gag to allow its myristylation permits virion assembly in mammalian cells (217) and does not block its function in avian cells (218).

Pro Gene Expression

The relative position of the *pro* gene on retroviral genomes is always similar— in between *gag* and *pol*. However, the *pro* gene is expressed in very different ways in different viruses. Sometimes it is fused in frame onto the 3′ end of *gag*, sometimes it is fused to the 5′ end of *pol*, and sometimes it is present as a separate reading frame. These various patterns have led to considerable confusion in the literature; sometimes *pro* is considered a portion of *gag*, or sometimes of *pol*. Because of these different patterns of expression, it is best to consider this ORF as a separate gene.

The various arrangements of the *pro* gene and its mode of expression are as follows. For the alpharetroviruses, *gag* and *pro* are fused and expressed as a single protein; *pol* is in a different reading frame, and a frameshift is used to express the Gag-Pro-Pol polyprotein. For the beta-retroviruses and deltaretroviruses, *gag*, *pro*, and *pol* are all in different frames and successive frameshifts are used to express Gag-Pro and Gag-Pro-Pol polyproteins. For the gammaretroviruses and epsilonretroviruses, *gag* and a *pro-pol* fusion are in the same reading frame and separated by a stop codon, and translational readthrough is used to make Gag-Pro-Pol. For the lentiviruses, *gag* and a *pro-pol* fusion are in different reading frames, and frameshifting is used to make Gag-Pro-Pol. Finally, for the spumaviruses, *pro* is fused to *pol*, and the Pro-Pol protein is expressed without Gag, from a spliced mRNA. More about these varied mechanisms of expression is in the following section.

Pol Gene Expression

The *pol* gene encodes several proteins needed at lower levels for replication of the virus, including the reverse transcriptase and integrase enzymes. The *pol* ORF is not expressed as a separate protein in most retroviruses, but rather is expressed as a part of a larger Gag-Pro-Pol fusion protein. The Gag-Pro-Pol protein must be made at the correct abundance, in proportion to the amount of Gag protein, for efficient assembly of infectious virus; expression of only Gag-Pro-Pol does not result in virion assembly (219,220). The formation of this protein is mediated by either one of two mechanisms, depending on the virus.

Translational Readthrough

In the gammaretroviruses and epsilonretroviruses, the Gag and Pro-Pol ORFs are in the same reading frame, and are separated by a single UAG stop codon at the boundary between Gag and Pro-Pol. Translation of Gag-Pro-Pol in these viruses occurs by translational readthrough— that is, by suppression of termination— at the UAG stop codon (221). Most of the time translation of the RNA results simply in the formation of the Gag protein. But approximately 5–10% of the time, ribosomes translating the RNA do not terminate at the UAG codon, and instead utilize a normal aminoacyl tRNA, usually a glutamine tRNA, to insert an amino acid at the position of the stop codon. Translation then continues, in frame, through the entire long *pro-pol* ORF, resulting in formation of a long Gag-Pro-Pol precursor protein. The high-level suppression of termination is specified by a specific structure in the RNA immediately downstream of the UAG stop codon (222,223). The precise features of this structure that are required for suppression are not completely known, but

they include a purine-rich sequence immediately downstream of the stop codon, and a pseudoknot formed from the next 60 or so nucleotides (224–229). The structure may slow translation, and it may also in some other way alter the balance between termination, which requires binding of termination factors eRF-1 and eRF-3 by the ribosome, *vs*. incorporation of an amino acid, which requires misreading of the codon by an aminoacyl tRNA. No changes in the tRNA pool occur during infection (230). The signals in the RNA can operate to mediate suppression of both UAA and UGA termination codons as well (231).

Translational Frameshifting

In the alpharetroviruses and lentiviruses, the *gag* and *pol* ORFs lie in different reading frames, and the formation of the Gag-Pro-Pol fusion is mediated by a translational frameshift mechanism (232). Most of the time, translation again results in the simple formation of the Gag protein. But approximately 10% of the time, as the translation approaches a specific site near the end of the *gag* ORF, the ribosome slips back one nucleotide (a-1 frameshift) and proceeds onward in the new reading frame. The ribosome passes through the stop codon out of frame and so continues to synthesize protein using the codons of the *pol* ORF. As for readthrough, the determinants of frameshifting lie in the RNA sequence and structure near the site of the event (233–236). The requirements for frameshifting include a "slippery site", a string of homopolymeric bases where the frameshift occurs; these are oligo U or oligo A in different viruses. In addition, the frameshifting requires either a very large and near-perfect hairpin or stem-loop structure; or a large pseudoknot structure, similar to those used in readthrough, though apparently containing a distinctive bend at the junction of the two paired sequences (237–240). As for readthrough, the proper frameshifting efficiency is crucial for normal virus replication.

In the betaretroviruses (e.g. MMTV) and deltaretroviruses (e.g. BLV, HTLV-1), the *pro* gene is present as a separate ORF, in a different reading frame from that of *gag* or *pol*. Two successive frameshifts are utilized to make the long Gag-Pro-Pol fusion protein (241–243). Near the 3′ end of the *gag* ORF, ribosomes carry out a first (−1) frameshift and continue into the *pro* ORF; near the 3′ end of the *pro* ORF, they perform a second (−1) frameshift and continue on into the *pol* ORF. These two frameshifts occur at extremely high frequencies – as much as 30% of the time that the ribosome transits through each site – so that the overall frequency of formation of the Gag-Pro-Pol protein is perhaps 10% that of formation of Gag.

Separate Pol Expression

The spumaviruses are unique among the retroviruses in that the synthesis of the Pol protein is not mediated by the formation of a Gag-Pol fusion protein. Instead, a separate subgenomic spliced mRNA (244) is translated directly to form a separate Pro-Pol protein (245,246). This protein must be directed to the assembling virion by distinct domains rather than by the Gag portion of a Gag-Pol fusion.

Env Gene Expression

In all retroviruses the *env* gene is expressed from a distinct subgenomic mRNA. The *env* message is a singly spliced mRNA, in which a 5′ leader is joined to the coding region of *env*. Thus, the bulk of the *gag* and *pol* genes are removed as an intron from the mRNA. The resulting message is exported to the cytoplasm and translated from a conventional AUG initiator codon. In the alpharetroviruses, the AUG is actually the same one used for Gag translation; it lies in the leader, and the splicing brings this AUG and the first six codons into frame with the *env* coding region. The first translated amino acids constitute a hydrophobic signal peptide, and direct the nascent protein to the rough endoplasmic reticulum. The leader is removed by a cellular protease (the signal protease) in the ER, and the protein is heavily glycosylated by transfer of oligosaccharide from a dolichol carrier to asparagine residues on Env. These residues lie in the conventional Asn-X-Ser/Thr motifs recognized by the modification enzymes. Near the end of the cotranslational insertion of Env into the ER, a highly hydrophobic sequence acts as a stop transfer signal to anchor the protein in the membrane. The remaining C-terminal portion of the protein stays on the cytoplasmic side of the membrane.

Before the Env proteins are transported to the cell surface, they are folded and oligomerized in the ER. The formation of oligomers is required for stable expression of the protein, and is sensitive to overall conformation; many mutants of Env show defects in oligomerization (247). There is considerable controversy about the oligomeric state of the Env protein in different viruses, and at different times during their transport (248–252). The most studied envelope proteins (ASLV and HIV-1) may pass through dimeric or tetrameric intermediates, but the nature of these intermediates is not clear. Although some laboratories disagree (e.g. (253,250,254,255)), ultimately these envelopes probably form trimers in the mature virus (248,256). The folding of the protein is presumably catalyzed by chaperone proteins in the ER; and the formation of disulfide bonds between various pairs of cysteine residues is similarly catalyzed by disulfide interchange enzymes.

The Env protein is then exported to the Golgi, and cleaved by furin proteases to form the separate SU and TM subunits. This cleavage is essential for the normal function of the Env protein. The cleavage occurs at a dibasic pair of amino acids (257), and produces a hydrophobic N-terminus for the TM protein that is required to mediate fusion of the viral and host membranes during virus entry.

In the Golgi the sugar residues are modiÞed by the sequential removal of mannose residues and addition of N-acetyl glucosamine and other sugars to many of the oligosaccharide. O-linked glycosylation and sulfation of Env glycoproteins have also been documented (258,259). The pathway by which Env is transported to the cell surface is not fully understood, but presumably host vesicular transport systems are utilized. There is evidence that clathrin adaptor complexes interact with the cytoplasmic tail of Env, and direct its movement to the plasma membrane (260). The protein typically becomes a prominent cell surface protein on the infected cell.

In polarized epithelial cells, Env proteins are often restricted to the basolateral surface of the cell (261). This localization is mediated by a tyrosine-based motif, Yxxϕ, present in the cytoplasmic tail of Env (262,263) (x, any amino acid; ϕ, hydrophobic residue). Remarkably, this targetting of Env can redirect the budding of Gag proteins to this surface.

Other Viral Gene Products

The complex retroviruses express a number of small proteins with a range of functions. The proteins are translated from subgenomic mRNAs, usually resulting from multiple splicing events that join a 5′ LTR to a number of small exons encoding the protein. A brief summary of these gene products and their functions is given here (see (176,264,172,265,266) for in-depth reviews).

Deltaretroviruses:

- Tax: The Tax gene product is a positive regulator of transcription from the viral LTR. Tax functions in association with the activating transcription factor/CRE-binding protein (ATF/CREB) by binding to three cAMP response elements in the viral LTR. Tax also plays a role in transformation, perhaps through E2F-1 activation or through effects on the cell cycle.
- Rex: The Rex gene product facilitates the export of unspliced and singly-spliced viral mRNAs from the nucleus. Its action is probably similar to that of the lentiviral rev protein.

Epsilonretroviruses:

- Orf a: The Orf A product of the piscine retroviruses is a cyclin D homologue that functions as a cyclin in yeast (267). The function of the protein in virus replication or tumor formation is uncertain.
- Orfs b,c: The function of these Orfs is unknown.

Lentiviruses:

- Tat: The Tat protein is a potent transactivator of transcription from the viral LTR. The protein acts by binding to a hairpin structure, the TAR element, encoded in the R region of nascent viral RNA, and recruiting host factors cyclinT and Cdk9 to the RNA. Tat does not increase the rate of RNA polymerase II initiation, but seems to enhance its processivity or elongation, perhaps by phosphorylation of the CTD of pol II.
- Rev: The Rev protein mediates the export of the unspliced and singly-spliced viral RNAs from the nucleus, thus permitting the expression of the Gag, Pol, and Env gene products. Rev binds to the Rev-responsive element (RRE) present in the HIV-1 *env* gene and by interacting with the importin Crm1 acts to export the viral RNAs through the nuclear pore.
- Nef: The Nef protein is a multifunctional protein not essential for replication in some cells in culture, but important for replication *in vivo*. Nef-defective viruses do not induce high-level viremia in infected animals, and progression to disease is delayed or prevented (268). Nef downregulates the CD4 receptor from the cell surface, facilitating virus release, probably by bridging CD4 to adapter proteins (APs) (269). Nef also down-regulates MHC class I levels, thereby inhibiting the CTL-mediated lysis of HIV-1 infected cells. Finally, Nef may enhance virion assembly and release through unknown mechanisms.
- Vpr: The Vpr protein, as noted below, is packaged at high levels into virion particles through an interaction with the p6 domain of Gag (270,271). Vpr may facilitate the import of the preintegration complex into the nucleus in non-dividing cells. Vpr also causes a strong cell cycle arrest in the G2 stage of the cell cycle, perhaps through an indirect inhibition of Cdc25 phosphatase activity.
- Vif: The Vif protein is expressed at high levels in the cytoplasm, and is packaged into virion particles of both homologous and heterologous viruses. Vif enhances infectivity of virus produced in certain non-permissive cells, perhaps by blocking the action of a cell-speciÞc inhibitor.
- Vpu: The Vpu gene product, found only in HIV-1, is a membrane protein that enhances virion production and also mediates the degradation of CD4 by the ubiquitin-conjugating pathway (272, 273).

Spumaviruses:

- Tas: The Tas (or Bel1) protein is a transactivator of transcription from the viral LTR, acting at sequences near the 5′ end of the genome. Its mechanism of action may be similar to that of the lentiviral Tat protein.
- Bet, Bel2, and Bel3: The functions of the *bet* (and the overlapping *bel2*) and the *bel3* genes are unknown,

though there is some evidence that the Bel3 protein may be a negative regulator of replication.

VIRION ASSEMBLY

As the Gag, Gag-Pro-Pol, and Env proteins are synthesized, they come together to form progeny virions (for reviews, see (274–278); see Fig. 4.6 for a schematic view of the process). The assembly of the retrovirus particle is driven primarily by the Gag precursor protein. Gag is required for the formation of a virion, and indeed is sufficient on its own to mediate the assembly and release of a "bald" particle—lacking infectivity and the "hair" of the Env protein. The Gag protein that is responsible for assembly is the uncleaved Gag precursor. This form of the protein is thus targeted for assembly and export—the "way out" of the cell. Once the Gag proteins are processed, changes in virion structure can occur to promote entry—the "way in" to the next cell.

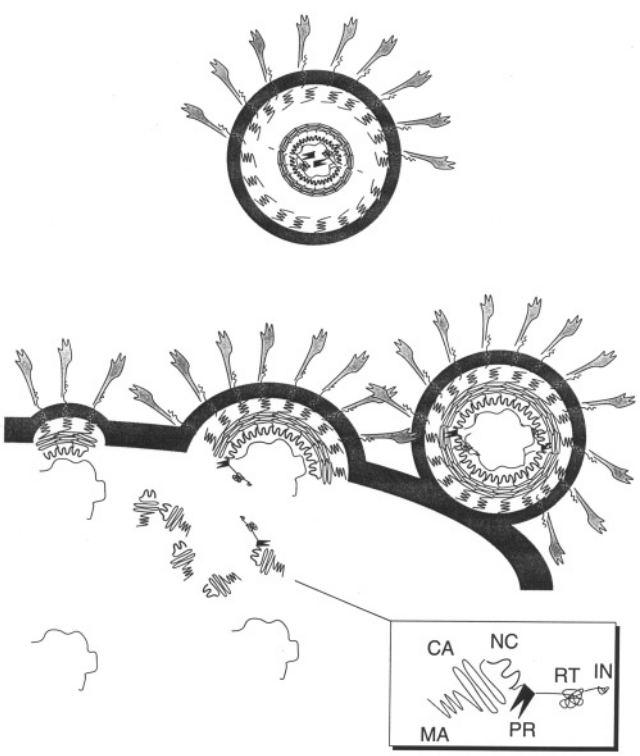

FIG. 4.6. A schematic diagram of the process of virion assembly. The Gag precursor, containing the MA, CA, and NC domains, and the Gag-Pol precursor, containing the MA, CA, NC, PR, RT, and IN domains (see blowup), are transported to the inner leaflet of the plasma membrane. The proteins bind the viral genomic RNA (thin line). Curvature is induced in the membrane as the virion grows, and the roughly spherical particle is finally pinched off and released from the cell. The virion proteins are reorganized upon processing by the viral protease to form the mature, infectious virus (top). From (486) courtesy of Lippincott, Williams and Wilkins.

Gag and Virion Assembly

For most retroviruses, the expression of the Gag precursor is sufficient to mediate virion assembly and release, earning the protein the name of the "particle making machine." (An exception to this rule is the foamy viruses, which also require the presence of the Env glycoprotein for efficient budding (279).) Because of its central role in virion assembly, Gag proteins have been subjected to intense mutational analyses to define the domains required for various steps in the process (280,274). Surprisingly small portions of Gag, containing only a few critical regions, can still assemble virions (281). Three domains seem to be crucial: a membrane-binding (M) domain; an interaction (I) domain; and a late assembly (L) domain. It is important to remember that the form of the Gag protein that is mediating assembly is the precursor; thus, the assembly domains need not lie neatly within any of the cleavage products that form later and can span cleavage sites.

The M Domain

The M domain, or membrane-binding domain, ranging from 30 to 90 residues in length, is located at the amino terminus of Gag, in MA. Mutations affecting this domain abolish assembly, but M mutants retain their ability to interact with other Gags and can be rescued into particles by the coexpression of a wild-type protein. The region seems to contain both hydrophobic and basic residues that are needed for proper interaction with lipid and with the acidic moieties of phospholipids. Structural information for the isolated M domain is consistent with this role (282).

For many retroviruses, myristylation of Gag, along with specific residues in MA, is required for membrane binding. This interaction with membrane, in turn, is important for virion assembly of the C-type viruses, and for their proper subsequent Gag processing (283). Mutational studies have led to the notion of a "myristyl switch," in which the myristic acid is exposed to mediate plasma membrane binding during virion assembly, but then can be sequestered in the compact globular core of MA after Gag processing (284–287).

The I Domain

The I or interaction domain is defined as a major region of Gag-Gag interaction, largely contained in the NC region. Although the major I domain has been suggested to lie in NC, some analyses have suggested that the C-terminal half of CA and NC are equally important for normal assembly (288,289). Mutations in the I domain block or reduce assembly, and those particles produced by these mutants have aberrantly low density, indicating

fewer and poorly packed Gag proteins. The key feature of the I domains is not the zinc binding residues of the cys-his box, but rather basic residues ßanking the boxes (290). The assembly function could involve the binding of RNAÑ either the genomic RNA or other RNAsÑ but it is not completely clear that RNA is necessary. The assembly functions of NC can be replaced by foreign proteins, and the key activity seems to be the formation of protein-protein contacts (291). Mutations in this region can also affect particle size as well as yield (292). Recently the I domain of HIV-1 has been proposed to be involved in the membrane association of the Gag precursor (293), but other studies suggest that NC is not required (294).

The L Domain

The third domain is the L or late assembly domain (295,296). Mutants affected in this function fail to produce and release particles efÞciently, and though the mutant Gag proteins form spherical structures, they accumulate under the membrane and do not progress normally. The buds remain tethered to the cell surface by a membrane stalk, suggesting that the function of the L domain is to mediate virus-cell separation. Recently, the domain has been shown to also be important in determining the size of the virion; the structures formed by L domain mutants are often large and heterogeneous in diameter (297). L domains lie at different locations in the Gag proteins of different viruses. In ASLV, MPMV, and the MuLVs, the L domain lies in the amino terminal third of the protein and its critical residues are PPPY. In HIV-1, the domain lies in p6, at the C terminus, and instead contains the motif PTAP. Remarkably, many of these L domain motifs are interchangeable among the various retroviruses, and show a substantial position independence for their function (298). It is likely that these motifs represent the binding site for some protein important for the late stages of budding, and indeed the PPPY motif has been identiÞed as the recognition sequence for the WW domain family of proteins, including the Yes-associated protein YAP, NEDD45, and many others (299). Recently the late domain of the EIAV Gag has been shown to associate with a cellular adapter protein, AP-2, which could mediate transport or localization steps (300). Which of these or other proteins that may interact with the L domain are most crucial for virion release remains uncertain. A curious additional link between two of these proteins is provided by the observation that both HIV-1 p6 and the MuLV p12 proteins are modiÞed by the addition of ubiquitin at low levels (301). It is possible that a PPPY-binding host protein is responsible for this modiÞcation.

Virion Assembly in Vitro

Recently Gag proteins and fragments of Gag have been shown competent to assemble *in vitro* to form various structures that more or less closely resemble virion cores (302Ð305). The CA-NC portions of ASLV and HIV-1 expressed as recombinant proteins can assemble to form particles or long hollow tubes; the formation of these structures is dramatically enhanced by addition of RNA, and the length of the tubes is determined by the length of the RNA (306). Larger Gag fragments that include more aminoterminal regions can assemble into spherical particles (307), and this assembly is stimulated by RNA and host cell extracts (308). Although HIV-1 Gag interacts with cyclophilin A *in vitro* and *in vivo*, addition of cyclophilin A to assembly reactions has only little effect (309). HIV-1 Gag CA-NC fragments can assemble into conical structures (2), with a pitch that falls into discrete values. Image reconstruction of these cones has allowed the formation of a model for the packing of the protein into hexagonal arrays. Virus-like particles have also been formed with the Gag proteins of MPMV in cell-free protein synthesis systems.

Incorporation of Other Proteins into Assembling Virions

During assembly, other proteins are incorporated into the particle by contacts to Gag; these include Gag-Pol, Env, and auxiliary proteins encoded by the complex viruses. The Gag-Pol precursor is thought to be incorporated into the assembling bud by virtue of the Gag protein present at the aminoterminus. Gag to Gag-Pol contacts can in some cases lead to the incorporation of mutants of Gag-Pol that do not retain the myristate modiÞcation to the aminoterminus (310), suggesting that the interaction is quite strong. Gag fusions to foreign proteins can be similarly incorporated into particles formed by Gag (311); this process can even be used to target antiviral proteins into virions. Consistent with this notion, many mutations that block assembly of Gag, when tested in the context of Gag-Pol, are found have similar effects on the incorporation of Gag-Pol (312,313). However, some mutations in HIV-1 Gag have also been identiÞed that speciÞcally affect the incorporation of Gag-Pol, suggesting that Gag-Pol utilizes some distinctive contacts not important for Gag-Gag interactions (314). Further, in the spumaviruses, Pol is incorporated without an appended Gag region, suggesting that distinct interactions must be utilized for its incorporation (245).

The Env protein is thought to be concentrated at the sites of budding and incorporated into the virions by virtue of contacts between the cytoplasmic tail of Env and the aminoterminal portion of Gag. These interactions have been difÞcult to document directly, though there is some biochemical evidence (315) and crosslinking studies (316) in support of these contacts. Genetics has provided good evidence for this interaction. Selected mutants of MA show defects in Env incorporation (317Ð319), and some mutants of the cytoplasmic tail of TM are not efÞciently

incorporated (320). In addition, Env proteins that are speciÞcally directed to the basolateral surface of polarized epithelial cells can redirect the sites of budding of Gag from a non-speciÞc assembly on both membranes to the exclusive assembly at basolateral membranes (262,263), and can similarly redirect Gag in neurons (321). Finally, mutants and revertants of these mutants with second-site suppressors in the binding partner have provided strong evidence for these interactions (322,319). However, it should be noted that the envelope proteins of viruses very distant from retroviruses, including VSV and inßuenza, can be functionally incorporated into retrovirus particles without any obvious sequence similarity in their cytoplasmic tails. Furthermore, truncating the tail of ASLV Env does not prevent its incorporation or function (323). Thus, there may be mechanisms to direct Env proteins to assembling virions without these speciÞc contacts to GagÑ a default pathway, or a pathway using other interactions. Indeed, other distinct parts of Gag, including the p6 region of HIV-1 Gag, have been implicated in Env incorporation (324).

The HIV-1 protein Vpr is efÞciently incorporated into assembling virions at very high levels, approaching equimolarity with Gag. This incorporation requires the presence of the p6 domain of Gag (271) and may be mediated by a direct interaction (270). The binding can be used to direct foreign proteins into the particle; a fusion between Vpr and a foreign protein will be targeted to virions. Furthermore, Vpr can be used to direct separately expressed versions of RT or IN to particles in a functional form, to complement mutations in the RT or IN domains of the Gag-Pol fusion (325).

Host Proteins in the Virion

A number of host proteins have been shown to be present inside the virion particle; in most cases the signiÞcance of the protein is unknown. Prominent among the virion-associated factors are a number of cytoskeletal proteins. These include actin (326Ð329), and various members of the Ezrin-Radixin-Moesin (ERM) family, speciÞcally including ezrin, moesin, and coÞlin (327). The Gag, and especially the nucleocapsid protein of HIV-1 have been shown to directly bind to actin (330,331,329), perhaps offering a mechanism for its incorportion into the particle. A complication in analyzing virion-associated proteins is that virion preparations tend to be contaminated with substantial amounts of microvesicles, entities released by cells that exhibit a density and size very similar to that of virions, and containing an array of host proteins (332).

The virions of HIV-1 contain substantial levels of cyclophilin A, a protein proline isomerase of uncertain function but implicated in protein folding and signal transduction (333Ð335). The incorporation of cyclophilin A is not required for assembly, but is important for efÞcient entry of HIV-1 into newly infected cells, before the process of reverse transcription is initiated (336). Its exact role is uncertain. Several other proteins have also been found in virions: a translational elongation factor, eIF-1a (337), and a protein known as H03 (338), with similarity to histytdyl tRNA synthetase, are additional examples.

RNA PACKAGING

The RNA genome is incorporated by virtue of interactions between speciÞc RNA sequences near the 5′ end of the genome, termed the packaging or Psi sequences, and speciÞc residues in the NC domain of Gag (see (339,340)). Both partners in this interaction have been intensively studied.

Gag Sequences Important for RNA Packaging

The Gag precursor is probably the form of the protein that is responsible for packaging the RNA (341), and the NC portion of the precursor plays the largest role. Mutations affecting the NC protein often reduce the incorporation of the genomic RNA into the virion particle (see (340) for review). The most crucial sequences are the Cys-His boxes, short sequence blocks resembling zinc Þngers and containing the motif Cys-X2-Cys-X4-His-X4-Cys; but basic residues elsewhere in the NC molecule are also important (342,343). The NC protein of various viruses contains either one or two copies of the Cys-His box. When two copies are present, they are not equivalent or interchangeable, suggesting that they mediate distinct interactions with RNA (344). Some viral cores can cross-package heterologous viral RNAs, suggesting good binding to the heterologous Psi region, and sometimes there is a strong preference for the homologous RNA. Exchanging the NC domains between viruses can sometimes transfer the preferential selectivity of a Gag protein for its cognate RNA, though the speciÞcity of these hybrid Gags is often poor, and in some cases other sequences in Gag can determine the preference for RNA packaging by chimeric Gags.

RNA Sequences Important for Packaging

The packaging or Psi regions on the viral RNA genome that are recognized for incorporation are quite distinct in nucleic acid sequence among the various viruses. The key Psi regions lie near the 5′ end of the RNA, generally between the LTR and Gag. However, other regions of the genome can affect RNA packaging, including sequences upstream in R and in U5, downstream in Gag coding regions, and even near the 3′ end of the genome. In the case of ASLV, a region of 270 nt is necessary and sufÞcient

to mediate the packaging of a foreign RNA (345–347). In the case of the MuLVs, sequences that are at least partially sufficient to mediate packaging have been similarly identified (348). These Psi regions are relatively autonomous; Psi can be moved to ectopic positions in the genome with at least some retention of function (349).

The various Psi sequences have been predicted or shown to form a number of stem-loops, often containing GACG in the loops. Reversion analysis of mutants with alterations in these loops confirms the importance of the stem-loop structure (350). Mutational studies show that several such loops may incrementally contribute to the efficiency of packaging of the RNA, though one or two are often found to be most important (351,352). Recently one of the stem-loop structures of the HIV-1 Psi was replaced by a completely foreign sequence that was selected on the basis of its binding activity with NC; the resulting RNA was efficiently packaged and utilized for replication, strongly suggesting that binding to Gag is the key function of Psi (353). A structure of the HIV-1 NC bound to one such stem-loop has been resolved by NMR, revealing specific contacts between both hydrophobic and basic residues of NC and nucleotides in the stem-loop of the RNA (354).

Dimerization of the Viral Genome

Mature virions contain a dimeric RNA that is highly condensed into a stable, compactly folded structure referred to as the 70S dimer on the basis of its sedimentation rate. Packaging of RNA is associated with the dimerization of the RNA, but it is not completely clear whether the genome is present as a dimer before it is incorporated into virions or is incorporated as a monomer and then dimerized after its incorporation. However, some ASLV mutants suggest that monomeric RNA can be packaged under some circumstances (355), implying that dimerization may follow packaging. There are specific sequences in the RNA, termed dimerization or dimer linkage sequences (DLS), that are required for RNA dimerization *in vitro*, and for the formation of the dimeric virion RNA *in vivo*. These DLS structures are in close proximity or even intermingled with sequences required for packaging of the RNA, often making it difficult to determine their separate contributions to these processes. The dimerization of viral RNAs can be induced *in vitro*, and is stimulated by addition of NC or the Gag precursor. However, it is uncertain to what extent these reactions reflect dimerization *in vivo*.

The viral RNA in newly budded virions is present as an unstable dimer, dissociated by heat at relatively low temperatures, and becomes condensed to a more stable dimer during virion maturation (356). This condensation requires the proteolytic processing of Gag (357) and may be mediated by the free NC upon its release from the precursor. A model for the process of dimerization, the "kissing loop" model, suggests that duplex formation between two RNAs is initiated between loops on the two RNAs and propagates outward through the stems to form a more stable duplex. It is possible, but by no means certain, that such changes in the duplex regions could account for the change in thermal stability upon maturation.

Many cells contain vast arrays of endogenous proviruses and retrovirus-like elements, a subset of which can be expressed constitutively or under various conditions of stress to produce large amounts of genomic RNA. If such a cell is infected by an exogenous virus or has been engineered by expression constructs to produce virions, the particles will incorporate the endogenous RNAs along with the viral RNA (358,359). The endogenous retroviral RNAs, notably the VL30 RNAs of rodents, contain highly efficient Psi sequences (360,361), presumably because they were selected to compete with the homologous genomes of exogenous viruses for packaging.

Virions also contain a number of host RNAs of uncertain significance. There are substantial levels of 7S RNA, a low-molecular weight RNA thought to function in host RNA splicing (362). In addition, there are low levels of host mRNA. Particles released without efficient packaging of the viral genome (as are produced by Psi-mutant genomes) may carry enhanced levels of host RNAs, and various mutants with alterations in NC can show selective enhancement of both endogenous viral and host RNAs (360). A variant avian leukosis virus, SE21Q1b, packages unusually high levels of host RNA (363,364), and is capable of transducing these host sequences into new cells by reverse transcription (365). This phenotype of high-efficiency transduction is associated with an unusually high level of proviral expression and particle production rather than any specific alteration in a viral protein (366).

tRNA Primer Placement

A very small subset of these tRNAs—two per virion—are annealed to the primer binding site (pbs), an 18-nt sequence near the 5′ end of the genome with perfect complementarity to the 3′ sequences of a specific primer tRNA. The pbs sequences are, as one would expect, essential for normal reverse transcription of the virus (367). The sequence of the pbs can determine the primer tRNA that is utilized (368), but changes in the pbs tend to revert back to the wild-type (369), suggesting that alternate tRNAs do not function well. An interesting aspect of reverse transcription provides for an efficient mechanism for this reversion: the use of the original tRNA even once during replication will convert the pbs back to the original sequence, because the tRNA itself is the template for the DNA copy of the pbs. Other sequence blocks of the tRNA are also paired with complementary sequences in R and U5 to form a large, complex structure required for proper tRNA primer placement and utilization (370–374). These other sequences are presumably responsible for the selectivity for the natural tRNA primer. In the

alpharetroviruses, *pol* gene products are required to mediate the placement of the tRNA on the genome; but in the gammaretroviruses, *pol* is not required (375). The Gag precursor, and especially the NC domain, is thought to play a major role in promoting the annealing of the tRNA to the genome. While NC can promote annealing of complementary RNAs and DNAs *in vitro*, its role and the mechanism by which it may act *in vivo* remain uncertain.

PROTEIN PROCESSING AND VIRION MATURATION

As retrovirions are budded from the cell surface, the Gag and Gag-Pro-Pol precursor proteins are proteolytically cleaved to release the smaller proteins present in the infectious virions (for review, see (376)). The cleavage of Gag and Gag-Pro-Pol is mediated by the viral protease PR, which is expressed either in Gag, Gag-Pol, or Gag-Pro-Pol fusion proteins. Thus, PR is responsible for cleaving itself out of a precursor protein, and then making a number of other cleavages in these proteins.

Activation of the Protease

The processing of Gag and Gag-Pro-Pol precursors is intimately linked to assembly and budding, and is controlled so that the precursors are not cleaved until they are assembled. It is not certain how PR is regulated during assembly to begin cleaving its substrates. The structure of PR has revealed that the active enzyme is a homodimer (see below), and thus its activation could be promoted by dimerization of the Gag or Gag-Pro-Pol precursor associated with assembly. As the virions form, one could imagine the high concentrations of the protein generating an active PR that would begin to cleave Gag and Gag-Pro-Pol, and would release the mature PR dimer as well. However, for the betaretroviruses like MPMV, this mechanism cannot explain the delay in processing. For these viruses, assembly occurs in the cytoplasm and should result in the establishment of a high concentration of Gag-Pro-Pol at that time. Yet cleavage does not begin in the cytoplasm, but rather is restrained until budding and export of the preformed virion particle. Thus, other unknown mechanisms, perhaps coupled to membrane association, must be responsible. Similar conclusions were reached from analysis of IAP virions, in which assembly in various intracellular locations did not result in processing; membrane association was required (377).

Various domains of Gag have been suggested to inhibit PR (378), and conformational changes could relieve this inhibition. In the alpharetroviruses, a cleavage at the NC-PR boundary is required to release active PR, so activating this cleavage could serve as a trigger (379). Similar cleavages at the p6*-PR boundary are important for full activation of the HIV-1 PR (380). Another possibility is the activation of the PR by a drop in the pH associated with virion release. It should be noted that the overexpression of PR in many artificial settings, both in bacteria and in animal cells, as a Gag-PR fusion or alone, can result in formation of highly active enzyme (381). The high level expression of PR is often toxic for cells, presumably due to its inappropriate action on many host proteins.

Protease Structure and Function

The retroviral proteases are aspartyl proteases with clear sequence similarity to members of the cellular family of aspartyl proteases (382–384). The three dimensional structure of many proteases, including those from ASLV, HIV-1, HIV-2, SIV, FIV, and EIAV, have been determined by X-ray crystallography (385–392). The viral enzymes are small, typically containing about 100 amino acids, and are homodimers as isolated from virions. Each subunit contributes to the active site a single aspartate residue, lying in a loop near the center of the molecule. There is a long cleft at the interface between the subunits where the substrate lies; there are pockets to interact with each of the side chains of the substrate, conferring specificity to the enzyme. Each subunit has a flap consisting of an antiparallel sheet with a b-turn that covers the cleft, and this flap moves out of the way to permit the binding of the substrate into the active site.

Retroviral proteases have a complex specificity for substrate peptides (393). The enzyme makes contact with approximately seven or eight side chains on the substrate, and thus can select its cleavage sites on the basis of at least these amino acids. The cleavage sites tend to be within hydrophobic sequences, and yet must lie in accessible and extended conformations. Some analyses of the various sites in Gag and Gag-Pol that are recognized by PR suggest that either one of two sequence motifs constitute a consensus site: one set has an aromatic residue or proline flanking the cleavage site, and the other set has aliphatic residues at these positions. Mutational analyses have allowed further definition of the residues on PR that make specific contacts to the substrate.

Protease Inhibitors

Studies of mutant viruses lacking PR demonstrated that the protease is essential for virus replication. Viruses lacking a functional PR can still express Gag and Gag-Pol precursors, and can mediate the assembly and release of immature virion particles. Thus, PR is not required for the process of virion assembly *per se*. However, these particles are non-infectious, and are blocked at an early step prior to the initiation of reverse transcription (394–396). Because of its essential role in virus infectivity, PR was appreciated early in the course of the AIDS epidemic as an attractive target for antiviral therapy. A number of molecules have

been generated that can bind and inhibit PR, including peptide mimetics with uncleavable, non-sessile bonds at the cleavage site (397,398). Some are transition state analogues, and may have inhibition constants (Ki) in the nanomolar or subnanomolar range. These inhibitors have been extremely effective antiviral agents, and because they target a distinct enzyme and distinct step in the life cycle from the RT inhibitors, they have been particularly effective in combination with earlier drugs targeted at RT. The combination of three drugs that include a protease inhibitor is now a standard method of treatment for AIDS, and such highly active antiretroviral therapy (HAART) can keep virus loads below detectable levels in some patients for many years. Ultimately, however, point mutations in PR that confer resistance to the drugs can arise (399), allowing some virus replication in spite of therapy.

Processing of the Gag Precursor

During and after release from the cell, the Gag precursor is cleaved by the protease into a series of products present at equimolar levels in the virion. The number and size of the products vary considerably among the various viruses; the spumaretroviral Gag is exceptional in undergoing the fewest cleavages. Although diverse, these products of most of the retroviruses share many features in common.

The Matrix Protein, MA

Beginning at the amino terminus, most Gags are processed to form a membrane-associated or matrix protein termed MA. The MA protein is thought to remain bound to the inner face of the membrane as a peripheral membrane protein, and can be crosslinked to lipid. MA may make contacts with the cytoplasmic tail of the envelope protein. When the precursor Gag is myristylated at the amino terminus, the corresponding MA protein retains that myristate and so is presumably bound tightly into the membrane. The compact structure of the MPMV MA protein has been elucidated by NMR (400,401). The MA proteins of HIV-1 and SIV have been shown to form trimers in crystallization studies (402,403), and can contribute to the ability of a larger Gag precursor to form trimers in solution (404). The protein can form extended sheets of trimers, with a large opening in the network. If similar structures were to form in a sphere, the surface could have openings into which the envelope tail may Þt.

The Capsid Protein, CA

Gag proteins are cleaved to generate a large product serving as the major capsid protein, CA, in the virion core. The CA protein is relatively well conserved among Gags, and contains the only highly conserved motif among Gags, the so-called Major Homology Region (MHR). The function of this motif remains uncertain; although mutations in the region affect virion assembly in some viruses (405Ð407), it is not absolutely required for this process, since the entire CA domain of ASLV can be deleted without blocking assembly. CA is thought to form the shell of the condensed inner core of the mature virus, and thus makes either a spherical, cylindrical, or conical structure, depending on the virion morphology. The protein has proved difÞcult to crystallize, and the structure of the complete protein is uncertain (408), but the structures of both the N-terminal and C-terminal fragments of the HIV-1 CA have been determined (409,410). Very recently the analogous structures of the RSV capsid (411), and of the EIAV CA protein (412) have been determined and used to model a structure of the virion core. The CA protein can form dimers in solution, and recombinant proteins containing CA, or CA plus NC, can assemble to form higher-order structures consisting of either tubes, spheres, and in the case of HIV-1, cones (2). CA has also been studied after tethering sheets of the protein to membrane (413). Image reconstruction of electron micrographs, coupled to the subdomain structures, have led to models for the packing of CA to form these large assemblies. The major CA-CA contacts must form after processing during the condensation of the virion core, and may be very different from any contacts that exist in the immature virion particle (414).

The Nucleocapsid Protein, NC

All Gag proteins except for those of the spumaviruses are cleaved to produce a nucleocapsid protein, NC, located near the carboxyterminus of the precursor. NC proteins are small, highly basic proteins containing one or two copies of the Cys-His motif, Cys-X2-Cys-X4-His-X4-Cys. These sequences bind a single Zn++ ion avidly, and fold around the ion into a characteristic structure that is smaller and rather different from the better-known zinc Þnger structure. The structures of NC proteins in solution have been studied by NMR, revealing a tightly folded knuckle with disordered ßanking sequences (415,416). The interaction with zinc results in the incorporation of substantial levels of Zn++ into all retrovirus virion particles (417).

The NC protein in virions is closely associated with the viral RNA, probably coating the entire RNA molecule; the stoichiometry of binding is such that each NC molecule can bind to about 6 nucleotides of RNA. NC proteins bind non-speciÞcally to heteropolymeric single-stranded nucleic acid with moderate afÞnity (418). However, NCs also exhibit speciÞcity. Tests of binding to nucleic acids of deÞned sequence have shown that NCs bind poorly to poly(A), and most tightly to nucleic acids containing GT dinucleotides, especially alternating (GT)n polymers (419). In addition, NC has been shown to exhibit sequence-speciÞc binding activity *in vitro* for nucleic acids

containing the Psi region, required for packaging of the viral RNA (420,421). The interaction can also be assayed in reconstructed systems in yeast via the so-called three-hybrid method (422,423). This binding presumably reßects at least some aspect of its role in packaging the genome. A speciÞc complex of the HIV-1 NC with a stem-loop derived from Psi has been studied by NMR, and the resulting structure shows a number of speciÞc contacts between hydrophobic residues of NC and bases in the four-nucleotide loop; and between basic residues and speciÞc phosphates in the stem and loop (354).

NC proteins change the base-pairing properties of nucleic acids, and thus can have profound effects on the kinetics and thermodynamics of annealing (424,425). Under various conditions *in vitro*, NC can stimulate the dimerization of RNAs, and duplex formation between tRNA and its complementary sequences at the primer binding site (426). Thus, NC can help promote primer tRNA placement during virion assembly (427). NC can also help melt out secondary structures, and may facilitate the movement of RT along the template during reverse transcription (428). In addition, it is clear that NC can bind to double-stranded nucleic acid, and thus is probably retained on the viral DNA after its synthesis by reverse transcriptase. NC mutants have been found that affect the course of DNA synthesis or DNA stability during the early stages of virus infection, suggesting a role in the processing of the DNA and protection of DNA from degradation (429,430). Finally, NC has been shown to promote the concerted integration of the two termini of the viral DNA into a target sequence (see above; (431)).

An important class of inhibitors of virus infectivity and replication that act by targeting the NC protein have been identiÞed (432,433). These compounds, disulÞde-substituted benzamides (DIBAs), eject the zinc ion from NC and cross-link the cysteines via disulÞde bonds. Virions treated with these compounds are potently inactivated without disrupting the virion structure, and the course of virion assembly in infected cells is similarly blocked (434–437). Drug-resistant variants are not readily recovered.

Other Gag Products

Some retroviral Gag proteins, including those of the alpharetroviruses, betaretroviruses, and gammaretroviruses, contain one or more poorly conserved domains of 10–24 kDa lying in between MA and CA. The functions of these proteins is unclear. The ASLV p2 protein, the MuLV p12 protein, and the MPMV p24 protein contain a PPPY motif that plays an important role in late stages of virion assembly (see above). The MuLV p12 protein has also been shown to play a role in the early stages of infection (312,438).

In the lentiviruses, a p6 domain is present at the carboxyterminus. The role of p6 is unclear, though it contains the late or L domain and thus may be important in virion release; it also is required to mediate the incorporation of Vpr into virion particles, perhaps by providing a direct docking site. Proteins can be targeted to virions by generating Vpr-X fusions, which are incorporated into lentiviral virions in a p6-dependent manner.

Processing of the Gag-Pro-Pol Precursor

At the same time that the Gag precursors are cleaved during virion maturation, the Pro and Pol region of the Gag-Pro-Pol precursor is also cleaved, giving rise to the PR, RT, and IN products. The Pro and Pol-containing precursors of different viruses are cleaved in diverse patterns (Fig. 4.7). In the gammaretroviruses, the Pol region is processed by complete digestion to form PR, RT, and IN (439,440). In the alpharetroviruses, the Pol region is cleaved to produce a heterodimeric RT with a larger β subunit and a smaller α subunit. The larger β subunit contains both RT and IN domains. It is not clear whether the IN domain in the context of this subunit performs an important function, although it is responsible for a weak nuclease activity associated with RT (441). A portion of the Pol precursor undergoes an additional cleavage to produce the α subunit of RT, an amino-terminal fragment of the β subunit, and the separate IN protein. In the lentiviruses, Pol is processed to give rise to PR, a heterodimeric RT, and IN. However, the RT of these viruses is not identical to the heterodimeric RT of the alpharetroviruses. Here the IN domain is fully removed from RT. One RT subunit remains intact (for HIV-1, this is the p66 subunit), and the other subunit undergoes an additional cleavage to remove a carboxyterminal domain (to form the p51 subunit). The functional signiÞcance of the different subunit structures of these various RTs is unclear, since they all perform a very similar set of reactions during virus replication. The processing of Pol precursors may be associated with the activation of the DNA polymerase of RT. In the alpharetroviruses, the immature Gag-Pol protein has very low DNA polymerase activity, and its maturation results in a large increase in activity (442,443). However, the immature Gag-Pol protein of MuLV and HIV-1 has high DNA polymerase activity, and there is only a very modest increase upon maturation (394).

The Gag-Pro-Pol precursor of the betaretroviruses and the non-primate lentiviruses is also processed to produce the dUTPase protein, DU. In the betaretroviruses, the *pro* ORF encodes both DU and PR; in the non-primate lentiviruses the enzyme is encoded in the *pol* ORF, and DU lies in between RT and IN in the polyprotein. This enzyme acts to reduce the levels of dUTP that could otherwise be incorporated into viral DNA. Mutants of FIV lacking the function indeed show increased rates of mutation during replication (444), and similar mutants of CAEV tend to accumulate G-to-A substitution mutations (445) presumably due to incorporation of dU residues that

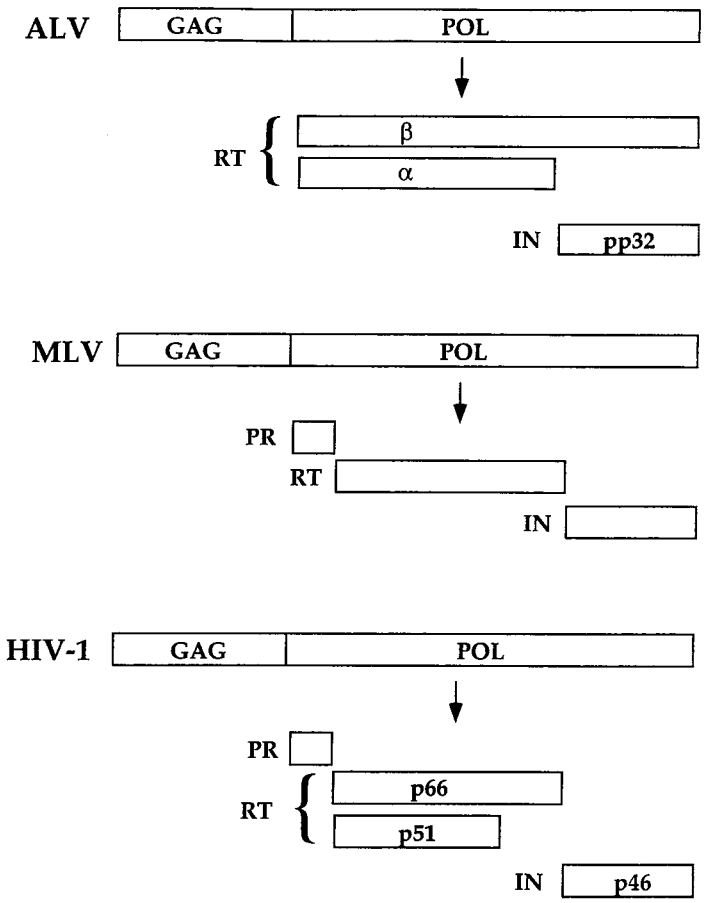

FIG. 4.7. Cleavage patterns during the processing of the Gag-Pol fusion proteins of various retroviruses. The structure of the mature cleavage products found in the virion particles are shown aligned with their location in the precursor. From (486) courtesy of Lippincott, Williams and Wilkins.

are subsequently read as dT. The FIV enzyme has been crystalized, and the structure of the protein has been determined by X-ray diffraction (446).

Processing of the Env Precursor

The major proteolytic cleavage of the Env protein to form the SU and TM subunits is performed during its transport through the ER and golgi by host proteases termed furins. This cleavage is essential for virus infectivity (447,448), and is thought to induce substantial rearrangements of the polypeptide chain. The TM subunit remains embedded in the membrane, and contains an extracellular domain, a membrane-spanning segment, and a cytoplasmic tail. The SU subunit lies wholly outside the cell, and after its incorporation into the virion particle, wholly on the extravirion surface. It is held onto the virion by contacts to TM, and most often by non-covalent bonds (449), though disulÞde links may occur in some viruses (450). SU is heavily glycosylated, and the presence of at least some of these sugars is important for virus infectivity. Perhaps the most important function of this heavy glycosylation is to hide the peptides on the surface of Env from neutralizing antibodies that would otherwise have access to the virion surface.

The Surface Subunit SU

For most viruses the major receptor-binding site is located in hypervariable sequences on the SU subunit, so that SU is a major determinant of host range. Chimeric SU proteins can be generated to demonstrate that the receptor utilization function maps to speciÞc regions of the protein. The key regions of the avian Env proteins have been similarly deÞned by selecting for changes in host range *in vivo*; these studies show that very small changes can result in the use of new receptors (451). The structures of two SU proteins have been recently determined at high resolution: a fragment of murine leukemia virus SU (452), and a fragment of the HIV-1 SU bound to its receptor CD4 (453,454). These structures suggest that the receptors make contacts to the envelope in shallow pockets that may not be readily bound by antibodies.

The Transmembrane Subunit TM

The TM subunit contains the so-called fusion peptide at its aminoterminus, and TM is thought to play the major role in fusion of the virion and host membrane (455Ð459). Many TM mutations are defective for membrane fusion (460,461). However, mutations blocking fusion can lie in SU as well (462). The entire Env protein probably acts as

a unified machine to mediate fusion, with complex interactions between the subunits (463), and with major movements of the subunits during the process of fusion. The fusion peptide of TM may simply insert into the host membrane, or it may make contacts to proteins. The major contacts for oligomer formation of Env are thought to lie in TM (464); isolated TM proteins form trimers in solution (465) and in crystals (466,452,467,468). The trimer is held together by a modified leucine zipper motif that bridges the monomers via hydrophobic interactions. This zipper region is crucial for virus infectivity (469–471).

It is possible to separate the two major functions of the Env protein onto two different molecules that cooperate to mediate these steps. Thus, the receptor binding function can be mediated by one Env protein, and the membrane fusion function can be mediated by another Env. This is apparent in the ability of two Env proteins to complement in mixed oligomers (472,473). It is also demonstrated by the ability of a wild-type Env to provide the membrane fusion function for a chimeric Env that on its own can only mediate cell surface binding.

The TM subunit of the murine leukemia viruses undergoes a second cleavage during virion assembly (474) that is mediated by the viral protease, PR. This step removes a short sequence called p2E, or the R peptide, from the carboxyterminus of TM (475). The cleavage step may require presentation of the tail to the protease, or some conformational change in the tail, that is mediated by Gag proteins; alterations in the MA or p12 Gag proteins can modulate the cleavage of TM (476,438). Astonishingly, the cleavage is necessary to active the fusogenic activity of the envelope protein and thus for virus entry (477,478). Mutants in which the tail is truncated at the site of cleavage are constitutively activated for fusion, and these viruses induce dramatic syncytia in receptor-positive cells. Mutants in which the tail is not removed are inhibited for fusion, and particular residues can be shown to be required (479). How the cytoplasmic tail inhibits the fusogenic activity of Env is very much unclear.

In a similar way, the cytoplasmic tails of the TM of M-PMV (480), and EIAV (481) are processed by the protease. In the case of M-PMV, the presence of the intact tail is necessary for efficient incorporation of Env into the virion. The majority of the retroviruses, however, do not carry out cleavage of TM, and for these viruses an intact tail is needed for infectivity (482). The replication of some viruses in host cells of foreign species can select for alterations and truncations of the TM tails (483,481,484). The selective advantage conferred by this truncation is not well understood, though various aspects of Env function seem to be enhanced by this truncation (485).

Morphological Changes Upon Virion Maturation

The maturation of retrovirus particles is a complex process that is required for the formation of an infectious virus. The particles that are initially assembled either at the plasma membrane (by most retroviruses) or in the cytoplasm (by the betaretroviruses) have a characteristic immature morphology: the particles are round, and stain with an electron dense ring and a relatively electron lucent center. After release from the cell, the morphology changes to a more condensed structure, with a central core largely detached from the surrounding envelope. In the alpharetroviruses, gammaretroviruses, and deltaretroviruses, the core is spherical and concentric with the envelope; in the betaretrovirus the core is spherical but eccentrically placed within the envelope; in the lentiviruses the core is cylindrical or conical, with thin connections to the surrounding shell. In the spumaviruses the morphology does not change dramatically after assembly.

Mutant viruses lacking the protease show little change in morphology. Thus, cleavage of Gag and Gag-Pol is required for the restructuring of the virion into the mature form (395). The changes in morphology visible in electron micrographs are probably associated with major rearrangements of the Gag proteins. Indeed, the physical properties of the virus change dramatically upon maturation. Whereas the immature core is quite stable to non-ionic detergents and harsh conditions, the mature virion core is relatively labile. This change may reflect the inability of the immature virion, and the acquired ability of the mature virion, to uncoat upon infection of new cells and initiate reverse transcription.

PERSPECTIVES

The study of retroviruses has led to a detailed characterization of many steps of virus replication, but also to important fundamental discoveries concerning host physiology and genetics. The viruses have served as entries into such phenomena as cell surface receptors, cell division, DNA synthesis, the cell cycle, mechanisms of gene expression, and intracellular transport. The value of focusing on retrovirus functions in unraveling cellular functions is clear: these agents have evolved over huge periods of time to exploit key aspects of the cell, and we should make use of their success to help identify those aspects. There is every reason to believe that their continued study will yet reveal new aspects of cell physiology.

Beyond the interest that all retroviruses serve as examples of complex biological machines, the primate lentiviruses obviously have particular significance as human pathogens. The AIDS epidemic will be remembered as one of the great pandemics of history, and HIV as its cause has accordingly been an object of both fear and fascination. All of its properties have been subjected to intense scrutiny. An understanding of the basic life cycle of the virus and the functions of its gene products has already allowed for development of potent antiviral drugs, and at great cost the virus can be at least temporarily halted. While it will likely prove difficult to eliminate HIV

from an infected individual, its replication can be controlled for long periods of time. Eventually, vaccination or other manipulations of the immune system may allow for less expensive control of the virus, and furthermore may interrupt its transmission. We strongly suspect that its Þnal control will be accelerated by a deeper understanding of the details of its molecular biology. However, because it has evolved an efÞcient life cycle and a profoundly insidious life style, it is likely that HIV will continue to be the cause of enormous human suffering throughout the world for many years to come.

ACKNOWLEDGMENTS

Chapter 5

The Neuropathogenesis of HIV-1 Infection

Howard E. Gendelman, Scott Diesing, Harris Gelbard and Susan Swindells

A constellation of cognitive, behavior and motor dysfunction comprise a neurological syndrome, named in its most severe form, human immunodeÞciency virus type one (HIV-1)-associated dementia (HAD), that follows progressive viral infection and immunosuppression in an infected human host. Potent combination antiretroviral therapies (PCAT) (also known as HAART) have diminished the incidence of disease, but have not eliminated it. Usually associated with severe immunosuppression, HAD is linked pathologically to HIV-1 encephalitis. Prior to the use of PCAT, the incidence of disease was 20%, it has now decreased to $<10\%$ (1). Nonetheless, the prevalence of disease may actually increase as patients live longer as a consequence of PCAT. Anti-retroviral treatment failures, viral mutation, a plethora of drug-induced neurological diseases and syndromes are all operative in the post-PCAT era. These demonstrate that HAD will remain a signiÞcant part of the overall disease complex. In regard to viral pathogenesis, HIV-1 invades the CNS soon after infection and many infected individuals develop neurological illness early in the course of disease. For example, aseptic meningitis develops soon after virus exposure and includes headache, fever, malaise and rash, typically resolving within a few days. Alternatively, a signiÞcant number of infected patients in the course of the disease develop subtle cognitive and motor impairments. Termed ÒminorcognitivemotordisorderÓ (MCMD), this may not herald progression to HAD (2). The pathogenesis of this disorder remains unclear, but MCMD has been associated with a diminished overall prognosis (3).

In addition to cognitive dysfunction induced by HIV-1 infection itself, the brain, spinal cord and peripheral nerves also succumb to a variety of cancers, fungal, parasitic and viral infections usually years following viral exposure and associated with CD4+ T lymphocyte depletion. Moreover, HIV-1 infection is also associated with peripheral neuropathies, myopathies, vacuolar and myelopathy.

When Þrst identiÞed more than two decades ago, the constellation of cognitive, behavioral and motor dysfunctions, now called HAD, was termed the AIDS dementia complex. Subsequently, a Þve-part staging system was developed (4). Ten years ago, the World Health Organization and the American Academy of Neurology generated more complex and detailed classiÞcation systems (5). Separate categories for myelopathy and dementia were included, and the new term, HIV-1-associated cognitive motor complex was Þrst introduced. HIV encephalitis is usually the pathological correlate of HAD. HIV encephalopathy remains the preferred term for disease in children (6).

Here we review the epidemiology, clinical manifestations and pathology of HIV-1-associated neurological disease and its associated encephalitis. Particular emphasis will be placed diagnosis, pathogenesis, and treatment options now available or under investigation in our laboratories and elsewhere. This chapter serves to complement other chapters of this book, which address the biology and pathogenesis of HIV, its effects on the immune system, the development of opportunistic infections and cancers, and treatment regimens.

CLINICAL MANIFESTATIONS

Interestingly, for HAD, disease is caused as a direct result of viral infection in brain, usually, but not always secondary to dysfunction and depletion of by CD4+ T

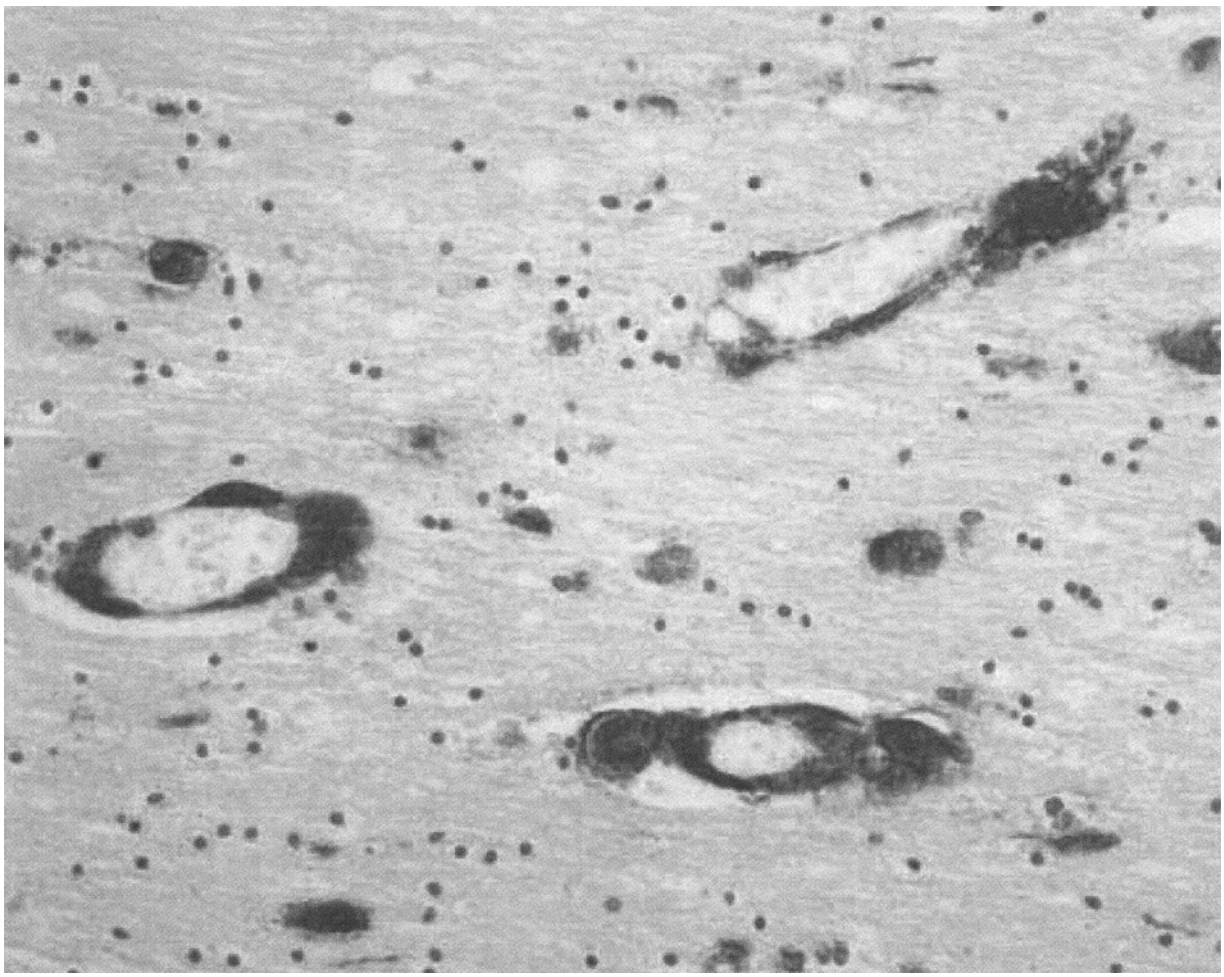

FIG. 5.1. Brain tissue from a subject with HIVE. Five mm sections of formalin- xed paraf n-embedded tissue were prepared for immunocytochemical stains. MP expression of HIV-1 p24 antigens is shown. In addition the typical histopathological features of HIVE are demonstrated including multinucleated giant cells, astrocytosis, microglial nodules, perivascular macrophages and myelin pallor. Original magni cation is x 20.

lymphocytes (1,7). HAD is a subcortical dementia of insidious onset. Cognitive deÞcits, the most frequent symptom complex seen in HAD, emerge early in the course of disease with mental slowing, forgetfulness, and difÞculty in concentration (7). Early motor symptoms include unsteady gait, limb weakness, and tremor. The most common motor symptom, however, is gait disturbance, but difÞculty with hand coordination can often be seen by impaired handwriting or typing skills. Behavioral abnormalities, are frequently observed, and include apathy, anhedonia, and social withdrawal (8). Degrees of impairment may vary between patients, and within patients over time. Symptoms usually progress at variable rates to a global dementia if the patient is not treated. Other late changes indicative of global neurological dysfunction include weakness, prominently of the lower extremities, causing inability to walk unassisted, lack of coordination, hyperreßexia and bladder or bowel dysfunction. Frontal lobe release signs such as the snout reßex may also be detected. In the terminal stages of disease affected individuals are unaware of their surroundings and progress to a spastic quadriparesis that ultimately results in death. HAD may be difÞcult to diagnosis because in its earliest stages, differentiating this syndrome from depression can be difÞcult. Screening for depression, bedside neuropsychological testing and additional information from friends or family close to the patient can be helpful. Other causes of dementia, including toxic/metabolic, vascular and opportunistic infections, must Þrst be ruled out by serum and cerebrospinal ßuid (CSF) analysis and neuroimaging studies examination before HAD is conÞrmed.

NEUROPATHOLOGY OF HAD, HIV-1 ENCEPHALITIS

Neuropathological abnormalities seen in brain tissues of patients with HAD are usually diffuse and predominantly localized to the white and deep grey matter regions (Fig. 5.1). They are referred to as HIV-1 encephalitis (HIVE) and include a characteristic dendritic pruning and vacuolation (9) both of which are indicative of neuronal

dysfunction and subsequent loss (10,11). Myelin pallor and inßammatory inÞltrates composed of macrophages and multinucleated giant cells (MGC) are the hallmarks of this disease process, although a spectrum of lesions has been identiÞed from encephalitis to leukoencephalopathy (12Ð14). A reactive astrocytosis and microgliosis is also typical (15) strongly coincident with the inÞltration into brain of peripheral monocyte-derived macrophages (MDM) (16,17). Microglial nodules form in close proximity to the vasculature (17). Myelin pallor represents a disruption of the blood-brain barrier (BBB) with ßuid accumulation in the brain parenchyma itself rather than frank white matter damage. HIVE is more difÞcult to diagnose in children because of immature myelination. The accumulation of macrophages, MGC, and reactive astrogliosis are common. The presence of MGC is considered a signature pathological Þnding. MGC results from the fusion of HIV-1 infected brain mononuclear phagocytes (MP); (perivascular and brain macrophages and microglia) with uninfected MDM or microglia (18,19). Giant cell formation is found throughout the brain in disease, but is characteristically seen primarily in the deep brain structures and most commonly subcortical white matter. Although pathognomonic of HAD, giant cells are only found in 50% of patients. Although HIV invades the brain early after viral exposure (20,21), functional changes in the CNS occur many years later. These are usually associated with the breakdown of innate and acquired immune mechanisms that serve to control ongoing viral replication, both in the periphery and the brain. The principle mediator of disease in the nervous system is the activated MP (see below). These cells exert their neurotoxic effects primarily through secretory factors (22Ð24). Unlike many other viral infections of the brain where neurons and/or glia are primary targets for persistent infection, HIV-1 predominantly infects MP. These are the cells that serve as a reservoir for persistent viral infection, a vehicle for dissemination of virus throughout the brain and a major source of neurotoxic products that affect neuronal function and lead to deÞcits in cognition. The predominant mechanism for disease is through soluble MP neurotoxins. Viral replication, nonetheless, appears necessary, but not sufÞcient for disease. Interestingly, clinical disease correlates with the number of activated macrophages more so than with viral load in the brain (15). Unlike many other viral infections of the brain which directly infect neurons, HIV-1 mediates neural damage through brain MP by inducing autocrine and paracrine immune ampliÞcation of neurotoxic secretions and affecting subsequent neuropathology. The indirect effect of virus on neural function by glial inßammatory products has led to the term ÒmetabolicencephalopathyÓ for HAD. Although HIV-1 is essential for the development of HAD, many patients never develop HAD, despite persistent high levels of HIV-1 RNA and a rapidly progressive disease course. Likewise, not all patients with HAD have high virus loads. Thus, the association between virus load and neurologic disease is complex, and the onset and progression of HAD are presumably reßective of a multifactorial pathogenesis (discussed below).

The other common histopathological features of HAD are leukoencephalopathy and diffuse polio dystrophy. Leukoencephalopathy is a diffuse neurodegenerative process, often observed without prominent signs of inßammation. Here considerable damage to white matter or myelin attenuation is seen in association with astrogliosis, macrophage accumulation and MGC cells. Diffuse polio dystrophy is reactive astrogliosis and microglia inßammation in gray matter often with associated neuron loss or dendritic damage. Spongiform changes are only seen in the most severe cases (14).

EPIDEMIOLOGY

Taken in the context of other serious illnesses developed as a consequence of HIV-1 infection, HAD may be under diagnosed, so the actual incidence is likely higher than reported. Indeed, autopsy examination of brain tissue of patients who died of HIV disease demonstrates neuropathological changes in as many as 80% of infected patients (25). Changes in antiretroviral therapy over recent years have impacted on the incidence of HAD in developed countries, with a decrease from 20 to less than 10% (26). Data from cohort studies demonstrated that the incidence of HAD was Þrst reduced following the general use of zidovudine and further decreased after the widespread use of potent combination antiretroviral therapy (27Ð29). This is also supported through animal model studies. Rhesus macaques treated with zidovudine had a signiÞcantly decreased viral load within the brain and a delayed onset of CNS dysfunction (30). During recent years, the use of protease inhibitor-based antiretroviral therapies has been associated with dramatic declines in overall morbidity and mortality attributable to HIV-1 disease, including HAD (31). The degree and durability of such improvements remain uncertain, but some estimates of the incidence of HAD are currently nearly 10 cases per 1,000 person years (27). However, such reductions in incidence have not yet been conÞrmed by histopathological examinations. Indeed, a recent neuropathological study from the University of California San Diego obtained over the last 15 years showed that HIVE was found in 25% of HIV-1 infected cases examined (25).

Even with the impact of PCAT on the prevalence of HAD, many neuroepidemiologists believe it remains the most common cause of dementia in 25Ð40 year olds worldwide. Although improved control of viral replication by PCAT has played a major role in the decreasing prevalence, it is not clear how long lasting this effect will be (32,33). Furthermore, the CNS provides a reservoir for virus and the BBB often restricts entry of drugs. Therefore infected persons may continue to be at risk for HAD (34). A number of superimposed biological factors support this

idea. First, resistant viral strains can continuously replicate and evolve (35). Second, as the survival of infected individuals continues to increase, it is likely that there will also be changes in disease prevalence, incidence and manifestations of HIV-1 infection of the CNS as a consequence of drug resistance or drug related evidence effects.

DIAGNOSIS OF HAD

HAD remains a diagnosis of exclusion. Although a number of clinical, laboratory and radiological tests are available to aid in a diagnosis, none as yet is conclusive. Nonetheless, a variety of evaluations may, taken together, permit a diagnosis to be made with near certainly. In addition to a careful history and physical examination including neurological examination, the following tests serve to strengthen the likelihood of HAD.

Neuropsychological Testing

Neuropsychological testing is helpful as an adjunct to neurological examination in deÞning better the type and extent of cognitive and motor impairment. Such tests generally demonstrate deÞcits in attention, memory, mental ßexibility and motor speed. Tests that are helpful in deÞning HAD include Trail Making B, Digit Symbol, Grooved Pegboard, and computerized reaction times (3,36,37). The inßuence of age, education, co-morbid conditions such as systemic illness, previous head trauma or substance abuse must be considered when interpreting any neuropsychological testing results. Moreover, while this testing remains the gold standard for cognitive evaluation, such an evaluation is not always available or practical for the generalist physician. Simpler test batteries, helpful in making a diagnosis of HAD, can be administered by clinicians at the bedside. For example, the HIV Dementia Scale is a reliable and quantiÞable adaptation of the Minimental Status Examination (38). Abbreviated screening tools for depression such as the ProÞle of Mood States can also be helpful in distinguishing depression from HAD.

Neuroimaging

Radiographic and functional imaging tests can delineate the structural and metabolic effects of HIV on the brain and differentiate them from other types of infectious diseases or cancerous lesions (Fig. 5.2). Computerized tomography of the brain characteristically shows cerebral atrophy in the majority of patients with moderate to severe dementia, but atrophic changes may also be present in asymptomatic individuals (39). Magnetic resonance imaging (MRI) is generally more sensitive, and can show white matter abnormalities (40).

More advanced techniques assess functional changes in brain metabolism. These include Single-Photon Emission Computed Tomography (SPECT), Positron-Emission Tomography (PET), functional MRI (fMRI) and magnetic resonance spectroscopy (^{1}H MRS). These techniques have the potential advantage of detecting early functional abnormalities before morphological changes occur. For example, MRS is a non-invasive method of quantitating neuronal loss performed with conventional resonance imagers. Assessment of *in vivo* metabolism gives biochemical information that complements the structural information from the MRI examination, and in a quantitative fashion. Several groups, including our own, have reported a reduction in *N*-acetylaspartate, a marker for neuronal loss, using *in vivo* proton ^{1}H MRS in patients with advanced HIV disease (41Ð44). ^{1}H MRS demonstrated progressive neuronal loss over time in HIV-infected individuals, and the degree of neuronal loss observed correlate with neurological impairment (44,45). Increased choline levels reßect glial membrane turnover indicative of the astrocytosis that follows HIVE. Evidence is also accumulating that 1H MRS may be helpful in differential diagnosis of HAD and other neurological disorders associated with HIV disease, for example other metabolic encephalopathies (46), and in differentiation of CNS toxoplasmosis and lymphoma (39). Moreover, such technologies may also be helpful in monitoring therapeutic responses to anti-retroviral therapies (41). Improving technology is increasing the sensitivity of MRS to detect metabolic alterations and neuronal loss much earlier than conventional neuroimaging and in a quantitative fashion with broad applicability for measuring neuronal loss, brain water content and/or membrane turnover. ACTG 700 was the Þrst multisite *in vivo* ^{1}HMRS study of HIV-related brain injury. Excellent reliability was shown among different sites, and preliminary analyses have revealed signiÞcant differences in regional metabolites between HAD subjects and controls (47).

Cerebrospinal Fluid Test Evaluation

Cerebrospinal ßuid (CSF) abnormalities in HAD are generally nonspeciÞc with mild elevations in protein and/or minimal pleocytosis (48). Generally, HIV-1 RNA levels in CSF correlate better with the presence of cognitive impairment than with plasma levels (49Ð54). Indeed, sensitive quantitative assays of HIV RNA have correlated CSF viral load levels with high levels throughout the brain (55). However, this is not diagnostic for neurological disease. Indeed, the precise relationship between HIV-1 RNA levels in CSF and risk of development or progression of cognitive and/or motor impairments is not established. Although CSF RNA levels have been shown to correlate with the severity of dementia in both children and adults, they also are often increased during other CNS infections (56Ð60). Because the level of HIV in the CNS is usually limited even in patients with neurological disease, CSF

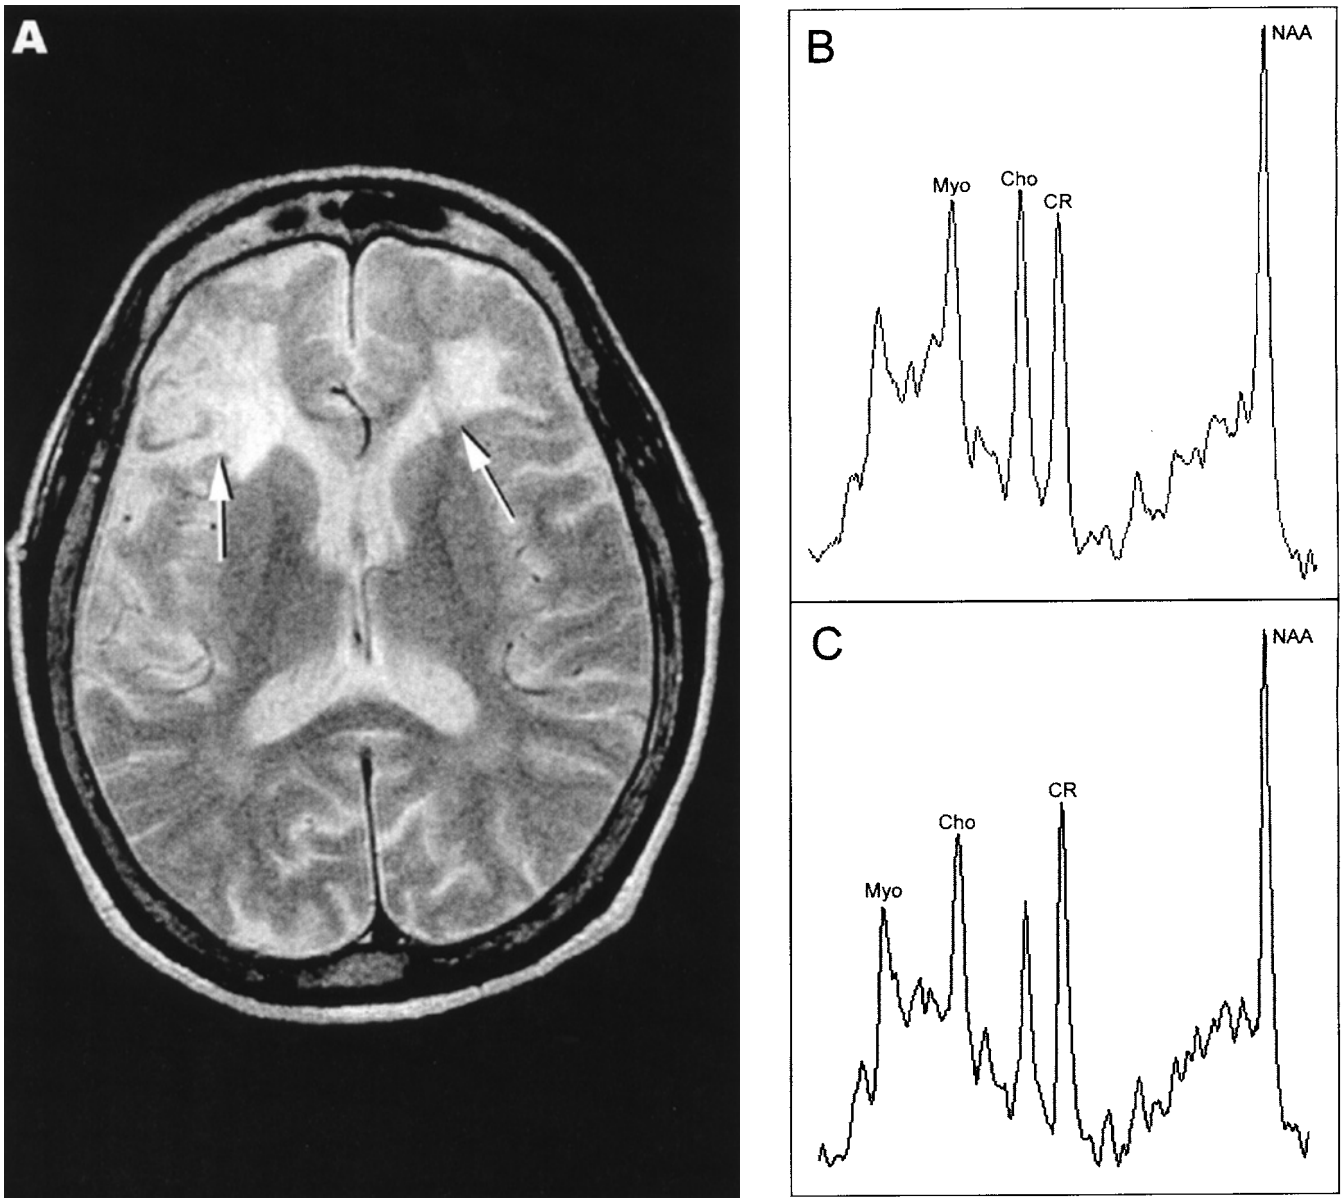

FIG. 5.2. MRI and MRS of HAD. MRI scans of the brain of a 60 year old female patient with moderate HAD (A). The third and lateral ventricles are enlarged and sulcal spaces are prominent, indicating cerebral atrophy. High signal abnormality within the subcortical deep white matter of both frontal lobes is consistent with gliosis (*arrows*). In (B), MRS is shown for Myo, myoinositol; Cho, choline; CR, creatine; NAA, N-acetylaspartate. Single voxel (8 cm^3) MRS within the white matter is abnormal with decreased *N*-acetyl aspartate NAA/Cr ratio of 1.48, elevated Cho/Cr ratio of 1.01, and the MI/Cr ratio is elevated at 0.89. The decreased NAA peak is indicative of neuronal loss. The gray matter spectroscopy shows a NAA/Cr ratio of 1.42, Cho/Cr ratio of 0.65, and a MI/Cr ratio of 0.88 (C). These ndings are consistent with HIVE.

RNA levels are also low (usually about one log lower than in plasma). Regrettably, the false negative rate of CSF RNA values is high as a predictor for disease. Moreover, minor cognitive motor dysfunction (MCMD) is not at all associated with high CSF HIV RNA levels (49,50). Complicating the use of viral load determinations as a diagnostic or predictive marker for disease are issues related to viral kinetics and the relationship between levels of virus in brain and CSF. HIV-1 RNA half-life was longer, the decay rate slower, and the variability of viral strains greater in CSF than in plasma in 15 HIV-infected subjects initiating or changing antiretroviral therapy (61). CSF HIV-1 RNA levels do not always predict viral burden in the brain. Although probably more biologically relevant, HIV RNA levels in brain are difficult to ascertain. Such studies are performed postmortem and provide only descriptive, single point in time determinations (60).

HIV-1 NEUROPATHOGENESIS: AN OVERVIEW

The principle mediator of HIV-1 disease in the nervous system is the activated MP, which includes perivascular

and parenchymal macrophages and microglia. These cells exert their neurotoxic effects primarily through secretory neurotoxins (both cellular and viral toxins) (22–24). In this way, viral replication may be necessary but not sufficient to incite disease. Interestingly, clinical disease correlates better with the number of activated macrophages in the brain than with viral load (16). Unlike many other viral infections of the brain which directly infect neurons, HIV-1 mediates neural damage by inducing an amplification, by autocrine and paracrine immune mechanisms, of neurotoxic secretions from brain MP. Such secretory products as tumor necrosis factor alpha (TNF-α) and IL-1β can induce their own secretion or other neurotoxic products. The indirect effects of HIV on neural function induced by MP inflammatory products has led to the term "metabolic encephalopathy" as it refers to HAD pathogenesis.

VIRAL ENTRY INTO THE CNS

HIV may enter the brain early in primary infection carried into the CNS inside infected cells, macrophages and/or CD4+ T lymphocytes, or alternatively as cell-free viral particles (Fig. 5.3). The movement of virus from the periphery into the brain is facilitated by immune dysfunction and structural BBB compromise. This occurs, in large measure, late in the course of disease and serves to speed the overall pathogenic process. Under normal circumstances, the BBB serves to restrict cell movement between the CNS and the circulation, including movement of ions, polar organic substances, and proteins. Structurally, the BBB consists of a monolayer of specialized non-fenestrated brain microvascular endothelial cells (BMVEC) with a capillary basement membrane on the abluminal side of the monolayer. Tight junctions connect the BMVEC, and there are no transcellular pores. These junctions are dependent on two processes: the first is high concentration of the integral membrane protein occludin and the second is intracellular signaling that determines phosphorylation of the junctional proteins (62). Astrocyte foot processes abut the abluminal surface of the endothelial monolayer. The second process relies on coordination of the BMVEC functions by the surrounding astrocytes (63–67). These together serve to restrict movement of cells and macromolecules including virus throughout much of HIV-1 infection.

Nonetheless, a number of biological situations allow for the trafficking of cells across the BBB. Specifically, monocytes and lymphocytes will induce or respond to signals from the BMVEC, which permits binding to and diapedesis through the BBB. The adhesion molecules, intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1), on the luminal surface of the BMEC bind LFA-1 and Vl-4 on the monocyte, resulting in migration of the monocyte between the endothelial cells during the early stages of viral infection. As inflammation proceeds during the later stages of disease, cellular trafficking into the brain is greatly enhanced. ICAM-1, VCAM-1, and E selectin are upregulated on the surface of BMECs and astrocytes after exposure to pro-inflammatory cytokines (for example, TNF-α and IL-1β) secreted from microglial cells and astrocytes and/or activated leukocytes from the periphery. These serve to augment the process of adhesion molecule expression not only on BMVEC but also on astrocytes (12,13,64,67,68). Moreover, pro-inflammatory cytokines induce a transient increase in endothelial permeability by increasing secretion of endothelial vasoactive factors, such as nitric oxide (NO) (14). TNF-α and IL-1β increase the production of other inflammatory mediators including arachidonic acid derived platelet-activating factor (PAF) (69–71). These serve to promote monocyte migration across the BBB and ultimately into the brain parenchyma (65).

Other inflammatory factors and changes in cellular biophysiology induced as a consequence of inflammation also influence transmigration of inflammatory cells into the CNS. For example, chemokines are secreted at sites of inflammation in all tissues including the CNS and guide leukocytes in a concentration-dependent manner. Importantly, specific chemokines will attract specific populations of leukocytes. Macrophage inflammatory protein-one alpha and macrophage chemotactic protein-1 (MIP-1α and MCP-1) are increased during HIVE and are potent chemoattractants for macrophages (65,66). Potassium channels expressed in MDM influence cell migration by altering cell volume and shape and are influenced by inflammatory responses (72). HIV-1 infection alters the BBB itself (73). Numerous functional and structural abnormalities are operative including damage to the basement membrane, morphological alterations of the BMEC, and subsequent protein leakage (73–78). Trafficking is also altered during HIV-1 infection. Macrophages themselves express more LFA-1 and VL-4 (74,75), concurrent with viral infection and/or immune activation, and upregulate adhesion molecule expression by the BMVEC (76). In this pathologic setting, HIV-1 infected monocytes and/or CD4+ T lymphocytes are able to cross the BBB (74). This is thought to be the primary route of entry into the CNS for HIV-1. Nonetheless, cell-free virus may also cross the BBB and subsequently infect MP. The relative proportion of viral entry by either route has not yet been determined.

Late in the disease process, inflammatory cytokines are produced at high levels and allow the BBB to be more easily breached. Increasing damage to the BBB impairs the ability to protect the CNS from the periphery. Cells and toxins are then able to reach the CNS unchecked. Levels of inflammatory factors greatly increase and lead to a cascade of events culminating in further BBB dysfunction. All of these processes contribute to MP-induced neuronal destruction during HAD.

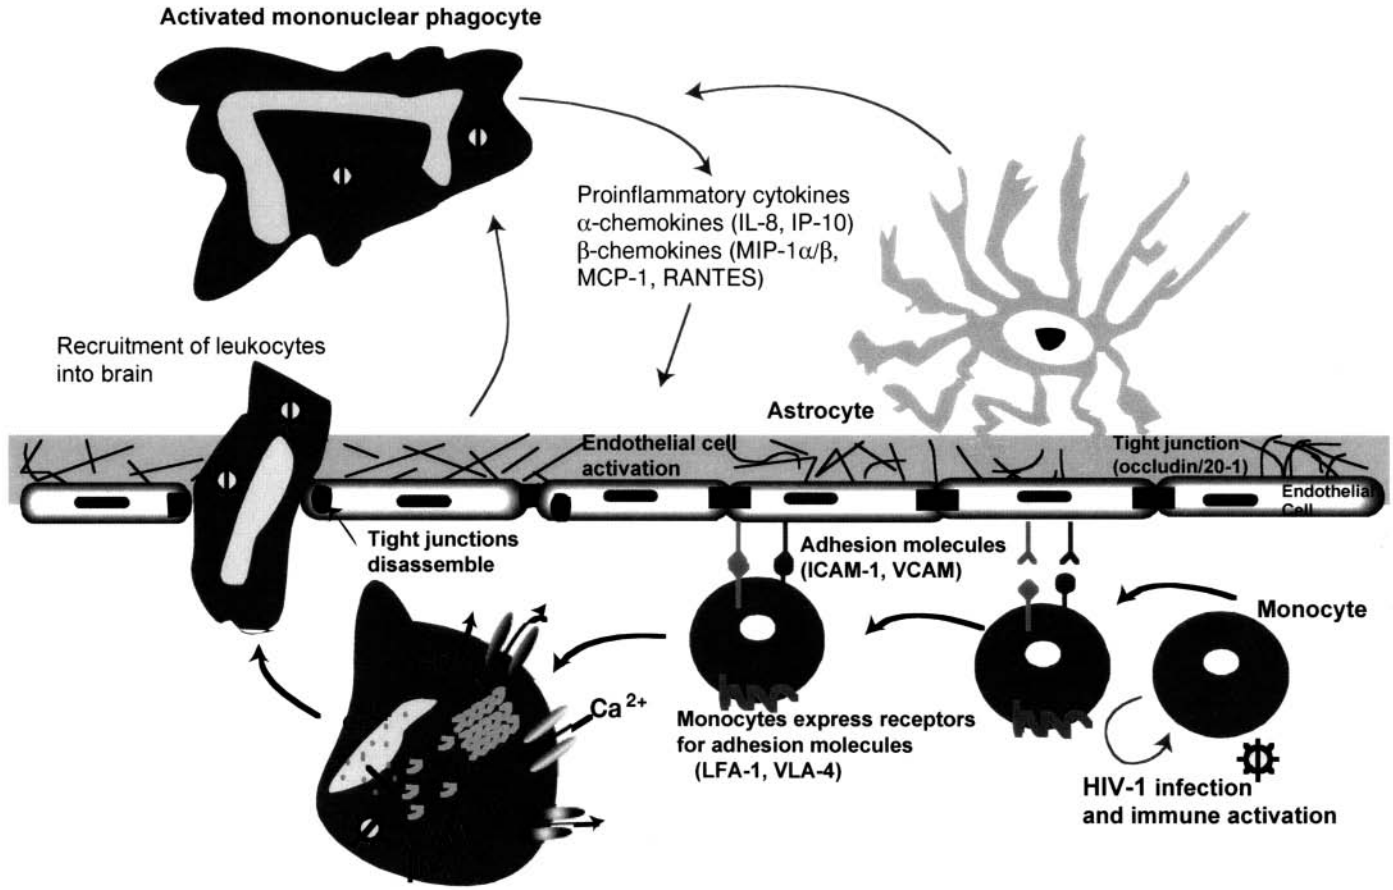

FIG. 5.3. Mechanisms for viral entry into the CNS. Virus is carried into the brain in differentiating macrophages or through lymphocyte-macrophage cell interactions. At the blood-brain interface, circulating monocytes have begun to differentiate into macrophages and acquire the abilities to be productively infected with HIV-1. Many of these cells are already immune competent as speci c CD14 + /CD16 + cells emerge during the onset and progression of cognitive dysfunction in infected people. The immune competent and virus-infected cells secrete a number of pro-in ammatory molecules that induce the upregulation of adhesion molecules (for example, ICAM-1 and VCAM) on the surface of BMVEC. Other factors secreted by macrophages affect tight junctions and cause their disassembly. Tight adhesion of cells occurs, and through expression of ion channels, the macrophages begin to change their shape and size to move freely through the BBB. Once inside the brain the cells represent new cellular targets for HIV-1 and sources of a variety of in ammatory factors including chemokines and cytokines that affect new chemotaxis events for monocyte entry into the brain alone with ongoing neurotoxicity.

HIV REPLICATION AND PERSISTENCE WITHIN THE CNS

HIV-1 is neuroinvasive and enters the CNS early in infection (20,21). Once inside, the CNS brain macrophages and microglia, and to a lesser extent astrocytes, serve as a reservoir for virus. Neuroinvasive viral strains predominantly infect MP (M-tropic), the more prevalent viral subtype early in the course of infection. In contrast, T-lymphocyte-tropic or T-tropic strains predominate later in the course of disease when levels of pro-inßammatory cytokines rise and serve to amplify the entry and replication of the virus through activated brain MP.

HIV-1 is not neurotropic in the sense that it does not infect neurons. Indeed, the virus productively infects only select cell types within the CNS and as noted above, predominantly cells of macrophage lineage (78). Astrocytes may be infected but are highly restricted (56,57,59). Infection of BMVECs has been shown in laboratory cell model systems (58), but there is no evidence that this occurs *in vivo* (79–81).

Tropism of HIV-1 for macrophages is largely determined by the V3 hypervariable region of HIV-1 gp120, the viral surface protein (48). HIV-1 gp120 binds CD4 to the surface of mononuclear phagocytes and T-cells among other CD4+ cell types. CD4 is mandatory for infection of these cells but not sufficient for effective infection by all strains of virus (82). The V3 function is distinct from the HIV-1 gp120–CD4 requirement and is more associated with post-CD4 binding interactions such as proteolytic cleavage and fusion, all of which is critical for productive infection of brain MP (49–53). Although the V3 region is crucial to the tropism of HIV-1, it is not the only factor. The V1/V2 region may also contribute independently or in concert with V3. Chemokine receptors are also associated with viral tropism (54,83). The β-chemokine receptor CCR5 expressed on macrophages is a determinant on m-tropic strains (84,85). T-tropic strains are associated with the α-chemokine receptor CXCR4. T-cells may be infected by either strain of virus.

HIV-1-CELL INTERACTIONS IN BRAIN TISSUE

Mononuclear Phagocytes

The MP is the primary mediator of CNS disease during HIV-1 infection. Included as parts of the MP family are circulating monocytes, meningeal, perivascular and parenchymal macrophages and microglia. Under normal conditions, monocytes become tissue macrophages after cellular differentiation and activation. The majority of monocytes are CD14+/CD16–, however, a subpopulation of monocytes expressing CD14low/CD16+ comprises approximately 8% of the circulating pool. This population is significant because it behaves biologically similar to tissue macrophages (86). The number of CD14+/CD16– cells and CD14low/CD16+ monocytes is increased during inßammation and HIV-1 infection, but the relative proportion of CD14low/CD16+ cells can increase to 40% in patients with advanced HIV disease or AIDS (87). Interestingly, CD4low/CD16+ cells are selectively decreased by systemic glucocorticoid administration (88). In this way these cell populations may serve as an important marker for inßammation and progressive neurological disease during advanced HIV-1 infection (89,90). Their actual role in the neuropathogenesis of HIV-1 infection remains to be determined.

Tissue macrophages throughout the body express low levels of adhesion molecules and MHC II. MP function as phagocytes, as effectors and antigen presenting cells and can kill microbial pathogens through phagolysosomal fusion mechanisms. Macrophages are activated and recruited into tissue during inßammation, and emigrate into the CNS only under like circumstances. However, thus inßux is transient and will revert to a quiescent state after the inßammatory process has subsided (91). For HIVE and HAD the process never subsides as brain inßammation is continuous and induced by ongoing viral replication. One population of MP, meningeal macrophages, is characteristically infected during primary HIV infection paralleling the development of an aseptic meningitis. Later in the course of the disease perivascular macrophages and microglia are infected preferentially (92,93). It is likely that the infected brain macrophage population, the extent of CNS inßammation and the numbers of recruited MDM into the brain predict the course and extent of neurological impairment.

The perivascular macrophages are an actively studied MP cell type involved in HAD pathogenesis. These cells under natural conditions exist between the glia limitans and basement membrane of the choroid plexus and CNS capillaries. They are in close association with the BMVEC, and this position allows them to serve as sentinels for the CNS. They are in fact intermediates between the circulation and the microglia. Since microglia are in contact with these macrophages, signals may be rapidly communicated deep into the CNS from interactions at the perivascular space. These cells are derived from circulating monocytes, but will not become fully active macrophages. Transmission of virus and/or inßammatory responses in the brain may occur between these perivascular macrophages and glial cells within the parenchyma.

Clearly, the most current data strongly suggest that such cells are likely to be responsible for the majority of transmission of virus into the CNS (33). Several observations support this hypothesis, including the presence of often high levels of infected perivascular macrophages. Through such cells virus can be readily transferred to microglia upon microglial activation since there is close contact between the two. Importantly, it is the perivascular macrophage that is the critical CNS resident MP that act as

an antigen-presenting cell to T-cells. Thus, they are at high risk for exposure and contact with infected T-cells and/or inducing T cell protective immunity. Importantly, there is relatively frequent turnover of perivascular macrophages when compared with microglia. Thus, they may bring HIV into the CNS after being infected in the periphery, and release or transmit virus after cell death or through interactions with T cell or microglia.

Parenchymal microglia form a web of opposing dendritic processes throughout the white and gray matter of the CNS (94,95), and extend foot processes to abut the endothelium. They are in signiÞcant numbers in the CNS and may constitute up to 10% of CNS cells. They enter the CNS during gestation and have a very low turnover rate. There are two morphological subtypes of microglia. RamiÞed microglia are resting cells with reduced secretory and phagocytic activity. They compose the web of microglia that spans the CNS. In contrast to perivascular macrophages, they have weak antigen presenting capability, but can be stimulated to do so (96). These cells express few if any adhesion molecules, CD4, or MHC but can be activated to express all three (97Ð99). These cells may convert to fully active macrophages in the CNS. The second type is amoeboid in form. It is a morphological intermediate and transitional cell between the ramiÞed microglia and the brain macrophage. This subtype is not found in the normal adult CNS, but in inßammatory and demyelinating conditions.

Clearly, the pathogenesis of HIV associated CNS disease centers around the macrophage (Fig. 5.4). The

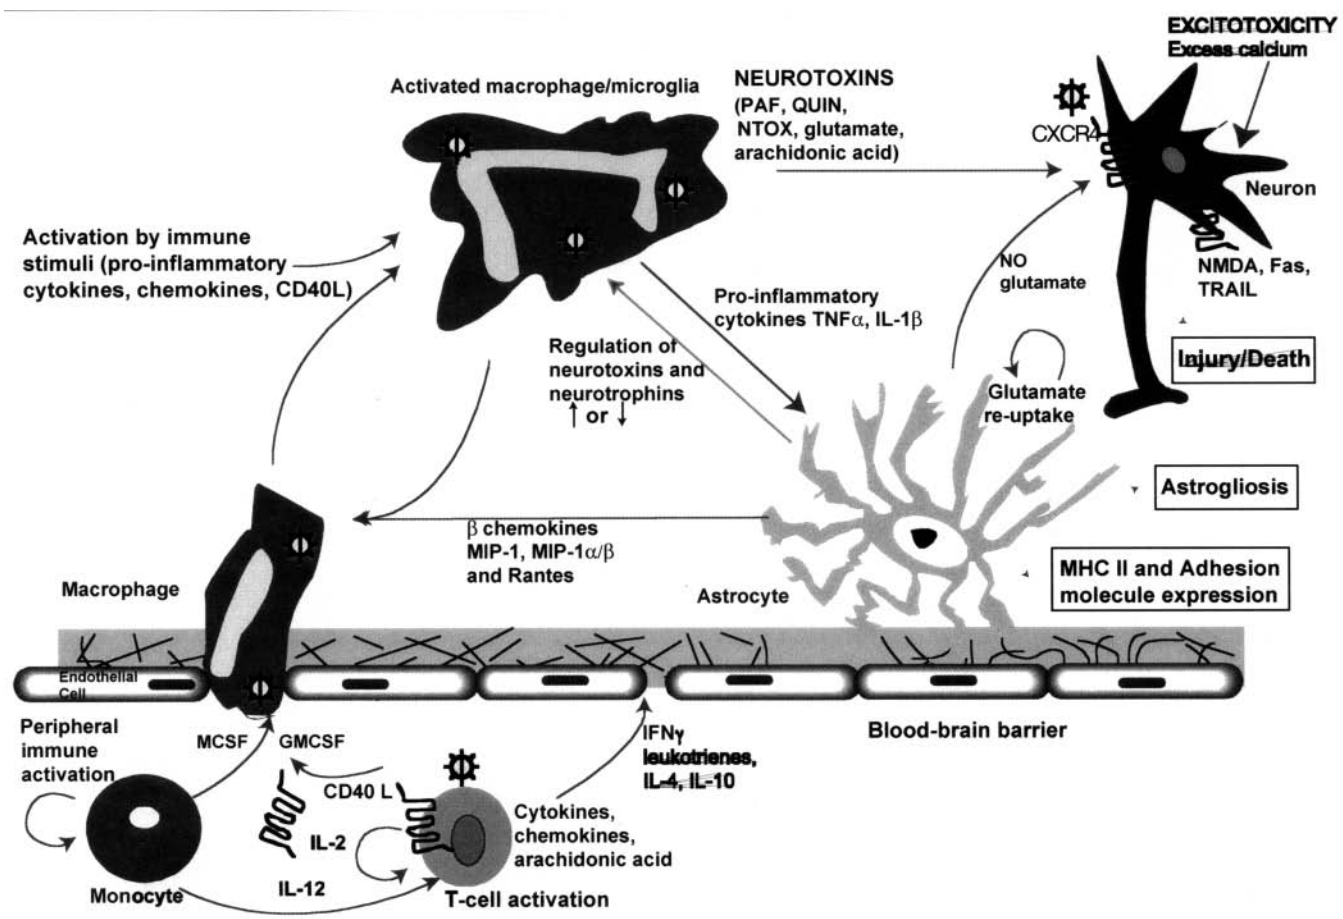

FIG. 5.4. Neuropathogenic mechanisms for HAD and HIVE. HIV-1 infected MP can affect neural function and pathology in a number of distinct ways. Virus-infected MP become immune-activated by a process that remains incompletely understood, but likely involves peripheral pro-in ammatory cytokines and/or cell-cell surface interactions with CD4 + T lymphocytes. CD40L-CD40 represents an example of the latter mechanism. Activated HIV-1-infected brain macrophages secrete a variety of factors (cellular and viral) that affect neuronal function through CNS in ammation. This may occur through excess calcium and excitation of neuronal NMDA receptors or through other mechanisms (for example, Fas and TRAIL). Interactions between MP and astrocytes or each individual cell type can lead to autocrine and paracrine ampli cation of neurotoxins and other in ammatory mediators of neural injury. Glutamate and α- and β- chemokines are secretory factors produced by infected, activated MP. These may affect BBB integrity as well as continuously inciting the recruitment of new monocytes into the brain. Chemokines, HIV-1 gp120, and progeny virions may interact with neuronal receptors to induce intracellular signal transduction alterations, the nal results of which are neuronal compromise and subsequent dementia. Paradoxically, some chemokines act contrary to this paradigm and induce neuronal survival, while others t the model by inducing neuronal apoptosis.

macrophage causes disease in this setting by amplifying the viral load, acting as a reservoir for virus, and secreting toxins that are neurotoxic. The virus replicates in the macrophage and microglia making these cells the target of HIV-1. The virus is able to hide within the macrophage for long periods of time by intracellular budding of progeny viral particles (100). Kolson, et al. speculated that microglia may serve as reservoirs for HIV-1 infection because they have an exceedingly long life-span (101). This in turn might complicate the measurement of viral load in the CSF since it may not adequately reßect viral load in affected brain regions. Moreover, CNS macrophages are, in part, protected from the effects of most antiviral medication because of the BBB. The nature of this viral reservoir and its abilities to harbor and support virus growth remains a key obstacle in eradication of HIV-1 infection from the CNS.

Astrocytes

Astrocytes both proliferate and undergo apoptosis in HIV-1 CNS infection (102Ð104). Astrocytes may be infected by T-tropic strains of HIV-1, and to a much lesser degree by M-tropic virus (105). Infection occurs via a CD4 independent mechanism possibly involving novel astrocyte surface molecules and HIV-1 gp120 (106). Astrocytes may also serve as a reservoir for virus. Latent HIV-1 infection may be maintained for years (105). The actual percentage of restrictively infected astrocytes in brains of patients with HIVE is unknown, but thought to be relatively small. The pathophysiologic signiÞcance of restricted infection in astrocytes remains unknown.

Astrocytes contribute to disease pathogenesis by three major mechanisms. Astrocytes normally regulate extracellular glutamate levels. In HIV-1 infection, astrocyte re-uptake of glutamate is impaired by gp120 (107), and by infection of the astrocyte itself (105). In addition, glutamate release from the astrocyte is induced by activated macrophages (22,108). Stimulation of metabotropic glutamate receptors on the astrocyte may also cause glutamate release (109). All these factors contribute to excitotoxicity. The second pathway involves ampliÞcation of neurotoxic signals. The HIV protein Tat induces expression in astrocytes of MCP-1, a chemoattractant for macrophages (110), and IL-8 and IP-10 which attract multiple leukocyte types (111). Induction of iNOS within astrocytes is promoted by viral proteins and cytokines (112). Fas potentiates inßammation in astrocytes, but induces apoptosis in microglia (113). The third pathway is through Fas ligand (FasL). Here culture supernatants from activated astrocytes and human FasL lead to elevated levels of LDH release and DNA fragmentation in human neurons. Concomitant caspase activation is operative in such neuronal cultures treated with IL-1β-stimulated astrocyte culture ßuids. FasL produced by these activated astrocytes may represent yet another unique pathway for neuronal injury during HAD (114).

CD4+ and CD8+ T Lymphocytes

CD4+ T lymphocytes, as previously discussed, are responsible for the majority of HIV replication in the periphery. HIV-1 may enter the CNS in infected lymphocytes, although this is more frequent in late stage disease. Activated T-cells enter the CNS. During HIV-1 infection, more T-cells are activated to a blast phase, called lymphoblasts (115). Once within the CNS, lymphoblasts search for antigen as they migrate through the parenchyma. If these activated T-cells are infected, they will be shedding virus as they migrate. At the same time, they are inducing CD4 expression on cells susceptible to HIV infection, rendering them even more susceptible. Furthermore, the CNS is normally a hostile environment for the T cell. Because of this, many die by apoptosis within the CNS. Macrophages become activated by way of scavenger receptors as they clear the debris of dead virus-infected cells (116).

INFLAMMATORY NEUROTOXINS

Activated macrophages and microglia are the primary perpetrators of neuronal injury in HIV-1 associated CNS disease (Fig. 5.4). It is widely accepted that these mononuclear phagocytes act to bring about neuronal injury primarily through indirect mechanisms. These indirect mechanisms are alterations in secretory function of chemokines, cytokines, arachidonic acid derivatives and Platelet Activating Factor (PAF), as well as nitric oxide (NO), free radicals, and excitatory amino acids (117). Direct mechanisms bring about neurotoxicity, but probably play a lesser role. These mechanisms consist of soluble viral proteins and glycoproteins that work through neuronal receptors (118,119).

The primary role of the macrophage in HIV neuropathogenesis is neurotoxin secretion (120,121). Among these toxins, excitatory amino acids (EAA) have come to the forefront of the Þeld as of late. Quinolate is one such EAA that acts via the neuronal NMDA glutamate receptor to induce excitotoxicity (60,122). There is a strong correlation between quinolate levels in the CNS and dementia (60). Macrophages have been shown to be the primary source of quinolate in the CNS (123). Other EAA are glutamate, L-cysteine (30), and Ntox.

Secretion of inßammatory mediators also plays a role in HIV-1 associated neurotoxicity. Cytokines and arachidonic acid derivatives, such as platelet activating factor, communicate the inßammatory state, along with a plethora of other functions, to other leukocytes and astrocytes. Macrophages are known to secrete IFN-α, IFN-β, IL-6, IL-1α, IL-1β, TNF-α, and TNF-β. IL-1β deserves special attention, as it is a very potent astrocyte stimulator. Other secretory products produced by the activated macrophage include reactive oxygen species and NO. However, the macrophage does not have the capacity to sustain the high

output production of NO required to cause neurotoxicity. It is more likely that the toxic amounts of NO come from astrocytes stimulated by the macrophage (124).

Macrophage activation during HIV-1 infection may occur by several mechanisms. Pro-inßammatory cytokines such as IFN-γ and TNF-α are potent macrophage activators. TNF-α allows astrocytes and macrophages to amplify the immune activation, resulting in co-activation of other macrophages. T-cells will also activate macrophages by cytokines as well as by direct contact. Activated T-cells will enter the blast phase and enter the CNS. As they migrate through the parenchyma, they secrete the cytokines that serve as a source for macrophage activation (115). As these T-cells die in the brain, their debris is removed by the brain macrophages, also contributing to macrophage activation.

Other mechanisms of macrophage activation involve injury of the axon. Axonal injury results in activation of microglia in the CNS. For example, injury to peripheral processes such as the axon of a motor neuron causes activation of the microglia within the anterior horn. Another theory is that there is exhaustion of T-cells late in the disease state, with compensation by granulocytes and phagocytes that are excessively stimulated. Chemokines are yet another method of macrophage activation. MIP-1β and RANTES act through CCR5 on the cell surface, and SDF-1α through CXCR4. Fractalkine binds CX3CR1 to mediate macrophage recruitment and activation. The mechanisms that involve cytokine and chemokine receptors promote activity of the p38MAPK. This in turn phosphorylates the transcription factorMEF2C. It has been shown that this p38 signal pathway is important in the activation of microglia (125). Inhibition of this pathway prevents the induction of TNF-α and iNOS in microglia (126).

MECHANISMS OF NEURONAL INJURY

Apoptosis

Ultimately, the pathologic processes that occur during progressive HIV-1 infection of the nervous system result in neuronal injury. Histopathological evidence demonstrates neuronal morphological and functional changes during HIVE including a decrease in synaptic density and vacuolation of dendritic spines. Interestingly, however, quantitative analysis of neuronal loss from post-mortem studies of patients with HIV-1 and neurologic dysfunction has not demonstrated a clear correlation between the magnitude of neuronal loss and neurologic disease. A thorough neuropathologic examination of archival post-mortem brain specimens from patients with HIV-1 infection conÞrms that neuronal apoptosis correlates with cerebral atrophy, but not pre-mortem cognitive disorders (127). Nonetheless, apoptosis appears to be the primary mode of neuronal death during progressive HAD and has been found early in the disease state (128,129). Injury and death of neurons by this mechanism is not the result of a single cause (127), but a consequence of multiple mechanisms by the activated MP. Neuronal apoptosis is triggered by calcium inßux. The calcium inßux may result from *N*-methyl *D*-aspartate receptor (NMDAR) dysfunction or other mechanisms. Regardless of the cause, the end cascade is the same. In this context, intracellular calcium triggers p38MAPK to induce chromatin condensation. Mitochondria react to increased calcium by releasing cytochrome-C (cytC) and reactive oxygen species (ROS). CytC subsequently activates caspases that cause chromatin condensation. ROS and free radicals generated in the cascade result in lipid peroxidation and eventual chromatin condensation leading to neuronal death. CXCR4 expressed on neurons may activate p30MAPK and induce apoptosis when bound by SDF-1 of gp120 (122). Indeed, the discovery of HIV-1-binding sites (chemokine receptors) on neurons and glial cells provides fresh insights into the pathways of neural injury during HAD, a rapidly expanding Þeld in NeuroAIDS research (122). Elucidation of the intracellular signaling events that control neuronal apoptosis could provide new approaches for therapeutic interventions.

Chemokines have been found to be inßuential in the signaling involved in neuronal apoptosis (Fig. 5.4). The α-chemokine receptor CXCR4 is expressed by neurons in many areas of the brain (130). The presence of this chemokine receptor may make these neurons susceptible to injury and apoptosis after exposure to gp120 or SDF-1. Soluble HIV-1 gp120 will bind CXCR4 on neurons in a CD4 independent mechanism, and induce neuronal apoptosis (118,131Ð133). SDF-1, the natural ligand for CXCR4, will also stimulate neurotoxicity (134). SDF-1 production is upregulated in astrocytes exposed to soluble factors from activated macrophages (132). SDF-1 is at increased levels in the CNS of demented AIDS patients. CXCR4 is the chemokine receptor preferred by T-tropic virus predominating in late infection and may be an important mechanism for apoptosis in late disease (135). Recent work demonstrates that activation of CXCR4 by SDF-1 induces a signaling cascade that leads to rapid extracellular release of TNF-α from astrocytes and microglia. Autocrine/paracrine TNF-α-dependent signaling inßuences prostaglandin production affecting glutamate release from astrocytes. The interplay between microglia and astrocytes occurs when activated microglia cooperate with astrocytes in the production of pro-inßammatory cytokines (for example, TNF-α) after CXCR4-SDF-1 engagement. This process is thought to lead ultimately to neuronal apoptosis. Thus, there are a variety of ways in which SDF-1-CXCR4 activation may affect neuronal injury during HAD (8).

Pro-inßammatory cytokines from activated or infected MP mediate neurotoxicity by a variety of ways. TNF-α and IL-1β are both major mediators of neuronal injury.

First, both cytokines can stimulate the release of L-cysteine, an excitatory amino acid from macrophages (30). Second, IL-1β inhibits long term potentiation (136). Third, TNF-α can act synergistically with Tat to induce oxidative stress and apoptosis (137), and is involved in the pathway to apoptosis by HIV-1 gp120. Lastly, TNF-α is elevated in the CSF of demented AIDS patients and can directly induce apoptosis (138).

HIV-1 Proteins

The viral proteins implicated in HIV-1 neuropathogenic processes include Tat, Nef, Vpr, gp120, and gp41. Neurotoxicity may be mediated both through direct and indirect mechanisms. HIV-1 gp120 can cause apoptosis by binding CXCR4 on neurons (118,131–133) and is able to elevate intracellular calcium through voltage gated calcium channels and *N*-methyl *D*-aspartate receptor (NMDAR) channels (139–144), as well as by mobilizing intracellular calcium stores (145). The rise in intracellular calcium is an indirect effect mediated by macrophage and microglial release of the excitatory amino acids cysteine and quinolinate. It is thought that HIV-1 gp120 primarily acts by inducing macrophage and microglia to secrete neurotoxins (125). This is potentiated by the ability of HIV-1 gp120 to impair glutamate uptake by astrocytes (119).

The HIV-1 protein Tat is implicated in neuronal injury both indirectly via release of soluble factors from macrophages (78), and by direct neurotoxicity. Tat has been found to potentiate excitotoxicity in neurons (146,147). Moreover, matrix metalloproteinases may be involved in the mechanism of Tat induced neurotoxicity (148). As discussed, there is some synergy with TNF-α to cause neurotoxicity (137). Tat has been shown to interfere with the electrophysiological activity of neurons (139). There is also evidence of signiþcant quantities of Tat measured in CSF of demented patients (149).

In addition to the complex interactions of HIV-1 gp120 and the recently studied effects of Tat on neurons, other viral proteins have neurotoxic properties. The protein HIV-1 gp41 was found to result in elevation of inducible NO synthase (iNOS) (112). Also, Vpr can have direct neurotoxic activity *in vitro*. The mechanism of this effect is by formation of cation permeable channels (150).

Other Mechanisms for Neuronal Injury in HAD: Oxidative Stress

Oxidative stress plays a signiþcant role in the neuropathogenesis of HIV-1. Free radical formation combined with impaired antioxidant capabilities brings about this stress (151). The free radical species in this situation are superoxide anions, nitric oxide, and peroxynitrite. NO is produced by neurons in response to excitation and changes in intracellular calcium. Neurons can be exposed to additional NO released from astrocytes, macrophages, and microglia which have been stimulated with pro-inßammatory cytokines such as TNF-α and IL-1β, HIV-1 gp120 (152,153), or HIV-1 gp41 (112). These stimulants upregulate the inducible isoform iNOS (154,155).

The major effector of oxidative stress is peroxynitrite. NO alone is also neurotoxic. However, when it combines with superoxide to form peroxynitrite, the effect is much more signiþcant. NO as discussed is produced by neurons, BMVEC, astrocytes, and MP. Superoxide anion comes from activated infected MP (154). One of the ways in which peroxynitrite damages neurons is by targeting neuroþlament, a structural protein (156).

HIV-1 infected patients lack the antioxidant glutathione and have reduced levels of the hydrogen peroxide scavenger, catalase, in CD8+ T-cells. These factors contribute to an impaired ability to clear free radicals. In addition, the levels of iNOS in HIV-infected patients are elevated. This elevation is even more signiþcant in demented AIDS patients (154). These factors all contribute to a chronic state of oxidative stress in HIV-1 infected patients.

Excitotoxicity is brought about by repeated and excessive stimulation of NMDA receptors on neurons. Overactivation of this receptor allows calcium inßux into the neurons, which in turn leads to apoptosis (122). If, however, the overstimulation is rapid, necrosis may ensue due to ionic imbalances (157). Stimulation of the NMDAR can be accomplished by glutamate, L-cysteine (30), quinolate (60), and Ntox (122). Other mediators can cause excitotoxicity indirectly. Platelet activating factor (PAF) is secreted by activated macrophages in response to TNF-α (Perry, 1998 #6443. PAF is a neurotoxin (24) causing glutamate release in the CNS (158,159) and increased calcium inßux in neurons (160). Other factors including HIV-1 gp120 have also been found to increase calcium inßux in vulnerable neurons (161).

Neuroprotective pathways are also operative. Activation of CCR5 on the neuronal surface by RANTES or MIP-1α interferes with HIV-1 gp120 and NMDAR associated toxicity (125,162,163). Fractalkine binding to CX3CR1 is neuroprotective for apoptosis induced by HIV-1 gp120, Tat or PAF (133,164). This mechanism is dependent on Akt activation, a protein kinase signaling pathway in neurons (160).

ANTIRETROVIRAL THERAPIES

Productive viral replication is a necessary component of the neuropathogenesis of HAD supporting the pivotal importance of antiretroviral agents in the prevention, treatment and reversal of dementia. This approach is both logical and well founded in disease mechanisms and is

supported by a multitude of basic and applied research studies. Nonetheless, despite remarkable recent advances made in the treatment of HIV disease, effective therapies for HAD remain incomplete. Remarkably, zidovudine is the only drug to date with clinical trial data demonstrating efficacy in the treatment of dementia (165–169). BBB penetrance, optimal dosing, the interface between peripheral and CNS viral load and the potential role of antiretroviral therapies in prevention of dementia remain unclear.

Potent antiretroviral combination therapies have been shown to suppress plasma viremia below the limit of detection of currently available assays, increase CD4+ T lymphocyte counts, and improve morbidity and mortality (31,170). Encouragingly, reports already suggest improvement in neuropsychological test performance and radiological abnormalities after initiation of therapy with protease inhibitors (26,28,29,171,172). Because neurologic disease does not correlate with neuronal loss, but rather the relative burden of MP in vulnerable brain areas, the question arises whether HAD is due to, in part, a reversible metabolic encephalopathy. Profoundly demented patients treated with triple anti-retroviral therapy at our center have evidenced dramatic reversal of cognitive impairment, concomitant with a reduction of viral load in plasma and CSF (173). Significantly, this was accompanied by a more profound reduction in levels of potential neurotoxins in plasma and in CSF. In further support of this concept, Fox et al. (173a) showed that when SIV-infected rhesus macaques were treated with antiretrovirals, neuropsychological deficits were ameliorated. Sensory evoked potentials (SEP), a measure of the integrity of brainstem polysynaptic pathways in response to an event-related stimulus (such as light, sound, or recognition of a singular event in a stimulation pattern), were also improved without reversal of motor deficits. Cessation of treatment led to a return of neuropsychological deficits and abnormal SEP. Because the brain-resident MP is the productively infected cell type in the CNS, there is ample evidence to demonstrate that they are the major source of candidate HIV-1 neurotoxins. Taken together these data strongly support the notion that HAD is a metabolic encephalopathy, and can be reversed, at least in the earliest stages of disease, by potent combination antiretroviral therapies.

Many of the available antiretroviral compounds are highly plasma protein bound, and therefore do not have good penetration of the blood-brain barrier (174). The degree to which some newer drugs in development penetrate the CSF is not known, and CSF penetration of available protease inhibitors is negligible (175–180).

Whether or not CNS penetration is critical, or whether suppression of plasma viremia may be adequate for prevention and treatment for CNS HIV-related diseases, is not known. Some experts believe that inclusion of a drug with good CSF penetration in antiretroviral combinations is an important component, although there are few data to guide the practicing physician. Combination antiretroviral therapy has been shown to decrease CSF HIV-1 RNA levels despite poor drug penetration (176,181,182). However, some investigators are concerned that the CNS may continue to present a potential viral sanctuary despite antiretroviral drugs (32,78). Reports of patients receiving and responding to antiretroviral therapy as evidenced by undetectable plasma viremia, while still developing CNS dysfunction, are disquieting (183). Preliminary findings support compartmentalization of virus with independent evolution in CSF and plasma (61,184,185). Autopsy studies suggest that tissues in which the main target for HIV-1 is the macrophage, predominantly the CNS, harbor viral sequences that cluster separately (186).

Moreover, 40–60% of patients in clinical practice will have detectable viremia after more than one year on combination therapy (187–190). High baseline viral load, low CD4+ T cell count, previous antiretroviral therapy, and non-adherance all contribute to risk of virologic failure (191). Drug exposure, as determined by adherence, absorption and metabolism is also an important factor. Although definitive evidence is lacking, limited drug penetration into tissues may allow for ongoing viral replication and further contribute to failure of antiretroviral therapy. Experts in the field believe that it is premature to conclude that control of viral replication in the periphery will prevent HIV-1-related CNS disease (32).

ADJUNCTIVE THERAPIES

As described above, the dementia produced by CNS infection with HIV elicits a cascade of events involving both resident and invading cell types and ultimately the devastating loss of neuronal function and cognitive deterioration. As the disease process occurs in a stepwise fashion it provides an opportunity for development of therapeutics directed at discrete pathogenic mechanisms (Fig. 5.5). Based on a clearer understanding of the neuropathogenesis of HIVE and HAD, the selection of rational adjunctive therapies for HAD has now been developed. There are several reasons for demand for such therapies. First, PCAT, while successful in decreasing viral burden and delaying the onset of HAD, does not prevent it. Second, combination antiretroviral therapies are not always well tolerated. Third, only a very limited fraction of the global population of HIV-infected persons has access to PCAT. This is not likely to change in the immediately foreseeable future. Fourth, because HIV-1 has an evolutionary advantage in its ability to adapt to most of the PCAT agents, and since most PCAT agents do not freely cross the blood-brain barrier, the need for adjunctive neuroprotective agents is likely to increase in future years. Fifth, overlapping pathogenetic mechanisms

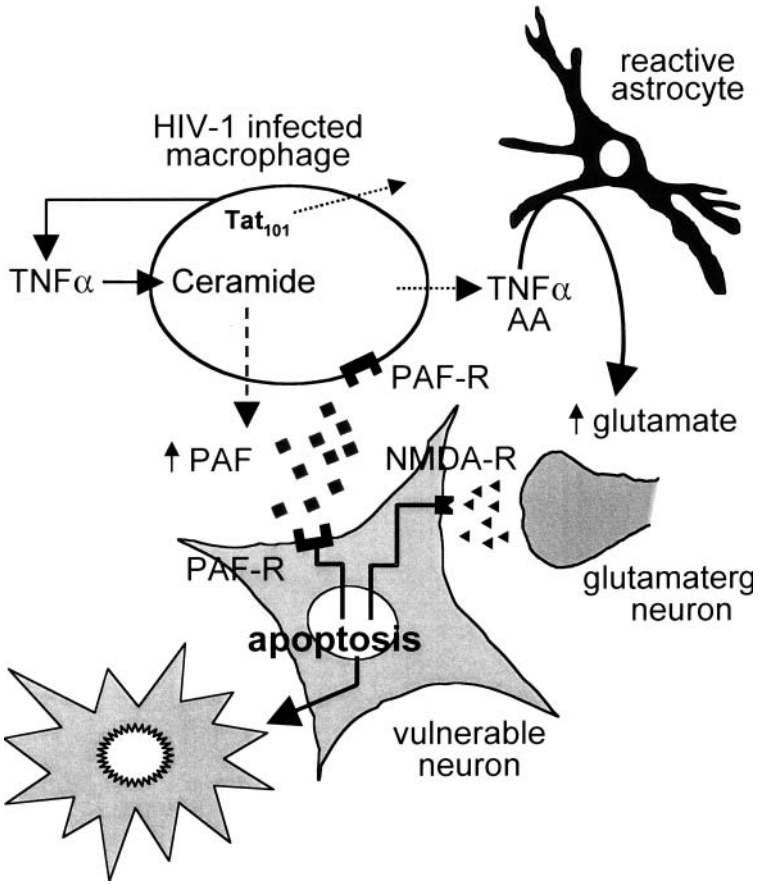

FIG. 5.5. MP neurotoxins including Tat, TNF-α, and PAF may also have direct effects on vulnerable neurons. Tat has been shown to induce hippocampal CA1 neuron depolarization, probably via a non-NMDA receptor mechanism, and induce neuronal apoptosis via a mechanism independent of nuclear factor kappa B (NFκB) activation. TNF-α can induce neuronal cell death in part by activation of non-NMDA (for example, AMPA) receptors. This TNF-α-induced neuronal death has the biochemical and morphologic features of apoptosis, involves oxidative stress, and is independent of NFκB activation. PAF can also induce neuronal cell death through apoptosis via a mechanism that involves activation of NMDA receptor channels. Because these three neurotoxins appear to work in part through activation of non-NMDA and NMDA receptors, it is important to note that NMDA receptor activation and production of nitric oxide (potentially through HIV-1 gp120) can also induce neuronal apoptosis.

are operative for other neurodegenerative diseases containing an inßammatory component (for example, AlzheimerÕs disease and stroke), making it likely that agents will have Ò cross-overÓ potential for a treatment of a wide range of neuro-destructive processes.

Based on these observations and despite diverse mechanisms of actions, a number of promising small molecules have already been identiÞed and are currently being used or soon will be employed for therapeutic trials in man. Outlined below are several adjunctive therapies which are being developed for treatment of HAD. Each act independently both of the viral life cycle and of conventional antiretroviral agents and affect secondary neurodegenerative processes elicited by MP secretory products. They include anti-inßammatory, neuroprotective and neuroregenerative compounds, which either target speciÞc neurotoxins, a wide range of toxins or protect neurons against their Ò down streamÓ effects. Because of the numbers of such drugs now developed, we have selected a few to review and describe their proposed mechanisms of action and possible clinical utility.

In AIDS Clinical Trial Group protocol 162, 41 HIV-1 infected patients with varying degrees of dementia were examined for whether nimodipine, a calcium channel blocker (192), could affect disease outcome. The results showed that nimodipine was safe, but the study was not sufÞciently powered for efÞcacy, and only a trend toward improvement in neuropsychological performance was seen. Clinical trials of other compounds are under way and described below.

GSK-3 Inhibitors

Some of the adjunctive drugs now being developed for treatment of HAD have had indications for other inßammatory-based diseases or are in general use for other secondary disease processes associated with progressive HIV-1 infection. One example is sodium valproate (VPA). Interest in VPA for treatment of HAD has increased recently as it is known that the drug possesses neuroprotective properties because it inhibits GSK-3 beta activity (193), and because of its cytoprotective effect on neurons exposed to HIV-1 neurotoxins. VPA has already been used in HIV-1 infected individuals to manage psychiatric disorders, and the drug appears to be generally well tolerated. Although the compound has never been systematically examined, it has no known adverse interactions with anti-retroviral agents. Thus, VPA represents an excellent potential candidate for neuroprotection in patients with or at risk for HAD. VPA is preferable to the other presently available inhibitor of GSK-3 beta, lithium. One conceptual concern for the use of VPA in persons with

HIV-1 infection is that it has been shown to enhance HIV-1 replication in certain cultured cell lines (194). This observation has not been reproduced, however, in biologically relevant primary host cells including macrophages and CD4+ T lymphocytes.

Dopaminergic Agents

A second class of therapies is dopaminergic agents. The utility of such compounds is based on data obtained in cell culture model systems, which have shown that HIV-1 gp120 is toxic for dopaminergic neurons (195). Studies have also shown that HIV-1 Tat can inhibit the activity of tyrosine hydroxylase, the major rate-limiting enzyme in the dopamine biosynthetic pathway. Furthermore, *in vivo* injection of HIV-1 Tat into the striatum of healthy rats induces a subclinical Parkinson's-like disease. Moreover, in HIV-1 infected humans, neurologic disease has been linked to changes in dopamine metabolism, and dopamine levels within the CSF are reduced. Based on these findings, it has been proposed that alterations in dopamine metabolism may contribute to motor deficits in persons with HAD. Pramipexole is a dopamine agonist with antioxidant and neuroprotective properties in small animal model systems and has been used particularly in the context of MPTP-induced injury, and ischemia (196–199). It has been shown to upregulate the expression of anti-apoptotic proteins such as Bcl-2, and to protect cultured neurons from pro-apoptotic insults (200). Bcl-2 and other anti-apoptotic gene products may represent the final effector proteins, which are responsible for NFκB-mediated neuroprotection. Furthermore, Bcl-2 can mediate neuroprotection against candidate HIV-1 neurotoxins, including HIV-1 Tat and TNF-α. Pramipexole has also been shown to have a beneficial effect in the context of Parkinson's disease, based on its dopaminergic properties. This drug has not yet been studied to any significant degree in the context of HIV-1 infection.

PAF Receptor Antagonists

PAF is a phospholipid mediator that may play a key role in NMDA receptor activation in HAD, as described above in the section on HIV-1 induced neurotoxins. Intriguingly, *in vivo* experiments using the SCID mouse model of HIVE demonstrate that PAF receptor antagonists are neuroprotective. A recent Phase I trial of the PAF receptor antagonist, lexipafant, in a cohort of patients with varying stages of HAD, demonstrated trends in improvement of neuropsychological parameters including verbal memory (201). Ongoing strokes are investigating the use of this compound in the setting of PCAT and other adjunctive therapies with distinct targets of action.

Glutamate Receptor Antagonists

It is well accepted that the neuronal dysfunction and death that occurs in HIVE and is associated with HAD may ultimately be mediated by pathologic activation of excitatory subtypes of glutamate receptors, in particular the NMDA receptor. Numerous examples in the literature demonstrate involvement of NMDA and non-NMDA receptor activation in vulnerable neurons after exposure to HIV-1 associated neurotoxins. One problem in designing a practical therapeutic approach to ameliorating excitotoxic neuronal damage is that most of the available small molecule agents that block ionotropic receptor function are uncompetitive or noncompetitive channel antagonists. Thus, administration of such an agent at concentrations that might be neuroprotective in the CNS might also significantly interfere with fast excitatory neurotransmission and thus have untoward clinical effects. Thus far the most promising NMDA antagonist currently in clinical trials for HIV-1 related neurologic disease is memantine, which appears to lack the side effects of dizocilpine. Recent clinical trials have not, however, demonstrated a significant positive effect on HAD.

SUMMARY

This chapter demonstrates both how far we have come and how far we still need to go in beginning to understand fully how HIV-1 infection of the brain results in neuronal injury and death. Aside from the significant morbidity induced by HIV-1 for cognitive, motor and behavioral function, the CNS represents an important reservoir for continuous virus production and the emergence of viral strain variance. Moreover, the mechanisms of how MP secretory products may damage neurons have potential wide applicability for other neurodegenerative disorders where inflammation is an important component of disease pathogenesis (for example, Alzheimer's disease, Parkinson's disease and amyotrophic lateral sclerosis). Finding potential strategies to retard the expression and effects of such neurotoxins remain one important primary goal for biomedical research efforts. Adjunctive therapies such as NMDAR blockers, chemokine and cytokine effectors, antioxidants, caspase inhibitors, and p38MAPK inhibitors, are all potential interventions and are being developed by many laboratories. If successful, these drugs may find utility in a broad range of neurodestructive processes.

Over, the past 18 years, since the first description of the neurological complications of HIV-1, surprising changes in the way we think about virus persistence and its abilities to elicit CNS inflammation and concomitant neurotoxicity have emerged. The frequency of and propensity for HIV-1 induced neurological disease represent some of the more significant realizations in AIDS research. Such information is essential for vaccine design, in understanding viral resistance and in utilizing pharmacological approaches to

reduce or perhaps eradicate viral infection in the CNS. Moreover, the uncertainty of the long-term efficacy of PCAT therapies suggests that neurological disease could increase in the future and other therapeutic modalities need be developed. Such adjunctive therapies should focus on brain inflammation brought about through MP neurotoxins. It is, after all, these inflammatory toxins that contribute in significant measure to a reversible state of neuronal dysfunction (a metabolic encephalopathy) that includes impairment of neuronal function and synaptic transmission. Importantly, many of the hallmarks of HIV-1 neuropathology are seen in chronic inflammation, have parallels to other neurodegenerative processes, and follow defective MP secretory function. Such observations provide an impetus for development of adjunctive therapies and support the hypothesis that rational therapeutic approaches for treatment should include compounds that intercede in critical steps of the pathogenic sequence and ultimately lead to reduced CNS inflammation. As can be seen by the information given in this chapter, the accomplishments made in basic and applied research into the neurological aspects of HIV-1 infection are significant and have brought about advances in the understanding of the disease process, its relatedness to other neurodegenerative disorders and therapeutic directions.

ACKNOWLEDGMENTS

The authors thank Ms. Robin Taylor for outstanding administrative, graphic and editorial assistance without whose dedication the work would not be completed. We also thank the scientists in the Center for Neurovirology and Neurodegenerative Disorders whose work is reflected in this review and remain a constant source of new ideas, information exchanges and vision for research in this field and include Drs. Yuri Persidsky, Tsuneya Ikezu, Anuja Ghorpade, Jialin Zheng, Huangui Xiong, Jenae Limoges, Larisa Poluektova, Annemarie Shibata and Kimberly Carlson.

Chapter 6

Viral Cofactors in the Immune Pathogenesis and Clinical Manifestations of HIV Infection

Jeffrey Laurence

"PathogenicityÓ refers to the ability of a microorganism to cause disease; ÒvirulenceÓ deÞnes variations in the magnitude of this effect (1). All replication competent isolates of HIV-1, -2 disrupt the immune systems of their human hosts. The intriguing differences are ones of degree.

But can exogenous factorsÑfor the purposes of this chapter, other virusesÑalter HIV virulence, shifting the balance between populations of quiescent, uninfected and latently infected T cells vs. virally-activated T cells, which may die either as a consequence of activation or via HIV-mediated cytolysis? There is *in vitro* evidence, and mounting clinical data, that this may be the case.

Virulence is a property of host-parasite interactions, but host Þtness is exceedingly difÞcult to assess in nature. Investigations of the extremes of this interplay in HIV infectionÑthe rapid progressors to AIDS versus long-term delayed (Ònon-)Ó-progressors (2)Ñsuggest models by which to sort out protective vs. pathologic mechanisms in HIV infection. These observations also provide an opportunity to assess the role of cofactors in the progression of HIV disease.

BACKGROUND: HIV KINETICS AND DISEASE PROGRESSION

To understand the impact of exogenous viral infections on HIV, we need to review the kinetics of HIV growth *in vivo*, and its transcriptional regulation, as deÞned *in vitro*. The marked differences in average viral load at various immunologic and clinical stages of HIV disease, coupled with the extraordinarily high turnover of HIV virions ($\sim 10^9$/day) and the rapid death of productively infected CD4+ T cells *in vivo* ($t_{1/2} = 2.0 + 0.9$ day), attest to the complex regulatory control of HIV replication (3Ð5). Some 99% of circulating HIV appears to derive from cells with a half-life of one to two days, suggesting that repetitive cycles of *de novo* infection, virus production, and cell destruction clearly occur. But the fact that CD4+ and CD8+ T cell turnover are virtually identical in HIV disease, while CD4+ T cells alone are HIV infected, argue for the prominence of indirect mechanisms of T cell death, and perhaps interference with precursor cell production or maturation in the thymus gland, bone marrow and elsewhere (3,4).

The 1% of HIV-infected cells that harbor latent virus, as well as ongoing viral replication in T cells at levels that are not detectable by standard measures of viral load, may play critical roles in the later stages of HIV disease. These and other reservoirs, existing in a milieu complicated by rapid development of drug resistant strains, and little affected by current highly active antiretroviral therapies (HAART) (5), may underlie the perplexing failure of our best anti-retroviral agents, alone or in combination, to effect more than a 2Ð3 log decrease in viral burden, along with the failure to normalize CD4:CD8 T cell ratios (4).

HIV also may be transiently rescued from latently infected cells by modulators of cell or HIV activation, providing another avenue by which viral cofactors may accelerate or, in certain cases, mitigate HIV replication. Indeed, studies begun over 30 years ago by the co-discoverer of reverse transcriptase, Dr. Howard Temin, demonstrated that the state of host cell activation at the time of a retroviral infection inßuences reverse transcription and retroviral expression (6). Either direct cofactor virus infections, or cytokines induced by such infections, could provide such cell stimulatory signals. These activation signals appear to be key factors in the T cell depletion characteristic of HIV/AIDS.

Jeffrey Laurence, M.D.: Professor of Medicine, Weill Medical College of Cornell University and New York Presbyterian Hospital, New York 10021.

Dr. William Paul, an early director of the federal Office of AIDS Research, and his associates summarized our current under-standing of T cell dynamics as affected by HIV stating, ÒThe intuitively appealing but simplistic vision of an ongoing competition between massive destruction and massive replacement of CD4+ cells (the Òtap and drainÓ model) is still energetically advocated by some. Others envision a classical confrontation between protective immune responses and an evasive virus. But a growing body of evidence and reasoning point to infection-induced immune activation both as the driving force behind virus replication and as a facilitator of CD4+ cell depletionÓ(7).

HIV infection results in high levels of activation and turnover of both CD4+ and CD8+ T lymphocytes. These cells then undergo several rapid rounds of cell division, finally dying by apoptosis, a phenomenon referred to as activation-induced cell death (AICD). Those few activated cells which escape such a fate enter, or re-enter, the population of resting, memory T lymphocytes (7). Large numbers of T cells may also be stimulated by antigens from HIV or co-infecting microorganisms, and the pro-inflammatory cytokines they induce.

It might be anticipated that each new cycle of immune activation in HIV infection would add to the memory pool. But, in the presence of persistent antigen and inflammation, as often occurs even in the most stable patients on HAART (8), the net change in memory cells appears to be a negative one, and a shifting steady state is realized. Normally, production and elimination of T cells is perfectly balanced, with Òelimination Ó including entry of naive and effector T cells into the memory compartment. But this homeostasis is disrupted in HIV infection as, with time and further increases in immune activation, the total T cell number is progressively shifted downwards.

This is particularly bad news when one considers that HIV appears to specifically infect the very cells that respond to it (9). In one study, HIV-specific vs. cytomegalovirus (CMV)-specific CD4+ memory T cells producing interferon-γ were obtained from 12 HIV-infected individuals (9 on HAART), sorted by flow cytometry, and compared with their unstimulated CD45RO+ general memory pool (9). Quantitative DNA PCR was used to determine viral copy number in these cells. There was no significant difference in terms of HIV load in CMV-specific vs. pooled memory CD4+ T cells; most of the HIV sat in the HIV-specific T cell pool. The total fraction of HIV-specific CD4+ T cells was relatively lowÑ 1.01% for those off therapy and 0.89% for those on HAARTÑ but the ratio for HIV DNA in HIV specific vs. other CD4 cells was high, varying from 2.1 to 5.3 (9). The authors concluded that, Òthis preferential but low-frequency infection of HIV-specific and other activated T cells may represent an evolutionary adaptation that enables persistent infection in an otherwise immunocompetent host, and prolonged host-parasite coexistenceÓ(9).

This also suggests that the salutary effects of HAART therapy may be based on something more than just suppressing viral replication. For example, Nobel laureate Dr. Rolf Zinkernagel has long argued, prior to any HIV kinetic studies or the clinical use of HAART, that immune activation, particularly of cytolytic CD8+ T lymphocytes (CTL), contributes greatly to the pathology of certain viral diseases, including AIDS (10). His group noted that certain protease inhibitors (PIs) markedly inhibit antiviral CTL activity and impair MHC class I-restricted viral epitope presentation in a mouse model of a persistent viral infection, lymphocytic choriomeningitis virus (LCM). They do so by selectively inhibiting the chymotrypsin-like activity of the 20S proteasome, an activity critical to viral epitope presentation (11).

Dr. Zinkernagel and associates proposed that while anti-HIV CTL contribute to initial control of viral replication, ÒAIDS may partially result from immunopathological damage by anti-HIV CTLs, (and) the direct effects of ritonavir on class I-restricted Ag (antigen) presentation may reduce the immunopathological destruction of Ag-presenting cells, CD4+ lymphocytes, and other HIV-infected cellsÓ(11). The concept of immune activation, and possibly related autoimmune phenomena, as important to immune pathogenesis in AIDS received a boost from clinical trials of immune suppressants in acute HIV infections, as detailed at the end of this chapter.

BACKGROUND: A MOLECULAR APPROACH TO VIRAL CO-FACTORS FOR HIV TARGET CELL ACTIVATION

Viral persistence may be viewed at three distinct levels: persistence in the population as a whole, in the individual host, and within a cell or group of cells (12). In terms of the latter, viruses may survive, despite an intact immune system, by limited growth in a cell population (carrier state); continuous multipli-cation without eliciting cytopathic effects (steady-state infection); true latency (complete absence of viral transcripts and protein); or cell-to-cell passage without maturation (intracyto-plasmic persistence, characteristic of infection of cells which normally remain in Go, such as monocytes) (12).

As noted above, 99% of HIV is produced by actively infected cells, but the small pool of latently infected cells appears to be a critical source for reactivation of virus. HIV has adopted a transcriptional strategy in both T cells and monocytes which resembles that used by cellular genes regulating T cell signalling and growth (13), with HIV replication modulated by a variety of signals to cell differentiation, activation, and/or proliferation (14). HIV growth can be dissociated from cellular proliferative responses, with both mitogenic and non-mitogenic activation signals provided by cofactor virusesÑ through antigen and superantigen stimulation, receptor cross-linking, and promotion of cytokine releaseÑ sufficient to induce HIV transcription (15).

Initiation of HIV reverse transcription occurs simultaneously in both activated and quiescent T lymphocytes, monocytes, and probably other cell types, but it terminates prematurely and proceeds more slowly in quiescent cells. Stimulation of such cells may reinitiate DNA synthesis off of partial reverse transcripts, but this mode of viral rescue is highly inefficient (16). And proviral DNA in quiescent cells is labile, degrading with a $t_{1/2}$ of <24 hrs *in vitro*. This may partially account for the low number of infected cells in the peripheral blood of most asymptomatic HIV-1 seropositive individuals (17).

VIRAL ANTIGENS AND SUPERANTIGENS

Cofactor viruses implicated in AIDS tend to be highly antigenic. For example, during antigen-specific immune activation, 100-fold less HIV-1 is required to initiate a productive infection in cultures which attempt to mimic the lymphoid microenvironment: CD4+ T cells admixed with HIV-pulsed dendritic cells (18). Optimal stimulation of CD4+ T cells requires engagement not only of their T cell receptor (TCR)/CD3 complex by antigenic peptides presented in the context of MHC-II, a process often referred to as "signal 1", but also critical co-stimulatory ("signal 2") events provided by cross-linking of accessory receptors on the T cell surface with ligands on antigen presenting cells (APCs), including dendritic cells, monocyte/macrophages, B lymphocytes, endothelial cells, and possibly CD4+ T cells themselves (19). These latter ligands include the β_2 integrin LFA-I (CD 11a), CD2, and CD28. Their engagement leads to translocation of protein kinase C, required for expression of previously silent cellular and viral genes, changes in cell phenotype, and entry of cells into G1 of the cell cycle. While signal 2 alone has no observable effects on APC or T cell phenotype (19), in the form of a B7-CD28 interaction it is sufficient to induce transcription and replication of HIV in naturally infected T lymphocytes (20). Subsequent progression through the cell cycle, as opposed to simple T cell activation, is dependent upon three main factors: local IL-2 concentration, IL-2 receptor (R) density on the cell, and the duration of the IL-2/IL-2R interaction. These aspects may be modulated, positively or negatively, by cofactor virus infections.

Viral cofactors may also activate HIV cell targets via superantigen (SAg) phenomena (21), blockade of factors linked to suppression of viral and cell growth, or do both. For example, mycoplasmas can enhance HIV replication, at least *in vitro*, both by inhibiting production of the antiretroviral product α-interferon and by cross-linking CD4+ T cells of specific TCR V_β subytpes, a SAg phenomenon leading to cell activation (22). Cytomegalovirus (CMV) is another potent superantigen in the stimulation of HIV replication (23,24). But, despite some early reports (25), it is unlikely that HIV itself serves as a SAg.

All these processes set two basic cellular events into motion: induction of sequence-specific cellular transcriptional factors, and chromatin reorganization to permit effective interaction of the induced factors with their proviral targets. Both can enhance uptake and integration of newly acquired HIV, or promote viral induction in latently infected hosts.

MECHANISMS FOR UPREGULATION OF HIV IN ACTIVATED HOST CELLS

One general pathway by which viral cofactors, in activating normal host cells, can in turn promote HIV replication involves NF-κB, a member of the *rel* family of transcriptional enhancers. It is found in nearly all eukaryotic cells, coupled to an inhibitor, IκB, in an inactive form. Cell activation, with or without cell proliferation, leads to upregulation of a variety of protein kinases one of which, IKK, in phosphorylating IκB, permits translocation of NFB to the nucleus, its binding to transcriptional enhancer sequences of the HIV LTR, and facilitation of RNA polymerase II activity (22). This induction of NF-κB transforms the HIV LTR into a type of housekeeping gene promoter, increasing the assembly of general transcription factors on the LTR to form pre-initiation complexes. It also proscribes transcriptional inhibition through cellular factors such as p53. A variety of exogeneous viruses, including all of the herpesviruses, share the NF-κB pathway with cellular and HIV genes, and thus may activate both the cell, and HIV within that cell (23). Viruses may also modulate transcription of normal cellular proto-oncogenes and tumor suppressor genes, influencing cell activation through increases in production of growth factors related to c-*myc*, c-*myb* and c-*fos*, and perhaps factors from other proto-oncogenes. Finally, under certain conditions, indirect suppression of HIV replication may occur, as discussed later in this section.

CYTOKINES AND CHEMOKINES

Cytokines and the cytokine chemoattractants, or chemokines, are an important means by which viral cofactors impact both HIV replication and manifestations of HIV disease. One might have anticipated that HAART would abolish many cytokine-mediated phenomena, as there is a sharp decline in proliferating T cells following such therapy (26,27), in parallel with decreased production of IL-2 (27). But this decline may be accompanied by a significant rise in T cell secretion of TNF-α, a key factor in the stimulation of HIV replication. Whether this rise occurs in the majority of infected patients (27), or just a subgroup (8) is controversial. A list of the most prominent molecules linked to HIV and viral cofactors for HIV induction, acting by direct viral infections or mediated by soluble viral products, is presented in Table 6.1 (28).

The character and quantity of the cytokines and chemokines involved may differ depending on the stage of

TABLE 6.1. *Cytokines and chemokines induced by viral infections and viral proteins**

Virus	Viral Protein	Induced Molecules
HSV	gD	TNF-α, IFN-α/β
CMV	gB	IL-1, IL-6
EBV	gp350	IL-1, IL-6, IL-8, TNF-α, MIP-1α, GM-CSF
	LMP-1	IL-1, IL-6, IL-10
	EBNA2	IFN-α/β
HBV	HBx	IL-6, IL-8, TNF-α
	HBsAg	IL-2, IL-10, IFN-γ
	HBc/eAg	IL-10, TNF-α, IFN-γ
HTLV-I	Tax	IL-1, IL-2, IL-3, IL-5, IL-8, L-15, TGF-β, TNF-α, IFN-γ, MIP-1α/β, GM-CSF
HIV	gp120	IL-1, IL-4, IL-6, IL-8, IL-10, IL-13, TNF-α, IFN-α/β, IFN-γ
	Tat	IL-1, IL-2, IL-6, IL-8, TGF-β, TNF-α, MCP-1

*Table adapted from (28).

HIV infection. In acute HIV infection, serum concentrations of IL-2, as well as soluble IL-2 receptor (R), IL-1, IL-4, and the pro-inßammatory cytokines tumor necrosis factor (TNF)-α and IL-6, may be equivalent to healthy controls (29). In contrast, levels of most of these factors are markedly elevated in the setting of acute EBV (Epstein-Barr virus) or CMV infection (29).

Later in the course of HIV infection, levels of these cytokines become chronically elevated, but virus-mediated shifts in plasma concentrations may occur at any stage. Of particular interest is the ability of the T_H2 type of CD4+ T cell, in secreting IL-4 and IL-6, to blunt the differentiation of TH1 CD4+ T cells, required for mounting an effective cytolytic anti-HIV response. These T_H2 responses can be induced by infection with measles, vaccinia, herpes simplex viruses (HSV), and human T cell lymphotropic virus (HTLV)-I,II (24,28), along with many other microorganisms. That such changes may have a clinical impact is suggested by therapeutic trials of some of these agents. For example, high-dose IL-2 infusions in HIV-1+ patients leads to transient increases in HIV viremia, even in the presence of effective anti-retroviral therapy (30).

Apart from activating HIV target cells and rescuing HIV from latently infected cells, immunocyte secretory products induced by viral cofactors may also inßuence the type of AIDS pathology expressed. For example, many viral infections can upregulate production of chemokines which recruit inßammatory cells, HIV infected or not, into the central nervous system, and have been postulated to mediate neuropathology in AIDS (31).

VIRAL CO-FACTORS FOR DIRECT HIV TRANS-ACTIVATION

Viral co-pathogens may also serve to regulate HIV replication directly through several transcriptional and post-transcriptional events. The former effects are linked to speciÞc and promiscuous transcriptional factors encoded by all of the herpesvirusesÑ CMV, EBV, HSV-1,2, and human herpesvirus type 6 (HHV-6)Ñ as well as by hepatitis B (HBV), HTLV-I and -II, and papovaviruses (32).

NF-κB, proto-oncogenes, and tumor suppressor genes were mentioned earlier in the context of viral activation of cellular replication. Similarly, tumor suppressor genes may directly impact on HIV transcription. For example, the wild type p53 tumor suppressor gene product inhibits HIV-LTR-directed transcription through bridging of certain gene promoter sites, known as Sp1 and TFIID, in the LTR (33). This is consistent with the Þnding of high rates of HIV replication in metastatic colon carcinoma cells from HIV+ individuals (34), as such tumors typically contain mutant p53 incapable of complexing with the HIV-LTR. Certain viruses which commonly infect HIV+ individuals also encode proteins which can complex with and inactivate p53, thereby promoting HIV transcription. These include the HBV X protein, E6 of human papillomavirus (HPV), and EBV nuclear antigen (EBNA)-V. Immediate early proteins produced by CMV can *trans*-activate the HIV LTR, a phenomenon also documented with other viruses that frequently co-infect HIV+ individuals, including HTLV-I,II, EBV, HSV-1,2, and JC papovavirus (32).

Apart from direct *trans*-activation of the HIV-LTR, or suppression of p53 activity and thus indirect promotion of transcription, viruses common in HIV infected individuals may also facilitate HIV replication by other mechanisms. Unlike the DNA tumor viruses, for which the order of gene expression is transcrip-tionally regulated, this process is controlled entirely at the post-transcriptional level in HIV (35). EBV may act on HIV through its latent membrane protein (36), and parvovirus via an early non-

structural gene product (37). HSV-1 encodes a late gene product, Us11, which can post-transcriptionally activate the expression of HIV-1 envelope proteins via interaction with a regulatory protein of HIV, Rev, which regulates the nuclear export of certain HIV transcripts (38). Many of the herpesviruses and other viruses also induce cellular heat shock stress proteins, which can modulate HIV transcription (32).

It should be emphasized that the clinical signiÞcance of *in vitro* phenomena dependent upon co-infection of single cells with two viruses is of much less impact than the broad inßuences on HIV replication that might be elicited by indirect mechanisms such as activation of cell stimulation and cytokine production. Indeed, some viruses implicated as cofactors in HIV/AIDS grow preferentially not in typical HIV host cellsÑ CD4+ T lymphocytes, monocytes and microgliaÑ but in neuronal and epithelial cells, and they often inhibit host cell gene expression soon after infection (35). This would be expected to down-regulate HIV as it is dependent upon host cells to express its genetic material.

CLINICAL EVIDENCE FOR VIRUSES AS CO-FACTORS IN AIDS

Cytomegalovirus

Selection of an appropriate *in vitro* system to predict *in vivo* effects of any virus as a cofactor for HIV disease is important, but not yet established. For example, transient activation of HIV-1 by CMV products can occur in cells in which HIV gene expression is limited, but under conditions in which both HIV and CMV undergo fully permissive infection, CMV may *repress* HIV expression (39). A similar problem arises in experiments with other herpesviruses.

Clinically, the risk of developing AIDS among hemophiliacs in the 1.3 to 9 years from time of Þrst recognition of HIV seroconversion was 2.5 times greater in individuals who acquired CMV than in those who remained CMV seronegative ($P = 0.020$) (40). This correlation was supported by the Þnding that the mean decline in CD4+ T cells in HIV-seropositive/CMV seronegative asymptomatic individuals was 85 cells/mm^3/year, but 170 cells/mm^3/year in the CMV seropositive (41). The presence of multiple CMV strains in HIV-1+ homosexual men is also associated with progression to AIDS (42). The extent of peripheral HIV replication and the rapidity of CD4+ T cell decline is highly correlated with CMV antigenemia (43,44).

Findings from those early studies were recently conÞrmed in a French cohort of 290 subjects who were HIV+ but CMV seronegative at the time of enrollment (45). After a median follow-up of 85 months, there were 61 CMV seroconversions. Although the risk of progression to a CD4+ T cell count below 200/mm^3 was not increased in the seroconverters, the risk of progression to AIDS was increased 2.1-fold ($p = 0.01$) (45).

One might anticipate that immune reconstitution associated with HAART might mitigate the pathogenic effects of a latent or newly acuired CMV infection. However, antigen-speciÞc CD4+ and CD8+ T cell defects often persist despite HAART, and have been reported in association with recurrent CMV disease (46).

Human Herpesvirus Type 6

HHV-6 can infect myriad types of hematopoietic cells, including CD4+ T lymphocytes (32). Nearly all people in the U.S. show evidence of infection by age two, but only a few healthy individuals continuously secrete HHV-6 in their saliva and blood. HHV-6 can trans-activate the HIV-LTR and promote the release of cytokines which stimulate both cell and HIV proliferation. But, despite the ability of HIV and HHV-6 to co-infect cells, HHV-6 does not appear to predispose to or affect the course of HIV infection (47,48). Indeed, some studies indicate that HHV-6 can inhibit, rather than activate, HIV *in vitro* (49), and HHV-6 genomes are found at higher frequency in individuals with higher CD4+ T cell counts (50).

Regardless of the actual HIV/HHV-6 interactions, if any, which occur *in vivo*, HHV-6 pneumonitis may be a cause of signiÞcant pathology in the setting of HIV (51). There also may be a link between HHV-6 and the promotion of B cell lymphomas in HIV+ individuals (52).

Human Herpesvirus Type 7

HHV-7 infection is almost universal among people in the U.S. by age Þve. In contrast to HHV-6, up to 80% of adults actively shed HHV-7 in saliva. Clinically, it has been associated with a roseola-like infection, as has HHV-6. HHV-7 is also a CD4+ T cell-tropic herpesvirus, using CD4 as its high-afÞnity receptor (53). This suggests the possibility that competition between HIV and HHV-7 for CD4 sites might be used to inhibit HIV infection. *In vitro*, HHV-7 is a potent inhibitor of HIV infection in monocytes, despite the inability of HHV-7 to replicate actively in such cells (54).

Human Herpesvirus Type 8

HHV-8, or KaposiÕs sarcoma (KS) associated herpesvirus (KSHV), was originally discovered in KS tissue from HIV+ patients through the application of representational difference analysis to isolate DNA sequences in KS that were absent from DNA of normal tissue (55). It has a high degree of homology to two γ-herpesviruses, EBV in humans, and *Herpes saimiri* in monkeys (56). It is also

present in non-HIV associated KS, and in two disorders increased in incidence in the setting of HIV: a rare form of B cell lymphoma known as body cavity-based or primary effusion lymphoma, and Castleman's disease, a multicentric angiolymphoproliferative hyperplasia (57).

The exact role of HHV-8 in causation of these disorders, and in the progression of HIV disease in general, is unclear. Identification of HHV-8 genes with homology to cyclin D and G-protein-coupled receptors, factors which could confer oncogenic potential (57), support its clinical relevance.

Herpes Simplex Virus, Types 1 and 2

Coinfection of keratinocytes and macrophages by HSV-1 and HIV-1 has been noted within cutaneous HSV lesions, with cyclical enhancement of proliferation of both viruses in single cells (58). In addition, transient but marked increases in HIV viremia may occur during clinically apparent HSV-1 reactivation (59). Serologic studies suggest that HSV-2 infection is a risk factor for subsequent or concurrent HIV infection (60), but these data give no indication of mechanism. HSV-2 may facilitate transmission of HIV, as it causes blistering, erosion, and bleeding of penile, ano-rectal and vulvovaginal mucosa, and HIV-1 has been isolated from such genital ulcers (61). Reciprocally, HSV-2 appears to be shed from the genital tract more commonly in individuals infected with HIV (62). This appears to be a common finding for all herpesviruses examined in HIV disease.

In one recent study of HSV/HIV coinfected women, 70% and 79% of subjects shed HSV from the oral cavity and anogenital area, respectively (63). Shedding of HSV occurred for a mean of 3.2 days for oral and 5.4 days for anogenital regions, but plasma HIV viral loads did not fluctuate with such shedding (63).

Human T Cell Lymphotropic Virus, Types I and II

Several independent reports (64–66) have implicated HTLV-I in the progression of HIV-1 disease. HIV/HTLV-I co-infection is a serious problem worldwide. Prevalence of HTLV-I is high in many developing countries where HIV is also common, including Haiti (13% coinfection) and northeast Brazil (19%) (66). Such co-infection is associated with much higher CD4+ lymphocyte counts and percentages at all clinical stages than is typical for HIV infection in the absence of HTLV-I (66). These higher mean CD4 counts do not offer immunologic benefit, however, suggesting that the T cells in such individuals are functionally effete. This has led to speculation that CD4+ T cell guidelines for initiation of prophylactic antibiotics and antiretroviral therapy may be inadequate for HIV+ individuals co-infected with HTLV-I (66).

In the U.S., anti-HTLV-I,II seropositivity has been reported in 8–19% of HIV+ individuals who were injection drug abusers or attended sexually transmitted disease clinics (66); however, most of these infections involve HTLV-II, not HTLV-I. The distinction between HTLV-I and HTLV-II infection is critical, and cannot be made on the basis of simple ELISA serology screens; competitive peptide ELISAs or PCR technology must be used. HTLV-II has not been linked to acceleration of HIV disease (66,67). This may relate to the fact that HTLV-I is associated with higher rates of spontaneous lymphocyte proliferation than HTLV-II (68).

Hepatitis Viruses

Five hepatitis viruses, A through E, cause more than 80% of cases of viral hepatitis (69). Extensive efforts are ongoing to identify etiologic agents for the remaining one-fifth of cases, which translates into some 68,000 annual instances of post-transfusion hepatitis of unknown etiology in the United States alone (70). Complicating this issue is the fact that definitive evidence for the involvement of many of the newer parenterally transmitted agents in acute or chronic liver damage is lacking. However, some interesting and clinically important interactions between the hepatotoxic or perhaps just hepatotropic viruses and HIV have recently been documented.

Hepatitis A

In a series of 9 HIV+ patients who developed acute hepatitis, all patients spontaneously recovered and there was no significant change in CD4 count or viral load in the six months following hepatitis diagnosis (71). Although HAART was suspended for the 7 of 9 patients who were receiving it, there is no evidence that HAART has a detrimental effect on the course of hepatitis A disease (72).

Hepatitis B and C

The HBV X gene can *trans*-activate HIV *in vitro* (73), but HBV infection appears to be unrelated to progression of immune deficiency or clinical symptoms of HIV infection in most studies (74,75). The reciprocal situation may be important, however. Hepatitis viruses A through D are prevalent among patients at risk for HIV, and the course of HBV, HCV, and delta virus/HBV disease does appear to be accelerated by HIV (75).

Increased carriage rates and replication of HBV, decline in anti-HBsAg titers, reactivation of latent HBV, and reinfection with another subtype of HBV have all been reported in HIV+ patients (75). HBV is a factor in the development of hepatocellular carcinoma in these individuals, as in HIV seronegative patients, a correlation similar to that between cervical and anal carcinoma and HPV (76),

TABLE 6.2. *Viral co-factors for neoplasia in HIV infection*

I. **Common associations, in the presence or absence of HIV**	
Malignancy	Viral Co-factor
Cervical carcinoma	HPV-16,18
Anal squamous cell carcinoma	HPV
Hepatocellular carcinoma	HBV
Adult T cell leukemia/lymphoma	HTLV-I
II. **Associations particularly important in HIV infection**	
High-grade B cell lymphomas	EBV
Kaposi's sarcoma	HHV-8
Body cavity based lymphoma	HHV-8

and EBV and malignant lymphomas (77). These associations are listed in Table 6.2.

HCV infects an estimated 200–400 million people, or up to 3% of the global population (78). HCV-related cirrhosis is poised to become the leading cause of death in patients coinfected with HIV (79), presently about one-half of the HIV+ population in resource-rich nations (80,81). Acknowledging that HIV markedly increases the 20% twenty year risk for cirrhosis found in HIV negative, HCV+ cohorts, in 1999 the U.S. Public Health Service added progressive chronic HCV infection to its list of AIDS-deÞning opportunistic infections (82).

Apart from virus-speciÞc cofactors, synergy among hepatitis viruses and HIV with anti-HIV therapies is an additional means by which infectious cofactors could augment the pathogenicity of HIV. This may be most evident with HCV. For example, six large clinical studies found that between 2% and 18% of HIV+ patients suffered severe transaminase elevations following HAART; most of this liver injury was related to pre-existing HCV infection (83).

A retrospective analysis of all HIV+, antiretroviral-naive patients seen in a single hospital in Madrid, Spain from January 1997 to January 2000 was conducted to examine HIV-hepatitis virus interactions (83). Mean follow-up was 245 days. Of the 222 individuals identiÞed, 38% were coinfected with HCV, 5% with HBV, and 2% with hepatitis D. Transaminase elevations of any grade were seen within a median of six months of HAART initiation in 31%. SigniÞcant independent variables for this occurrence included alcohol abuse, HCV infection, and didanosine therapy. Use of the nucleoside reverse transcriptase inhibitor lamivudine was linked to a highly signiÞcant protection against liver damage ($p = 0.001$). Lamivudine is an inhibitor of HIV as well as HBV replication (84), as both require reverse transcriptase at some point in their life cycle. However, speciÞc note of the subsets of patients showing such protection with lamivudine was not provided, and only 5% of the cohort were HBV infected.

Severe transaminitis was seen in only 5% of HCV negative study subjects, but in over triple this fraction, 16%, of individuals with HCV coinfection (83). Similar enzyme elevations were recorded in 27% of HBsAg+ subjects and in 8.5% of HBsAg negative subjects. There was no relationship between classes of drugs used in the various HAART regimens and either incidence or severity of ALT/AST elevations. In a multivariate analysis, alcohol abuse, anti-HCV antibody, and older age (greater than the median of 35 years) were the only signiÞcant variables for development of grade 3 or 4 liver injury.

HBV infection was not an important factor in this group. Indeed, it was noted almost a decade ago, pre-HAART, that the overall prevalence of HBV markers is greater in HIV+ patients who progressed to AIDS (85). But this difference, though signiÞcant, was small (89% vs. 80%). Although the prevalence of HBsAg, a marker of persistent infection, was twice as great in those who progressed to AIDS (10.7% vs. 4.7%), a survival difference attributable to HBV was not seen (85). However, HBV reactivation of various degrees of severity, including fulminant hepatitis, does develop in 20–50% of HIV negative patients undergoing immune suppressive treatments or cancer chemotherapy (84). The frequency of such reactivation may be reduced by lamivudine prophylaxis (84), something which might be considered in the HBV/HIV co-infected population in late stages of immune suppression.

HCV is currently the more pressing issue. It is unclear why the profound interaction between HAART and HCV noted in the Madrid cohort and several prior, smaller studies occurred. The mitochondrial toxicity typical of all antiretroviral drugs is one possibility. Immune-mediated damage, elicited by the partial immune recovery typical of HAART and involving HCV antigen targets on hepatocytes, is an intriguing mechanism. This might be part of the immune reactivation syndromes, involving cytomegalovirus, Mycobacterium avium complex, and possibly other opportunistic infections, documented within days to weeks after initiating HAART. The authors of the Madrid analysis concluded that a more aggressive stance against chronic HCV infection should be taken, including pre-treatment with α-interferon and ribavirin. ÒThe risk of

developing severe hepatic injury on HAART should be lower on a ÔhealedÕ liver,Ó they felt (84).

A recent pathologic study (86) of 58 HIV/HCV coinfected patients showed advanced Þbrosis in 45% of those with CD4 counts <200, compared with only 10% in HCV+/HIV negative controls. Care was taken to match groups by other risk factors for advancing liver disease, including age at infection, duration of infection, sex, and alcohol use. As Þbrosis was more severe in those with CD4 counts <200 (45%) vs. those >200 (17%; $p=0.04$), enhanced HCV replication in the face of increased HIV-related immune suppression was suggested (86).

In conclusion, up to 18% of HIV-infected patients who start HAART have a severe rise in transaminases. Most of this rise is attributable to alcohol use and HCV infection. Attempts to limit the former, and perhaps to treat the later prior to initiating HAART, may be warranted. Some of the increases in ALT/AST on HAART will resolve spontaneously. But, as patients with HIV disease live longer, mortality from HCV and HBV liver disease is expected to account for over one-third of all AIDS-related deaths in the industrial world (87).

TT Viruses

TT virus (TTV) is a non-enveloped, circular, single (minus)-stranded DNA virus of 3.8kb Þrst isolated from a patient with post-transfusion hepatitis in Japan (88). It has been provisionally classiÞed in the Circoviridiae family and is transmitted parenterally. It is also shed via the bile into feces, making fecal-oral transmission a potential route (88). Persistent infection with TTV of genotypes 1Ð16 is common among healthy individuals (5%), but markedly increased in the HIV+ population (23%) (88).

The high titer viremia observed in AIDS patients and those with high HIV load or low CD4 counts suggests that TTV replication is facilitated in the immune compromised (88). Whether TTV itself mediates any aspect of HIV-related disease is unclear.

Hepatitis virus GB-C

There is some potential good news from the hepatitis-HIV coinfection saga. GBV-C, also referred to as hepatitis G (HGV), is a common, usually non-hepatotoxic RNA virus of the Flaviridae family related genetically to hepatitis C. But, unlike virtually every viral agent discussed thus far, it appears to *decrease* HIV mortality (89,90).

The pedigree of the GB viruses A through C is confusing, but well outlined in one review (91). Brießy, it was discovered in 1967 that acute phase plasma from surgeon GB, who acquired hepatitis within four weeks of becoming icteric, caused transaminitis when inoculated into tamarin monkeys. Sera from these animals were used in serial passage experiments with additional tamarins. Then, using representational difference analysis, previously mentioned in the context of the discovery of HHV-8, two novel clones of virus were obtained from the 11th monkey passage. One of these, GBV-A, is almost certainly a monkey virus contaminant. The other, GBV-B, may have been the etiologic agent of the surgeon GBÕs hepatitis.

Based on recombinant proteins prepared from GBV-A and -B genetic material, ELISAs were developed and used to screen blood obtained from West African natives. One positive sample yielded GBV-C. HGV appears to be an independent isolate of a GBV-C virus.

Although GBV-C is clearly hepatotropic, it is an uncommon cause of liver disease. But it has grown in prominence because of its salutary effects on HIV mortality.

One recent study involved 197 HIV+ patients, 33 with detectable GBV-C RNA, 112 anti-GBV-C antibody positive, and 52 GBV-C negative, that have been followed since 1993 (90). Survival and progression to AIDS were signiÞcantly prolonged in those with GBV-C antibody. GBV-C positivity also correlated with a lower HIV viral load, but not with higher CD4 counts.

A second study (89) involved 362 HIV+ patients, 144 with GBV-C viremia. Again, the mortality rate for those coinfected was signiÞcantly decreased. 28.5% of the GBV-C group had died over the mean 4.1 year follow-up, compared with 56.4% of the controls ($p<0.001$).

As with other infectious cofactors for HIV, it is unclear whether GBV-C is directly involved, or simply a marker for something else. Nor is it clear, should this virus prove protective against HIV progression, if it needs to coinfect the same cell to reduce HIV replication. Given the paucity of cells typically infected with HIV, this would be unlikely. Peripheral blood cells infected with HIV *in vitro* produce lower levels of HIV Gag core antigen (p24) when GBV-C is added to the cultures, despite the fact that membrane levels of the high afÞnity HIV receptor, CD4, and its chemokine co-receptors, CXCR4 and CCR5, were unchanged (89).

Approximately 2% of voluntary blood donors, and up to 20% of injection drug users in the U.S. have detectable levels of plasma GBV-C RNA (89,92). It is not screened for in blood collections. Whether this epidemiologic correlation can translate into new forms of HIV therapy is unclear, but clearly in the investigatorsÕ minds.

ADDITIONAL CONSIDERATIONS

Viral Suppression of HIV Infection

Apart from the apparent suppression of HIV replication *in vivo* suggested by epidemiologic and *in vitro* studies of GBV-C, at least two other viruses and one bacterium have been linked to similar interactions. All may provide leads

to new avenues of anti-HIV therapy. *In vitro*, HHV-6, described above, as well as inßuenza virus (93) may inhibit HIV replication. *In vivo*, *Orientia tsutsugamushi*, the etiologic agent of scrub typhis, has a similar effect (94). Finally, plasma levels of two potential HIV suppressive factors, RANTES and IL-10, were elevated during acute measles virus infection, and acute measles infection was associated with marked decreases in plasma HIV load (95). Measles virus is highly immune suppressive *in vivo* (96); dampening of certain types of immune activation which facilitate HIV replication and augment activation induced cell death (AICD) by measles may account for its salutary role in HIV coinfection.

Viral Immunizations

It is reasonable to speculate that any stimulus to the immune system, whether by intercurrent infection, exposure to novel or recall antigens, injury accompanied by inßammation, or immunizations might enhance HIV expression, at least transiently. This is consistent with the fact that primary and secondary effector cells and memory cells express a variety of activation antigens and accessory molecules not found on naive lymphocytes (97). An elevation in numbers of infected PBMC, ranging from 2- to 25-fold, was seen within one to two weeks of administration of inactivated vaccinia or HBV vaccines to HIV-1 infected chimpanzees (98). This parallels the increase in HIV transcripts (>10-fold) and viral titers (>5-fold) seen in plasma following inßuenza immunization of HIV+ individuals (99). A peak in virus replication was noted at one to two weeks after immunization, falling to baseline values only after several months. This raises the issue as to the risk-beneÞts of certain vaccinations in HIV+ individuals, particularly for those diseases, such as inßuenza, which do not cause increased mortality in the setting of HIV.

However, recent records from the Adult and Adolescent Spectrum of HIV Disease Surveillance Project, involving more than 25,000 HIV+ patients between 1990 and 1999, showed that there was a slight decrease in the progression to AIDS-deÞning opportunistic disease among patients who were vaccinated against inßuenza (100). Thus there appears to be no clinical risk to such vaccinations. The basis for the ostensible improvement in mortality could not be determined, and may have been related to increased preventive care or overall interest in physical health (100).

Superantigen Effects And Host Cell Activation

In vivo animal data support the concept of a clinically relevant viral SAg effect, similar to the *in vitro* effects described earlier in this chapter. Pre-activation of uninfected CD4+ T lymphocytes may also lead to enhanced viral replication and accelerated T cell death following viral exposure. This has been demonstrated in animals inoculated with PBj-14, an unusual isolate of the simian immunodeÞciency virus (SIV) which, in pig-tailed macaques and cynomolgus monkeys, leads to immediate skewing of CD4+ T cells towards an activated phenotype and death of all animals within six to ten days (101). In contrast, rhesus macaques, with fewer circulating activated T cells pre- and post-viral exposure, have a much more prolonged course following PB_j-14 inoculation (101). Unlike HIV, for which a direct SAg effect has not been demonstrated, this simian isolate has a SAg-like effect, *in vitro* and *in vivo*, inducing T cell proliferation in a V- restricted manner.

Pre-existing target cell activation has also been linked epidemiologically to enhanced susceptibility to acquisition of HIV infection (102). This may account, at least in part, for the facility with which HIV appears to be acquired heterosexually in Haiti, Africa, India, and parts of Southeast Asia, where multiple parasitic and venereal infections among HIV at-risk populations are associated with activated T cells, both in the lymphoid network and in mucosal tissues (18,102).

Expansion of Cellular Targets for HIV

It has been suggested that the AIDS epidemic in Africa is distinct in comparison with other areas of the world in terms of clinical manifestations, if not rate of disease progression (103). Immune activation linked to viral, bacterial and protozoal cofactors have been implicated in this difference (103). For example, HIV co-receptor expression may be modulated by environmentally-driven infectious co-factors. CCR5-speciÞc transcripts and protein were signiÞcantly increased in HIV negative individuals of Italian or African descent living in sub-Saharan Africa, but not in African subjects living in Italy (104).

Other receptor-based phenomena may link HIV and viral cofactors. CMV can code for or induce expression of Fc receptors on CD4 negative cells, enabling HIV to infect such targets via antibody-HIV complexes taken up by Fc (32). HHV-6 can induce *de novo* expression of the high-afÞnity receptor for HIV, CD4, on mature CD8+ T cells, again potentially broadening the range of HIV susceptible lymphocytes (47). It may also form viral pseudotypes with HIV, as can several of the herpesviruses. This would expand the host range for HIV, at least through one life-cycle, as the outer coat and receptor afÞnity of the herpesvirus, packages and transports the genetic material of HIV (32). But these receptor strategies may go both ways, depending upon the cofactor virus involved. For example, as discussed earlier, HHV-7 can compete with HIV for CD4 binding, blocking HIV infection of CD4+ T cells *in vitro*.

The chemokine co-receptors may also be inßuenced by viral co-factors, either directly or via cytokine-mediated

processes (28). Such interactions have been extensively studied with a probable bacterial co-factor for HIV disease, *Mycobacterium tuberculosis* (105). Expression of HIV co-receptors CXCR4 and CCR5 is elevated on CD4+ T cells from patients with active tuberculosis as well as T cells obtained from healthy donors and exposed to mycobacterial lipoarabinomannan *in vitro* (106).

VIRAL COFACTOR-BASED THERAPEUTIC STRATEGIES IN HIV/AIDS

Careful consideration of viral cofactors implicated in the clinical progression of HIV disease should have a direct bearing on the design of new forms of therapy for HIV infection (Table 6.3). Apart from preventionÑ the use of CMV negative blood in CMV seronegative patients, for exampleÑ anti-viral drugs would be the most direct means to suppress cofactor viruses. The probable clinical impact of anti-herpes drugs in HIV/AIDS has been shown in retrospective analysis of HHV-8 linked Kaposi sarcoma (107).

Agents that block virally-mediated HIV target cell activation should inhibit induction of HIV, regardless of their impact on cell or viral proliferation (15). Cell activation with induction of protein kinase C is essential for HIV-infected T cells to become fusogenic and form multinucleated giant cells. Cholera toxin, an inhibitor of protein kinase C through its effect on inositol triphosphate and diacylglycerol production, and H7, an isoquinoline and non-competitive inhibitor of protein kinase C, can both prevent unstimulated CD4+ T cells from forming syncytia (108). While these drugs are too toxic for *in vivo* use, suppression of inappropriately activated T lymphocyte and APC populations has been accomplished clinically in HIV/AIDS utilizing cyclosporin A (CsA) (109) and glucocorticoids (110).

CsA and glucocorticoids may also directly suppress HIV replication. CsA disrupts the interaction between Gag core protein and cellular cyclophilins A and B, associations essential in the life cycle of HIV (111). Glucocorticoids are of particular interest, as various disorders frequently found in HIV disease are treated with short-term or prolonged courses of steroids, including severe *Pneumocystis carinii* pnemonia, immune thrombocytopenic purpura, and nephropathies. Surprisingly few adverse reactions have been reported with their use (110,112). Glucocorticoids can suppress HIV replication *in vitro*, at least in T cells, through speciÞc interactions with the HIV LTR (113). They can also block HIV-associated induction of apoptosis or accelerated programmed cell death (110). Apoptosis is initiated in activated T cells by several viruses, including EBV, vaccinia (114), and HIV (115), and may be pathophysiologically relevant in HIV disease (116).

CsA has yielded the most intriguing results, though in speciÞc types of HIV+ patients. For example, nine adults with primary HIV-1 infection were treated with kidney transplant-level doses of CsA, 0.3Ð0.6mg/kg, orally every 12 hours, along with HAART (117). CsA was discontinued at week 8. Viral replication was suppressed to equivalent levels in these patients and 29 contemporary controls receiving HAART alone, with approximately a 4 log decrease in viral load maintained through the 64 week study. CsA had no adverse effect on virus-speciÞc CD8 or CD4 responses. But CsA was associated with a much greater rise in CD4 counts, returning them to normal levels by week 8, a change which persisted and increased throughout 64 weeks of observation. CD4+ naive and memory cells were elevated to equivalent degrees.

The authors of this trial noted that Òthis is the Þrst study that provides proof that the beneÞts achieved with HAART during primary HIV-1 infection may be extended via the use of an immune-modulating strategy that interferes with early pathogenic eventsÓ (117). However, these results may not be generalizable to the vast majority of cases of HIV, which are not detected within the seroconversion period.

For example, a randomized, double-blind, placebo-controlled trial of a higher dose of CsA (2mg/kg, orally twice daily) for 12 weeks in 15 individuals on no therapy and 13 on HAART showed no beneÞt in these patients with stable, early HIV disease (118). It was also associated with a small but signiÞcant rise in viral load, concerns that led the investigators to advise caution in monitoring organ transplant patients receiving CsA (118). Given the recent interest in immune activation states as major contributors

TABLE 6.3. *Summary of mechanisms by which viruses may serve as co-factors in HIV pathogenesis*

- Activation of cellular targets for HIV infection
- Induction of proliferation in resting, latently infected cells via mitogenic, antigenic, or superantigen stimulation
- Induction of cytokines or stress molecules (e.g. heat shock proteins) which act to transcriptionally activate HIV replication, or cellular proliferation, or both
- Induction of chemokines which modify disease manifestations through altering the traf cking of HIV+ and HIV uninfected cells
- Upregulation or suppression of HIV receptors
- Formation of viral pseudotypes with altered host tropism
- Coinfection of single cells, either directly stimulating or suppressing HIV replication, by both transcriptional and post-transcriptional mechanisms togenic, antigenic, or superantigen stimulation

to T cell death in AIDS, I suspect that many more immune suppressants will be tried in combination with HAART.

Novel applications of agents such as hydroxyurea (119), which can affect the size of intracellular deoxynucleoside pools essential for HIV replication, are also being pursued, along with certain antiretroviral drugs, in the combination therapy of HIV disease. Finally, speciÞc cytokine inhibitors, including pentoxyÞlline (120) and thalidomide (N-pthalimido-glutarimide) (121), which block TNF-α effects, can inhibit HIV replication, *in vitro* and *in vivo*. The challenge is to deÞne how one might take advantage of interactions between HIV and viral and other cofactors for HIV progression to anticipate the need for pharmacologic intervention, and have a panoply of therapeutics available (122).

Chapter 7

Virologic and Biologic Features of Human Immunode ciency V irus Type 2 (HIV-2)

Jean-Louis Sankalé and Phyllis J. Kanki

Human immunodeÞciency virus type 2 (HIV-2) is the second human immunodeÞciency virus in the class of human retroviruses, it constitutes the closest known virus related to the prototype AIDS virus, HIV-1. HIV-2 shares many virologic and biologic features with HIV-1, both being transmitted by the same routes, both infecting the same cells, and both exhibiting considerable genetic variation in the outer envelope gene. As with other retroviruses, both HIVs induce lifelong infection, with permanent integration of viral genetic material into the host cellÕ DNA. Based on these initial similarities, some believed that HIV-2 might cause a second worldwide AIDS epidemic. However, over 17 years since its discovery, research studies conducted both in the laboratory and in HIV-2 infected people have highlighted distinct biological differences between these related viruses (1,2). Some of these unique properties include a distinct global distribution of the virus with limited spread, signiÞcantly reduced perinatal and sexual transmission, slower rates of progression to AIDS and the potential protective effect of HIV-2 infection on subsequent HIV-1 infection (2). A complete review and update of all aspects of HIV-2 infection are beyond the scope of this chapter, rather, the purpose is to highlight those biological aspects of HIV-2 which have been of most interest from a comparative perspective. Based on current understanding, the distinct biological differences between these related viruses suggest that viral properties may be more responsible than host determinants for the unique pathogenic mechanisms employed by HIV viruses in general. It is hoped that the further characterization of such properties will be useful for the design of effective HIV interventions.

Jean-Louis SankalŽ and Phyllis J. Kanki: Department of Immunology and Infectious Diseases, Harvard School of Public Health, Harvard AIDS Institute, Boston, MA.

GENETICS OF HIV-2

The antigenic relatedness of both SIV and HIV-2 to the prototype HIV-1 virus prompted both the discovery and further classiÞcation of these related viruses (3Ð5). When sera from West African female sex workers were screened for antibodies to HIV-1 antigens, testing revealed extensive cross-reactivity for the virus core antigens but minimal antibody binding reactivity for the HIV-1 envelope (3). Yet, when the same West African human sera were assayed on SIV antigens, they reacted strongly with the envelope proteins as well as the core antigens, suggesting infection with a virus that was more closely related to SIV than HIV-1. As more sequence data have become available from various HIV-2 and SIV strains, it has also become apparent that no branching order of divergence can be speciÞed and that these virus types may in fact share a common ancestor (6,7)

It has been estimated that the HIV-1 and HIV-2/SIV groups of viruses might have diverged from each other as recently as 50Ð60 years ago (8,9). The SIVs of mangabeys and macaques are the closest relatives of HIV-2s (10Ð12). As a group, the SIVs apparently vary more between strains recovered from between different species and subspecies of monkeys than different HIVs vary from each other (10,12Ð14). As HIV-2s appear to be largely limited to West Africa, it is not surprising that they are most closely related to SIVs originating from monkeys in that region (10Ð12).

By comparison to HIV-1, the genetic diversity of HIV-2 is less extensive and only two subtypes (A, B) have been well characterized; other studies have reported the existence of four additional subtypes (C, D, E and F), but subsequent attempts to isolate viruses or obtain additional samples to sequence from these identiÞed subtypes have been unsuccessful (15). An unusual HIV-2 isolate Abt96 from an asymptomatic blood donor from Ivory Coast has

been sequenced and phylogenetic data suggest a novel HIV-2 subtype, preliminarily designated as subtype G. Thus far, HIV-2 subtype A is the most well characterized subtype and appears to be the major variant circulating in West Africa (16–20) The Ghanaian isolates, subtype B (21,22) are believed to be most distant from the prototype HIV-2/-mangabey/macaque virus (10). A recent study from Ivory Coast, however, suggests a predominance of HIV-2 subtype B in that country (23). Similar to the situation with HIV-1 subtypes, the potential impact of subtype differences on the epidemiology, pathogenicity and transmission of HIV-2 is not yet well appreciated.

HIV-2 VIROLOGY

HIV-2s are spherical, 100–120nm virions, morphologically similar to HIV-1s. The length of the entire genome of HIV-2 is about 9 kilobases similar to HIV-1. The open reading frames of HIV-2 are also similar to those of HIV-1. For different HIV-1, HIV-2, and SIVs, the genes may be in different reading frames, but the level of conservation within each gene is high. The gag and pol messages are unspliced, the env singly spliced, and the major regulatory genes doubly spliced and made from multiple messages. The regulatory gene sequences appear to vary more among HIV-2s when compared with HIV-1s (6,24,25). HIV-1 has one gene, vpu, which is not found in HIV-2 (26–28). However, the function of the HIV-1 vpu, namely the ability to increase viral particle release, may be provided by HIV-2 envelope (29). HIV-2 has one gene, vpx, which is not found in HIV-1 (30–33). While a complete review of HIV-2 virology is beyond the scope of this chapter, speciÞc updates are highlighted herein.

HIV-2 infects the same range of cells as HIV-1, including CD4 bearing helper T-lymphocytes, monocytes, and macrophages, and microglia cells in the central nervous system. Although HIV-2 infects through the same CD4 receptor, it apparently does so with a 10- to 100-fold greater afÞnity than HIV-1 (34–36). Although the HIV-2 envelope protein appears to be slightly less glycosylated than in HIV-1, this does not appear to account for the differences in binding efÞciency (36). It is believed that infection by HIV-2 is inhibited more efÞciently by soluble CD4 than is HIV-1 (37).

Several members of the chemokine receptor family have been shown to function in association with CD4 to permit HIV-1 entry and infection in various types of cells (37–39). Similar to HIV-1, certain HIV-2s have been shown to utilize Fusin/CXCR4, as both a coreceptor (in the presence of CD4) and as an alternative receptor, in the absence of CD4 (38,40). HIV-2 viruses appear to be more promiscuous in their utilization of various coreceptors, compared with HIV-1, including CXCR4, CCR15, and the coreceptors designated BONZO/STRL33 and BOB/GPR15 (38,40,41). Most CCR5-requiring isolates are non-syncytium inducing, whereas isolates utilizing multiple coreceptors were syncytium inducing. However, the efÞciency with which the coreceptors are utilized by HIV-2, appears to vary greatly among various isolates (42).

In vitro studies of HIV-2 isolates by a number of laboratories have described differences in cytopathicity of HIV-2 as compared with HIV-1 (43–46). In comparison with HIV-1, HIV-2 isolates demonstrate decreased cell killing, less syncytial cell formation, reduced virus replication, and differences in interaction with CD4, in some cases related to the clinical stage of the HIV-2-infected individual (46). The V3 loop of rapid/high HIV-2 isolates is signiÞcantly more heterogeneous and has a higher net charge than the V3 sequence from slow/low isolates. Mutations at amino acid positions 313 and 314, to positively charged amino acids, has also been signiÞcantly associated with the rapid/high phenotype; similar to that of HIV-1 (46). These amino acid changes in the V3 loop of HIV-2 also appear to determine the co-receptor usage for CXCR4 and CCR5. The distinct co-receptor usage of two reference HIV-2 molecular clones allowed identiÞcation of the region of gp120 important for co-receptor speciÞcity. By constructing a series of chimeric viruses between GH-1 and ROD, the C-terminal half of the V3 loop region of gp120 was found to determine the differential co-receptor usage between GH-1 and ROD. Notably, the shift in the co-receptor usage from CCR5 to CXCR4 was associated with an increase in the net positive charge in the V3 region (47).

One of the most important characteristics of HIVs that makes them different from other retroviruses is the ability to regulate their own expression (48). The long terminal repeat (LTR) regions at the ends of the viral genome contain sequences necessary for activation of transcription and for termination of the transcripts, but an important element of control for these viruses occurs through RNA processing or splicing. The LTR of HIV-1 is more responsive to cellular activation signals than the HIV-2 LTR, indicating that HIV-2 has different response elements (49,50). Whereas HIV-1 has two NF-kB enhancer binding sites, only one can be identiÞed for HIV-2 or most SIVs (51). Studies also suggest that activation of the HIV-2 enhancer may require four or more cis-acting elements, most of which are not in HIV-1 (52). This may be of biologic signiÞcance, as studies of two different strains of SIV with dramatic difference in virulence *in vivo* have demonstrated the duplication of the NF-kB binding sites in the virulent strain (53).

The gag gene products are essentially the same for HIV-1 and HIV-2 (54) and are highly conserved. A 55-kD precursor is myristylated and cleaved by the viral protease to form p17 (MA), p24 (CA), p2, p7 (NC), pl, and p6. The matrix protein (MA) p17 is at the amino terminus, and in its cleaved form surrounds the nucleocapsid. The capsid (CA) p24 is slightly larger for HIV-2 or SIV and is sometimes described as p27 (3,55). It provides the structure for the core that contains the genome and the polymerase and integrase enzymes (56). Workers have identiÞed NC p7–8 as a nucleic acid binding protein (57),

and both zinc Þnger motifs are involved with the speciÞcity of packaging the genomic viral RNA into the virions (58).

The envelope glycoprotein precursor is slightly smaller for HIV-2, as are the external glycoprotein and the transmembrane protein. Although usually described using the terminology for HIV-1 (gp160, gp120, gp41, respectively), the HIV-2 glycoproteins are sometimes designated with lower sizes (e.g. gp140Ð145, gp105Ð110, gp32Ð40). By analysis of the primary amino acid sequence for N-linked glycosylation sites, the HIV-2 and SIV gp120s have signiÞcantly fewer conserved sites. This could presumably account for the lower molecular weight of the HIV-2 gp120, as carbohydrates make up 50% or more of the HIV-1 gp120 (59Ð61).

HIV-2 envelope sequences vary to approximately the same degree as HIV-1 sequences 124 30, 62Ð68). Although the V3 regions correspond in both virus types, HIV-2s do not have the conserved GPGR amino acid sequence at the tip of the V3 loop (30,67). External glycosylation sites appear to be conserved between HIV-1 and HIV-2 as are the sites for CD4 binding (6,69), precursor processing (70), fusion (70), principal neutralizing domain at V3 (67,71,72), cytolytic T cell activity (73,74), and perhaps for antibody dependent cell cytotoxicity (72,75,76). With HIV-1, much of the envelope glycoprotein appears to generate binding antibodies. Antibodies from people infected with HIV2, demonstrate binding activity concentrated in the middle of gp120, including the V3 loop (77,78), as well as the amino terminus of the transmembrane protein (77,79). Another region, at the carboxy terminus of gp120, may be slightly less immunogenic, but it appears to be the most cross-reactive between HIV-1 and HIV-2 (79).

The most type-speciÞc region of HIV-2 g120, the V3 loop region, is also the principal neutralizing domain, as it is for HIV-1 (67,71,72). Two distinct antigenic sites in the third variable region (V3) of HIV-2 have been identiÞed that appear to correspond to the principal neutralizing determinant (PND) of HIV-1; the conserved Phe-His-Ser-Gln and Trp-Cys-Arg motifs (positions 315Ð318 and 329Ð331) possibly interact to form a discontinuous antigenic site based on computer simulation modeling (80). However, other neutralizing regions of lower activity have been described, including a linear epitope in V2 and one conformational epitope outside V1, V2 and V3 (72,81). Some investigators have described cross-neutralization between HIV-1 and HIV-2 with human antibodies (82,83), although weakly bidirectional, they appear stronger for serum from HIV-2-infected people for cross-neutralization of HIV-1 (82,83).

As with HIV-1, the polymerase activity of HIV-2 is error prone, and as a result extensive variation occurs between isolates (84). This is primarily exhibited in the envelope gene against which much of the selective pressure of the immune system is exerted. This results in differences in env of as much as 1% per year for evolutionary selection (48,67). Limited studies on the inter-patient variability of HIV-2 have shown that the range of variability in the envelope V3 sequence is similar to the inter-patient variability of HIV-1 (16,67). Tissue-speciÞc quasi species has been identiÞed in HIV-1 infection *in vivo*, and this has also been demonstrated in the analysis of blood and brain viral sequences from an HIV-2 infected individual (68,85). Evaluation of intra-patient variation in the V3 envelope region of HIV-2 in asymptomatic and symptomatic individuals followed over time has shown a lower variation when compared to HIV-1 (16). This lower intra-patient variation appears to be a distinct feature of HIV-2 infection that may result from decreased viral burden and also contribute to lower rates of transmission and disease development.

HIV-2 DIAGNOSIS

Studies of HIV-2 epidemiology and natural history are heavily dependent on accurate HIV-2 viral diagnosis. The same procedures for serologic testing, virus culture, and detection at viral nucleic acids such as polymerase chain reaction (PCR), that were developed for HIV-1 have been modiÞed for HIV-2 diagnosis and improved over the years. The close relationship of HIV-2 to HIV-1 on a genetic and antigenic level has necessitated the development and implementation of type-speciÞc diagnostic assays. Because most of the tests were developed for HIV-1 using HIV-1 antigens, the degree of cross-reactivity and speciÞcity for HIV-2 is variable. Most of the Þrst generation tests used whole virus antigens, where core antigens such as p24 and pol p66/p51 are well represented. These antigens are more strongly cross-reactive than envelope antigens, especially gp120 (3,4,86,87).

Blood bank screening for HIV-2 was instituted in the United States in 1990, following the lead of many European nations. As a result, the vast majority of commercial HIV ELISA assays utilize a combined antigen source that incorporates HIV-2 speciÞc antigens. ConÞrmation of HIV-2 serostatus requires HIV-2 speciÞc immunoblot assay, or speciÞc peptide assays. Immunoblots demonstrating a proÞle of major structural gene products are typically used to conÞrm HIV-1 and HIV-2 diagnosis using standard criteria. HIV-2 speciÞc diagnosis by immunoblot requires antibody reactivity to env ± gag ± pol antigens. In the absence of reactivity to gag or pol antigens, the presence of reactivity to two envelope antigens is required (gpl2, and gp32 transmembrane protein) (88).

Various investigations have focused on identifying type-speciÞc antigens to allow conÞrmatory tests that will distinguish between HIV-1 and HIV-2. Most have been made as synthetic peptides (89Ð92), but some are larger bacterially expressed peptides (93,94); these peptides vary in sensitivity and speciÞcity. As most were selected for speciÞcity, one might expect that sensitivity could be

compromised. Thus, although appropriate for type-speciÞc conÞrmation, they may not be as useful as larger HIV-2-speciÞc antigens for initial screening.

The HIV dual antibody proÞle is characterized by antibodies with strong reactivity to the env antigens of both HIV-1 and HIV-2 by immunoblot and/or radioimmunoprecipitation analysis (RIPA) (3,87,93,95Ð97). Several possible biologic explanations for this phenomenon can be entertained including: extensive cross reactivity by either of the HIVÕs, dual infection or infection with a recombinant virus. When human serum samples have been tested in places such as Ivory Coast, Senegal, and Burkina Faso, a disproportionately large fraction of the samples often test as Òdual positiveÓ because they appeared reactive on both HIV-1 and HIV-2 conÞrmatory tests (4,94,98,99). These geographic sites have substantial rates of both HIV-1 and HIV-2 infection, and distinction of viruses and designation of dual reactivity remains a diagnostic challenge for the typical HIV laboratory.

Isolation of both HIV-1 and HIV-2 has been reported from selected HIV-dual positive case, and PCR evidence of both viruses has ranged from 30Ð80% in serologically deÞned dual reactives reported from similar populations (100Ð102). It is unclear whether the low and variable rate of concordance between serology and PCR is due to extensive HIV-1 cross reactivity as suggested, misclassiÞcation of samples based on serodiagnosis or insensitivity of the PCR assays. Improvement of PCR assays with Southern blot detection of ampliÞed product has maximized the sensitivity and speciÞcity for HIV-2 provirus detection (103,104). The further development of such assays will be critical to studies that seek to characterize HIV-2 biology and its interaction with HIV-1 *in vivo*. Largely due to such problems, it has been difÞcult to predict from the published literature what the interactions of these two distinct HIV type viruses would be in human populations. It seems clear that reports of dual infection in certain parts of Africa as well as the rest of the world, in the absence of HIV-2 infection alone, were more likely misinterpreted laboratory data than a true biological entity.

EPIDEMIOLOGY AND GLOBAL DISTRIBUTION

In 1985, the discovery of HIV-2 in West Africa prompted numerous serologic studies to determine the geographic distribution. Since that time, HIV-2 infection has been well documented in most West African countries, a distinctly different worldwide distribution compared to HIV-1 (2). Largely due to relatively low prevalence rates in most places outside of West Africa, it has been difÞcult to compare the prevalence rates in different countries due to differences in study design and diagnostic methodologies. Often times serosurveys were conducted with methods that failed to distinguish HIV-1 from HIV-2, and thus erroneously reported type speciÞc prevalence rates; in addition, there were difÞculties with diagnosis and distinction of HIV-dual infections resultant from the lack of HIV speciÞcity in the serologic or nucleic-acid based assays.

Isolation of a second retrovirus, HIV-2, led to fears that a second AIDS pandemic would occur, similar in scope and magnitude to that caused by HIV-1. However, the peculiar biologic properties of HIV-2, namely the lower transmissibility of this virus through both sexual and vertical routes, has contributed to a more regionalized endemic distribution of the virus. Studies conducted shortly after the discovery of HIV-2 found substantial rates of HIV-2 in a number of West African countries, frequently with low to absent rates of HIV-1 infection (4,105). In the late 1980s, in countries such as Guinea Bissau, Gambia, Cape Verde and Senegal, the prevalence of HIV-2 infection exceeded that of infection with HIV-1, but in most instances, HIV-1 infection has now increased and has exceeded rates of HIV-2 infection (4,98,106,107). Rates of HIV-2 infection are highest in sexually active populations such as commercial sex workers, sexually transmitted disease patients, prisoners and people hospitalized with infectious diseases (4,98,108,109).

In most other countries of West Africa such as Burkina Faso, Ghana, Ivory Coast, Nigeria, and Mali, infection with HIV-1 is also more prevalent than with HIV-2, ranging from a 3Ð24 fold rate ratio (HIV-1 versus HIV-2) (2,110Ð114). For example, in a study from Bamako Mali, HIV-2 infection was found in 3.9% of 176 commercial sex workers, in contrast to a 20.4% rate of HIV-1 infection. Comparison of previous HIV-1 and HIV-2 seroprevalence data from Mali shows a signiÞcant rise in HIV-1 prevalence and a signiÞcant decrease in HIV-2 prevalence and conÞrms similar trends observed in neighboring countries (19).

The existence of substantial rates of both HIV-1 and HIV-2 infections in many of these countries raised the question of what outcome would result from the interaction of these viruses at a population level. Anderson and May analyzed the available biological and epidemiological data on the pathogenicity, transmissibility and antigenic similarity of HIV-1 and HIV-2, and used simple mathematical models to study the competition between the two viral types (115). The mathematical model of the concomitant transmission of the two viruses transmitted within the same sexually active population, suggested a positive association between pathogenicity and reproductive success, suggesting that HIV-1 would competitively displace HIV-2 in the long term. This is supported by studies that measure and compare the rates of sexual and perinatal transmission of the two viruses, as well as the temporal reduction in HIV-2 prevalence throughout the region (116Ð119). Thus, the current data suggest that HIV-2 has been present in certain populations for a long time in order to establish endemic infection and its spread outside of these endemic areas is limited by a low transmission potential. It therefore seems unlikely that this virus will cause a global pandemic similar to that of HIV-1.

A second epidemiologic pattern of HIV-2 infection has been suggested from reports of HIV-2 in Portugal, Mozambique, Angola, southwestern India and Brazil, all areas with former ties to Portugal (120) which appear to have low but stable rates of HIV-2 in the population (111). These countries once shared common historical-political ties, with economic relationships existing even today. HIV-2 has also been detected in the large cities of southwestern India (121), perhaps because of interactions with the former Portuguese colonies of Africa. Goa, a former Portuguese colony, situated south of Bombay on the western coast, has reported 4.9% HIV-2 and 9.8% HIV-1 infection in STD patients (122), whereas, substantial rates of HIV-2 infection have not been reported in other parts of Asia to date.

TRANSMISSION OF HIV-2

Although HIV-2 is transmitted by sex and blood, as is HIV-1, the rate of infection in West Africa appears more stable than for HIV-1. In Senegal, during an eight-year period of follow-up, there was a 26-fold increase in the rate of HIV-1 infection, whereas the rate for HIV-2 infection remained relatively constant (116,123). This implies that HIV-2 may have been in the human population in Africa at least as long as HIV-1, and in West Africa HIV-2 has apparently been present considerably longer. The relative poveits of HIV-2 infections in Europe, North America and Asia in the face of HIV-1 expansion also supports the general observation that HIV-2 is spread less efficiently than HIV-1 (4,115,116,120, 124–130).

Case reports of HIV-2 infections transmitted by blood and blood products have been published, but the common practice of HIV testing in blood bank settings has limited the risk of this mode of transmission (131,132). The most frequent routes of HIV transmission in HIV-2 endemic areas are perinatal and heterosexual transmission. Since most West African countries have been afflicted with both HIV-1 and HIV-2 infections, direct comparison of transmission rates between the two viruses has been possible. In Senegalese female commercial sex workers followed over an 11 year period, the annual incidence of HIV-l infection dramatically increased, with a 1.18-fold increased risk per year and a 13-fold increase in risk over the entire study period. The incidence of HIV-2 infection remained stable, despite higher HIV-2 prevalence (116,133). In this high risk group the heterosexual transmission of HIV-2 was significantly lower than that of HIV-1, which strongly suggests differences in the infectivity potential of these two related immunodeficiency viruses (116,133).

In followup study of 1948 women followed from 1985 to 1999, we have compared sexual transmission probability of HIV-1 and HIV-2. New nonparametric competing risks failure time methods were used, which minimized modeling assumptions and controlled for risk factors for HIV infection. The HIV-1 versus HIV-2 infectivity ratio over time was estimated by nonparametric kernel smoothing of the HIV-1/HIV-2 infection hazard ratio in sex workers adjusted by an estimation of the relative HIV-1 versus HIV-2 prevalence in the partner population. HIV-1 was found to be significantly more infectious than HIV-2 throughout the follow-up period ($p < 0.0001$). The HIV-1/HIV-2 infectivity ratio was inferred to be approximately constant over time, with an estimated ratio of 3.55 (134).

Maternal (vertical) transmission of HIV-2 also occurs (135), but this rate appears to be less efficient than for HIV-1 (136–138). Prospective studies of HIV-2 perinatal transmission have been conducted in Guinea Bissau, Ivory Coast, France and Senegal, all demonstrating extremely low rates of perinatal transmission of HIV-2 (0–3.7% transmission) in contrast to that of HIV-1 (15–45% transmission) (117–119,139,140). In studies that measured perinatal transmission of both viruses, the rate of HIV-1 transmission was 10–20-fold higher than that of HIV-2.

PATHOGENESIS OF HIV-2

Early reports included descriptions of cases of AIDS in HIV-2-infected people (108,141,142). Disease characteristics, including tuberculosis, chronic diarrhea, and *Candida* infections, seemed similar to that seen in HIV-1-associated AIDS (108,143,144). Central nervous system involvement was also occasionally seen in HIV-2-infected people (145,146). However, classical African AIDS-associated diseases such as tuberculosis often had only a weak epidemiological association with HIV-2 infection, even in HIV-2 endemic areas (2,147,148).

Our prospective studies conducted in a registered female sex worker cohort in Dakar, Senegal, has provided the unique opportunity of measuring disease progression rates of both HIV-1 and HIV-2 infections (147–149). Importantly, these prospective studies have compared disease progression in individuals with known time of infection, and the cohort has been now observed for over 17 years, representing one of the longest HIV natural history studies conducted. The Kaplan-Meier analysis of HIV-2 incident infected individuals indicate that 85% (95%CI = 50–96%) remain AIDS-free after eight years of HIV-2 infection which was significantly less then that observed in HIV-1 infected patients (99) (Fig. 7.1). These differences in probabilities between HIV-2 and HIV-1 were also seen for development of CDC IV disease and for reduction of CD4+ lymphocyte counts to 400 and below 200 cells/mm^3, as outcomes.

In our prospective study of HIV-2 infected individuals, we have also identified individuals that fit a definition of long-term non-progression and can determine a rate of this phenotype in the study population (148,149, unpublished data). Using a definition of long-term non-progression of ≥ 8 years infection in the absence of AIDS or related symptoms, and stable CD4+ lymphocytes > 500 cells/

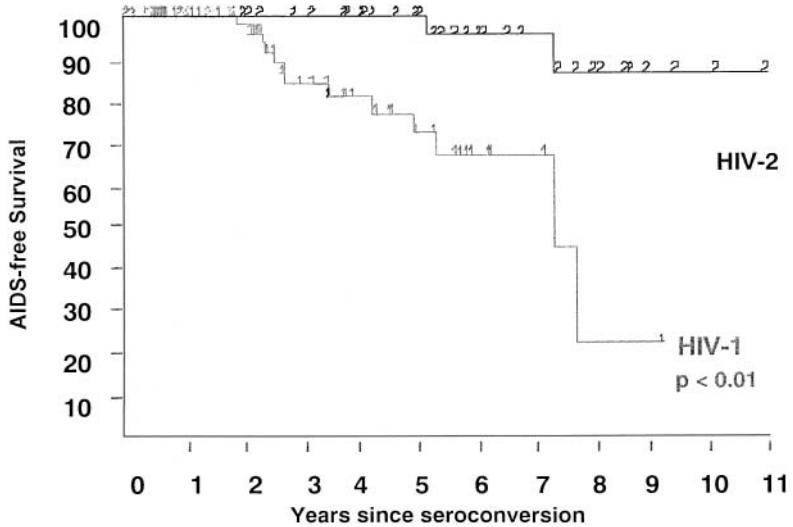

FIG. 7.1. Kaplan-Meier analysis of AIDS-free survival in HIV-1 and HIV-2 infected commercial sex workers from the Dakar cohort with known time of infection.

mm^3, we have found that 39 of 41 (95%) of our women would be classiÞed as long-term non-progressors.

In cross-sectional studies, T4 lymphocyte counts and T4 : T8 ratios appear reduced in HIV-2-infected healthy carriers, but less dramatically than for HIV-1-infected carriers (148,150Ð152). Alterations in T-cell subsets evaluated prospectively have shown similar results, where immunosuppression in HIV-2 infected people was signiÞcantly slower than HIV-1-infected patients and could not be demonstrated in all followed subjects (149,153). Skin test anergy to various antigens is also less pronounced in HIV-2 infection (148,152).

This dramatic difference in pathogenicity provides a unique opportunity to identify viral and host immune mechanisms involved in a closely related and relevant virus system that has been observed to have a signiÞcantly slower course of progression. Evidence for a lower viral burden in HIV-2 infected individuals has been reported from both virus isolation and PCR studies (103,104, 154Ð157). The isolation rate of HIV-2 from peripheral blood mononuclear cells or plasma of asymptomatic HIV-2 infected individuals was lower than the isolation rate for HIV-1 (154). At lower CD4+ lymphocyte counts, however, virus isolation was equally efÞcient in both infections. Studies in the Gambia and Senegal, suggest that proviral HIV-2 copies increase with disease development and with a drop in CD4+ lymphocyte count (104,155).

HIV-2 is less pathogenic than HIV-1, but the mechanisms underlying this difference have not been deÞned. We developed an internally controlled quantitative reverse transcriptase-polymerase chain reaction to measure HIV-2 viral load and determined levels of plasma virus in a cohort of registered commercial sex workers in Dakar, Senegal (156). The assay has a lower limit of detection of 100 copies/mL and is linear over 4 logs. HIV-2 viral RNA was detectable in 56% of all samples tested; the median load was 141 copies/mL. Levels of viral RNA in plasma were inversely related to CD4+ cell counts. HIV-2 and HIV-1 viral loads were compared among the seroincident women in the cohort; the median viral load was 30-fold lower in the HIV-2-infected women ($P < 0.001$, Wilcoxon rank sum test), irrespective of the length of time infected. This suggests that plasma viremia is linked to the differences in pathogenicity of the two viruses (156). Similar Þndings have been described in the Gambia, and Guinea Bissau (157,158).

Levels of virus in plasma are closely related to pathogenicity of HIV-1 and infection with HIV-2 leads to a signiÞcantly lower plasma viral load. To identify further the source of this difference, we measured both viral RNA and proviral DNA in matched samples from 34 HIV-2 infected individuals. The median level of HIV-2 RNA for the group was 189 copies/ml. Levels of HIV-2 RNA were below the limit of detection in nearly half the women, consistent with what we have previously reported in this population (159). Levels of HIV-2 proviral DNA failed to correlate with levels of viral RNA. Thus, it appears that signiÞcant differences occur upon expression, release and/or maintenance of virions in the bloodstream. It is formally possible that shifts in splicing patterns could be responsible for differences in virion production between HIV-1 and HIV-2, but further studies would be required to verify such an explanation. Comparative studies of both viral and host factors that may affect expression will be useful for understanding differences between HIV-1 and HIV-2 pathogenesis.

Since slower disease course appears to be common in HIV-2 infection, we reasoned that certain subsets of the population would possess host characteristics that might predispose to a more rapid disease course. We conducted a case-control study investigating possible associations between HLA and the risk of disease progression in persons with HIV-2 infection (160). The HLA class I status was molecularly typed in 62 female sex workers from the Dakar, Senegal, cohort; lack of antibodies to

HIV-2 antigen p26 was used as a surrogate marker for risk of disease progression (161). Statistical analysis showed that HLA B35 was associated with lack of p26 antibodies ($p < 0.05$), and higher risk of disease progression. The same association was found for the class I haplotypes B35-Cw4 and A23-Cw7 ($p < 0.05$), similar to the association with HIV-1 (162). Our data shows that certain HLA molecules are associated with risk of disease progression in HIV-2 infections and that some of the alleles and haplotypes involved in susceptibility to disease are similar for both HIV-1 and HIV-2.

HIV-2 Immunity

The attenuated phenotype of HIV-2 infection *in vivo* has sparked considerable interest in understanding the immunopathogenesis of this particular HIV infection. Although certain viral determinants appear to be central to the lower replicative capacity *in vivo*, the virus also appears to differ from HIV-1 in its effects on the immune system. The degree of immune activation and apoptosis in lymphocytes were compared in healthy West African patients infected with HIV-1 or -2. The lower decline of CD4 T cells in HIV-2 compared with HIV-1-infected donors was associated with lower levels of immune activation, evaluated by HLA-DR expression on lymphocytes and serum concentrations of IgC and beta2 microglobulin (151,152,163). *Ex vivo* apoptosis was found in both infections in all lymphocyte subsets, including CD4 and CD8 T cells, as well as B cells, but was less in HIV-2 than in HIV-1 infection (164). These observations support the hypothesis that long-term activation of the immune system, weaker in HIV-2 infection, signiÞcantly contributes to T cell deletion and disease evolution (164).

As with HIV-1, the antibody response to most viral structural proteins occurs shortly after infection and is thought to persist. In HIV-2 infection, over 90% of seropositives evaluated in Senegal demonstrated strong antibodies to gag, pol and env-encoded antigens (165,166). As already noted, the cross-reactive response to analogous HIV-1 antigens is signiÞcant in highly conserved gene products such as gag and pol and less with envelope antigens.

Previously, the presence of circulating p24 antigen of HIV-1 was a useful marker of virus replication *in vivo*, although this testing has been largely replaced with more direct measurements of virion particles using PCR technology. Analogous studies with HIV-2 have not been described, perhaps because antibodies to p26 are found in the majority of HIV-2 infected sera and therefore it has been assumed that complexing by free circulating p26 is less frequent. In our studies, we have found that the lack of antibodies to p26 is a Þxed phenotype, not a result of complexing of free p26, and predictive of a more rapid disease course (160,161).

HIV-2 neutralizing antibodies have been described (71,82,83,167,168), and in studies with fresh isolates, the broadness of the HIV-2 neutralizing response has been unusual and distinct from the neutralizing antibody response to HIV-1 (169). Virus neutralization studies have shown that a proportion of HIV-2 sera are also capable of cross neutralizing HIV-1 isolates in addition to HIV-2 isolates (82,86). The degree to which HIV-1 positive sera can cross-neutralize HIV-2 isolates remains controversial. It is still not known whether some of the conserved domains of env will be capable of eliciting a cross-protective response to both viruses.

Studies of HIV-2 humoral immunity have now been extended to evaluate the highly related mucosal immune response. Evaluation of HIV-2 antibody responses in cervicovaginal secretions have shown that only a third of infected women generate lgA responses to HIV-2 envelope antigens in this compartment, suggesting lower levels of viral replication compared to HIV-1. Of interest, cross-reactivity by IgG and IgA to heterologous envelope antigens was more frequent with HIV-2 infection (170). Cervicovaginal cross-reactivity was more pronounced for HIV-2-speciÞc antibodies to HIV-1 epitopes than conversely. Such features could be relevant to a differential heterosexual transmission of one type of HIV in an individual infected by the other type, in accordance with epidemiologic studies showing that HIV-2 infection protects from HIV-1 infection, and that HIV-1 infection does not appear to protect signiÞcantly from HIV-2 infection.

Knowledge of immune mechanisms responsible for cross-protection between highly divergent viruses such as HIV-1 and HIV-2 may contribute to an understanding of whether virus variability may be overcome in the design of vaccine candidates, which are broadly protective across HIV subtypes. In early CTL studies of HIV-2, responses against HIV-2 gag, pol and nef proteins were described; HLA-B53 restricted, HIV-2 gag-speciÞc CTLs did not recognize target cells expressing HIV-1 gag proteins suggesting the absence of a cross-protective cellular response (171). More recently, however, Bertoletti and colleagues also working in the Gambia, have shown that the majority of HIV-2-infected individuals regardless of HLA haplotype possess a dominant cytotoxic T-cell response which is able to recognize HIV-1 Gag protein (172). Furthermore, HLA-B5801-positive subjects have shown broad cross-recognition of HIV-1 subtypes since they mounted a T-cell response that tolerated extensive amino acid substitutions within HLA-B5801-restricted HIV-1 and HIV-2 epitopes. These results suggests that HLA-B5801-positive HIV-2-infected individuals have an enhanced ability to react with HIV-1 that could play a role in cross-protection (172).

We have applied the sensitive Elispot technique to quantify further the HIV-2 speciÞc CTL response in HIV-2 infected individuals (173). To assess the antigen delivery system using the modiÞed non-toxic form of the anthrax toxin, we fused the HIV-2 gag (P-26) to the terminal domain of Lethal Factor (LFn; 255 aa). The LFn-HIV-2 recombinant protein was expressed and used as antigen to

stimulate CTL in a ELISPOT assay in comparison to the classic delivery system using recombinant vaccinia Virus (rVV) expressing HIV-2 gag. We found that 87.5% of individuals in our study showed a speciÞc gag CTL response. Our results have shown that priming cells with the LFn-P-26 gave better sensitivity and resolution when subjects had a low frequency of CTL precursors. Interestingly, we found that the group with strong cellular immune response had no detectable HIV-2 plasma load.

CORRELATES OF IMMUNITY

The developing world, particularly regions of Africa, continue to bear a signiÞcant portion of the global HIV burden, and they are unlikely to beneÞt from recent advances in therapeutic regimes in the foreseeable future. Important to vaccine design is the understanding of pathogenic mechanisms of HIV infection and the potential immunologic responses or correlates necessary for HIV containment. IdentiÞcation of such correlates has been hampered by relatively rare instances of natural immunity that have withstood the challenge of viral exposure.

Demonstrated differences in the infectivity and disease potential of HIV-2 compared to HIV-1 support the notion that the mechanism for such protection might be analogous to the attenuated virus vaccine model. In our studies of the female sex worker cohort in Dakar, Senegal, we tested the hypothesis that the attenuated phenotype of HIV-2 infection might protect from subsequent HIV-1 infection (174). HIV-1 infection was documented over the study period with both serology and PCR assays. A Poisson regression model was used to estimate the independent effect of demographic, behavioral, and biologic variables on the risk of HIV-1 infection. Despite a higher incidence of other sexually transmitted diseases (STDs), HIV-2 infected women had a lower incidence of HIV-1 infection than HIV-2 seronegatives, with an incidence rate ratio (IRR) of 0.32 ($p = 0.008$). This analysis led to the conclusion that HIV-9 infection conferred a signiÞcant reduction in the subsequent risk of HIV-1 infection. Continued analysis of the Dakar cohort has extended the observation period from the Þrst published report to over 13 years, and HIV-2 protection ranges from 52Ð74% depending on the method of analysis (2,174,175).

The generalizability of these Þndings has been questioned by studies from other West African sites. In Ivory Coast, Guinea Bissau and the Gambia, studies originally designed as cross-sectional surveys were analyzed for short periods of longitudinal observation (176Ð178). As a result of their design, these studies failed to possess sufÞcient statistical power, capable only of detecting an extremely high protected fraction ($> 99\%$) of HIV-1 infection due to HIV-2 infection (175). In addition, a mixture of serologic methods were employed by these studies, failing to meet the PCR based, gold standard for diagnosis of dual infection, critical to the objective evaluation of HIV-2 protection *in vivo* (176Ð178). In a longitudinal study conducted in police ofÞcers in Guinea Bissau, Norrgren et al. failed to report a statistic signiÞcant result; however, only a portion of the samples was diagnosed by PCR technology (179). Unbiased, powerful studies, using sensitive and speciÞc classiÞcation methods, will be needed to address the generalizability of the observation of HIV-2õ protective efÞcacy against subsequent HIV-1 infection.

Studies from research groups including our own have described *in vitro* interactions of HIV-1 and HIV-2 that support a protective role for HIV-2: these range from virus-virus interactions to potential immune mediated mechanisms for HIV-2 protection. Arya et al. have reported that HIV-2 inhibits the replication of HIV-1 at the molecular level. This inhibition was selective, dose-dependent, and nonreciprocal. Though the exact mechanism remains to be deÞned, the inhibition appeared to be mainly due to an intracellular molecular event because it could not be explained solely on the basis of cell surfuce receptor mediated interference. The results support the notion that the inhibition likely occurred at the level of viral RNA, possibly involving competition between viral RNAs for some transcriptional factor essential for virus replication (180,181).

One might hypothesize that HIV-2 would differentially protect against certain HIV-1 subtypes better than others. To investigate the HIV-1 subtypes involved in dual HIV-1 and HIV-2 infections, we sequenced the env region from 29 dually infected female commercial sex workers from Senegal (182,183). The majority of women (23 of 29) were infected by HIV-l subtype A; within the HIV-1 subtype A sequences, 14 of 23 (60.8%) clustered with the West African associated A/G recombinant form (IbNG), and 9 of 23 (39.2%) formed a separate cluster distinct from the A/G IbNG. In contrast, in HIV-1 singly infected individuals, non-IbNG subtype A was found in only 13 of 98 (13.3%). Therefore, the lack of protection and/or interaction with HIV-2 was associated with a distinct HIV-1 A genotype. These results suggest differences in the biological properties of HIV-1 genotypes and their *in vivo* interaction with HIV-2 (183).

Beta chemokines have now been identiÞed as potent soluble suppressors of macrophagetropic HIV infection *in vitro*. Studies of multiply exposed uninfected individuals have implicated the role of elevated beta-chemokines in HIV resistance, in many cases, independent of genetic mutations in the chemokine receptor (184Ð186). Macaque studies have also suggested a role for beta-chemokines in vaccine induced protective immunity using a variety of vaccine candidates and live virus challenge (187). We used an HIV-1 *in vitro* challenge system to determine if PBMCs from HIV-2 infected individuals showed altered susceptibility to HIV-1 infection (188). Peripheral blood mononuclear cells were stimulated and infected with either R5 or X4 HIV-1 viruses. 14 of 28 (50%) HIV-2

PBMCs demonstrated over 90% inhibition of R5/HIV-1 infection compared to 0 of 19 HIV negative controls (Fisher exact test, p value = 0.0002). In contrast, HIV-2 positive and HIV negative control cells were equally susceptible to HIV-1/X4 infection. RANTES, MIP1α, MIP1β, the natural ligands of the CCR5 receptor, were measured in culture supernatant by ELISA, and supernatant levels of MIP-1α (r = −0.56, p = 0.03) and MIP-1p (r = −0.69, p = 0.004) were inversely correlated with HIV-1 replication. Using polyclonal antibodies to RANTES, MIP1a and MIP1b, resistance was neutralized. A significant proportion of HIV-2 infected PBMCs demonstrate HIV-1 resistance *in vitro*; this resistance was beta-chemokine dependent (188). Studies are further needed to characterize this potent anti-viral activity and determine its potential contribution to *in vivo* protection.

HIV-2 infection might dramatically influence beta-chemokine production by enhancing, it in magnitude and duration, thus enabling HIV-2-infected individuals to cope favorably with subsequent exposure to HIV-1. This is supported by studies demonstrating that binding of the HIV-2 envelope to the alpha chain of CD8 stimulates much higher levels of beta-chemokine production in comparison to HIV-1 gp120 activity (189). Not only does this implicate a novel viral suppressive mechanism but one that may be adapted for immunoprophylaxis. Antiretroviral vaccine strategies that incorporate beta-chemokine induction or other receptor-blocking functions raise some encouraging possibilities for vaccine design and development.

HIV-2 infected baboons (*Papio cynocephalus*) provide a valuable animal model for the study of HIV pathogenesis since many features of disease progression resemble HIV-1 infection of humans. In some HIV-2-infected baboons that are clinically healthy, a CD8+ cell antiviral response, that was partly mediated by a soluble factor, appeared to control viral replication *in vitro*. A soluble factor was found to be active against the chemokine-resistant, syncytium-inducing HIV-1 isolates and was relatively heat stable. Therefore, the soluble suppressing activity of CD8+ cells in HIV-2-infected baboons may be analogous to the CD8+ cell antiviral factor described in HIV-infected asymptomatic people (190).

HIV-2 is primarily in West Africa where it infects an estimated 1–2 million people. It is spread less efficiently than HIV-1, making projections for future infections much lower than for HIV-1. For these reasons, development of an HIV-2 vaccine has not been a high research priority. However, HIV-2 infects monkeys whereas HIV-1 does not, and the HIV vaccine model uses viruses that are closer to HIV-2 than HIV-1. The development and testing of an HIV-2 vaccine might therefore be simpler than the development of an HIV-1 vaccine. A few reports with HIV-2 have described experimental studies with limited vaccine protection (191,192), but immune correlates of protection have not been identified (193–195). Nonetheless, the data from human studies which suggest that HIV-2 may afford protection from HIV-1, is suggestive that a candidate vaccine based on HIV-2 might provide necessary cross-immunity for HIV-1 protection, and is worthy of further consideration.

THERAPY

Drugs that have efficacy against HIV-1 are generally assumed to be effective against HIV-2. However, with a few exceptions (196), most HIV-1 drugs have not been tested for activity against HIV-2. In addition, experience with antiretroviral therapy (ARV) has been largely confined to the developed world where HIV-1 non-B subtypes and HIV-2 are rare. Hence, it is still not clear that current ARV therapeutic regimes will be as efficacious in the developing world given the difference in virus subtype or type. Further, the natural history of HIV/AIDS in Africa differs from the disease in the developed world, since in Africa there are distinct endemic opportunistic infections, multiple common infectious disease agents, as well as different standards of clinical care. This suggests that certain aspects of HIV clinical management in African settings may be relatively unique. ARV of HIV-1 is directed at lowering *in vivo* virus replication, but this is problematic for managing HIV-2-infected patients because of the absence of a commercially available HIV-2 plasma viral load assay. We have had limited experience in the therapy of HIV-2-infected patients in the U.S., where it appears that standard HAART can readily reduce viral load levels below detection (197,198).

The reverse transcriptase (RT) and protease genes from twelve HIV-2-infected individuals who had been exposed to antiretroviral drugs were examined for the presence of mutations, which could be involved in drug resistance. Four individuals carried virus genotypes with amino acid substitutions potentially associated with resistance to nucleoside analogues: two at codon 70 (K → R) and two at codon 184 (M → V); the latter two patients harbored a codon Q151M mutation which has been associated with multidrug resistance in HIV-1. Substitutions associated with resistance to protease inhibitors at codon 46 were observed in all individuals. Moreover, minor resistance mutations, as well as new ones, were often seen in the protease gene. Thus, amino acid changes in the HIV-2 RT and protease genes, which could be associated with drug resistance, seem to occur at positions identical to those for HIV-1 (199).

Smith and colleagues have reported on the clinical management of seven HIV-2 infected patients followed in the U.K. on antiretroviral therapy (9). HIV-2 viremia was detectable only at CD4 counts $< 300 \times 106$/ml. Two patients with high viral loads (> 50,000 copies/ml) failed to respond to therapy, although these patients were given sub-optimal therapy. One of these patients had a viral load > 50,000 copies/ml and a CD4 count of 66; his initial regimen was dual therapy followed by sequential single

drug switches. Drug resistance data on this patient's virus demonstrated a 20-fold higher IC_{50} to 3TC (after six months of therapy) and a 10-fold higher IC_{50} for SQV after nine months of therapy. In four patients, ARV therapy led to a fall in viral load and a rise in CD4 cell count, although all had initial viral load levels of < 50,000 copies/ml. From the few published studies including our own, we are not able to adequately assess the clinical utility of the NNRTI class of antivirals as a treatment option for HIV-2, although, *in vitro* data suggest that this class of drugs may be less effacious for HIV-2 compared with HIV-1. Similar to our observations, it appears that HIV-2 differs from HIV-1 in the risk of disease progression at any given CD4 cell count and may therefore have different implications for the timing and management of ARV therapy (200).

SUMMARY

HIV-2 was first described in West Africa in 1985, since that time there has been considerable progress in understanding the virology and epidemiology of HIV-2. HIV-2 and HIV-1 have unique and striking differences in their geographic distribution, epidemic trends, perinatal and heterosexual transmission rates and incubation periods to the development of AIDS. The virologic determinants and mechanisms for these apparent biological differences are still unknown. The comparative approach to understanding the biologic differences between HIV-2 and HIV-1 may prove informative to understanding HIV pathogenesis in general. This is best exemplified in studies that indicate that HIV-2 infection via viral, host and immune mechanisms may confer significant protection from subsequent HIV-1 infection. A further understanding and characterization of HIV-2 immunity and cross-immunity may be useful for HIV vaccine design and development. Finally, our appreciation of the biologic diversity found in closely related HIV viruses may better help us anticipate the future consequences of HIV infections at the host and population level.

Chapter 8

Laboratory Detection of Human Retroviral Infection

Stanley H. Weiss and Elliot P. Cowan

The characterization in 1984 of a new human retrovirus, the human immunodeÞciency virus (HIV), is the foundation for understanding the acquired immunodeÞciency syndrome (AIDS) epidemic (1Ð3). The evidence is overwhelming that HIV infection is necessary for a person to develop AIDS (4Ð6). The development of disease in otherwise healthy workers who have occupationally acquired HIV indicates HIV is sufÞcient, as well (7). The spectrum and natural history of retroviral infections have been well-deÞned (5,6,8).

In 1988, a nomenclature committee suggested that the term human immunodeÞciency virus be used for this generic class of viruses (9), rather than the earlier terms Òlymphadenopathy associated virusÓ (LAV) or ÒhumanT-cell lymphotropic virus type IIIÓ (HTLV-III) (1,10). SigniÞcant genetic variations occur among HIV strains (11Ð14). Nearly all HIV infection in the United States is due to HIV type 1 (HIV-1), but in other parts of the world, such as West Africa, HIV type 2 (HIV-2) predominates (15,16). In light of the many differences in the serological, immunological, clinical and therapeutic correlates of different HIV strains (17), biologicals derived from speciÞc isolates should specify the viral strain of origin (e.g. HTLV-IIIB), and tests based upon HIV reagents should reference the precise sources.

This chapter reviews the methods and limitations of assays to detect evidence of HIV exposure, and provides an approach to the rational use and interpretation of these tests. In order to interpret past literature, an historical context is provided.

The period from initial exposure to HIV until tests can rule infection in or out is of great relevance in terms of maximizing the safety of the blood supply as well as to the follow-up and counseling of persons who have had a speciÞc exposure. These issues, including the early dynamics of infection and the meaning of the Òwindow Ó period in the context of our current test armamentarium, are reviewed in detail.

Given that the human T-cell lymphotropic family of viruses (HTLV) (18) are sometimes confused with HIV (particularly given historical changes in nomenclature), that the U.S. blood supply is routinely screened for HTLV-I and HTLV-II, that HTLV-I is the etiologic agent of adult T-cell leukemia-lymphoma syndrome (ATL), HTLV-I-associated myelopathy/tropical spastic paraparesis (HAM/TSP) and other diseases, and the general similarity in testing methodologies, a brief separate section discusses tests for HTLV.

Whereas Arabic numerals are usually used to differentiate the HIV species (HIV-1, HIV-2), for historical reasons Roman numerals are usually used for HTLV (HTLV-I, HTLV-II).

HIV testing in the United States makes use of several different types of tests. For example, testing historically usually began with an enzyme immunoassay (EIA) to detect antibody to HIV. Rapid tests have become available in recent years to provide a test result to the patient in a single visit. Direct testing for the virus includes assays that detect antigen or nucleic acids. These and other tests are described in detail below, including the variations in testing approaches as they pertain to testing patients, persons believed at risk, and screening of blood donors.

A current, complete listing of FDA licensed or approved assays can be found at *http://www.fda.gov/cber/products/*

testkits.htm. There are also unlicensed assays sold for "research use only" and there are tests that are used only "in house" by commercial or research laboratories. (These assays are not approved or licensed by the FDA for clinical use in the U.S.) Each individual assay has its own associated special characteristics and is not interchangeable with other assays, even within a given class of test.

GENERAL APPROACHES TO THE DETECTION OF INFECTIOUS AGENTS

Infectious agents can be detected either directly, by detecting the agent itself (or a component), or indirectly through what are referred to as surrogate markers of infection. Examples of surrogate markers are the immune response to the agent or a clinical consequence of the infection. A laboratory measure that directly detects the presence of an infectious agent is highly desirable since there is usually a delay between the time that the host is infected and when a host response is generated (discussed in detail later in this chapter). For some agents, such as hepatitis B virus, large quantities of viral antigen are produced during active infection and tests that effectively measure viral antigen are available. However, for many other viral agents, antigen may not be directly detectable even during active infection (19).

The presence or absence of antibodies (a humoral or serological response) is one way to detect whether or not a response to the agent by the host's immune system has occurred. In general, antibodies can be generated in response to either a live or a killed infectious agent. The presence of antibodies can thus mean:

a. there was exposure to antigen from the infectious agent, but no live infection existed;
b. there was active infection in the past that has resolved;
c. there is a latent infection; or
d. there is an active infection.

It is important to remember that many viruses, including HIV, are characterized by persistence; i.e. the presence of antibodies does not indicate resolution of infection. Exogenous retroviruses, such as HTLV and HIV, can integrate within the genome (DNA) of the host cell. It is uncertain whether continual viral expression must occur to sustain antibody production over a prolonged time, e.g. by periodically or continuously re-challenging the immune system. In this vein, prospective epidemiologic serologic studies indicate that once an adult produces antibodies to HIV ("seroconversion" to a "seropositive" status), complete loss of antibodies ("seroreversion") is rare (20); virus can usually be recovered from seropositive persons. The presence of anti-HIV antibodies is therefore generally interpreted as evidence of persistent infection, not resolution of past infection.

An important exception is the infant less than 18 months of age whose mother was HIV seropositive at delivery (21). Since maternal IgG antibodies can cross the placenta to high titer, it is not surprising that it can take many half-lives of decay for these to reach an undetectable level. Serological studies based on cord blood thus give useful data on maternal, but not newborn, infection. Only a fraction of initially seropositive newborns are actually HIV-infected.

PERFORMANCE MEASURES FOR TESTS TO DETECT HIV INFECTION: SENSITIVITY, SPECIFICITY, AND PREDICTIVE VALUE

When considering the performance of a test to detect HIV infection, we are concerned about the ability of the test to identify correctly individuals who are either infected or uninfected. These performance criteria are most commonly addressed by the sensitivity and specificity of the test (see Table 8.1). For the "perfect" test, sensitivity and specificity would both be 100%. However, real-world technical limitations dictate a balance between sensitivity and specificity. For example, a test that simply identified everyone as "infected" would be 100% sensitive by definition, but the test result, in fact, would be meaningless.

The balance between sensitivity and specificity will vary depending on the application of the test. For example, although the intended purposes of HIV testing in the blood bank and clinical/diagnostic settings are similar, the practical applications of tests to detect HIV infection are quite different. In the former situation, the intent is to identify a blood donor who is infected with HIV. Therefore, it is critical to minimize non-reactive results on specimens from infected individuals (known as false negative results), in order to maximally assure the safety of the blood supply and blood products. In the latter clinical instance, the goal is to counsel correctly persons concerning whether or not they have been infected, with implications for behavioral modification, medical evaluation and appropriate therapy.

Medical and non-medical considerations concerning AIDS and the HIV epidemic have elevated the impact of HIV testing to a level that is far greater than for most other laboratory tests (3). HIV testing is perceived as an invasive procedure in our society. Fears concerning the medical implications of reactive tests results and concerning potential social risk in the event of a break in confidentiality have foundation (3). False positive results similarly raise special concern. To address these issues, a written informed consent procedure in advance of testing was initially recommended in 1985, prior to FDA licensure of the first test to detect HIV infection (3), and is now used by many to document pre-test discussions.

Receiver operator characteristic ("ROC") curve analysis is a useful method to compare the performance of assays when congruent definitions of sample groups have been provided, and to assess claims of vendor improvement (a

TABLE 8.1. *Epidemologic assessment of tests: DeÞnitions*

Sensitivity*—The probability that a test result will be positive if infection is present, which is the ratio of (true positives)/(all those with infection).

Specificity*—The probability that a test result will be negative if infection is not present, which is the ratio of (true negatives)/(all those without infection).

Positive Predictive Value—The probability of infection being present given a positive test result, which is the ratio of (true positives)/(true positives + false positives) (equivalently: (true positives)/(all those with a positive test result)).

Negative Predictive Value—The probability of infection not being present given a negative test result, which is the ratio of (true negatives)/(true negatives + false negatives) (equivalently: (true negatives)/(all those with a negatives test result)).

Gold Standard (Reference Standard)—A de nitive means of categorization, widely accepted by experts in the eld, for absolutely de ning the presence or absence of a condition (such as HIV infection).

Silver Standard (Criterion Standard)—The best currently available (or the accepted) standard, which is expected to be superseded as technology advances; used as an interim reference standard when a gold standard either does not exist or is otherwise unavailable.

Supplementary Test—An additional test that further clari es the result of a screening assay . Does not necessarily have truly independent** qualities. Usually used as part of a sequence of tests, which may be referred to as a "testing algorithm."

Confirmatory Test—A supplementary test that is maximally independent** from any other tests that have been utilized. A well-performing con rmatory test will be part of a "con rmatory algorithm," the results of which would serve as the basis for optimally de nitive test result categorization.

* Laboratory personnel frequently use these terms differently, with the terms applied to detection and strength of a "test signal" (e.g. titer) rather than the epidemiologic, statistical de nitions above.

** For example, if a specimen were to give a false positive result on multiple assays, those assays are not maximally independent. For HIV, if the antigens used in both an EIA and WB were derived from whole viral lysate, then anti-HLA antibodies to the cell line used to grow the virus might cause false positive reactions for both, so that the assays would not be truly independent (51).

ROC curve is a plot of sensitivity vs. (1 Ð speciÞcity)). Such analysis, for example, might show that a purportedly improved prototype EIA (22) apparently had, in fact, poorer performance than a predecessor assay (23).

One should note that sensitivity and speciÞcity as deÞned by the epidemiologist for laboratory tests (Table 8.1) reßect aspects of the test conÞguration as deÞned by the manufacturer, and remain constant for all approved uses. Alternative interpretive criteria or cut-off values will affect the sensitivity and speciÞcity (23). It is also important to consider the statistical limitations to these estimates, which are generally reßected by 95% conÞdence intervals and are a function of the number of specimens used to derive point estimates in clinical trials.

Much more important to the users, in practice, are the positive and negative predictive values. These will vary depending upon the (estimated) ÒtrueÓ positivity proportion in the population being tested; ideally, a gold standard would be employed to determine this proportion (Table 8.1). For example, for a hypothetical test with 99.5% sensitivity and 99.5% speciÞcity, the predictive values vary with the HIV prevalence in the population.

In each of these settings, except for the case of very high prevalence (last row in above table), the negative predictive value would be quite high. Likewise, in the very low prevalence setting (Þrst row of above table), the positive predictive value of this particular test would be low.

When dealing with an individual patient, the predictive values depend upon the Òprior probability of infectionÓ or (analogously) the Òprior probability of diseaseÓ (24), which represents an estimate of the relevant population proportion. A *pre*-test probability assessment is required whenever test results are to be meaningfully interpreted. Thus, in the setting where a patient ÒclearlyÓ has AIDS (e.g. assume 99.9% assurance based on clinical and epidemiologic grounds pre-test), a negative result is very likely to be falsely negative (as can be seen in the last row of Table 8.1). CDC has developed a series of guidelines for counseling, testing, and referral to assist clinicians in the proper interpretation and reporting of test results to patients (25Ð29).

Although health care professionals who order HIV tests have become increasingly familiar with these tests, it is important for the laboratory report to provide the clinician with considerable guidance concerning the implications and limitations of the test results. Further consultation with the laboratory (or blood bank) director, infectious disease specialist, or other expert may be particularly important in circumstances of an ÒunexpectedÓ result. Such experts should be able to assist the clinician in employing standard principles of decision theory to apply the battery of tests appropriately and efÞciently to a given situation. For example, blood donor screening assays have been developed to maximize sensitivity to meet the specialized needs of safety for the blood supply. This results in decreased speciÞcity, identifying the need for conÞrmatory testing of reactive samples.

ConÞdentiality concerns may severely limit the information that is routinely provided to the testing laboratory by the referring professional. Since clinical data impacts on the Òpre-test probabilityÓ assessment and thus on the predictive value of a test, such direct discussions may help resolve the clinical interpretation of putatively Òindeterminate Ó results. The types of tests and considerations regarding them are discussed in depth below.

In newborns, the presence of anti-HIV antibodies indicates passive acquisition of antibodies from the mother

and/or active HIV infection. Tests that detect the virus itself can thus be particularly informative in this clinical setting. These specialized tests are also important to detect virus in a person who is infected, but antibody negative (Òseronegative)Ó This would occur in special circumstances such as in the peri-seroconversion period, and in the case of certain strains of HIV not well detected by some standard assays (e.g. HIV Group O).

ANTIBODY DETECTION

The enzyme-linked immunosorbent assay (ELISA), or enzyme immunoassay (EIA), was originally successfully employed to detect antibodies to HTLV (30), and led to the development of a prototype HIV EIA that was reproducible, sensitive and speciÞc (23,31,32); the methodology is described in these studies. The research breakthrough enabling production of puriÞed HIV type HTLV-IIIB in large quantities was integral to the development of these assays (2).

The FDA Þrst licensed anti-HIV-1 antibody EIA kits for commercial distribution to screen donated blood products in the U.S. in 1985. ÒAlternative test sites,Ówhere persons who considered themselves at increased risk for HIV infection could be tested voluntarily, were also developed (33). In the ensuing years, testing for HIV became more widely available, and in 1996 home specimen collection with samples sent to a central laboratory that uses standard assays became an FDA-approved option. The Centers for Disease Control and Prevention recommends that all states and territories conduct surveillance for cases of HIV infection (34). States vary as to whether personal identiÞers are required as part of the conÞdential reporting of positive HIV test results to their health department.

Tests that detect anti-HIV antibodies can be divided into two broad categories, screening tests and supplemental tests (Table 8.1). The latter are usually more speciÞc tests that are used to conÞrm a screening test result as part of a testing algorithm. The FDA has licensed and approved anti-HIV antibody screening tests and supplemental tests from multiple vendors and for use with a variety of specimen types. For example, screening and supplemental tests are available for use with whole blood, serum, plasma, dried blood spots, urine, and/or oral ßuid.

In the absence of gold standards, the true sensitivity and speciÞcity for the detection of HIV antibodies remain somewhat imprecise. Initial generation HIV EIAs primarily detected IgG, not IgM or IgA, antibodies. Current EIAs may also detect IgM. HIV p24 antigenemia and/or IgM antibodies can precede the expression of IgG antibodies. Thus, even if an IgG assay were perfectly sensitive for such antibodies, some persons truly infected with HIV could not and would not be detected by serologic tests for HIV IgG antibody. The frequency, duration, and importance of the seronegative window period remain the subject of investigation (35,36). Concern about narrowing the window led the FDA to license and the U.S. blood banking industry to implement sequentially revised and additional screening methodologies for the U.S. blood supply (see below).

SCREENING TESTS

There are currently two types of screening tests in use in the U.S. to detect anti-HIV antibodies, EIAs and rapid HIV tests.

EIA

The EIA (ELISA) was the Þrst type of test to be licensed in the U.S. to detect infection with HIV. The Þrst generation of commercial EIAs had sensitivities and speciÞcities (see Table 8.1 and reference (23) for deÞnitions and formulae) of approximately 98% (37,38). However, comparative data on the EIAs were limited and complicated by the absence of a generally accepted gold (or even silver) standard (see Table 8.1). Licensure required correct identiÞcation of sera in an FDA test panel, but the panel was limited in extent and was designed as but one of several essential minimum requirements. Different manufacturers have used different panels of sera in their evaluations. Therefore, apparent observed differences sometimes merely reßect differences in patient selection and not true differences among the tests.

Lacking an established reference laboratory standard, in 1984 a prototype HIV EIA was assessed on the basis of clinical-epidemiologic considerations, which included a panel of sera drawn from healthy blood donors prior to the AIDS epidemic who were considered Òtrue negativesÓon epidemiologic grounds (23). The subsequent FDA assessments of vendor products rely upon current blood donors to determine how a given product performs, with assessments in both high and low risk populations and individuals known to be infected with HIV, complemented by specialized historical collections such as seroconversion panels to assess not only the clinical sensitivity and speciÞcity, but also the analytical sensitivity of a given test (24,39,40).

Screening of a person for HIV as of this writing most often begins with an initial screening EIA (23,41), and may begin with a rapid test in some other situations (see below). If the EIA is reactive, the EIA is repeated in duplicate on the same specimen. If repeatedly reactive, the specimen is tested with a more speciÞc supplemental test to validate the EIA results and to prevent notiÞcation based on false-positive results that might occur with the screening tests. Supplemental tests include the Western blot (WB) or the indirect immunoßuorescence assay (IFA)

(see below). This algorithm is used with serum, plasma, dried whole-blood spots, cadaveric and oral ßuid specimens (42Ð50).

To perform an EIA, the specimen is diluted and added either to a well that is coated with HIV antigens (whole virus lysates, recombinant HIV proteins, or HIV peptides) or to a well containing an antigen coated bead. Antibodies present in the solution bind to the HIV antigens. Following an incubation and wash step to remove unbound material, a conjugate is added that binds to the anti-HIV antibodies that are present. For example, anti-human IgG conjugated to an enzyme, such as horseradish peroxidase, is used in some systems. Bound conjugate is detected by adding a substrate that changes color in the presence of the enzyme. The result is read by a spectrophotometer. Negative or positive controls (or both) are also run and used to calculate a cutoff value for the assay. Results are typically reported in terms of the signal to cutoff ratio, or S/CO. S/CO values > 1.00 are considered to be reactive. Similar to the EIA is the chemiluminescent immunoassay (ChLIA). In this system, the readout is photons that are read by a luminometer.

The Þrst generation HIV EIA kits used puriÞed disrupted whole virus, which included steps that attempted to remove the cellular contaminants during the manufacturing process. However, simply removing cellular debris from HIV preparations produced in human cell lines, such as H9/HTLV-IIIB, did not remove residual reactivity to high-titer HLA-antibody sera due to the physical association of HIV virions with HLA class II molecules. Although it turned out that there was very little such reactivity with the prototype assay itself, reßecting high antigen purity (23,51), problems associated with false HLA reactivity were noted subsequent to licensure for at least two other Þrst generation commercial assays (52,53). Methods to reduce HLA reactivity were by necessity subsequently developed (54) and the second generation of HIV EIAs had improved speciÞcity. Another opportunity for problems with speciÞcity came about with the advent of viral components produced through recombinant methods in bacteria such as *Escherichia coli* (55). Injection drug users use non-sterile works (paraphernalia involved in injections) and are frequently repetitively exposed to bacterial pathogens, including the ubiquitous *E. coli*. It is suspected that this may account for why such persons had particularly high rates of false reactivity on these recombinant assays.

EIA currently remains the method of choice to screen blood donors for antibodies to HIV (Table 8.2). Whereas these tests are technically complex to perform and require dedicated equipment in a centralized testing laboratory, they are well suited to processing large numbers of specimens efÞciently. There are currently several licensed or approved EIAs that detect antibodies to only HIV-1, one that detects antibodies to HIV-2, and others that detect antibodies to both anti-HIV-1 and HIV-2 (referred to as ÒcombiÓ tests). In the U.S., the latest generation of licensed EIA screening tests typically has sensitivities of ³99.99% and speciÞcities of ³99.9% when using serum, plasma, or dried blood spot specimens. These performance values are based on clinical trial information provided by the manufacturer is support of licensure or approval.

The reference body ßuid for antibody testing is blood, utilizing either serum or plasma. Antibodies may also be reliably detected in urine, both with research assays and with minor modiÞcation of the recommendations by the vendor of commercial assays (56Ð65). The relatively acellular nature of a clean-catch urine in the absence of genital or bacterial urinary tract infections may balance the apparently lower titer of antibody, to enable the attainment of a reasonable sensitivity/speciÞcity trade-off. The original reports used tests designed for blood with modiÞcation, whereas newer assays are designed speciÞcally for testing urine. There was a controversial report in 1993 claiming to Þnd HIV antibodies in urine despite absence of antibodies in blood (66). In licensing urine assays in 1996 (67), the FDA required as the criterion standard demonstration of HIV infection based on blood tests.

Detection of HIV antibody in oral ßuids has been somewhat more problematic (68Ð70). One possibility is that proteins or other substances may bind to HIV antibodies, impairing detection. False positives clearly can occur (71). Results on paired serum and saliva samples have been reported (72). There may be differences between testing saliva and oral ßuid.

Assays licensed for use with other specimen types such as urine or oral ßuid have performance characteristics that are generally lower. As of this writing, according to clinical data supplied by the manufacturer and listed in the package insert of the test kit, a urine EIA (Calypte® HIV-1 Urine EIA) had sensitivity of 99.0% and its speciÞcity varied in studies from 82% to 99.14%. An oral ßuid EIA (Oral Fluid Vironostika® HIV-1 Microelisa System) had sensitivity of ³98.6% and speciÞcity of ³97.7%. Tests that use these alternative specimen types are useful when collection of a blood specimen is not possible, but it must be recognized that sensitivity and speciÞcity are lower.

The ability to test dried blood spot specimens by EIA and by supplemental testing led to the development and approval of a test system for self-use by people who wish to obtain anonymous HIV testing (Home Access HIV-1 Test System, Home Access Health Corp., Hoffman Estates, IL). In this case, the test subject is provided with materials to self-collect a dried blood spot specimen that is shipped to a central testing center. The testing center performs EIA on the specimen and supplemental testing as necessary. The test subject is instructed to call the center within one week, using a unique identiÞer to receive the test results. Results are provided by an appropriately trained individual who explains the test result and its interpretation. Counseling and referral are also provided as part of the service. Such a system has been useful for

individuals who, for whatever reason, wish to maintain anonymity in the testing process.

The Public Health Service recommends that repeatedly reactive EIA results not be reported to the test subjects until they are conÞrmed by supplemental testing as discussed in detail below (73).

Rapid HIV Tests

Tests used to screen blood donors for HIV infection were developed for efÞciently testing large numbers of specimens. As such, these tests are technically complex, requiring multiple timed, temperature-sensitive steps and, in most cases, dedicated equipment is necessary to perform the test effectively. Therefore, these tests are performed in centralized laboratories. This testing has served and continues to serve blood donor screening well with tests that are highly sensitive and speciÞc. However, the needs in the blood donor screening arena are very different from those in the diagnostic arena. Whereas the intent of blood donor screening is primarily to determine the suitability of a donated unit of blood or plasma for medical use (i.e. product-oriented), the intent of diagnostic testing is to provide the patient and the professional caregiver with information that will be used to allow for counseling to change behavior and reduce the risk of transmission, to notify partners of the infected individual, and to make medical decisions. Therefore, diagnostic testing is patient-oriented. Using a blood donor screening test for diagnostic purposes requires two visits to the testing site, one to collect the specimen and another to receive the test results, often one to two weeks later. Such

TABLE 8.2. *Evaluation of potential sources of error with HIV EIA screening tests*

I. *Dichotomous Interpretation of Results*
The test is actually a continuous measurement: the chance of misclassi cation varies with the relative test reactivity strength of the sample. Thus, if the test result is merely classi ed as negative/positive, information is lost. As an alternative, results may be classi ed as:
a. Non-reactive
b. "Gray zone positive," weakly reactive, or borderline
c. Reactive
d. Strongly reactive

II. *Procedural Error*
a. Physical mixing up of specimens during testing (retesting correctly labeled sera would reveal a discrepancy).
b. Subsequent incorrect linkage of test results (testing of a newly acquired specimen from the same subject would reveal a discrepancy).

III. *Technical Error During Testing*
a. Erroneous dilution (or omission) of sera or reagents
b. Splashing during test sera or reagent addition, or pipette contamination
c. Washing errors
d. Incorrect absorbance measurement (e.g. wrong wavelength; bubbles on wet plate or scratches on plate; equipment or electronic malfunction).

IV. *Test Kit Error*
a. Variability in kit reactivity (related to vendor quality control)
b. Instability or deterioration of reagents

V. *False Positive Results*
Although some occur in association with certain clinical conditions, speci c con rmatory tests are important.
a. Recognized Problems
1. HLA-antibodies: (particularly related to the viral puri cation process of some early test kits; poses a diagnostic question for multiparous women and others with repeated HLA exposures)
2. Repetitive freeze/thaws (e.g. some stored sera)
3. Other retroviruses
4. Heating of sera
5. Autoantibodies (e.g. ? antinuclear antibodies as in systemic lupus erythematosus, or anti-mitochondrial antibodies) (419)
6. Hypergammaglobulinemia, “sticky sera” (e.g. specimens from Africa)
7. Cross-reactive proteins (e.g. 25–30 Kd) (420)
8. Non-speci c IgM binding (e.g. after vaccination; possibly also related to acute or in ammatory phase responses) (421–425)

VI. *False Negative Results*
a. Group-O or other variants (see text) (94)
b. HIV-speci c antibodies may decline as a function of severity of HIV related immune dysfunction
c. Viremic patients without (IgG) antibodies—including those persons recently exposed/infected.
d. Hypogammaglobulinemia (including congenital conditions) as a variant of (B) above.
e. States of antigen excess.
f. Heating of sera.
g. Transient seronegativity (? selected pediatric infection)

a system can result in considerable anxiety for the patient. In addition, CDC estimates that 8,000 HIV-infected people who come into public clinics for HIV testing do not return to receive their test results. Even in hospital settings it can take at least 24 hours to receive an HIV test result. One possible way to remedy this situation is through the use of point-of-care tests that permit test results to be provided to patients at the time that their specimen is taken, commonly referred to as rapid HIV tests.

Alternative screening formats besides EIA had been developed; for example, dot-blots and latex agglutination formats. The latter can yield results in seconds (74), analogous to some home pregnancy kits. Early developmental work indicated frequent pro-zone phenomena, in which sera with high levels of HIV antibody gave false negative results. Dilution of sera both identified and resolved this problem, but the sensitivity and specificity have remained below that of the EIAs. Thus, these kits were recommended only where sophisticated laboratories were impractical or rapid preliminary results were very valuable.

Rapid HIV tests are, at present, immunoassays that can be in a few different formats. In the flow-through immunoconcentration system, a specimen is mixed with HIV-1 antigen-coated latex particles. If anti-HIV antibodies are present, they will bind to the antigen on microparticles. This mixture is applied to a membrane housed in a cartridge. Absorbent material below the membrane facilitates flow through the membrane. Antibody bound to the latex beads is detected by means of an anti-human antibody conjugated to a readout system, such as an enzyme and a substrate. In this type of system, a series of wash steps are needed following the addition of each reagent.

A second type of immunoassay used for rapid HIV tests is the lateral flow immunochromatographic system. In this case, a specimen is added to a dilution buffer, and the test device containing a test strip is inserted into that solution. The solution flows up the device by capillary action and rehydrates a colored conjugate that binds to antibodies in the solution. The mixture then passes through a region of the test strip containing immobilized HIV antigens. If antibodies to HIV are present, the anti-HIV-conjugate complex binds to that portion of the membrane and a line appears. This type of test may also include a second line that captures conjugate complexed with any human IgG, thus serving as a procedural control. (Some home pregnancy test kits have used similar methodologies.)

A third type of device is a cross between the first two, a flow-through device containing a membrane on which antigens are bound. All tests are typically manually performed and visually read qualitative tests.

The first rapid HIV test available for use in the U.S. was Recombigen, a latex agglutination test licensed by the FDA in 1989. However, it was not widely used because it was not as accurate as other licensed HIV tests, and it is no longer available.

The Single Use Diagnostic System (SUDS) manufactured by Abbott/Murex was licensed in 1992 for the detection of antibodies to HIV-1 in serum and plasma. The test requires refrigerated storage of the test kit reagents and takes approximately 30–45 minutes to perform with multiple washing and incubation steps.

Rapid HIV tests should ideally have several characteristics to be useful in point-of-care settings as an aid in the diagnosis of HIV infection. They should (1) provide a test result within about 20 minutes, (2) not require the use of specialized equipment, (3) not require special storage conditions, (4) be simple to run with few manipulations, and (5) be nearly as sensitive and specific as licensed blood donor screening tests.

One such test is the OraQuick Rapid HIV-1 Antibody Test (OraSure Technologies, Inc., Bethlehem, PA), which was approved by the FDA in November 2002 (26). This visually read immunoassay provides a test result on a whole blood specimen obtained via fingerstick within 20–60 minutes, with a stated sensitivity of 99.6% (95% C.I = 98.5%–99.9%) and specificity of 100% (95% C.I = 99.7%–100%), according to data provided by the manufacturer in support of FDA approval.

According to guidelines set by CDC (25), reactive rapid test results should be confirmed by more specific testing, such as WB, requiring a return visit by the test subject to obtain the confirmatory test result. On the other hand, recognizing that highly accurate tests have a very high likelihood of a correct result and that there is a clear benefit to the test subject and the test subject's contacts, a reactive result may be reported to the test subject as a preliminary positive result, with appropriate information on the meaning of that result in the context of the test subject's risk factors, if any. A non-reactive test result is reported as negative, but careful explanation of the interpretation of that test result is needed, especially in the case of a test subject who may have had a recent exposure placing that subject in the window period before seroconversion (see below).

As additional rapid HIV tests become available in the U.S., the appropriateness of using different combinations of such tests will be evaluated. A multitest algorithm could conceivably allow a test subject to receive a highly accurate test result in a single, relatively short visit to a testing site.

SPECIAL SCREENING ISSUES

HIV-2 and HIV-1

The initial serologic studies in West Africa that found reactivity to a second, related HIV were based on cross-reactivity to simian retroviruses. Isolation and characterization of LAV-2 led to the acceptance of what became known as HIV-2 as a virus distinct from HIV-1, but controversy existed initially regarding pathogenicity

since most persons infected with HIV-2 appeared to be healthy in several of the initial serosurveys in Africa.

In 1988, the first instance of AIDS in an HIV-2 infected individual in the United States was confirmed (75). This case helped to establish the fact that HIV-2, at least in some persons, can cause clinical AIDS (76). Importantly, this case of HIV-2 infection highlighted the limitation of some HIV-1 screening tests for detection of HIV-2, indicating the limitations involved in depending solely upon cross-reactivity between antibodies to HIV-2 and HIV-1 antigens (77). As a result, screening tests for HIV-2 were developed, incorporating HIV-2 viral lysates. In addition, tests were developed that detect antibodies to HIV-1 and HIV-2. These screening tests are quite useful in countries with a very low prevalence of HIV-2, such as the United States (78–80). Contrary to some theoretic expectations, the sensitivity of the early combined assays was comparable to many of the individual HIV assays. Since implementation of testing for HIV-2 in the United States, additional cases of HIV-2 infection have been documented (81). There are currently one licensed EIA to detect antibodies to HIV-2 and two licensed EIAs to detect antibodies to both HIV-1 and HIV-2.

Serologic discrimination of HIV-1 and HIV-2 can be difficult (82), so that confirmation by nucleic acid testing is helpful (77,83,84) and has been utilized to demonstrate apparent co-infection with both HIV-1 and HIV-2. Other possible approaches include competitive EIAs (85) or assays containing type-specific synthetic peptides. The size of the HIV-1 and HIV-2 antigens also differ somewhat (confer Table 8.3), so that WB and radioimmunoprecipitation assays prepared with the respective viruses (see below) also can provide some assistance (77,86–88). Because of the serological cross reactivities between HIV-1 and HIV-2 (Fig. 8.1), in certain populations it is difficult to ascertain whether an individual is infected with HIV-1,

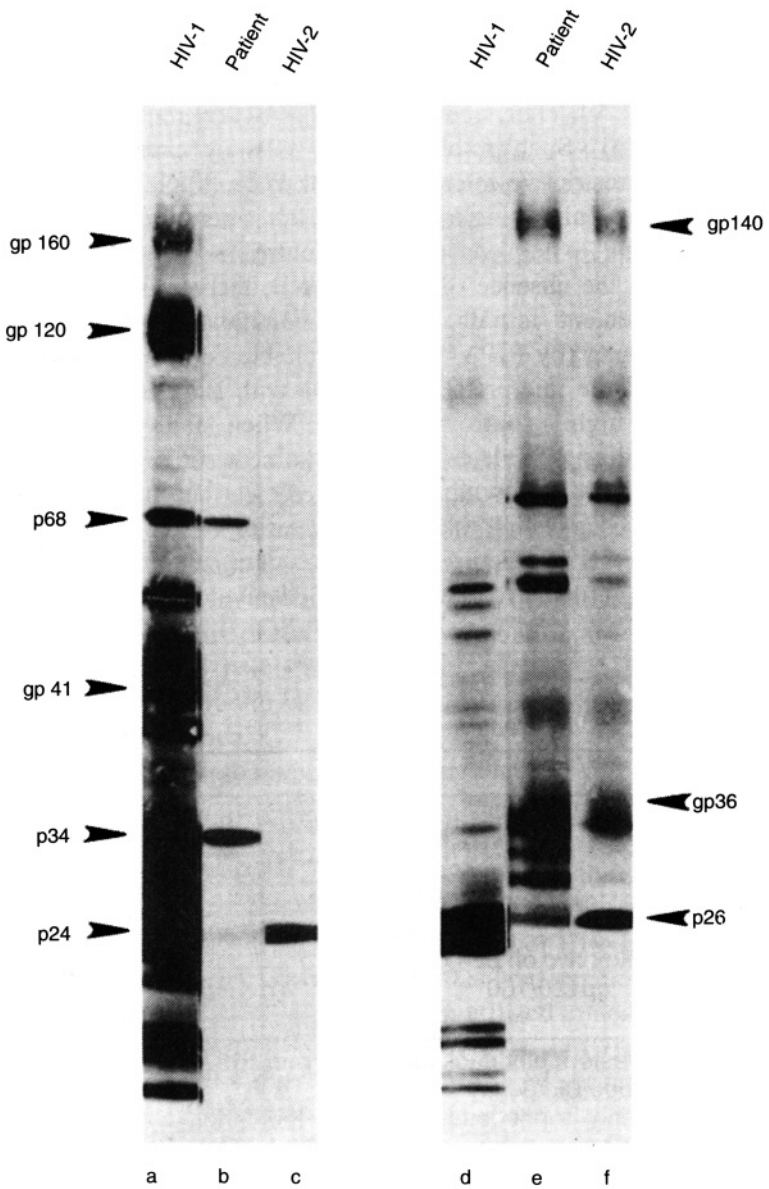

FIG. 8.1. Western blot analysis of sera samples from a HIV-1 control, an AIDS patient with PCR-confirmed HIV-2 infection (77), and a HIV-2 control on HIV-1 antigens (lanes a through c) and on HIV-2 antigens (lanes d through f). Reactivity and cross-reactivity of HIV-1 and HIV-2 are demonstrated in the *gag* (p24/p26), *pol* (p31/p34 and p66/p68) and *env* (gp41/gp36 and gp160/gp140) gene products. Figure courtesy of Joseph M. Lombardo, M.D., Ph.D. and Stanley H. Weiss, M.D.

HIV-2, a new viral type, or whether the individual is infected simultaneously with multiple viruses (88). More speciÞc tests such as viral isolation or molecular probes (e.g. nucleic acid ampliÞcation) remain necessary to distinguish between infections with these viruses in some populations (89).

Dual EIA Assays to Detect Recent Infections

An interesting use of EIAs has been described that is effective in identifying recently infected individuals (90,91). This strategy is based on the knowledge that during the Þrst three to four weeks following exposure to HIV, circulating antibody levels progressively increase (see Window Period section below). At this time, conventional EIAs are effective at detecting these relatively low levels of antibodies. On the other hand, an EIA that is run using a modiÞed protocol to make it less sensitive (a so-called ÒdetunedÓ assay) cannot detect anti-HIV antibodies at this stage of the infection. Therefore, a specimen that is repeatedly reactive using the conventional assay but is negative using the detuned assay most likely represents a recent infection. This strategy is being employed by CDC to distinguish recently infected individuals from those who have established infections, in an effort to better understand the spread of HIV.

HIV Group O

In classifying HIV-1 strains, most are classiÞed under Group M (Òmain)Ó, but some are classiÞed as Group (O) (ÒotherÓ). These Group O strains were initially noted on rare occasions in some African sera that had screened negative for HIV antibodies with some commonly employed tests. Tests using recombinant products (with increased speciÞcity) instead of cultured viral products (with potential broader range of detection) appear to be more likely to give false negative results with Group O infections. With the detection of sera from a Group O infected person in the U.S., increased emphasis has been placed on monitoring for these strains and the potential need to modify current screening procedures (92Ð94). As also discussed further below, in persons in whom HIV infection is strongly suspected, additional testing may be necessary even if the initial screening test is negative (77,94). Although there are currently no serological assays licensed or approved to detect antibodies to HIV-1 Group O, and these strains currently still remain very rare in the U.S.

IgM and IgA Assays

Research serological tests for IgM and for IgA antibodies have been developed (95). Since IgM and IgA do not cross the placenta, particular attention was placed on the potential for use in neonatal diagnosis. Some negative HIV IgM tests during the Þrst month of life, however, occurred in children who were later shown to be HIV-infected. These misclassiÞcations, due to biologic phenomena (the child having been infected pre-partum) rather than technical issues, led to alternative methodologies to resolve whether a newborn is infected. Neither IgM nor IgA assays have been commercialized.

ANTIBODY CONFIRMATION ASSAYS

Due to the imperfect speciÞcity of screening tests, reactive EIA results are not sufÞcient to make the absolute determination that an individual is infected with HIV. Given the low prevalence of HIV infection in the U.S. and the high speciÞcity of HIV screening tests, the negative predictive value for EIA screening tests in blood donors is high (see above). CDC has recommended that repeatedly reactive EIA results and reactive rapid test results be followed up with supplemental testing, sometimes referred to colloquially as Òconfirmatory testingÓ (see Table 8.1). There are two types of supplemental tests in common use today, the WB and the indirect immunoßuorescence assay.

Spectrum of HIV Antibodies

While the disrupted whole virus EIA detects HIV antibodies, the precise spectrum of component antibodies remains undetermined. Several confirmation assays enable the visualization of speciÞc antibody reactivities. With the sequencing of the nucleic acid structure of several isolates of HIV, the functional structure of this RNA virus was rapidly unveiled. The HIV genome includes several Òopen reading framesÓ related to essential viral components, including:

1. *gag* Ðthe viral core,
2. *pol* Ð the enzymes reverse transcriptase (which is essential in creating a DNA copy of the viral RNA) and endonuclease,
3. *env* Ðthe envelope of the virus, including the glycoprotein (gp) membrane,
4. *tat* Ða trans-acting protein related to the control of viral replication.

Serologic work based on cloned monoclonal reagents (96Ð98) along with concordance to predictions based on the viral genome have provided an evolving picture of the relationship of various component viral proteins to HIV-1 (Table 8.3). (The gene product sizes for HIV-2 differ somewhat; confer (77,83,84,86,99) and Table 8.3). These components vary in inherent immunogenicity, and may be produced to varying degrees during the course of infection. Antibodies to some viral components, e.g. the HIV-1

TABLE 8.3. *Major genes and gene products of HIV-1, HIV-2, and HTLV*

Miscellaneous			p38 tax, p42****

* Represented by: p = protein or gp = glycoprotein; plus the approximate molecular weight of the antigen in kilodaltons (kd).
** Endonuclease and reverse transcriptase.
*** Can be produced in high titer by recombinant methods.
**** p42 is of uncertain origin; some believe it may be *gag* related, but it is not included in current standard genome maps.

regulatory gene tat-III (14 KD), are not detected by standard techniques.

Western Blot

The Western blot (WB), also known as immunoblot, procedure has become a mainstay in supplemental testing since it readily permits visualization of the component antibody reactivities and, in essence, reveals the reason behind the reactivity in the screening assay (31,32) (Fig. 8.1).

Preparation of the WB begins with puri Þcation of HIV virions from cultured cells, followed by dissociation of the concentrated HIV with detergent. The viral proteins in this lysate are then resolved by polyacrylamide gel electrophoresis, separated by their molecular weights, after which they are electrophoretically transferred to a solid support, such as nitrocellulose paper, and then cut into strips. Individual strips are reacted with either test or control sera; bands where the serum antibodies have bound are normally detected by anti-human-IgG conjugated either directly or indirectly (through biotin-avidin) to an enzyme (e.g. horseradish peroxidase or alkaline phosphatase) and reagents that react with the conjugate to produce a band. Whereas the viral lysate puri Þcation steps in early assays resulted in the loss of gp120 and gp160, second generation WBs use puri Þcation techniques that allow gp120 and gp160 to be saved. WB results are given as a series of intensity readings for each band.

Several alternative criteria had been proposed for HIV-1 WB interpretation (Table 8.4). As discussed further below, since the CDC recommends the ASTPHLD criteria based on CDC evaluations, the other criteria are rarely now applied. The Cambridge Biotech HIV-1 Urine Western Blot Kit, which is manufactured by Calypte Biomedical, has different criteria; only a gp160 is required for positivity.

Radioimmunoprecipitation

The radioimmunoprecipitation assay (RIPA) requires HIV to be grown in cell culture in the presence of a radioactive label, puri Þed, and disrupted (100Ð102). Standard techniques lead to poor labeling of gp41, but lentil-lectin enhancement or alternative radiolabels may be utilized if gp41 detection by RIPA is desired. In this technically complex procedure, the radiolabeled lysate is reacted with the test serum, the immune complexes

TABLE 8.4. *Criteria for Òconfirmed positiveÓ HIV-1 Western Blot result on serum, plasma or dried blood spot*[1]

Organization	Minimum Band Pattern Required

2. DuPont-Biotech[3]	p24 *AND* p31 *AND* (gp41 OR gp120/160)
3. Consortium for Retrovirus Serology Standardization (426)	(p24 OR p31) *AND* (gp41 OR gp120/160)
4. American Red Cross (148)	At least one band from *each* gene product group: *gag AND pol AND env*

[1] The “Cambridge Biotech HIV-1 Urine Western Blot Kit” which is manufactured by Calypte Biomedical has different criteria; only a gp160 is required for positivity.
[2] Also supported by the Centers for Disease Control and Prevention (42,427), and utilized in the current package inserts by Bio-Rad Laboratories and Calypte Biomedical Corp.
[3] Food and Drug Administration-licensed DuPont Western blot package insert from 1987. However, the criteria for this blot, which is now called the “Cambridge Biotech HIV-1 Western Blot Kit” which is manufactured by Calypte Biomedical Corp., per the current package insert now conforms to the ASTPHLD criteria.

isolated by precipitation, washed, resolved electrophoretically, and exposed to Þlm to reveal the viral components bound by the patient specimen. The entire process takes several days to over a week. Since RIPA reliably detects gp120 and gp160 antibodies, it was the reference standard for these large envelope antibodies until WBs were improved. RIPA analysis routinely includes a comparison against control material from a radiolabeled uninfected cell culture, to differentiate cellular bands from viral bands.

Utilization and Interpretation of WB and RIPA

WB and RIPA are said to conÞrm a repeatedly reactive EIA screening test result because they can readily reveal the speciÞc anti-HIV antibodies responsible for the reactive result. When classic patterns are present, positivity is a virtual certainty (Table 8.4). When several related antibodies are detected, the pattern still has high predictive value. Thus, the WBÕs that detect gp120 and gp160 are helpful in classifying potentially ambiguous sera. In some lots of WB reagents, the gp120 and gp160 bands may not be sufÞciently separated to appear as clearly independent bands.

A broad gp41 WB band was initially accepted as adequate conÞrmation of sera from a person at high risk of HIV. It was also clearly necessary to have further conÞrmatory evidence for sera from very low risk group sera. Since a solitary sharp (thin) WB band at p40 was likely to indicate reactivity unrelated to HIV, an experienced virologist and laboratory were crucial in making this critical but subjective distinction during the Þrst years of HIV testing. As in other areas of medicine, adequate training in subtle differences can be essential.

Greater experience and the extension of testing to many labs revealed that signiÞcant variations in WB reactivity were observed in practice, with results frequently discordant compared to those from reference WB laboratories (103). Thus, aberrant Þndings clearly required follow-up (104). Such problems led to calls for more formalized and restrictive interpretation of WBs (Table 8.4). In some states, only a single centralized lab is permitted to perform testing to help ensure quality control.

In the absence of gp41 on WB, there initially was widespread agreement that the combination of p24 and pr53gag (by RIPA) provided reliable conÞrmation. However, the interpretation of WBs with isolated reactivities was highly controversial (105). When single bands were noted as the sole reactivity, in some instances subsequent testing of follow-up sera showed clear-cut broad reactivitiesÑ suggesting that the initial result was consistent with early HIV infection (106). Some data suggested that p24 core antibody frequently preceded envelope antibodies.

However, persons with solitary p24 bands may be found among historic blood donor sera (23) and instances of prolonged persistent p24 reactivity in low risk subjects have been noted. This persistent reactivity pattern can be associated with a relatively sharp (i.e. atypical) p24 region. Whereas the initial CDC WB interpretative criteria accepted p24 alone as sufÞcient for WB conÞrmation of sera that were repeatedly reactive by EIA, retrovirologists now routinely treat such WB patterns as equivocal. Thus, in some early epidemiologic studies some persons may have been misclassiÞed. Incorrect classiÞcation by WB can occur (107).

The observed sequence of development of HIV antibodies is dependent upon the inherent technical sensitivities of the assays employed as well as the biology of infection. Thus, although gp41 antibody may be absent on WB, other *env* antibodies such as gp120/160 may be detected. Some sera that have appeared to have antibodies solely to the p24 core antigen can be shown to also have *env* reactivity with RIPA and other newer assays. Commercial HIV antibody assays have tended to Þrst detect p24 antibody in seroconverters.

The interpretation of other WB and RIPA patterns in terms of speciÞcity and sensitivity for HIV infection remains uncertain (39,87,108). Persons without evidence of HIV antibodies or with unusual WB reactivity patterns have sometimes been found to be HIV-infected by culture (39,109) or had positive PCR results (110,111), as discussed below.

Several alternative criteria have been proposed for HIV-1 WB interpretation (e.g. see (112,113)), and all are in agreement that the lack of any bands on the WB is considered to be a negative result. CDC has recommended that a positive result when testing serum, plasma or dried blood spots is deÞned as at least two of the following: p24, gp41 and gp120/160 and it is this interpretive scheme that is generally followed (Table 8.4). (42). When testing urine, the Cambridge Biotech HIV-1 Urine Western Blot Kit has different criteria; only a gp160 is required for positivity. Any other pattern on these assays is considered to be an indeterminate result.

No WB is currently licensed in the U.S. for conÞrmation of HIV-2; although the long-term follow-up of indeterminate results from research assays has been examined (114), limited data exist.

Indirect Immunoßuorescence Assays

The indirect immunoßuorescence assay (IFA) relies on the ability to detect anti-HIV antibodies from patient serum or plasma that bind to the surface of infected test cells. Acetone-Þxed HIV-infected and uninfected (control) cells are typically applied to slides or isolated wells, incubated with test sera, and counter-stained (e.g. with ßuorescein-conjugated anti-human IgG). A dilution series of a given serum is usually run to assess strength (titer) of reactivity. The reactions are viewed microscopically. The ßuorescent staining pattern, when read by a skilled observer, is quite informative. Anti-nuclear antibody and

anti-mitochondrial antibody reactivity patterns may be causes of non-speciÞc reactivity. Furthermore, the titration-endpoints of the reactions on the infected and uninfected cells can be compared. This information is then synthesized as a positive or negative result. There is signiÞcant potential for observer bias in these subjective assessments. Reactions against both infected and uninfected cells may suggest non-speciÞc reactivity. However, such an IFA pattern might also occur concomitantly with true HIV-speciÞc antibody, such as in high-risk persons with high anti-HLA titers (51). There is currently one FDA-licensed IFA available for clinical use.

OTHER ANTIBODY TESTS

Neutralizing Antibodies

Some HIV antibodies have neutralizing properties *in vitro*, detected by inhibition of syncytial formation (115Ð118). The protective role, if any, of antibodies detected by these methods remains to be determined (119,120). These research assays have found particular application in the HIV vaccine developmental efforts (120). Antibodies to puriÞed thymosin alpha-1 also show some evidence of neutralizing capability *in vitro*, which may be related to its similarity to HIV p17 (121). SpeciÞc antibody may sometimes reduce mother-to-child transmission (122Ð124).

The principal neutralizing domain of HIV appears to be in the V3 hypervariable region of the envelope (the ÒV3 loopÓ) (125Ð130), although other viral regions may also prove to be important. Limited variation, either in the V3 loop (131) or outside of it, can affect neutralization. The reactivity pattern to various neutralizing antibodies were useful in classifying the viral strain (132Ð138), but this approach has been supplanted by newer techniques.

Neutralizing antibodies appear to be in higher titer in HIV-2 infection than in HIV-1 infection, and they may be more important in the clinical epidemiology of HIV-2 as compared with HIV-1 (139). In this context, it is interesting to note that the natural history of HIV-2 is associated with slower progression to disease than is seen with HIV-1. These Þndings carry possible implications for vaccine development. Unless tests for neutralizing antibody to HIV prove to be important clinically, diagnostic assays will likely remain in the province of research laboratories.

Control Assays

HIV antibody detection tests generally involve the use of preparations containing one or more HIV antigens. An analogous assay may be run in parallel with comparable reagents but excluding HIV antigen, providing a comparison (control) assay for the evaluation of reactivity. Absence of reactivity on the control assay in the face of reactivity on the primary assay implies the reactivity was related to HIV itself, i.e. a true positive. This technique was used historically in research evaluation studies of EIA (e.g. the proprietary H9 control plate), immunoßuorescence, and WB methods, and it was a critical parallel control in radioimmunoprecipitation and in early direct viral detection methods. While reactivity in the control assay indicates the presence of some reactivity to non-viral constituents (e.g. related to HLA antibodies or antinuclear antibodies), it cannot rule out the possibility of concomitant true reactivity. Thus, false positivity cannot be presumed. With the advent today of many alternative HIV assays, this type of control assay (which could not deÞnitively discriminate between true and false positivity, and as tests that directly detect conditions associated with false reactivity (e.g. HLA antibodies) do not rule out true positivity (51,53)) has few uses today. In summary, although control assays assisted in data interpretation, they could not be relied upon as conÞrmation tools.

ISSUES PRIMARILY RELEVANT HISTORICALLY OR DURING DEVELOPMENT OF TESTS

Repository or Other Stored Specimens

Specimen integrity can have a signiÞcant impact on the performance of any assay. Manufacturers generally recommend that their kits be used on fresh sera.

Repetitive freezing and thawing of sera increases the probability of false positive reactions (reßecting decreased speciÞcity, usually manifested as weak reactives), and may potentially also decrease sensitivity. Likewise, if sera are heated in an attempt to inactivate virus as a laboratory biosafety measure, both assay sensitivity and speciÞcity may be impaired.

An analysis of speciÞc clinical conditions that have given difÞculties for certain tests in practice and knowledge concerning the design of these tests (and thus the theoretical problems) can help guide the discriminating laboratory manager in judiciously evaluating the results from a commercial assay (Table 8.2).

Reactivity Strength

Reactivity in the whole virus EIA, which detects reactivity to any of a variety of viral components, can vary depending upon the clinical status of the patient. For example, AIDS patients with opportunistic infections have been shown to be signiÞcantly less reactive by EIA than AIDS patients with KaposiÕs sarcoma (23). This probably reßects the observation that during the course of HIV infection, not only cellular immunity but also humoral immunity is impaired resulting in decreased levels of speciÞc antibodies. In contrast, persons with HIV-associated lymphadenopathy tend to be very strongly reactive

by EIA, as well as by immunoßuorescence (140), suggesting an enhanced humoral response.

The relative titers of viral component-speciÞc antibodies vary over time in individuals, leading to systematic differences in EIA reactivity (and, consequently, detection rates) among various populations or patient groups. Furthermore, in some persons HIV antigen may be produced in sufÞcient quantity to form immune complexes with corresponding HIV antibodies, potentially reducing the ability of those antibodies to bind to viral antigens in the assay and giving a false negative test result. As discussed above, in several panels of sequential sera from seroconverters, antibody to p24 was the Þrst to be routinely detected by WBs or monoclonal reagents.

Serologic evidence of anti-HIV antibodies reactive with live HIV-infected cells have been described recently, and called Òearly antibodies.Ó These may mark a relatively early immune response to HIV (141). The speciÞcities of these antibodies are characterized by the recognition of type-speciÞc conformational epitopes of gp160 and gp41 (see Table 8.3). It has been claimed that they may occur earlier than many other markers of HIV infection (141).

In late stages of HIV infection, given the existence of a spectrum of viral antigens, immunologic reactivity usually persists to at least some components. In early infection, the phenomenon of immune complex formation probably contributes to the Òseronegative windowÓ (see below). AcidiÞcation techniques, which disrupt immune complexes, were brießy used historically to improve the sensitivity of some early HIV antigen assays.

Special Problems for Tests that Detect Anti-HIV Antibodies

Studies undertaken in Africa suggested the occurrence of non-speciÞc, weak HIV EIA reactivity, particularly among persons with high antibody titers against species of malaria (142). Additionally, assays may be changed continually during their development, as investigators vary reagents and conditions, and it should be assumed that the performance characteristics will also change. Indeed, the non-speciÞc association seen with malaria in some early studies in Africa (142) may have been partly related to an insufÞcient accounting for this source of variation (143). This again highlights the issue of interpreting low level (Òweakly reactive result)Óreactivity on a screening test, in the absence of conÞrmatory assays.

Subsequent early investigators also found African sera to be unusually falsely reactive on certain EIAs (144). This would be consistent with the hypothesis that the higher immunoglobulin levels observed in this population may, in effect, systematically shift the standardization curve for African sera as compared to U.S. and European sera. Since a competitive EIA out-performed other screening methodologies in some research studies of African sera (145), there may be selected circumstances for specialized approaches. Exposure to other retroviruses related to HIV, human and/or non-human, may explain some of the low level reactivities in regions such as Africa. The early Þndings of very low titer (or low reactive) antibodies to HIV in stored sera from Uganda is consistent with such a possibility (146). Infrequently, high titer HTLV-I antibodies can lead to falsely reactive HIV screening results (23), perhaps relating to p24 *gag* protein cross-reactivity (147). With the continuing discovery of additional retroviruses, ongoing research is likely to clarify gradually these cross-reactivity issues.

Transient Issues

The ability to conÞrm a serological screening test result for HIV in the U.S. depends upon the availability of tests approved or licensed for that purpose. Early on, this was a problem as no conÞrmatory test was licensed when the Þrst screening tests became available. This became an issue again, transiently, in 2002 when the Public Health Service became aware of a potential shortage of licensed WBs (41).

INTERPRETATION OF HIV SEROLOGIC TEST RESULTS: DETAILED ISSUES

An essential part of the testing process takes place even before testing done; that is, the estimation of the probability of infection (the Òpre-testÓprobability). This is necessary in order to interpret a test result appropriately, whatever the purposeÑ whether it is clinical, counseling or researchÑ and can dramatically impact the predictive value after testing (or Òpost-testÓprobability).

In the absence of any information to assess the pre-test probability, as in the blinded laboratory, the positive predictive value can be maximized (and false positives minimized) by using extremely conservative classiÞcation criteria. This is done at the expense of classifying many samples Òindeterminate.ÓIn part, this explains the rationale for conservative WB criteria (148) (Table 8.4). The use of such criteria is analogous to the assumption that the pre-test probability is very low.

Gray Zone

Licensed clinical laboratories are required to adhere strictly to the package insert of licensed products, which represents the vendorÕs recommendations as approved by regulatory agencies. Historically and for research purposes, some laboratories have utilized additional cut-off points compared to the vendorÕs recommendation, since simple dichotomization (reactive vs. non-reactive) may be misleading (Table 8.2). Indeed, during a development process (such as clinical trials) or post-licensure surveillance of a productÕs efÞcacy, vendors may bring

"in-house" both reactive specimens as well as those with somewhat lesser reactivity. A threshold of 10%, and occasionally even 20%, below the standard cut-off is chosen; the gray zone (weakly reactive results) is defined as those between this threshold and the standard cut-off.

Epidemiologic assessment of HIV tests confirmed early on that HIV EIA reactivity was monotonically associated with positivity (23). A lower EIA cut-off value provides higher sensitivity but lower specificity for a given assay than obtained with a higher cut-off (23).

The nature and extent of further evaluation, and the ultimate clinical interpretation, vary as a function of the strength of EIA reactivity and the pre-test assessment.

Persons at High Risk

When the prior probability is high (as for persons at high risk from hyper-endemic regions or high risk groups), the positive predictive value of a reactive or strongly reactive EIA is extremely high (Table 8.2). Although a confirmatory assay, such as a WB, may give an "indeterminate" result based on simple application of some generic criteria (Table 8.4), the use of alternative interpretative criteria or additional tests can often be utilized to confirm the diagnostic impression.

A weakly reactive screening result, still likely to be truly positive based on risk factors, requires further testing to obtain confirmation if the WB is not clearly positive. Thus, it is important to evaluate the actual absorbance values, and not simply a reactive/non-reactive result, and these values should be routinely obtained from the testing laboratory in such circumstances.

A non-reactive result from a high-risk patient has only a moderate negative predictive value in this situation. Therefore, it is important to rule out technical or procedural error (Table 8.2), recheck the clinical history, and possibly employ alternative and/or more sensitive assays. Thus, an unexpected negative result should not be accepted as final without further evaluation, since it is essential to minimize false negative results. An historical example is the case of a patient in the United States with clinical AIDS who had multiple negative HIV-1 screening tests. Epidemiologic investigation found that this person had recently entered the U.S. from West Africa, where one research study had just reported finding a high prevalence of HIV-2. Thus, specific evaluation for HIV-2 was warranted on both epidemiological and decision theory grounds (75,77). In the U.S., HIV screening now routinely includes HIV-2.

Persons at Low Risk

For an asymptomatic person at very low HIV risk, such as a blood donor, the negative predictive value of a non-reactive EIA result is extremely high. In the event of a reactive result, procedural or technical error should be ruled out (Table 8.2), since most will be false positives. Thus, specimens with initially reactive results are retested in duplicate. Many will be clearly negative on both repeat tests. Given the very low pre-test estimate, the overwhelming likelihood is an erroneous first result. However, if the person's history raises any suspicion of risk, which would revise the pre-test estimate upwards, additional testing by another methodology would be warranted. A repeatedly reactive result is likely to be a true positive, but confirmatory tests may be necessary to attain an acceptable positive predictive value. (Regulatory practices may mandate that a confirmatory test be run in any event.) For example, an indeterminate WB may be clarified by other tests or by clinical follow-up. The related finding, that most persons with repeatedly reactive screening test results and persistently indeterminate WB appear to be uninfected with HIV (149,150), is consistent with these expectations based upon decision analysis considerations.

Care must be taken, however, when interpreting the results from a sequence of tests. Assays are generally not strictly independent, since one source of bias may simultaneously affect multiple laboratory techniques. For example, EIA, WB and IFA are all techniques that detect antibodies to HIV, as opposed to techniques that detect viral antigens of viral RNA directly (see below). Pure Bayesian analysis, which assumes strictly independent tests, will typically therefore lead to overestimation of predictive values with most "supplementary" tests (see Table 8.1).

A weakly reactive result often suggests the need for clinical reassessment, and thus further discussion with the patient. If there is a possibility that the result reflects an early seroconversion, repeat antibody testing several weeks later might clarify an equivocal result. Alternatively, other diagnostic tests may be done immediately, e.g. WB, antigen assays or other direct viral detection methods, or screening assays from other vendors. If the subject has a condition associated with false positive reactions, a negative confirmatory test (e.g. WB) is strong evidence that the patient is not infected with HIV.

Among low risk persons, the repeat clinical history may continue to indicate no risk behaviors or exposures, which means that the pre-test probability remains extremely low. In this case, even an initial positive confirmatory test implies only a low positive predictive value and further evaluation may be appropriate, e.g. by reference research laboratories.

Additional Considerations in HIV Testing

Although the intended use in the blood bank and in clinical/diagnostic settings is similar, the practical applications of tests to detect antibodies to HIV are quite different. In the former situation, the intent is to identify a blood donor who is infected with HIV. Therefore, it is

critical to minimize non-reactive results on specimens from infected individuals (known as false negative results), in order to assure maximally the safety of the blood supply and blood products. In the latter clinical instance, the goal is to counsel persons correctly concerning whether or not they have been infected, with implications for behavioral counseling, medical evaluation and appropriate therapy.

Since some current donors are HIV-infected, the operative assumption that Òall blood donors are true negativesÓ is false. This would lead to a paradoxical situation that perfect speciÞcity (no false positives) would be attained only for a test that detected absolutely *no* positives among current blood donors. A test that was never positive would have perfect speciÞcity (but zero sensitivity). This paradox might tempt manufacturers to adjust assays to take advantage of this speciÞcity loophole, leading to undesirable results. Furthermore, the inclusion of true positives that get tabulated as false positives would wrongly underestimate the assay characteristics. Thus, all repeat reactives that come up in the low prevalence population (assumed zero prevalence) are tested further in current clinical trials, and, if shown to be infected by other methodologies, are permitted to be excluded from the speciÞcity calculations. In essence, the control (very low prevalence) group is redeÞned post-facto to avert the preceding paradox. If the reclassiÞcation as true positive were erroneousÑ as could occur if there was a condition leading to false reactivity on the screening assay which also led to falsely positive conÞrmatory assay(s)Ñ there would be a serious problem and circulatory in deÞnition. For this reason, the reclassiÞcation needs to be done using methodologies as disparate as possible.

CELLULAR IMMUNOLOGIC DETECTION OF INFECTION

Before the discovery of HIV, the diagnosis of AIDS relied upon clinical criteria (151Ð158). Early studies also characterized immunologic impairment, particularly low CD4 counts, comparatively elevated CD8 counts, and a low CD4/CD8 ratio. Persons without AIDS, but who had similar risk behaviors as those with AIDS, frequently also had similar abnormalities. These and other immunologic tests were useful in epidemiologic studies to examine risk factors associated with the epidemic (159Ð166). The advent of HIV serology indicated that tests of immune function remained useful for staging patients, but conÞrmed the expectation that they were not sufÞciently accurate to be used to predict if a given individual were infected with HIV (167Ð174).

Helper T-cell defects occur early in HIV infection (175Ð178). Lymphokine production (such as interleukin-2) can be used to detect antigenic peptide recognition by T-helper lymphocytes, in symptomatic and asymptomatic persons known to be infected with HIV (179Ð182). These tests are also useful to monitor the response of persons receiving prototype vaccinations against HIV (183Ð185). HIV-1-speciÞc T-helper cell responses have been reported in HIV seronegative individuals at high risk of HIV exposure, including several studies in which extensive virologic studies were negative (186Ð192). At least two people with this immunologic proÞle subsequently seroconverted while under prospective study (193) (and SH Weiss et al., unpublished data), indicating that these responses do not indicate complete, if indeed any, protection. Although a correlation between these responses and a novel HLA antibody was reported (187), so far the possibility of a serologic marker for this has not come to fruition. Further studies and follow-up remain of interest to interpret these immunologic Þndings, which

a. may be non-speciÞc,
b. may represent an immunologic response following exposure to non-viable virus,
c. may represent an immune response to a HIV infection that is cleared, without residual latent infection, and/or
d. may indicate early evidence of HIV infection in seronegative persons.

DIRECT HIV DETECTION METHODS

Several methods of direct detection, including tests that measure viral load (typically, the level of ribonucleic acid), are summarized in Table 8.5 with a note of some key limitations of each method, and are reviewed in detail below.

Antigen Assays

Current tests designed to detect antibodies to HIV are able to detect infection following a window period of at least 22 days (see Figs. 8.2Ð8.5). Identifying infected individuals earlier in the infection (closing the window period) is the goal of a number of other methods that can directly detect the virus, as opposed to detecting a host immune response to it.

One of these methods is the detection of HIV-1 p24 antigen, which can detect HIV-1 approximately 16Ð17 days following infection (see Fig. 8.5). These assays typically make use of a monoclonal antibody to HIV-1 p24 antigen coated on a solid support. Antigen in the specimen is captured by the antibody and detected by a second antibody and a system to allow a colorimetric readout. The speciÞcity of these assays can be as high as 99.92% and the sensitivity up to 99.0%. However, note that p24 antigen may only be detectable until approximately 45 days following onset of infectivity (see Figs. 8.4 and 8.5). Therefore, HIV-1 p24 antigen testing should be used as an adjunct to a non-reactive serological screening test for anti-HIV antibody in an individual at risk for HIV infection, and not as a stand-alone screening test.

TABLE 8.5. *Direct viral detection methods and limitations method*

	METHOD	LIMITATIONS
1.	Viral p24 (core) antigen	Limited by detection by latency and immune complex formation. Latter may be partly overcome with acidi cation techniques (see text). See Figs. 8.4 and 8.5.
2.	Nucleic acid ampli cation tests	Prone to false positives due to reaction contamination. False negative results possible with viral variants (232), if a variable region is ampli ed or limited number of cells or organisms (see text).
3.	*In vitro* propagation (viral culture)	Variable success rates. Generally qualitative. Viral strains cultured may be highly selected.
4.	Southern blot or *in situ* hybridization for viral nucleic acid	Sensitivity limited by the number of infected cells.

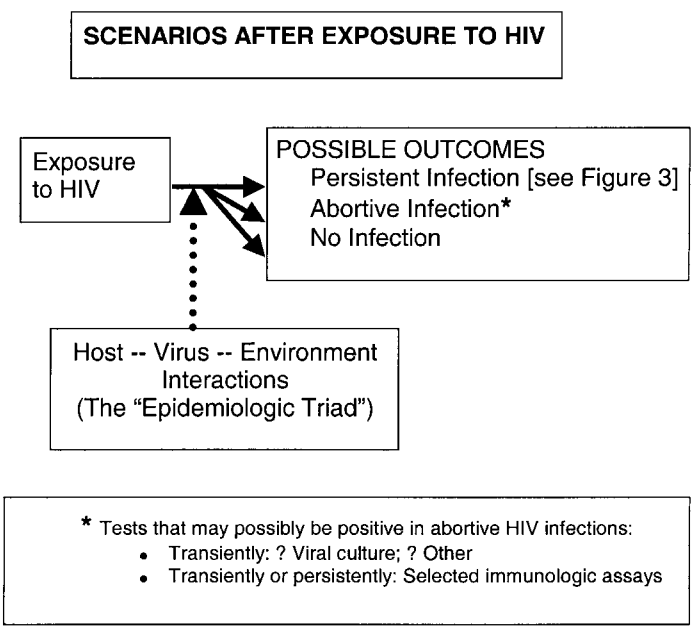

FIG. 8.2. Outcomes after exposure to HIV.

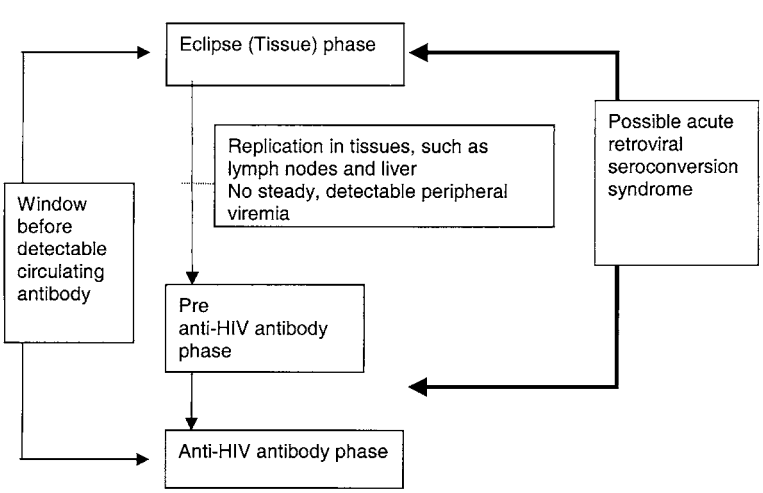

FIG. 8.3. Phases in persistent HIV infection.

SCHEMATIC REPRESENTATION OF KEY EVENTS IN HIV TRANSMISSION DYNAMICS

	E →	T →	I →	X_i →	A →	M
Event	**E**xposure to HIV	Beginning of **T**issue-only period	Onset of high **I**nfectivity	Time test *i* (NAT, Ag, culture) first becomes positive	**A**ntibody detectable	**M**orbidity and mortality
Relative infectivity risk	Low		Very high		Variable	

CHARACTERISTICS OF THE ABOVE INTERVAL PERIODS:

Interval Period	Characteristics
E-T	This interval is probably short
T-I	Intermittent low-level viremia hypothesized
I-X_{NAT}	HIV still not reliably detected
X_{NAT}-X_{Ag}	NAT, but not Ag or Ab, detectable (see Figure 5)
X_{Ag}-A	NAT and Ag, but not Ab, detectable
I-A	Infectious, Ab negative, period
A-M	Ab detectable*; Ag test may turn negative for an extended period after the appearance of Ab

NAT – Nucleic acid amplification tests
Ag – p24 antigen
Ab – anti-HIV antibody
* Some newly infected persons may have a reactive EIA, and a negative or an indeterminate WB, before they develop a positive WB (205;428;429).

FIG. 8.4. Schematic representation of key events in HIV transmission dynamics.

Parenteral sharps injuries among health care and laboratory workers exposed to HIV have led to HIV transmission only infrequently (5,194Ð196). This suggested that the usual titer of viable HIV in peripheral blood was much lower than typical hepatitis B virus levels. *In vitro* hybridization experiments, which indicated that HIV infected cells are rare in blood, brain and lung (197Ð199), suggested that detection of HIV antigen in tissue homogenates would also likely require sensitive assays. Sensitive *in vitro* HIV antigen detection systems have been developed (200Ð204) and are currently in use in the U.S.

Demonstration that an assay speciÞcally measures viral antigen was a challenging task, insofar as there are no independent laboratory criteria. The speciÞcity of a given assay is likely to prove greater in an acellular sterile body ßuid such as cerebrospinal ßuid. Furthermore, antigen that is detected need not represent viable virus, so care in clinical and epidemiologic interpretation may be necessary. Circulating HIV p24 antigen may precede detectable HIV antibodies and thereafter become non-detectable (see Fig. 8.4), only to reappear in some persons with severe clinical immunosuppression (204Ð206). Antigen has some value in evaluating response to therapy (207). Viral load measures (see below) are alternative surrogate markers for assessing response, and appear to be better for this purpose (208). In some circumstances such as measurements in ßuids other than blood, antigen tests have been claimed as more useful than viral load (209).

In regions where HIV transmission and seroconversion rates are high, and conÞdential self-exclusion programs are too non-speciÞc or otherwise of limited value, screening of blood for HIV antigen is warranted (210). The beneÞts of various screening algorithms is, in part, a function of seroprevalence and policy decisions concerning screening will vary (112,113,211,212). In 1995Ð1996, there was a controversy in the U.S. regarding whether the U.S. blood supply should be routinely screened for HIV antigen. Some studies had suggested that screening HIV seronegative blood donors for antigen might detect many false positives (213,214) in a setting of limited residual infection (215Ð217). In 1996, the FDA decided that the additional safety margin was warranted on public policy grounds. Two new HIV p24 antigen tests were licensed and U.S. blood banks implemented p24 antigen as part of their screening.

The initial p24 antigen assay licensed in 1996 in the U.S., the Coulter HIV-1 p24 Antigen Assay, did not include performance criteria. The Abbott HIVAG-1 Monoclonal Kit, which was licensed the next month, claimed a 99.92% speciÞcity and sensitivity of 99.0% amongst a panel of HIV-1 EIA seropositive subjects. This was a marked improvement to a sensitivity of only 79% for the prior Abbott p24 antigen assay that had been licensed in August of 1989.

Historically, acidiÞcation in the p24 antigen assay was used in some settings, since it can lead to detection of

antigen in a higher percentage of HIV seropositive persons (218). This acidiÞcation step disrupts immune complexes that exist between p24 antibody and antigen, but it also reduces total detectable p24 antigen as evidenced by neutralization. Some investigators also used alkalinization successfully. Innovations in testing by various vendors also widened the scope of application for antigen assays (218,219).

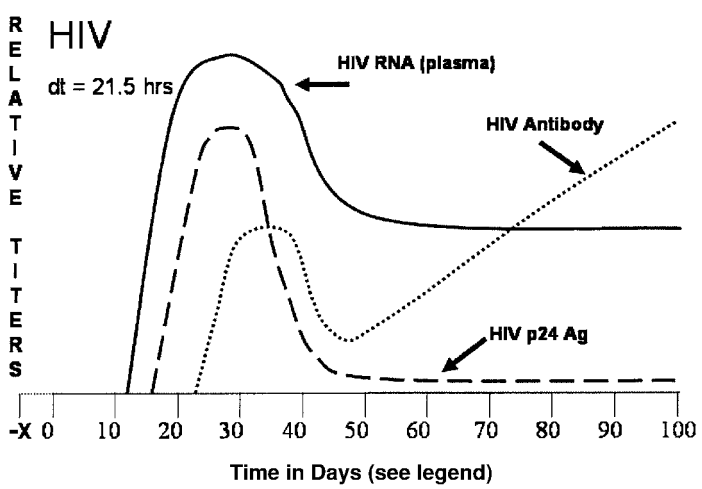
Nucleic Acid AmpliÞcation Tests (NAT) and Viral Load Measures

Techniques

Another approach to the direct detection of HIV is through the detection of viral nucleic acid through what is commonly referred to as nucleic acid testing (NAT). The challenge of NAT is to detect a minimal amount of material in a relatively small sample. Several technologies have met this challenge through novel chemistries that amplify either the nucleic acid itself or the signal that detects it.

Gene AmpliÞcation Techniques

The methodology can be used to amplify either DNA or RNA and are referred to as Ònucleic acid testsÓ(NAT). The principles are outside the scope of this chapter and have been reviewed by others (220,221). These methods have led to the routine assessment of viral titer in plasma (Òviral loadÓ which for HIV-1, an RNA virus, is a measure of RNA level) (28,222Ð224) as well as in lymphoid tissue (225). Two gene ampliÞcation techniques are presently available, that rely on ampliÞcation of either DNA or RNA copies. Gene ampliÞcation, utilizing the polymerase chain reaction (PCR) technology (originally developed by Cetus) as well as other methodologies, has opened a new window on the detection of infectious agents. In polymerase chain reaction-based assays, commonly known as PCR, HIV RNA is reverse transcribed, and DNA copies are ampliÞed exponentially through a series of repetitive reactions. The signal is then detected colorimetrically. Transcription-mediated ampliÞcation (TMA) (226,227) and the related nucleic acid-based signal ampliÞcation (NASBA) (228) are also based on reverse transcribed RNA to DNA, but in this case RNA copies are made. Rather than amplify the nucleic acid, the branched DNA signal ampliÞcation (bDNA) assay (229) relies on the ampliÞcation of a signal when it binds to the HIV-1 target RNA.



LEGEND: Virologic events during primary human immunodeficiency virus (HIV) infection: a schematic summary of window period dynamics. Time is number of days subsequent to initiation of infectivity (on Day 0), which is a time point occurring X days consequent to a causative HIV exposure (on Day – X).

After a person is exposed to HIV on Day **-X**, several biologic steps including propagation of HIV in tissues such as lymph nodes may occur (Figs. 8.2, 8.3 and 8.4). A person is presumed to be infectious to others beginning sometime later, on Day 0. (Fig. 5 does not depict low-level intermittent viremia that may precede the ramp-up viremia described above.) See text for details.

(Figure adapted from M.P. Busch (316), with permission.)

CI = confidence interval

FIG. 8.5. Virologic events during primary human immunode ciency virus infection.

TABLE 8.6. *Degrees of polymerase chain reaction contamination**

	METHOD	LIMITATIONS
CLASSIFICATION	VOLUME OF CONTAMINANT	APPROXIMATE NUMBER OF COPIES OF PCR PRODUCT PRODUCED AFTER 30 CYCLES
1. Spill or gross contamination	1 to 100 μl	10^7 to 10^9
2. Smudge	10^{-4} to 0.1 μl	10^3 to 10^6
3. Aerosol	10^{-9} to 10^{-5} μl	0.01 to 100

* Adapted from McCreedy et al. (234).

Each of these techniques has been approved for different applications) (222,227,228,230).

For DNA PCR amplification, synthetic primers complementary to the region bordering each side of the area of interest are used. Efficiency considerations lead to the design of primers of 15 to 35 bases in length. The region chosen for detection and amplification requires care; for example, sequences where hairpin turns or loops can form need to be avoided.

Theoretically, the nucleotide area of interest will double with each cycle; in practice, 80 to 90% efficiency is often achieved. This exponential doubling leads to sufficient amounts of DNA to be amenable for many forms of analysis. Probes for the amplified region aid in detection. Amplifying pro-viral integrated HIV within the human genome is analogous to finding successfully the proverbial needle-in-a-haystack. Examples of HIV primer-probes have been reviewed (220).

False negative PCR results can occur for technical reasons. Heparin, for example, can inhibit PCR (231). Acid citrate dextran (ACD) solution is the preferred anticoagulant for specimen collection, especially when cells will not be processed and extensively washed, to reduce false negatives. Specimens collected with heparin that are then tested quantitatively (e.g. "viral load" measurements) will have systematically, artifactually reduced viral titers. (Such systematically reduced load measurements can be internally consistent within a given, standardized research study. Although the trends in such studies have clinical relevance, the specific values will not translate directly and consistently with measurements made on ACD specimens.)

Biologic reasons for false negatives include (a) genomic variation in HIV (232): the nucleotides flanking a presumed constant region may vary (primer failure) or the amplified region may vary (probe failure); and (b) virus below the detectable level.

False positive PCR results have raised even greater concern (233). The exponential amplification carries great risk of inadvertent contamination, which may vary from gross contamination to amounts consistent with aerosol passage, as may occur with simply flicking open a specimen tube cap near an adjacent specimen (Table 8.6).

When the number of expected copies produced by PCR approaches one (or less), then statistical considerations (which can be modeled as a Poisson distribution) predict the likelihood of PCR positivity. With very low original copy number in a sample, PCR is predicted to be positive only some of the time. When a positive result is not consistently confirmed, it can be difficult to determine whether this represents a true positive with low copy number (e.g. few infected cells in a terminal, severely CD4 depleted AIDS patient or perhaps a seronegative person at high exposure risk) versus aerosol contamination. In viral load assays with "undetectable" results or numeric results below the standard "positive" threshold cut-off value, these issues must be carefully considered when interpreting the result. Limits of detection for plasma viral HIV RNA are the subject of ongoing certification programs and have been recently reviewed (222).

In devising a commercial PCR diagnostic center, Roche built a facility in North Carolina to minimize the risk of contamination (234,235). Since carryover has been identified as a major cause of contamination, separate rooms for reagent preparation, specimen preparation, PCR set-up, and analysis exist. Movement of materials only proceeds forward to the next self-contained room, never backwards. Manufacturers have developed closed-type systems to reduce contamination in laboratory settings (236). Furthermore, multiple different PCR reactions ("multiplex PCR") can be carried out in a single tube with retention of specificity and sensitivity (237–239).

False positive results may be further minimized by requiring the PCR be positive on two of more gene products. PCR reactivity on only one gene would be classified as indeterminate, and require further investigation to clarify its meaning. Viral variation or defective viruses, or insufficient sample material may contribute to indeterminate results. In preliminary HIV PCR trials by the Roche facility, indeterminate HIV PCR results have been rare (234).

PCR may be performed on fresh or cultured lymphocytes. Obviously, in either case virus siblings (variants) that differ in the primer region will not be amplified. In addition, conformational or related issues may lead to varying efficiency in replication for different sibling variants, which may give rise to large differences in relative copy number over many PCR cycles. Subject to the above caveats, on fresh material the results will reflect the underlying HIV sibling distribution. Since defective

retrovirus variants may be among those amplified, and at least in theory might be the only HIV detected, a positive PCR result (particularly in a seronegative individual) does not necessarily indicate active infection. If the cells are cultured first, then only viruses capable of *in vitro* replication will be detected, and the relative ability to replicate in culture will heavily influence the distribution of viral variants that are detected. This latter methodology is thus inferior when attempting to understand molecular epidemiologic events and sibling evolution.

Applications of NAT

NAT offers the possibility to close the window period for HIV detection further than can be achieved with assays that detect an immune response to HIV or viral antigen (240). Studies have shown, for example, that NAT can reduce the window period (see below) to approximately 11 days following the onset of infectivity. At this writing, two NAT assays have been licensed to screen blood donors for HIV-1 infection (241). The PCR-based UltraQual HIV-1 RT-PCR Assay (National Genetics Institute, Los Angeles, CA) is licensed to detect HIV-1 in pooled source plasma. The TMA-based Procleix assay from Gen-Probe (San Diego, CA) is licensed to detect HIV-1 RNA in human plasma from donations of whole blood and blood components for transfusion. Both of these tests are qualitative assays, but have the ability to detect less than 40 copies of HIV-1 RNA per milliliter.

Beyond screening, NAT has an application in the prognostic assessment of HIV-1 infected patients, and in monitoring the effects of anti-retroviral therapy through the determination of viral load. The Roche Amplicor HIV-1 Monitor Test (Roche Molecular Systems, Branchburg Township, NJ) was the first test approved for this use, in 1996. Two additional assays have recently been approved, NASBA-based NucliSens HIV-1 QT (bioMerieux, Durham, NC) and bDNA-based VERSANT™ HIV-1 RNA 3.0 Assay for the quantitation of HIV-1 RNA in plasma.

NAT also has the ability to provide useful information that can be applied to specific therapeutic modalities for an infected patient. The TRUGENE HIV-1 Genotyping Kit and OpenGene DNA Sequencing System (Visible Genetics, Toronto, Ontario, Canada) identifies HIV genomic mutations in regions of the virus known to confer drug resistance to particular anti-retroviral medications. PCR-amplified material is subjected to nucleic acid sequencing to provide this information. This test has been cleared as an aid in the therapeutic management of HIV-1 infected patients.

NAT when used qualitatively (absent/present) have very high specificity (nearing 100%), but cannot demonstrate whether or not the detected agent is in an infectious state. False negative results can commonly occur in a number of circumstances, limiting the sensitivity of these approaches. Thus, despite the great power to amplify by NAT (see below), it is still true that viral load below given thresholds can be "undetectable" (i.e. limitation due to a limited number of organisms or viral particles). This issue can lead to diagnostic difficulty in ruling HIV infection in or out by these methods, exemplified by the problems in diagnosing neonatal infection (at a time when maternal antibodies limit the utility of other standard approaches such as antibody assays). Furthermore, substances can inhibit the reactions (e.g. heparin interferes with some assays) and lead to false negative results.

The quantitative application of nucleic acid amplification tests in both epidemiologic studies and clinical trials has become increasingly common. However, the reproducibility of a specific titer result is limited. In 1996, it was proposed that at least a three-fold change in titer (approximately an 0.5 log change) should be considered the minimum "significant" change. As these assays continue to evolve and the minimum detectable threshold value decreases, the epidemiologic and clinical value of testing is likely to further rise. Differences in interpretation of some clinical trials has, in fact, been attributable to different testing algorithms for viral load and the associated limitations of those algorithms, related to varying vendor assays, sensitivities, and modes of data analysis (including varying categorical cut-offs). When these laboratory characteristics are taken into account, contrasting results of different studies can be understood in context and the clinical implications may be seen to be convergent rather than disparate.

The potential uses of NAT are considerable, including

a. confirmation of serologic results (242–246), examination of other bodily fluids (247,248) or stored material (249), and staging (250)
b. resolution of indeterminate WB (150)
c. resolution of infective status in infants (251–257)
d. reassurance of persons at low HIV risk (258,259)
e. screening for retroviral infection risk (240,260,261)
f. identification of latent and primary infections in seronegative persons at HIV risk (110,240,262–275)
g. quantitation of viral load (218,222–225,244,276)
h. detection of defective or aberrant retroviruses (277)
i. evaluation of viral variation (232,278–283).

These applications are still being refined (275,284). Possible interpretations of positive NAT results in seronegative persons range from:

- false positive, to
- transient infection with clearing, to
- window period of infection (e.g. primary HIV infection), to
- latent infection.

In part, this controversy reflects our still emerging understanding of the biology of retroviral infection (see below).

NAT and viral culture have been used to generate sufficient substrate for genetic sequencing. In conjunction

with statistical techniques such as phylogenetic analysis, these molecular epidemiologic analyses have helped delineate some major macroscopic variations in HIV strains around the world and assisted in mapping geographic transmission patterns (285–293). However, the picture is greatly complicated when trying to extend these techniques to the assessment of "epidemiologic" linkage (280,294–302). HIV variation is influenced by many factors, including the biology of HIV and immunologic pressures, and there are issues related to possible recombination between HIV clades and coinfection or exposure to multiple strains (303–306). Molecular epidemiologic analyses thus remain a research tool, with many theoretical and practical limitations to more generalized use.

OTHER DIRECT DETECTION METHODS

In Situ Hybridization

The technique of *in situ* hybridization (direct detection of the viral nucleic acid in individual infected cells) offers a direct approach for localization of HIV nucleic acid sequences in cellular preparations (197–199). The limited proportion of infected cells *in vivo*, the low viral sequence copy number per cell, and the need to examine slide preparations by hand with light microscopy limit its application outside highly sophisticated research laboratories. Recent studies demonstrate higher proportions of infected cells than reported in the early studies. It is uncertain whether these differences reflect improved technique versus an artifact related to stage of HIV illness in the early reports.

Tissue Culture Of Virus

HIV virus isolation by cell culture involves the use of carefully selected permissive cell lines (such as some malignant T-cell lines) or co-cultivation with fresh, normal lymphocytes which have been stimulated with mitogens and maintained with T-cell growth factor (and sometimes alpha-interferon) (1,2,307). HIV isolates with a propensity for growth in specific lines, e.g. monocyte/macrophage lines, have been described, and may reflect differences in cellular biology among HIV isolates (300,308–310). Culture enhances viral titer and permits detection by other assays (311). Retroviruses can be detected by testing the culture at periodic intervals for specific Mg^{++}-dependent reverse transcriptase activity in the medium and/or viral antigen detection (as described above). These findings are then further confirmed by detection of viral antigens within the cultured cells, as by electron microscopy and/or with in situ use of monoclonal reagents.

Positive cultures may indicate either active or latent HIV infective states. These culture methods require advanced technology within the context of adequate provisions for biosafety and are not feasible beyond the research setting. The cost is great, and the laboratory equipment and skilled research technicians are extremely limited. The limited sensitivity and difficulty of HIV cultures does not allow widespread use for the determination of HIV carrier states.

Ligase Chain Reaction

The ligase chain reaction (LCR) originally seemed a potentially promising technique for amplifying DNA (312,313), but in light of HIV variation, LCR has so far had limited application in terms of HIV, and LCR holds greater promise with regard to other infectious agents.. LCR, like PCR, uses oligonucleotides that anneal to specific, complementary sequences on the target DNA to be amplified. In contrast to PCR, LCR will only amplify stretches of DNA that have the entire exact sequence utilized, essentially combining both an amplification and a detection step. Specific DNA alleles can be selectively amplified (314).

TEMPORAL DYNAMICS OF HIV ACQUISITION AND TRANSMISSION: SEROCONVERSION AND "WINDOW" ISSUES

Exposure to an infectious agent does not invariably lead to active infection: the classic epidemiologic triad involving interaction amongst the agent, the host and the environment govern initial dynamics and response (Fig. 8.2). If the agent is defective or disrupted, introduced into an inhospitable body compartment, necessary receptors not present, etc., no infection may occur at all. Even if it begins to multiply, an abortive infection may occur, e.g. if host immunological defenses are effective.

There will be a period until the concentration is sufficient (high enough titer) to be detected by a given methodology (Figs 8.3 and 8.4). Furthermore, shedding may only be intermittent, so samples from a given time point may be true negatives, which fail to reflect the full biologic picture given the underlying biologic complexities. There will also be a period until antibodies begin to be produced in highest titer to be detectable, and the host generates a series of multiple different antibodies.

The "window" period refers to the time from acquisition of infection by the host until a test can detect the specific presence of that infection. The window will vary with the infectious agent and test methodology, and likely varies as well with route and dose of the original exposure, and host immunologic factors. In terms of screening of blood donors, the interval I-A in Fig. 8.4 reflects a subset of this overall window period, in which a seronegative (anti-HIV antibody negative) donor is infectious.

The HIV Window Period for Seroconversion

Much of what we know about the HIV infectious window period comes from analyses of serially collected specimens from seroconverting subjects such as plasma donors, hemodialysis patients, or persons enrolled in high-risk cohort studies. Statistical analysis of the data has resulted in the model shown in Fig. 8.5. Some of the clearest data has come from epidemiologic studies concerning recipients of blood transfusions (315), but the high dose of exposure involved in those cases likely leads to more rapid and more limited variation than other types of exposures.

For those persons who become persistently infected with HIV, Busch and colleagues have estimated the mean time points of initial HIV detection (Fig. 8.5):

¥ HIV RNA becoming detectable in plasma on days 10 through 12,
¥ HIV-1 antigen (p24) on day 17, and
¥ HIV antibody on day 22 (using current generation EIAs) (316Ð319).

Subsequently, HIV p24 antigen often becomes undetectable, and HIV antibody level may decrease temporarily owing to complexing with HIV-1 antigen (antigen-antibody complexes may form). After that transient decline, HIV antibody levels continue to increase during the initial three to six months of infection and persist indeÞnitely. Antibody may be lost or non-detectable in the pre-terminal stage of HIV disease, paralleled by a surge in viral burden that heralds collapse of the immune system. Plasma levels of HIV RNA generally remain detectable throughout the course of infection, but may decrease to undetectable levels during treatment with highly active antiretroviral therapy (HAART).

Mathematical modeling, in a study of blood donors that utilized earlier generation antibody EIAs (1985Ð1990), estimated the mean interval from onset of infectiousness until HIV antibody detection (the Òseronegative windowÓ) as 45 days (95% CI, 34Ð55 days) (320). The upper 95% CI estimate of the point by which 90% of seroconversions occur was 141 days from the onset of infectiousness. The upper 95% CI estimate of the point by which 95% of seroconversions occur was 214 days. Thus, few donors appear to remain infectious and seronegative for more than six months.

The interval (X days) is potentially quite variable, and will be a function of mode of acquisition, exposure dose, and other factors of the Òepidemiologic triadÓ (Fig. 8.2). This interval, from the original HIV exposure until onset of infectiousness, was not estimated in the above models. However, this additional time period is highly relevant when considering for how long a person who was exposed to HIV (e.g. a health care worker who has a sharps exposureÑ see Chapter (NOTE TO EDITOR: insert right chapter # by SHW Weiss & Leschek from this book) should be monitored to rule-out acquisition of HIV infection.

Data from Other Persons at Risk

Horsburgh and colleagues examined 27 homosexual and 12 hemophiliac males with stored blood samples collected before and after HIV seroconversion (321). By statistical modeling, they estimated that the time from infection with HIV (assessed by detection of HIV DNA) to Þrst detection of HIV antibody was 2.4 months for the median individual, with a standard deviation of 2.1 months (321). This observation of a much longer interval than that suggested by Busch and colleagues (315) may reßect the marked differences between their respective patient groups and suggests that mode and dose of exposure may be important parameters that affect the interval. Not addressed in these studies is whether prophylaxis with antiretroviral drugs might also affect the dynamics.

Modeling of 45 published cases of HIV infection with known exposure gave a median estimate of 2.1 months from exposure to antibody detection, with 95% of cases expected to seroconvert within 5.8 months (321). They concluded that HIV infection for longer than six months without detectable antibody (assuming no false negative tests) seemed to be uncommon (321). Given the apparent limited residual risk after six months, the standard recommendation for one year of observation is likely sufÞcient in the absence of chemoprophylaxis. Furthermore, these data suggest that testing at three and six months will implicitly diagnose most of the ultimate seroconversions.

Delayed HIV Seroconversion

There are limitations to these data. For example, with increasing time between an exposure and documentation of infection, the task of ruling out potential competing exposure risks deÞnitively grows more difÞcult, with increased reluctance to ascribe a seroconversion to an occupational incident. Indeed, in France the assumption is made that a potentially contaminating accident must be before the sixth month, *a priori* dismissing delayed seroconversion from consideration (322). If more than one (potential) exposure to HIV occurs, it may be difÞcult to ascertain which one led to the acquisition of HIV infection.

Complicating the picture is that some instances of delayed seroconversions might not be detected. There is also the possibility that the seroconversion might not be attributed to the correct event, as more proximal events within the anticipated window might systematically be considered as more likely, a form of circular logic. Thus, arbitrary selection of the incident based on the assumptions above may further bias our estimates. Some false

negative screening tests do occur (35,323). Finally, even if delayed seroconversions occur, the initial temporal data distributions will be biased from the early occurring cases. (This phenomenon led to progressive lengthening of the median Òtime to AIDSÓ estimates, since the short interval cases are the Þrst to be observed.) The modeling of Horsburgh relied upon cases published in the literature only up until 1989, and they excluded some cases the CDC considered controversial or which were complicated by the above factors. In summary, the current distribution curves are likely somewhat biased in terms of inclusion of shorter seroconversion intervals.

Acute Retroviral Seroconversion Syndrome

These issues pertain as well to acute viral syndromes in temporal association with HIV seroconversion (see Fig. 8.3) (324,325). Persons with such symptoms, even though non-speciÞc, are more likely to be carefully evaluated for seroconversion (325). (It is also important to note that such persons should be carefully monitored, in order to render appropriate care and prevention advice in a timely manner.) If occurrence of the retroviral seroconversion syndrome were associated with the magnitude of viral replication, it seems reasonable that persons with delayed seroconversion might exhibit such symptoms less frequently. Thus, there are multiple reasons why persons without such a syndrome or with delayed seroconversion might be more likely to be missed.

However, only a limited number of cases of delayed seroconversion have been reported (322,326). A woman accidentally pricked by a needle at a clinic where she worked as a cleaner had negative HIV serology at the third and sixth months after the accident. She did not receive any antiretroviral chemoprophylaxis. HIV antibodies were detectable at the eighth month and thereafter, with conÞrmation by detection of HIV-1 RNA (see below) and WB. (Interestingly, HIV could not be isolated by culture on successive samples (322).) The authors noted that the possibility of a serologically silent window of more than six months has public health consequences. ÒThe underestimation of the diagnosis of HIV infection may wrongly lead to the reassurance of individuals remaining negative 6 months after the potentially infectious accident and thus may contribute to further transmissionÓ (322).

A speculative issue is whether some people treated with anti-retroviral therapy might experience delayed seroconversion. For research purposes, it would be worthwhile to extend the follow-up monitoring period to help resolve these issues. In practice, outside the realm of research studies, duration should be individualized based on magnitude of exposure risk. The decision concerning length of monitoring also needs to balance the psychological pressures attendant to extended follow-up. In general, it still appears to be reasonable to use negative tests at six months in an asymptomatic worker as strong reassurance, while still counseling concerning the need for further follow-up. These issues pertain to the monitoring of persons after an at-risk exposure to sharps as well as other occupational exposures (see the chapter in this text on ÒOccupational Risk in the HIV Era.Ó) Additional factors at play in the Òepidemiologic triadÓ (Fig. 8.2), such as post-exposure treatment with anti-retroviral therapy, may potentially signiÞcantly alter the dynamics from that observed in the seroconversion modeling data.

DIAGNOSIS OF HTLV

HTLV-I was the Þrst human retrovirus to be discovered (327;328), followed shortly by HTLV-II (329,330). HTLV-I infects 15Ð20 million people worldwide, with endemic foci in southeastern Japan, the Caribbean, Melanesia, sub-Saharan Africa, and some areas of Central and South America (331). The worldwide prevalence of HTLV-II is less certain, but HTLV-II prevalence is of similar magnitude within the U.S. to that of HTLV-I, with high prevalences in some regionsÑ especially among at-risk persons such as injection drug users and some Amerindian tribes in the Americas (332Ð339).

HTLV-I is causally associated with an aggressive leukemia and lymphoma syndrome (340Ð345), as well as neurologic disease. Both HTLV-I and human HTLV-II are associated with immunologic abnormalities (346Ð349). It remains uncertain whether HTLV-II is linked to an increased risk for cancer (350,350Ð352). There have also been claims of association of HTLV-II with neurologic disease and some infectious diseases (332,353,354).

The development of the HIV EIA methodology was aided by the developmental work that had been done for the HTLV-I EIA (23,30). The discovery of the second instance of HTLV-II infection, in an intravenous drug user who died of *Pneumocystis carinii* pneumonia prior to the discovery of HIV, was prompted by atypical reactivity on the existing HTLV-I diagnostic tests and required viral isolation to prove its near identity to the HTLV-II Mo prototype (330). It is not surprising that there are many similarities in the diagnostic modalities for HTLV and HIV. This section highlights the differences.

In 1988, a blood screening program for HTLV-I was instituted in the United States utilizing EIAs licensed by the FDA (355,356). Due to some antigenic cross-reactivity HTLV-I and HTLV-II, the HTLV-I based assays were able to detect some of the instances of HLTV-II infection. (330,332,333), but considerable numbers of HLTLV-II infection were missed (357Ð362).

Subsequently, in 1997 and 1998, two EIAs were licensed to detect antibodies to both HTLV-I and HTLV-II. These assays are based on HTLV-I and HTLV-II infected cell lysates as the source of capture antigen, along with a recombinant form of the HTLV-I p21 envelope protein (p21e) in one of the assays; these screening assays do not differentiate between HTLV-I and HTLV-II.

HIV-1 can be cultured to much higher titers than HTLV-I, so that the antigen preparation for the whole virus EIA can be puriÞed more easily for HIV than for HTLV. Cellular contamination of the viral preparation leads to cross-reactivity and non-speciÞc (false positive) reactions more frequently for HTLV than HIV. Serologic assays for HTLV antigen have been used to monitor HTLV cell cultures, but have not found clinical application since measurable cell-free HTLV concentration have not been detected in peripheral blood. This absence of signiÞcant cell-free virus is in contrast to HIV, and may help explain some of the differences in transmission patterns.

Further complicating the picture, many persons infected with HTLV have only low titers of antibody. In contrast, the titers for HIV antibody tend to be relatively high. Some HTLV samples have low titer antibodies, as occur particularly in some asymptomatic HTLV-I carriers as well as persons co-infected with both HTLV-II and HIV (333,363). Such specimens are particularly difÞcult for some assays to detect (363,364), leading to limited sensitivity. In Japan, a particle agglutination test has been used for HTLV-I screening with good success (365Ð367).

If a conÞrmatory test cannot detect antibody titers as weak as the screening test can detect, some true positives will be unconÞrmed and categorized erroneously as negative. This situation has been noted with HTLV diagnostics (and, more rarely, with HIV; see footnote in Fig. 8.4). Thus, care must be taken in interpreting HTLV results, both when counseling patients and when critically reading the literature.

A research use HTLV-I/II WB makes use of not only an HTLV-I viral lysates, but also recombinant forms of HTLV-I p21e, HTLV-I gp46, and HTLV-II gp46 (Genelabs Diagnostics, Singapore). Thus, this WB is able to distinguish between antibodies to HTLV-I and HTLV-II. The U.S. Public Health Service has recommended that a positive HTLV WB have bands for both gp46 and p24, though there is evidence that p21e reactivity may be sufÞcient for the env component in place of gp46.

If both *gag* and *env* reactivity are required for conÞrmation, a WB alone will conÞrm only a limited proportion of the true-positive sera (368). WBs used for conÞrmation of EIA reactive specimens among injecting drug users within the U.S. may be indeterminate or negative in a majority of individuals (337,369Ð371). In addition, the relative titers of HTLV speciÞc proteins vary greatly depending upon both the cell line and HTLV variant used to produce HTLV for the test kit (SH Weiss, unpublished observations).

An algorithm for HTLV testing for diagnostic purposes in a clinical laboratory is outlined in Fig. 8.6 (372). If the initial screening EIA is reactive, a repeat assay on the same specimen is performed in duplicate. If one or both of the repeat tests are reactive, the specimen is classiÞed as repeatedly reactive. The repeatedly reactive specimens are

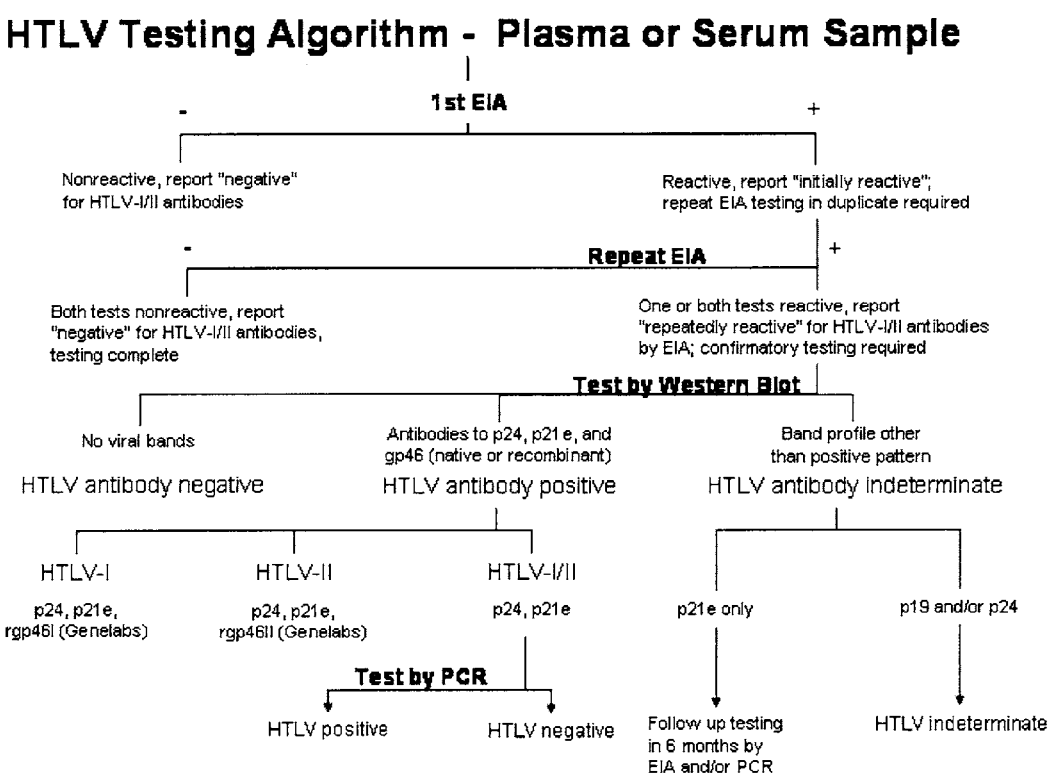

FIG. 8.6. HTLV testing algorithm—plasma or serum sample. Figure courtesy of Charlene S. Dezzutti, Ph.D., Elliot P. Cowan, Ph.D. and Renu B. Lal, Ph.D.

subjected to conÞrmatory supplemental testing which is typically done by WB.

Some investigators have routinely used RIPA to conÞrm the indeterminate HTLV WB patterns. There are some limitations to their implementation, as in theory the WB negative sera should also be tested by RIPA. However, RIPA frequently cannot detect low titer antibody, so even the WB plus RIPA conÞrmation schema will miss some true positives. RIPA is available only in select research laboratories, further limiting its application. In summary, standard WBs have limited utility, and cannot play the same role as they do in HIV diagnostics. Neither RIPA nor the research use WB is available for clinical use in the U.S.

The current PHS diagnostic criteria for supplemental testing require that a specimen demonstrating antibodies to p24gag and to native gp46env or gp61/68env are considered seropositive for HTLV-I or -II (372). Specimens reacting with any of the bands, but not satisfying the above criteria, are designated indeterminate. In the majority of cases, indeterminate specimens do not represent true HTLV infection, with one exception. Specimens with p21e reactivity may represent an early seroconverter, and repeat testing should be performed within six months. Persons who have clinical neurological symptoms and HTLV-I and -II indeterminate reactivity should be further investigated for possible retroviral infection. Further testing could include PCR in conjunction with serologic testing. Specimens with no immunoreactivity to any bands upon repeat testing are considered negative for antibodies to HTLV-I and -II (false-positive EIA specimen). Persons with HTLV-I or -II positive or indeterminate test results are counseled according to the guidelines established by the PHS Working Group (373). These guidelines state that persons should be informed that HTLV is not the acquired immunodeÞciency syndrome (AIDS) virus and their risk of developing HTLV-related diseases is low. HTLV-I- or -II-infected persons are also asked not to donate blood, semen, body organs, or other tissues as well as not to share needles or syringes with anyone. To prevent transmission of HTLV, the infected person is asked to use protective measures during sexual relations and women are asked to refrain from breastfeeding. Persons who have indeterminate results on two separate occasions at least three months apart should be advised that their specimens were reactive in screening for HTLV-I/II, but these results could not be conÞrmed by tests that are more speciÞc. Further, they should be reassured that indeterminate results are rarely caused by HTLV-I or HTLV-II infection. Repeat testing should be offered (372).

Historically, competitive EIAs were used to conÞrm HTLV screening results, and to categorize whether the infection is due to HTLV-I or HTLV-II (332). Although extraordinarily time consuming, this approach was the Þrst to demonstrate high rates of HTLV infection in a cohort of U.S. intravenous drug abusers, and also the Þrst to show HTLV-II seroprevalence rates that exceeded HTLV-I (332,374).

Immunoßuorescence was also used in many early HTLV studies either for screening or for conÞrmation of EIA results (364,375,376). When HTLV-II infected cells, in addition to an assay with HTLV-I infected cells, are used for immunoßuorescence, in light of the existence of high HTLV-II seroprevalence in the U.S., only a few additional sera were actually conÞrmed (333,377). Many HTLV-II sera, including the Mo HTLV-II prototype, react well on HTLV-I assays, including immunoßuorescence. Immunoßuorescence patterns consistent with anti-nuclear antibodies (ANA) were also seen frequently among the intravenous drug users. Since true infection simultaneous with ANA is possible, interpretation in this high-risk group is difÞcult.

HTLV-II p24 antibodies can strongly cross-react with HTLV-I p24 antigen, so that a radioimmunoassay (RIA) utilizing puriÞed HTLV-I p24 has been suggested as an alternative HTLV conÞrmatory test (378). However, HTLV-II may tend to give systematically lower reactivity than HTLV-I on this HTLV-I based assay (S. H. Weiss, unpublished data). Given all these problems with the standard assays, an alternative approach was suggested in 1987 utilizing concomitant reactivity on an HTLV-I EIA, an HTLV-I p24 RIA, and on either an HTLV-I or HTLV-II immunoßuorescence assay (333). The rates of HTLV infection reported in that study were quite high. Subsequent work nevertheless indicate that these criteria were too strict, and underestimated true seroprevalence (379,380).

A signiÞcant proportion of HTLV-II was missed with HTLV-I-only assays, with the problem particularly acute in regions or among groups at high risk for HTLV-II (363,364,381Ð386). Transmission of HTLV-II by HTLV-I screened blood has been documented (387). HTLV-I based diagnostics have been shown to have limited sensitivity and speciÞcity for HTLV-II (358). The FDA Blood Products Advisory Committee reviewed HTLV-II test kit criteria, leading to the revised recommendation that HLTV-II antigen(s) needed to be part of a kit designed to detect antibodies to HTLV-II. The advent of WB spiked with recombinant proteins, including p21e and HTLV-I and HTLV-II speciÞc proteins, have been demonstrated to have roles as alternative conÞrmatory tests, with differentiation of HTLV-I from HTLV-II (370,380,388) (Fig. 8.7). Other serologic approaches have also been used (389Ð396). The currently available EIAs contain antigens from both HTLV-I and HTLV-II, and these antibody tests have Þlled the prior gap. However, some assays may still give false-negative results on HTLV-II-positive specimens (362,397).

PCR has proven extremely useful in conÞrming and delineating the type of HTLV infection, but remains unlicensed (380,398Ð402). The multiplex PCR approaches discussed above also hold promise for simplifying the approach to testing for multiple agents. It is reasonable to

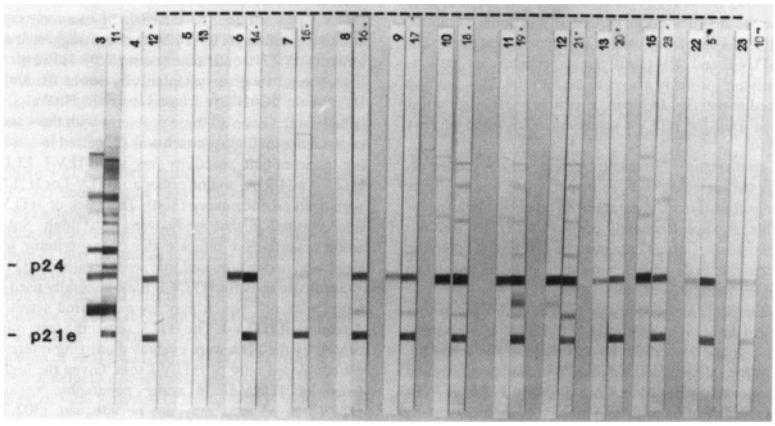

FIG. 8.7. Paired Western Blot results comparing standard Biotech/DuPont strips with the Cambridge Biotech strips containing added recombinant p21e protein The major bands represented are p24 and p21e. Strips 3 and 11 were incubated with HTLV-I positive control serum, strips 4 and 12 with HTLV-II postive control serum, and strips 5 and 13 with control serum negative for HTLV-I and HTLV-II. Al remaining pairs represent individuals from a study of intravenous drug users in New Jersey who were both HTLV EIA (Abbott Laboratories) reactive and con rmed by PCR to represent HTLV-II infection (380). Figure courtesy of Paul E. Palumbo, M.D., Steven S. Alexander, Ph.D., and Stanley H. Weiss, M.D.

expect that different primer pairs will have different sensitivities concerning identiÞcation of HTLV-I and HTLV-II within given populations (380). Differences in PCR ampliÞcation efÞciency have been noted for HTLV primer pairs SK 43/44 and SK 110/111 (B. McCreedy, unpublished observations). Primer set SK 43/44 and probe SK 45 appear to yield better results following ampliÞcation of low copy number HTLV DNA than does the primer pair SK 110/111 and probes SK 112 and SK 188. Further research is this area is necessary (380).

In addition, nucleotide sequence diversity and the issue of defective or incomplete retroviral elements may need to be considered. Sequence diversity among HTLV-II isolates has received recent attention (403Ð409). However, deleted HTLV-I proviruses have been shown to exist in fresh leukemic cells of patients with adult T-cell leukemia-lymphoma syndrome (410,411). Hall and colleagues found deleted HTLV-I provirus in HTLV EIA seronegative patients with mycosis fungoides (277). Some analyses of HTLV EIA reactive cohorts by means of PCR have found 12% to 24% of the HTLV infection non-typeable (401,412), although others found almost all specimens to be typeable with the newer primers and probes (380). The ability to detect all HTLV-II infected individuals by EIA screening assays, or to conÞrm infection by WB or PCR, may therefore be limited by sequence diversity and possibly proviral deletions. Further characterization of optimal PCR primer pairs, EIA and WB capture antigens (388), and possible newer serological assays (such as the use of synthetic peptides (395,396)) should be a target of future research.

One study has linked sexual transmission of HTLV-I with the presence of anti-HTLV-I-tax antibody (413). Thus, selective assays may be important in further deÞning epidemiologic transmission characteristics. For HIV, studies of speciÞc antibody have been controversial with respect to prediction of transmission (122). More work in this area for HTLV is also necessary.

Currently, multiple assays are necessary to deÞne accurately the prevalence of HTLV-I and -II in a given population. Further work is required for the development of assays that are highly sensitive and speciÞc. Recent studies suggest that HTLV-II may have immunologic and health consequences (346,379,414Ð417), as does HTLV-I (18,418). SpeciÞc laboratory assays will be important tools in further clarifying the epidemiology of HTLV-II. These newer approaches, in combination with an EIA that includes HTLV-II antigens, hold promise for improving HTLV diagnostics.

The initial commercial HTLV WB that was commonly used by blood banks to conÞrm repeat HTLV EIA reactivity was inadequate for conÞrmation of HTLV-II infection. Since counseling of donors by blood banks is done when EIA results are conÞrmed, the sensitivity and speciÞcity of the conÞrmatory tests are critical. As discussed above, the conventional WB needs to be replaced or supplemented by other easily performed assays, particularly in geographic regions where the prevalence of HTLV-II represents a signiÞcant proportion of the HTLV serologic reactivity (358,359,363,382).

CONCLUSIONS

The armamentarium of HIV and HTLV detection systems has continued to grow rapidly. Testing alternatives will continue to move from the research bench to the clinical laboratory. The judicious choice of these tools will depend upon an increased understanding of the dynamics of retroviral infection, critical head-to-head comparison testing, and cost-beneÞt decision analyses. Further development and evaluation are warranted for direct HIV detection methods as well as other immunologic tests of HIV exposure, and serologic detection and conÞrmation of HTLV infection. The context within which any test is used is of critical importance to its interpretation. No test, per se, should be the basis for diagnosis on its own, but rather a test is merely an aid in correct diagnosis. The practitioner must use test results in the context of a clinical picture to reach an accurate diagnosis.

AIDS and Other Manifestations of HIV Infection
Fourth Edition, edited by Gary P. Wormser

Chapter 9

Molecular Diagnostic Techniques and Other Tests for Direct Detection of HIV

Joseph DeSimone and Roger J. Pomerantz

Since the discovery that human immunodeÞciency virus type 1 (HIV-1) is the causative agent of the acquired immunodeÞciency syndrome (AIDS) in 1984, enormous progress has been made in our ability to detect the presence of both HIV-1 as well as human immunodeÞciency virus type 2 (HIV-2). Serologic testing has been greatly reÞned, vastly improving the sensitivity and speciÞcity of such testing. HIV antigen testing, as well as HIV culture techniques, have become useful in certain clinical situations. Finally, polymerase chain reaction (PCR) testing has allowed direct detection of both HIV complementary DNA (cDNA) as well as RNA. Plasma viral RNA measurement, by PCR or other methodologies, has become an essential component of HIV clinical care, particularly when implemented as a prognostic tool.

P24 ANTIGEN DETECTION

p24 is an HIV-1 core protein encoded by the *gag* gene. It is expressed soon after acquisition of HIV-1, and antibody to p24 forms shortly thereafter (3,18). p24 antigen can be detected in serum, plasma, and cerebrospinal ßuid (19). Assays to detect p24 antigen utilize an antigen capture with ELISA technique. The patientÕs serum is added to a plate or beads coated with anti-p24 antibody, allowing the p24 antigen to be captured. An enzyme-linked anti-HIV-1 IgG is then bound to the complex, and is subsequently measured colorimetrically. Results can be conÞrmed with a neutralization step thereafter. The level of detection of p24 antigen with current assays is 10 pg/mL. Since antigen-antibody complexes can limit the level of detection of p24 antigen, a dissociation step to separate these immune complexes has been added to the assay. This dissociation step has increased the sensitivity of the assay signiÞcantly (20, 21). Though uncommon, false positive p24 antigen results, presumably due to cross-reacting proteins, have occurred in uninfected patients (22).

Prior to the advent of plasma HIV-1 viral RNA measurement, the p24 antigen assay was used as a prognostic tool. Levels of p24 antigen were found to reappear or increase in HIV-1-infected patients shortly before or during the development of AIDS (23Ð25). A decline in HIV-1 core antibodies is the postulated source of the p24 antigenemia during this transition to AIDS (26). Similarly, this assay was useful in measuring the antiretroviral effect of medical therapy (21,27,28). Again, use of the p24 antigen assay in these roles has been mostly supplanted by quantitation of plasma HIV-1 RNA assays.

Measurement of p24 antigen in serum may be clinically useful in HIV-1-infected patients prior to seroconversion. Detectable p24 antigen levels have been noted in both serum as well as cerebrospinal ßuid in acutely HIV-1-infected individuals (18,19). Use of the p24 antigen assay in the setting of acute HIV-1 infection is discussed in detail below. Finally, measurement of p24 antigen may also be useful in detecting HIV-1 in children born to women with HIV-1 infection. Due to passive transfer of maternal antibody, serologic diagnosis of an infant born to an HIV-1-infected mother is not helpful, and p24 measurement in such children has assisted with the diagnosis (29,30). Sensitivity in this setting, however, varies with age, and is signiÞcantly less if the infant is younger than one month old (31,32). The presence of p24 antigenemia at birth, however, has been associated with development of early and severe HIV-1-related disease (33).

Roger J. Omerantz: The Dorrance H. Hamilton Laboratories, Center for Human Virology, Division of Infectious Diseases, Department of Medicine, Jefferson University, 1020 Locust Street, Suite 329, Philadelphia, Pennsylvania 19107. E-mail: roger.j.pomerantz@mail.tju.edu

CULTURES OF HIV-1

HIV-1 can be cultured from plasma, serum, peripheral blood mononuclear cells (PBMCs), cerebrospinal ßuid (CSF), saliva, semen, cervical specimens, and breast milk (5). Standardized culture methods for recovery from blood usually utilize the patientÕs plasma or PBMCs, which are incubated with uninfected donor PBMCs. Interleukin-2 (IL-2) is present to activate and stimulate cell growth. The culture supernatant, which now contains progeny HIV-1 virions, can then be tested qualitatively or quantitatively for the presence of HIV-1 with assays for reverse transcriptase or p24 antigen. Most cultures from HIV-1-infected patients, excluding those on virally-suppressive highly active antiretroviral therapy (HAART), become positive within 21 days (34). Sensitivity of these culture methods in patients who are HIV-1 seropositive has been reported at greater than 97%, with a speciÞcity of 100% (35,36).

In the age of plasma viral RNA testing, the utility of HIV-1 culture in clinical management is minimal. The *in vitro* rate of replication when culturing HIV-1 has been shown to correlate with the patientÕs clinical status and may serve as a means of measuring response to antiretroviral therapy (37Ð40). However, when compared with plasma viral RNA testing, culture methods for HIV-1 are far more laborious, time-consuming, and less sensitive. Similarly, although culture may be useful in diagnosing HIV infection in infants born to women who are HIV-1-infected, the sensitivity of this test is far lower when compared with a diagnostic method such as proviral DNA polymerase chain reaction (PCR) testing (33,41). For these reasons, culture of HIV-1 has mainly been relegated to the research and clinical trial realm.

PCR AMPLIFICATION OF PROVIROL DNA

Upon entering human cells, HIV-1 RNA is converted into a complementary strand of DNA by reverse transcriptase. These linear DNA molecules then integrate into the host genome, becoming the proviral form of HIV-1. By using the PCR, the presence of proviral DNA can be detected. In the HIV-1 DNA PCR assay, PCR using oligonucleotide primers ampliÞes a segment of the highly-conserved HIV-1 *gag* gene. This is followed by hybridization of an identifying DNA probe, with a subsequent qualitative enzymatic colorimetric assay. The sensitivity of this technique has been reported as greater than 95%, with a speciÞcity of greater than 98% (42,43).

Failure to detect group O isolates and non-clade B isolates with the HIV-1 DNA-PCR method has led to the recommendation that this method not be used as a general screening measure for diagnosis of HIV-1 infection (44Ð46). Because of the somewhat high inaccuracy rate, this test can not be recommended as a routine screening measure (47). The DNA-PCR assay has been used in diagnosing infants born to women who are HIV-1-infected. The sensitivity in this setting, ranging between 75Ð97%, is better than that of the p24 antigen and HIV-1 culture assays. Nevertheless, as with other diagnostic methods, the sensitivity of DNA-PCR is signiÞcantly less for infants who are less than six months of age (41,42).

HIV-1 RNA QUANTITATION

Quantitation of circulating virion-associated HIV-1 RNA in plasma, commonly referred to as the plasma viral load, has had an enormous impact on management of HIV-1 infection. This measurement has allowed greater understanding of HIV-1 viral dynamics, and the continuous, high-level rate at which viral replication occurs (48,49). The advent of the plasma viral load allowed investigators to understand that a basal level of high viremia is continuously present, regardless of the patientÕs clinical stage (50,51). With this information, the natural history of HIV-1 infection was more clearly deÞned, and the expected clinical course is now well-established (Fig. 9.1). Furthermore, knowledge of the extraordinary rate at which HIV-1 replication occurs has helped explain the development of antiretroviral-resistant quasipecies, and the reasons behind antiretroviral drug failure (48).

Perhaps most importantly, though, the advent of assays to quantitate plasma HIV-1 RNA in the early 1990s gave clinicians a powerful new prognostic tool. Prior to the use of plasma viral load, clinicians caring for patients with HIV-1 infection relied on numerous, albeit often inadequate, surrogate markers for disease activity and prognosis. For example, assays for serum p24 antigen (an HIV-1 core antigen), B_2-microglobulin (a component of the class I major histocompatability complex), and neopterin (a marker for activated macrophages) had some predictive value, but lacked the sensitivity and speciÞcity necessary as optimal prognosticators (52Ð54). The CD4+ T-lymphocyte count, an adequate marker to gauge risk for development of opportunistic infection, did not necessarily determine disease activity and long-term prognosis. Day-to-day variability in the CD4+ T-lymphocyte count made interpretation even more difÞcult. Furthermore, the CD4+ T-lymphocyte count was not adequate in evaluating response to antiretroviral therapy. Quantitative culture of HIV-1 in plasma or PBMCs had been utilized, but was laborious and marked by a high degree of variability (55,56). Thus, a reliable and sensitive prognostic assay was clearly in need, and the plasma HIV-1 RNA quantitation assays Þlled this role.

Several studies performed during the mid-1990s consistently conÞrmed that the risk of progression to AIDS and death from HIV-1 infection was directly related to the plasma viral load (57Ð61). In addition, the plasma viral load was found to predict strongly the decline of CD4+ T-lymphocytes (62,63). Subsequent studies revealed the superiority of the plasma HIV-1 RNA level over the CD4+

Figure 9.1 to be supplied by author . . .

FIG. 9.1. The natural history of HIV disease.
Saag M. *Nature Med* 1996;2:625. Permission for use pending.

T-lymphocyte count in predicting disease progression, but importantly the combined measurement of both plasma HIV-1 RNA and the CD4+ T-lymphocyte count was found to be a better prognosticator of disease progression than either single test (62,64,65). New, simpler, and more rapid techniques of quantitating plasma HIV-1 RNA have allowed the plasma viral load to become the most clinically useful and meaningful prognostic tool.

Of equal importance has been the impact of plasma viral load on the use and understanding of antiretroviral therapy. With the advent of the plasma viral RNA assays, investigators had a reliable means of measuring both the short and long-term impact of antiretroviral therapy (59,66Ð70). Viral load reduction has now become the standard measure for determining response to antiretroviral therapy, as well as when comparing efÞcacy of different antiretroviral medications in clinical trials. Indeed, it was the response in plasma viral load that allowed investigators to propose that use of dual or triple antiretroviral drugs is of greater beneÞt than monotherapy (71). Finally, the plasma viral load has proven useful in predicting disease progression in the setting of antiretroviral therapeutic response, and the progressive change in this level has been shown to be even more predictive of disease progression than the pre-therapy level (64,72).

The two most common methods of quantitating plasma HIV-1 RNA in the clinical setting are the reverse transcriptase polymerase chain reaction (RT-PCR) assay and the branched DNA (bDNA) assay (73Ð77). In the RT-PCR assay, HIV-1 RNA from the patient is converted to complementary DNA (cDNA) by adding reverse transcriptase. A well-preserved portion of the *gag* gene is ampliÞed by PCR and hybridized to an enzyme-linked DNA probe. Simultaneously, a competitive RNA template, with a known standard copy number, is used in competitive titration (Fig. 9.2). The ratio of detected signal is compared to the signal of the known standard, thus determining the amount of HIV-1 RNA in the patientÕs plasma.

The bDNA technique for measuring viral RNA differs in concept from the RT-PCR method (Fig. 9.3). In this assay, HIV-1 RNA is captured by probes on to a microplate. Multiple DNA probes are hybridized to speciÞc *pol* (or *gag*) gene segments of the bound RNA, thereby amplifying the signal. Alkaline phosphatase is then added in the presence of a substrate to generate a chemiluminescent reaction. The chemical light units are then compared to a standard to determine the amount of RNA in the sample. Thus the bDNA method is based on signal ampliÞcation rather than target ampliÞcation.

A third method for quantitating plasma HIV-1 RNA, the nucleic acid sequence-based ampliÞcation assay

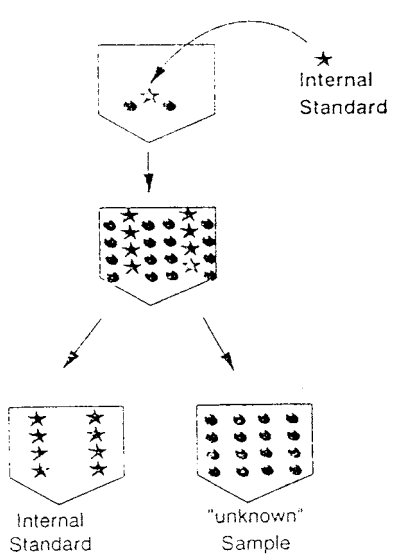

FIG. 9.2. Quantitative reverse transcriptase-polymerase chain reaction (RT-PCR) for measurement of HIV-1 plasma RNA. After HIV-1 RNA from the patient is converted to complementary DNA (cDNA), a portion of the *gag* gene is ampli ed by PCR. Competitive titration with a known standard copy number allows for quantitation of patient HIV-1 RNA. Harrigan J. *AIDS* 1995;10:139. Permission for use pending.

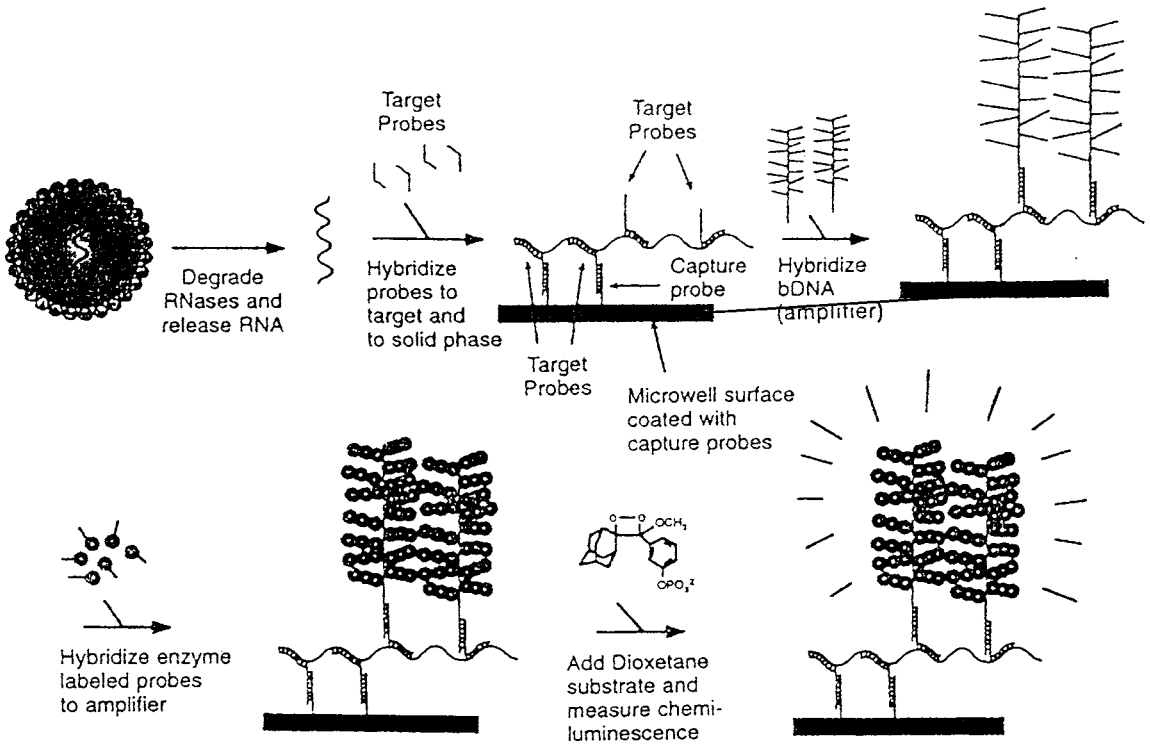

FIG. 9.3. The branched DNA (bDNA) assay for measurement of HIV-1 plasma RNA. After HIV-1 RNA from the patient is captured on to a microplate, DNA probes are hybridized to speci c gene segments of the baound RNA, thereby amplifying the signal. A chemiluminescent reaction is then used to quantitate the amount of RNA in the sample. Harrigan J. *AIDS* 1995;10:139. Permission for use pending.

(NASBA), is also commercially available, but less frequently utilized at this time. This assay, like the RT-PCR method, involves repetitive rounds of target amplification (78). Unlike the RT-PCR method, the NASBA method amplifies viral RNA as opposed to cDNA.

These three assay methods appear to be equivalent in sensitivity and specificity, particularly when measuring high or moderately high levels of viremia (79,80). Variability among the assays, however, may be more pronounced when evaluating low or undetectable viral loads (81). Currently, only the RT-PCR viral load test has been approved by the FDA for determining prognosis and for monitoring the response to therapy. Also, absolute levels of nucleic acid can vary among the assays. For example, the levels of viremia when determined by RT-PCR are typically two times higher than when measured by bDNA (62). For these reasons, direct comparisons of viral load should occur only if the same methodology is utilized, and the same assay should be used when serially testing viral loads.

The issue regarding HIV-1 viral load differences in men compared with women is not yet resolved. Some studies have noted that women tend to have lower HIV-1 RNA levels than men at seroconversion and early in infection, although other studies revealed no such differences (82–86). Even when viral load was found to be lower in women than men at seroconversion, the plasma HIV-1 RNA levels appeared to equalize with time (87). More recent data suggest that because viral loads are lower at seroconversion in women, and since the rate of progression to AIDS is similar in both sexes, guidelines recommending when to initiate therapy should be different for men and women (88). Until the issue of gender differences on plasma HIV-1 viral load is clarified, it is unlikely that different treatment recommendations for males and females will be made.

A number of factors can lead to variation in viral load for an individual patient. This variation can be related to assay methodology or can be biological in nature. For example, use of heparin as an anticoagulant can result in lower quantities of HIV-1 RNA than with use of EDTA as the anticoagulant (62,89). Similarly, time to processing of the specimen can alter levels of RNA (90).

In addition, plasma viral load can be transiently affected by a number of host or biologic factors. Vaccination against tetanus, the pneumococcus, and influenza have all been shown to cause a moderate, but transient, increase in plasma HIV-1 RNA levels (91–94). The cellular activation that results from vaccination may explain the increased HIV-1 viral expression and replication. Interestingly, those patients with higher CD4+ T-lymphocyte counts, and those who mounted the best response to the vaccine, typically developed a higher increase in plasma HIV-1 RNA.

Several infectious diseases, such as tuberculosis, herpes simplex virus infection, and bacterial pneumonia have also been shown to cause a transient increase in HIV-1 viral load (95–97). In fact, a transient increase in viral load has been associated with the development of any of several opportunistic infections, such as *Candida* esophagitis or *Pneumocystis carinii* pneumonia (98). Again, this may be related to cellular activation in response to infection.

Transient changes in plasma viral load may occur for less obvious reasons. A decrease in plasma viral load had been demonstrated in ovulating women, particularly during the early follicular phase to the mid-luteal phase, perhaps as a result of hormonal regulation of lymphocytes or cytokines (99). Also, missing even a few doses of antiretroviral therapy prior to measurement of viral load can result in an increased RNA level (65). Given the above variability in viral load, it is strongly recommended that decisions regarding therapy be based on at least two plasma viral RNA determinations separated over time (100,101).

Recommendations regarding use of plasma HIV-1 RNA levels in guiding therapeutic decisions have been made by the Department of Health and Human Services, as well as by the International AIDS Society (102,103). For patients who are naïve to antiretroviral therapy, determination of baseline plasma viral load, in addition to the CD4+ T-lymphocyte count, is essential. The plasma HIV-1 RNA threshold values used in determining when to initiate therapy differ slightly between the two sets of recommendations. The guidelines by the Department of Health and Human Services also consider different threshold values based on which assay method for plasma viral load is used.

Both sets of guidlelines state that if combination antiretroviral therapy is instituted, the goal of therapy is to obtain and maintain a plasma viral load below the level of detection. The level of detection, however, will depend on the sensitivity of the assay. Both the RT-PCR and bDNA methods for plasma HIV-1 RNA can detect viremia as low as 50 copies/mL. Currently, the guidelines suggest that a viral load less than 50 copies/mL is optimal, and there are some data to suggest that a more durable virologic response is obtained if such a viral load can be achieved (104–106).

It is expected that a 1- to 2-log reduction of plasma HIV-1 RNA should occur within four to eight weeks after starting therapy, and that the plasma viral load should be undetectable within sixteen to twenty-four weeks. One factor that can affect the time it takes for the viral load to become undetectable after beginning therapy is the level of viremia at baseline. A viral load that is greater than 100,000 copies/mL has been associated with a poorer chance of attaining an undetectable viral load with highly active antiretroviral therapy (102,107,108). It has also been demonstrated that the less time it takes to obtain an undetectable viral load after initiating therapy, the more likely the viral load will remain undetectable while on therapy (107). Thus, the lower the nadir, and the less time it takes to achieve an undetectable viral load, the greater the chance of successful therapy.

The optimal frequency for performing plasma viral load measurements once therapy has begun is not clear. Current guidelines recommend measuring the plasma viral load within one month after initiating or changing therapy, monthly until the goal of therapy is reached, and every two to three months thereafter (102). The guidelines also make recommendations regarding a change in antiretroviral therapy if viral rebound or failure to attain an undetectable viral load occurs. This issue is somewhat less clear, since the exact plasma viral load threshold for changing therapy is unknown, and other factors such as immune status as well as adherence and side effects of medications should be considered before altering therapy.

THE DIAGNOSIS OF ACUTE HIV-1 INFECTION

Although development of antibodies to HIV-1 can occur within weeks after exposure to the virus, routine serologic testing for HIV-1 using ELISA and Western Blot assays may initially be negative or indeterminate, particularly during the first few days to weeks after exposure. Diagnosis and treatment of HIV-1 infection shortly after exposure may be beneficial. Potential benefits of identifying and treating HIV-1 infection during the acute phase include preserving immune function, reducing the risk of transmission, and potentially altering the natural history and progression of disease (109). Initial viremia is thought to occur approximately four to eleven days after mucosal exposure (110). Quantitation of HIV-1 and p24 antigen during this period has revealed extraordinarily high levels of HIV-1 in the plasma (19,50,111,112). Control of viremia and a subsequent decrease in these levels occur shortly thereafter, reflecting the development of antibody and a cytotoxic T-lymphocyte (CTL) response (113,114). Presumably, at this time a plasma viral set-point is established. It is felt that antiretroviral therapy during acute HIV-1 infection may limit viral replication and thus lower the viral set-point, improving overall prognosis (115,116). Therapy at this time may also result in an enhanced CTL and T-helper lymphocyte response, thereby also potentially affecting outcome (117,118). Thus, making the diagnosis of acute HIV-1 infection, combined with early intervention, may be very beneficial.

Unfortunately, making this diagnosis can also be difficult. Although a well-described mononucleosis-like syndrome occurs in at least 50% of patients with acute HIV-1 infection, the findings are variable and non-specific, and can be easily attributed to other viral illnesses. In fact, less than 10% of cases of acute HIV-1 infection are diagnosed by clinicians (119). These symptoms usually occur two to six weeks after exposure and last for approximately one to two weeks (120). Since HIV-1 serologic tests become positive an average of at least 22

days after exposure, other methods of detection of primary HIV-1 infection are necessary (121).

Measurement of serum p24 antigen, HIV-1 DNA in plasma or PBMCs, or plasma HIV-1 RNA may be useful during this time period. As mentioned above, p24 antigen levels are often initially high, but may wane after one to two weeks (112,122). One recent study determined that the sensitivity of the p24 antigen assay during acute HIV-1 infection is approximately 89%, with a speciÞcity of 100% (123). A more sensitive method of diagnosing acute HIV-1 infection may be the plasma HIV-1 RNA level. Studies evaluating the use of this marker in diagnosing acute HIV-1 infection have found that the plasma viral load is nearly always greater than 50,000 copies/mL, and often greater than 100,000 copies/mL (115,123). The sensitivity of this assay during acute HIV-1 infection was 100% in a recent study, with a speciÞcity of 97% (123). It should be noted, however, that false positive plasma viral loads (usually with less than 5,000 copies/mL) have occurred and can lead to misdiagnosis (70,124). Although the above tests are more easily performed, a third option for diagnosis of acute HIV-1 infection is PCR for HIV-1 DNA in plasma or PBMCs. The sensitivity of this assay in this situation is not known. Finally, if a diagnosis of acute HIV-1 infection is made based on the above tests, standard serologic testing should still be performed at a later date to conÞrm the diagnosis.

Chapter 10

Simian Retroviruses

Murray B. Gardner, Maria P. Carlos and Paul A. Luciw

Animal retroviruses are classiÞed within seven different genera (Fig. 10.1), of which members of Þve genera (Table 10.1) are present in primates: (1) C-type virus; (2) D-type virus; (3) Human T-cell leukemia virus (HTLV), Simian T-cell lymphotropic virus (STLV), Bovine leukemia virus (BLV); (4) Lentiviruses; and (5) spuma Ð or foamy viruses (1). This chapter will review the salient biology of each of these Þve viral groups, in the order given with relevant information available up to the present time (2003). Emphasis will be placed on the D-type simian retroviruses (SRVs) and lentiviruses (SIVs) because of their etiologic association with simian AIDS (SAIDS). In the last 20 years it has become evident that humans also harbor retroviruses: two strains of human T-lymphotropic virus (HTLV-1 and HTLV-2), with simian counterparts (STLV-1 and STLV-2); and two major strains of lentivirus, human immunodeÞciency virus (HIV-1 and HIV-2), which also have simian counterparts (SIVs). Humans apparently are not infected with any exogenous D-type or C-type viruses nor do they carry any indigenous spumaviruses. Of all the animal lentiviruses, SIV is genetically most closely related to HIV and apparently was the source of HIV by cross-species spread from infected chimpanzees and sooty mangabeys in Africa. SIV is a heterogeneous group indigenous to many species of African non-human primates, including chimpanzees. In the natural African simian hosts, SIV causes no disease but experimental infection of captive macaques with certain SIV strains, especially from the sooty mangabey, produces a progressive and fatal immunodeÞciency syndrome similar to AIDS in humans, making this primate lentivirus model very useful for research into AIDS pathogenesis, vaccines and antiviral therapy. In recent years much headway has been made using the SIV macaque model for these purposes (2Ð5). This animal model is also covered by FultzÕs chapter in this volume.

MAMMALIAN C-TYPE VIRUSES

This genus of C-type retroviruses, formerly called RNA tumor viruses, oncoretroviruses or oncornaviruses, was the target of extensive research in the 1970s seeking to identify cancer-causing retroviruses in animals and man. Several prior reviews (6,7) have thoroughly covered this material; this section will only highlight the major features of this viral group. C-type viruses are further divided into two major groups depending on their endogenous or exogenous route of transmission under natural conditions.

Endogenous C-Type Primate Viruses

Evidence became available in the early 1970s that C-type viral-related genes were present in the genomic DNA of many mammalian species, including primates (8). Most of these endogenous elements Þrst appeared in the primate germline prior to the New World/Old World divergence over 40 million years ago, but then underwent major ampliÞcation in Old World primates (9). All known human endogenous retroviruses (HERVs) were thus integrated into the germline prior to the speciation of Homo Sapiens and higher apes. Although all of these endogenous retroviral sequences are defective in humans and unable therefore to synthesize infectious viruses, a few endogenous viral isolates were obtained in the 1970s from non-human primates (baboon, macaque, owl monkey) by cocultivation of their cells with permissive cells of heterologous host species. These endogenous virus isolates are not infectious for cells of their species of origin,

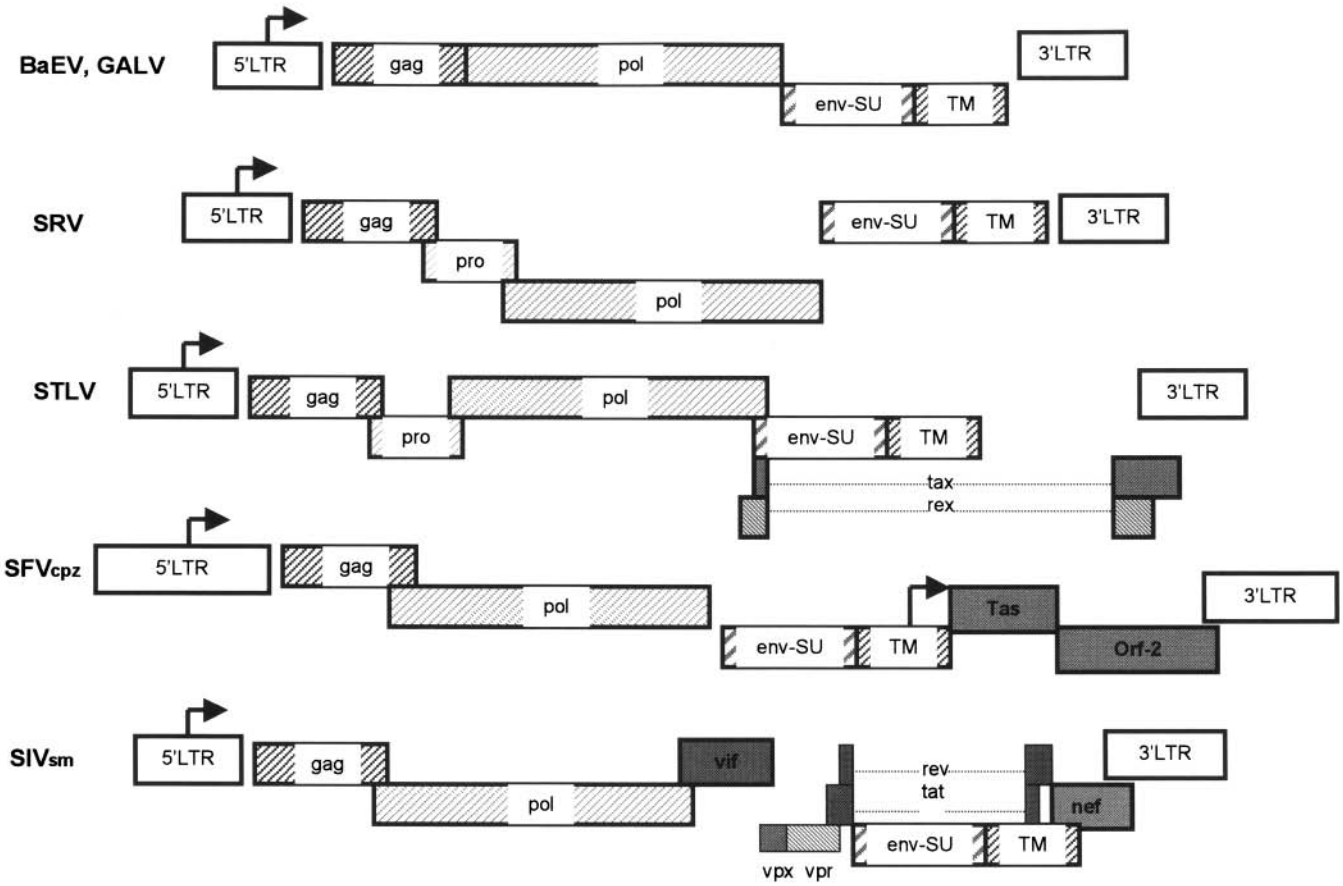

FIG. 10.1. Genomic organization of primate retroviruses. The genetic structure of the proviral form of several primate retroviruses is shown, Abbreviations for viruses are given in Table 10.1. Long terminal repeats (LTRs) ank the provirus. Genes for structural proteins incorporated into virions are crosshatched. Accessory or auxiliary genes are shaded. Table 10.3 contains a description of retroviral gene functions for the primate lentiviruses. The arrows indicate the transcriptional promoter in the LTR and the internal promoter for the foamy viruses (e.g. SFV_{cpz}).

i.e. they have a xenotropic host range. The endogenous viral genes appear to be well conserved in evolution and to represent part of the natural inheritance of the species. It is assumed that the endogenous viral genes are evolutionarily conserved relics of ancient infections by exogenous retroviruses, primarily of the same animal species, but occasionally across species barriers. This phenomenon of retroviral integration into the germ line can be accounted for by the presence of the viral-encoded reverse transcriptase enzyme, which provides the mechanism for converting the complete RNA genome of exogenous retroviruses into double-stranded DNA (10,11). Another viral enzyme, the integrase, functions to insert this proviral information, more or less at random, into the chromosomal DNA of somatic and, on rarer occasions, into germ cells. There is evidence from *in situ* hybridization that endogenous retroviruses may show speciÞc integration site preferences (12). It was discovered that: (a) not only all chickens and mice contain such C- type information in their cellular genomes, but that this holds true for all mammals; (b) endogenous C-type viral genes coding for core proteins, envelope glycoproteins and the enzyme reverse transcriptase, are expressed under independent regulation; and (c) the endogenous C-type viral genes are expressed in many instances in the absence of virus production. In certain inbred strains of chickens and mice, the inherited endogenous C-type viral genes become activated spontaneously to form complete viruses, which are infectious for their own speciesÕcells (i.e. ecotropic host range). In the inbred line AK at Rockefeller Institute, NY (AKR) and related leukemia-prone strains of inbred mice (but not in outbred feral mice) (13), such endogenous ecotropic viruses (i.e. murine leukemia virus) may recombine with other endogenous defective C-type-related viral genes, and eventually cause thymic lymphomas (14).

The viral oncogene hypothesis that guided much of cancer virus research in the 1970s was based on the similar idea that activation of endogenous virogenes might also include viral oncogenes and lead to cancer (15). However, this generalization, although of tremendous heuristic value, did not prove entirely accurate. Pioneering studies of animal retroviruses, primarily in chickens, mice and cats, did indeed lead to the discovery of oncogenes, but in the mid-1970s it was realized that these sequences were

TABLE 10.1. *Simian retroviruses*

Virus Genera	Host	Exogenous	Endogenous	Pathogenic
C Type	Tree shrew		TRV-1	No
	Baboons		BaEV	No
	Baboons		SERV*	No
	Baboons		PcEV*	No
	Rhesus Macaques		Mac-1	No
	Stumptail Macaques		MMC-1	No
	Colobus		CPC-1	No
	Owl Monkey		OMC-1	No
	Gibbon Apes	GaLV		Lymphoma and myelogenous leukemia
	Wooly Monkey	SSAV/SSV		Sarcoma
HTLV/STLV/BLV	African and Asian Monkeys and Apes		STLV-1	
	Lymphoma			
	Macaques	STLV-1		No
	Spider Monkeys	STLV-2		No
	Pygmy Chimpanzees	STLV-2		No
D-Type				
	Macaques	SRV 1–5 (MPMV)		
	SAIDS			
	Hanuman Langur	SRV-6		No
	Spectacle Langur		Po 1-Lu	No
	Squirrel Monkey		SMRV	No
Lentivirus	African Monkeys (natural host)		SIV	No
	Macaques (experimental host)	SIV		SAIDS
Spumavirus	African and Asian Monkeys, Apes and Chimpanzees; Squirrel, Spider, and Capuchin Monkeys	SFV		No

* Complete endogenous proviral DNA based on PCR ampli cation and DNA sequence analysis, but not detectable as virus particles

not viral but instead represented normal cellular growth promoting genes present in all eukaryotes (16). In animals, such oncogenes could be activated by nearby insertion of C-type viral DNA, and thus lead to leukemia. Rarely, such oncogenes were transduced, i.e. Òpicked upÓ by exogenous C-type retroviruses, to create rapidly acting avian, murine or feline sarcoma viruses (6,7). In humans, by contrast, oncogenes are generally activated by mutations such as chromosomal translocations, rather than by retroviral infection, and no human sarcoma viruses have been discovered.

The presence of endogenous, ecotropic (i.e. infectious) C-type viruses in inbred chickens and mice is clearly an effect of inbreeding. In outbred feral mice (the progenitor of inbred lab mice), as found later in humans (i.e. HTLV), such leukemia viruses are transmitted solely by exogenous means, mainly by milk (13). Although a number of useful roles and possible pathogenic sequelae for endogenous virogenes have been postulated, it has not been possible, as yet, to demonstrate any biologic function for these genes in primates, including humans (17), despite the fact that over 1% of the human genome is represented by such endogenous retrovirus-like sequences (18).

Analysis of the newly available human genome reveals that coding sequences comprise less than 5% of the genome whereas repeat sequences account for at least 50% (19). Most human repeat sequences are derived from transposable elements, among which retrovirus-like elements are one major class. Among these transposable elements are LTR retrotransposons comprising LTRs that contain all of the necessary transcriptional regulatory elements ßanking gag and pol genes. Exogenous animal retroviruses probably have arisen from such retrotransposons by acquisition of a cellular envelope gene (*env*). In the human genome, in marked contrast to the mouse, LTR retrotransposon activity has been essentially extinct for the past 40 million years. Therefore, it is easily understandable why infectious endogenous retroviruses have not been generated in modern evolutionary times in human or the closely related non-human primates.

Baboon Endogenous Virus (BaEV)

The Þrst infectious, endogenous C-type virus isolate of primate origin was from baboon placenta (20). Subsequently, many independent but closely related isolates

were obtained from diverse normal adult and embryonic tissues of several different species of baboons. Like most other endogenous viruses, these could only be grown in permissive cells of certain species different from the species of origin (i.e. xenotropism). BaEV was not shown to have oncogenic activity and its biological role, if any, remains unknown. This prototype endogenous primate C-type virus (BaEV) became a useful tool for probing the evolutionary relationship of various primates. Non-infectious sequences related to those of BaEV virus were found in all other Old World monkeys with the degree of relatedness determined by the evolutionary distance between species (21).

More recently, PCR amplification and sequencing of two BAEV proviral DNAs in a baboon (*Papio cynocephalus*) genomic library revealed full length proviruses with little sequence variation and no evidence for the rearrangements or large deletions commonly observed in endogenous viral genomes from other mammalian species (22). A novel complete endogenous proviral genome was also isolated by PCR amplification from a yellow baboon genomic library (23). The *gag* and *pol* genes are closely related to BaEV, but the *env* gene was apparently contributed by an endogenous Type D provirus (SERV) also isolated by PCR from the baboon genomic library (24). PCR analysis of primate DNA suggests that SERV is ancestral to both BaEV and simian Type D retroviruses (SRV). In addition, the same library yielded proviral sequences with BaEV core and Type C *env* genes (PcEV) (25). Neither of these endogenous proviruses are expressed as complete virus particles. The distribution of these baboon endogenous proviruses among non-human primates appears to be the consequence of cross-species spread of exogenous viruses in antiquity among different primate species sharing the same habitat (26). Several similar examples were noted of suspected cross-species transmission of endogenous C-type viruses among animals in evolutionary times (27). For example, BAEV proved partially related to the endogenous, xenotropic feline C-type virus, RD114 (28). Because RD114 DNA was not present in the genomic DNA of most members of the Felidae family, it was concluded that BaEV spread from ancestral baboons to ancestors of the domestic cat about 5 million years ago (29). PCR sequence analyses now suggest that RD114 is actually a new recombinant between PcEV Type C core genes and the env gene of BaEV (30).

Sequence homology between HTLV-1 and STLV-1 isolates from specific geographic regions has also suggested the transmission of ancestral viruses of this retrovirus genus between primate species including humans (31) (see STLV section). In current times, it has been very difficult to document transpecies spread of any animal retrovirus, endogenous or exogenous, under natural conditions. However, four important exceptions, discussed later in this chapter, have become apparent in retrospect: (a) the inadvertent infection about 25 years ago of Asian macaques in USA primate centers by the exogenous lentivirus (SIV) from African sooty mangabeys, an event that caused simian AIDS (32); (b) the recent (□□30 years) spread of SIV from sooty mangabeys to humans in West Africa to give rise to HIV-2 (33); (c) the spread of SIV in the early or mid-1900s from chimpanzees to humans to give rise to HIV-1 (34); and (d) the accidental infection of several primate handlers with SIV or possibly SRV (35–37). It will be of interest to see how often humans given xenotransplants of baboon liver or bone marrow become infected with BaEV or other simian viruses, e.g. STLV, SIV, SERV or foamy virus. Indeed, retrospective PCR analysis of tissues from two human recipients of baboon liver transplants revealed the presence of BaEV and simian foamy virus in multiple tissues (37). The presence of baboon mitochondrial DNA in the same tissues suggested that infected baboon leukocytes in the liver transplants were the source of these viruses.

In recent years, several laboratories cloned the human receptor for BAEV, and identified it as a sodium-dependent neutral amino acid transporter (39–41). This same receptor functions for the feline endogenous retrovirus RD114, all strains of SRV and the avian reticuloendotheliosis group. This receptor was previously mapped in humans to chromosome 19q13.3 (42). Infection of cells with RD114 or SRV resulted in impaired amino acid transport suggesting a mechanism for virus toxicity and immunosuppression (41). Knowledge of this retrovirus receptor may facilitate gene therapy using vectors derived from this virus group.

In addition to BaEV, five other primate endogenous retroviruses, *in toto*, have been isolated and characterized, making a total of six distinct genetically transmitted retrovirus groups in primates (43) (Table 10.1). These isolates included C-type virions from tree shrew, stumptail and rhesus macaques and an owl monkey, and D-type viruses from the squirrel monkey and a langur monkey. Like BaEV, these other endogenous primate retroviruses have no known biologic role. Apart from the baboon and owl monkey, endogenous retroviral genes are powerfully repressed at the cellular level in their primate hosts, and, as in humans, are not expressed as complete infectious virus particles.

Gibbon Ape Leukemia Virus (GaLV) and Simian Sarcoma Virus (SSV)

The first exogenous primate C-type virus (GaLV) was isolated in the early 1970s from several captive gibbon apes that developed spontaneous leukemia (44). At about the same time, a closely related virus called simian sarcoma virus (SSV) was recovered from a pet wooly monkey with a spontaneous fibrosarcoma (45). GaLV was then shown to be fairly common in captive gibbon apes and to be spread horizontally as a purely exogenous virus (46). Molecular hybridization analysis suggested that it might have been acquired in the evolutionary past by

transpecies infection with an endogenous C-type virus of feral Asian mice (27). By contrast, SSV was found only in the one wooly monkey; it was neither endogenous nor exogenous in this species. Because the GaLV-infected gibbon ape and SSV-infected wooly monkey had frequent physical contact in the same household and because the GaLV and simian sarcoma associated or helper virus (SSAV) were so closely related, it was assumed that SSV was derived from GaLV by transpecies infection. The sarcoma-inducing property of SSV was later shown to be caused by the transduction of the *sis* oncogene (β-chain of platelet-derived growth factor) from the wooly monkey genomic DNA by infection with the GaLV (47). This was a rare one-time event, and still represents the only example of a sarcoma virus oncogene rescued from a solid tumor of a non-human primate. Experimental studies of SSAV/SSV cell transformation and induction of sarcomas or gliomas in marmosets (48) were very helpful in elucidating the molecular mechanisms underlying its rapid oncogenicity, e.g. defectivity of sarcoma viruses, rescued by helper type C viruses (such as GaLV), and transduction of the *sis* oncogene.

Because GaLV occurs naturally in gibbon apes in captivity, it was assumed to occur in gibbon apes in the wild, but this has not been studied. GaLV was isolated on several occasions and at different locations from additional cases of spontaneous malignant lymphoma or myelogenous leukemia occurring in captive gibbon apes (49). Subsequently, the virus was also isolated from healthy seropositive carriers. The virus causes a systemic bloodborne (cell-associated and cell-free) infection of multiple tissues, and can be readily isolated from many organs. It has a wide *in vitro* host range for a number of non-hematopoietic cell types of diverse species including humans and is non-transforming and non-cytopathic. All of the GaLV isolates are closely related one to another, but individual isolates can be distinguished by highly sensitive immunologic, *in vitro* infectivity, or nucleic acid hybridization assays (50). Experimental transmission studies showed that the GaLV isolates were very stable and could induce the same tumors (e.g. myelogenous leukemia with latent period of 6–14 months) as that seen in the animal from which the virus was initially isolated. Infectious molecular clones of GaLV were not then nor now available for *in vivo* pathogenicity study. Natural transmission of GaLV was documented several times in captive gibbon apes, but the route of spread was not shown (46). Congenital transmission also was observed. Neutralizing antibodies were protective against fulminating viremia and subsequent development of tumors. Despite extensive surveys, and numerous false alarms, GaLV infection of humans was never found (51). In the late 1970s, the NIH-supported gibbon ape colonies were disbanded and biologic studies of GaLV and SSV came to a halt. The cell surface receptor for GaLV and SSV in human cells has been characterized as a channel for sodium phosphate ions (52, 53). A closely related receptor functions for amphotropic murine leukemia viruses and feline leukemia virus subgroup B (54, 55). These receptors are expressed on human adult and fetal tissues including hematopoietic stem cells and umbilical cord blood cells. Thus, GaLV and amphotropic MuLV have provided a useful source of envelope for retroviral vectors frequently used in current gene therapy protocols (56–59).

A novel Type C retrovirus was recently detected by EM and PCR in the blood and tissues of many wild and captive koalas and in three animals with lymphoma (60). The virus (KORV) is apparently endogenous in koalas but not other marsupials and phylogenetic analysis showed that, paradoxically, it clusters with GaLV, thus suggesting yet another example of relatively recent cross-species transmission. Its pathogenicity remains to be determined.

Human Endogenous Retroviruses

In the last 20 years, since human endogenous retroviral elements (HERVs) were first isolated (61), a number of sequences related to non-human (i.e. chicken, mouse, cat, primate) endogenous and exogenous retroviruses have been cloned and sequenced or found by polymerase chain reaction (PCR) analysis in human genomic DNA (17). Most of these sequences are related to primate and murine Type C viruses (BAEV, GaLV/SSAV, MuLV), murine Type B viruses and intracisternal A particles (IAP) or HTLV (62–64). Phylogenetic analysis shows that the HERV-W family entered the human genome more than 25 million years ago (65). Sequences detected in the purified retrovirus-like particles from human placentae, have the highest homology to B- and D-type retroviruses (66). Historically, in 1973, it was the detection by electron microscopy (EM) of such budding C-type particles in baboon and human placentas (67) that prompted the isolation of BaEV from baboon placenta (20) and led to a massive search for replicating human endogenous retroviruses. However, no direct evidence for replication of complete, infectious endogenous retroviruses from human placenta or any other human tissue has ever been observed (17,18,51). The immunologic detection of HERV antigens or antibodies and the occasional sighting by EM of budding retrovirus particles that, when purified, contain reverse transcriptase (RT) activity, in human tissues, especially placenta and germ cell tumors, suggest a biologic function for some of these sequences (68–74). HERV envelope proteins are expressed in the syncytial trophoblast layer of the placenta and may be involved in the development of the structure (75). Several tumor cell lines, mainly teratocarcinoma, bladder carcinomas, testicular and lung tumors, also express significant levels of HERV transcripts including full length *gag*, *pol*, and *env* domains (76–79). Several HERVs with open envelope reading frames were further characterized by an *in vitro* transcription/translation approach (80). Premature stop

codons were present in the great majority of env genes of such HERVs. The results suggest the lack of conservation of a functional envelope gene of possible beneÞt for the host. Some of the HERV *env* genes including those expressed in the placenta contain sequences related to the so called immunosuppressive domain of other retroviruses (79, 81), and it has been suggested that this env domain protect the fetus from the maternal immune response and may allow tumor cells to escape immune rejection in immunocompetent hosts (75,82). Expression of a HERV has also been tentatively linked to patients with multiple sclerosis (83Ð85). Recently, the envelope glycoprotein of a placenta-related HERV-W was able to form pseudotypes *in vitro* with defective HIV-1 virions thus enforcing tropism for CD4 negative cells (86). Thereby, the HERV-W env gene was demonstrated for the Þrst time to encode functional properties of a retrovirus envelope glycoprotein. Nevertheless, no replication competent HERV has been described and the cumulative data suggest that the human genome does not contain an entire, intact proviral copy of any HERV. In conclusion, any health related signiÞcance of these endogenous retrovirus-like elements in humans, as in non-human primates, remains unknown, despite the many speculative roles assigned them (17).

SIMIAN T-LYMPHOTROPIC VIRUS, TYPE 1 (STLV-1)

STLV-1, the simian counterpart of HTLV, was discovered in Japanese macaques (*Macaca fuscata*) shortly after the discovery of HTLV-1 (87). STLV-1 and HTLV-1 share many molecular features and pathogenic properties (88). Naturally-occurring STLV infection is highly prevalent in feral populations of at least 30 species of African and Asian non-human primates (87Ð97). The genomic organization of both STLV-I and HTLV-I is similar consisting of LTR-gag-pol-env-tax/rex-LRT and genomic sequences exhibit an overall similarity of 90Ð95% (98). Because of their close phylogenetic relationship, these simian and human viruses have been classiÞed as primate T-cell lymphotropic virus Type 1 (PTLV-1). Indeed, simian strains cannot be distinguished from human strains by phylogenetic criteria (99).

Serosurveys and virus isolation indicate that STLV-1 is a common infection in feral Cercopithecoidea and apes in Africa and, in feral macaques and orang-utans in Asia and Indonesia (87Ð97). Infection is also frequent in captive monkeys and apes in primate centers and zoos (100Ð106). In Africa, infection rates of 10Ð60% are found among feral troops or captive colonies of African green monkeys, baboons, mandrills, Sykes, and patas monkeys, and in Indonesia, similar infection rates are found in Celebes and cynomolgus macaques and siamongs. In primate centers, approximately 20Ð50% of captive rhesus monkeys and sooty mangabeys and 10% of chimpanzees may be infected with STLV-1. An increasing seroprevalance with age suggests that the virus is horizontally spread; sexual transmission (107) and Þghting among males (97,108) may account for most of this spread. Vertical transmission may occur less frequently. Like HTLV (and BLV (109), STLV is transmitted in a T-lymphoid cell-associated and not cell-free manner. Almost all of the monkeys or apes carrying STLV remain healthy. However, the spontaneous occurrence of adult T-cell leukemia (ATL), similar to ATL in HTLV-1-infected humans has been documented in African green monkeys (110,111), baboons (90,102,112) and gorillas (113,114). Neurologic disease similar to that associated with HTLV-1 infection of humans (i.e. tropical spastic paraparesis) has not, as yet, been observed in STLV-1 infected monkeys or apes. In naturally infected African green monkeys, STLV-1 speciÞc killer T cells are activated *in vivo*, which may help hold the virus in check (115). In captive sooty mangabeys, coinfections with STLV-1 and SIV are also non-pathogenic (103). Experimental infection of macaques with STLV-1 resulted in a latent low level infection without seroconversion. Even in SIV experimentally infected macaques, STLV-1 infection apparently does not affect the course of SIV-disease (116). Nor does STLV apparently contribute to the development of lymphoma in naturally-infected macaques, despite a single report to the contrary (117). Recently, experimental infection of pigtailed macaques with STLVsm or HTLV-I resulted in an unexpected high mortality within days from a hypothermic syndrome unrelated to AIDS (118).

Because of the evolutionary age (> 25 M years), relative genetic stability (0.5% variation within an individual) and limited horizontal transmission of the PTLVs, molecular epidemiology and phylogenetic analyses of these viruses have revealed the movements and contacts of ancient human and non-human primate populations (94,99, 119Ð127). In general, and in marked contrast to the simian lentiviruses (SIV), PTLV sequences evolve slowly and segregate according to their geographical origin rather than according to host species, suggesting the repeated interspecies transmissions in the distant past of these viruses between primate species including human. The greater overall sequence variation between STLV-1 strains (1Ð18%) compared with HTLV-1 strains (0Ð9%) supports an ancient simian origin of the modern viruses in all species. Phylogenetic analysis reveals three major HTLV-1 clusters or clades: cosmopolitan (subtype A), Central Africa (Zaire) (subtype B) and Melanesian- (subtype C), and 7 STLV-1 clades in Asia and Africa with the most primitive (i.e. genetically diverse) clade involving several Asian primate species. Each of the three major HTLV-1 lineages appears to have arisen from separate ancient interspecies transmissions between STLV-1 infected monkeys and humans (128). The African STLV-1 isolates are more closely related to HTLV-1 than Asian STLV-1 isolates suggesting an African origin for most strains of HTLV-1 (129Ð131). Despite a higher evolutionary rate of PTLV-1 in Asia than Africa, phylogenetic analyses are compatible with an ancient origin of PTLV from either old

world continent (119,132). In humans, the cosmopolitan lineage (HTLV-1 subtype A) has the widest global distribution (Japan, Caribbean, South American, India, and West Africa) and probably arose from a West African STLV strain. The central African subtype (HTLV-1 subtype B) is clearly descendant from an STLV-1 chimpanzee-like ancestral simian strain in the former Zaire, and the Melanesian strain (HTLV-1 subtype C) probably descended from an Asian STLV-1 strain. The distribution of the cosmopolitan HTLV-1 clade suggests a close connection of Caribbean and South American natives with the Japanese, probably dating back to the migration of the lineage to the American continent via the Bering strains in the Paleolithic era. Consistent with this idea is the PCR detection, in 1,500 year old Andean mummies, of HTLV-1 proviral sequences that are similar to those in contemporary Andeans and Japanese (133). HTLV-1 subtype B remains focused in Central Africa. Clustering of HTLV-1 isolates from a B/C intermediate genotype (subtype D) in Central and West Africa with yet other Caribbean isolates suggest that some Caribbean isolates originated from Central and West Africa via the slave trade. Mandrills in Gabon, Central Africa, are apparently the natural reservoir of HTLV-1, subtype D (134). Close sequence relatedness between STLV-1 isolates in Celebes macaques in South East Asia and the HTLV-1 subtype C Melanesian strains suggest the interspecies transmission of STLV-1 to early Australoid settlers during their migration from South East Asia to the Australian continent (122). Interestingly, in South Africa, the known HTLV-1 strains do not share a common origin with non-human primates in that region (135,136). By contrast, as mentioned above, mandrills in Gabon carry the same PTLV-1 subtype D as found in humans in that area, and STLV-1 infected chimpanzees probably transmitted the virus (STLV-1 subtype B) to African green monkeys and baboons as well as humans in Central Africa (137). No speciÞc clustering of virus subtypes has been observed in relation to manifestations of HTLV-1-related diseases. Thus, the topology of the HTLV-1 phylogenetic tree reßects the interspecies transmission of STLV between non-human primates and humans and the movement of people carrying the viruses in the past.

At the Southwest Foundation for Biomedical Research (San Antonio, TX), about 40% of the 3,400 free-ranging baboons have been infected with STLV-1 (102). The risk of ATL developing in the infected animals is 3Ð4% during their lifetime; thus, in any single year a dozen or more lymphomas occur in this colony. Most of the tumor cell lines from these baboons have monoclonal integration of complete STLV-1 proviral DNA, whereas a few tumor cell lines show monoclonally integrated defective proviruses. A high incidence of STLV infection and associated lymphoma has also been observed in baboons at the former (now disbanded) Sukhumi Primate Center in southern Russia (Georgia) (90). Sequence analysis indicates that the baboons at this center acquired STLV-1 by recent cross-species transmission of the virus from rhesus macaques (112). In summary, STLV-1 has a natural history and biology in non-human primates that is very similar to HTLV-1 in humans (and BLV in cows) (109) and, as mentioned, the genome structure and degree of homology between STLV-1 and HTLV-1 (and BLV) are very similar. Clearly, the leukemogenic potential of STLV-1 is analogous to that of HTLV-1 and BLV.

Each of the PTLV has the same genetic constitution encoding typical *gag*, *pol* and *env* gene products as well as unique regulatory and accessory genes not present in the C type viruses, and located in four open reading frames (ORF) of the 3′ region (98,138). Two of these ORFs, analogous to *tat* and *rev* in HIV and SIV, encode the Tax and Rex proteins, respectively. Tax is a 40 kDa nuclear phosphoprotein, which activates viral transcription from the LTR and also activates many cellular genes involved in host cell proliferation and cell cycle control (139Ð143). Tax can also activate HIV-1 transcription *in vitro* (144). Rex is a 27 kDa nucleolus localizing phosphoprotein that increases the cytoplasmic accumulation of unspliced and singly spliced viral RNA. The other two ORFs are less well characterized, and encode various transcription factors (145). For both STLV-1 and HTLV-1, the natural target cells are mainly T-cells, mostly of CD4+ phenotype (146). Like HTLV-1, STLV-1 can immortalize cultured T-cells by a mechanism involving Tax activation of cellular transcription factors and other cellular genes (139,147). Several cytokines (IL-6, TGF-β, GM-CSF), involved in cellular proliferation and cell cycle control are released from STLV-1 transformed T-cell lines (140). The cellular receptor for STLV-1 or HTLV-1, thought to be located on human chromosome 17 (148), is still uncharacterized.

Obviously, STLV-1 could serve as an excellent experimental surrogate for HTLV-1 infection of man except that, like HTLV-1, the lymphoma/leukemia incidence is usually so low (1Ð5%) and the latent period so long (several decades), that it has not been used as a practical experimental model for studies focused on neoplasia. However, this opportunity could now be provided by the Southwest baboon colony described above (102). It is important to screen African and Asian monkeys in primate centers for infection with this virus, because it could yet prove to be a confounding cofactor in studies with SIV or other viruses.

An STLV-2 isolate, virtually identical to HTLV-2, has been recovered from New World Spider monkeys (*Ateles fusciceps*) (149). This is the Þrst link between HTLV-2 and a simian reservoir in the New World. PTLV-II viruses have been isolated, to date, from only IV drug users and their sexual partners (in which they are rapidly spreading (150), several Amerindian tribes (151) and Spider monkeys in the New World, and human Pygmys (152), and pygmy chimpanzees or bonobos (*Pan paniscus*) in Central Africa (153,154). So far, no disease has been found in association with PTLV-II infection of non-human primates or humans. Compared to PTLV-I viruses the PTLV-II viruses are evolving more slowly and exhibit less transcontinental

genetic differentiation (132). Several highly divergent STLV isolates have been recently isolated from feral Hamadryas baboon (155,156) and pygmy chimpanzee (153,154). These isolates are distinct in genetic sequences and genomic structure but are more closely related to HTLV-2 than HTLV-1 (157–159). These new STLV isolates constitute several distinct STLV-3 strains occurring in different African monkey species (160). It will be important to monitor whether such STLV variants can be transmitted to humans, especially following organ xenotransplantation. In contrast to SFV, SRV and SIV, no evidence has yet been found for transmission of STLV-1 to animal handlers in primate facilities.

The geographical prevalence of HTLV-1, and the low degree of variability compared to HIV-1, indicate that people in areas of high prevalence, such as southern Japan, and people of developing countries would beneÞt most from a vaccine against HTLV-1. Cynomolgus monkeys (*M. fascicularis*) have been used as an HTLV-1 vaccine model. In one experiment (161), four monkeys were immunized with a recombinant HTLV-1 *env* gene product produced in *E. coli* and challenged with live MT-2 cells, a high HTLV-1 producer cell line. After challenge, all four control non-immunized monkeys were infected and all four of the immunized monkeys were protected. Protection correlated best with vaccine induction of speciÞc antibody against envelope glycoproteins (gp68 and gp46) of HTLV-1, including high-titered syncytial inhibiting neutralizing antibody. A vaccinia-based HTLV-1 envelope vaccine also protected cynomolgus monkeys from infection by HTLV-1 (162). A highly attenuated HTLV-1 *env* poxvirus vaccine (ALVAC) induced protection against HTLV-1 infected cells in rabbits (163). In yet another study (164), three monkeys were immunized with an HTLV-1 gag and env subunit vaccine and challenged with an STLV-1 infected cell line. After challenge, the two controls were infected; the three vaccinates apparently were uninfected. However, an increase in antibody titers in the vaccinates after challenge suggests that they had been transiently infected. Protection correlated with induction of HTLV-1 (and to a lesser extent STLV-1) syncytial inhibition antibody and lymphocyte-mediated cytotoxicity (CTL) against STLV-1 infected cells. Thus, as previously shown in murine and feline C-type virus and BLV systems (165), vaccine protection via neutralizing antibody is also effective against the HTLV/ STLV group of primate retroviruses under laboratory conditions. Most recently, the squirrel monkey (*Saimiri sciureus*), a south American non-human primate, free of STLV, has been found susceptible to experimental infection with HTLV-1 immortalized syngeneic or allogeneic cells (166). The strong seroconversion and persistent latent infection, especially in lymphoid organs that ensues, indicates another promising animal model for evaluating candidate vaccines against HTLV-1 (166,167). An HTLV-1 vaccine protocol consisting of an env DNA primer followed by recombinant vaccinia (NYVAC) gag-env boosts protected all three squirrel monkeys against IV challenge with HTLV-1 infected allogeneic cells (168). It seems clear that, in contrast to HIV and SIV, an efÞcacious vaccine against HTLV (and STLV) should be quite feasible to develop, at least from the scientiÞc standpoint.

D-TYPE VIRUSES

Epidemiology, Natural History and Experimental Transmission

Exogenous Type D retroviruses, called simian retroviruses (SRV), of several serotypes (SRV 1–5), are indigenous in feral Asian macaques and cause a potentially fatal immunosuppressive disease resembling AIDS in captive macaques worldwide (2,169,170). In the early 1980s, before the discovery of SIV in 1985, the disease was called simian AIDS or SAIDS but this term is now generally restricted to the AIDS-like disease in macaques caused by simian immunodeÞciency lentivirus (SIV). Because SIV is more closely related to HIV in structure and function than is SRV, research on SIV is considered more relevant to AIDS and has largely replaced research on SRV. The original D-type virus, isolated in 1970 from a macaque with spontaneous breast cancer, was called Mason-PÞzer monkey virus (MPMV) (171). A serologic survey of U.S. primate centers, taken in the mid-1970s indicated that about 25% of all macaques had antibody reacting to MPMV; this observation revealed the widespread distribution of this infection in captive macaques prior to the 1980s (172).

Before the causative Type D retrovirus (i.e. SRV-1) was identiÞed in 1983 at the New England, Washington, and California Primate Centers and NIH, a cage exposure experiment was set up at the California Primate Research Center (CPRC) to prove the infectious nature of an immunosuppressive AIDS-like disease in an outdoor corral (NC-1) of rhesus macaques in which many deaths from SAIDS had occurred (173,174). Nineteen of 23 (83%) healthy tracer juvenile rhesus died of a fatal immunosuppressive disease within nine months of introduction into the resident affected population. In contrast, 21 healthy sentinel juvenile rhesus placed in the same outdoor enclosure but denied physical contact with the SAIDS affected group by a 10-foot wide buffer zone remained healthy and seronegative for 2 1/2 years. This result indicated that direct physical contact was required for spread of the disease. The most likely route of natural transmission was by percutaneous inoculation of virus-containing saliva and blood, via biting and scratching (175). Following the isolation of SRV-1 from affected rhesus in NC-1 and the development of appropriate serologic and virologic assays for its detection, it was found that all monkeys with SAIDS in NC-1 were persistently infected with this D-type virus. All of the healthy ÒsentinelÓ monkeys located within the same

enclosure, but denied physical contact with the affected animals, were free of infectious SRV-1 and antiviral antibody. In NC-1, the speciÞc mortality rate from simian AIDS was higher in juveniles than in adults and the overall prevalence of SRV-1 antibody in all ages ranged from 68Ð85%. Passive maternal immunity to SRV-1 may have protected some of the infants. Antibody prevalence increased with age to such a degree that, essentially, all animals over three years of age were seropositive. Seroconversion was found to be a poor indicator of current infection; about 50% of virus-positive juveniles had no antibody detectable by enzyme-linked immunosorbent assay (ELISA). In disease-free breeding colonies of rhesus monkeys, the prevalence of SRV-1 antibody was only 4% by ELISA.

Repeated viral isolations from all animals in NC-1 revealed the following patterns of infection: (a) SRV-1 viremia with clinical SAIDS; (b) transient viremia with clinical recovery; (c) intermittent viremia suggesting reactivation of latent infection; (d) viremia in a one-day-old infant, suggesting transplacental transmission; and (c) persistent viremia and virus shedding in several healthy animals. In a retrospective epidemiologic analysis, one healthy carrier in NC-1 was linked by direct physical contact to 34 cases of SAIDS over a three-year period (174). Simian AIDS was experimentally transmitted to two juvenile rhesus by inoculation of SRV-1, containing saliva from this adult female monkey (175). Although SRV-1 could be isolated from PBMC and most body secretions of infected animals, the most plentiful source of virus was saliva, which was the major natural source of virus transmission. Transmission of SRV in semen was not evaluated. Although SRV-1 is present in vaginal secretions, female-to-male sexual transmission of this virus also remains undetermined. Perinatal transmission of SRV-1 transplacentally or via milk appeared to occur infrequently.

Experimental transmission of SRV-1 from tissue culture media conÞrmed the virulence of this virus that had been indicated by the natural cage exposure observations and by experimental inoculations of infected blood, saliva and tissue homogenates (176). Intravenous inoculation of SRV-1 into 14 juvenile (9Ð11 months) rhesus led to the same spectrum of clinical disease as seen naturally in NC-1. All animals became infected; six died acutely 7Ð20 weeks after inoculation, six remained persistently infected up to one year after inoculation, and two developed neutralizing antibody, became non-viremic and remained healthy after one year. Monkeys dying acutely had a high level of persistent viremia and no serum antibody response by ELISA, whereas monkeys with a more indolent clinical course had a low grade viremia and only transient initial antibody response to the major core antigen (p27) (177). Monkeys that never became ill and were either non-viremic or transiently viremic and developed high levels of serum antibody, including neutralizing antibody to the virus envelope. Therefore, in the SRV simian AIDS model system, one can correlate disease resistance with humoral antibody levels and neutralizing activity. These observations further establish the etiologic role of SRV-1 in this fatal immunosuppressive disease. Conclusive proof of this etiology came later with induction of an identical, fatal disease spectrum, using molecularly-cloned infectious SRV-1 (178) and the prevention of this disease with SRV vaccines (see below).

Since 1983 D-type viruses (i.e. SRV) were identiÞed as the causative agents of a naturally-occurring infectious immunodeÞciency disease in eight species of macaques at Þve of the seven primate centers in the United States (170). The centers primarily affected with this disease were New England, California, Oregon, Washington, and Wisconsin. The Yerkes and Delta primate centers in the southeastern United States currently were largely spared of this problem. Infection appears to be highly prevalent in Asian macaques in captivity (179), the natural hosts of the SRV subfamily. SRV infection has been found in healthy feral macaques in India, but the prevalence of infection with the different serotypes in these feral animals remains to be determined. Nor has any disease linked to SRV infection in feral macaques yet been reported. SRVs are related to the endogenous D-Type retrovirus (PO-1-Lu) of the spectacled langur (*Presbytis obscuris*), another Asian monkey from which the exogenous SRVs may have had their evolutionary origin (180). Alternatively, the SRVs may have been derived evolutionarily from an endogenous Type D provirus (called SERV for simian endogenous retrovirus) recently detected by PCR ampliÞcation of genomic DNA in all Old World Monkeys of the subfamily Cercopithecinae, but not present in apes or humans (23). This intact endogenous Type D provirus is the putative ancestor of both non-pathogenic BaEV and the pathogenic SRVs. According to this hypothesis, the SRVs could be the products of recombination between the SERV gag-pol genes and a GP70 Env protein gene of unknown origin. Endogenous Type D retroviruses are also present in the New World squirrel monkey (181), mice (182,183) and the common brushtail possum (TuERV), an Australian marsupial (184). D-type viruses have not been isolated from any African monkey species trapped and caught in Africa. However, SRV antibodies have been detected in African talapoin monkeys (185) and in Indonesian orang-utans (186). D-type virus (i.e. SRV-2) has also been recovered from baboons at the Washington Primate Center, presumably by cross-species infection from SRV-2 infected macaques. All of the contemporary D-type virus isolates associated with simian AIDS are related to MPMV, but are distinct envelope variants falling into Þve major serotypes. SRV-1 is the serotype in macaques at the California and New England Primate Centers, and the SRV-2 serotype is present in macaques at the Oregon and Washington Primate Centers (187). The original MPMV is the third distinct serotype (SRV-3), now thought to be present in macaques at the Wisconsin Primate Center. Experimental transmission of MPMV in the early 1970s led to death in

many infant rhesus monkeys from a wasting syndrome with thymic atrophy and profound neutropenia, anemia, lymphoid depletion and opportunistic infections (188). Features of this immunosuppressive syndrome were the same as those observed occurring spontaneously in captive macaques in the early 1980s. In 1986 at the California Primate Center, re-isolation and experimental transmission of MPMV from its initial source, a frozen sample of the spontaneous rhesus mammary carcinoma, conÞrmed the earlier observation that this virus, like SRV-1 and SRV-2, was immunosuppressive and apparently non-oncogenic (189). Fatal SAIDS has been induced with an infectious molecular clone of SRV-1 (178). A molecular clone of SRV-2, recently obtained from rhesus monkeys at the Oregon Primate Center seems to be less pathogenic because it induces only mild immunosuppression *in vivo* and has a reduced ability to infect speciÞc T cell lines (190).

Clinical Features

The clinical features of SAIDS induced by SRV include generalized lymphadenopathy, splenomegaly, fever, weight loss, diarrhea, anemia, lymphopenia, granulocytopenia and thrombocytopenia (191). Necrotizing gingivitis (noma) is occasionally observed. Despite the striking depletion of peripheral blood cellular elements, the bone marrow is frequently hypercellular. Evidence of immune activation, so prominent in HIV/SIV infection is lacking in SRV-induced SAIDS. Electrophoresis of sera of ill animals reveals hypoproteinemia, hypoalbuminemia, and hypogammaglobulinemia, the latter consistent with the histologic absence of plasma cells in lymph nodes and the early impairment of B cell function. In contrast to SIV infection of macaques, lymphomas are not a feature of SRV induced SAIDS.

Concentrations of immunoglobulin G (IgG), immunoglobulin A (IgA), and immunoglobulin M (IgM) are decreased, but the complement component C3 is not changed and C4 is increased (192). The absolute lymphocyte count decreases, but the OKT4/OKT8 ratio remains unchanged when compared to controls, reßecting an absolute decrease in both helper and suppressor T cells. Thus, in comparison to human AIDS and SIV-induced SAIDS, an inverted T-cell helper-to-suppressor ratio is not found in disease induced by the D-type virus. A decreased response to mitogens concanavalin A (Con A), phytohemaglutinin (PHA) and to allogeneic lymphoid cells, occurs early and becomes more severe near death. Response to pokeweed mitogen (PWM) is variable. Interleukin-2 causes a complete or partial restoration of the response to the mitogens Con A and PHA. A major difference between SRV, SIV, and HIV, is the broader immunosuppressive effect of the D-type virus on both T and B cells, with a consequent depression of both T and B-cell function (193). This difference is correlated with the broader tropism of the D-type virus for both T and B cells *in vitro* compared to the more restricted T4 tropism of HIV and SIV.

Numerous bacterial, protozoan and viral agents have been identiÞed in SRV immunosuppressed macaques, including cytomegalovirus (CMV) and leukocyte-associated herpes virus. Disseminated CMV has been the most frequent opportunistic infection (194). Retroperitoneal Þbrosis (RF), associated mainly with SRV-2 infection, apparently represents the simian counterpart of the herpes virus associated KaposiÕs sarcoma in immunosuppressed humans (see below). Elevated levels of neopterin in serum and CSF of monkeys with SAIDS probably reßected local inßammatory responses (195). Neuropathologic signs or symptoms do not occur in SRV infection. The major similarities and differences between SRV and SIV are listed in Table 10.2.

Pathology

At necropsy, affected animals show severe depletion of lymphocytes in both germinal centers and paracortical regions of lymph nodes, as well as an absence of plasma cells. The histopathology of the lymph nodes is virtually indistinguishable from that of lymph nodes in the terminal stage of human AIDS (196). The distribution of SRV-1 in tissues of infected macaques was studied by virus isolation, electron microscopy (EM), immunohistochemistry, and molecular hybridization (197). Virus could be isolated from PBMC, plasma, serum, urine, saliva, lymph nodes, tears, breast milk, cerebrospinal ßuid, and vaginal secretions of sick monkeys, as well as of some healthy carriers. Separation of peripheral blood T and B cells by panning and ßuorescent cell-sorting indicated that animals with SAIDS harbored infectious D-type virus in both T and B cells but more in T4 cells than in T8 cells (193). Virus was also detected in macrophages but not in mature neutrophils or platelets. Macrophage and neutrophil function was not impaired early in the course of disease (198). Serial titrations suggested that only 0.1% to 1% of lymphocytes were infected in peripheral blood. Testing of the susceptibility of normal macaque lymphocytes to infection with SRV *in vitro* was possible, but difÞcult, because of the inability to establish long-term cultures of macaque lymphocytes. SRV-1 will grow in established human T-cell lines such as human T-cell line 78 (HUT 78) as well as in certain Epstein-Barr virus (EBV) transformed human B cells such as Raji cells. The ability of simian D-type viruses to induce syncytia in Raji cells is the basis for an infectious virus assay (199), and serum inhibition of such syncytia is the basis for a neutralizing antibody assay (187). Apart from syncytia, the virus has no direct cytolytic effect and it is non-transforming. OKT4 antibodies do not block infection of Raji cells.

By immunohistochemistry with a monoclonal antibody to the SRV-1 transmembrane glycoprotein (gp20), viral

TABLE 10.2. *Comparison of simian retrovirus (SRV) and simian immunodeÞciency virus (SIV)*

Similarities
Exogenous lymphotropic retroviruses that induce fatal immunode ciency in macaques after a long incubation period
Pathogenic molecular clones have been derived
Persistent infection despite host immune response
Length of survival correlates directly with vigor of antiviral antibody response
Relatively high levels of virus expression *in vivo*; predominantly cell associated and systemic distribution
Neurotopic
Syncytia induction *in vitro*
Transmission by close physical contact with blood or body secretions
Differences
SIV does not cause disease in its natural host, i.e. African monkeys: SRV does cause disease in its natural host, i.e. Asian macaques
SIV is genetically more closely related to HIV than to SRV
SIV is more virulent for macaques than is SRV
SRV neutralizing antibody can allow for recovery from infection. SIV neutralizing antibody does not allow for recovery from infection. Vaccine induction of neutralizing antibodies will strongly protect against SRV; not true of SIV vaccines
SIV uses CD4 receptor and chemokine coreceptors; SRV has a different receptor, a neutral amino acid transporter, and wider cell tropism including epithelial cells.
SIV envelope mutates more rapidly than SRV, thus allowing for escape mutants.
SIV causes neuropathology; SRV does not.
SIV is more T-cell cytopathic than SRV.

protein was identiÞed in epithelial cells of the mouth, upper gastrointestinal (GI) tract, sweat glands, mammary glands, and choroid plexus, as well as in lymphoid cells in lymph node, spleen, and thymus, but not in the brain parenchyma (197). Viral antigen was commonly detected in germinal centers of lymph node and spleen, and viral particles were seen by EM at the same location, apparently in association with antigen-processing dendritic reticulum cells. The amount of viral antigen increased as the disease progressed, and it appeared predominantly in the peri-follicular capillary endothelial cells of the spleen. The only other *in vivo* site where abundant virus particles were detected by EM, was the salivary glands. Southern blot analysis revealed SRV-1 DNA in lymph nodes, salivary gland and brain and SRV-2 DNA in lymph nodes, spleen, PBMC and retroperitoneal Þbromatosis tissues, but not in the skeletal muscle or liver of affected macaques (200). By *in situ* hybridization, SRV-1 RNA was detected in salivary gland and brain parenchyma of rhesus monkeys with no overt neurological symptoms. A Þnding of SRV-1 nucleic acid in the absence of detectable core antigen or neuropathology in the brain of monkeys suggested viral latency in the central nervous system (CNS). A partial transcriptional block to SRV expression in the brain parenchyma was suggested by the Þnding that very few cells were positive by *in situ* hybridization for viral RNA, seemingly too few to account for the signal seen by Southern blot for viral DNA. The cell types infected have not been identiÞed, and macrophages or giant cells characteristic of HIV-infected human brains or SIV-infected macaque brains, have not been seen. No evidence of activation of D-type virus from this latent state in the CNS has been observed during 20 years of observation. Despite the evidence for latency in the CNS, cell-free SRV-1 could be isolated from cerebrospinal ßuid of over 50% of neurologically normal monkeys with SRV-1-induced SAIDS. A few scattered epithelial cells in the choroid plexus appear to be the source of this cell-free virus in the cerebrospinal ßuid (197).

Two further D-type serotypes, SRV-4 and SRV-5, consist respectively, of single isolates from a cynomolgus macaque at the University of California at Berkeley and a rhesus macaque imported to the Oregon Primate Center from Beijing, China. The SRV-4 isolate has not yet been further characterized for biologic activity, whereas the SRV-5 isolate has been partially sequenced and has produced generalized lymphoid hyperplasia when transmitted into a juvenile rhesus macaque (201). Serial epidemiologic and virologic surveys have shown that D-type viruses (SRV-1Ð8-serotypes) are the primary cause of almost all cases of spontaneous SAIDS in each of the Þve centers where endemic infection with these viruses exist (170). However, variations in severity of this disease and its manifestations with the different SRV serotypes and the different species of macaques at each center are observed under conditions of both natural and experimental exposure. Findings from the Washington Primate Center Medical Lake facility have conÞrmed the rapid natural transmission of SRV-2 among group-housed cynomolgous macaques and the same pattern of infection and immune response as observed with SRV-1 in rhesus macaques (202). In London, a small collection of mostly asymptomatic cynomolgous macaques (*Macaca fascicularis*), naturally infected with SRV-2 was followed virologically over an eight-month period (203). Virus loads in blood varied greatly but remained steady and no signiÞcant sequence variation was found within individuals over time. However, no clear disease pattern emerged in the period of observation.

The SRV-2 serotype is particularly associated, not only with immunosuppression, but also with a proliferative disorder called retroperitoneal Þbromatosis (RF), which has some features in common with KaposiÕs sarcoma (KS) (204,205). These features include an origin of RF cells from vascular smooth muscle (206) and the production by RF cells of basic Þbroblast growth factor (207), which serves as an autocrine growth factor. However, in contrast to HIV-1 associated KS, SRV-2 is detectable as a productive infection in RF lesions (200). Recent evidence indicates that a simian herpes-virus, related to Kaposi sarcoma-associated herpes-virus (KSHV), is associated with RF (208,209). Elevated levels of IL-6 are found in the herpes viremic animals. Clearly, a common pathogenesis appears to exist between the induction of RF by an activated herpes virus in macaques immunosuppressed by SRV infection and the induction of KS by an activated homologous herpes-virus in humans immunosuppressed by HIV infection (210).

A novel simian type D retrovirus was recently isolated from a feral Indian Hanuman langur (*Semnopithecus entellus*) (211). Based on sequence analysis from the 3′ orf and env regions of the viral genome, this SRV is phylogenetically related to, but distinct from, the Þve known SRV serotypes. This novel SRV is provisionally named SRV-6. The relatedness of SRV-6 to the endogenous Type D virus of the spectacled langur (PO-1 Lu) (180,212), obtained from a different langur species, could not be determined because the latter virus has not been sequenced. Because of the greater genetic distance (62% homology) of SRV-6 from the SERV sequences in the baboon (23) than from exogenous SRV-2 in macaques (72% homology), SRV-6 is considered an exogenous retrovirus in langurs. There is no evidence that macaques (or humans) are infected with SRV-6.

In the last two decades, extensive serologic surveys of humans, including primate center animal handlers, have shown no proof of D-type virus infection, despite numerous claims based on serologies and isolation results, which were not supported by further analysis. Many putative human D-type virus isolates were found to be contaminants of MPMV or SRV-1 growing in HeLa cells. The detection, by PCR ampliÞcation and Southern hybridization, of MPMV-like gag and env sequences in healthy Africans from Guinea (213) may or may not prove to be a contaminant. A survey of several hundred lymphoma patients, HIV-1 infected and uninfected, persons with unexplained low CD4 counts and persons with HTLV seroindeterminate test results failed to Þnd any serologic or PCR evidence of SRV infection (214,215). However, RNA sequences related to the protease and reverse transcriptase of Type B and Type D retroviruses were detected by reverse PCR in salivary gland or lymphoid cells of eight individuals with SjogrenÕs syndrome (216). Although these sequences were present in sucrose density gradient fraction corresponding to that of enveloped retrovirus particles, no complete virus could be isolated. Because these sequences were not detectable in human genomic DNA the viral sequences were considered exogenous. Assuming that these viral sequences might represent a natural human infection, the virus was provisionally designated HRV-5. Subsequently, however, this virus was determined not of human origin but, instead, an endogenous retrovirus of rabbits (217). A recent survey of 231 people occupationally exposed to non-human primates found two individuals (0.9%) strongly seropositive, showing reactivity by Western immunoblot against multiple SRV antigens representing *gag*, *pol*, and *env* gene products (37). Repeated attempts to isolate SRV in tissue cultures and to detect SRV genes by PCR were negative. Both individuals remain healthy and one has seroreverted to SRV negative. Inoculation of whole blood from the one persistently SRV-seropositive person into an SRV-negative macaque failed to transient the seropositivity. These results suggest that people occupationally exposed to SRV-infected macaques, may become immunized, perhaps by transient infection.

Cell Receptor

The receptor for the Type D viruses has recently been cloned and sequenced (218). This same receptor is utilized by the endogenous Type D viruses from the squirrel monkey and langur, by the endogenous Type C viruses of the cat (RD114) and baboon (BaEV) and by the exogenous avian C-type reticuloendotheliosis viruses (219,220). This receptor was localized to chromosome 19 in human cells (42). It was initially demonstrated that a cell receptor of indentical molecular weight was bound by the envelope proteins of all 5 SRV serotypes (221). Different amino acid regions for the envelope protein of SRV-1 as compared to SRV-2 interacted with the same cell receptor and infectivity of these viral serotypes could be speciÞcally blocked by antisera to these respective peptides. Recent cloning and sequencing of the receptor, based upon transfer and expression of cDNAs from susceptible to resistant cells, revealed that it was an allele of a previously cloned neutral amino acid transporter ATB (218). Interestingly, infection of cells with Type D retroviruses resulted in impaired neutral amino acid transport. This result could suppress the metabolism and proliferative capacity of the chronically infected B and T lymphocytes, such as occurs in the SRV induced immunodeÞciency.

Pathogenesis

The immune system suppression caused by SRV is not well understood at the molecular level. The general ablative effect on many lymphoid and other hematopoietic cell types resembles the natural history of infection with certain strains of feline leukemia virus (FeLV) (222). Insofar as neither SRV nor FELV are directly cytolytic, the

generalized cellular depletions that they cause must have indirect mechanisms, mediated by cytokines, e.g. tumor necrosis factors (TNF), released from infected or activated lymphocytes. Also, an effect of the so-called Òimmunosuppressive peptideÓ (81) present in the amino end of the transmembrous protein, or an autoimmune component such as antilymphocytic antibodies, could play a pathogenic role. Alternatively, the immunodepletion may be the result of lymphoid proliferative dysfunction resulting from blocking of the SRV cell receptor by the viral envelope (218). A pathogenic effect related to viral load is supported by the Þnding that SRV infection is fatal primarily in those monkeys that cannot mount an adequate immune response and in which the viral load is therefore high. A major difference between SRV and SIV and other lentiviruses is that SRV is much more genetically stable, and therefore escape mutants that can avoid immune surveillance seldom if ever arise. Consequently, in contrast to SIV infection, many SRV-infected monkeys can generate a sufÞciently strong immune response either to contain the virus in a latent state or to completely eliminate it.

SRV Genetic Structure and Function

SRV-1, SRV-2, and SRV-3 (MPMV) have been molecularly cloned and sequenced (223Ð225). All three viruses have a similar genetic organization with four separate translation frames encoding the group speciÞc antigen (*gag*), protease (*prt*), RNA-dependent DNA polymerase (*pol*), and envelope glycoprotein (*env*). Partial sequence analysis of PCR generated clones of SRV-4 and SRV-5 indicate that they are gentically distinct from SRV 1,2,3 and from each other. The putative SRV-6 from Indian langur is only distantly related to SRV-2. SRV-1 Gag-Pol ribosomal frameshifting take place efÞciently via a proposed secondary RNA pseudoknot structure, similar to that of the mouse mammary tumor virus (MMTV) and feline immunodeÞciency virus (FIV) (226Ð227). The three dimensional structure of the SRV-1 pseudoknot has been determined by NMR (228). The *prt* genes of HTLV-2, BLV, MMTV, and hamster intracisternal A particles (IAP) are also in separate translational frames from the *gag* and *pol* genes. A comparison of amino acid mismatches based on nucleotide sequences shows that SRV-1 is more closely related to MPMV than is SRV-2. Whereas the *gag*, *prt*, *pol* and c-terminal *env* domains of the three viruses differ only by 5% to 15%, the externally located N-terminal domains differ by 17% in comparison between SRV-1 and MPMV and by 42% between SRV-1 and SRV-2. The long terminal repeats (LTR) of SRV-1 and MPMV are 88% homologous; SRV-2 shows 70% LTR homology with either virus. In keeping with their distinct neutralization serotypes, SRV-1 and SRV-2 show more envelope amino acid variation (□40%) than seen so far between different HIV-1 isolates (□25%). Computer sequence analyses indicate that a segment of the *prt* gene has been transposed between SRV-1 and visna virus (229), and that SRV-1 and SRV-3 contain a gene segment in the polymerase gene that is lacking in the primate lentiviruses (230). This gene represents a protease-like element related to the aspartate proteinase and possessing dUTPase activity (231), a function that may enhance SRV replication in macrophages. Each D-type virus has a *gag* precursor polypeptide cleaved by the *prt* enzyme into six proteins identiÞed as p10, pp18, p12, p14, p27 and p4 (232,233). The Type D viral gag polyprotein interacts with the cytosolic chaperonin TriC which probably assists in gag folding and/or capsid assembly (234). Each D-type virus utilizes tRNA lysine as a primer for minus-strand DNA synthesis. Visna virus, MMTV, HIV-1 and SIV also utilize tRNA lysine as primer. Although similar in ultrastructural features, the D-Type particles are morphologically distinct from HIV and SIV particles (235). However, the simian D-type viruses have a markedly different genetic organization from HIV and SIV and lack extensive homology with these agents. Transactivation of LTR sequence-mediated gene expression is not a property of D-type virus replication (236). The D-type viruses contain a 219-nucleotide sequence called the constitutive transport element (CTE), located in an untranslated region near the 3′-end of the genome. The CTE is capable of substituting for the Rev and Rev-response element (RRE) of HIV and SIV in promoting transport from nucleus to cytoplasm of intron-containing viral RNA (237Ð240). The CTE thus can efÞciently substitute for Rev in expression of Gag/Pol and Env proteins from subgenomic constructs. It is suspected that CTE functions by interacting with evolutionary conserved cellular factors essential for cellular export (241), analogous to that of the Rev protein. Further molecular studies of the CTE reveal a possible interaction between the CTE and the polyadenylation signal at the 3′ untranslated region of the viral genome (242). Secondary structural determinants in this region and multiple protein interactions are involved in function of the CTR in nuclear export of unspliced SRV RNA. The properties of the SRV CTE have provided a valuable component for lentiviral vectors used in gene therapy (243,244) and for SIV DNA vaccine constructs (245).

Control of SRV

D-type virus infection can be eliminated in group-housed monkeys by serial testing for antiviral antibodies and virus isolation, and subsequent removal of positives (246). Recently, detection of SRV proviral DNA in macaque PBMCs has enhanced the efÞciency of SRV diagnostics (247). Inactivated whole SRV-1 vaccine and recombinant vaccines consisting of SRV-1, SRV-2 or SRV-3 envelope glycoproteins (gp70) expressed in live vaccinia virus, have been able to protect macaques against persistent infection and disease, following experimental challenge (248Ð250). Protection correlated with the induction of neutralizing antibodies and was long-lasting (251).

SRV-1 and SRV-3 separately immunized monkeys showed cross-protection against each of these virus strains, in keeping with their close genetic relationship. The SRV-1 and SRV-3 cross- reactive sera failed to neutralize SRV-2 *in vitro* because the latter is genetically more distinct. SRV-2 vaccinated monkeys have yet to be challenged with SRV-1 or SRV-3. A polyvalent vaccine consisting of SRV-1 (or SRV-3) and SRV-2 env antigens would probably be required to protect against these three most common SRV serotypes present in captive macaques. SRV vaccines have yet to be tested under cage exposure conditions in which the horizontal transmission of SRV continues to cause signiÞcant morbidity and mortality among these important research animals. Nucleoside analogues, especially 3TC, have a potent antiviral effect against SRV-1 and SRV-2 *in vitro*, but these drugs have not been tested *in vivo* (252).

In summary, simian D-type viruses and associated immunosuppressive disease are highly prevalent and account for over 99% of the related morbidity and mortality from naturally occurring simian AIDS in macaque colonies at various primate centers and breeding facilities. SRV infection differs from SIV and HIV infection in that SRV is genetically much more stable; resistance to infection and recovery from SRV is correlated with the presence of neutralizing antibodies, and SRV is not as restricted to or cytopathic for T4 cells. Despite these differences between D-type virus and SIV or HIV, the highly reproducible and rapid experimental transmission of SRV disease, along with the short turn around time (7–10 days for *in vitro* assays), makes this an attractive primate model for studying the mechanism of immune suppression from an acquired retrovirus. The availability of molecularly cloned and sequenced viruses representing each of the three major D-type virus serotypes, the ability to produce fatal simian AIDS with molecularly cloned SRV-1 and SRV-2, and cloning of the SRV receptor, are further attractive attributes of this model, because they make possible identiÞcation of the critical virus genes involved in pathogenesis. The herpesvirus associated retroperitoneal Þbromatosis (RF) in SRV-2 infected macaques represents an intriguing counterpart of KSHV associated Kaposi's sarcoma in HIV-1 infected humans. From a practical standpoint, SRV can be readily controlled by testing, and removal of infected animals or by vaccination. Adequate screening for SRV as well as STLV, SIV and SFV is critical to exclude infected monkeys and prevent potential confounding of research results (253).

LENTIVIRUSES

Simian ImmunodeÞciency Viruses (SIV)

Epidemiology and Natural History

The phylogenetic relationship of primate and other animal lentiviruses is shown in Fig. 10.2 (235). The SIV constitute a family of naturally occurring lentiviruses indigenous to certain simian species in Africa (2). In their natural African simian hosts, these viruses apparently cause no disease. In their natural hosts, SIV is probably horizontally transmitted by Þghting/biting and sexual contact, and less often vertically transmitted at birth via maternal blood and milk. By contrast, SIV infection of macaque species of Asian and Indonesian origin, does not occur naturally, but accidental or inadvertent infection in captivity with certain strains of SIV (mostly of sooty mangabey origin) causes persistent infection with eventual death (2 months–3 + years) from an AIDS-like disease showing many parallels to human AIDS (255). Both HIV and SIV achieve viral fusion and cell entry by an interaction of their external envelope glycoproteins with the CD4 cell surface protein and one of the chemokine receptors.

Altogether, at least 30 different species of African non-human primates harbor SIV asymptomatically; these include four species of African green monkeys (*Cercopithecus aethiops*) (256–258), sooty mangabey (*Cercocebus atys*) (259–263), redcapped or cherry-capped mangabey (*Cercocebus torquatus*) (264,265), Sykes' monkey (*Cercopithecus mitis*) (266), mandrill (*Papio sphinx*) (267,268), drill monkey (*Mandrillus leucophaeus*) (269), L'Hoest's monkeys (*Cercopiithecus lhoesti*) (270–272), talapoin monkey (*Myopithecus talapoin*) (273), colobus monkeys (*Colobus guereza*) (274), and chimpanzee (*Pan troglodytes*) (275–282). Complete sequence analysis of 13 of these isolates reveals a very large and heterogeneous family consisting of at least six approximately equidistant lineages of lentiviruses with considerable heterogeneity within species and extensive divergence between species. A recent serologic survey of 788 monkeys in the rainforests of Cameroon found SIV reactivity in 13 of 16 primate species – 16.6% of the animals tested, and molecular analysis identiÞed Þve new phylogenetic SIV lineages (283). Asymptomatic SIV infection of sooty mangabeys and, to a lesser extent, other African non-human primates are also quite prevalent in primate centers and zoos (100). Recombination and cross-species transmission in the wild have undoubtedly contributed to the genetic complexity of primate lentiviruses (268,284). For example, evidence indicates cross-species spread in nature of SIV from African green monkeys to baboons (285). The sooty mangabey SIV group, perhaps, is the most diverse in a single monkey species (286,287). The chimpanzee SIVs (SIV_{cpz}) are most closely related to HIV-1 (288), and almost certainly provided the origin of HIV-1 via the bushmeat trade in Central Africa (281). The prevalence of SIV in chimpanzee (approximately 1%) appears far lower than in other primates (10–90%) (282). In West Africa, none of 387 wild chimpanzees (Pan troglodytes) were infected with SIV_{cpz} (289). No pygmy chimps, i.e. bonobos (*Pan paniscus*) were found infected with SIV (290). None of 143 orangutans in Indonesia were infected with SIV (291). The envelope variation among SIV isolates within a

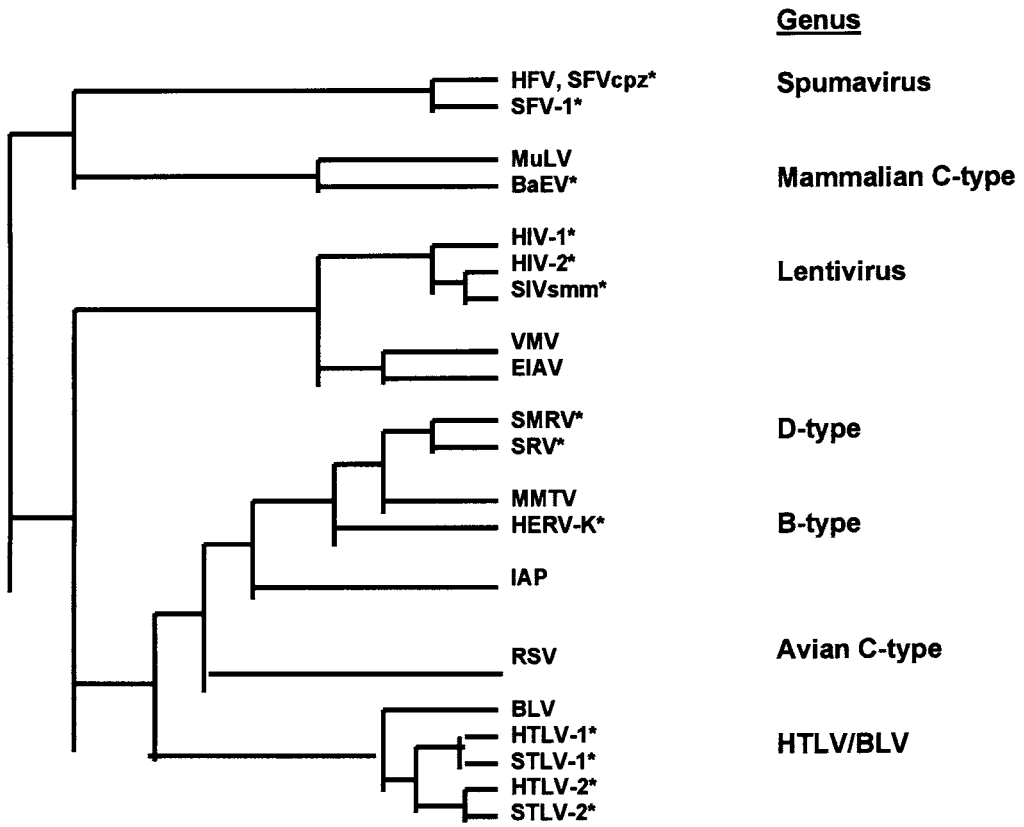

FIG. 10.2. Phylogenetic classi cation of representative retroviruses. The family Retroviridae contains seven genera (1). Asterisks identify primate retroviruses. Abbreviations for viruses are given in Table 10.1 and the Glossary. Figure adapted from Cof n 1992 (1).

single species appears at least as great as among HIV-1 isolates (25%), and the variation between species may possibly be as much as between HIV-1 and HIV-2 (50%). SIV isolates from African non-human primates other than the sooty mangabey generally have not been pathogenic for macaques, although they have not been extensively tested nor serial passaged in macaques. One SIV strain from an African green monkey has induced AIDS after serial passage in pigtailed macaques (292,293). The SIV isolates from African green monkeys (SIV_{agm}), Sykes monkeys (SIV_{syke}) and mandrills (SIV_{mdr}) are less closely related to SIV_{mac}, SIV_{sm} or HIV-2 and are about equidistant from HIV-1 and HIV-2 (256,257,261,268). This suggests that SIV may have existed in these African monkey species for a very long time.

Of all the SIV strains from African simian hosts, the sooty mangabey SIV isolates are the most closely related to SIV isolates from captive macaques in primate centers and to HIV-2 isolates from humans in West Africa (294D296). Geographic clustering in West Africa of SIV strains from feral sooty mangabeys with closely related HIV-2 strain, supports the likelihood that HIV-2 subtypes have arisen by recent (40D300 years) independent cross-species transmission events from monkey to human with divergent SIV_{sm} strains (286). That such cross-species infection can occur indeed has recently been documented by accidental infection of several laboratory workers with SIV_{sm} (35,36). Recent seroepidemiological evidence also suggests the possible cross species transmission of SIV from mandrill to a human in Cameroon (268). The close similarity between SIV_{sm} and SIV from macaques (SIV_{mac}), together with the knowledge that SIV is not indigenous in Asian macaques, suggested that SIV in macaques was acquired accidentally by cross-species spread from sooty mangabeys or closely related species in U.S. primate centers. Retrospective studies have conÞrmed this hypothesis (32,297). Two prototype strains of SIV isolated from rhesus macaques (SIV_{mac}) (255,298) and stumptailed macaques (SIV_{stp}) (299,300), originated in the early 1970s by cross species infection with SIV_{sm} from cohoused sooty mangabeys at the California Regional Primate Research Center. Because SIV infection and AIDS-like disease were then unrecognized, surviving carrier macaques were inadvertently sent to the New England and Yerkes Primate Centers, where they Ò seededÓ the viruses that were isolated a decade later after recognition of human AIDS (297,301). The closely related SIV_{mne} strain isolated from a single pigtailed macaque at the Washington Primate Center (302) in 1986 probably also came from contact with a SIV-infected sooty mangabey, although this transmission event is not documented. The isolation, also in 1986, of the closely related

SIV_{smB670} strain at the Tulane Primate Center occurred accidentally, following experimental inoculation of rhesus macaques with tissue extracts from natural SIV-infected sooty mangabeys with leprosy at the Yerkes Primate Center (260). Non-invasive detection of new SIV lineages in sooty mangabeys (303) and chimpanzees (304)Ñ by viral ampliÞcation from fecesÑ promises to further expand our knowledge of the epidemiology and phylogeny of the SIVs.

Based on viral sequence analysis to calibrate phylogenetic trees, the evolutionary origin of HIV-1 is almost certainly SIV from the chimpanzee (34,281), an event that probably occurred several times this century by contact with chimpanzee blood and body ßuids during the processing or eating of chimpanzee meat. The diversity of HIV-1 M subtypes and possible recombinant viruses and unclassiÞed strains circulating in the Democratic Republic of Congo suggests that the HIV-1 pandemic originated in Central Africa (305). The origin of the major HIV-1 group M viruses was calculated to be about 1930 (306). Inadvertent contamination of polio vaccines with SIV_{cpz} in the 1950s has been conclusively ruled out as a possible source of HIV-1, although the use of a common needle for mass vaccination at that time might have helped adapt the virus to humans (307Ð309).

Comparison of Natural and Experimental SIV Infection

A comparison of viral and host factors in the naturally SIV infected but asymptomatic African simian species with the macaque species that develop AIDS after experimental infection with the same SIV strain should provide insights into the pathogenesis of the disease. Most thoroughly studied of the naturally infected African non-human primates are sooty mangabeys (sm) (310Ð312), African green monkeys (313Ð319), and chimpanzees (275Ð282). Experimental pathogenicity for macaque species (which do not naturally harbor SIV) is most thoroughly demonstrated with SIV_{sm} (i.e. SIV_{mac}), and to a much lesser extent with SIV_{agm}. Based on viral sequence diversity in the different species and subspecies of naturally infected African non-human primates, it is apparent that these animals have been infected for eons, and thus are well-adapted to the virus. Contemporary African non-human primate populations presumably represent the survival of the Þttest selected in the distant past for resistance to AIDS, a hypothesis perhaps supported by the apparent reduction of HLA variation in chimpanzees (320). In short, the lack of disease in the natural host cannot be attributed to lack of replicating virus, even at high levels, to distinct target cells or viral reservoirs, to lack of viral variation or to induction of a strong protective antiviral immune response. Indeed, the humoral and cellular immune responses are much less active in the natural infection than in the experimentally infected macaques (317). HIV-1 or SIV_{cpz} infected chimpanzees do not have increased beta chemokine positive cells in contrast to HIV-1 infected human or SIV_{mac} infected macaques (321). Abnormal immune activation is thus strongly correlated with immune deÞciency in the pathogenesis of AIDS. The wide range of viral RNA levels in plasma and lymph node (2×103 to $> 6X\ 10^6$ copies/ml) of naturally infected AGMs (318,319) or SMs (322,323) often exceeds the minimum pathogenesis threshold value ($> 10^5$ RNA copies/ml) of SIV_{mac} infected macaques and HIV-1 infected humans during progression to AIDS (324). In the natural host, the gut is a major site for SIV replication *in vivo* and appreciable levels of virus are also found in brain parenchyma and CSF. However, T-cell turnover is normal in SIV infected sooty mangabeys compared with rapid turnover in SIV_{sm} infected macaques (325). High levels of virus replication during experimental primary infection of naive AGM with SIV_{agm} are non-pathogenic, even in newborns (326,327), and are rapidly controlled by host immune responses, although not neutralizing antibody (328). In AGMs, preinfected with a nef deÞcient SIV_{agm}, the plasma virus load was dramatically decreased after wild type SIV_{agm} challenge compared to naive controls, in the absence of neutralizing antibody (329). Uninfected AGMs vaccinated with inactivated whole SIV_{agm} vaccine or passively immunized with SIV_{Ig} were not protected against SIV_{agm} challenge infection, even in the presence of neutralizing antibody (330). Clearly, neutralizing antibodies do not control SIV infection in the natural host and cannot be responsible for the lack of disease. In contrast to HIV-1 infected humans or SIV-infected macaques, MHC-restricted CTL killing of SIV-infected cells is barely detectable and thus does not appear responsible for lack of disease in the natural host. Innate immunity, e.g. NK cells or viral-suppressor factors released by CD8+ lymphocytes may help hold the virus in check in the natural host (317,322). Apparently SIV is not cytopathic in its natural host and this resistance of CD4+ T-cells and dendritic reticuluin cells to virus induced lysis or apoptosis must be a major reason for the normal T-cell turnover and lack of pathogenicity in the natural host (310,331). The major difference between natural and pathogenic SIV infection may well lie in the indirect cell killing that results from abnormal T-cell activation.

Experimental Transmission of SIV and Pathogenesis of Simian AIDS

In so far as HIV-1 infection does not induce AIDS in chimpanzees or any other animal species, at least in a reasonably short time (10 years), the reliable and highly reproducible infection of macaques with SIV_{mac}, or closely related strains, and induction of SAIDS in a relatively short time (6 monthsÐ2 years), makes this the model of choice for studies of pathogenesis, antiviral drug testing, immunotherapy, and vaccination. Standardized stocks of

SIV, with dose titrations *in vitro* and *in vivo* and standardized virologic and immunologic assay systems and reagents, are in place at a number of primate centers. For rapid antiviral drug screening, one acutely lethal variant of SIV_{macPBJ} is also useful (332,333). The reproducible induction of simian AIDS with several SIV molecular clones or plasmid DNA (e.g. SIV_{mac239}) (334) conÞrms that this virus is both necessary and sufÞcient for inducing this fatal AIDS-like disease and provides a valuable tool for studying pathogenesis.

All species of macaques appear vulnerable to experimental infection and induction of SAIDS with SIV_{mac}, SIV_{stm}, SIV_{mne}, or macaque-adapted SIV_{sm} (2,4,5,335). However, species speciÞc variation in SIV disease, progression has been noted between Chinese and Indian subspecies of rhesus macaques (336). The age of the animal is not a critical factor, although newborns or fetuses are most susceptible to infection and disease (337,338). Infection readily occurs via intravenous inoculation with cell-free or PBMC-associated virus and across intact rectal (339Ð340), oral (337,341) or genital mucous membranes (342) with cell-free but not cell- associated virus. A higher dose of cell-free SIV is generally required for rectal or vaginal infection than for IV infection and the time required for systemic infection to occur is slightly prolonged after vaginal exposure. Oral exposure to cell-free SIV in adult macaques induces infection and SAIDS more readily than rectal exposure (341). CD4+ tonsillar T-cells become infected after oral SIV infection (343). The successful genital, oral or rectal mucosal transmission and induction of SAIDS with SIV present useful models for heterosexual or homosexual transmission of HIV. In the heterosexual model, Langerhans cells, macrophages and T-helper cells within or just beneath the vaginal mucosal membrane, have been shown to be primary cellular targets that carry the virus to regional lymph nodes (344,345). Thinning of the vaginal mucous membrane from progesterone therapy increases susceptibility to experimental SIV infection via this mucosal route (346) and thickening of the vaginal mucosa from estrogen therapy decreases susceptibility to experimental infection (347). Infection of newborn or fetal macaques by oral or systemic routes constitutes an excellent model for retardation of intrauterine growth and induction of pediatric SAIDS (337,338,348).

Most (90%) inoculated animals become persistently infected from about two weeks after inoculation until death from SAIDS, which occurs within two months to three or more years depending in part on the vigor of the antiviral and innate immune responses. Factors of innate immunity such as NK cells, gamma delta T cells and other T cells that spontaneously produce interferon, beta chemokines and soluble antiviral factors, are important defense mechanisms against diverse pathogens (349), but they have not been much investigated in the SIV macaque model. Psychosocial stress may also shorten survival in SIV-infected macaques (350). Once the threshold of infection is reached, the induction of disease and incubation period are essentially dose-independent. Transient infection with clearance of virus, or persistence of a non-productive latent infection, sometimes with evidence of residual SIV cell-mediated immunity, may occur following limiting dose inoculation (351,352), experimental infection via genital or rectal mucosa (339Ð342,351Ð356), infection with less virulent SIV strains (357) or non-pathogenic SIV molecular clones (358Ð360). Low doses of infectious SIV that fail to induce antibody or CTL responses fail to protect against subsequent IV inoculation of a high dose of SIV (361). The level of virus replication is also dependent on the properties of the infecting SIV and disease outcome is usually less variable among monkeys infected with the same virus strain than between groups of animals infected with different viruses. The route of inoculation is associated with the extent and breadth of the genetic complexity of the viral variant population in the acute stage of systemic infection (362). A more diverse population of SIV variants tends to occur after IV as compared to intravaginal infection. However, no speciÞc viral variants (e.g. macrophage vs. T cell tropic) are consistently transmitted by intravaginal inoculation. The length of survival of infected animals correlates directly with the viral load and the strength of the humoral, cell-mediated and innate immune responses during acute infection (363Ð369). MHC class I alleles inßuence viral load set point and survival time (370). Monkeys that express Mamu A-01 exhibit the best control of viral replication (371). SIV speciÞc T cells peak just after the level of viremia starts to fall suggesting that CTLs are responsible (372). Depletion of CTLs by infusion of anti-CD8+ antibody abrogates the early control of virus and increases the virus level during the chronic phase of infection (373). Virus levels are again suppressed with the appearance of SIV-speciÞc positive T cells. CTLs are thus critical in control of virus, a view supported by the frequent selection of CTL escape mutants *in vivo* (374), especially during acute infection (375,376). Experimental depletion of B cells with anti-CD20 antibody suggests that humoral immune response contribute to SIV control in the post acute phases of primary infection (376). About 20% of SIV-infected macaques make little or no detectable antiviral antibody responses; they show a persistently high virus load, progressive decline in total plasma Ig level and number of T4 cells and die from SAIDS after two to six months. Such animals are particularly proven to develop SIV encephalopathy (377). The longer survivors remain persistently infected but show higher antibody titers to both core and envelope proteins, including broadly reactive neutralizing antibodies, and have an increased total plasma Ig and only a late decrease in T4 cells (378). Complement Þxing antibodies and antibody dependent cell mediated cytotoxicity may also play a protective role (379,380).

There is strong selection for viruses that can evade humoral and cellular immune responses, and antibody and

CTL escape variants may have increased replicative Þtness (374Ð376,381Ð383). Neutralization escape variants of SIV_{mne} exhibit changes in the extracellular envelope glycoproteins (384) and cytopathicity is determined by mutations in *gag* and *env* intracytoplasmic tail (385). Monkeys infected with mutant forms of SIV lacking certain glycosylation sites in the external envelope glycoprotein exhibit a markedly increased neutralizing antibody response (386). A Òglycan shieldÓ may well protect SIV/HIV from neutralizing antibodies (387). No deÞnite role for complement-mediated antibody-dependent enhancement of SIV infection *in vivo* has been demonstrated, despite evidence of enhancing antibodies (388). The neutralizing epitopes of SIV, e.g. the V3 loop, differ somewhat from T-cell adapted strains of HIV-1 (389,390), but sequences in SIV_{mac}, that correspond to V3 in HIV-1 can affect entry, cell tropism and CD4 binding in a manner analogous to that of HIV-1 V3 (391Ð393). Antiviral CTLs in blood (364,365,396) and vaginal mucosa (395), and T-cell soluble cytokines (396,397) or chemokines (398) that suppress SIV (and HIV) infectivity, may contribute to survival but, eventually, virtually all SIV infected macaques die from SAIDS. High levels of IL-4, IL-10, MIP-1α, MIP-1β, MCP-1 and RANTES in lymph nodes correlate with increased virulence of the SIV strain (399). Elevated levels of TNF-α are present in serum of macaques during acute infection with SIV (400). SIV induced perturbations in chemokine expression and dendritic cell associated markers suggest a profound disruption of homeostasis (401). The cellular and humoral antigenic epitopes in SIV and the SIV neutralizing and binding activity of various monoclonal antibodies have been reviewed elsewhere (402Ð404). Many SIV CTL epitopes, their restricting MHC Class I molecules and inßuence on disease progression have been recently deÞned (405Ð408). However, differences exist between T cell epitopes recognized after immunization and after infection (409).

Throughout the course of infection, virus is widely disseminated and can be readily isolated from PBMCs, plasma, lymph nodes, GI tract, spleen, bone marrow, brain, cerebrospinal ßuid, salivary gland, placenta, genital organs and secretions, and other tissues. Infected cells include mainly CD4+ T cells, macrophages, microglial cells and, possibly, dendritic cells. As in HIV-1-infected humans (410,411), virus turnover in SIV-infected macaques is extensive (412), tissue-speciÞc viral variants accumulate (413Ð415), and a higher infectious virus burden is present in lymphoid organs and GI tract than in blood (416Ð421). IN SIV acutely infected monkey with high viral loads, the turnovers rate of T cells in blood and cell organs is increased about two-fold and that of memory T cells about three-fold; B cells and NK cells turnover is also increased about 3% per day (422,423). With the onset of SAIDS, proliferation rates return towards control levels. Progression to SAIDS tends to be associated with widespread distribution of proviral DNA in tissues (424) and occasionally, a change from macrophage-tropic non-cytopathic SIV variants to T-cell tropic syncytia-inducing variants (425). Variants with enhanced infectivity as well as CD4 down-regulation may emerge during the course of infection (426). On the other hand, CD4 independence and macrophage tropism are also associated with neutralization sensitivity and reduced pathogenicity (427). As in HIV-1 infection, the number of CD4+ lymphocytes in the peripheral blood decreases soon after infection, then plateaus within several months at $\square 1000/mm^3$ until progressively decreasing to less than $400/mm^3$ shortly before death. Similarly, T-cell memory and non-speciÞc mitogenic proliferative responses are diminished before the CD4+ cell count is markedly reduced and a marked CD8+ lymphocytosis occurs during acute SIV infection (417,418). In acute SIV infection of macaques, the decline in CD4 cells in the peripheral blood may, at least in part, be due to lymphokine (IFN-γ and TNF-α) mediated sequestration of these cells in lymphoid tissues (417). As mentioned, the appearance of CD8+ cells may help to curtail SIV replication by both cytotoxic activity and release of soluble antiviral factors. However, functional impairment of virus speciÞc CD8+ T cells during acute and chronic infection may impair their protective role (428,429).

Cell entry of SIV, like HIV, is mediated by interactions between the viral envelope glycoprotein and a cellular receptor complex that consists of CD4 and one or more members of the CC or CXC chemokine receptor family of proteins (430,431). All of the co-receptors so far identiÞed are G-protein coupled signaling receptors involved in controlling activation and immigration of various leukocytes. The speciÞcity of this interaction largely determines the cell tropism of the virus. Whereas the main co-receptors for HIV-1 are CCR-5 (ÒR5Ó), present on macrophages, and CXCR4 (ÒX4Ó), present on T cells, the main receptor for SIV is CCR5 (432Ð434). However, SIV gp120 can bind to rhesus CCR5 independent of CD4 (435) suggesting the presence of unindentiÞed receptors. Two new SIV coreceptors termed Bonzo and Bob, that appear to play only a minor role in infectivity, have been identiÞed (436,437); the natural ligands for these receptors remain unknown. SIV from a red-capped mangabey uses CCR2 as its primary coreceptor (438). Interestingly, the CXCR-4 gene is present and functional for X4 tropic SIV *in vitro* but is not used by primary SIV *in vivo* (436). Also, X4 tropism usually does not develop during progression to SAIDS in SIV or SIV infected macaques (384,439,440), in contrast to such a switch in tropism often seen in HIV-1-infected humans. Thus, the correlation between X4 tropism and AIDS may be more speciÞc to humans, (and domestic cats).

One to three weeks after inoculation and prior to the onset of clinical disease, SIV-infected macaques, like some HIV-1-infected humans, develop a transient skin rash (441). Immunohistochemical evidence suggests that this rash may be the consequence of injury to SIV-infected Langerhans cells by cytotoxic T cells. The main clinical

features of SAIDS are wasting with a loss of 15% to 60% of body weight (442) and persistent diarrhea. Lymph nodes may be initially enlarged with follicular hyperplasia associated with a polyclonal B-cell reaction and paracortical expansion of CD8+ lymphocytes, but in time the follicular framework becomes disrupted and hyalinized or "burned out." Immunohistochemical staining of lymph nodes in the early stages reveals a decrease in CD4+ cells and an increase in both CD8+ and B cells. Lung tissue is minimally infected during acute SIV infection (443). In chronic SIV infection of macaques, CD8+ cells and macrophages show signs of cell activation (444) and increased CD8+ cell activity may contribute to lymph node pathology (394,417). SIV antigen appears on dendritic reticulum cells within germinal centers as well as in scattered CD4+ cells, macrophages and giant cells. Just as in HIV-1 infected humans, macaque dendritic cells (DC) bind and internalize SIV and transmit the virus to CD4+ T cells (445), a process enhanced by DC-SIGN, a C-type lectin (446). Dendritic cells in the lymph nodes of SIV-infected macaques express elevated levels of monocyte chemoattractant protein 2 (447). The absence of intraepithelial DC-SIGN positive cells in mucosal tissues suggests that CD-SIGN does not play a significant role in transmucosal passage of HIV/SIV (448). Infection of lymphoid tissues and thymus is accompanied by depletion of follicular dendritic cells and cortical thymocytes, respectively (449–452). SIV-induced apoptosis of thymocytes (CD4+, CD8+) and lymphocytes, is associated with an increase of surface FAS expression and profound decrease of bcl-2 positive cells, indicating a disruption of the anti-apoptotic pathway (453–454). As mentioned, a high viral load in lymph node follicles and high plasma viral RNA or infectious virus load early in SIV infection, indicates a more rapid disease course. The dynamics of rapid and active virus replication and antigenic variation throughout the course of infection are alike in SIV-infected macaques and HIV-1 infected humans (410,411).

Clinical lesions associated with the respective organ sites of SIV infection include hematopoietic dysfunction (455), hemolytic anemia (456), enteropathy (457,458), arthritis (459), ocular disease (460), oral hairy leukoplakia (461), pneumonitis (462), cardiomyopathy (463,464) and encephalopathy (465–468). Insights into the molecular pathogenesis of these lesions are becoming evident. Encephalopathy and pneumonitis are associated with an *in vivo* selection of macrophage-tropic SIV variants (401–402), exhibiting nucleotide changes in the envelope (471–474), and increased blood and cerebrospinal fluid (CSF) levels of quinolinic acid from activated macrophages (475). Adaptation of SIV to replication in macrophages apparently results from its ability to infect these cells in a mostly CD4 independent fashion (476). The SIV-associated encephalopathy in macaques is indistinguishable from HIV encephalopathy and undoubtedly has a similar molecular pathogenesis (465–467). Increased glutamate and decrease γ-amino butyric acid concentrations in the CSF reflect excitotoxic damage with microglia as a major contributor (477). Viral proteins, e.g. gp120, Tat, may also exert both direct and indirect toxic effects on the CNS (478). Reproducible infection of the CNS with selection for specific *env* sequences has also been achieved by serial passage of neuroendothelial or microglial tropic strains of SIV (479,480). Microglial cells apparently select for replication of neurovirulent SIV genotype (481,482). Expression of endothelial cell adhesion molecules may affect viral and inflammatory-cell-trafficking to various tissues such as intestinal tract and CNS (483,484). Release of various cytokines, such as TNF alpha, IL-1, IL-6 and IFN alpha or gamma, from infected or activated macrophages, microglia, and T cells, may influence SIV production and undoubtedly contributes to the pathology of the CNS and other tissues (485–488). Elevated levels of benzodiazeprime receptor expression, a marker of microglial and macrophage activation,are found in the subcortical white matter of SIV infected macaques (489). Alcohol administration enhances SIV induced cognitive impairment (490). Elevated levels of indoleamine 2,3-dioxygenase in the CNS from activated macrophages can lead to neurotoxicity through the generation of quinolinic acid (491). The extensive viral replication and CD4+ T-cell loss that occurs in the GI tract during acute SIV infection depends on these cells coexpressing CCR-5 and having an activated memory phenotype (492–494). Such cells, including intraepithelial lymphocytes, are a prominent source of cytokines and antiviral cytotoxic activity (493,495). The envelope glycoprotein of SIV contains an enterotoxin domain that may contribute to diarrhea without histologic alterations (494). Vaginal CD4 T cells that express high levels of CCR5 are also rapidly depleted by SIV infection (495). The pathogenesis of SIV_{pbj} induced rapid death from diarrhea in pigtailed macaques (332) involves extensive T-lymphoid hyperplasia in the gut and an increase in plasma levels of IL-6 and tumor necrosis factor (498). The T-lymphoid proliferation induced by SIV_{pbj} appears to be a superantigen effect (499) and also involves an enhanced responsiveness of the SIV LTR to NFκβ (500).

Opportunistic infections may be caused by adenovirus, cytomegalovirus, Epstein-Barr-related herpes virus (EBV), papovavirus (SV40), candida, cryptosporidia, and mycobacteria (501). Experimental coinfection of macaques with SIV and BCG can induce a tuberculosis-like disease (502). Although seldom occurring spontaneously, pneumocystis carinii pneumonia can be experimentally induced in SIV infected macaques (503). Non-Hodgkin's lymphomas of B-cell origin occur sporadically as opportunistic tumors in SIV-infected macaques (504). The tumors are monoclonal, mostly extranodal, including the CNS, of high-grade malignancy and often associated with an EBV-like herpes virus. Cytokine gene transcription patterns appear similar in HIV-1 and SIV associated lymphomas (505). Unlike HIV-1-infected

humans, typical KS does not occur in SIV-induced SAIDS. Two divergent lineages of gammaherpes virus homologue (rhadinovirus) of the KS associated herpes virus (HHV-8) found in humans have been identiÞed in rhesus and pigtailed macaques (209). In macaques coinfected with SRV, the rhadinovirus is associated with KS-like retroperitoneal Þbromatosis (208), whereas in macaques coinfected with SIV the rhadinovirus is associated with B-cell lymphoproliferative diseases (506Ð508). Different strains of macaque rhadinovirus apparently contribute to these different retroviral diseases.

In summary, although the disease course is shorter, the clinical, histopathologic, virologic, immunologic manifestations and opportunistic infections in SAIDS are remarkably similar to the counterpart lesions in human AIDS, and the correlates of protective immunity, to the extent that they exist, appear similar in simian and human AIDS (509). Accordingly, the molecular pathogenesis of human and simian AIDS must be highly alike.

Genetic Organization and Regulation of SIV

The molecular biology of SIV and HIV has been recently reviewed (4,510) and, therefore, will only be summarized here. SIV has a complex genetic organization almost identical to HIV-2, and includes genes for virion precursor proteins (i.e. gag, pol, and env) as well as six accessory genes (*vif, tat, rev, vpr, vpx, and nef),* some of which (*tat* and *rev*) regulate viral gene expression in infected cells (Table 10.3; Fig. 10.3) (511). LTRs ßank the viral genes and contain critical sequence elements for viral RNA synthesis and integration. Genetic and sequence similarities of SIV/HIV-2 with HIV-1 indicate that the virion proteins of both virus groups have similar properties and functions. One difference from HIV-1, however, is that cyclophilin A does not bind to SIV gag polyproteins and is not required for SIV replication (512). Various SIV/HIV-2 isolates encode a gene designated *vpx*, which encodes a protein that is packaged into virus particles, whereas HIV-1 does not encode an open reading frame for the *vpx* gene. The HIV-1/SIV_{cpz} group of viruses encode *vpu*, a gene for a small non-virion protein, located between *tat* and *env,* whereas the SIV/HIV-2 group does not contain *vpu*. Knowledge of the molecular biology of SIV has been coupled with analysis of viral mutants and variants in experimentally infected non-human primates; such studies in animals offer critically important opportunities to determine the role of various viral genes in transmission, virus distribution within the host, persistence, and patterns of pathogenesis.

Transcriptional promoter elements in the LTR are a TATA box for initiation of viral RNA synthesis by cellular RNA polymerase II, and several upstream elements which include targets for the SP1 factor, and an enhancer sequence recognized by NFκβ (510). It has been hypothesized that cell activation signals, which function through the NFκβ site to augment viral gene expression, may be important for converting a low-level infection to a state of

TABLE 10.3. *Genes and proteins of primate lentivruses*

Gene[a]	Dispensable for Replication	Protein Localization	Function
gag	No	$pr55^{gag}$	polyprotein precursor for virion nucleocapsid proteins MA (p17), CA (p24), NC (p9), p7 Virion nucleocapsid
pol	No	$pr160^{gag\text{-}pol}$	polyprotein precursor for virion enzymes PR-p10, RT and RNAse-H-p51/p66, IN-p32 Virion (nucleocapsid?)
vif	yes[b]	p23	viral infectivity factor, function unresolved. Cell cytoplasm
vpx[c]	yes	p16	virion protein, related to vpr, function unresolved Virion
vpr	yes	p15	virion protein, cell cycle arrest, nuclear import Virion
tat	no	p14	transcriptional transactivator, binds TAR and cell factor(s) (initiation and elongation of viral transcripts). Primarily in cell nucleus
rev	no	p19	post-transcriptional transactivator, binds RRE and cell factor(s) (splicing and/or transport of viral mRNA). Primarily in cell nucleus
vpu	yes	p16	In uences virion release, augments turnover of CD4 antigen Integra cell membrane protein
env	no	gp160	precursor for envelope glycoprotein: SU (gp120)-CD4 receptor binding TM(gp41)-membrane fusion and entry Virion envelope, plasma membrane
nef	yes	p27	necessary effector for pathogenesis, down-regulates CD4 receptor, in uences T-cell activation, enhances virion infectivity Cell cytoplasm, plasma membrane

[a] gene nomenclature is based on that in 511
[b] dependent on cell type
[c] encoded only by HIV-2 and several SIV strains
[d] encoded only by HIV-1 and SIV_{cpz}

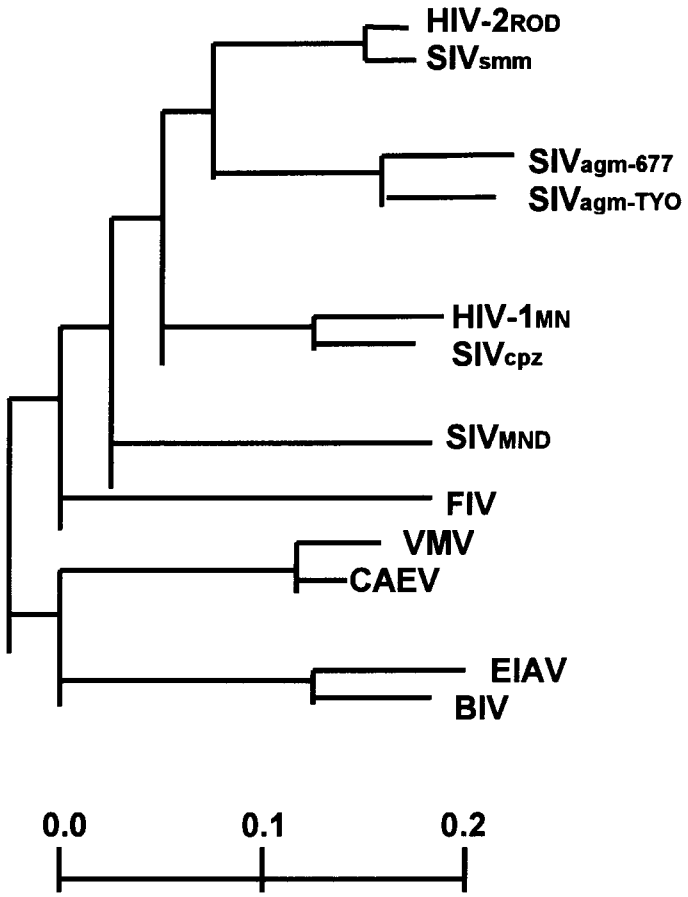

FIG. 10.3. Phylogenetic classi cation of the lentivirus genus of retroviruses. The scale indicates percentage difference in *pol* gene nucleotides. Abbreviations for viruses are given in Table 10.1 and the Glossary. Figure adapted from Myers and Pavlakis 1992 (235).

active viral replication. However, analysis of molecular clones of SIVmac239 containing deletions in the NFκβ site, reveals that this *cis*-acting element is not required for persistent infection and pathogenesis in macaques (513).

A regulatory gene found in all simian and human lentiviruses is the transactivator (*tat*) (514). The target (TAR) for *tat* is a sequence downstream from the cap site in the U5 portion of the LTR which folds into a stem-loop structure. The mechanism of *tat* function may involve both initiation of transcription and elongation of newly initiated transcripts; these effects are mediated by cellular proteins, which interact with *tat* (515).

The posttranscriptional transactivator designated the regulator of viral expression (*rev*), functions to shift viral replication from an early phase characterized by synthesis of spliced messages for viral regulatory proteins to a late phase in which unspliced and singly-spliced *(env)* messages for virion proteins accumulate (516). *Rev* may function by promoting transport of unspliced and singly spliced viral messages and by affecting the host cell's splicing mechanism. A target element responsive to *rev* (RRE) is a sequence about 200 bases long that adopts a secondary structure which is important for recognition by *rev*. A model for regulation of lentivirus gene expression with an early and late phase takes into account the properties of viral regulatory genes (516). Soon after infection, a low level of transcription produces double-spliced *tat* and *rev* messages. After accumulation of both tat and rev proteins, the splicing pattern changes so that synthesis of messages (unspliced and singly-spliced mRNA) predominates for virion structural proteins.

The *nef* is encoded by an open reading frame, which extends from the end of *env* into the 3′-LTR (517). *Nef* is dispensable for viral replication in a variety of tissue culture cells. Expression of this viral gene is associated with down-regulation of cell surface CD4 antigen, the binding receptor for virus. Some studies support the notion that *nef* down-regulates viral gene expression; however, other studies show that deletion of *nef* has no effect on or increases viral replication in tissue culture cells (517–519). Importantly, *in vivo* studies have demonstrated that SIV *nef* is essential for high level virus replication and pathogenesis in infected adult macaques (520). This pathogenesis function of *nef* may be attributed, at least in part, to its association with several cellular protein kinases leading to T-cell activation, which in turn augments viral replication in the infected host (521,522).

Primate lentiviruses also encode other accessory genes whose function in viral replication are under current investigation. The viral infectivity factor *(vif) is* encoded by the known primate lentiviruses and some of the animal lentiviruses (such as feline immunode ciency virus) but

not by the equine infectious anemia virus (523). *Vif* appears to play a role in production of infectious virus particles, perhaps by functioning at a step in virion assembly. The requirement for SIV *vif* in viral replication is cell-type dependent (524,525). Vif has recently been shown to overcome the effect of a cellular gene, CEM 15 that inhibits HIV-1 and presumably, SIV infection (526). A small gene, designated *vpr*, has been shown to augment expression directed by the LTR and to mediate cell cycle arrest (527). *Vpr* contains a nuclear localization signal, and appears to facilitate transport of viral preintegration complexes from the cytoplasm to the nucleus. The *vpr* gene is dispensable for SIV and HIV replication because viruses with deletion mutations in this gene productively infect some types of lymphoid cells; however, *vpr* is required for efficient replication in macrophage cultures. The *vpx* gene also encodes a small virion protein apparently required for nuclear import of viral DNA (528). Because *vpx* and *vpr* appear to be related genes that arose by duplication, *vpx* can substitute for *vpr* in some situations. Efficient viral replication *in vitro* in macrophages requires *vpx* (519); however, this gene is dispensable in lymphoid cell cultures. Molecular clones of SIV_{mac239} with a deletion in either *vpr* or *vpx* produce SAIDS in infected macaques (529). However, a viral clone with a deletion in both of these accessory genes is attenuated and does not produce high virus load or disease in macaques.

Several strains of SIV recovered from molecularly cloned viral genomes have been shown to cause fatal disease in experimentally-infected macaques (530–532). Other molecular clones of SIV are infectious for macaques but appear not to cause disease (533). Therefore, it is feasible to identify viral determinants of pathogenesis by analysis of recombinant genomes, constructed between SIV strains which show distinct biological properties either in tissue culture systems (e.g. macrophage-tropism) or *in vivo* (e.g. pathogenic potential). In addition, knowledge of the molecular biology of SIV and HIV-1 genes and proteins has made it possible to utilize genetic engineering methods to construct recombinant genomes between SIV and HIV-1 (SHIV) to investigate the roles of specific HIV-1 genes (e.g. *env*) in viral replication and pathogenesis in non-human primates, and to test anti-HIV vaccines and therapies in this animal model.

SIV Macaque Model: Molecular Pathogenesis

For a better understanding of the molecular pathways by which HIV evades immune clearance, continues to mutate, and eventually causes fatal CD4 cell depletion, the SIV macaque model appears indispensable, because only in such a relevant animal model can the critical experiments be done to define systematically viral and host determinants of viral persistence and pathogenesis. A unique advantage of this experimental model, not possible in humans, is the opportunity it provides to analyze in blood and other tissues the earliest stages of infection, following different routes of inoculation with well-defined biologic and molecular clones of SIV.

At the onset of infection, factors that affect the viral phenotype and level of replication appear critical to the clinical course (337,359,534–536). The fate of the infected animal appears to be determined within the first few weeks of infection, based on the virulence of the virus and how well the animal's immune response is able to control the initial level of replicating virus. A clear-cut dose relationship between infection and disease is not apparent; once the threshold of infection is reached the fate of individual animals appears to depend mostly on other viral and host factors. Host factors responsible for relative resistance or sensitivity to infection might involve MHC genes, β-chemokines and the balance of T-helper 1 (Th1) and T-helper 2 (Th2) lymphoid subsets and their cytokines (537). An important, as yet unanswered, question with direct relevance to HIV infection of humans that can perhaps best be answered in this model is whether or not it will be possible, by reducing but not necessarily eliminating virus replication at the onset of infection, by vaccination or therapy, to allow development of a long-lasting protective immune response that would otherwise be inhibited or overwhelmed by the virus itself. In other words, is it possible to permit a low level of virus replication, e.g. after vaccination or antiviral treatment, that remains too low to overwhelm host defense mechanisms but sufficient to induce a protective immune response to virulent virus? Although an affirmative answer to these questions is clearly the situation with most other viruses, including many animal oncoretrovirus infections, it remains to be seen whether this will apply to the immunosuppressive lentiviruses of animals and men in which even a little productive infection may inevitably, eventually, spell AIDS.

The opportunity to identify viral genes essential to pathogenesis is provided by the availability of several infectious, pathogenic, and closely related non-pathogenic, molecular clones of SIV that have been completely sequenced and characterized *in vitro* and *in vivo* (538). The prototype pathogenic molecular clone, SIV_{mac239} (530), and several closely related non-pathogenic molecular clones, e.g. $SIV_{mac1A11}$ (539) and BK28 (540), were independently derived from the same parental biologic isolate of SIV_{mac251}. A highly cytopathic variant of SIV_{BK28}, with several critical envelope mutations, was also derived (541). The SIV_{mac239} clone induces fatal AIDS in ~50% of macaques within one year, whereas monkeys infected with $SIV_{mac1A11}$ and SIV_{BK28} remain healthy for up to seven years. Pathogenic molecular clones are also available from the acutely pathogenic $SIV_{smPbj14}$ (531) and from the less virulent SIV_{mne} strains (542). From mutational studies of these molecular clones, several viral genes required for cell tropism and pathogenesis have been identified. It appears that *in vitro* growth characteristics of specific SIV

clones do not correlate well with differences in virulence observed *in vivo*; however, additional studies are needed to deÞne *in vitro* tissue culture conditions which might discern differences between pathogenic and non-pathogenic SIV clones. As is seen also with the oncoretroviruses, *env* gene sequences play a critical role in determining cell tropism, cytopathology and pathogenesis of SIV and other lentiviruses. The SIV biologic isolates consist of a mixture or Òswarm Óof related but genetically distinct virus variants (a quasispecies) which, when molecularly cloned, show unique degrees of lymphotropism or monocyte/macrophage-tropism and associated cytopathic effects. Selection for these viral variants may occur in different host cells and tissues and thus may account for different disease manifestations.

To attempt to identify viral functions essential to disease induction, macaques were infected with SIV_{mac239} clones in which various point and deletion mutations had been made in the accessory genes not required for virus replication (543). Results indicated that the *nef* gene is required, *in vivo*, for high viral replication and pathogenesis, because a stop codon or partial deletion of this gene (Δ *nef*) led to a reduction in virus load and absence of disease in adult macaques (520). In several animals, the stop codon in *nef* was repaired *in vivo* and this genetic event was associated with an increase in virus titer and disease. Thus, the virus selects for an intact *nef in vivo*. SIV (and HIV-1) Nef is a multifunctional protein known to downregulate CD4 and to associate with cellular kinases involved in cell activation (517,522,544Ð546). Mutations in the regions of SIV_{mac239} Nef that bind cellular serine kinases show reduced infectivity *in vivo* and a strong tendency to repair the mutation with reversion to high virus load and virulence (522). Thus, this association of Nef with a cellular serine kinase, tentatively identiÞed as a member of the P21-associated kinase (PAK) family, is one mechanism involved in the pathogenesis of SIV and HIV. Especially noteworthy was the observation that adult monkeys chronically infected with the SIV_{mac239} *nef* deletion mutant were protected against superinfection with a high dose (1000 animal infectious doses) of virulent SIV (547). This degree of protection, independently conÞrmed (548), was far more dramatic than that obtained with any of the previous conventional or novel vaccines tested in this model. The mechanism of protection afforded by *nef* deletion mutants remains unexplained although some aspect of cellular immunity is suspected. Of note, however, is that newborn macaques infected orally with the Δ *nef* mutant developed AIDS (549), without repair of the *nef* deletion, indicating that this SIV *nef* mutation alone does not guarantee safety in all age groups.

The involvement of other viral genes in addition to *nef* in pathogenesis and protection against superinfection was indicated by experiments in which rhesus macaques were infected with recombinants of attenuated ($SIV_{mac1A11}$) and pathogenic SIV_{mac239} clones (534,538). Genetically, $SIV_{mac1A11}$ is 98% related to SIV_{mac239} differing only by two 3 bp deletions within the envelope V1 region and stop codons in *Vpr* and in the cytoplasmic tail of the envelope transmembrane (TM) envelope (gp41) (539). In contrast to SIV_{mac239}, which is infectious for T cells but not macrophages. $SIV_{mac1A11}$ is both T-cell and macrophage-tropic *in vitro*. Macaques inoculated with the $SIV_{mac1A11}$ clone have only a transient infection lasting about six weeks, after which the virus can no longer be isolated from PBMC or tissues, and is only occasionally demonstrable at these sites by PCR. Low-level humoral and CTL immune responses persist, however, probably reßecting a low level of persistent virus expression. In general, the virus load of $SIV_{mac239/1A11}$ recombinant viruses in PBMC of infected monkeys was intermediate between the parental types, and the virus load and pathogenic potential *in vivo* most closely resembled the parental virus that made up most of the recombinant genome. For example, the recombinant carrying the SIV_{mac239} envelope on the $SIV_{mac1A11}$ background replicated only slightly better than $SIV_{mac1A11}$ and caused no disease. The reciprocal recombinant carrying the $SIV_{mac1A11}$ envelope on the SIV_{mac239} background replicated just a little less well (ten- to a hundredfold) than the SIV_{mac239} clone and was capable of causing disease within two years postinfection. The strength of the humoral and cellular immune response was directly proportionate to the level of virus replication in PBMC, thymus, and lymph nodes. In general, in animals chronically infected with these $SIV_{mac239/1A11}$ recombinants, the extent of resistance to superinfection with virulent uncloned SIV_{mac251} was also directly proportional to the level of virus replication. These Þndings add further credence to a concept that applies also to HIV-infected humans (550), that initial virus level is indeed an important determinant of pathogenicity, and also indicate that, in addition to *nef,* at least one or more viral genes are required for pathogenicity. These Þndings also suggest that some aspect of the immune response, yet to be determined, is responsible for protection against superinfection.

The role of other viral genes in pathogenesis has recently been tested via the same mutation strategy used to deÞne the critical role of *nef.* As mentioned in the preceding section, molecular clones of SIV, with deletions in *vpr* or *vpx*, were shown to infect macaques at only a slightly reduced level of viral replication, compared to SIV_{mac239} and both *vpr* and *vpx* deletion mutants were able to induce AIDS after a relatively short incubation period and without repair of the deletions (529,551). Thus, neither of these genes is required for *in vivo* replication or pathogenesis, although they may contribute a slight additive effect to these viral properties. Although the *vif* gene was shown to contribute to more rapid and efÞcient virus replication in certain cell types *in vitro* (524); its importance to *in vivo* pathogenesis has not yet been determined. Mutants of SIV_{mac239} bearing stop codons in the cytoplasmic tail of the TM protein (gp41) were infectious but non-pathogenic in macaques (552,553). However, in two of four monkeys, repair of these stop

codons was selected for *in vivo*, and this event correlated with an increase in virus titer and reversion to virulence. These findings suggest that this cytoplasmic portion of the viral envelope is critical to pathogenesis, and indicates yet another region of the viral genome, in addition to or instead of *nef,* that might be purposefully deleted to make an attenuated live virus vaccine. The cytoplasmic tail of SIV and HIV *env* TM contains two amphipathic alpha helices that alter cell membrane permeability (554) and bind calmodulin, an integral component of cellular signal transduction pathways (555). The lack of pathogenesis of $SIV_{mac1A11}$ clone may thus be attributed to the two stop codons in gp41 that preclude expression of these domains. Additionally, through studies of a viral mutant *in vivo* the intracytoplasmic domain of SIV_{mac239} Env glycoprotein was shown to be important for pathogenesis (556).

SIV Macaque Model: Vaccines

The remarkable similarities that exist between SIV infection and disease in macaques and HIV-1 infection and disease in humans have made this the animal model of choice for research towards a prophylactic AIDS vaccine (557). The species of macaques utilized have been mostly rhesus (*M. mulatta*), with fewer numbers of longtailed (*M. cynomolgus*) and pigtailed (*M. nemestrina*). The results, not surprisingly, have been mixed and no single candidate vaccine has yet emerged that appears consistently effective or highly promising for large scale, phase 3 human clinical trials. This sobering but realistic state of affairs reflects our continued uncertainty concerning the mechanisms of pathogenesis and immune protection against any of the animal or human lentiviruses. However, the vaccine successes, albeit limited, that have been achieved in the SIV macaque model, do engender some optimism (557). The best results in terms of strength and duration of protection against SIV infection and disease have been obtained with modified live SIV vaccines, but some degree of protection, such as lowering of the level of challenge virus infection and delay of disease onset, has also been achieved with other vaccine approaches, used alone or in combination vaccines, including inactivated whole virus, native envelope glycoprotein, recombinant envelope subunits, live vectors presenting SIV antigens, SIV peptides and, most recently, viral DNA. Four biologic strains of SIV, for which pathogenic molecular clones also exist, have primarily been used for vaccine research: SIV_{mac} and SIV_{sm} are closely related and usually cause a virulent infection, with about 95% mortality from AIDS within six months to two years (the average is 11–12 months). SIV_{mne} is less virulent and causes death from AIDS in about 50% of animals after two years of infection. SIV_{pbj} is highly virulent and causes death from diarrhea in 10–14 days. Most recently, recombinants of SIV and HIV-1 env (SHIV env) have been used as attenuated live vaccines or as a challenge for macaques that were immunized with various HIV-1 immunogens or modified live SIV. Encouraging results, summarized in the next section, have been obtained with SHIV DNA vaccine protocols against pathogenic SHIV challenge infection in rhesus macaques.

Inactivated Whole Virus

In early experiments (1989–1992) vaccine protection against SIV_{mac} challenge infection was unexpectedly achieved by use of inactivated whole SIV_{mac} or SIV_{sm} cell-free or cell-virus vaccines. A number of laboratories in the United States and Europe found that macaques immunized with inactivated whole SIV vaccines, in which vaccine and challenge virus were both propagated in human T-cell lines, could be completely protected against low dose (1–100 animal infectious doses) IV challenge infection with homologous or heterologous SIV strains (558,559). However, this protection did not extend to HIV-2, which differs by about 20% in nucleotide sequences. This complete protection was called "sterilizing immunity" because, using sensitive detection methods, the vaccinees had no virologic or serologic evidence of transient infection or anamnestic immune response after inoculation. This type of immunity appeared to last up to about one year, and was also effective against challenge infection by rectal application of SIV grown in human T cells (560), but, with one exception (561), not against vaginal mucosa inoculation with SIV grown in simian PBMCs (562,563). Interestingly, the best correlate of protection with the inactivated whole virus vaccines proved not to be antiviral neutralizing antibody, as might have been expected, but rather, antibodies against the human T-cellular antigens, viz, MHC class I and II proteins, present on the cells in which the vaccine and challenge viruses were grown (564, 565). It was shown that the same vaccinated animals that had been protected against live SIV_{mac}, grown in human T cells were not protected against the same dose of the same virus grown in rhesus PBMC. Nor was protection usually obtained against challenge with virus-infected rhesus PBMC. Some monkeys were completely protected against SIV_{mac} grown in human T cells by vaccination with uninfected human T cells (564), and even with semi-purified MHC I protein or MHC II DR proteins alone (566,567). Immunization with other cell surface antigens, such as β-2 microglobulin and CD4 protein, did not protect. Protection could be passively transferred by serum containing antibodies to the human T-cell antigens, with little or no SIV neutralizing antibody, possibly by the mechanism of antibody mediated complement lysis of virions (568). By contrast, protection could not be passively transferred by SIV neutralizing antibodies (569). Therefore, the immune protection achieved with the inactivated whole SIV vaccines could be attributed mostly to the xenogeneic MHC antigens picked up by the virions from the human T-cell lines in which the vaccine and challenge viruses had been propagated. Antibodies to the

CCR5 receptor may also have contributed to this protection (570). Some protection against SIV grown in rhesus PBMC was also obtained by immunization of macaques with uninfected allogeneic rhesus PBMC, indicating that alloantigens as well as xenoantigens could provide partial protective immunity against experimental SIV infection (571). Immunization of macaques with allogenic B cells expressing high levels of MHC Class I and Class II molecules elicited antibody responses to these antigens but did not protect against systemic infection with SIV_{mac} (572). However, the average virus-infected cell load was reduced in the immunized animals. This finding supports the idea that relative resistance to HIV-1 infection in certain high-risk individuals and the rate of progression of HIV-1 infection may be linked to MHC genes, and, possibly, alloantigen-induced autoimmunity (573). This notion is further supported by the observation that the rapidity of the clinical course in SIV-infected macaques is inversely correlated with the strength of MHC-II DR antigen expression on monocyte-macrophages and B cells (574). In HIV-1 infected humans, a single amino acid polymorphism in a MHC Class I molecule has a substantial effect on the rate of progression to AIDS (575). Perhaps, this resistance will be linked to increased β chemokine production or other aspects of innate immunity. The possibility of developing an efficacious HIV-1 whole virus vaccine using the SIV macaque model is still being investigated at the National Cancer Institutes (NIH) (576). However, because of safety concerns and patent issues, there is relatively little industrial interest in inactivated whole HIV vaccines.

Recombinant SIV Subunits and Live Vectors

Recombinant SIV subunit vaccines have, in general, not been able to provide complete protection ("sterilizing immunity") against systemic or mucosal SIV challenge infection. However, they have usually conferred partial protection, evidenced by a 1–2 log reduction in challenge virus level in comparison to naive controls. Only one example of apparently complete protection, using a recombinant SIV env (gpl60) vaccine, has been achieved (577); in this study pigtailed macaques were immunized with live vaccinia virus expressing gpl60 of SIV_{mne}, boosted one year later with subunit gpl60 and then challenged with a biologic clone (E11s) of the less virulent SIV_{mne} strain. None of these vaccinated animals had virus isolatable from PBMC following SIV challenge, or seroconversion to SIV proteins. Neutralizing antibody appeared to be the best correlate of protection of this study. CTL responses postchallenge revealed the induction of reactivity to SIV proteins not included in the subunit vaccine, suggesting that a low-level of SIV infection did occur following exposure of the vaccinated hosts to SIV (578). When these animals were boosted with the same vaccine and challenged with a genetically more diverse uncloned biologic SIV_{mne} strain, some of them became infected, indicating that the protection obtained in this system was primarily against a genetically uniform virus population. Using the SIV_{mne} pigtailed macaque model, a profound but not complete suppression of challenge virus was obtained by immunization with a mixture of four Env peptides expressed in E. coli as β-gal fusion proteins (579). Protection appeared to correlate with level of neutralizing antibody, which could passively protect a majority of recipients (580). But, again, animals immunized with this env peptide vaccine were not protected against challenge with a related but more diverse SIV strain. The same gp160 vaccine was highly effective against intrarectal infection with either cloned or uncloned SIV_{mne} (581). Protection appeared to correlate with neutralizing antibody activity and low level challenge infection. These results indicate that under ideal conditions envelope antigens alone can confer strong protective immunity to a genetically uniform, homologous SIV, but not to genetically diverse SIV, as present in natural SIV and HIV isolates (582). A summary of work in the SIV_{mne} pigtailed macaque model led to the conclusion that the best results in terms of preventing infection or reducing virus load after intravenous challenge are obtained with recombinant vaccines that include the entire env (gp 160) rather than only the external portion (gpl30), that combine core antigens with env and that use a live vaccinia vector priming, followed about a year later by a baculovirus expressed subunit gpl60 boost (583).

A subunit vaccine consisting of native gp130 oligomers but not of gp130 monomers protected rhesus macaques against productive infection with SIV_{mac} (584). Escape from neutralizing antibody was associated with the development of V-1 env mutation in the challenge virus (585). On the other hand, vaccines consisting of recombinant SIV_{mac} env ISCOMS alone or combined with gag ISCOMS and nef peptides were unable to protect macaques or lower the virus load following IV challenge with the homologous virus, despite the presence of vaccine induced neutralizing antibodies and CTLs (586).

A number of live vector systems, e.g. baculovirus (587,588), attenuated vaccinia virus (Ankara) (NYVAC) (589–593), Canary pox (ALVAC) (593–594), vesicular stomatitis virus (595), Semliki Forest virus (596,597), Mengovirus (598), Poliovirus (599,600), Adenovirus (601), Salmonella (602), and BCG (603) have been used for priming or boosting monkeys, different subunit expression systems; e.g. mammalian cells (CHO) (604,605), baculovirus (606), vaccinia virus, *E. coli*, yeast Ty, have also been used, together with a number of different adjuvants, cytokines (607) and vaccination protocols. Most of the recombinant vaccines expressed the SIV_{mac} *env* gene (gp160 or gp130), and many vaccines also expressed gag or pol genes (590,592,608–611). One recombinant env vaccine induced neutralizing antibodies selected for viral escape mutants and enhanced the infection, but such enhancement has not been commonly

observed (612). None of the recombinant live vaccinia or baculovirus vaccines, or recombinant CHO cell vaccines, conferred strong protection against IV challenge infection with pathogenic SIV_{mac} or SHIVs (see below), even when the recombinant antigens were expressed as virus-like particles and induced a high titered immune response. Although none of these recombinant live virus vaccines completely protected macaques against IV or mucosal challenge with a low to moderate infectious dose (10–100 ID/50) of cell-free homologous SIV_{mac}, the virus titer in PBMC and plasma of many recipients was reduced 1–2 logs during the acute infection phase after challenge, compared to controls. Most of the vaccinated animals developed antibodies and T-cell responses to the SIV antigen and some had neutralizing antibody, but the role of humoral and cellular immunity (as measured by T-cell proliferation and CTLs) in reducing the challenge virus titer during acute infection remains uncertain. Non-MHC restricted CD8+ T cell antiviral activity may have contributed to protective efficacy (613). An ALVAC SIV vaccine and the macaque MHC class I (A*01) genotype conferred partial protection against intrarectal challenge with SIV_{mac251} but no protection against pathogenic SHIVs (614). Immunization with the NYVAC SIV vaccine resulted in the appearance of CD8+T cells at mucosal sites even when the vaccine was delivered by non-mucosal routes (615). The same kind of vaccine partially protected cynomolgus monkeys from mucosal SIV_{sm} challenge (616). By contrast, using a non-virulent virus host model, vaccination of cynomolgous monkeys with a vaccinia virus expressing the SIV_{agm} *env* gene induced high titers of anti-SIV_{agm} antibodies and markedly reduced the replicability of the challenge polyclonal nonpathogenic SIV_{agm} (617). Inactivated SIV whole virus (grown in human T-cells) or a recombinant baculovirus envelope and core subunit vaccine injected into the iliac lymph nodes conferred complete or partial protection against rectal challenge with a molecular clone of SIV_{mac} (611). Protection was correlated with the induction of Th2 responses in circulating CD4+ T cells reflecting the expansion of SIV specific IgG producing cells followed by IgA secreting cells (618). Anti-SIV IgA secreting cells were also present in the iliac lymph nodes (619). The most significant correlate of protection with the targeted lymph node vaccines was the induction in the iliac lymph nodes of CD8 suppressor factors and β-chemokines (620), that prevent binding of SIV (or macrophage-tropic HIV) by the CCR5 coreceptor. Gamma-delta T cells may also have generated antiviral factors and β-chemokines (621).

Although not completely protected against challenge infection, vaccinated animals with reduced levels of acute viremia after challenge with pathogenic SIV have generally experienced a more prolonged asymptomatic infection than the non-vaccinated controls (622). Immunization of newborn rhesus monkeys with modified vaccinia virus expressing SIV gag, pol and env delayed the onset of AIDS after challenge at four weeks of age with virulent SIV_{mac251} (592). Similarly, low virus load in blood and lymph node during primary infection has repeatedly been shown to correlate with prolonged survival in HIV-1-infected individuals (623,624). Lessons learned from the SIV macaque models would indicate that partial vaccine protection, by lowering the level of initial infection, and thus, delaying or preventing disease onset for a long time, represents a more feasible and reasonable goal for an AIDS vaccine, rather than completely preventing infection (sterilizing immunity) (571, 625). The major reason for delaying Phase III human clinical trials was because the antibodies induced by the HIV-1 env vaccines did not neutralize field isolates (in contrast to T-cell line adapted HIV-1 strains) (626) and because of breakthrough infection of some high-risk individuals who had received these vaccines (627,628). Also, there is considerable concern that high-risk individuals, receiving candidate-unproven HIV vaccines, may feel that they are now protected against infection, and therefore will practice less safe sex. Nevertheless, Phase III trials are now underway with recombinant gp120 vaccines in the USA, Canada, Netherlands and Thailand.

SIV Peptide and DNA Vaccines

Immunization of macaques with a mixture of lipopeptides derived from nef and gag proteins or peptides representing CTL and neutralization epitopes elicited epitope specific antibodies and CTLs but did not protect against infection (629,630). The emergence of CTL escape mutants supported the necessity of eliciting broad CTL responses. With this goal in mind, a degenerative peptide cocktail representing the hypervariable epitopes of SIV (631,632) and HIV-1 (633) Env vaccine has induced broad and long-lasting humoral and cellular responses in rhesus macaques (631–634), but has not yet been tested for efficacy against SIV challenge. An SIV gp120 C4 domain peptide immunogen coupled with recombinant gp120 expressed in adenovirus did not protect against rectal SIV challenge (635). Immunization of macaques with SIV recombinant Nef protein revealed an inverse correlation between Nef specific CTL precursor frequency and virus load measured after challenge (636). Immunization with SIV Nef expressed by vaccinia virus or nef DNA elicited T cell responses and antibodies but did not protect against SIV infection (637). Oral immunization of macaques with SIV Gag protein and cholera toxin elicited both mucosal IgA and systemic IgG immune response but these animals were not challenged (638).

Genetic immunization with HIV-1 and SIV_{mac} *env* naked DNA has induced modest levels of anti-SIV humoral and cellular immunity in mice and macaques, and partial protection vs. SHIV or SIV challenge of macaques (639–642). The genetic immunization approach is considered especially attractive because it mimics the intracellular processing of a live virus by antigen presenting cells but is free of the safety concerns raised by

replicating virus (643). Incorporation of a lymphokine gene (e.g. IFN-g, IL-2, IL-4, IL-12, GMCSF) or MHC Class I or II genes in the recombinant vaccine may enhance the immune response or attenuate the potential virulence of the vector (644–648). Immunization of macaques with a CTL epitope gene-SIV DNA prime, and vaccinia virus (Ankara) boost regimen elicited high levels of epitope specific CTLs, that correlated with tetramer staining of PBMC and post challenge control of viremia (649,650). Vaccination with a SIV DNA gag-env prime and NYVAC gag, pol, env boost significantly suppressed viremia within two months after mucosal exposure to SIV_{mac251} (651) or SIV_{mac239} (652). However, most of these animals progressed to AIDS. Pigtailed macaques immunized with plasmid DNA expressing all SIV genes alone or boosted with recombinant gp160 plus gag-pol particles were partially protected against rectal challenge with SIV_{mne} (653). Protection seemed to correlate with a dominant Th1 response. Vaccination of macaques with SIV DNA producing inactivated virus-like-particles induced strong mucosal immune responses, including rectal IgA, and conferred partial protection against rectal infection with SIV_{mac239} (654). Another SIV DNA vaccine partially protected rhesus monkeys from intrerectal challenge with homologous virus (655,656). Vaccination of macaques with DNA of a chimeric SIV, in which SIV env was replaced with Friend MuLV env, together with DNA of the MuLV receptor, induced SIV gag specific cellular immune responses and partial resistance against SIV_{mac239} challenge (657). This novel strategy may be useful for development of safe and effective vaccines against various kinds of pathogenic viruses. Vaccination of macaques with SIV_{nef} DNA elicited multi-specific T cell responses recognizing variants present with the SIV_{mac251} isolate (658). These animals were not challenged with SIV. In summary, SIV DNA vaccination, often combined with subunit boosts, appears to be a promising strategy deserving of more research. The protection achieved is generally equal to or better than that obtained with recombinant SIV subunits, live vectors or peptides alone but not as strong as seen with attenuated live SIV vaccines.

Attenuated Live SIV Vaccines

Unquestionably, the best protection in the SIV macaque model has been obtained using genetically attenuated live virus vaccines. Such a result is perhaps not surprising in view of the historical precedence of successful modified live virus vaccines (659) and the reported success with modified live equine infectious anemia (a horse lentivirus) vaccines (660). Macaques immunized by infection with one of several different SIV_{mac} or HIV-2 molecular clones or recombinants that are relatively non-pathogenic, were uniformly protected as well or better against challenge with virulent SIV than observed with any of the other vaccine approaches (661–664). In general, the animals preinfected with the attenuated live SIV or HIV-2 clones are able to suppress the level of superinfection markedly, or even to prevent superinfection following challenge with high dose (100–1,000 ID/50) virulent homologous or heterologous virus strains, and such animals show a significant delay of disease (>4 years). Inoculation of macaques with subinfectious doses of SIV has also been considered as a way to induce primarily cell mediated virus responses (Th1) that might confer protection (665). The most thoroughly studied attenuated live vaccines are the nef-deleted (Δ*nef*) (661) and triple deletion mutants (Δ3) of SIV_{mac239} (666,667) and the closely related naturally attenuated 1A11 molecular clone of SIV_{mac239} (open nef) (668). The Δ*nef* clone 8 (C-8) has a 12-base pair deletion in the *nef/3′-LTR* and can revert to virulence after *in vivo* repair of this attenuating lesion (669).

The Δ*nef* and Δ3 clones replicate better *in vivo* than the 1A11 clone and protect better. Recombinants between the attenuated 1A11 clone and the intact virulent 239 clone of SIV_{mac}, replicate to various levels in rhesus macaques and the degree of protection against virulent virus challenge correlates with the relative level of replication (662). The same can be said for different nef deletion mutants of SIV_{mac}. Unfortunately, a window of safety has not been defined in which a level of replication can be tolerated that will not induce disease and yet will be protective in macaques of all ages. The higher the level of replication, the better the protection against superinfection with virulent virus, but the more likelihood that the recombinant virus eventually will cause disease. The lower the level of replication, the less will be the extent of protection against challenge with virulent virus, but also the less likelihood that the recombinant virus will cause disease. In newborn macaques, the SIVΔ3 clone induces a high level of virus replication and fatal AIDS (670). Given sufficient time (approximately six years), the SIVΔ3 vaccine is also pathogenic in most adult macaques (671). By contrast, infection of newborn macaques with the more attenuated $SIV_{mac1A11}$ clone induces only a transient viremia, yet completely protects some recipients against a low dose of SIV_{mac}, (10 ID/50) given orally, a dose that readily infects and eventually kills all controls (672). Perivaginal inoculation with the same attenuated live SIV clone, followed by a second perivaginal inoculation with whole inactivated SIV_{mac} substantially reduced viral load after intravaginal challenge with uncloned SIV_{mac251} (563). Adult macaques infected with the $SIV_{mac1A11}$ clone became superinfected when challenged with a high dose (1000 AID) of SIV_{mac} but they survived more than three times longer than controls (668). Similar results were obtained when macaques infected with nonpathogenic HIV-2 were superinfected with virulent SIV (663). SIV_{mac239} Δ*nef* infected adult monkeys withstood a very large dose (1000 ID) of virulent homologous SIV challenge infection given IV or intrarectally (547,548), and were also resistant to IV and IR infection with cell-free SIV_{mac} or SIV_{mac} infected rhesus

spleen cells (673,674). SIVΔ*nef* infected monkeys were also resistant to heterologous SIV challenge infection (675). None of the other SIV or modified live virus vaccines approach this magnitude of protection. Macaques infected with a macrophage tropic recombinant of SIV_{mac239} were protected against a heterologous SIV strain as well as against the homologous virus (676). Neutralizing antibodies appeared to correlate with this protection, which could also be passively transferred. By replicating in antigen-presenting cells, macrophage-tropic viruses may be more immunogenic, and such viruses are also implicated in the mucosal transmission of HIV-1 and SIV. SIV_{mac239} Δ*nef*-infected monkeys are also resistant to IV or rectal challenge with the more divergent SIV_{sm} or a SIV/HIV recombinants (SHIV) bearing the HIV-1 envelope (677,678). These latter results indicate an unexpectedly broad range of protection that cannot be attributed to envelope antibodies.

The mechanism of protection from these attenuated molecular clones of SIV is not clear. Protection does not appear to be by MHC alloantigens (678) or viral interference at the cell surface receptor level, as described with oncoretroviruses (679). Most likely the mechanism is immunogenic because a period of time (10–20 weeks) is required to obtain maximal protection (680). However, the mechanism may be distinct from classical humoral or cellular immunity and may involve factors of innate immunity e.g. NK cells, IFN-γ (681). The protection cannot be transferred with immune serum (682) and apparently does not involve neutralizing antibody (683,684). In those monkeys not protected from pathogenic virus challenge a minimum of viral diversity occurred with no selection for specific V-1–V-2 genotypes (685). Inhibition of SIV replication in SIV_{mac} Δ*nef* immunized monkeys apparently does involve T helper responses and CD8+ MHC restricted (i.e. CTL) and unrestricted mechanisms, the latter due to soluble factors other than known β-chemokines (686). Undoubtedly, by one means or another, CD8 T cells do play an important role in controlling replication of the live attenuated SIV *in vivo*. However, partial depletion of circulating CD8+ cells or total lymphocytes prior to challenge failed to abrogate the protection conferred by SIVΔ*nef* (687,688). Moreover, another study found no correlation between the anti-SIV CTL response and protection against infection in SIVΔ*nef* infected animals (689). Rechallenge of vaccine did not induce vigorous T-cell responses (690). Clearly, we do not as yet have a clear picture of the mechanisms of protection versus superinfection conferred by live attenuated SIV.

Whether attenuated live HIV vaccines will ever be acceptable for human use remains unlikely. Safety concerns, based on fears of recombination or reversion to virulence, or insertional activation of cellular oncogenes, are a major obstacle (691,692). The development of AIDS in newborn and adult macaques infected with the SIV_{mac239}Δ*nef* (670,671) certainly invites caution. However, the possibility remains that a safer, more attenuated SIV clone might yet be found that is immunogenic and protective in newborns as well as in adults. Also, the incorporation of lymphokine genes, e.g. IFN-τ (693), into the attenuated SIV might enhance its safety and efficacy. Other modified live virus vaccines might he constructed to have deletions in critical regions such as the integrase domain (694) of the *pol* gene, the cytoplasmic tail of the transmembrane envelope (695) or mutations in variable regions of the env gene (696). Good protection from mucosal challenge with SIV_{mac251} was achieved by live attenuated SIV with point mutations in the env transmembrane protein (697). Removing carbohydrate molecules from the viral envelope might also enhance the presentation of neutralizing antibody epitopes (698). Further study of macaques protected with genetically modified live SIV molecular clones is a most promising approach toward understanding the viral determinants of pathogenesis and the mechanism of apparent immunity. An annual update of worldwide SIV and SHIV challenge studies in vaccinated non-human primates, already about 250 in number (699), will provide information needed to guide the development of the most effective HIV-1 vaccines for phase III efficacy trials in men. Hopefully, effective AIDS vaccines may yet be deployed in high risk population around the world.

SIV Macaque Model. Antiviral Therapy

The urgency of the AIDS problem and the desperate desire of AIDS patients to try any potential treatment have prompted the application of most antiviral therapy directly to humans after only preliminary *in vitro* evaluation of toxicity and efficacy. Thus, preclinical testing of candidate drugs against HIV, and against most of the opportunistic pathogens encountered in AIDS, has not depended on the SIV macaque model. Fortunately, since 1994, these preclinical trials have led to new effective highly active antiretroviral therapy (HAART) employing potent combinations of three or more antiviral drugs directed at the RT and protease enzymes. HAART can accomplish lengthy and near complete suppression of virus replication in many HIV-1 infected persons, although multidrug resistance virus, latency and residual replication remain major problems (700). The nucleoside antireverse transcriptase (RT) inhibitors and peptidomimetic protease inhibitors (PI) are equally effective against the respective enzymes of HIV-1 and SIV (701). However, the non-nucleoside RT inhibitors do not inhibit SIV or HIV-2. Nonetheless, the SIV monkey model has served a useful purpose in confirming the efficacy and safety of the anti-HIV-1 RT nucleoside analogues, and in discovering and evaluating several other potent antiviral agents (i.e. PMPA), before clinical application (702–704). Currently the SIV macaque model is proving useful for evaluating the viral dynamics of primary viremia (705) and the efficacy of combined HAART and therapeutic vaccination or intermittent vs. continuous therapy against acute and chronic infection and

disease (706,707). The application of SIV/HIV recombinants (SHIVs) and HIV-2 infection of macaques for studies of antiviral therapy will also be highlighted in this section. Perhaps the major beneÞt of the monkey model is the ability to test the pathogenicity *in vivo* of drug resistant viral mutants although the speciÞc drug induced nucleotide mutations in RT or protease enzymes may not necessarily be identical in HIV-1 and SIV. For example, site speciÞc mutations made in RT residues, M184V and E89G, of SIV_{mac}, analogous to the drug resistant mutation found in clinical HIV-1 isolates, have been tested for ddc resistance (708) and SIV Þtness and virulence in macaques (709,710). Interestingly, a combination of PMPA with 3TC selects for the K65R mutation and against the M184V mutation in SIV RT (711). The major drawbacks of the monkey model are its expense, reluctance of drug companies to rely on non-human primate tests and the difÞculty in administering reliable oral doses of antiviral drugs.

In general, each of the RT nucleoside analogues inhibits HIV-1 and SIV RT with similar *in vitro* efÞcacy and, when started shortly before or shortly after SIV inoculation of macaques, these antivirals have been found to either prevent infection or suppress acute SIV infection (712Ð715). In early studies, AZT and ßuorodeoxythymidine (FLT) were shown to penetrate the brain and systemic tissues in extracellular concentrations that exceeded *in vitro* antiviral concentrations (716). In some of these studies (717Ð719), the onset of disease and time to death were delayed. Lowering the challenge dose of SIV in monkeys resulted in a more dramatic antiviral effect of FLT, including complete prevention of infection in some animals (720,721). However, FLT proved too toxic for human application. Long-term AZT treatment of SIV chronically infected macaques resulted in suppressed viremia and slightly prolonged survival (717), similar to results with AZT monotherapy of HIV-1-infected humans. Early treatment with AZT could even prevent infection of newborn macaques with a low dose of SIV given orally, but had no effect on the course of disease when treatment was started after infection had been established (718). These results in SIV-exposed macaques are consistent with the prophylactic effect of AZT on lowering incidence of infection in newborns of HIV-1 infected pregnant women (722). AZT treatment signiÞcantly decreased virus load within the CNS and delayed onset of CNS dysfunction and immunodeÞciency in rhesus monkeys perinatally infected with SIV_{sm} (719). AZT resistant mutants of SIV are derived by *in vitro* and *in vivo* selection but not necessarily with the same kinetics and same point mutations as occur with HIV-1 (Tom North, pers. comm.). The macaque model provides a unique opportunity to test the infectivity and pathogenicity of such AZT-resistant SIV mutants occurring *in vivo*; one such mutant, Q151M, has been shown to be pathogenic in newborn macaques (723). The toxic effects of AZT in SIV-infected monkeys are similar to those observed in AIDS patients treated with AZT. Prophylactic treatment of macaques with didanosine (ddI) completely protected against SIV_{mac} infection and ddI, but not hydroxyurea, protected macaques against a lethal dose of the highly pathogenic SIV_{pbj114} (724). During acute infection ddI markedly reduced the virus load in SIV_{mac} infected macaques (725). A lipophilic dideoxy nucleoside analogue (6-cl-ddg) had a beneÞcial antiviral effect in rhesus monkeys acutely and chronically infected with SIV_{mac} (726,727).

The nucleoside analogue RT inhibitors (PMEA, PMPA) had a prophylactic or long-lasting therapeutic effect on SIV infection *in vivo*, if given before or soon after infection, but less effect if given therapeutically after infection is established (728Ð732). In macaques acutely and chronically infected with SIV_{mne}, treatment with PMEA had a more dramatic anti-SIV effect compared to AZT (732). In the last eight years, the most dramatic protection against SIV infection in the macaque model has been achieved with PMPA (Tenofovir), an acyclic nucleoside phosphonate inhibitor of HIV-1 and SIV RT. One hundred percent (25 of 25) of pigtailed macaques (*M. nemestrina*) given PMPA either before or up to 24 hours after challenge were completely protected against infection (733). The effectiveness of postinoculation therapy with PMPA depended critically on the timing of initiation and duration of treatment (634). PMPA is already phosphorylated and does not require cell cycle dependent thymidine kinase to become phosphorylated, as does AZT. Therefore, PMPA is active in resting cells, a property that may help explain its antiviral potency. Also, drug-resistant mutants may arise more slowly against PMPA than against PMEA or AZT. Short term treatment of newborn infected macaques with PMPA reduced virus level and prolonged survival (735,736). Early after PMPA treatment of acutely infected macaques, activated memory CD4+ T-cells repopulated the intestinal mucosa but showed a decreased ability to produce IL-2 (494). Infant macaques receiving prolonged treatment with PMPA developed SIV mutants with Þve-fold reduced susceptibility to PMPA *in vitro* (737). These mutants had the characteristic K65R mutation in RT and were cytopathic *in vitro*. PMPA still offered a strong therapeutic effect on macaques infected with these mutant viruses (738). PMPA also had a beneÞcial prophylactic effect on preventing oral infection of newborn macaques by the mutant SIV with a reduced susceptibility to PMPA (737). A topical PMPA gel prevented vaginal transmission of SIV (739). However, topical administration of PMPA failed to protected infant macaques against multiple oral exposures of low dose SIV (740). Administration of PMPA to gravid and SIV-infected macaques showed a signiÞcant placental transport, a sustained reduction in viral load in SIV infected fetuses and infants and improved survival (741). Unfortunately, severe growth retardation and bone related toxicity were noted in about 25% of the infants (742) along with transient effect on material bone biomarkers (734).

Treatment of acutely and chronically SIV-infected monkeys with PMPA led to a several log reduction in viral load, not quite as dramatic as the antiviral effect of HAART therapy in HIV-1 infected individuals (700). However, viral loads rebounded to pretreatment level by 2 weeks after termination of therapy. Post-exposure macaques that were protected by PMPA treatment from persistent productive infection had preserved SIV-speciÞc immune function, especially CD8+ lymphocytes, and were partially or completely protected from subsequent homologous virus rechallenge (744,745). The degree of protection conferred by PMPA is unprecedented in the simian AIDS model and suggests a promising role for PMPA in HIV-1 prophylaxis and post-exposure therapy in humans, if toxicity is not too severe.

Because of considerable dissimilarity between the SIV and HIV-1 proteases in their active sites (746), it was generally assumed that SIV would be less susceptible than HIV-1 to protease inhibitors. Therefore, protease inhibitors have not extensively studied, so far, in the SIV macaque model. One peptidomimetic protease inhibitor (U-75875) was shown to have a modest prophylactic effect in SIV-infected monkeys, by slightly reducing virus replication and slightly delaying disease onset (747). Recently, the susceptibility of SIV was found similar to HIV-1 and to three protease inhibitors, indinovir, saquinavir and ritonavir (701). Therefore, the SIV macaque model will be useful for studies of HAART, such as reservoirs of residual replication. Whether protease-resistant mutants arise just as quickly in the SIV model as with HIV-1 infection (748) remains to be determined. HAART is now being tested in this model against both SIV (749) and SHIV (750) challenge infection either alone or in combination with therapeutic vaccination (749,751). Toxic effects of protease inhibitors seen in humans, e.g wasting, lipodystrophy, have not been reported in the macaque model.

Attempts at immunotherapy using non-speciÞc immune modulating drugs, such as phosphocarbohydrates (752), IFN-α (753), IFN-γ, IL-2 or IL-12 (754), have been reported in the SIV or SHIV model often in combination with vaccination. Recombinant rhesus IL-12 had a signiÞcant protective effect vs. SIV infection and disease (749). In pathogenesis and vaccine-related studies, recombinant live SIV and infectious SIV vectors, expressing IFN-γ (693), IL-2 (755) or IL-4 (647) in the place of nef, have been constructed and tested *in vivo*. SIV IFN-γ or IL-4 constructs were attenuated for virulence and gave partial protection against challenge infection with virulent SIV (693,647). In newborn macaques, an SIV IL-2 recombinant caused acute death with lymphoproliferation and high virus load (644). In adult macaques, a similar recombinant was non-pathogenic and prone to deletion of the IL-2 gene (756). IL-2 treatment helped to restore CD8+ T cell effects or function in SIV infected macaques (757). Short-term treatment of chronically SIV infected macaques with IL-12 was well tolerated but caused no measurable change in virus load (758). Recombinant rhesus IL-16 reduced the infectivity of SIV_{mac} for rhesus PBMC *in vitro* (759). In SIV infected cells interferon blocked an early step in viral replication, between virus binding and reverse transcription (760).

Non-speciÞc antigenic stimulation with conventional antigens during primary infection of macaques with SIV increased the virus load and, possibly, accelerated the disease (396). T-cell activation is well known to enhance replication of SIV and HIV in resting lymphocytes (761). HIV-1 chronically infected adults given IL-2 also had a sudden increase in virus load, but tended to also show an increase in CD4 T cells (762). Similarly, transient activation of HIV-1 replication has been observed after inßuenza vaccination or antigenic stimulation of HIV-1-infected individuals (763Ð765). Methadone, a treatment for opiod dependency, was found to induce CCR5 and activate SIV replication *in vitro* (766).

Other targets for therapeutic intervention, such as the CD4 receptor or chemokine coreceptors, and the viral Tat, Rev, Nef, Vpu, Vpr, Vif and nucleocapsid proteins, can also be targeted in the SIV macaque model (767). Both passive administration of recombinant soluble human CD4 to SIV-infected monkeys (768), or active immunization of infected or uninfected monkeys with this protein, which elicited CD4 binding antibodies, had only a transient beneÞcial effect on virus expression (769,770). A humanized anti-CD4 antibody transiently decreased plasma viremia in SIV infected macaques but its effect was limited by development of anti-antibody responses and CD4 independent SIV variants (771,772). Adaptive transfer of SIV naïve CD4+ cells to SIV chronically infected macaques rescued cell mediated immune responses and induced long-term non-progressor status, even in the absence of continued antiviral therapy (771). Gene therapy with antisense RNA against SIV, engineered into CD4+ or Cos-1 cells through a retrovirus vector or transfection, inhibited SIV replication *in vitro* (761,773). Macaques infused with autologous CD4 enriched lymphocytes, transduced with a retroviral vector expressing an antisense *tat/rev* gene, had a signiÞcant reduction in viral load and maintained stable CD4+ cells for more than one year after SIV challenge (774). Transduction of rhesus CD34+ hematopoietic stem cells with a hairpin anti-SIV ribozyme protected T cells and macrophages from SIV infection *in vitro* (775). Macaques infused with interferon engineered lymphocyte appeared to gain some protection against SIV disease (776). As a possible model for autotransfusion therapy, rhesus CD4+ T cells were activated and expanded with anti-CD3/CD28 coated beads; such cells maintained their immune function but exhibited an unstable anti-SIV effect *in vitro* requiring continuous exposure to the CD3/CD28 antibodies (777). A human chorionic gonadotropin associated factor in pregnant womenÕs urine had a beneÞcial effect on SIV infection *in vitro* and *in vivo* (778). For future antiviral and pathogenesis research, a full battery of macaque lymphokine genes has been cloned and sequenced (779,780).

Lentivirus-derived vectors are promising gene delivery systems because, unlike murine leukemia virus-based vectors, they are able to transduce nonproliferating differentiated cells. Highly efficient vectors derived from SIV_{mac251} were constructed and shown capable of transducing human primary dendritic cells, which might provide a novel approach to immunotherapy (781). A novel lentivirus vector consisting of an HIV-1 derived genome encapsidated by SIV_{mac} core particles and pseudotyped with VSV glycoprotein efficiently transduced human lymphocytes, macrophages and bone marrow stem cells (782). This vector may be safer than HIV-1-based vectors because of the decreased likelihood of recombination between transfer and packaging vectors.

The SIV macaque model has demonstrated the efficacy of vaginal microbicides as a strategy against HIV sexual transmission (783). Topical application of the spermicide non-oxynol-9 (784), PMPA (739), cellulose acetate phthalate cream (785) or estrogen (786), were effective in blocking transmission of SIV_{mac} across the macaque vaginal mucosa.

The need to evaluate other novel therapies in the SIV or HIV-2 macaque models will become even more imperative when we learn more about the molecular mechanisms of pathogenesis and are able to pinpoint more specific viral and host targets for drug intervention. The potential clinical benefit of early treatment, at or before seroconversion, can best be defined in the macaque. Such antiretroviral treatment may help control not only SIV disease but also opportunistic infections such as mycobacteria (787). Convincing evidence, obtained in the SIV macaque model, that enhancing cellular immune responses (788) and lowering the initial virus level by anti-SIV drug treatment or vaccination (or a combination of both) leads to a significant restriction of virus replication and significant delay in disease onset, provides further impetus for early drug and vaccine intervention in HIV-1 infected persons.

Antiviral Treatment Against SHIVs

Some non-nucleoside RT inhibitors now in clinical trials (delaviridine, nevirapine) are active only against HIV-1 RT and not against SIV or HIV-2 RT (789). To test RT inhibitors of this type, recombinants of SIV bearing a functional HIV-1 RT gene (RT-SHIV) have been constructed and shown to be infectious and pathogenic in macaques, and acute infection of macaques with this RT-SHIV has been suppressed by pretreatment with a novel HIV-1-specific RT inhibitor (790,791). Short term (4 weeks) post-exposure prophylaxis (PEP) commencing 8–24 hours post infection reduced viral load to undetectable levels for a prolonged period of time (90 weeks) and led to long term disease protection. In cell culture, the non-nucleoside RT inhibitors selected for similar mutations in SHIV-RT as in HIV-1 RT (792). As expected, RT-SHIV was also similar to SIV in susceptibility to protease inhibitors (701). The RT-SHIV macaque model thus offers the opportunity to study HAART with all classes of drugs currently approved for therapy of HIV-1.

Macaques treated with PMPA for eight weeks starting 7–14 days after infection with RT SHIV had suppressed viral replication (793). After chemotherapy ended, two of the six monkeys continued to maintain a low virus load and were able to resist infection with a highly pathogenic heterologous SIV. This treatment thus mimicked a vaccination effect similar to that induced by live attenuated SIV. In one of two RT-SHIV chronically infected macaques, PMPA treatment caused a decrease in viremia, which was apparently sustained after SIV subunit vaccination (794), thus giving further support for a combined chemotherapy vaccination approach. Cynomologus macaques infected with RT-SHIV and treated with the non-nucleoside RT inhibitor nevirapine developed RT mutants which corresponded to the HIV-1 mutations in nevirapine resistant HIV-1 patients (795).

PEP with PMPA was able to reduce perinatal infection with SHIV33 env given IV and SIV_{mac251} given orally (796). PMPA given 1 week after infection with SHIV-env (KU) and continuing daily for 83 days led to a reduction of virus burden below the level of detection and stabilization of CD4+ T cell levels (797,798). After cessation of therapy, animals subsequently controlled the virus, maintained normal T-cell counts and developed virus specific neutralizing antibody, T-helper cells and CTLs. These results suggest that antiviral treatment, if started early during infection, might help the host mount an effective immune response. However, PEP with HAART could not completely protect macaques from SHIV infection (799). By contrast, topical vaginal administration of a broadly neutralizing human monoclonal antibody could protect macaques from SHIV infection through the vagina (800). SHIV 89.6 P intravaginal infection has also been inhibited by novel chemical virucides that might prove useful in humans as "chemical condoms" (801).

HIV-2 Macaque Model: Antiviral Therapy

Early postinfection antiviral therapy with an RT nucleoside inhibitor (d4T), even of limited duration, has proven effective for long time (>1 year) control of pathogenic HIV-2287 challenge infection in pigtailed macaques (802). PMPA was able to prevent intravaginal infection of pigtailed macaques with pathogenic HIV-2287, if treatment was initiated 12–72 hours following HIV-2 exposure and was continued for 28 days (803). HAART therapy suppressed the maternal virus load and prevented the mother to fetus transmission of HIV-2287 in pigtailed macaques, if treatment was started 30 minutes after HIV-2 inoculation (804). None of these studies were carried out long enough to test for the emergence of drug resistant HIV-2 mutants.

SIV and SHIV Macaque Models. Therapeutic or Passive Immunization

In contrast to the well established rationale for passive immunotherapy with antibody or immunoglobulin, the concept of actively immunizing already infected individuals with viral immunogens from the same kind of virus causing the infection is novel and controversial (805). Proven successes in humans of a combination of passive and active vaccination against rabies and hepatitis viruses before infection becomes established, and against genital herpes virus infection in chronically infected guinea pigs (806), suggested that HIV-seropositive, asymptomatic humans, who were still immunocompetent, might be able to respond immunologically to inoculation with HIV immunogens and thereby hold the virus in longer abeyance. Historically, previous efforts at postinfection immunization of non-immunosuppressive lentivirus infections in sheep and goats were not successful and caused enhanced disease (807). Whether or not such therapeutic vaccination strategies will be effective or harmful in treatment of the immunosuppression lentiviral diseases of cats, monkeys, and man remains uncertain. Initial efforts to evaluate the feasibility of this therapeutic strategy in chronically infected macaques, using either inactivated whole SIV or live attenuated SIV were unsuccessful (808,809). No detectable effect on virus titer, immune response or clinical course was noted, even when the immunogen was administered soon and repeatedly after infection. Results of phase I and II trials of an inactivated whole HIV-1 preparation and of recombinant HIV-1 env gp120 immunogens in HIV-1 seropositive humans, have indicated that some of the volunteers do indeed register antibody and cell-mediated immune responses to additional HIV epitopes, not recognized during the natural infection (810,811). However, phase III trials have shown no clinical beneÞt in terms of virus load, CD4 count, opportunistic infections, or survival (812). Of current interest is the possibility that active vaccination after potent antiviral therapy has markedly reduced the viral load may prove of beneÞt to infected individuals. Support for the notion has been demonstrated in the SIV macaque model (751,813).

Passive immunization experiments in the SIV macaque model have given conßicting results, probably attributable to differences in the challenge virus, host species, age and quality or quantity of antibody transferred. In the prototypic SIV_{mac} rhesus macaque model, passive transfer of high-titered neutralizing antibodies from asymptomatic carriers failed to protect against challenge infection with the homologous virus (568,569) and, in one study (568) may have enhanced infection. Passive protection that was achieved using antibodies from macaques immunized with inactivated whole SIV_{mac} vaccines was attributed to antihuman cellular antibodies rather than to neutralizing antiviral antibody.

Infusion of serum immunoglobulins (SIVIG) puriÞed from SIV_{mac251} infected macaques into other SIV_{mac251}-infected macaques undergoing a rapid disease course had only a modest, transient effect on SIV RNA and cell-associated virus load, an effect that was not attributable to neutralizing antibody (814). Interestingly, passive immunoglobulin transfer failed to protect African green monkeys from SIV_{agm} infection despite the presence of neutralizing and ADCC antibodies (330). On the other hand, partial or complete passive protection of adult macaques against SIV has been achieved in other clinical settings using SIVIG (815) or inactivated serum-from SIV-infected macaques (816,817), and in newborns challenged orally with SIV after subcutaneous administration of SIV hyperimmune serum (818). Newborn macaques were also protected by the passive transfer of antibodies from SIV vaccinated mothers (819). An extensive passive immunotherapy study of symptomatic HIV-1 infected individuals, showed only a minimal viral suppressive effect, and no evidence of disease acceleration (820).

Passive protection in the SHIV-env macaque model has proven successful using anti-HIV-1 neutralizing monoclonal antibodies and HIV-1 immunoglobulin, alone or together (821Ð824). Antibody treated macaques were either completely protected against infection or against disease manifestations of SHIV infection following IV, oral or vaginal challenge. However, to achieve sterile protection vs vaginal SHIV exposure required serum neutralizing antibody titers of about 1:400 (825). Best results were obtained using three human monoclonal antibodies together, a contribution that was previously shown to the synergistic *in vitro* (826). By contrast, anti-SHIV neutralizing serum that protected macaques against IV inoculated pathogenic SHIV failed to protect against intrarectal challenge with the same virus (827). Anti-SHIV antibodies obtained from an HIV-1 infected chimpanzee were able to protect macaques against iv challenge with a pathogenic SHIV but only if the antibodies had anti-SHIV neutralizing activity as determined *in vitro* (828). The titer of neutralizing antibody in the plasma calculated to protect 99% of virus challenged monkeys was 1: 38 (829).

Taken together these passive immunization experiments against SIVs and SHIV envs indicate that under appropriate lab condition, passive protection can be successful against systemic or mucosal virus exposure. Neutralizing antibodies and possibly ADCC antibodies can be effective when they are directed at a sufÞcient narrow window of envelope epitopes. Just as with active immunization, achieving passive protection against the diversity of HIV-1 genotypes in circulation worldwide remains a formidable obstacle.

HIV-2 Infection of Macaques and Baboons

HIV-2 strains are closely related to the SIV_{mac}/SIV_{sm} subgroup of primate lentiviruses and probably originated

within the last 40–300 years (830) from multiple cross-species transmissions of SIV to humans from feral sooty mangabeys in West Africa (33,831). HIV-2 infection is still largely confined to West Africa (832), where it has reached epidemic proportions, but it has begun to spread worldwide (833). In humans, HIV-2 infection is less pathogenic than HIV-1 (834), and HIV-2 infection may confer partial protection against HIV-1 coinfection (835), although this is by no means certain (836). *In vitro* evidence suggests that B-chemokine mediated resistance may contribute to HIV-2 protection against HIV-1 infection (837). Cross-reactive CTLs could also play a role in cross protection (838). The genetic diversity and prevalence of HIV-2 isolates suggest that some strains may represent dead-end infections (831). *In vitro*, the HIV-2 Env protein gp105 has stronger immunosuppressive properties than HIV-1 Env gp120 (839). *In vivo*, this effect could be beneficial to the host by dampening immunocellular activities and bursts of viral replication that characterize HIV-1 infection. HIV-2 infection of humans is covered in the chapter by Kanki in this volume.

Initially, several different strains of HIV-2, including molecular clones, were inoculated into different species of macaques, sooty mangabey, and baboons, and although causing either transient or persistent infection and humoral and cellular immune responses, failed to induce AIDS (840–842). As also seen in SIV-infected macaques and HIV-1 infected humans, the CTL recognition in HIV-2-infected macaques was very broad, comprising the major structural virion proteins as well as regulatory proteins (844). Compared to pathogenic infection of macaques with SIV or humans with HIV-1, HIV-2-infected asymptomatic macaques showed little viral variation and lacked neutralization escape mutants (845,846). Such animals also showed helper T cell proliferative response to infection (847). In several HIV-2-infected monkeys antiviral CTL activity was detected only in lymphoid tissues and not in blood; therefore monitoring of PBMC only may not adequately represent the situation *in vivo* (848).

By contrast, highly reproducible induction of unequivocal simian AIDS has been accomplished at the University of Washington Primate Center by serial passage of the EHO strain of HIV-2 in pigtailed macaques (*Macaca nemestrina*) (849). The pathogenic strain, designated HIV-2287 and the parental HIV-2_{EH0} strain both predominantly use the CXCR4 co-receptor but the 287 strain shows greatly enhanced replicative capacity in macaque PBMCs (850). Within 10–14 days post infection with HIV-2_{287} the lymph nodes especially in the gastrointestinal tracts show a dramatic shift from disseminated infected cells to virus concentrated in follicular centers with cell destruction (851). This shift in virus localization indicates a narrow window for therapeutic intervention at this early stage of HIV infection. This is also a useful model for maternal-neonatal transmission (852). Another chronic disease causing HIV-2 strain, HIV-2_{GB122}, was shed in semen of acutely infected pigtailed macaques, thus providing a basis for evaluating antiviral therapies targeting male genital tract expression (853). Importantly, several other HIV-2 $strains_{UC\text{-}2,\ UC\text{-}14}$ have induced persistent infection, loss of CD4 lymphocytes and AIDS-like symptoms including retroperitoneal fibromatosis in baboons (854,855). Serial transmission of HIV-2 (UC-2) in baboons has led to increased kinetics of viral replication in baboon PBMC and cytopathicity (856). Control of HIV-2 infection in baboons may in part be attributed to soluble antiviral factors released from CD8+ cells (857), and other effects of immune activation (858). It thus appears that, given the right virus-host combination, persistent infection and progression to AIDS can result from HIV-2 induction of pigtailed macaques and, possibly, baboons. Asymptomatic baboons preinfected with one strain of HIV-2 were resistant to superinfection with another strain of HIV-2 (859). Pigtailed macaques preinfected with one non-pathogenic strain of HIV-2 could be superinfected with a second non-pathogenic strain of HIV-2 only within 8 hours of the first infection (860). Molecular clones of HIV-2, infectious but non-pathogenic for macaques and baboons, are available (861,862). Both the HIV-2 287 pigtailed macaque and baboon HIV-2 models appear suitable for AIDS pathogenesis and vaccine studies (863).

Vaccination of Macaques vs. HIV-2

Partial, or complete, long-lasting (>1 year) protection of cynomolgous or rhesus macaques against homologous HIV-2 strains grown on macaque PBMC has been achieved by vaccines made of inactivated whole virus (864,865), inactivated whole virus plus booster immunization with V3-derived synthetic peptides (866), native envelope (867–869), recombinant env, gag, and pol expressed in attenuated vaccinia virus or canary pox virus (870–872), and by passive immunization with plasma from whole virus immunized monkeys (873). Partial protection or delayed infection in rhesus or cynomolgous macaques immunized with the attenuated vaccinia virus or canary pox recombinant plus protein or peptide boosts has been associated with an anamnestic neutralizing antibody response on challenge although no clear cut immunologic correlation with protection was apparent (872,874,875). Protection against a heterologous strain of HIV-2 was not achieved with another recombinant vaccinia HIV-2 vaccine (876). An HIV-2 recombinant salmonella vaccine given orally failed to protect macaques against the homologous virus (870). In all of these studies, the correlates of immune protection remained uncertain. In particular, there was no correlation between the levels of neutralizing antibodies or the presence of virus specific CTL and protection against infection with HIV-2 or SIV_{mac} in the HIV-2 vaccinated monkeys (871). In contrast to the immune protection conferred by inactivated whole SIV vaccines, antihuman cellular antibodies were not involved

in protection since the challenge virus was grown in allogeneic monkey cells. Prior infection of some but not all macaques with live attenuated HIV-$2_{SBL-6669}$ or HIV-2_{rod} prevented superinfection with pathogenic SIVs given IV or intrarectally and markedly delayed disease in those animals that were superinfected (663,877,878). Disease was similarly retarded in macaques infected with HIV-2 and superinfected with SIV_{mac}, which also reactivated the latent HIV-2 infection (879). This partial protection appeared to depend on a speciÞc proliferative T-cell response early after infection. By contrast, preinfection of macaques with the weakly pathogenic HIV-2rod isolate protected only one of six macaques from intrarectal infection with SIV_{mac}, but no protection from superinfection or progression of disease was evidenced in the other Þve monkeys (880). Vaccination of cynomolgus monkeys with a canary pox (ALVAC) HIV-2 vaccine followed by exposure to live HIV-2 induced cross protection against mucosal infection with SIV_{sm} which seemed more effective than immunization with live HIV-2 alone (881). Pigtailed macaques infected with a non-pathogenic HIV-2 molecular clone (HIV-2KR) were largely protected from superinfection with the highly pathogenic HIV-2287 strain (882,883). Protection appeared to correlate with strong CTL responses and antigen speciÞc T-helper type 1 responses (884). Of note, crossprotection against HIV-2 challenge was obtained in rhesus macaques by immunization with an HIV-1 recombinant poxvirus vaccine (NYVAC) (885). No clear correlates of protection were discerned. However, rhesus macaques immunized with NYVAC HIV-2 were not protected against SHIV challenge (886). This demonstration of at least partial experimental cross protection between HIV-1 and HIV-2 adds further evidence that viral variability may not be an insurmountable obstacle in the design of a global AIDS vaccine.

SHIV Infection of Macaques

Chimpanzees are the only animals susceptible to HIV-1 infection, but they do not develop disease, at least within 10 years after infection, and they are too impractical and limited in number for AIDS research. After initial unsuccessful efforts to infect rhesus and other macaque species persistently with HIV-1, it was found that pigtailed macaques (*Macaca nemestrina*) were more susceptible to infection with certain T-cell-adapted HIV-1 strains (887). However, further research conÞrmed that only transient (8Ð24 weeks) productive infection and no disease occurred despite a high dose HIV-1 inoculum. Moreover, the majority of primary HIV-isolates were unable to infect these monkeys (888).

Therefore, for the purpose of developing a non-human primate model for replication of HIV-1 genes on a SIV genetic background, many recombinants (chimeras) between SIV and HIV-1 (SHIVs) have been constructed in the last 10 years and tested for infectivity and pathogenesis in macaques and baboons. Nomenclature of some of the SHIVs, confusing because of the lack of systemic designation, and their tropism and pathogenicity for macaques is shown in Table 10.4. The Þrst recombinants replaced the *env*, *tat*, *rev* and *vpu* genes of SIV_{mac239} with their counterparts from HIV-1 T-cell tropic IIIB strain and related subgroup B strains (SHIV*env*) and were non-pathogenic for macaques and baboons (889Ð891). Other non-pathogenic or weakly pathogenic SHIV envs were constructed from macrophage-tropic as well as T-cell-tropic strains of HIV-1 (892Ð895). The initial non-pathogenic HIV-1 SHIVenv constructs induced a high level of acute viremia, a transient decline in CD4 T cells and a low-level persistent infection. In baboons, the SHIV *env* recombinants induced only a transient infection and no disease. SHIV env-infected macaques made antibodies to the HIV-1 env and SIV core antigens and cytotoxic T lymphocytes speciÞc for HIV-1 env glycoprotein. In general, the viral load of the non-pathogenic SHIV-env recombinants in rhesus macaques was 10Ð100 times greater than that of HIV-1 IIIB infection of pigtailed macaques (887) and equal to the viral load seen during the acute stage of infection if rhesus macaques with SIV_{mac}, but after six to eight weeks, the level of SHIV-env infection dropped signiÞcantly. Virus persisted for more than one year, as demonstrated by PCR ampliÞcation of viral DNA in all animals and by virus isolation in some animals.

After serial passage (1Ð3X) of blood or bone marrow in macaques, at least Þve of the initially non-pathogenic SHIV envs reverted to virulence (896Ð902). These monkeys had a persistently high virus load, profound lymphoid activation (903,904), precipitous and irreversible fall of CD4 T cells in blood, lymph node and gut, and developed AIDS in two to four months. This dramatic loss of CD4+T cells was more severe than seen with HIV-1 infection of humans and its pathogenesis remains uncertain. Sequence analysis of SHIVs recovered from monkeys with accelerated AIDS revealed HIV-env mutations associated with escape from neutralizing antibodies and tissue speciÞc selection of HIV-1 env genotypes (905). These env mutations were also associated with increased chemokine receptor binding, increased CD4 cell apoptosis (906), and increased membrane-fusing capacity (907).

Pathogenic SHIVs have also been derived by SIV recombinants with HIV-1 RT (RT-SHIV) (902,908) (see above) and HIV-1 Nef (SHIV-nef) (909Ð911). Non-pathogenic SHIVs or weakly pathogenic SHIVs have been constructed from HIV-1 env subgroup A (912), HIV-1 env subgroup E (912,913), HIV-1 env subgroup C (914,915) and HIV-2 core and env (916). In baboons, one HIV-1 subgroup C SHIV env construct caused persistent infection but no disease (917).

Although useful for experimental transmission by various routes including mucosal (918Ð921), and for pathogenesis (905,922,923) and antiviral studies (see

above), SHIVs Ð envs have been employed primarily for vaccine research directed at inducing immunity against HIV-env determinants. Particularly useful will be the SHIVs bearing HIV-1 env glycoproteins from non-B subgroups found commonly in Africa and Asia. In general, live attenuated SIV or SHIV envs or HIV-1 env ± gag or tat recombinant proteins have constituted the vaccines against challenge with non-pathogenic or pathogenic SHIV envs or pathogenic SIV. Not surprisingly, vaccine partial protection has been easier to achieve: (1) with live attenuated virus rather than recombinant vaccines; (2) against non-pathogenic rather than pathogenic SHIV variants; (3) and against homologous rather than heterologous SHIV challenge (Tables 10.5 and 10.6). Protection has been achieved against systemic or mucosal challenge and has been characterized by a persistent and signiÞcant (approximately 2Ð3 log) reduction of viral load and lack of disease (< 6 months) compared to sham vaccinated controls. To date, the vaccine and challenge HIV-1 env antigens have been homologous and from subgroup B isolates. In line with most SIV macaque vaccine studies no consistent correlates of protection have become apparent. Humoral, cellular and innate immunity all contribute to protection but broad protection against the diversity of viral variants faced in nature remains a formidable vaccine obstacle yet to be overcome.

SigniÞcant protection was achieved by SHIV env DNA vaccines against pathogenic SHIV env challenge (936,937). SHIV 89.6P challenge followed immunization with DNA expressing homologous SIV core and HIV-1 subgroup B env proteins. Boosts were given with either an IL-2/Ig fusion protein (936) or vaccinia vectors expressing the same immunogens (937). In the Þrst study (936), all IV challenged monkeys became infected but suppressed the virus and suffered no clinical disease for at least 140 days after challenge by which time half of the controls had developed SAIDS. In the second study (937), macaques were similarly partially protected against intrarectal challenge given seven months after the last boost. The virus was still under control 70 weeks post challenge (962). A modiÞed vaccinia (Ankara) SIV vaccine alone appeared to achieve protection equal to that of the monkeys Þrst

primed with SIV DNA (963). The same DNA + boost vaccines without env DNA did not protect as well (964). Evidence suggested that protection was mediated mainly by cellular immunity, viz, CTLs, but CD8 T cell depletion studies showed that neutralizing antibodies also contributed to virus control (966). Another SHIV DNA prime protein boost vaccine also showed some efÞcacy vs. pathogenic SHIV challenge (966). These and other SIV and SHIV vaccine results, raise hope that prophylactic HIV-1 vaccines may signiÞcantly prolong life of HIV-1 exposed humans even if they do not prevent infection. Unfortunately, these vaccines may fail because of the eventual development of viral CTL escape variants (967). However, it remains to be seen whether the same

beneÞcial effects on virus load and disease will be observed in vaccinated humans exposed to more heterogenous virus mixtures and where the pathogenesis may differ somewhat from the highly virulent, artiÞcial SHIV model.

SIMIAN FOAMY VIRUSES

Simian foamy viruses (SFV), members of the spumavirus genus of retroviruses, are prevalent in a variety of non-human primates and other animal species, including cats, hamsters, sea lions, horses and cows, in which they cause persistent latent and asymptomatic infections (968, 969). Non-human primates known to harbor multiple strains (serotypes) of these viruses include prosimians, macaques, African green monkeys, baboons, mandrills, apes and chimpanzees. In their natural host, these viruses are highly prevalent and the latent infection occurs in the presence of neutralizing antibody. Proviral DNA without detectable viral RNA or protein expression can be detected in all organs of the natural hosts and in peripheral blood lymphocytes, especially CD8+ T-lymphocytes, whereas minimal virus replication is restricted to the oral mucosa (970Ð972). Despite Þnding the same SFV serotype in different species, genetic comparisons imply that SFVs have generally coevolved with their hosts, rather than spreading between species (973Ð976). Although a putative human foamy virus (HFV) isolate was reported in 1971, it now seems, based on the lack of further independently derived human foamy virus isolates, and on close genomic and functional similarities between HVF and the chimpanzee foamy virus (SFVcpz), that HFV represents a human cell culture contaminant with a foamy virus from chimpanzee (977,978). Indeed, HFV has recently been renamed SFVcpz (hu) to identify its origin from a chimpanzee. Screening of over 10,000 human sera from all over the world using current serologic assays and PCR probes has failed to conÞrm any foamy virus prevalence in man (979). Moreover, the reported association of human foamy virus in the pathogenesis of Graves disease, autoimmune thyroiditis, chronic fatigue syndrome, amyotrophic lateral sclerosis, or as a cofactor in AIDS, could not be conÞrmed. However, this screening revealed a few cases of accidental human infection after monkey bites or laboratory contamination, thereby indicating that humans are susceptible to primate foamy viruses. Among 231 humans occupationally exposed to non-human primates in U.S. and Canadian primate facilities, four individuals (1.8%) were found infected with SFV from an African green monkey (one person) (980) and baboons (three people) (981). Among 133 zoo keepers who worked with primates, 4 individuals (3%) were seropositive for SFV, primarily with chimp-like viruses (982). Two of 46 primate facility workers were latently infected with macaque foamy virus (983). However, SFV infection was not detected in any of 17 hunters exposed to wild monkeys in West Africa (984). Importantly, no health problems were associated with these accidental infections, and no evidence was found for human-to-human transmission. Following accidental infection of humans, SFV persists as proviral DNA without any production of infectious virus (980,983). In the future, we cannot, of course, ignore the risks of SFV infection in transplant recipients of baboon organs (985).

In vitro, the foamy viruses (FV) are highly cytopathic, i.e. syncytia inducing, and have a broad host range, including cultured epithelial, Þbroblast and lymphoid cells. In common with oncoviruses, but unlike lentiviruses, SFV requires host cell proliferation for productive infection (986). The virus can be isolated from coculture of several organs and tissues including lymph nodes, brain and PBLs. Apoptosis of Þbroblast or lymphoid cell *in vitro* can be induced by SFV-1 (987). The fusogenic property of all foamy viruses is controlled by an evolutionarily conserved postively charged amino acid in the membrane spanning domain of the virus envelope protein (988). A critical cleavage site in HFV env controls virus maturation, infectivity and syncytia formation (989). Fine structural analysis of HFV env glycoprotein reveals a trimer with long tapering spikes 14 nm in length (990), which accounts for their characteristics appearance under the electron microscope. The cellular receptors for SFVs have not yet been identiÞed although they are ubiquitous and speciÞcally bind recombinant SFV envelope protein (991). Integration of SFV_{cpz} (hu) intact proviral DNA into HFV-infected human erythroleukemia-derived cells (H92) occurs at multiple independent sites on different chromosomes (992). Although these viruses have not been causatively linked to any histopathological changes or disease in any species (2), rabbits experimentally infected with SFV appeared to become transiently immunosuppressed (993), and transgenic mice expressing FV genes have developed neurological disease (994,995). The major signiÞcance of these viruses has been the annoying cytopathic effect that they cause *in vitro*. The derivation of herpes-virus saimirii-transformed T-cell lines from macaques, a necessary research tool for studies of cellular immunity in simian AIDS, has been markedly hampered by the reactivation of SFV with consequent cytopathic effect (996). Also, because they are retroviruses with reverse transcriptase activity, foamy viruses are apt to cause false alarms in the search for other potentially pathogenic retroviruses such as SRV, SIV or STLV. FV replication is resistant to most nucleoside analog RT inhibitors. Only zidovudine was equally efÞcient against HIV-1 and SFV (997,998).

The molecular biology of foamy viruses (FV) has revealed interesting and unique features of their replicative cycle and functional differences, including the method of packaging genomic RNA, the mechanism of pol expression and aspects of regulating viral gene expression (2). The genomes of simian foamy virus type 1 (SFV-1) and type 3 (SFV-3) isolates obtained from a rhesus macaque and African green monkey, respectively, have been molecularly cloned, completely sequenced, and compared

to the sequences of the cloned SIV_{cpz} (hu) (999–1002). More recently, another strain of SFV from the Taiwanese-*Macaca cyclopus* was isolated, cloned and sequenced (1003). The genomes of SFV-1 and SIV_{cpz} are closely related, with about 80% homology in the *pol* genes and about 70% homology in the *env* gene. The SFV-1 LTR is unusually long (1621 base pairs) and shows about 85% homology with SIV_{cpz} in the R and U5 regions but considerable divergence in the U3 region (25% homology). The FV genome encodes a large open reading frame (ORF) beyond the *env* gene that has been shown by transient expression assays *in vitro* to encode a transcriptional transactivator (*Tas*, also known as bel-l in SIV_{cpz} (hu). Tas is a DNA binding protein that acts on two separate and independent promoters, one in the U3 portion of the LTR and the other internal in the 3′ portion of the envelope gene (1004). Differential use of the LTR and internal promoters (IP) for initiating differently sized genomic transcripts appears to be a means of temporal regulation of foamy virus gene expression in different cell types (1005–1008). The IP direct expression of Tas and a second accessory protein, Bet, which functions as a negative regulator of basal IP activity (1009). The ony known inhibitor of FV replication, the promyelocytic leukemia protein, which binds Tas, does not mediate FV latency *in vitro* (1010). In lytic infections both the LTR and IP are efficiently transactivated by *Tas*, while in persistent latent infections, the IP is efficiently transactivated by *Tas*, but the LTR is not (1011). The DNA target elements in the IP which bind *Tas* and allow its transactivating function were further defined (1012). The SFV-1 tas DNA binding site has been narrowed down to a 25 bp consensus sequence in the IP (1013). A *Tas*-responsive enhancer element was recently identified at the 3′-end of *gag*, immediately upstream of the *gag-pol* overlap region (1014). Mutational analysis of the 5′ leaders region of SFV-1 has further defined separate *cis*-acting elements required for genome dimerization and packaging (1015). Certain cellular genes are also induced by Tas in HFV-infected human cells (1016).

An understanding of the regulation of FV gene expression will further our understanding of the molecular mechanisms that control retrovirus latency, persistence, and replication in the host animal. Also, because of their efficiency of transfection and large packaging capacity, non-infectious FV vectors made by replacing the *Tas* gene, a portion of the envelope gene and other modifications, have proven to be efficient gene transfer vehicles and, thus, may prove useful for a wide variety of gene transfer applications (1017,1018). At least two *cis*-acting elements, one in the leader region, one in the *pol* gene, are required for SFV-1 vector construction (1019,1020). The first stable packaging cell lines for SFV-1 vector are now available, a step toward the use of SFV-1 vector delivery systems for gene therapy (1021). A minimum SFV-1 genome vector system capable of accommodating a minimum 8930 base pair heterologous DNA fragment has been constructed (1022). SFV vectors have been able to stably transduce marker genes into the host cell genomic DNA *in vitro* (1023,1024), and an SFV-1 vector has successfully transduced human umbilical cord blood, CD34+ cells capable of repopulating NOD/SCID mice (1025,1026).

GLOSSARY

Primate Retroviruses

TRV = Tree shrew endogenous virus
BaEV = Baboon endogenous virus
Mac-1 = Stumptail macaque endogenous virus, strain 1
MMC-1 = Rhesus macaque endogenous virus, strain 1
CPC-1 = Colobus monkey endogenous virus, strain 1
OWC-1 = Owl monkey endogenous virus, strain 1
GaLV = Gibbon ape leukemia virus
SSAV/SSV = Simian sarcoma associated virus/simian sarcoma virus
STLV-1 = Simian T-lymphotropic virus, strain 1
HTLV-1 = Human T-lymphotropic virus, strain 1
STLV-2 = Simian T-lymphotropic virus, strain 2
HTLV-2 = Human T-lymphotropic virus, strain 2
SRV = Simian Type D retroviruses, strains 1–6
MPMV = Mason Pfizer monkey virus (SRV-3)
Po-1-Lu = Langur (Presbytis) endogenous virus
SMRV = Squirrel monkey endogenous retrovirus
HIV-1 = Human Immunodeficiency Virus, Strain 1
HIV-2 = Human Immunodeficiency Virus, Strain 2
SIV = Simian immunodeficiency virus
SFV = Simian foamy virus
HFV = Human foamy virus
SAIDS = Simian acquired immunodeficiency syndrome
HERV = Human endogenous retrovirus
SERV = Simian endogenous retrovirus
PcEV = Papiocynocephaleus retrovirus

Non-primate Retroviruses

MuLV = Murine leukemia virus
MMTV = Murine mammary tumor virus
ALV = Avian leukosis virus
BLV = Bovine leukemia virus
BIV = Bovine immunodeficiency virus
FeLV = Feline leukemia virus
FIV = Feline immunodeficiency virus
EIAV = Equine infectious anemia virus
SMRV = Squirrel monkey retrovirus
IAP = Intracisternal A particle
CAEV = Caprine arthritic encephalitis virus
KoRV = Koala retrovirus
TuERV = Bushtail possum endogenous retrovirus
RD114 = Feline endogenous retrovirus
VMV = Visna maede virus
RSV = Rous sarcoma virus

Antiviral Therapy

AZT = 3′-azido-3′-deoxythymidine
ddC = 2′,3′-dideoxycytidine
ddI = 2′3′dideoxyinosine
d4T = 2′3′-didehydro-2′Ð3′-dideoxythymidine
PMEA = 9-(2 phosphonylmethoxyethyl)adenine
PMPA = 9-(2 phosphonylmethoxypropyl)adenine
FLT = ßurodeoxythymidine

ACKNOWLEDGMENT

We wish to thank Francisco Javier Holquin for preparing the Þgures.

Chapter 11

Immunode ciency in HIV -1 Infection

Ahmad R. Sedaghat and Robert F. Siliciano

Infection with the human immunodeÞciency virus type 1 (HIV-1) (1,2) initiates an intricate and fascinating series of host-virus interactions, the ultimate consequence of which is profound impairment of the host immune system. The extraordinary complexity of the host-virus interactions in HIV-1 infection results in part from the fact that HIV-1 infects two cell types that are involved in virtually all immune responses, CD4 + T lymphocytes and cells of the monocyte-macrophage lineage. How virus infection of these cell types leads to immunodeÞciency is the central question in AIDS immunology.

The acquired immunodeÞciency syndrome (AIDS) (3Ð7) resulting from HIV-1 infection is characterized by numerous immunologic abnormalities, the most prominent of which are severe quantitative and qualitative defects in the CD4 + T lymphocyte compartment. In their initial clinical studies describing an acquired immunodeÞciency condition in homosexual men, Gottlieb et al. (5) made the fundamental observation that affected individuals had a decreased concentration of CD4 + T cells in the peripheral blood. Subsequently, prospective studies have shown that much of the decline in CD4 + T cell counts occurs during the asymptomatic period between initial infection and the development of clinical immunodeÞciency. In adults, the average length of this asymptomatic period is 8Ð10 years. Opportunistic infections usually do not occur until the CD4 + T cell count has dropped from the normal level of 1,000 cells/μl. to below 200 cells/μl. Several studies have shown that the degree of loss of CD4 + T cells is an excellent predictor of progression to AIDS (8Ð11), and a CD4 + T cell count below 200 cells/μl is considered to be an AIDS-deÞning condition. As the CD4 count drops below 200 cells/μl, susceptibility to particular opportunistic infections appears in a surprisingly predictable way. Susceptibility to some infections such *Pneumocytsis carinii* pneumonia appears as the CD4 count falls below 200 cells/μl, while other infections are seen only in patients whose CD4 counts have fallen to below 100 cells/μl (disseminated *Mycobacterium avium* complex infection) or 50 cells/μl (cytomegalovirus retinitis). These Þndings suggest that the loss of CD4 + T cells is central to the development of clinical immunodeÞciency. Therefore, understanding the mechanism of CD4 depletion is the key problem in AIDS pathogenesis. In addition to the quantitative defects in the CD4 + T cell compartment, HIV-1-infected individuals also show defects in the functional capacity of the surviving CD4 + T cell population (12).

Although the numerical and functional defects in the CD4 + T cell compartment are particularly dramatic, functional defects in other cell types also occur in the disease. This chapter will consider recent advances in understanding the molecular mechanisms by which HIV-1 infection produces immunodeÞciency, focusing in particular on quantitative and qualitative defects in the CD4 + T cell compartment. Two questions will be considered in detail. First, what causes the loss of CD4 + T cells in HIV-1 infection? Second, what factors are responsible for the functional defects observed in those CD4 + T cells that are not depleted? As a prelude to a discussion of the mechanisms responsible for immunodeÞciency in HIV-1 infection, the molecular mechanism and cellular dynamics of HIV-1 infection of CD4 + cells are considered. The immune response to HIV-1 and the reasons that this response eventually fails to control the infection are also discussed. For recent reviews of the immunopathogenesis of HIV-1 infection, the reader is referred to the following articles (13,14).

MOLECULAR MECHANISM OF HIV-1 INFECTION OF CD4 + CELLS

HIV-1 selectively infects host cells expressing CD4, a 55 kd protein found on one subset of mature T lymphocytes. CD4 is also expressed on some subpopulations of

Department of Medicine, Johns Hopkins University School of Medicine, Baltimore MD 21205.

thymocytes and at low levels on cells of the monocyte-macrophage lineage (15). The tropism of HIV-1 for CD4+ cells results from the fact that the HIV-1 envelope (env) glycoprotein has a high afÞnity for CD4 (16Ð19). The env protein consists of two subunits. The gp120 subunit, which contains the binding site for CD4, is present on the exterior of the virus particle where it is non-covalently associated with the second env subunit, the transmembrane protein gp41. The Kd for the CD4-gp120 interaction is in the nanomolar range. Oligomers of three gp120/gp41 complexes comprise the ÒspikesÓ seen to be protruding from the virion surface in electron micrographs. The high afÞnity of HIV-1 gp120 for CD4 permits viral attachment to CD4+ T cells and macrophages. This strong binding reaction is the critical initial step in the life cycle of the virus. As is discussed below, HIV-1 entry also requires in addition to CD4 a Òco-receptorÓ Although some cell types that do not express CD4 can be infected by HIV-1 *in vitro*, the infection appears to be limited to CD4+ cells *in vivo*.

Entry of the viral genetic information into the host cell cytoplasm requires fusion of the viral envelope with the host cell membrane. This membrane fusion event is triggered by a conformation change in the env protein that exposes a hydrophobic fusion domain located at the N terminus of gp41 (Fig. 11.1). This hydrophobic domain inserts into the membrane of the target cell, initiating the fusion of the viral envelope with the host cell membrane. For many other enveloped RNA viruses such as inßuenza, fusion occurs only after uptake of the virus particle into a low pH endocytic compartment. In the case of inßuenza virus, low pH triggers a conformational change in the inßuenza virus hemagglutinin that exposes a buried hydrophobic domain. This domain inserts into the membrane of the endosome. In contrast, entry of HIV-1 occurs at neutral pH and does not require endocytosis of the virus particle (20). Following binding of HIV-1 to CD4, the next step is a conformation change that allows binding to the Òco-receptorÓ Subsequently, there is a conformation

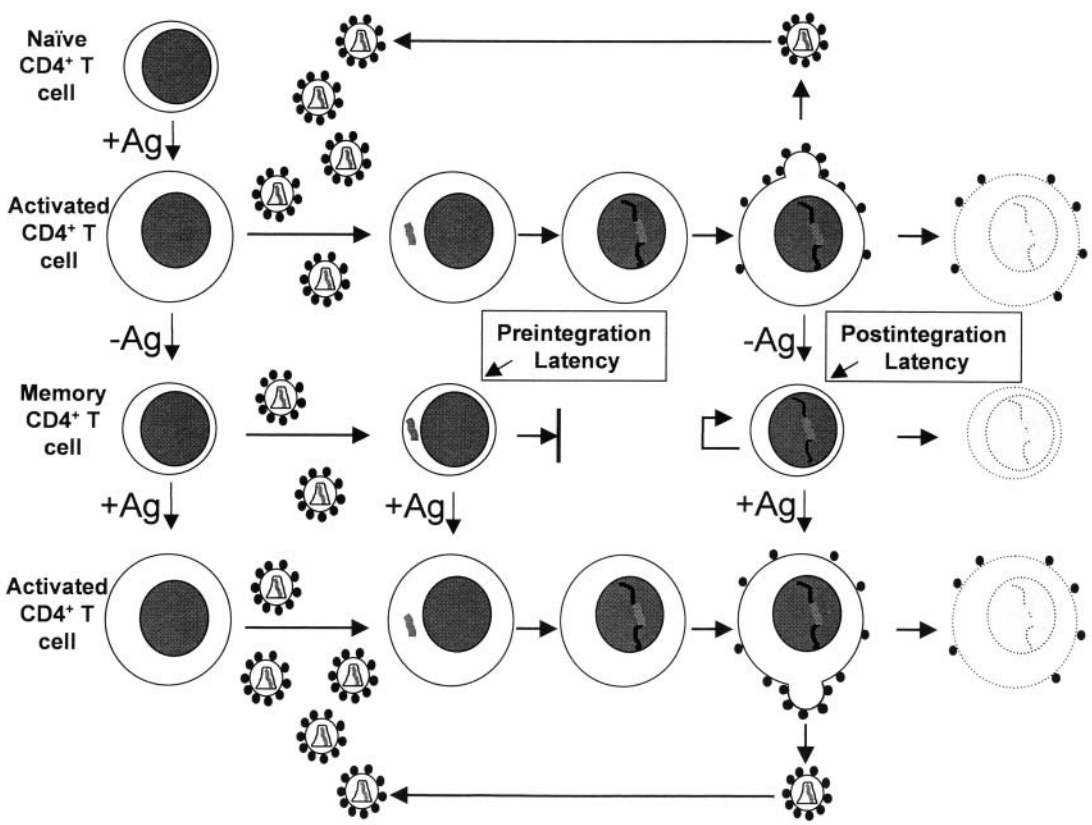

FIG. 11.1. Mechanism of infection. Step 1: HIV 1 attaches to CD4+ cells following high af nity interactions between the gp120 subunit of the env protein and CD4. The Kd of the binding reaction between gp120 and CD4 is $4 \times 10–9$ M. Note that on the surfaces of infected cells and HIV 1 virions, the env protein likely exists in the form of multimers of 3–4 gp120- gp41 complexes. It is probable that the co-receptors also play some role in the initial binding. Step 2: Binding of gp120 to CD4 and to the co-receptor induces a conformational change in the gp120-gp41 complex, resulting in exposure of the N-terminal hydrophobic domain of gp41. This hydrophobic domain inserts into the target cell membrane. Note that the chemokine receptor CCR5 can serve as a co-receptor for entry of macrophage-tropic isolates of HIV-1. Step 3: Fusion of the viral envelope with the plasma membrane and delivery of the viral capsid into the cytoplasm of the CD4+ cell. These events occur at neutral pH and do not require endocytosis of the virion prior to fusion.

change in the transmembrane subunit of the env protein (gp41) in which two alpha helical domains of the protein snap together, resulting in an intimate approximation of the viral envelope and the cell membrane and subsequent membrane fusion (Fig. 11.1).

One of the most exciting recent discoveries in the AIDS field has been the identification of "co-receptors" for HIV-1 entry that appear to serve as triggers for the fusion reaction. It has been clear for some time that the fusion reaction requires another host cell protein in addition to CD4. Mouse cells transfected with human CD4 can bind HIV-1 virions, but successful fusion and entry does not take place, presumably because the human version of this "co-receptor" is not present (19). In 1996, Edward Berger and colleagues showed that a seven transmembrane domain protein called CXCR4 or fusin, functions as a co-receptor for certain isolates of HIV-1 (21). CXCR4 is a member of a family of membrane proteins which serve as receptors for chemotactic cytokines (chemokines). Co-expression of human CD4 and CXCR4 allows infection of non-human cell types by certain isolates of HIV-1.

The discovery that chemokine receptors function as co-receptors for HIV-1 entry has also provided a coherent explanation for three seemingly unrelated sets of observations in the AIDS field. The first of these is that CD8+ T cells from HIV-1-infected donors can suppress virus replication *in vitro* through a non-cytolytic mechanism (22–24). It is now clear that the elaboration of chemokines by CD8+ T cells may account for the suppressive effect (25–27). Chemokines such as RANTES, MIP-1a, MIP-1b, and SDF-1 have been shown to suppress HIV-1 replication, presumably because interaction of these chemokines with their receptors on CD4+ T cells prevents an interaction of the HIV-1 env protein with chemokine receptors that is essential for fusion. Although dramatic suppression of HIV-1 replication *in vitro* can be achieved using chemokines, it is still unclear whether chemokines play a significant role in suppressing viral replication *in vivo*.

The second important phenomenon related to HIV-1 co-receptors involves differences in the capacity of different HIV-1 isolates to infect different types of CD4+ cells. Virus transmitted by the sexual route has the ability to infect activated T cells and macrophages and was referred to in the older literature as macrophage-tropic. In some infected individuals, sequence variation in the env protein gives rise to variants that infect CD4+ T cells but not macrophages (orignally termed T cell-tropic). Following the discovery of chemokine receptors as co-receptors for HIV-1, it rapidly became clear that macrophage-tropic viruses use different chemokine receptors than T cell-tropic viruses. The chemokine receptor CCR5 is a major co-receptor for macrophage-tropic viruses (28–30), while T cell-tropic viruses utilize CXCR4. Thus viral tropism reflects co-receptor usage (Table 11.1). In the new nomenclature, viruses that utilize CCR5 are referred to as R5 viruses while viruses that utilize CXCR4 are called X4 viruses. The "switch" from R5 to X4 viruses that is seen in some patients is associated with more rapid disease progression, perhaps reflecting the fact that X4 viruses are more pathogenic and/or infect a wider variety of cells (31,32). Infection by R5 viruses is inhibited by the chemokines that bind to CCR5 (RANTES, MIP-1a, MIP-1b), while infection by X4 viruses is inhibited by chemokines that bind to CXCR4 (SDF-1).

A third phenomenon that can now be at least partially explained in terms of co-receptors is the phenomenon of resistance to HIV-1 infection in certain repeatedly exposed individuals (33). A fraction of these individuals are homozygous for a 32 base pair deletion in the gene encoding CCR5 (34,35). This deletion is frequent in Caucasians, with 13% of the population being heterozygous and 1% being homozygous. There is no obvious immunologic impairment in individuals who are homozygous or heterozygous for the defective CCR5 gene. Homozygotes, but not heterozygotes, are protected from infection by the frequently transmitted R5 forms of HIV-1.

Because interactions between the HIV-1 env protein and its cellular receptor (CD4) and co-receptors (CXCR4, CCR5) are the critical initial events in the life cycle of the virus, they represent logical targets for therapeutic intervention. One conceptually attractive approach involves the use of recombinant soluble forms of CD4 which should bind to gp120 on free virus particles and thereby interfere with the initial step in infection. Clinical trials of various forms of soluble CD4 have thus far been disappointing. One problem is that clinical isolates of HIV-1 are less

TABLE 11.1. *Co-receptors for HIV-1 entry (see text for references).*

	Important HIV-1 Co-receptors	
Property	CCRS	CXCR4
Family	CC chemokine receptor family	CXC chemokine receptor family
Ligands	CC (β) chemokines (RANTES, MIP-1a, MIP-1b)	CXC (a) chemokines (SDF-1)
Expressed on CD4+ T cells	Yes (primarily on activated T cells)	Yes (resting and activated)
Expressed on macrophages	Yes	Not in a functional form
Used by	R5 ("macrophage-tropic") HIV-1 isolates	X4 ("T cell-tropic") HIV-1 isolates
Resistance conferring mutations	32 bp deletion in 1% of caucasians	?

susceptible to inhibition by soluble CD4 than are laboratory strains, for reasons that are not entirely clear (36). New multivalent forms of soluble CD4 are being developed. A very promising new drug called T20 interferes with the rearrangements of alpha helical domains of gp41 during fusion. Other new drugs in development block virus binding to CCR5 and CXCR4. These entry inhibitors are discussed in more detail elsewhere in this volume.

THE CELLULAR DYNAMICS OF HIV-1 INFECTION

As a result of the high afÞnity of gp120 for CD4, HIV-1 virions can attach to any CD4+ cell. Fusion occurs if appropriate co-receptors are expressed. However, the course of subsequent events in viral replication depends upon the cell type (CD4+ T cell vs. macrophage) and the state of activation of the cell.

The cellular dynamics of infection of CD4+ T lymphocytes by HIV-1 are illustrated in Fig. 11.2. In the periphery, the majority of mature CD4+ T lymphocytes are in a resting state. Activated T cells normally represent only a minority of cells in the peripheral T cell pool, although the proportion of activated cells is increased in infected individuals and increases with disease progression. HIV-1 virions can bind to and fuse with both resting and activated CD4+ T cells. The next step in the virus life cycle is reverse transcription of the viral genomic RNA by the reverse transcriptase (RT) enzyme carried by the virion. RT is a component of the high molecular weight preintegration complex that provides a structural framework for the reverse transcription and integration reactions. Reverse transcription can occur in both resting and activated T cells (37), but the next step, entry of the preintegration complex into the nucleus, does not occur in resting T cells, possibly due to the absence in resting cells of sufÞcient metabolic energy for transport of the complex through the nuclear pores (38). Thus, in resting T cells, partially or completely reverse transcribed HIV-1 genomes reside in the cytoplasm for a Þnite period of time (days) before being degraded. If the T cell is activated by antigen before the preintegration complex (PIC) becomes nonfunctional, then the subsequent steps of nuclear import, integration into host chromosomes, virus gene expression, and release of infectious virions can occur. In this sense, resting T cells carrying unintegrated HIV-1 DNA represent a labile reservoir for the virus (39,40). In asymptomatic HIV-1-infected individuals, most of the viral DNA present in circulating CD4+ T cells is in this unintegrated form (40Ð42). Because transcription of unintegrated viral DNA in the cytoplasm cannot occur, latently infected cells carrying this form of viral DNA presumably escape detection by immunologic mechanisms.

Following encounter with antigen, resting naive or memory CD4+ T cells undergo blast transformation and enter a state in which they are highly susceptible to productive infection by HIV-1. In activated T cells, there is no block to nuclear import and the infection progresses rapidly to integration, viral gene expression, and virus production. The HIV-1 LTR has sequence elements capable of binding some of the same host transcription factors that are upregulated in activated T cells (43,44). NFκB seems to be particularly important in this regard. As a result, viral gene expression from the HIV-1 LTR occurs

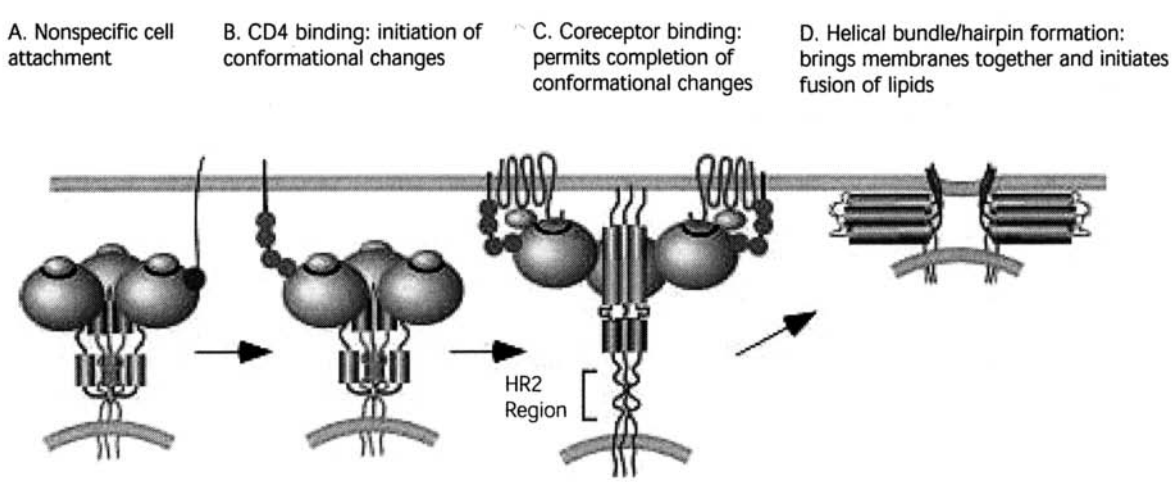

FIG. 11.2. Cellular dynamics of HIV 1 infection of CD4+ T cells. Successive steps in the life cycle of the virus are indicated by horizontal arrows. Transitions between resting (small) and activated (large) CD4+ T cells are illustrated by vertical arrows. HIV-1 can infect resting and activated CD4+ T cells, but integration of the reverse transcribed HIV-1 provirus, which is necessary for virus production, occurs only in antigen-activated T cells. Note that unintegrated HIV-1 DNA in the cytoplasm of resting cells is labile. Productive infection requires antigen-driven activation of recently infected resting CD4+ cells or infection of antigen-activated CD4+ T cells. Productively infected cells generally die within a few days from cytopathic effects of the infection, but some survive long enough to go back to a resting state, thereby establishing a stable latent reservoir.

readily in activated T cells. Thus infected activated CD4+ T cells begin to produce and release infectious virus.

From this point, there are several possible fates for cells in this state (Fig. 11.2). *In vitro* and *in vivo* studies show that in the case of activated CD4+ T cells, the infection can be highly cytopathic and can induce cell killing by mechanisms that are described below. Thus, many of these activated infected cells are likely to die from cytopathic effects of the virus. Some of these cells can also be destroyed by immunologic mechanisms including HIV-1-speciÞc cytolytic T lymphocytes (CTL). Studies (45,46) of the decay of plasma virus following the intiation of antiretroviral therapy have provided compelling evidence that the half-life of productively infected CD4+ T cells is relatively short, generally <2 days (see below). This short half-life reßects destruction by viral cytopathic effects and/or cytolytic host effector mechanisms.

Not all productively infected cells die. Some escape both the viral cytopathic effects and immunologic effector mechanisms and revert to a resting state carrying integrated provirus. In doing so, these cells are following a normal pathway in which some of the effector cells activated in response to a particular antigen revert back to a quiescent state and survive for long periods of time, allowing future responses to that same antigen. In a resting state, these memory CD4+ T cells are likely to have little or no virus transcription and are therefore also invisible to the immune system. Because the viral DNA is in an integrated state in these cells, it is highly stable. Thus these cells in the state of post-integration latency potentially represent a long term, stable latent reservoir for the virus. Upon subsequent exposure to antigen, these cells will become activated and release infectious virus (41,47). Thus, as is emphasized in Fig. 11.2, antigen plays a critical role in driving CD4+ T cells into states in which they are susceptible to productive infection by HIV-1 and subsequent destruction by viral cytopathic effects or immune mechanisms. For example, in the pre-HAART era, several studies showed that immunization of seropositive donors with antigens like tetanus toxoid results in a transient increase in plasma viremia (48). However, the generality and long term signiÞcance of these increases in viremia are currently unclear. At the present time, immunization of seropositive donors against other infectious diseases is still an important part of the medical management of HIV-1 infection (see Chapter ??).

For macrophages, the cellular dynamics of HIV-1 infection are different. It is of considerable interest that HIV-1 can replicate in macrophages (49–51). For most retroviruses, integration and replication can occur only in dividing cells. SpeciÞc amino acid sequences in several different HIV-1 proteins that are part of the preintegration complex target the complex for nuclear import, permitting integration and replication in some non-dividing cells such as macrophages (52,53). In macrophages, infection is not cytopathic. *In vitro* studies suggest that infected macrophages can continue to produce virus over long periods of time (49,50). This Þnding has led to the notion that infected macrophages may serve as a reservoir of virus *in vivo*. Virus production by macrophages is particularly apparent late in the course of disease when few CD4+ T cells remain and in the setting of opportunistic infections (54).

Important insights into the cellular dynamics of HIV-1 infection have come from studies (45,46) in which infected individuals have been treated with powerful antiretroviral agents that block infection of new cells but that do not inhibit release of virions by cells that are already infected (Fig. 11.3). In such individuals, plasma virus drops by approximately two logs within about two weeks, indicating that the half-life of plasma virus and the half-life of productively infected cells are both very short (<2 days). Thus, most of the plasma virus is produced by cells that are only recently infected. The infection is sustained by continuous new rounds of viral replication. Chronically infected macrophages or latently infected cells CD4+ T

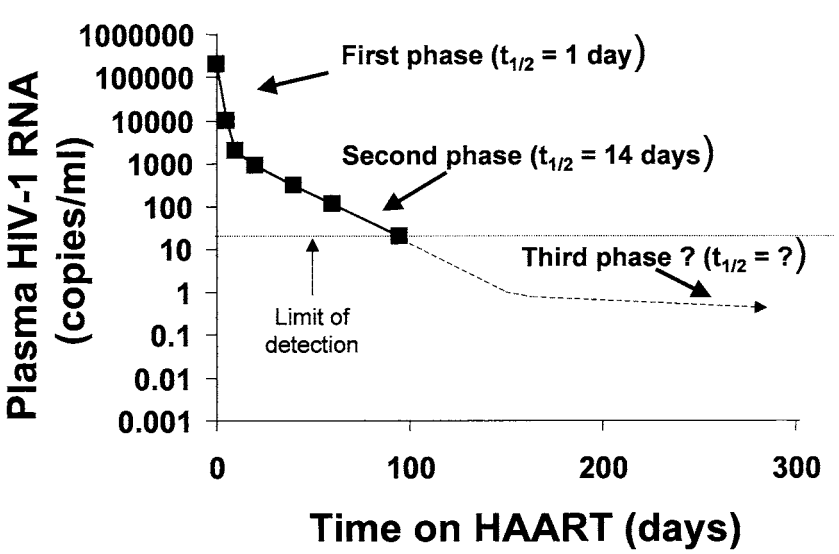

FIG. 11.3. Hypothetical plot of plasma virus in a patient who is started on an effective regimen of drugs that block infection of new cells. Plasma virus drops rapidly in the first two weeks of treatment, reflecting the short plasma half-life of the virus and the short half-life of productively infected cells. The decline in plasma virus shows a second, slower phase which is due to turnover of cells infected before initiation of therapy. These may be persistently infected macrophages or CD4+ T cells that have been reactivated from a state of post-integration latency. The second phase brings the viral load down to below the limit of detection, but the virus persists in reservoirs, including an extremely stable reservoir of latent virus in resting memory CD4+ T cells.

cells make a relatively minor contribution to plasma viremia in untreated individuals (1%). However, it is clear that eradication of the infection will require elimination of these reservoirs.

Having considered the dynamics of HIV-1 infection at the cellular level, we will now discuss the clinical characteristics of the infectious process and mechanisms by which HIV-1 infection leads to immunodeficiency.

HOST-VIRUS INTERACTIONS IN PRIMARY HIV-1 INFECTION

The natural history of HIV-1 infection may be divided into three phases (Fig. 11.4). During the initial phase, known as primary HIV-1 infection, virus present in the infecting inoculum replicates in the host, eventually producing a viremia that is controlled by the emergence of a vigorous anti-viral immune response. These events occur during the first several weeks following exposure to HIV-1. Primary HIV-1 infection has been studied most carefully in the 50–70% of individuals who develop constitutional symptoms (see reference #55 for a review). In those individuals, a transient illness resembling infectious mononucleosis appears one to twelve weeks after exposure. Symptomatic primary HIV-1 infection is characterized by fever, lymphadenopathy, pharyngitis, arthralgia, myalgia, rash, lethargy, and occasionally aseptic meningitis. Symptoms persist one to two weeks. The severity varies dramatically. Many infected individuals give no history of such an acute illness. At the other extreme are rare individuals who develop serious manifestations such as candida esophagitis. Severe symptomatic primary HIV-1 infection may be associated with a more rapid overall disease course (55). During the acute illness, assays for the HIV-1 gag protein p24 in the serum are typically positive, reflecting high levels of free virus and viral antigen in the circulation. Assays for antibodies to HIV-1 are initially negative. Seroconversion (the development of a detectable antibody response to HIV-1) usually occurs within a few weeks after onset of the acute illness. IgM antibodies precede IgG antibodies by about a week. During symptomatic primary HIV-1 infection, the levels of infectious virus and of infected cells in the circulation are both very high (56). This level is 30–300-fold higher than the levels typically observed during the asymptomatic phase of infection. It has been proposed that the initial systemic seeding of the peripheral lymphoid organs with HIV-1 occurs as a result of the high levels of viremia that develop during primary HIV-1 infection.

As the immune response to HIV-1 develops, there is a dramatic reduction in viremia and in the amount of viral antigen in the circulation in most patients. The CD4+ T cell count is typically reduced during symptomatic primary HIV-1 infection, but it is unclear whether this reflects virus-induced CD4+ T cell depletion or sequestration of circulating CD4+ T cells in the peripheral lymphoid organs. After the acute illness resolves, CD4+ T cell counts generally rise again but often not to preinfection levels. Another interesting observation is that of a CD8+ lymphocytosis during primary HIV-1 infection, perhaps reflecting a CTL response to the virus (57). Primary HIV-1 infection provides clues regarding the importance of various immune effector mechanisms in

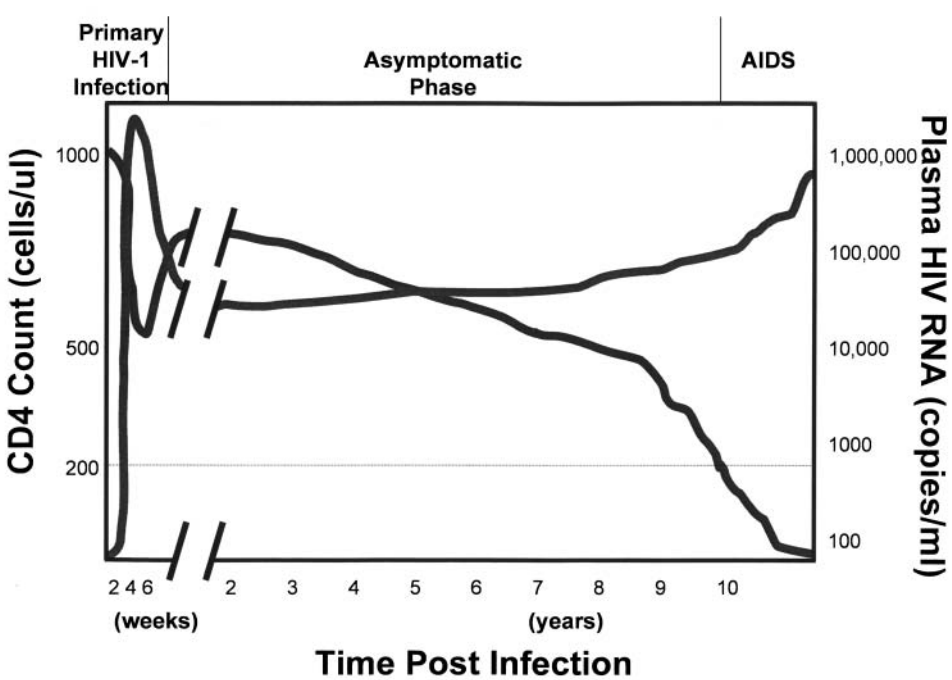

FIG. 11.4. The three stages of disease in a hypothetical case of HIV-1 infection.

controlling HIV-1 infection. Knowledge of factors responsible for the dramatic decline in the levels of infectious virus and infected cells in peripheral blood may be particularly valuable in the design of vaccines and immunotherapeutic strategies. Antibodies capable of neutralizing autologous virus isolates can be detected in serum samples taken 2–3 weeks after the onset of symptomatic primary HIV-1 infection (58,59). Several reports suggest that virus-specific CTL may appear even earlier and may represent a critical host factor in the control of acute HIV-1 infection. HIV-1-specific CTL can be detected in the first weeks after infection, prior to or coincident with the development of a detectable antibody response (60–63). Compelling evidence in this regard comes from recent studies of acute simian immunodeficiency virus (SIV) infection of rhesus macaques (64). SIV and HIV-1 show many striking similarities including virtually identical genomic organization, a tropism for CD4+ cells, and the capacity to induce a fatal immunodeficiency syndrome. SIV-specific CTL can be detected in the first weeks after inoculation of rhesus monkeys with the virus, prior to or coincident with the development of a detectable antibody response. In animals experimentally depleted of CD8+ T cells, control of viremia is not observed, and the animals progress quickly to AIDS (64). Thus is it very likely that through the lysis of infected cells and perhaps also through the release of chemokines like MIP-1α, MIP-1β and RANTES that inhibit HIV-1 entry, these cells help to reduce the level of circulating virus to the lower levels that are characteristic of the asymptomatic phase of infection.

The initial immune response to HIV-1 contributes to reducing the level of plasma virus to a lower plateau level (the "set point") that is different in different patients and that determines the rate of disease progression (65). Typical set point levels might be 10,000–100,000 copies of HIV-1 RNA/ml of plasma. This set point level of viremia reflects a balance between viral replication and host immune responses that plays out over the course of the second phase of HIV-1 infection.

HOST-VIRUS INTERACTIONS IN THE ASYMPTOMATIC PHASE: THE SIGNIFICANCE OF VIRAL LOAD

The second phase of HIV-1 infection is the long asymptomatic period between primary infection and the development of clinical disease. The most important and characteristic pathophysiologic feature of the asymptomatic phase of HIV-1 infection is the gradual loss of CD4+ T cells. Levels of CD4+ T cells may be initially stable but inevitably begin to drop. The fall is generally gradual and steady, with a more rapid drop in the 18 months preceding development of an AIDS-defining illness. The loss of CD4+ T cells is primarily responsible for the development of frank immunodeficiency observed in the final stage of the illness. It is important to stress that although the asymptomatic phase may represent a phase of clinical latency, the virus replicates continuously during this period as indicated by the "set point" level of viremia (66). While the CD4 count is the best predictor of clinically significant immunodeficiency, the level of viremia determines the rate at which CD4+ T cells are lost (65). The higher the set point, the more rapidly CD4+ T cells are lost. This suggests that viral infection is somehow involved in the destruction of CD4+ T cells, but the precise mechanism is unclear. Because HIV-1 is cytopathic for T cells *in vitro*, it was originally presumed that direct viral cytopathic effects were responsible for CD4 depletion (2). However, subsequent studies of virus load in HIV-1 infection have raised significant questions about whether the fraction of cells infected is high enough to account for the depletion of the entire CD4+ T cell compartment. Therefore, the issue of virus load is central to understanding the mechanisms by which HIV-1 produces immunodeficiency.

Clinically, viral load is measured by the determination of the level of HIV-1 RNA in the plasma (65,66). However, this is ultimately a reflection of the number of productively infected CD4+ T cells and macrophages in various sites throughout the body. Viral load has also been evaluated by measurement of infectious virus in plasma (67,68), limiting dilution analysis of the frequency of cells in the peripheral blood capable of producing infectious virus (41,67), PCR analysis of viral DNA in cells in the peripheral blood (40,41,47,69–71), lymph nodes (41,72,73), and central nervous system (74), and quantitation of viral mRNA species in productively infected cells (75–79). Although these approaches all confirm that in untreated individuals HIV-1 replicates actively and continuously, regardless of stage of disease, there remains some confusion over the fundamental question of what fraction of CD4+ T cells are infected, with widely divergent answers coming from different experimental approaches. Part of the confusion results from the fact that many of the experimental approaches used to study this issue do not provide information about the distribution of virus between latent and active states, between defective and replication-competent forms, between CD4+ T cell and macrophage compartments, and between circulating and tissue sites. All of these factors are important in understanding viral load.

CD4 depletion as a result of direct cytopathic effects can only occur for cells that are productively infected with HIV-1, and this enumeration of infected cells is important in understanding pathogenesis. An early *in situ* hybridization study suggested that even in patients with AIDS, only a small subset ($< 1/10{,}000$) of the total pool of lymphocytes was productively infected, as evidenced by high levels of viral mRNA (75). Subsequent PCR studies detected HIV-1 DNA in a larger fraction of CD4+ T cells (69–71) and were interpreted as indicating that most of the infected cells were in a state of latent infection. Careful analysis of the fraction of CD4+ T cells from which virus

can actually be cultured have shown that CD4+ T cells harboring replication-competent provirus are rare (<0.01%) (41). Since productive infection requires integration of reverse transcribed viral DNA into the host genome, the issue of virus load can also be addressed by analysis of the frequency of CD4+ T cells carrying integrated provirus. In the peripheral blood of seropositive individuals in the asymptomatic phase of infection, most of the detectable viral DNA is in an unintegrated form (40,41). Integrated virus is found in >0.01% of CD4+ T cells and macrophages (41). The notion that CD4 depletion is the direct result of infection and subsequent death of large numbers of CD4+ T cells is not consistent with the low fraction of infected cells.

Some evidence suggests that the extent of infection is greater in the lymph nodes rather than in the peripheral blood (72,73). Lymphocytes in the circulation represent only a small fraction (<2%) of the total lymphocyte pool. Complex factors, including expression of various cell adhesion molecules, determine the trafÞcking of lymphocytes between these compartments. During the asymptomatic phase of the infection, the proportion of cells carrying HIV-1 DNA is higher (3Ð10-fold) in the lymph node than in the peripheral blood (73). For example, HIV-1 DNA may be detected by a sensitive PCR assay in 1/10,000 peripheral blood mononuclear cells while in the same individual the proportion of infected cells in the lymph nodes is typically 10-fold higher (1/1000). However, analysis of virus burden by methods that distinguish integrated and unintegrated HIV-1 DNA has shown that only a small proportion of CD4+ T cells (<0.01%) harbor integrated provirus and that the proportion of CD4+ T cells harboring integrated virus is not dramatically different in the blood and lymph nodes (41).

During the asymptomatic period, virus particles are readily detected in the germinal centers of the lymph nodes where they are found associated with the network of follicular dendritic cells (FDC) (73,80). FDC are unique antigen presenting cells that form a complex cellular network within the germinal centers. These cells express Fc receptors and three types of complement receptors (CR1, CR2, and CR3) and as a result are capable of binding antigens that have bound antibody and/or activated the complement system. FDC may serve as Þlters that trap virus particles and thereby lower the level of infectious virus in the circulation. FDC normally play an important role in the activation of B lymphocytes in response to antigen. During the asymptomatic phase of HIV-1 infection, there is progressive disruption of the normal architecture of the lymph nodes, with loss of the FDC network. It is possible that the loss of FDC is in part responsible for the abnormal B cell function observed in HIV-1-infected individuals. In addition, it has been proposed that the concentration of extracellular virus on the membranes of FDC provides a reservoir of virus which can infect CD4+ T cells migrating through the lymph node. Blood-derived dendritic cells, which are distinct from FDC and which have an important role in the presentation of antigens to CD4+ T cells, are also capable of binding virus and of transmitting the virus to the CD4+ T cells with which they interact during the course of an immune response. Controversy exists over whether the extent to which these dendritic cells can be productively infected (81). Blood-derived dendritic cells (DC), which are distinct from FDC and which have an important role in the presentation of antigens to T cells, can bind virus and transmit the virus to the CD4+ T cells with which they interact during the course of an immune response (81Ð83). A recently discovered lectin-like receptor expressed by DC, called DS-SIGN, can interact with carbohydrate ligands on gp120, facilitating attachment of virions to DC (84). Following stimulation with imßammatory cytokines, immature tissue DC migrate to the lymph nodes where they present antigens taken up in the tissues to T cells in the lymph nodes. It has been proposed that DC can carry virions bound via DC-SIGN to the nodes where they mediate infection of CD4+ T cells (84).

In summary, although virus replication occurs throughout the asymptomatic phase of HIV-1 infection, the fraction of susceptible cells that are productively infected at any given time is low. It is thus unclear whether direct viral cytopathic effects can account for the depletion of CD4+ T cells. The next section of this chapter reviews potential mechanisms for depletion of infected CD4+ T cells. Mechanisms for the depletion of CD4+ T cells that are not infected are considered in a subsequent section.

MECHANISMS OF CD4 DEPLETION: PRODUCTION AND DESTRUCTION

In considering the mechanisms responsible for the quantitative and qualitative defects in the CD4+ T cell compartment in HIV-1 infection, it is important to note at the outset that this compartment is heterogeneous with respect to several critical parameters. As mentioned above, only a very small proportion of the CD4+ T cells in an HIV-1 seropositive individual are productively infected at any given time. Therefore, the CD4+ T cell compartment consists of a small number of infected cells and a much larger number of uninfected cells. In addition, CD4+ T cells differ in their states of activation (resting vs. activated), prior history of antigen exposure (naïve vs memory), and commitment to particular patterns of cytokine production (Th1 vs. Th2). This heterogeneity is important to keep in mind when considering mechanisms of CD4+ T cell depletion.

CD4+ T cell depletion can be viewed in terms of a virus-induced alteration in cell kinetics within this compartment (for a review, see reference 85). In infected individuals, the rate of CD4+ T cell loss exceeds the rate at which CD4+ T cells are produced through thymic differentiation and/or clonal expansion of peripheral CD4+ T cells. CD4+ T cells may be lost through a

number of potential mechanisms, some of which operate on infected cells. Interestingly, there are other mechanisms for CD4+ T cell depletion that operate on non-infected cells.

Before considering mechanisms for CD4+ T cell destruction, the possibility that the production of CD4+ T cells is decreased in HIV-1 infection will be discussed. The decline in naive CD4+ and CD8+ T cells in the peripheral blood of infected individuals has been interpreted as indicating a defect in thymopoeisis in HIV-1 infection (86,87), a conclusion that is supported by the Þnding that na•ve T cell levels increase upon control of viral replication with HAART (88). Unfortunately, it is difÞcult to directly measure the rate at which new T cells are produced in the thymus. Thymic size can be measured radiologically, but direct measurement of function requires other approaches (89). To monitor ongoing thymic production of new T cells, recent studies have quantitated T cell receptor excision circles (TRECs) produced as a by-product of the VDJ recombination reactions that occur in the thymus as new T cells are generated (90,91). These DNA circles are stable in cells after the gene rearrangements that produce functional T cell receptors occur. Lower than normal TREC levels in peripheral blood CD4+ and CD8+ T cells have been observed in some HIV-1-infected adults, with partial reversal upon treatment. Interpretation of TREC measurements is complicated by the fact that TRECs can be diluted out by proliferation of mature T cells (92).

Pathologic examination of thymuses from AIDS patients suggests that HIV-1 infection accelerates the thymic involution that normally occurs with age (for a review, see reference 93). The mechanism is unclear. Infection of progenitor cells from bone marrow has not been consistently demonstrated. HIV-1 provirus is not detected in circulating monocytes or B lymphocytes (69), suggesting that stable infection of bone marrow stem cells either does not occur *in vivo* or does not lead to vertical transmission of the virus to progeny cell populations. In immunodeÞcient mice reconstituted with fetal human thymus, infection and depletion of thymocytes can be demonstrated (94). However, in this system, the virus is often directly innoculated into the thymic graft, and it is not clear how closely this model mimicks HIV-1 infection in humans. Since HIV-1 provirus is not detected in circulating CD8+ T cells, infected double negative or double positive thymocytes apparently do not survive *in vivo* to produce mature T cells. Taken together, these results suggest that HIV-1 infection may interfere with T cell production. Because HIV-1 can induce the loss of mature T cells by other mechanisms, the decrease in thymic production of new T cells may be especially signiÞcant.

Most of the current evidence suggests that accelerated CD4+ T cell loss is a critical factor in CD4+ T cell depletion. Under some experimental conditions, HIV-1 infection of susceptible cell types *in vitro* results in death of the infected cell population. The initial Þnding that HIV-1 was cytopathic for CD4+ T cells (2) led to the notion that direct cytopathic effects of the virus on infected cells produced the CD4+ T cell depletion that is characteristic of HIV-1 infection in humans.

Two general types of HIV-1 induced cytopathic effects have been observed *in vitro*. In some experimental systems, syncytia or multinucleated giant cells form by the fusion of infected cells expressing env protein and non-infected cells expressing CD4 (95,96). Infected cells expressing gp120 were shown to fuse with non-infected cells expressing CD4. Inclusion of non-infected CD4+ T cells in short-lived syncytia provides a potential mechanism for CD4+ T cell depletion. The process of syncytium formation involves membrane fusion events initiated by the interaction of gp120 and CD4 on opposing cell surfaces. Co-receptors are essential for the fusion reaction. The extent to which syncytium formation contributes to CD4+ T cell depletion *in vivo* is unclear. In pathologic studies of lymph nodes and spleen from infected individuals, giant cells are observed only rarely, but this may reßect the fact that syncytia are labile structures. Recent studies suggest that syncytia may form in the mucosal lymphoid tissue (83).

In the older literature, HIV-1 isolates were classiÞed based on capacity to form syncytia in *in vitro* cultures of transfomed CD4+ T cell lines. Not all HIV-1 isolates induce syncytia in these *in vitro* culture systems. Isolates from different infected individuals show variation in biological properties including ability to induce syncytia in various cell types, rates of replication *in vitro*, and ability to induce cytopathic effects (97Ð100). In some infected individuals, the capacity of HIV-1 isolates to induce cytopathic effects *in vitro* increases with disease progression. Isolates with the capacity to induce syncytia in cell lines *in vitro* emerge with disease progression in certain individuals, although in about 50% of cases progression to AIDS is not accompanied by a transition from non-syncytia-inducing (NSI) to syncytia-inducing (SI) phenotype (100). High *in vitro* replication rates appear to correlate with the SI phenotype and with rapid CD4+ T cell loss *in vivo*. Several recent studies have conÞrmed that association of the SI phenotype with more rapid decline in CD4+ T cell counts and progression to AIDS. Nevertheless, CD4+ T cell depletion occurs during the asymptomatic phase of infection when the predominant viral species are usually of the NSI phenotype. Unfortunately, all of the older literature in this area requires reinterpretation in light of the discovery that different virus isolates utilize different co-receptors. Syncytium formation in cultures of T cell lines most likely reßects capacity of the viral isolate to infect those lines by utilizing the chemokine receptor CXCR4. However, use of transformed cells lines that express only CXCR4 will not provide information about the syncytium-inducing capacity of isolates that utilize CCR5. Thus, there is still considerable confusion about the role of syncytium formation in CD4

depletion. A careful study by Mullins and colleagues suggests that X4 viruses may emerge more commonly that previously thought but may not become dominant (31).

There are also cytopathic effects that operate at the level of individual infected cells; that is, under some conditions, HIV-1-infected T cells appear to die from the infection independent of any cell-cell fusion events (101–103). Most potential mechanisms for HIV-1-induced single cell killing involve the env glycoprotein, a protein that is poorly tolerated by many cell types. In some studies, susceptibility to cytopathic effects is related to levels of CD4 expression, perhaps reßecting toxic consequences of intracellular interactions between newly synthesized env protein and CD4 (104–105). Other studies suggest that the fusogenic properties of the env protein are an important determinant of the intrinsic toxicity of this protein for host cells (106). HIV-1 has evolved mechanisms to control the toxicity of this protein. For example, an intrinsic internalization signal sequence in the cytoplasmic tail of gp41 (107,108) mediates endocytosis of excess env protein that is not destined for incorporation into virions (109). This may reduce toxic effects of env protein expression on infected cells and allow the cells to survive longer and produce more virus. Other HIV-1 proteins including tat and vpr have also been implicated in the death of infected cells (110). Although the earlier literature suggested that infected cells die through apoptotic mechanisms, more recent studies suggest that infected cells undergo necrosis (106,111). Which viral proteins are most important in this process remains controversial, with a recent study implicating viral proteins other than the env protein (111).

Another potential mechanism for the loss of CD4+ T cells in HIV-1 infection involves the destruction of such cells by components of the immune system, particularly CD8+ CTL. As is discussed below, the natural immune response to HIV-1 infection includes a strong CD8+ CTL response, and it is quite likely that CD8+ CTL mediate destruction of infected cells *in vivo*. Most of the current evidence (reviewed in 112) suggests that CTL play a beneÞcial role by lysing infected host cells. An alternative view, proposed by Zinkernagel and Hengartner (113), is that CTL induce immunodeÞciency through the lysis of infected CD4+ T cells. This view is problematic for several reasons. First, it is based on the assumption that the virus is not cytopathic *in vivo*. If so, then the destruction of infected cells by CTL might do more harm than good. However, as discussed above, there is actually a great deal of evidence that the virus is cytopathic for T cells. Second, this view assumes that most of the CD4+ T cells that are lost are infected. There are several potential mechanisms for CD4+ depletion that operate on non-infected CD4+ T cells (see below). Third, the Þnding that many long-term nonprogressors have vigorous HIV-1-speciÞc CTL responses argues against a pathogenic role for CTL. A more popular view, which is consistent with much of the current evidence, assumes that infected cells are likely to die from the cytopathic effects of the virus. Therefore, the destruction of productively infected cells by CTL is beneÞcial to the host because it leads to a more rapid cessation of virus production from cells that are destined to die.

MECHANISMS FOR THE DEPLETION OF NON-INFECTED CD4+ T CELLS

While the the highly cytopathic nature of HIV-1 provides a potential explanation for the characteristic depletion of CD4+ T cells in patients with HIV-1 infection, the low frequency of infected cells makes it likely that direct cytopathic effects of the virus on infected CD4+ T cells are not the only factors. In the last several years, it has become clear that HIV-1 infection may contribute to a global dysregulation of T cell dynamics, affecting the turnover of both infected and uninfected CD4+ T cells. Initial studies by Ho and Shaw and their colleagues demonsrated a very rapid rebound in CD4+ T cells counts following the initation of antiretroviral therapy. Although it has subsequently been shown that CD4+ T cell rebound following initiation of therapy is due in part to the redistribution from lymphoid organs into the blood stream (114), these investigators used the rate of CD4+ T cell rebound as an indirect reßection of the rate of CD4+ T cell turnover *in vivo*. This analysis led to the suggestion that as many as 1–2 × 109 CD4+ T cells were produced and destroyed daily in HIV-1-infected individuals (115). Because this rapid destruction of CD4+ T cells had to be balanced in the short term by rapid T cell production, HIV-1 infection was likened to a sink with an open tap and an open drain. In other words, HIV-1 infection induces a state of high CD4+ turnover, eventually exhausting the bodyÕs proliferative T cell reserve and leading to an inevitable collapse of the immune system.

These results were partially supported by subsequent studies that directly measured the turnover rate of CD4+ T cells in both SIV-infected rhesus macaques and HIV-1-infected humans using radiolabeled nucleotide analogs or precursors that could potentially be incorporated into the DNA of dividing cells (116,117). Upon introduction of BrdU, a nucleoside analog, to the drinking water of SIV-infected rhesus macaques, the percentage of BrdU+ CD3+CD4+ lymphocytes increased from zero to a peak value, as expected. When BrdU was stopped, the percentage of BrdU+ CD3+CD4+ lymphocytes subsequently decreased. This rise-and-fall dynamic of BrdU+ lymphocytes was most pronounced for SIV-infected macaques with high viral loads. A graded response was observed for lower viral loads and the least pronounced dynamic was observed in normal macaques. When a system of differential equations was Þtted to the data, the best-Þt parameters indicated a statistically signiÞcant increase in

both the CD4+ T cell production rates and death rates in infected macaques as compared to uninfected macaques (116). Additionally, the replacement rate of CD4+ T cells (presumably by the thymus) was calculated as the difference between the best-Þt CD4+ death and production rates and shown to be two to three-fold higher in SIV-infected macaques versus controls. Thus, SIV infection was observed to be associated with a signiÞcantly increased CD4+ lymphocyte turnover rate as well as an accelerated proliferation rate of CD4+ T cells.

Additional studies with human subjects using deuterated glucose labeling of DNA in dividing cells showed similar results (118). In a series of experiments from the same group, labeling and delabeling kinetics of DNA in CD4+ T cells in the blood were studied in HIV-1-infected, treatment na•ve patients and normal volunteers. Detection of labeled DNA became possible with a half time of approximately 0.5 days. On infusion of 2H-glucuse, the group of normal volunteers demonstrated a slow increase of labeled CD4+ T-cells followed by a gradual decrease. Additionally, only a small peak fraction of CD4+ cells was labeled (~ 0.04). The kinetics of DNA labeling and delabeling of CD4+ T cells in HIV-1-infected patients were different. The most striking differences were the signiÞcantly higher rates of labeling and delabeling of the CD4+ T cells in HIV-1-infected patients and a peak fraction of labeled CD4+ T cells that was as much as Þve times greater than the normal control group.

Several subsequent experiments were carried out to conÞrm that the higher rate of DNA labeling and delabeling of CD4+ T cells in the HIV-1 infected represented increased CD4+ T cell turnover (118). A mathematical model of CD4+ T cell dynamics, which estimated CD4+ T cell proliferation and death rates, was formulated to Þt to the data from the described DNA labeling experiments and predicted signiÞcantly higher mean proliferation and death rates of CD4+ T cells in the HIV-1 infected group than in the normal control group. Analysis of the data using this model provided no evidence that HIV-1 infection decreases the introduction of CD4+ T cells from intrinsic sources, e.g. thymus or na•ve/memory CD4+ T cells that may be activated into clonal expansion. In order to test these predictions, some treatment-na•ve patients were placed on a potent four-drug regimen. Second and third periods of 2H-glucose labeling were carried out on days 35Ð77 and 245Ð875, respectively. For most patients, the second period episode yielded signiÞcantly slower rates of deuterium incorporation and CD4+ T cell loss. Additionally, the observed peak fraction of labeled cells was less than before treatment. Qualitatively similar effects were observed at the third labeling episode (although to a lesser degree), suggesting slower CD4+ T cell turnover after initiation of drug therapy.

Based on the results obtained from all of the aforementioned important studies, these investigators concluded that the loss of CD4+ T cells during HIV-1 infection was due to increased CD4+ T cell turnover, turnover at a rate which the body would inevitably be unable to maintain, leading to immune failure. There are, however, a number of additional complexities. First, the CD4+ T cell compartment is composed of several distinct subpopulations, including activated, memory and na•ve CD4+ T cells and cannot be realistically treated as a single homogeneous compartment. Another concern is whether CD4+ T cell dynamics observed in the blood can be extended to the whole body. It is now clear that the rapid rise in CD4+ T cell counts seen shortly after the initiation of therapy may simply reßect redistribution of T cells from the lymph nodes and spleen into the blood. At any given time, only 2% of the lymphocytes are in the blood, the remainder being distributed throughout the body in various lymphoid organs and in non-lymphoid tissues. A minor change in trafÞcking patterns can result in signiÞcant changes in blood levels. The redistribution seen after initiation of therapy may result from decreases in the overall activation state of the immune system (see below). Lastly, it is important to note that qualitative, functional defects in the CD4+ T cell compartment cannot be explained alone with a quantitative destruction of CD4+ T cells.

What is the cause of the increased CD4+ T cell turnover in HIV-1 infection? CD4+ T cell replication dynamics follow one of two pathways: either the cells undergo regenerative or ÒburstÐlikeÓ replication (119). Regenerative replication is exhibited by quiescent CD4+ cells as a means of maintaining a steady-state population size, while burst-like replication occurs after antigenic activation of a na•ve or memory T cell. During any sort of infection, HIV-1 included, CD4+ cells speciÞc for the relevant pathogen are stimulated, leading to activation and rapid replication of antigen-speciÞc cells. Some cells of irrelevant speciÞcity may also be stimulated by cytokines released in the process. Eventually, as the infection resolves, there is deletion of most of these activated cells by apoptosis. A small fraction of these activated CD4+ cells avoid clonal deletion and instead convert to resting memory cells. Some researchers have argued that CD4+ depletion during HIV-1 infection is due to CD4+ cell death from HIV-1 antigenic stimulation of CD4+ cells. Thus it is proposed that a substantial fraction of CD4+ cells are killed indirectly by HIV-1Ñ as bystandersÑ through apoptosis subsequent to the massive antigenic burden presented by HIV-1 infection. This would provide an explanation for the increased T cell turnover observed in the BrdU or (2H)-glucose labeling studies discussed above. The rapid rise of labeled cells is consistent with rapidly dividing activated cells while the rapid fall of labeled cells after ceasing infusion of the label is consistent with the rapid death of activated CD4+ cells. Ultimately, it is believed that the negative effect of chronic activation on the balance between CD4+ T cell production and death in the presence of HIV-1 mediated CD4+ cell death leads to CD4+ depletion, mostly through destruction of non-infected bystander CD4+ T cells.

FUNCTIONAL DEFECTS IN CD4+ T CELLS

In addition to the quantitative depletion of CD4+ T cells that occurs during the course of HIV-1 infection, there are also qualitative defects in the function of the surviving CD4+ T cells. In a pivotal early study, Lane and colleagues showed that unfractionated peripheral blood mononuclear cells (PBMC) from AIDS patients showed decreased responsiveness to mitogens and to soluble recall antigens (12). When puriÞed CD4+ T cells were tested, responses to mitogens were normal but responses to soluble antigens were depressed indicating that the lower response seen with unfractionated PBMC from patients was not simply due to a lower percentage of CD4+ T cells. Rather, CD4+ T cells from AIDS patients had a marked defect in responsiveness to soluble antigen presented by monocytes (12). This defect was shown to be intrinsic to the T cell and did not occur at the level of antigen-presenting cell.

One possible explanation for these functional defects is that activation with antigen renders the T cell highly susceptible to productive infection, particularly if the antigen presenting cell is infected with HIV-1. Macrophages and dendritic cells infected with or exposed to with HIV-1 *in vitro* can present antigen to T cells and the encounter results in transfer of infection to the responding T cell population (82).

DEFECTS IN B CELL FUNCTION

In addition to the effects on CD4+ T cells described above, infection with HIV-1 results in dramatic effects on B-lymphocyte function. Normal absolute numbers of circulating B cells are found in HIV-1-infected individuals. However, there are several major lines of evidence suggesting that HIV-1 infection results in abnormalities in B-cell function. First, there is strong evidence for an increased degree of B-cell activation in infected individuals. Increased B-cell activation occurs early in the disease process as evidenced by high levels of antibody-producing B cells and by hypergammaglobulinemia (120Ð122). There is a higher than normal percentage of immature B-cells and an increased number of activated B cells (123). Spontaneous *in vitro* B-cell proliferation is also characteristic of HIV-1 infection (120,124). Circulating immune complexes (125Ð127) can be detected in the sera of AIDS patients. Also part of the clinical picture of HIV-1 infection is immune complex-associated pathology including autoimmune thrombocytopenia (128) and anemia (129).

The polyclonal B-cell activation seen in HIV-1 infection is often termed Òspontaneous,Ó although there is some evidence that much of the hypergammaglobulinemia actually results from a strong humoral response to HIV itself (130). Other proposed mechanisms for nonspeciÞc B-cell activation in HIV-1 infection include direct effects of HIV-1 virions or HIV-1 proteins as well as activation mediated by EBV and activation by membrane forms of the cytokine TNF-α expressed on activated T cells (131). Importantly, B cell abnormalities in HIV-1 infection tend to normalize after effective therapy is started, suggesting that viral replication drives the B cell hyperactivity *in vivo* (132,133). Recent evidence suggests that abnormal B cell function in the setting of ongoing replication may be due to the presence of a subset of B cells with decreased expression of the complement receptor CD21, plasmacytoid features and poor proliferative responses (132). It is also important to note that patients with HIV-1 infection have an increased risk for B cell malignancies (134).

The polyclonal B-cell activation seen in HIV-1 infection is found in conjunction with decreased *in vivo* humoral responses to speciÞc antigens. In an important early study (120), Fauci and colleagues demonstrated that AIDS patients had reduced responses to a T-independent B-cell mitogen Staphylococcus aureus Cowan strain, indicating an intrinsic B-cell defect. Healthy seropositive individuals also show B-cell functional defects. These defects, in conjunction with defects in helper T cell function and with alternations in the germinal center environment where B cell responses originate, may explain the defects in speciÞc antibody responses in HIV-1 infection.

THE IMMUNE RESPONSE TO HIV-1: ANTIBODY RESPONSES

The immunologic abnormalities in HIV-1-infected individuals must be viewed in the context of the ongoing immune response to HIV-1. ImmunodeÞciency develops despite the presence of readily detectable B and Tlymphocyte responses to HIV-1 (for a review, see reference 112). In fact, in many ways, HIV-1 is a highly immunogenic virus. Virtually all infected individuals develop antibody responses to several of the protein products of the HIV-1 genome. Even more striking is the Þnding that most infected individuals also have very high levels of virus-speciÞc CTL activity (60Ð63,112,135Ð137). The frequency of HIV-1-speciÞc CTL in the peripheral blood of some seropositive individuals is sufÞciently high that cytolytic activity can be detected in freshly isolated PBMC preparations without any *in vitro* restimulation (135) and that CTL speciÞc for particular HIV-1 epitopes can be directly quantitated using recently developed tetramer technology (138). Given that HIV-1 infection generally induces vigorous B and T lymphocyte responses, it is important to consider whether these responses exert beneÞcial anti-viral effects.

The potential of speciÞc antibodies to control HIV-1 infection is measured in *in vitro* neutralization assays in which serum from an infected individual is incubated with known quantities of infectious virus and the reduction in infectivity of the virus sample is measured (139,140). In general, levels of neutralizing antibodies are low even

when high levels of antibodies to HIV-1 env glycoproteins are present, indicating that many anti-env antibodies are not neutralizing. There has been intense interest in determining the nature of neutralizing epitopes on the env protein. For some laboratory isolates of HIV-1, a significant proportion of the neutralizing antibody response is directed at an epitope located in the third hypervariable (V3) region of HIV-1 gp120 (141–143). This V3 loop has a conserved tip flanked on either side by variable residues. Current evidence suggests that this region of gp120 is involved in fusion events following the binding of virions to CD4+ cells. Mutations in the V3 loop decrease the capacity of the env protein to mediate membrane fusion events, but such mutations do not affect binding to CD4 (144). This region of gp120 is involved in interactions with the chemokine receptors that function as co-receptors for HIV-1. Regions of gp120 that are involved in binding to CD4 have been identified and can now be directly visualized due to the success of crystallographic studies (reviewed in reference 145). Neutralizing antibodies directed at the CD4 binding site have also been detected in HIV-1 seropositive individuals and are of particular interest because they neutralize diverse isolates of HIV-1 in contrast to V3 loop-directed antibodies, which are highly type-specific. Unfortunately, these antibodies appear slowly during natural infection and have proven difficult to induce with experimental AIDS vaccines, probably because the CD4 binding site on gp120 is located in a relatively "hidden" region protected by N-linked oligosachharides (146) and is surrounded by the variable loops which can accommodate mutations that allow escape from neutralizing antibodies (145).

There are several possible explanations for the failure of neutralizing antibodies to halt disease progression. One is that the neutralization of viral infectivity *in vivo* is more difficult than *in vitro* assays because of the much higher concentrations of infectable target cells in *in vivo* sites such as lymph nodes (147). If this is the case, high-titer neutralizing antibodies may be required to prevent infection and/or disease progression. A second explanation for the failure of neutralizing antibodies to prevent disease progression is that antibodies to the env protein may in some cases facilitate the uptake of HIV-1 by cells that express Fc receptors, such as monocytes and macrophages (148,149). This effect has been demonstrated *in vitro* but its *in vivo* significance remains to be established. Finally, as is discussed in the next section, failure of neutralizing antibodies to prevent disease progression may be due to the continuous emergence of neutralization-resistant variants, which is a reflection of the striking propensity of HIV-1 to undergo genetic change (reviewed in reference 150). Recent evidence suggests that the virus evolves so quickly that the neutralizing antibody response never "catches up" with the evolving virus. Late in the course of disease, there is also most likely a declining capacity to mount *de novo* antibody responses to new antigenic determinants. AIDS patients have greatly diminished antibody responses to novel and recall antigens both because of decreased T cell help and because of intrinsic B-cell abnormalities (120). One might, therefore, expect that late in the disease course infected individuals would have a decreased capacity to generate antibodies to newly emergent, neutralization-resistant variants.

CYTOLYTIC T-LYMPHOCYTE (CTL) RESPONSES TO HIV-1

The primary function of CD8+ cytolytic T lymphocytes is to lyse virally infected cells. HIV-1 specific CD8+ CTL are readily detected in healthy seropositive individuals and are sometimes detected in patients with AIDS (60–64,112,135–138). There is considerable current interest in whether these cells exert a beneficial antiviral effect by lysing HIV-1-infected T cells and macrophages (reviewed in 112). As discussed above, CTL appear early in response to acute HIV-1 infection and help to control the high level viremia characteristic of this stage of infection (60,64). CTL may also control viral replication through the release of chemokines (25). CTL isolated from infected individuals have been shown to lyse HIV-1-infected macrophages (136) and CD4+ T cells (151,152) *in vitro*. As discussed above, CTL may also control viral replication through the release of chemokines. Vigorous HIV-1-specific CTL responses are observed in many long term survivors of HIV-1 infection (153,154). Convincing evidence for the importance of CTL is the dramatic increases in viral load observed in SIV-infected macaques when CD8+ T cells are depleted (64). Interestingly, there is increasing evidence that MHC genotype can influence the rate of disease progression, likely through presentation of viral epitopes to CD8+ CTL (for a review, see 155). Particular class I MHC alleles have been associated with slower disease progression, probably as a result of the capacity of the relevant alleles to present conserved epitopes in HIV-1 proteins to CTL. The breadth of the CTL response is also important and perhaps as a consequence, heterogeneity at the class I loci is also associated with slower disease progression (156).

The frequency of HIV-1 specific CTL has been shown in some studies to decline as the clinical and immunological status of the patient deteriorates (136,157). In addition, there is evidence that the functional capacity of HIV-1-specific CTL is reduced in the setting of ongoing viral replication. Although further longitudinal studies will be needed to determine whether the drop in levels of virus-specific CTL is causally related to disease progression, it is quite likely that the CD8+ HIV-1-specific CTL response exerts a significant antiviral effect *in vivo* and is therefore beneficial to the host. Such a mechanism, while limiting the spread of infection, probably also contributes to CD4+ T cell depletion through the destruction of infected cells. As is discussed below, the emergence of viral variants with changes in epitopes recognized by CTL may permit viral escape from this component of the immune response.

HELPER T CELL RESPONSES TO HIV-1

The one component of the immune response to HIV-1 that is not readily demonstrable in most infected people is the helper T cell response to HIV-1 proteins (158). It appears that HIV-1-speciÞc CD4+ T cells are deleted or inactivated early in the course of the infection. They can be readily detected only in those rare individuals in whom the disease does not progress (long-term non-progressors). Interestingly, recent studies have shown that treatment of infected individual with HAART early in primary HIV-1 infection allows this HIV-1-speciÞc immune response to develop (158). In such individuals, multiple cycles of interruption of HAART has been shown to boost HIV-1-speciÞc immune responses, allowing eventual control of viremia at low levels in the absence of drugs (159).

In summary, vigorous B and CD8+ T cell responses to HIV-1 have been demonstrated in infected individuals. Although such responses ultimately fail to control the infection, they may delay the onset of symptomatic disease for a period of years. Subsequent sections discuss two principle mechanisms that allow HIV-1 to evade host immune responses. These are sequence variability and latency. The ability of the virus to evade these responses through these mechanisms, coupled with the progressive virus-induced destruction of CD4+ T cell compartment, eventually leads to immunodeÞciency.

SEQUENCE VARIABILITY IN HIV-1

HIV-1 exhibits a striking degree of genomic heterogeneity that is evident when the nucleotide sequences of viral isolates from different infected individuals are compared (160Ð165). This heterogeneity arises in part from the fact the HIV-1 reverse transcriptase has a high error rate (1/1,700Ð1/4,000 nucleotides) (166,167). Even distinct molecular clones of HIV-1 obtained from a single infected individual show sequence heterogeneity (168Ð170). Although viral clones from a given individual are more closely related to each other than to HIV-1 clones from other infected individuals, the level of genetic heterogeneity that occurs within a given individual is sufÞcient to produce variants with signiÞcantly different biological properties (97Ð99). Viral diversity can be assessed as divergence from the founder strain and as diversity of clones replicating at a particular time point. Both divergence and diversity increase with time although diversity eventually levels off as patients near the Þnal stages of the infection (31). Elegant studies by Mullins and colleagues have demonstrated a temporal relationship between changes in the degree of diversity and the rate of CD4 depletion (31). Of the protein products of the HIV-1 genome, the env glycoprotein gp120 shows by far the most sequence variability.

There is considerable current interest in the issue of whether or not this natural variation may contribute to the pathogenesis of AIDS by permitting the *in vivo* selection of variant viral clones that are not recognized by existing neutralizing antibodies or virus-speciÞc CTL (for a review, see reference 150). In other lentiviral systems, including visna virus infection in sheep and equine infectious anemia virus infection in horses, the emergence of viral variants resistant to neutralizing antibodies has been well documented (171). For HIV-1, neutralization-resistant variants have been obtained *in vitro* in infected cultures maintained in the presence of neutralizing antibody (172). In addition, neutralization-resistant variants have been isolated from gp120-immunized chimpanzees infected with HIV-1 (173). Neutralization resistance has also been studied extensively in a laboratory worker accidentally infected with a reference strain of HIV-1 (174). Numerous studies suggest that anti-gp120 antibodies arising in the setting of natural infection fail to neutralize contemporaneous virus; they have activity against previously circulating variants (150). With respect to CTL responses, viral escape has been documented in experimental systems (175) and in HIV-1-infected individuals (176) from the host CTL response. HIV-1 sequence variability may in principle affect T cell recognition of viral proteins in several ways. Mutations within an epitope may affect the binding of the processed viral antigen to the relevant MHC molecule or the recognition of the resulting peptide-MHC complex by the TCR. In the case of some epitopes, a considerable degree of naturally occurring sequence variability can be tolerated without loss of binding to the presenting MHC molecule, although for other epitopes even a single conservative substitution at a critical residue can prevent recognition in the context of the relevant MHC molecule. It has been proposed that mutations that lead to low afÞnity interactions with the TCR may actually antagonize the response (177). The role of CTL escape mutants in infections by HIV-1 and SIV has been controversial (150,175,178Ð181), but there is now substantial evidence that CTL exert selective pressure for mutations in critical epitopes (182) and that mutations can contribute to disease progression (183).

VIRAL LATENCY

Another factor that may contribute to the inability of the anti-viral response to eliminate HIV-1 infection is the latent reservoir of virus that is invisible to the immune system (reviewed in 184). The latently infected cells may contain viral nucleic acids in integrated or unintegrated forms as is discussed above. Cells in the post-integration state of latency provide a stable and inaccessible reservoir for the virus. Recent studies suggest that this latent pool persists even in individuals on effective antiretroviral therapy (184).

CONCLUSIONS

HIV-1 infection initiates an extraordinarily complex set of HIV-virus interactions that ultimately destroy the CD4+ T cell compartment of the immune system, resulting in profound immunodeÞciency. The key pathophysiological process is the loss of CD4+ T cells. CD4 depletion appears to be driven by viral replication. Most infected CD4+ T cells live only a short time due to viral cytopathic effects or destruction by host CTL. In addition to the death of infected cells, uninfected CD4+ T cells are depleted, probably as a result of the high levels of immune activation that are characteristic of HIV-1 infection. HIV-1 invokes a vigorous host immune response, but this response fails ultimately to control the virus due to the combined effects of viral variation, latency, and virus-induced immunodeÞciency.

Considerable progress has been made in *in vitro* analysis of the numerous potential immunologic and virologic mechanisms by which HIV-1 can induce immunodeÞciency. Critical areas for future research include analysis of which of the many potential mechanisms outlined above are actually responsible *in vivo* for the quantitative and qualitative defects in CD4+ T cells observed in HIV-1 infection. This will depend on the development of methods for monitoring these processes *in vivo* in natural infection in humans or in the closely related SIV model in macaques. Research in this direction is likely to be critical for the design of new therapeutic approaches and for the development of AIDS vaccines.

Chapter 12

The Role of Host Genetic Variation in HIV Infection and its Manifestations

Richard A. Kaslow, James (Jianming) Tang, M. Tev k Dorak

PERSPECTIVE, APPROACHES AND LIMITATIONS

As with ÒresistanceÓ and ÒsusceptibilityÓ to many other infectious agents, the likelihood and the consequences of becoming infected with HIV-1 vary greatly among individuals. In general, nearly all humans have some resistance to HIV-1, but quantitative differences do exist. A very small proportion of uninfected Caucasians are nearly completely protected against infection by a double deletion in a viral coreceptor gene (see below). Among infected persons, although viral replication is extremely rapid, early fulminant disease is rare. A few individuals, when left untreated, do succumb to serious immune deÞciency in a matter of months after initial infection, while many more retain intact immunity for years.

The sequence, structure and expression of human genes that control the response to HIV-1 are also extraordinarily variable. This variation (i.e. polymorphism) is believed to have evolved under long and steady pressure from the microbial pathogens, culminating in a wide range of immune responses from highly advantageous to distinctly disadvantageous. The theme of this chapter is ÒintrinsicÓ resistance and susceptibility to HIV/AIDS as determined by those human genes. After a brief review of the general approaches and pitfalls in unraveling how this host genetic variability contributes to the differential response, we summarize current knowledge about speciÞc genetic determinants of (1) transmission of infection; (2) early equilibration of virus concentration and disease progression; (3) occurrence of AIDS-deÞning opportunistic diseases; and (4) response to treatment and vaccines.

While laboratory tools have simpliÞed sequencing of genes and screening for their variants, there are no standardized approaches to designing studies, identifying candidate variants to pursue, and analyzing the data generated. Family studies, ordinarily a basic tool of the geneticist, have been largely limited to mother-infant pairs because informative kinships with and without HIV infection have generally been unavailable in the settings where genetic techniques are most readily applicable. Nearly all of the work summarized and cited here has derived from studies of unrelated individuals (population studies), often based on specimens banked from cohorts including dozens to hundreds of volunteers monitored regularly. The principal patient groups include (1) homosexual and hemophilic men in American, European and Australian cities; (2) female sex workers or heterosexual discordant couples in East Africa and Asia; (3) heterosexual adolescents and adults in the U.S.; and (4) infants of infected mothers in the U.S., East Africa, and South America. The more reliable studies have been those large enough to offer homogeneous subgroups of uninfected persons with detailed HIV-1 exposure history or of infected persons with carefully deÞned disease categories, staging and rate of progression.

Even in larger population studies there are obstacles to the analysis and interpretation of genetic data. An almost universal concern is that unaffected individuals selected for comparison with the affected, even from within the same cohort, may have different genetic backgrounds that could account for differences observed for the target loci (1,2). Ethnic admixture in a population group as heterogeneous as North American Caucasians reinforces this

James (Jianming) Tang, D.V.M., Ph.D.: Division of Geographic Medicine, Department of Medicine, University of Alabama at Birmingham, Birmingham, AL 35294.

M. TevÞk Dorak, M.D., Ph.D.: Department of Epidemiology, University of Alabama at Birmingham, Birmingham, AL 35294.

concern. The distribution of genetic polymorphisms further complicates the analysis. Each of the two inherited copies of a gene may show different deletions, insertions, inversions, duplications or other simple allelic variation such as single-nucleotide polymorphisms (SNPs). These genetic variations are distributed throughout the genome, with sequences corresponding to untranscribed, promoter and transcribed regions (introns and exons). Individual SNPs seldom sufficiently reveal the extent of genetic diversity. Rather, alleles consisting of multiple SNPs within a single locus are generally more informative. Furthermore, closely adjacent variations, either SNPs or alleles, occur in varying degrees of linkage disequilibrium (LD) with each other; that is, they may be inherited more often together as a unit (haplotype) than would be predicted by their individual frequencies. Such units often have evolutionary significance, having been preserved by a usually unexplained historical advantage. In a sense, LD is one form of *cis* interaction. Alleles at homologous loci may be identical or differ; of course, they may show different kinds of *trans* interaction reflected in their dominant, co-dominant or recessive expression. Sorting out all of these properties and properly accounting for them in the design of genetic studies and analysis of genotyping data is obviously not a simple matter.

Beyond the difficulty of evaluating effects of genetic variation in any single study population, influences of host genetic variants on HIV/AIDS almost surely differ in different settings. Genetic effects may be modulated by viral characteristics (e.g. HIV major group, subtype and phenotype and steady-state plasma concentrations) and by non-genetic host factors (e.g. race, age, and perhaps other inadequately studied features like gender, nutrition, co-infection, and route of exposure). Moreover, the effects of any of these factors or their combinations may differ with timeÑ because the virus is evolving rapidly within individuals and within a population. Thus, while effects observed consistently across viral subtypes or racial boundaries can provide some reassurance about their likely biologic significance, inconsistently observed effects are difficult to reject without substantial iterative analysis.

Several broad categories of genetic systems have been examined in the context of HIV-1 transmission, pathogenesis and intervention (Table 12.1). Within the space

TABLE 12.1. *Quantity and quality of evidence for human genetic polymorphisms associated with a feature of HIV-1 infection*[1]

Locus	Disease Control/ Progression	Transmission/ Acquisition	Secondary/ opportunistic manifestations[2]	Treatment effects
Major histocompatibility complex

constraints we discuss the most consistently reported or promising genetic variation in some detail, but only briefly mention other markers whose involvement seems less certain at this time.

MAJOR HISTOCOMPATIBILITY COMPLEX

Class I (*HLA-A*, *-B* and *-C*)

Background

Within the 4-megabase-long major histocompatibility complex (MHC) on human chromosome 6 are numerous genes responsible for both innate and adaptive immunity. Among them are the human leukocyte antigen (*HLA*) class I system, which consists of the major products of *HLA-A*, *-B*, and *-C* loci along with catalytic, transporter, chaperone and other components working in concert. Each A, B and C protein, coupled with a β_2-microglobulin molecule, has a pocketed groove that binds antigenic peptides arising intracellularly in the course of normal cell function or from tumors or viruses. Resting in the specific different binding grooves, peptides 8–11 amino acids long are cradled by *HLA* molecules as they are shuttled to the cell surface. There the protein-peptide complex interacts with receptors on CD8+ T-lymphocytes to initiate a variably effective, primarily cytolytic response.

Presumably through long, continuous and differential environmental exposure, a large number of variations (e.g. gene conversions, duplications, recombinations) have accumulated in the sequence of DNA and corresponding amino acids in *HLA* molecules, especially in the residues along the peptide-binding groove. There are more than 400 forms of the *HLA-B* molecule alone and dozens of variants at each of the other class I loci (3); this extreme *HLA* polymorphism has drawn great investigative attention. A sizeable body of experimental and population research has documented how allelic variants carried by individuals differentially influence their response to antigenic challenge, and increasingly refined techniques for molecular typing have improved the ability to discriminate subtle differences among the variants that may explain the diversity (4).

The evidence for involvement of the *HLA* class I system in the pathogenesis of viral infections is conclusive, and its importance in immunity to HIV infection is increasingly clear. Much effort is being devoted to elucidating the events by which class I molecules differentially restrict HIV peptide binding, control peptide transport and presentation, and evoke critical specific CD8+ cytotoxic T-lymphocyte (CTL) responses. Briefly, in human as well as non-human primates, efficient control of viral replication is lost as a result of deficiency in CD4+ cells coupled with a malfunction of CD8+ T-cells (5–11). These derangements may be delayed or reversed by efficacious vaccines (12–15) and effective antiretroviral therapy.

Disease Progression and Early Host/Virus Equilibration

Much early research on the effects of class I polymorphism in HIV infection was conducted in cohorts of Caucasians, who were infected with HIV-1B relatively early in the epidemic and followed long enough to observe divergence in late clinical outcomes (16–19). Only recently have results begun to emerge from investigations in populations of African ancestry infected with A, C, and D subtypes and Asian populations with subtype E and A/E recombinants. Careful comparisons of class I effects in groups infected more recently with those infected earlier with the same subtype have not yet been performed, and it is not clear whether "intra-clade" evolution has been paralleled by a drift in the effect of any specific class I marker associated with slower or faster progression (see below). Both similarities and differences across races and viral subtypes have been reported, but most will require considerably more work before meaningful inferences are possible. The few generalizable observations are summarized in Table 12.2.

Rather consistently, homozygosity at a single class I locus has been found to accelerate onset of disease, and further reduced diversity (at two or three class I loci) is even more disadvantageous (20–22). With similar but not complete consistency, certain individual class I alleles have been associated with a favorable (B*27 and 57) or an unfavorable (B*08, the B22 serogroup, B*35, and B*53) natural history of infection (21–33). Particularly intriguing is the persuasive demonstration in Caucasian and African ethnic groups with subtype A, B or C infections that B*57 is a uniformly favorable allele (21,22,27–31,33–35). It apparently mediates effective CTL responses to highly conserved Gag epitopes, presumably critical to viral replication (34–36). On the other hand, it has been suggested that a subset of B*35 alleles (B*3502 and 3503) along with B*53, which share a binding pocket motif that distinguish them from other B*35 alleles, fully account for the deleterious effects of B*35 seen rather consistently in Caucasians (32). The importance of that degree of allelic specificity has not been widely corroborated epidemiologically or confirmed experimentally. Finally, a number of other alleles have shown more variable effects, again documented largely in Caucasians infected by clade B virus and confirmed to varying degrees in African-Americans with clade B as well as Africans with clade A infection (37,38).

Efforts to summarize the multiple effects of markers more consistently associated with relatively extreme outcomes have taken fairly simple combinatorial approaches. One uses an algorithm that simply assigns individual values to each marker, sums the values to produce a profile for each individual, and categorizes individuals with similar profiles. It begins to capture the impressive collective impact of the most informative *HLA* class I (and *CCR2-CCR5*) markers (Figure 12.1), but this and other relatively simple approaches (39,40) will most

[1] Based on two independently assembled and *HLA*-typed populations (seroconverters or seroprevalents with closely estimated duration of infection and median duration of follow-up > 6 years) with > 100 main endpoints (AIDS cases) in studies showing consistent associations.
[2] A, B and C = HIV-1 subtypes studied; 0, no effect; –, unfavorable effect; +, favorable effect; double symbols indicates greater strength and consistency of association.

likely be replaced by more sophisticated ones as understanding of these genetic effects increases.

Recent effort has begun to extend the Þndings to earlier stages of infection. Preliminary studies of subtype B infection suggest that homozygosity and many of those individual markers at class I loci clearly associated with a better or worse long-term prognosis exert a sizable portion of their effects on HIV-1 RNA concentration as early as six months after seroconversion. The strong linear relationships between early viral load and the algorithm-based proÞle seen in Caucasians (R. A. Kaslow et al., unpublished) appears to hold for African-Americans (37); however, as exempliÞed by Þndings with CCR, it is premature to predict the extent to which early and late effects can be expected to parallel each other within the same ethnic group or even in the same cohort (41,42). On the other hand, if activation of CD8+ CTLs and perhaps other related pathogenetic mechanisms mediated by class I gene products occurs soon after infection, and *HLA* class I polymorphism substantially inßuences the ultimate outcome of HIV infection by governing early viral replication dynamics, the implications for prognostic assessment and other applications are important.

Transmission and Acquisition

*a. Sexual*Ñ The evidence for a critical role of CTL response or differential effects of *HLA* class I markers in protecting against transmission of infection from person to person is accumulating, but the Þndings are not quite so persuasive as for control and progression of disease

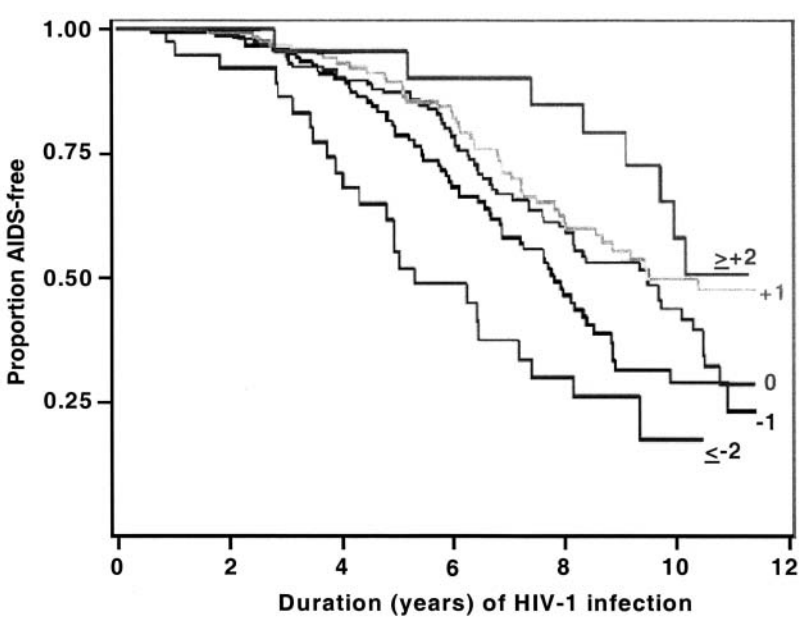

FIG. 12.1. Progression of HIV-1 infection according to pro le of polymorphisms in *HLA* class I and *CCR2-CCR5* genes in a cohort of 470 HIV-1B-infected Caucasian men. Each man was scored using an algorithm based on established marker effects (–1 or –2, respectively, for homozygosity at 1 or > 1 *HLA* class I locus; –1 for *HLA-B*54Þ56*, *B*35*, *B*53*, and *CCR5* promoter genotype E/E; +1 for *B*27*, *B*57*, *CCR5-D32*, *CCR2Þ64I*, and +2 for the Δ32/64I combination.

(43–48). Much of the information on acquisition in adults comes from highly exposed but persistently seronegative (HEPS) individuals—usually uninfected sex workers or gay men selected for intense sexual activity. HIV-specific CTL responses to viral products if not replication-competent virus have been detected in HEPS (47,49–52), but protection by those CTLs has been difficult to establish. Few studies have been designed to assess risk of transmission between members of HIV-discordant cohabiting couples (53,54). A serious obstacle to documenting the role of class I-mediated immunoregulation is the prominence of other elements of immunity (55,56) and particularly of non-genetic factors (e.g. gender, intensity of exposure to the virus, modes of transmission) that are often overlooked or omitted in studies of HEPS.

Enhanced transmission due to sharing of class I alleles has been examined in three studies comparing HIV-concordant and discordant heterosexual couples (45,53,54). A small, ethnically mixed group in the U.S. showed no difference in allele sharing by discordant and concordant couples. Caucasians in Edinburgh showed an association of transmission with overall concordance for any allele at the A, B or DR locus (53). Conclusions may have been limited by sample size, ethnic heterogeneity, serologic typing, or statistical analytic approach. In a larger and more comprehensive prospective investigation of cohabiting Zambian couples discordant for HIV-1C (57–59), sharing of one or more *HLA-B* alleles by partners was independently associated with heterosexual transmission of virus documented as identical in the donor and recipient (54), whereas class I homozygosity did not confer increased risk. The allele-sharing effect in partners with identical virus may be due to allogeneic "priming," in which susceptibles are exposed more and respond more intensely to infected partner cells bearing non-identical ("foreign") class I allelic forms than to cells that carry one or more shared forms. One way or another, donor virus may have "pre-adapted" to the likely CTL repertoire in the prospective recipient host, under close control of *HLA-B* and perhaps other class I alleles.

Individual class I alleles have also been associated with promotion or inhibition of transmission. However, again, small sample sizes, ethnic diversity, absence of details of behavioral or virologic exposure, and analytic differences have left uncertainty for many single alleles (45). An apparent protective relationship with A*6802 and the A2/6802 supertype to which it belongs was originally described in the primarily HIV-1A-infected Kenyan sex workers (48) and subsequently reported to inhibit transmission to their infants (60). A similar effect has been observed in HIV-1B-infected Caucasians in the large Multicenter AIDS Cohort Study (MACS) (61) but has not been reproduced in other settings. Correlative epitope mapping data now suggest that the critical viral antigenic peptides likely to stimulate a protective response are often preferentially targeted in HEPS (62,63). Another suggestive finding in the MACS was that B*3502 and *3503 subtypes of the broader risk marker, B*35, conferred increased risk of seroconversion (61) as similar to that observed for disease progression (64), ostensibly due to their distinctive peptide-binding profiles. Zambians differed, however, with little if any effect for B*53, despite its preference for epitopes identical to those bound by B*3502 and *3503 (33). The converse also occurs: although B*57 is consistently involved in suppressing viral replication and retarding development of immunodeficiency in infected individuals, no study of transmission recognized corresponding protection of uninfected individuals by this allele. Such distinctions could be crucial for vaccine development. As for other alleles, relationships in single and usually small populations have not yet been reliably replicated and thus should be viewed with particular caution.

b. Perinatal— In Kenyan sex workers, maternal-fetal allele sharing at class I loci in general has been associated with increased perinatal as well as with sexual transmission (65). The protective effect of the A2/A6802 supertype noted above with horizontal transmission was also observed for vertical transmission (48,60). No other studies have been reported.

Secondary Manifestations

Limited research into possible class I influences on secondary opportunistic features of HIV infection has been performed, most of it on Kaposi's sarcoma (KS) in infected men. To date the findings in several studies remain unconvincing because of their small size and typing techniques now considered imprecise. It must be emphasized that any investigation of determinants of a secondary event must exclude confounding by either the effect of the risk factor in modulating the course of HIV infection or by its independent association with one of the other frequent secondary outcomes.

Treatment and Vaccine Responses

a. Abacavir hypersensitivity— Concerted effort to evaluate host genetic influences on virologic and immunologic responses to treatment is impeded by the difficulty in excluding variable adherence to complicated antiretroviral regimens and in interpreting the significance of resistance mutations in HIV isolates. However, adverse responses can be examined more readily. Accordingly, two recent parallel studies in two separate groups of patients taking the nucleoside analogue abacavir have yielded impressively strong evidence for an association between drug hypersensitivity and *HLA-B**57, with or without other MHC genes in the haplotype including DRB1*0701 (66, 67). Hypersensitivity occurs in 10–15% of patients taking abacavir, but the two case-control studies implicated B*57 in the vast majority of cases, with relative odds >30 in

both. Withholding of the drug from individuals found for other reasons to carry B*57 would be prudent; however, the mechanism for this phenomenon is not yet known, and carriage of the allele is not considered a sufficiently reliable predictor of an adverse reaction to warrant routine HLA screening. Various other genes being screened in these studies did not show any appreciable effects on therapy.

b. HIV Vaccine Response—Vaccine-generated CTL response mediates protection against simian immunodeficiency virus (68–70), but CTL-dependent efficacy has not yet been demonstrated for any human vaccine (71). Differential restriction of responses by polymorphic *HLA* class I and/or class II gene products had been suggested with vaccines against other human viral pathogens (72–74). Early trials of an HIV-vaccinia combination (75) also hinted at such regulation. The most direct evidence comes from a trial of recombinant HIV-1-canarypox vaccine in uninfected recipients (71,76–78) in which class I alleles (B*27 and B*57) recognized as the most consistently advantageous in infected individuals generated earlier and/or more sustained HIV-1-specific CD8+ CTL responses than did the other alleles in aggregate (79).

Other Markers in the Class I Pathway—*TAP1/TAP2*

The transporters associated with antigen processing (TAP1 and TAP2) form a heterodimer that pumps enzymatically degraded cytoplasmic peptide fragments into the lumen of endoplasmic reticulum. There peptides are loaded to the class I heavy chain by tapasin and other chaperone molecules. *TAP1* and *TAP2* genes display only modest polymorphism, but variant forms are still being defined (80–82). Functional significance of TAP alterations and disease associations (83–89) fit with limited and not always consistent experimental evidence that certain polymorphisms alter peptide processing (90,91). Earlier positive findings with single variants of each gene (22,27,92) have not been examined in other cohorts, and these analyses did not fully account for all relevant alleles or extended haplotypes. It will be difficult to sort out concurrent relationships with HLA, TAP1, TAP2, tapasin and other accessory molecules in the class I pathway because close functional interactions among them may obscure the effect of any single marker.

Class II (*HLA-DRB1*, *-DQA1*, *-DQB1*, *-DPB1*)

Background

The class II response pathway and its principal effector cell, the CD4+ T-lymphocyte, is the critical coordinator of the immune response to HIV—regulating generation of CTLs, cytokine expression, antibody production, and other functions involved in control of the infection (93,94). Epitope-specific CD4+ cell enhancement in HIV infection has recently been emphasized (95). At the centromeric end of the *HLA* region, genes in the class II pathway encode products specialized for capturing lysosome-derived peptides and presenting them to regulatory or cytolytic CD4+ T-cells. The genetic structure and function of these genes governing interaction with CD4+ cells are well described (96–98). The highly polymorphic classical class II genes (*DRB1*, *DQA1*, *DQB1*, and *DPB1*) encode molecules have a longer binding groove, open (flexible) enough at each end to permit binding of peptides of more variable length and composition than for the class I products. Common alleles are readily sorted by standard molecular techniques that concentrate on the hypervariable region of exon 2 (4).

Disease Progression and Early Host/Virus Equilibration

Associations of specific *DR* or *DQ* alleles/haplotypes with variable control of early HIV infection or subsequent clinical course have been more difficult to demonstrate than for class I markers, and their differential impact remains unclear. In contrast to the importance of heterozygosity at class I loci, *DRB1* and *DQB1* heterozygosity appears to offer little or no advantage in delaying onset of disease (20). Inconsistencies have also been observed for relationships of individual alleles or haplotypes, particularly among earlier studies of smaller numbers of subjects, but larger cohort studies may help resolve them (22,28,29,99,100) (Kaslow, unpublished). The difficulty in establishing a role for class II polymorphism may be explained by the more accommodating class II binding grooves, which do not discriminate as precisely as those of class I among the large array of available peptides. High degree of redundancy in class II alpha and beta chains may further compensate for the specificity of certain allelic effects. However, these explanations are not entirely satisfying because for infection with the highly mutable hepatitis C virus (HCV), there is growing evidence of specific class II allele/haplotype-regulated control of viremia rather than indifference to such variation (101–103).

Transmission and Acquisition

Only minimal effort has been devoted to date to examining the role of class II markers in acquisition and transmission of infection (48,104) and no clear effects have yet been confirmed.

Secondary Manifestations

An initial study of disseminated Mycobacterium avium complex (DMAC) (105) suggested relationships with

*DRB1*1502-DQB1*0602* compatible with those observed in tuberculosis and leprosy and with *DRB1*0701*. They remain to be conÞrmed.

CHEMOKINE RECEPTOR AND LIGAND GENES

CCR2, *CCR5* and *SCYA3Ð5*

Background

The families of human C-C and C-X-C chemokine genes encode molecules that accumulate and act where inßammation occurs. These secretory products {e.g. regulated on activation, normal T expressed and secreted (RANTES), macrophage inßammatory proteins 1 alpha and beta (MIP-1α and MIP-1β), and others} bind to a range of receptors in the CCR family, while stromal cell-derived factor 1 (SDF-1) is the exclusive ligand for CXCR4 (106). These interactions govern cell adhesion, cell migration into sites of inßammation, internalization of receptors for recycling and/or degradation, and gene expression along the separate pathways of Th1 and Th2 lineages with their corresponding immunoregulatory functions. The majority of chemokine genes (in particular, *SCYA3-SCYA5*, encoding MIP-1β, MIP-1α and RANTES) reside on chromosomes 4 and 17 (107Ð113). *CCR* and *CXCR* genes encoding the corresponding receptor proteins are mostly arranged on chromosomes 2 and 3 (114Ð119).

The Þrst link between the chemokine receptor and ligand family members and the pathogenetic process of HIV infection was forged by the discovery of increased levels of RANTES, MIP-1α and MIP-1β in uninfected persons with suppressed replication of macrophage (M)-tropic HIV-1 (120Ð123). M-tropic HIV-1 competes with C-C chemokines for positions on any of several CCR receptors, but particularly CCR5; receptor preference has led to its alternative designation as R5 virus. T-cell-tropic HIV-1 competes with SDF-1 as the natural ligand for receptor CXCR4; this form of virus is designated X4 (124). Certain viruses are dual tropic (124Ð126). During transmission and initial stages of HIV infection, the non-syncytium inducing (NSI) and largely R5 phenotype in the virus population utilizes CCR5 as the preferred coreceptor (127Ð131). Later in the course of infection CXCR4-using X4 virus often becomes dominant. Several reviews provide additional detail (132,133). Another chemokine receptor, CX3CR1, has recently been implicated as a co-receptor for HIV; investigation of its role and that of its ligand fractalkine are at earlier stages.

Receptor ligand interaction have been linked to alteration of CD4+ cell counts and viral RNA concentration (viral load) during HIV-1 infection. However, the functions of chemokine receptors and their ligands in HIV-1 infection are obscure and complicated (134Ð136). Their full effects are not easily captured by simple correlations of circulating viral RNA or disease progression, or even by focusing on cell lineage-speciÞc chemokine production or receptor expression (137Ð140).

Polymorphisms in the genes encoding chemokine receptors and ligands have been extensively investigated for corresponding variation in their genetic, biochemical, and physiologic properties (141Ð143). This work has been difÞcult to follow because of the profusion of molecular variants and multiple simultaneous genetic designations; hopefully, an ongoing effort to catalogue the expanding number of genes and standardize their sequence nomenclatures (144) will soon reverse the confusion. The redundancy and ambiguity has affected population studies of receptor/ligand polymorphisms as well as the documentation of the basic research, but simplifying approaches have begun to resolve clinically and epidemiologically relevant contributions of *CCR2* and *CCR5* alleles and their haplotypic lineages (41,42,145).

Disease Progression and Early Host/Virus Equilibration

*a. CCR2 and CCR5*Ñ Polymorphisms in the coding or promoter and regulatory regions of certain chemokine receptors are unequivocally linked to critical events in the pathogenesis of HIV-1/AIDS. The most important observations and well established relationships are summarized in Fig. 12.2. The evidence for a causal relationship is strongest for the 32-base pair deletion (D32) at the distal end of the coding region of the *CCR5* gene. The deletion truncates the gene sequence and aborts the production of message. About 15Ð20% of Caucasians carry the deletion on one chromosome and 1Ð2% on both; in the latter homozygosity abolishes cell surface CCR5 expression altogether (129,146Ð149). Presence of a single copy of this variant has repeatedly been associated with more slowly evolving immunodeÞciency in HIV-1-infected individuals and with delayed disease onset (19,41,42,146Ð148,150). Reduced receptor expression due to this deletion appears responsible for lower equilibrium concentrations of HIV-1 RNA relatively early in the course of infection in essentially untreated (19,42,151,152) treated (153Ð155), or mixed (156) groups of patients. Elevated levels of CCR5 in Δ32 heterozygotes have likewise been associated with decreased HIV-1 RNA levels (157). Additonal mutations in the *CCR5* coding region include a point mutation encoding that confers *in vitro* resistance to HIV-1 when it occurs in conjunction with ΔD32 (158).

Although the receptor function of CCR2 in HIV infection remains uncertain, a 190G-to-A substitution produces a 64I variant in the gene for that receptor (Fig. 12.2) that has been associated with slower disease progression somewhat less consistently than D32 (19,41,42,156,159Ð166) and with establishment of a more favorable early viremic equilibrium in Caucasians (19,42). The effect may be due to its linkage with variants in the *CCR5* promoter region rather than to the 64I polymorphism itself (41,143,160,167,168).

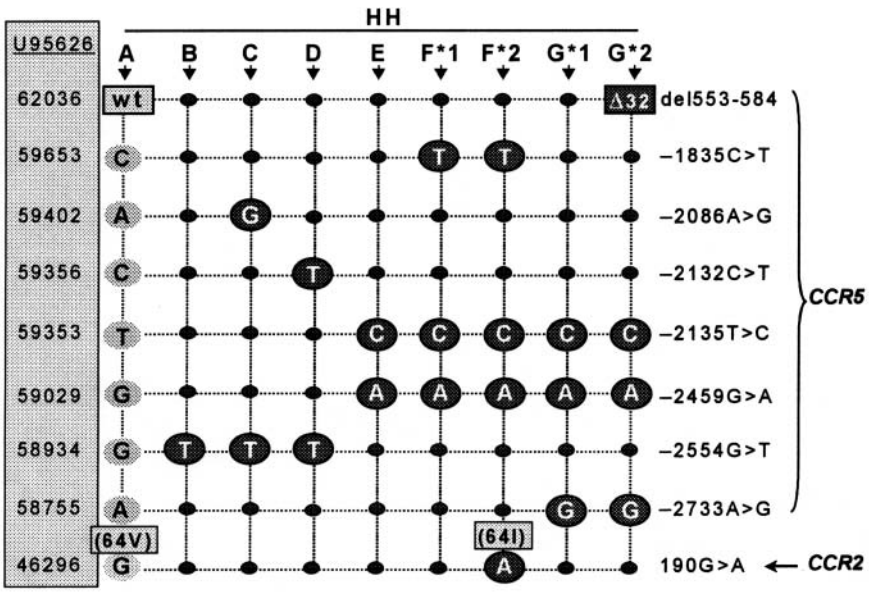

FIG. 12.2. *CCR2-CCR5* haplotypes on chromosome 3. Eight single-nucleotide polymorphisms (SNPs) and a 32-bp deletion (Δ32) de ne nine major human haplotypes (HH) known as A through G*2 (top). Sequences identical to these shown in haplotype A are indicated by dots. The 5-digit numbers (left) are based on Genbank sequence U95626, while 3- or 4-digit numbers (right) refer to positions relative to the ATG translation start site in the transcribed *CCR2* (lled box) and *CCR5* (open boxes) sequences. The open reading frame (ORF) of *CCR5* is part of exon 3. The *CCR2* 190G > A SNP has been commonly referred to 64V/I to re ect the predicted amino acid substitution.

The major CCR effects involve: (1) *CCR5-Δ32* (G*2 haplotype)—Homozygotes for this largely Caucasian variant show virtually completely protection against acquisition of HIV-1 infection, and in larger studies heterozygotes show partial protection. Heterozygotes have been consistently reported to experience slower disease progression (19,41,42, 146–148,150). (2) *CCR5* promoter genotype E/E—This is a more precise set of SNPs associated with susceptibility to infection and repeatedly with faster progression in both Caucasians and those of African descent (41,42,173,174). This is included in the less speci c genotype P1/P1 (combinations of 59029A, 59353C, and 59356C) reported rst with rapid progression (170). All of these are reciprocal to the 59029G SNP originally reported with slower disease progression (169). (3) *CCR2* SNP 190A encoding 64I (F*2 haplotype)—This variant has been repeatedly but not uniformly associated with slower progression (19,41,42,156,159–166). (4) *CCR5* promoter genotype D/D—This has been reported with vertical transmission in African-Americans (180). (5) Other promoter SNPs, haplotypes and genotypes—These have been reported to show relationships in single studies (158). Adapted from Ref (133).

TABLE 12.3. *Association of CCR2-CCR5 genotypes with acquisition of HIV-1 infection in MACS based on the comparison of heavily exposed and persistently seronegative (HEPS) caucasians with all or with heavily exposed caucasian seroconverters (Scs)*

			Seroconverters (SCs)[a]				Analysis with All SC[a]				Heavily exposed SCs[a]			
CCR2-CCr5 Genotype	HEPS (90)[a]		All (469)		Heavily exposed (270)		Model 1[b]		Model 2[b]		Model 1[b]		Model 2[b]

[a] As de ned in the text, HEPS had up to 500 + homosexual partners between 1984 and 1986 while heavily exposed SCs had 50–500 + (median = 113) partners during the same period.
[b] Model 1 includes G*2/any, E/E, and others (ref); A/G*2 replaces G*2 in model 2.
[c] Odds ratio (OR) and p values are based on logistic regression (LR) by maximum likelihood estimate.
Reproduced from Tang et al. (42), with permission.

Numerous efforts to demonstrate effects of one or more SNPs in the promoter region of *CCR5* have led to wide acceptance of a role for certain combinations of *CCR2* and *CCR5* markers in altering the regulation of HIV infection, but precise relationships remain uncertain. Several SNPs along the sequence of the *CCR5* promoter have been associated with either slower or faster disease progression (41,156,169–172). Adults treated variably and even aggressively with HAART also showed some effect of promoter polymorphism (153–156). However, the full array of common *CCR2* and *CCR5* single-nucleotide polymorphisms (SNPs) and their interrelationships had not been examined comprehensively until recently (41,42,173,174). Thorough documentation of the extended *CCR2* and *CCR5* haplotypes has suggested that speciÞc haplotypes, including the one carrying Δ32, either alone or paired as genotypes, inßuence the course of HIV-1 infection. Some more consistent relationships are summarized in Fig. 12.2.

Efforts to unravel these intricate receptor-virus relationships have still not deÞnitively shown how polymorphic variants might differentially alter *in vivo* HIV-1 pathogenesis at any speciÞc time or over the course of infection. Haplotype-speciÞc regulation of CCR receptor expression could shift production dynamics of viral phenotype toward ascendance of X4 virus using predominantly CXCR4 or dual-tropic virus (175). Thus, as a result of altered tropism, over time, earlier unequivocal effects of *CCR5* polymorphism may dwindle and previously less prominent ones may emerge. Finally, although most of the reported relationships were found in Caucasian populations, there is some but not total consistency in groups of African ancestry (41,133,174) as well as suggestions that the inßuences of these haplotype combinations may differ according their racial distribution (41,145,173). Such variations could have a differential impact on the course and the burden of disease in ethnically diverse populations (133,145).

*b. SCYA3–5 (MIP-1a, MIP-1b, RANTES)*Ñ Polymorphisms in genes encoding these ligands for *CCR5* have more recently been implicated directly in the control of expression. Two SNPs in the *SCYA5* (RANTES) promoter (–28C/G and –403G/A) reportedly alter transcription activity and differentially inßuence HIV disease progression in both Japanese and Caucasians (176,177). Although the two studies seem inconsistent at Þrst pass, the Þndings were typical of a combined (i.e. haplotype) effect, perhaps operating differently according to ethnic background. *SCYA5* haplotype effects have also been studied (145), as have *SCYA3* (MIP-1a) genotypes, deÞned by two SNPs (+113C/T and +459C/T). These promising preliminary observations will undoubtedly receive further attention.

Transmission and Acquisition

*a. CCR2 and CCR5*Ñ Innumerable studies have documented the effect of a single copy of Δ32 in inhibiting M-tropic HIV from penetrating an otherwise susceptible cell, and virtually complete protection from infection among the small fraction of Caucasians with both copies deleted (129,146–149). More recently, comparison of highly exposed but uninfected participants and seroconverters in the MACS (42), as well as analysis of horizontal and vertical transmission in other populations (178,179), have documented more subtle degrees of protection against initial HIV-1 infection among Δ32 heterozygotes. An independent role of the *CCR2*–64I mutation in acquisition has been less consistently documented (42,180,181) and remains rather uncertain. Homozygosity for a another haplotype (Fig. 12.2) found largely in ethnic Africans has been reported to be more frequent in perinatally infected than uninfected African-American (180).

*b. SCYA3–5*Ñ Less work on these variants has been done for transmission than for disease progression. In a preliminary study, the *SCYA3* CT haplotype, found mostly in those of African ancestry, was reported to be more frequent in HIV-1-negatives than -positives (145).

CXCR4 and *SDF1*

The Þnding that the common 801A variant in the 3′ untranslated region of *SDF1* may be involved in upregulation of its expression led to further observations on SDF-1 inhibition of binding of T-tropic HIV to CXCR4. As originally observed, infected homozygous A/A individuals experienced slower progression (182), but this relationship has not been readily reproducible (19,183–186). Some studies have actually described a more unfavorable disease course (183,187) higher rates of viral replication (188), or more complicated relationships (189).

Along with ambiguity surrounding the *SDF1* 3′A/A effect in HIV-infected individuals, it seems doubtful that heavily exposed uninfected homozygotes are protected. In a study of Kenyan infants, heterozygous mothers actually transmitted HIV to their infants, particularly those who were breast-fed, at signiÞcantly higher frequency than mothers carrying the wild type (190). Infant genotype appeared to play no role in acquisition. While the products of the wild type and *SDF1* variant may compete differentially with HIV for the CXCR4, the apparent involvement of the latter in perinatal transmission during breastfeeding but not in the immediate peripartum period would be difÞcult to explain biologically. Acquisition of HIV was also unaffected by infant carriage of the variant in an Italian study of vertical transmission (187).

CX3CR1

Reports from two Caucasian cohorts on this member of the chemokine receptor family provided contrasting results on the relationship of 249V/I and 280T/M genotypes or

the 249I-280M haplotype to infection and progression (191,192). The 280M homozygotes were concentrated in the seroconverters among European but not American patients, while 280M heterozygosity was associated with slower disease progression in the Americans and with either unaltered or faster progression in separate European subgroups. Those discrepant population effects of the *CX3CR1* polymorphisms remain unexplained (193). Reduced coreceptor activity was demonstrated in an initial study employing a cell-cell fusion assay with plasmid or vaccinia recombinants containing the 280M variant, but coreceptor surface expression was normal (192). No polymorphisms in the corresponding ligand fractalkine have been described in conjunction with HIV infection. In short, the importance of variations in the genes of this system is unclear.

Secondary Manifestations

*a. CCR2-CCR5*Ñ There is growing interest in the chemokine receptor/ligand systems as determinants of AIDS-related neoplasms (184,194,195). In a comparison of patients with non-Hodgkins lymphoma with other HIV-infected patients who were comparable in their course of infection, D32 was associated with a three-fold lower risk; no difference in risk was seen for Kaposiõ sarcoma (194). High levels of SDF-1 may occur in conjunction with the *SDF1* 3′A variant (homozygous and heterozygous) in non-Hodgkins lymphoma among HIV-infected but not among uninfected lymphoma patients (189).

CYTOKINES

TNF/LTA and *IL10*

Tumor necrosis factor alpha (TNFα) and the closely related lymphotoxin alpha (LTα) {formerly (TNFβ)} are potent pro-inßammatory cytokines. In a variety of circumstances the former is an antagonist of il-10. *TNF* and *LTA* are encoded together in the central MHC on chromosome 6 and share sequence motifs and function as trimers (196). Their complex mechanisms of action are not fully understood. TNFα appears to beneÞt the virus more than its host by increasing virus concentration, exacerbating treatment failure, and accelerating onset of AIDS (197Ð201). The *IL10* gene on chromosome 1 encodes a protein that down-regulates expression of MHC class I and II molecules and production of Th1 cytokines (202Ð206) and may upregulate *CCR5* expression and function (207). Both TNFα and *IL-10* also activate components of HIV-1 itself (i.e. LTR, Vpr, Rev, Gp120).

Well-described SNPs in the *TNF* promoter region (Ð238 and Ð308, also designated Ð237 and Ð307 (208)), microsatellites (*TNFa-e*), or other markers (e.g. *LTA*) in the extended MHC haplotype identify subsets of individuals with perturbed levels of circulating or locally produced TNFα (209). Disproportional distributions of certain *TNF* and *LTA* variants, repeatedly invoked to explain dozens of disease processes, have not been closely correlated with altered TNFα levels or occurrence of disease; moreover, the strong linkage disequilibrium with other alleles in extended MHC haplotypes has often been ignored (210Ð212). Reports of association of the Ð308A variant with enhanced transcriptional activity have conßicted (213,214). Overall, the few studies on differential effects of *TNF* polymorphism on HIV-1 occurrence and disease progression have been unpersuasive (215Ð217). Newly described variants in *TNF* require reassessment, and further claims for pathogenetic involvement in HIV must exclude the strong effects of disequilibrium with alleles at other MHC loci.

For *IL10*, three promoter SNPs (at Ð1082, Ð819, and Ð592 relative to the transcription start site (218)) form three combinations (ATA, ACC, GCC) that appear associated with differential IL-10 expression, and under certain circumstances the ATA combination codes for suppressed production (219). *IL10* SNPs individually or in the corresponding haplotype have been associated with both HCV and HIV-1 infection (220,221). In a large study of HIV-1 infection in multiple cohorts, the single Ð592 5′A SNP in the promoter was associated with increased risk of HIV infection and relatively rapid progression to AIDS (220). Because the Þndings were based on large numbers in multiple cohorts and internally consistent, it seems likely that reÞnement of the lineages involved and conÞrmation by other investigators will corroborate those relationships.

IL6

No work on the effects of *IL6* variants in HIV-1 infection has been presented to date. For KS, among several pro-inßammatory cytokines and growth factors thought to enhance its development, an *IL6* polymorphism has been associated with the disease both in experimental work and an unconÞrmed population study (222). The *IL6* Ð174 G/G promoter genotype found in conjunction with higher IL-6 production showed a signiÞcant association with that AIDS complication, in contrast to the C/C genotype ($p < 0.01$). Attempts to replicate this relationship are underway.

Other Cytokines

Single studies on such other cytokines as *IL4* (223) and *IL1RA* (224) have also begun to appear, but they cannot yet

be properly placed in the context of HIV/AIDS pathogenesis.

OTHER

MBL2 (Mannan Binding Lectin 2)

Relatively small individual studies of the gene encoding mannan binding lectin (MBL, also called mannan binding protein) have not produced readily interpretable Þndings. Among 131 HIV-1-infected homosexual seroconverters, men with a variant of the gene progressed relatively more slowly to AIDS (particularly Kaposiõs sarcoma) and death (225). In exposed HIV-uninfected as well as infected children compared with controls, a homozygous variant at position Ð550 of the *MBL2* gene altered vertically transmitted infection and its outcome (226). More work is obviously needed to reach any conclusion about the role of these variants.

ANTIRETROVIRAL DRUG METABOLISM

A recently published pharmacogenetic investigation of the multi-drug resistance transporter gene (*MDR1*) in European Caucasians undergoing protease inhibitor therapy (227) produced the Þrst evidence of host-mediated variation in response to antiretroviral agents. Patients homozygous for the T form of *MDR1* showed signiÞcantly lower expression of the encoded transcript for P-glycoprotein, lower plasma concentrations of nelÞnavir and efavirenz and greater increases in CD4+ cells after initiation of treatment than those with C/T or C/C genotypes. Although unconÞrmed, the results suggest that T/T homozygosity is advantageously associated with reduced expression of the transporter protein and redistribution of protease inhibitors in ßuid and cell compartments. In the same patient group measurements of sequence variants known to predict altered function of the cytochrome P450 gene *CYP2D6* also suggested a differential allelic effect on drug concentration.

SUMMARY

Human genetic polymorphisms (variants) contribute signiÞcantly to variability in the acquisition, course and complications of HIV infection. Two major gene systems, the classical *HLA* class I and the chemokine receptor/ligand systems, have well established roles in determining the variability in occurrence of infection and disease progression; for several others, supporting data are suggestive to different degrees but not yet conclusive. With *HLA* class I alleles, both HIV-negative sex partners of HIV-infected adults and infants of infected mothers who share the same allele are more prone to infection. Overall diversity (i.e. heterozygosity) of class I alleles is advantageous in delaying disease progression. Certain individual alleles clearly retard (*B*27* and *B*57*) or accelerate (some if not all *B*35* alleles) the disease process, probably by regulating the host-virus equilibrium relatively early in the infection. With the key chemokine receptor gene (*CCR5*), a deletion of a portion of its coding region reduces expression and function as the major HIV-1 coreceptor. Individuals who have inherited the 32-base pair deletion on both chromosomes (i.e. homozygotes) are almost completely protected from infection, and heterozygotes appear partially protected. Haplotypes containing combinations of mutations in the *CCR5* promoter region also differentially regulate receptor expression and host control of the virus. Similarly, variations in the genes for chemokine ligands appear to alter their expression and competition with HIV for their receptors. Investigations into these and other inßuences of variations in human genes on HIV infection have demonstrated the importance of cumulative small effects. Increased knowledge of genetic variation in response to should be increasingly useful for planning and interpreting research and ultimately for managing HIV/AIDS patients in the clinical setting.

Chapter 13

Care of the Adult Patient with HIV Infection

Harold W. Horowitz and Gary P. Wormser

Skillful management of the HIV-infected patient involves blending common sense and compassion with knowledge of recent pertinent scientiÞc discoveries. Care of HIV-infected patients is constantly changing and improving, which is reßected by objective increases in patient survival (1Ð5). These rapid changes impose challenges on the clinician to remain updated on recent developments (6).

Until the latter part of the 1980s therapy was directed to treatment and prevention of opportunistic infections (OI) accompanying an inevitable immunologic deterioration. Patients also developed numerous other sequelae often more difÞcult to treat than OIs such as HIV-associated nephropathy, cardiomyopathy, neuropathy, and dementia among others. Today most of the challenges in the care of HIV-infected patients in the Western world revolve around decisions on how to use antiretroviral therapy (ART) effectively. Unfortunately, there are few evidence-based answers to many of the questions regarding treatment of HIV infection. Therefore, the clinician providing care to HIV-infected patients must practice with a great deal of uncertainty.

A partial list of drugs used in the care of HIV-infected patients, but that were not United States Food and Drug Administration (FDA) approved until after the epidemic began is found in Table 13.1 (7). Furthermore, older drugs such as dapsone and clindamycin have found new usages in the treatment or prevention of HIV-related infections. An understanding of the numerous interaction among drugs commonly employed in patients with HIV infection is essential and new information on this is rapidly emerging (see Chapter **??**) (8). Diagnostic procedures and methods are also in ßux, continually being tailored to the speciÞc needs of this patient population.

Harold W. Horowitz, MD: Division of Infectious Diseases, Department of Medicine, New York Medical College, Westchester Medical Center, Valhalla, New York 10595.
Gary P. Wormser, MD: Division of Infectious Diseases, Department of Medicine, New York Medical College, Westchester Medical Center, Valhalla, New York 10595.

Information on the natural history of HIV infection has demonstrated the importance and proper timing for beginning prophylaxis for prevention of *Pneumocystis carinii* pneumonia (PCP), central nervous system disease due to *Toxoplasma gondii* infection, and disseminated *Mycobacterium avium* complex (dMAC) infection (9). Use of measurements of CD4 + lymphocyte counts in conjunction with HIV in plasma (viral load), to determine when to initiate and change ART therapy is giving greater precision to clinical management. Introduction of highly active antiretroviral therapy (HAART) (loosely deÞned as the use of more active drug regimens consisting of multi-drug combinations) has had a major impact on the natural history of HIV infection and has introduced certain new challenges in the care of HIV-infected patients in terms of managing drug resistance and adverse effects. Because the complexities of patient management are much greater now than a decade ago, improved patient outcomes will likely depend even more on receiving care by experienced health care providers (6,10).

Furthermore, as the HIV-infected population ages, patients may develop illnesses such as coronary artery disease, diabetes mellitus, hypertension, hyperlipidemia and osteoporosis that may be related to HIV infection, to ART, or to the aging process itself. Health care providers specializing in HIV disease who may not have been practicing primary care medicine are Þnding themselves in need of refresher courses on managing these illnesses.

INITIAL ASSESSMENT AND MONITORING OF PATIENTS

Table 13.2 outlines one approach to the initial assessment of the HIV-infected adult patient (11) Although the diagnostic term AIDS is rigorously deÞned (albeit with several revisions (12Ð15) and has been immensely helpful for surveillance in tracking the epidemic (especially prior to the discovery of HIV), it is of limited value to clinicians in the care of individual patients. It is preferable to think in

TABLE 13.1. *Partial list of drugs used in the care of HIV-infected patients and given FDA approval in the United States after 1981*

Antiretrovirals (year)[a]	Antiinfectives (year)[a]	Others (year)[a]
Zidovudine (AZT) (1987)[b]	Intravenous and oral ganciclovir (1989, 1996)	Interferon-alfa 2 (1986)
Didanosine (ddI) (1991)[b]	Fluconazole (1990)	Epoetin alfa (1989)

[a] Year approval granted by the U.S. Food and Drug Administration; [b] Medications with newer preparations since initial FDA approval.

TABLE 13.2. *Assessment of HIV-infected patients (frequency of follow-up)*[a]

Strongly recommended for all patients
History and complete physical examination (at each visit)
Complete blood count with differential and platelet count (every three months)
Chemistry pro le, including LDH, CPK, liver function tests (every three months)
Fasting cholesterol and triglyceride levels (every three to six months, especially if on protease inhibitor)
CD4 + cell count and percentage (every three months)
HIV quantitative plasma assay (every three months)
HIV resistance testing (if within six months of acute infection or switching therapy due to failure)
Treponemal antibody test (yearly if at risk)
IgG for *Toxoplasma gondii* (if negative repeat every one to two years)
Hepatitis B surface antigen and antibody, core antibody (if core and surface antibody negative, repeat every one to two years if at risk)
Hepatitis C virus antibody (if negative, repeat yearly depending upon risk)
Puri ed protein derivative of tuberculin (if negative, repeat yearly)
Papanicolaou smear for women (twice during rst year , then yearly)
Chest roentgenogram if from high-risk tuberculosis population (repeat as determined by clinical necessity)
Tests to be considered
Hepatitis A IgG antibody (if considering vaccination)
Glucose-6 phosphate dehydrogenase enzyme level (if initiating dapsone or primaquine)
Rectal papanicolaou smear (if receptive anal intercourse)
Stool for ova and parasites (for homosexual men and for those with risk due to geographic exposure)

CPK = creatine phosphokinase, LDH = lactate dehydrogenase; [a] Testing may be needed at different frequencies depending upon the clinical situation.

terms of HIV infection per se and the clinical, virologic and immunologic consequences thereof. The deÞnition of AIDS has been principally based on events that occur secondary to a state of advanced immunodeÞciency. For example, using prior deÞnitions, the day after the diagnosis of PCP was made, the patient had AIDS; the day before the patient did not, despite the same degree of immunodeÞciency. An updated case deÞnition now includes cases based solely on the presence of immunodeÞciency, as deÞned by certain laboratory criteria, in the absence of an opportunistic infection or neoplasm (15). Since 1993 all HIV-infected patients with a helper T-cell (CD4 +) count of < 200 cells/mm^3 or a CD4 percentage of $< 14\%$ are considered to have AIDS (see Chapter **??**). Once a patient has been diagnosed with AIDS, he/she will always carry this diagnosis even if immune reconstitution occurs with a rise in the CD4 + lymphocyte count to levels > 200 cells/mm^3.

Other diagnostic entities, such as ÒAIDS-related complexÓ(ARC) or Òpersistent generalized lymphadenopathyÓ

(PGL), previously used to characterize subsets of HIV-infected individuals, are no longer helpful in patient management (16).

CD4+ Lymphocyte Count

An important component of the management approach for the HIV-infected patient is to focus attention on and monitor the course of HIV-induced immune deficiency. The most helpful, readily available laboratory test to do this is the number of helper T-cells (CD4+) in peripheral blood. The CD4+ lymphocyte count is critical in deciding both when to begin and when to discontinue various prophylactic strategies to prevent opportunistic infections, and when to initiate ART (9,17,18). Although some studies suggest that viral load measurements early in course of HIV infection are lower in women than men, there are no documented gender differences in the relation of CD4 cell count to risk of opportunistic infections (18–20).

CD4+ cells are expressed either as a percentage of the total lymphocyte count, or as an absolute number, which is calculated value derived from the percentage of CD4+ cells multiplied times the total lymphocyte count. For healthy non-HIV-infected adults, the average CD4+ cell count is approximately 1,000 cells/mm^3. However, the values may range widely, from as low as approximately 500 to as high as 1,500 cells/mm^3 (21). A CD4+ cell count of 200/mm^3 marks an especially important point in the course of HIV-infected patients, since serious opportunistic infections infrequently occur before this level of immune deficiency is reached (2,22–24).

As vital as the CD4+ cell count has become in the general management of the HIV-infected patient, there are several noteworthy limitations. First, any single determination may be aberrant. The reasons why a particular count may be inconsistent with other values for a specific patient are not always apparent. Since the CD4+ count is dependent on the total lymphocyte count, fluctuations and variability in the total white blood cell or differential count determinations will greatly impact test results (25–31). Inappropriate storage conditions and delayed transportation of blood samples to the laboratory may adversely affect CD4+ lymphocyte determinations (32). In addition, factors such as test methodology, quality control, and type of laboratory equipment employed may influence the accuracy of the test (33–36).

Stress, exercise, season, use of exogenous glucocorticoids, serum cortisol level, and the presence of acute or chronic illness, have all been reported to affect CD4+ cell counts (31,37). In addition, there is a normal diurnal variation of CD4+ cells/mm^3 in HIV-infected patients, with the highest values present in the evening (30,38–42), implying that specimen collection times should be standarized. The effect of diurnal variation is greatest for persons who have relatively high CD4+ cell counts. Splenectomy is associated with a large and prolonged increase in peripheral blood CD4+ lymphocyte count, often several hundred cells/mm^3 in magnitude (43,44). In these patients, the CD4+ lymphocyte percentage reflects the level of immunodeficiency more accurately (44).

When OKT4 monoclonal antibodies are used to identify T-helper cells, falsely low CD4+ cell counts are observed in up to 11% of Blacks (and in lesser numbers of Asians and Caucasians) who lack or have a partial deficiency of the OKT4 epitope (34–36). These individuals may appear to have no CD4+ cells when in fact they have normal numbers of T-helper cells if identified by other monoclonal antibody markers (e.g. Leu 3a).

The initial CD4+ lymphocyte count for a patient, or counts significantly out of line with prior determinations, should be confirmed by repeat testing. During the first year of HIV infection, in the absence of antiretroviral drug therapy, the CD4+ cell count falls approximately 400 cells/mm^3 (45,46). Thereafter, the average decline in CD4+ cells in untreated patients is approximately 60–100 cells/mm^3 per year (47–49), except for those patients who have entered into an accelerated phase (in which a decline of approximately 160 CD4+ cells/mm^3 per year may be anticipated) (50). Patients with an accelerated CD4+ lymphocyte decline are more likely to have detectable p24 antigen in serum, higher viral loads, syncytium forming strains of virus, and develop a serious opportunistic infection (50–53) (see Chapter **??**). A small proportion of patients (up to 7%) maintain near normal numbers of CD4+ cells over many years (54). These "long-term nonprogressors" usually have fewer than 103 HIV RNA copies/ml of plasma (55–57). Factors including defective HIV (54,58), a strong cytotoxic T cell response (59,60), deletions of HIV coreceptors on CD4+ lymphocytes (making these cells more resistant to infection by HIV) (61–63), and certain HLA haplotypes (63–68), seem to be important in keeping long-term nonprogressors well.

In view of the expected slow rate of decline of the CD4+ cell count, it is not surprising that the estimated mean duration of survival from time of onset of HIV infection to death in patients receiving standard preventive therapies (as described below), is more than 10 years, even in the absence of ART (69).

Caution should be exercised in over interpreting small changes in CD4+ lymphocyte test results. Patients often attach undue significance to minor rises or falls in these counts. They should be counseled that the overall trend of the CD4+ lymphocyte count is more important than any single value. In general, there is less test-to-test fluctuation in CD4+ cell percentage compared with absolute number (25–27). The frequency of CD4+ cell count testing is dependent in part on the rapidity of the drop in counts and upon the need for testing after a change in antiretroviral therapy. For patients with CD4+ cell counts around 300 cells/mm^3 testing should be done at least four times annually. At counts of under 50 CD4+ cells/mm^3, however, there is no need to do additional testing routinely, unless further management changes are made that might

lead to higher values (see section on antiretroviral therapy below).

Viral Load Measurement

Testing for the amount of HIV in plasma by measuring viral RNA is a standard component in the management of HIV-infected patients. The amount of virus in plasma has been demonstrated to have important prognostic implications (53,57,70–81). Patients with higher viral loads tend to progress more rapidly both immunologically in terms of the rate of CD4+ cell count decline and clinically in developing opportunistic infections. The plasma viral load correlates with the risk of disease progression after the acute retroviral syndrome (82), in early symptomatic disease (76,83–85), and in chronically infected patients (71,73,75). Furthermore, plasma levels of HIV directly correlate with the risk of perinatal transmission in pregnant women (86–88), and with the risk for heterosexual transmission to uninfected partners (89). Patients with high CD4+ lymphocyte counts, even above 600 cells/mm^3, can be placed into prognostic groups based upon the plasma viral load (90). Patients with viral loads $< 5{,}000$ HIV RNA copies/ml copies/ml of plasma have the lowest risk of progression. Plasma viral load measurements are used in evaluating the effectiveness of antiretroviral drug regimens (17,18,91,92). Due to measurement variation, only a change of 0.5 logs (three-fold) is considered significant evidence of a change in viral load (17,93). For example a patient with a true viral RNA of 10,000 copies/ml could have, on a single measurement, an HIV-1 RNA value that ranged from 3,100 to 32,000 RNA copies/ml (93).

Several different methods to quantitate plasma viral RNA measurements are commercially available at present. All use amplification techniques to determine the amount of HIV in plasma. It should be kept in mind that these tests measure total viral RNA copies, not infectious virions. The lower limit for detection of HIV RNA by reverse transcriptase polymerase chain reaction (RT-PCR) is approximately 50 copies/ml. Although the various assays generally correlate well, they may not give identical numerical results (94–98). Therefore, it is prudent to use the same assay when following the course of individual patients.

Subtype B is the predominant subtype of HIV-1 found in the United States (see Chapter **??**) (99). Since only a single primer set is used, it is important to recognize that RT-PCR may be less accurate than other methods for detection of certain HIV-1 subtypes uncommonly found in the United States, including A, E, and F (99,100). Inclusion of additional primers for HIV subtypes other than subtype B (101), will enhance sensitivity for non-type B strains.

HIV plasma RNA measurements should be done on initial assessment. Some authorities prefer to measure the baseline viral load twice, two to four weeks apart (17,18). After initiating ART or changing therapy, a measurement should be performed approximately four weeks later. Thereafter, measurements should be done every three to four months, but may be done sooner if there is reason to believe that the patient's clinical or immunologic status has deteriorated.

It is important for the clinician to recognize that recent immunizations and acute illnesses may have consequences for viral load testing (102–108). Immunizations against tetanus (103) and pneumococcus (102) may cause a transient increase in HIV plasma levels (up to 300 times) that usually return to baseline levels by four weeks post immunization. Several opportunistic infections (106), as well as active tuberculosis (107) and reactivated genital herpes infection (108), have also been associated with transient elevations in viral load. It is likely that other intercurrent infections will do the same. Therefore, it is probably best to postpone viral load testing for approximately one month after either immunization or acute infections.

Appropriate specimen handling is critical to ensure accurate HIV plasma load measurements (109–111). Samples must be processed and frozen within six hours so that RNA degradation does not occur, thereby leading to falsely low viral load measurements. The appropriate anticoagulant for the particular assay must be used, and plasma rather than serum should be assayed (109).

History and Physical Examinations

A thorough history and physical examination is necessary to uncover symptoms and physical findings that may at the outset require further evaluation. Particular attention should be given to systemic complaints, visual disturbances, neurologic abnormalities, and gastroenterologic or respiratory problems. Inquiry should be made into finding out where a person has lived and traveled, whether there is exposure to animals, drug use history, and the nature of sexual activities, in order to determine whether the patient may be at risk for exposure to certain infectious agents. For instance, exposure to *Coccidioides immitis* or *Histoplasma capsulatum* is limited to certain geographic regions. Intravenous drug use places the patient at risk for bacteremia as well as endocarditis due to several bacterial pathogens (112). These histories must be updated as they change over time. Symptoms related to potential drug toxicities should be explored at each visit. For patients on ART, it is critical to assess patient adherence regularly, as poor adherence may promote the development of HIV resistance to antiretroviral drugs leading to failure of viral suppression (113).

Physical examination should carefully document the patient's weight, cutaneous or oral mucosal abnormalities, and presence of enlarged lymph nodes. It is also important to look for evidence of lipohypertrophy and lipoatrophy,

TABLE 13.3. *Selected test results in HIV-infected patients*

Test	Expected result
Hemoglobin	Progressive reduction as immunode ciency worsens: 10–20% of asymptomatic HIV-infected persons are anemic and up to 70% of AIDS patients
Leukocyte count	Progressive reduction as immunode ciency worsens: leukopenia present in 10% of asymptomatic HIV-infected persons and up to 65% of AIDS patients
Platelet count	Reduced in 10% of asymptomatic HIV-infected persons and in up to 45% of AIDS patients
Neutrophil count	Reduced in 20–50% of AIDS patients
Lymphocyte count	Reduced in 70% of AIDS patients with opportunistic infections
Serum sodium	Hyponatremia present in □30% of AIDS patients, often attributed to renal salt wasting and less commonly to hypoadrenalism
Serum potassium	Hyperkalemia may complicate therapy with trimethoprim-containing regimens or pentamidine because these drugs are sodium channel inhibitors and therefore function as potassium-sparing diuretics
Serum glucose	Pentamidine (especially parenteral) and a PI-based antiretroviral regimen may cause hyperglycemia and diabetes
Creatinine	Increased in a small proportion of cases, especially among black men who are intravenous drug users
Liver function tests	Abnormal in 90% but usually mildly, i.e. □two-fold above upper limits of normal; also may be abnormal due to antiretroviral therapy especially PIs and nevirapine
Creatine phosphokinase	Usually normal; when elevated may indicate the presence of myopathy due to either HIV or AZT
Lactate dehydrogenase	Frequently mildly elevated; elevated in 90% of patients with *Pneumocystis carinii* pneumonia
Serum lactate	Elevated in approximately 10% and associated with lactic acidosis less often; associated with NRTI use
Serum globulins	Hypergammaglobulinemia (polyclonal) is usual
Amylase	Increased in 8–30%
Triglycerides	Elevated in 50% of HIV-infected patients pre-HAART and may be a complication of HAART
Cholesterol	Elevated on PI-based antiretroviral therapy
HbsAg	Present in approximately 10%
HbcAb	Present in 90%
PPD	Positivity rates high in Haitians, intravenous drug users, prisoners, and the homeless
Treponemal antibody	Positive up to in 45% of HIV-infected homosexual men
Toxoplasma IgG	Positive in 15–80%
Cytomegalovirus antibody	Positive in 70–100%

PI = protease inhibitor, NRTI = nucleoside reverse transcriptase inhibitor, HAART = highly active antiretroviral therapy, HbsAg = hepatitis B surface antigen, HbcAb = hepatitis B core antibody, PPD = puri ed protein derivative (of tuberculin).

which are potential adverse effects of ART (see Chapter **??**).

Laboratory Testing: Complete Blood Count and Blood Chemistry Testing

A complete blood count with platelet count is recommended as an initial screening test and at approximately three to six month intervals in the routine care of HIV-infected patients (Table 13.3). Mild leukopenia and anemia may be seen and are especially common in the setting of advanced immunodeficiency (CD4+ cell count $<200/mm^3$) (114–118). These hematologic abnormalities complicate the use of drugs that may further suppress the bone marrow, such as zidovudine (AZT) or ganciclovir.

Depressed platelet counts may occur secondary to a variety of opportunistic processes including infections and lymphoma, or as an adverse effect of many of the drugs used to manage the HIV-infected patient (see Chapter **??**) (119–121). Equally or more common as a cause of thrombocytopenia, however, is the entity termed HIV-associated idiopathic thrombocytopenia purpura (ITP), which arises as a result of immune destruction of platelets that are coated with either immune complexes or antiplatelet antibody (122,123). Impaired marrow production of platelets may also be a contributing factor (124). Thrombocytopenia may occur at any level of CD4+ cell count but is more common in advanced disease (120,121,125).

In the absence of bleeding, no treatment is needed for patients with platelet counts above 20,000/mm^3 (126). When therapy is needed, a variety of options are available, which are discussed in Chapter **??**.

Blood chemistry testing is done in the initial assessment of the HIV-infected patient and should be followed at approximately three month intervals. This testing is useful to pinpoint abnormalities of liver function, which may be due to a variety of causes including chronic viral hepatitis, many of the drugs used to treat HIV infection or its complications, and opportunistic infections (Table 13.3) (127–132). Patients with chronic hepatitis are more likely to have liver function abnormalities when given ART, particularly protease inhibitor (PI) drugs (133,134). Liver dysfunction may affect the pharmacokinetics of medications, which should be taken into account when any drug is prescribed.

A baseline lactate dehydrogenase level (LDH) is useful to serve as a basis for comparison during suspected bouts of PCP since the LDH level is characteristically elevated in this form of pneumonia (135). A baseline creatine phosphokinase (CPK) may be helpful in detecting HIV-related myopathy or to serve as a basis for comparison should muscle pain or weakness develop during AZT therapy (AZT-induced myopathy) (see Chapter **??**) (136–138).

Serum glucose level is an important blood chemistry to evaluate and follow with serial determinations. For patients with an elevated level, fasting glucose levels should be assessed. The incidence of hyperglycemia appears to be increased in patients taking PIs (139–143).

Syphilis Serology

It has been observed that the prevalence of a positive serologic test for syphilis is up to five times higher among HIV-infected homosexual men compared to those without HIV infection (144). For this reason testing is recommended at baseline and possibly on an annual basis for those patients who remain at risk for this infection. HIV-infected individuals with latent syphilis, based on the isolated finding of a positive serology, who have never been adequately treated or evaluated, should undergo a lumbar puncture (145). Cerebrospinal fluid abnormalities, even if nonspecific, warrant strong consideration for the parenteral administration of penicillin in doses adequate for the treatment of neurosyphilis (145,146). In the absence of cerebrospinal fluid abnormalities, benzathine penicillin G at a dose of 2.4 million units should be given intramuscularly weekly for three consecutive weeks to those patients judged to have late latent syphilis (145). However, benzathine penicillin cannot be relied on in patients with neurosyphilis due to very low cerebrospinal fluid drug levels (146a,147). HIV-infected patients with neurosyphilis should be treated with aqueous crystalline penicillin G at a dose of approximately three million units IV every four hours for 10 to 14 days (145). The serum Venereal Disease Research Laboratory (VDRL) or Rapid Plasma Reagin (RPR) values should be closely followed after treatment in all patients, with particularly frequent testing done for patients with early syphilis (primary, secondary, or early latent, i.e. a year or less) (145,148–150).

Tests for Hepatitis B

Hepatitis B (HB) surface antigen is present in approximately 10% of HIV-infected patients (151,152). This infection may be associated with chronic liver disease and may pose an additional occupational hazard for health care workers with parenteral blood exposures to these patients. Patients without prior hepatitis B infection (i.e. with a negative test for HBcAb) should be considered for hepatitis B vaccination (see below).

Hepatitis C Antibody

Coinfection with hepatitis C is very common among HIV-infected intravenous drug users and hemophiliacs (>50%) and disease progression is exacerbated by HIV infection (153,154). This form of hepatitis may explain abnormalities of liver function studies in these patients and, like hepatitis B, may pose an additional occupational risk for health care workers with needle-stick accidents (155,156). Therapy for hepatitis C which is routine for non-HIV-infected individuals (157), should be considered for HIV-infected patients without advanced immunodeficiency (see Chapter **??**) (158,159).

Purified Protein Derivative (PPD) Testing

PPD is recommended at baseline for HIV-infected patients with no history of a prior positive skin test or active tuberculosis (9). Thereafter, especially, in persons at high-risk for tuberculosis such as prisoners, intravenous drug users and the homeless, testing should be done yearly (9,160,161). Patients who have low CD4+ lymphocytes may be anergic and test negative on PPD testing. When the CD4+ lymphocyte count rises it is worthwhile to repeat PPD testing on these individuals.

The PPD skin test-positive HIV-infected patient has a 5–10% risk per year of developing active tuberculosis (162) and consequently should receive chemoprophylaxis (160,161,163). Induration at the PPD skin test site of 5 mm (versus the usual 10 mm) is regarded as indicative of tuberculous infection for HIV-infected patients (160). Patients who have had a positive tuberculin skin test in the past and did not receive prior antituberculous treatment or chemoprophylaxis should also be given chemoprophylaxis (see Chapter **??**) (160). Presently, it is impossible to judge

the need for prophylactic therapy in an anergic person whose skin test history is unknown (164).

Stool Examination for Ova and Parasites

Homosexual men, or persons who have resided in areas endemic for *Strongyloides stercoralis* (most tropical and subtropical areas), should have stool examinations for ova and parasites. Patients who are infected with *S. stercoralis* may be at risk for developing dissemination of this helminth as the immunodeficiency progresses (165). Consequently, all carriers should be treated, with ivermectin being the treatment of choice (166). Homosexual men infected with *Giardia lamblia* or *Entamoeba histolytica* should also receive appropriate chemotherapy (166).

Serum Triglyceride Level

The fasting serum triglyceride level is often elevated in HIV-infected patients even in the absence of ART (167) and may be one factor contributing to the increased incidence of pancreatitis in this patient population (168–170). Elevated serum triglyceride and/or cholesterol levels also are an adverse reaction of ART (140,141,143,171–175), particularly with PI therapy. Fasting of at least eight, and preferably twelve hours, is important for accurate measurement of lipid levels. Testing for fasting triglycerides, total cholesterol, and HDL cholesterol should be done at baseline with follow-up every three to six months.

Lactic acid

Lactic acid levels may increase in patients with HIV who are treated with ART. This has been associated most directly with the use of nucleoside RTIs, in particular D4T (176–179). Patients may complain of fatigue, muscle aches, weight loss, vomiting, and abdominal pain (180,181). Hepatic and muscle enzymes including transaminases, CPK, and LDH may be elevated. When venous lactic levels rise to >10 mmole/L, symptoms are universal and the disease is often fatal (182). Despite the severity of this illness, routine evaluation of the asymptomatic patient is not recommended because mild lactic acid elevations are frequent in HIV-infected patients on ART and not predictive of more severe disease (183), and because substantial technical problems are associated with lactic acid testing (17). Measurement of lactic acid requires a standardized mode of sample handling, including prechilled fluoride-oxalate tubes, which should be transported immediately on ice to the laboratory and processed within four hours after collection; blood should be collected without using a tourniquet, without fist clinching, and if possible, without stasis (17,184).

Papanicolaou Smear

Because of the high incidence of papillomavirus infection (31–67%) (185–187), cervical dysplasia (32%) (188,189), and cervical cancer (190) among women with HIV infection, Papanicolaou smears should be performed at initial evaluation, repeated at six months and annually thereafter if normal (9,145). See Chapter **??** on the management of HIV-infected women.

Anal PAP smears should be considered in gay men and in women who have had anal receptive intercourse or anogenital warts, at baseline and then yearly. As with cervical carcinoma in women, squamous intraepithelial lesions (SIL) and anal carcinoma are linked to infection with HPV (191). In gay men the prevalence of HPV is in the range of 60% to 75% (192). The frequency of anal carcinoma is markedly higher than in the non-HIV infected population (193–195).

Chest Roentgenogram

In asymptomatic HIV-infected patients the chest roentgenogram is typically normal. A baseline film may be useful for comparison with later studies done for the evaluation of respiratory tract symptoms.

Toxoplasma Gondii Serology

Toxoplasma gondii serology (IgG) should be performed at the time of initial evaluation and if negative, when the CD4+ lymphocyte count falls to <100 to 200 cells/mm^3 when patients become at risk for toxoplasmosis. The seroprevalence of toxoplasma antibody in adults varies widely according to geographic location (from 15% to 80%) (196). Since most cases of active toxoplasmosis among HIV-infected patients represent reactivation of latent infection, only those with a positive IgG antibody test are, in general, at risk (197–199). This serologic result is helpful in the evaluation of neurologic abnormalities and may be a factor in guiding the choice of chemoprophylactic regimen for prevention of PCP (see below). Seronegative persons should be counseled on how toxoplasmosis is acquired (i.e. through ingestion of undercooked meat containing tissue cysts of *Toxoplasma gondii* or any food contaminated with oocysts that originate in cat feces) and on ways to reduce this occurrence (9,196).

Serum Amylase

For unclear reasons, serum amylase levels are modestly elevated in approximately 8–30% of HIV-infected patients who have no clinical signs of pancreatic disease (200,201). Results of a baseline amylase level may be helpful for use

in comparison to subsequent testing in patients with abdominal pain, nausea, or vomiting, and in patients prior to treatment with didanosine, which is associated with the development of pancreatitis in up to 10% of patients receiving the drug (202).

Vitamin B12 and Folate Levels

Vitamin B12 levels are modestly depressed in up to 15% of HIV-infected patients due to malabsorption, which may occur even in the absence of diarrhea or other clinical or laboratory abnormalities indicative of intestinal disease (203). Because low B12 or folate levels may be associated with increased hematologic toxicity from trimethoprim-sulfamethoxazole, pyrimethamine, trimetrexate, or AZT, replacement therapy should be given (see Chapter **??**). Vitamin B12 and folate levels should also be determined for patients with peripheral neuropathy.

Glucose-6-Phosphate Dehydrogenase Levels

Regimens including the drugs dapsone or primaquine are sometimes utilized in prevention and treatment of PCP for patients intolerant of trimethoprim-sulfamethoxazole (Chapter) (204–208). Because of the risk of hemolysis in glucose-6-phosphate dehydrogenase (G-6-PD)-deficient patients, this enzyme should be assayed prior to administration of these agents (doses of dapsone of 50 mg or less per day, however, are not associated with G-6-PD-related hemolysis (209)).

INTERVENTIONS FOR HIV-INFECTED ADULTS (Table 13.4)

Counseling

Various counseling activities are an important part of the care of HIV-infected persons (Table 13.5) (210). Counseling often first begins at the time that an individual requests or is advised to have HIV antibody testing. Because of the extraordinary psychosocial impact of a diagnosis of HIV infection, it is essential for the person being tested to have a clear understanding of the implications of the test results. The purpose and meaning of the test, the testing procedure itself, and issues of potential discrimination should be explained to the patient (see Chapter **??**). Informed consent is obtained prior to testing.

HIV test results should generally be communicated in person, at which time posttest counseling is done. This should include a discussion of coping strategies after learning of a positive result, issues regarding potential discrimination, behavioral changes to reduce the risk of secondary transmission, available medical treatments, and the importance of notifying needle-sharing and/or sexual partners. Food safety issues to reduce transmission of *Toxoplasma gondii* and enteric pathogens such as *Salmonella sp*. and Cryptosporidia should also be discussed (9). These discussions should not be limited to the first or second patient visit but should continue thoughout the long-term care of the individual. It is also important that patients understand that measures for risk-reduction for transmission of HIV must be continued even if undetectable plasma viral loads have been achieved while on ART because HIV may be still present in certain cells and genital secretions. The importance of adherence to medication regimens and various appointments that may need to be scheduled should also be stressed.

Vaccinations

HIV-infected adults respond less well than their HIV-uninfected counterparts to many vaccines. Response to hepatitis B vaccine, influenza A and B vaccine, pneumococcal vaccine and hepatitis A vaccine depends upon the degree of immunodeficiency present at the time of vaccination (211–214). Asymptomatic HIV-infected patients with CD4+ cell counts well in excess of 200/mm^3 respond the best.

TABLE 13.4. *Standard interventions for HIV-infected patients*

Counseling
Pneumococcal vaccine, with single revaccination after five years
Influenza A and B vaccine yearly
Isoniazid (or other therapy as indicated) for nine months if PPD positive (now or untreated in past)
Evaluation and treatment of syphilis (including asymptomatic seropositive patients)
Initiation of highly active antiretroviral therapy
Initiation of PCP prophylaxis for patients with CD4+ lymphocyte counts < 200 cells/mm^3
Initiation of prophylaxis for cerebral toxoplasmosis for toxoplasma IgG positive patients with CD4+ lymphocyte count < 100 cells/mm^3
Initiation of prophylaxis for disseminated *Mycobacterium avium* complex infections for patients with < 50 CD4+ cells/mm^3
Discontinuation of chemoprophylaxis for opportunistic infections when the CD4+ lymphocyte count rises to appropriate levels
Caloric dietary supplementation, as needed

PPD = purified protein derivative (of tuberculin), PCP = *Pneumocystis carinii* pneumonia.

TABLE 13.5. *Topics to be covered during pre- and post-HIV test counseling*

Pre-test counseling
Methods of HIV transmission and how to reduce the risk of infection
Purpose of testing and the meaning of test results
Partner noti cation (sexual partners and needle-sharing partners)
Psychosocial issues related to a diagnosis of HIV infection
Post-test counseling—test negative
Meaning of test results
Methods of reducing risk of acquiring HIV infection
Post-test counseling—test positive
Meaning of test results
Partner noti cation
Methods to reduce transmission
Psychosocial issues related to a diagnosis of HIV infection
Food safety issues to prevent toxoplasmosis, cryptosporidiosis, and salmonellosis
Natural disease progression and impact of antiretroviral therapy
Timing of various interventions and use of laboratory data to make therapeutic decisions
Importance of adherence with medication usage

Since inactivated vaccine preparations appear safe and potentially beneÞcial, they should be routinely administered to HIV-infected individuals (see Chapter **??**). The pneumococcal vaccine is given once with a subsequent single revaccination after Þve years (215,216). The latest preparation of the inßuenza A and B vaccine is given annually during the fall (217). Patients who are susceptible to hepatitis B (HBcAb-negative) and who remain at risk of exposure to this virus should be vaccinated. An exception would be the patient with a recent exposure to hepatitis B who may be incubating the virus. For unclear reasons, hepatitis B vaccination of such individuals has been associated with an increased rate of chronic HBsAg carriage (218) HIV-infected patients who are at risk for hepatitis A infection, particularly those who are infected with hepatitis C, should be vaccinated against hepatitis A (219). Patients should be informed that the extent and duration of protective efÞcacy of these vaccines are still uncertain. Whether there may be a role for booster doses of hepatitis B vaccines in this patient population is unknown.

Antiretroviral Therapy (ART)

Antiretroviral therapy began in March 1987 when the FDA gave approval for the nucleoside RTI, zidovudine (AZT). Since then additional nucleoside RTIs (NRTIs) have been approved, such as didanosine (ddI), zalcitabine (ddC), stavudine (D4T), abacavir and lamivudine (3TC) (7,17,18,220). Tenofovir is a nucleotide analogue RTA (NtRTA). The drugs, nevirapine, delavirdine and efavirenz, also inhibit reverse transcriptase but structurally are not nucleoside analogues (NNRTI) (221). A second major target for anti-HIV chemotherapeutic agents is the viral protease enzyme. Drugs which inhibit this enzyme (PIs) are also structurally different from nucleoside analogues and include such agents as saquinavir, ritonavir, indinavir, nelÞnavir, amprenavir and lopinavir (see Chapter **??**) (222,223). The status of ART is rapidly changing and much improved over even just a few years ago (Tables 13.6Ð13.8). It is clear that with current agents, more than two drugs must be used and that when on therapy, adherence to taking all of the medications should be at least 95% (113,224). Basic questions, however, remain unanswered such as: When should therapy be started? What combination of drugs should be used? When should therapy be changed and to what? And can or should therapy be stopped for various periods?

The primary goal of ART is to achieve prolonged suppression of HIV replication (17,18,225). Current multidrug regimens decrease the HIV level not only in the peripheral blood but also in lymphoid tissue (226,227), the central nervous system (227), and the genital tract (228). However, these regimens do not completely eliminate HIV, even when the viral load in plasma remains below 50 copies/ml for several years (229Ð231). HIV can still be reactivated in lymphocytes even after suppression in the peripheral blood for several years (229,231) and can be found in some patients in genital secretions when no longer detected in plasma (232). The current paradigm is that treatment for HIV will need to be for life until new strategies for eliminating HIV from the body or appropriately stimulating the immune system to suppress HIV are developed.

Clinicians involved in the care of HIV-infected patients may Þnd the use of antiretroviral drugs particularly challenging for several reasons. First, because new drugs are continuously being added to the antiretroviral armamentarium, physicians may lack familiarity with some of these drugs and may not have a clear idea how to integrate them into their practice. These new drugs may inßuence the toxicity, dosing, and viral susceptibility of older drugs.

TABLE 13.6. *Selected features of antiretroviral medications*

Generic Name (common name)	Brand Name	Preparations	Recommended Doses	Food
Nucleoside Reverse Transcriptase Inhibitors (NRTI)				
Zidovudine (AZT, ZDV)	Retrovir	capsules: 100 mg, 300 mg syrup: 50 mg/5ml IV: 10 mg/ml	300 mg bid	with or without food
	Combivir	combination: 300 mg with 150 mg lamivudine	1 tablet bid	with or without food
	Trizivir	combination: 300 mg AZT with 150 mg lamivudine plus 300 mg abacavir	1 tablet bid	with or without food
Didanosine (ddI)	Videx and Videx EC (enteric coated)	Buffered tablets: 25, 50, 100, 150, 200 mg Powder packets for oral solution: 167, 250 mg Enteric coated capsules (Videx EC): 125 mg, 200 mg, 250 mg, 400 mg	≥60 kg weight— tablets 200 mg bid powder 250 mg bid EC 400 mg qd <60 kg weight— tablets 125 mg bid powder 167 mg bid EC 250 mg qd	30 minutes before or two hours after a meal
Zalcitabine (ddC)	HIVID	Tablets: 0.375 mg, 0.75 mg	0.75 mg po q8h	with or without food
Stavudine (D4T)	Zerit	Capsules: 15, 20, 30, 40 mg Oral solution: 1 mg/mL solution	≥60 kg, 40 mg bid <60 kg, 30 mg bid	with or without food
Lamivudine (3TC)	Epivir	Tablet: 150 mg Oral solution: 10 mg/mL	150 mg bid or 300 mg qd	with or without food
Abacavir	Ziagen	Tablet: 300 mg Oral solution: 20 mg/mL	300 mg bid	with or without food alcohol increases levels 40%
Nucleotide Reverse Transcriptase Inhibitors (NtRTI)				
Tenofovir	Viread	Tablet: 300 mg	300 mg qd	with meal
Non-nucleoside Reverse Transcriptase Inhibitors (NNRTI)				
Nevirapine	Viramune	Tablet: 200 mg Oral suspension: 50 mg/5 mg	200 mg qd x 14d then 200 mg bid	with or without food
Delavirdine	Rescriptor	Tablet: 100 mg, 200 mg	400 mg tid	with or without food; separate from antacids or buffered ddI by one hour
Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTI)				
Efavirenz	Sustiva	Capsules: 50 mg, 100 mg, 200 mg 600 mg	600 mg qd (before sleep to minimize central nervous system side effects)	without food

TABLE 13.6. *continued*

Generic Name (common name)	Brand Name	Preparations	Recommended Doses	Food
Protease Inhibitors (PI)				
Saquinavir	Fortovase	Soft-gelatin capsules: 200 mg	1,200 mg tid[a]	with a meal or up to two hours after a meal to increase absorption
Saquinavir	Invirase	Hard-gel capsules: 200 mg	400 mg bid with ritonavir[b]	with ritonavir no meal effects
Ritonavir	Norvir	Capsules: 100 mg Solution: 600 mg/7.5 mL	600 mg bid[c]	take with food to decrease adverse reactions; separate by two hours from buffered ddI
Indinavir	Crixivan	Capsules: 100 mg, 200 mg, 333 mg, 400 mg	800 mg q 8 h	take one hour before or two hours after meals or with lowfat snack; separate by one hour from buffered ddI
Nel navir	Viracept	Tablets: 250 mg Oral powder: 50 mg/g	1,250 mg bid or 750 mg tid	take with a meal to increase absorption
Amprenavir	Agenerase	Capsules: 50 mg, 150 mg Oral solution: 150 mg/mL	1,200 mg bid capsules[d] 1,400 mg bid oral solutiond	avoid high fat meal but can be taken with or without food
Lopinavir/ Ritonavir	Kaletra	Capsules: 133 mg lopinavir plus 33 mg ritonavir Oral solution: 80 mg lopinavir plus 20 mg ritonavir/mL	400/100 mg bid	take with food to increase absorption

mg = milligram, mL = milliliter, bid = twice daily, qd = daily, kg = kilogram, q8h = every eight hours.
[a] = standard doses; when used with ritonavir doses decreased—see Table 13.14.
[b] = generally not prescribed without ritonavir.
[c] = rarely used in full doses, most often lower doses to enhance other drugs—see Table 13.14.
[d] = if body weight > 50 kg.

TABLE 13.7. *Dose adjustments of antiretroviral medications for renal and hepatic disease*

Drug	Dosage in Renal Disease	Dosage in Hepatic Disease
Nucleoside Reverse Transcriptase Inhibitors (NRTI)		
Zidovudine	CrCl < 10 mL/min 100 mg q8h hemodialysis = 100 mg q8 peritoneal dialysis = 100 mg q8h	Insuf cient data but prudent to reduce dose with severe liver disease
Combivir	Do not give if CrCl < 50, instead give drugs individually	Do not give as combination in patients with severe liver disease
Trizivir	Combination not recommended if CrCl < 50 ml/min—give individual drugs	Not recommended with severe liver disease
Didanosine	*Dosage* *CrCl (mL/min)* — *60 kg* — *< 60 kg* 30–59 — tablets 200 mg qd or 100 mg bid; powder 100 mg bid — tablets 150 mg qd or 75 mg bid; powder 100 mg bid 10–29 — tablets 150 mg qd; powder 167 mg qd — tablets 100 mg qd; powder 100 mg qd < 10 — tablets 100 mg qd; powder 100 mg qd — tablets 75 mg qd; powder 100 mg qd	Monitor closely for toxicity, dosage adjustment not certain
Zalcitabine	*CrCl (mL/min)* — *Dose* 10–50 — 0.75 mg q 12 h < 10 — 0.75 mg q 24 h Insuf cient data regarding hemo- or peritoneal dialysis	No dosage adjustment but use cautiously
Stavudine	*Dosage* *CrCl (mL/min)* — *> 60 kg* — *< 60 kg* > 50 ml/min — No change — No change 26–50 ml/min — 20 mg q12h — 15 mg q12h 10–25 ml/min — 20 mg q24h — 15 mg q24h < 10 ml/min — Insuf cient data Hemodialysis or peritoneal dialysis — Insuf cient data	No dosage adjustment but use cautiously
Lamivudine	*CrCl (mL/min)* — *Dose* 30–49 — 150 mg qd 15–29 — 150 mg × 1 then 100 mg qd 5–14 — 150 mg × 1 then 50 mg qd	No dosage adjustment anticipated
Nucleoside Reverse Transcriptase Inhibitors (NtRTI)		
Abacavir	Minimal renal excretion so dosage adjustment not anticipated; data not suf cient for speci c recommendation	Data insuf cient

TABLE 13.7. *continued*

Drug	Dosage in Renal Disease	Dosage in Hepatic Disease
Nucleotide Reverse Transcriptase Inhibitors (NtRTI)		
Tenofovir	Pharmacokinetics not evaluated in renal insuf ciency but dosage decrease expected due to primary renal excretion	Not evaluated but little hepatic metabolism so dosage adjustment not anticipated
Non-nucleoside Reverse Transcriptase Inhibitors (NNRTI)		
Nevirapine	Pharmacokinetics not evaluated in renal failure; give standard doses cautiously because metabolites largely eliminated by kidney	Pharmacokinetics not evaluated in liver failure, nevirapine mostly liver metabolized. Use standard doses cautiously
Delavirdine	Pharmacokinetics not evaluated in renal failure; give standard doses cautiously because metabolites largely eliminated by kidney	Consider dose reduction with severe liver disease; pharmacokinetics not evaluated
Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTI)		
Efavirenz	Standard doses likely due to hepatic metabolism but data lacking Hemodialysis 600 mg qd Peritoneal dialysis—unknown	Consider empiric dose reduction
Protease Inhibitors (PI)		
Saquinavir	Standard doses likely but data lacking Hemodialysis—standard doses likely Peritoneal dialysis—standard doses likely	Primarily metabolized in liver. Consider dose reduction with severe liver disease
Ritonavir	Standard doses likely but data lacking Hemodialysis—standard doses likely Peritoneal dialysis—standard doses likely	Primarily metabolized in liver. Consider dose reduction with severe liver disease
Indinavir	Standard doses likely but data lacking Hemodialysis—standard doses likely Peritoneal dialysis—standard doses likely	In mild to moderate hepatic failure 600 mg q 8 h
Nel navir	Standard doses likely but data lacking Hemodialysis—standard doses likely Peritoneal dialysis—standard doses likely	Consider dose reduction
Amprenavir	Standard doses likely but data lacking Hemodialysis—standard doses likely Peritoneal dialysis—standard doses likely	Moderate hepatic failure 450 mg BID Severe hepatic failure 300 mg BID
Lopinavir/Ritonavir	Standard doses likely but data lacking Hemodialysis—standard doses likely Peritoneal dialysis—standard doses likely	Data insuf cient

Cr/Cl = creatinine clearance, mL = milliliters, min = minute, mg = milligram, q8h = every 8 hours, d = day, bid = twice a day.

TABLE 13.8. *Selected adverse reactions and drug interactions of antiretroviral drugs*[a]

Drug	Selected Adverse Effects	Selected Drug Interactions
Nucleoside Reverse Transcriptase Inhibitors (NRTI)		
Zidovudine (AZT)	Anemia, granulocytopenia, myalgia, myopathy, nausea, headache, darkening of nger nails, lactic acidosis	Avoid if possible drugs that suppress the bone marrow; probenecid increases blood levels 100%; avoid with D4T[b]
Combivir	Similar to AZT and 3TC	Similar to AZT and 3TC
Trizivir	Similar to AZT, 3TC, and abacavir	Similar to AZT, 3TC, and abacavir
Didanosine (ddI)	Pancreatitis, lactic acidosis, peripheral neuropathy,[c] diarrhea	Try to avoid with other drugs that cause pancreatitis or neuropathy; allopurinal increases levels four-fold; itraconazole and ketoconazole should be administered two hours after ddI; administer two hours after or six hours before cipro oxacin; administer indinavir or delavirdine before ddI; tenofovir increases levels ~40%—uncertain signi cance consider decreasing ddI dose by 50% when used with tenofovir and separate time of administration
Zalcitabine (ddC)	Peripheral neuropathyc, pancreatitis, lactic acidosis	Avoid drugs that cause pancreatitis or peripheral neuropathy; probenecid and cimetidine reduce ddC elimination; bioavailability reduced with magnesium/aluminum containing antacids; avoid use with 3TC due to theoretical risk of antagonism
Stavudine (D4T)	Peripheral neuropathy[c], lactic acidosis, lipoatrophy, (reduce dose to 20 mg bid if peripheral neuropathy)	Avoid use with AZT;[b] use with caution with drugs that cause pancreatitis or peripheral neuropathy.
Lamivudine (3TC)	Lactic acidosis, headache, nausea	Avoid use with ddC due to theoretical risk of antagonism.
Abacavir	Hypersensitivity reaction[d], lactic acidosis, nausea	Alcohol increases levels 40%
Nucleotide Reverse Transcriptase Inhibitors (NtRTI)		
Tenofovir	Abdominal pain, diarrhea, nausea elevated liver function tests; uncertain if causes lactic acidosis	Increases ddI levels 40%; decrease ddI dose 50%
Non-nucleoside Reverse Transcriptase Inhibitors (NNRTI)		
Nevirapine	Fatal hepatotoxicity,[d] fever, rash,[e] Stevens-Johnson syndrome, nausea, headache	Induces CYP3A hepatic enzyme and should be used with caution with drugs metabolized by this enzyme; contraindicated with St. John's Wort, ketoconazole, rifampin; increase dose of indinavir to 1,000 mg q8h and lopinavir/ritonavir to 533/133 mg bid; lowers ethinyl estradiol levels so use other contraceptive methods; lowers methadone levels and if withdrawal symptoms, increase methadone dose

TABLE 13.8. *continued.*

Drug	Selected Adverse Effects	Selected Drug Interactions
Delavirdine	Rash,[f] Stevens-Johnson syndrome, fever, headaches, increased liver function studies	Inhibits cytochrome P450 liver enzymes; avoid use with rifampin, rifabutin, ergot derivatives, astemizole, terfenadine, cisapride, midazolam, triazolam, simvastatin, lovastatin, H_2 blockers, proton pump inhibitors; may increase level sildena l—use with caution and start with low doses sildena l; drugs that decrease the level of delavirdine are carbamazepine, phenytoin, phenobarbitol, rifampin, rifabutin; administer one hour apart from antacids or buffered ddI due to decreased absorption; H_2 blockers decrease absorption; delavirdine 400 mg tid with lower dose; indinavir 600 mg tid or fortovase 800 mg tid
Efavirenz	Rash;[f] Stevens-Johnson syndrome rarely; central nervous system effects[g] including confusion, impaired thinking and concentration, abnormal dreams, depersonalization; hyperlipidemia; elevated liver function studies; teratogenic in animals	Induces and inhibits CY3A hepatic enzyme so that effects on drugs metabolized by this pathway variable; concurrent use with astemizole, terfenadine, midazolam, triazolam, cisapride, clarithromycin, and ergot alkaloids contraindicated; for most interactions, efavirenz dose does not need to be changed; increase dose rifabutin to 450–600 mg/day or 600 mg two to three times per week; may reduce levels phenobarbital, phenytoin, carbamazepine, warfarin—monitor levels; when used with indinavir, increase indinavir dose to 1,000 mg q8H; increase lopinavir/ritonavir to 533/133 mg bid; not recommended with saquinavir because decreases levels of saquinavir by 60%
Protease Inhibitors (PI)		
Saquinavir (soft or hard gel preparations)	Nausea, abdominal pain, diarrhea, headache, hepatic toxicity; class adverse reactions include: increased triglycerides and/or cholesterol, hyperglycemia, osteoporosis, possible increased bleeding among hemophiliacs, fat maldistribution	Although the ability of different PIs to inhibit CYP3A4 varies, in general the warnings and contraindications for all of these drugs should be similar. Contraindications: terfenidine, astemizole, cisapride, triazolam, midazolam, rifampin, ergot alkaloids, simvastatin, lovastatin, pimozide, St. John's Wart; the anticonvulsants phenytoin, phenobarbitol, carbamazepine may lower PI levels; in most instances birth control other than ethinyl estradiol should be used due to decreased ethinyl estradiol levels, however, indinavir increases levels; rifabutin doses should be 150 mg daily or 300 mg twice weekly and indinavir and nel navir should be increased to 1,000 mg tid with rifabutin; closely monitor patients on methadone for withdrawal due to decreased levels; close attention to toxicity while patient taking itraconazole or ketoconazole; antiarrhythmics ecainide, propafenone, amiodarone, lidocaine, encainide should be used with caution due to increased levels and possible increased arrhythmias; calcium channel blocker levels may increase so use with caution; sildena l levels increased so use with caution starting at 25 mg and slowly increase doses; immunosuppressants such as cyclosporine, tacrolimus, rapamicin levels increase so monitor levels closely reducing dosage as needed; monitor levels of warfarin closely

TABLE 13.8. *continued.*

Drug	Selected Adverse Effects	Selected Drug Interactions
Ritonavir	Nausea, vomiting, anorexia, abdominal pain, taste perversion, circumoral or peripheral paresthesias, hepatotoxicity (see Saquinavir for class adverse reactions)	See Saquinavir
Indinavir	Nephrolithiasis, urolithiasis, interstitial nephritis, asymptomatic hyperbilirubinemia; hepatitis; gastroenterologic intolerance; paronychia; dry skin, eyes, mouth; ingrown toenails (see Saquinavir for class adverse reactions)	See Saquinavir
Nel navir	Diarrhea (see Saquinavir for class adverse reactions)	See Saquinavir
Amprenavir	Gastroenterologic intolerance with diarrhea, nausea, vomiting; rash; headache; perioral paresthesias (see Saquinavir for class adverse reactions). Note that drug is a sulfonamide	See Saquinavir Oral solution contains 55% propylene glycol and is contraindicated in renal or hepatic failure, pregnant women, or patients receiving disul ram or metronidazole; avoid vitamin E
Lopinavir/Ritonavir	Diarrhea (see Saquinavir for class adverse reactions)	See Saquinavir

mg = milligram, bid = twice daily, tid = three times daily; [a] for more speci c information, package inserts should be reviewed; [b] D4T and AZT compete for same phosphorylase and therefore may be antagonistic; [c] peripheral neuropathy may be more likely when D4T and ddI used concurrently, or if ddI and ddC are used together; [d] abacavir must be stopped and not reinitiated if a hypersensitivity reaction occurs; [e] when initiating nevirapine, liver enzyme levels should be followed closely; [f] rashes due to NNRTIs may not necessitate drug class discontinuation if mild because administration of other NNRTIs may not lead to same reaction; [g] central nervous system adverse reactions may be decreased if given before sleep, and these symptoms may improve over several weeks.

TABLE 13.9. *Status of antiretroviral drug therapy*

1.	Combination antiretroviral therapy can suppress HIV replication for several years but no regimen has been demonstrated to eliminate the virus.
2.	Maximal duration of HIV suppression is not known.
3.	Adherence to antiretroviral therapy should be > 95% to maximize the chances for viral suppression.
4.	Whether long-term survival will be possible with combination therapy is not known.
5.	When during the course of HIV infection to initiate therapy has not been determined but the CD4 + cell count should not be allowed to drop to < 200 cells/mm^3.
6.	Which combination of drugs (and how many drugs) is best to start therapy with is not known.
7.	Which speci c changes to make to "optimize" a failing antiretroviral regimen is not known.
8.	The bene ts of HIV resistance testing for designing antiretroviral therapy appear to be maximized when used after a rst or at most second failing treatment regimen.
9.	All antiretroviral drugs have adverse effects and the long-term consequences of these drugs alone or in combination is not known. The impact on quality of life should be considered when recommending therapy and in devising regimens.
10.	Although treatment interruption is being studied as a method of reducing long-term side effects of antiretroviral therapy, there is insuf cient information to recommend this approach.
11.	It is likely that management approaches for the treatment of HIV-infected patients will continue to change and improve as knowledge of how to use antiretroviral therapy improves.

Second, clinicians may not be accustomed to the tendency for decisions about the clinical management of patients to be made on the basis of what seems biologically plausible rather than on the results of rigorous long-term clinical trials. Third, a sizable number of patients request placement on speciÞc (sometimes investigational) regimens on the basis of optimistic but preliminary observations that have been published in the lay literature. Fourth, physicians may Þnd that interpretation of the signiÞcance of certain clinical studies is confusing because of conßicting results, the small number of patients upon which studies are based and the use of surrogate markers rather than clinical endpoints to measure efÞcacy. Furthermore, because of different basic inclusion criteria for patients under studyÑ such as prior antiretroviral drug exposure, CD4+ lymphocyte counts, and viral loadsÑ comparison between studies frequently is not possible. Fifth, the extremely high-pressure marketing that the pharmaceutical industry employs to inßuence health care providers to adopt particular drugs also creates confusion. And sixth, health care providers realize that with over 1,000 possible combinations of available antiretroviral agents, the number of studies being reported is burgeoning and impossible to keep up with even for those integrally involved with the Þeld.

The status of ART is summarized in Table 13.9. Use of a single antiretroviral drug has caused resistance to emerge during therapy to all tested drugs and may occur within days to weeks for drugs for which only a single mutation leads to resistance such as the NNRTIs and lamivudine (51). Therefore, only combination drug therapy is recommended (17,18). Although studies have demonstrated viral suppression for as long as four years, whether or not this efÞcacy will last for more prolonged periods of time is not known. The single exception to the use of multi-drug regimens may be the pregnant woman for whom the choice of multiple drugs versus either AZT or nevirapine alone can be offered (17). However, even in pregnancy, three drug regimens are preferred (17).

Because of the extraordinary results that have been seen using combination therapy, the paradigm for HIV infection has shifted from a slowly but relentlessly progressive immunodeÞciency associated with OIs, frequent in-patient hospitalizations, and inevitable mortality, to that of a chronic, manageable illness (233). In this setting, ART may need to be taken for prolonged periods of time. The consequences of such prolonged therapy are not known. This has led investigators to test the concept of treatment interruptions (see below) in order to minimize the amount of antiretroviral agents taken, thereby reducing toxicity.

In a Þeld that is changing so rapidly, speciÞc recommendations regarding a particular combination ART regimen to use are difÞcult to make. However, the options are wide and increasing. Frequently updated recommendations from a National Institute of Health panel can be obtained at the HIV/AIDS Treatment Information Service Web site, http://www.hivatis.org. Combinations that require fewer pills and fewer daily doses, factors that may contribute to better adherence with medication usage, are now available. Furthermore, regimens can be developed that spare the use of PIs, thereby reducing the possibility of adverse reactions associated with this class of drugs. However, it is important that clinicians keep in mind that all drugs have associated toxicities and that long-term toxicities may not be known at this time. Table 13.10 outlines one approach to using antiretroviral therapy.

With the increasing appreciation of the potential for long-term drug toxicities, initiation of antiretroviral therapy is being delayed to later time points. Recent guidelines suggest withholding therapy until the CD4+ cell count falls to < 350 cells/mm^3 and/or the plasma viral load by RT-PCR is > 55,000 copies/ml (or bDNA > 55,000 copies/ml) (17). However, many authorities do not use the viral load when determining when to begin therapy because although higher viral loads may lead to a more rapid

TABLE 13.10. *Antiretroviral drug regimens*

Regimen	Uses
Monotherapy	
AZT Nevirapine	Generally not recommended; can be considered for pregnant women who prefer not to use combination therapy and for women who present in labor
Two-drug therapy	Not recommended to treat HIV infection but sometimes recommended for post-exposure prophylaxis of a low-risk exposure[a] from a low-risk source
Three-drug therapy	
3 NRTI[b]	Preferred initial regimen for most patients Initial therapy for patients with low viral load; alternative to PI-based regimen for patients with adverse reactions to PIs or NNRTIs, for patients with adherence problems due to many pills
2 NRTI plus 1 NNRTI	Initial therapy to spare PIs; for patients with adverse reactions to PIs; may allow single daily dosing
2 NRTI plus 1 PI	Initial therapy (particularly if low CD4 + cell count and/or high viral load); for salvage of patients with resistance using 3 NRTI or 2 NRTI plus NNRTI regimen
1 NRTI, 1 NNRTI, 1 PI[c]	Possible salvage therapy; use with caution in early treatment because this regimen has toxicity of all three drug classes and if regimen fails may have resistance to all antiretroviral classes
Four-drug therapy	
Ritonavir (low dose) plus 2nd PI plus either 2 NRTI or 1 NRTI plus 1 NNRTI;	Possible initial therapy for patients with high viral load and low CD4 cells; allows twice daily dosing PIs; salvage therapy for patients failing 3 NRTI or 2NRTI plus NNRTI regimen
1 PI plus 3 NRTI or 1 PI plus 2 NRTI plus 1 NNRTI	Salvage therapy
3 NRTI plus 1 NNRTI	Intensi ed antiretroviral therapy regimens
> Four drugs	
2 PI[d] plus 2 NRTI plus 1 NNRTI or 2 PI plus 3 NRTI	Salvage therapy

[a] Low-risk exposure from a non-severe, super cial or solid needle injury.
[b] Certain NRTI combinations, such as AZT plus D4T, or ddC plus 3TC, are not recommended to be used together because these drugs appear to share the same phosphorylation pathway, possibly leading to a decrease in the intracellular concentrations of active drug. ddI plus ddC is not recommended because of the theoretical risk that this combination will increase the risk of peripheral neuropathy, a well-recognized adverse effect of each drug individually. d4T plus ddI should be used with caution due to the potential for increased neuropathy and lactic acidosis.
[c] Saquinavir plus efavirenz is not recommended due to lower serum levels of saquinavir.
[d] Indinavir plus saquinavir is not recommended because of *in vitro* antagonism.
NRTI = Nucleoside or nucleotide reverse transcriptase inhibitor.
NNRTI = Non-nucleoside (or nucleotide) reverse transcriptase inhibitor.
PI = Protease inhibitor.

CD4 + cell count declines, they are not associated with a higher risk of OIs independent of the CD4 + lymphocyte count. Studies are currently being performed to compare prospectively the strategy of beginning therapy at 350 CD4 + cells/mm^3 versus delaying treatment to 250 CD4 + cells/mm^3.

The decision to initiate ART must be made on the basis of a patientÕs desire for treatment, an assessment of the likelihood that the patient will take the prescribed medications, and a consideration of the patientÕs underlying diseases that may affect drug tolerability (eg, ddI should be avoided if possible in patients with a history of pancreatitis). Advances, such as a better understanding of the pharmacokinetics of some of the RTIs, utilization of drug-drug interactions for pharmacokinetic advantage, and new drug discovery by the pharmaceutical industry, have led to the development of therapeutic regimens that can be taken twice daily and even once daily (234,235). These changes should translate into improved adherence.

Although no single combination regimen is guaranteed to work for any one individual, for patients beginning their Þrst antiretroviral regimen (Ònai•veÓ), the chances are quite good (approaching 80Ð90%) (235Ð240), that HIV can be suppressed at least in the short-term using any of multiple

TABLE 13.11. *Advantages and disadvantages of different HIV resistance tests*

Assay	Advantage	Disadvantage
Genotype	Low cost	Interpretation dif cult
	Rapid	Requires viral load > 1,000 copies/ml
	Mutations may be detected before resistance found on phenotypic assay	HIV strains with < 20% representation not detected Interplay of multiple mutations not accounted for
Phenotype	Easy interpretation—similar to bacterial testing	High cost Longer turnaround time
	Effects of multiple mutations can be assessed	Arbitrary testing cut-offs
		Requires viral load > 500–1,000 copies/ml
		HIV strains with < 20% representation not detected
Virtual Phenotype	Less expensive than phenotype	If few matches in database, dif cult to determine if resistance present
	Rapid Rapid turnaround time	Requires viral load > 1,000 copies/ml
	Effects of multiple mutations can be assessed	HIVstrains with < 20% representation not detected
	Easy to interpret—similar to bacterial testing	

regimens, provided that the patient is adherent. Figures 13.1a and 13.1b demonstrate such responses with the use of different ART combinations. For instance, antiretroviral regimens using three NRTIs (such as AZT, 3TC, and abacavir), two NRTIs plus one NNRTI (such as AZT, 3TC, and efavirenz; or ddI, D4T, and nevirapine), two NRTIs plus a PI (such as AZT, 3TC, and indinavir; or ddI, AZT, and nelfnavir), or a drug from each class (such as AZT, delavirdine, and indinavir), have all led to HIV viral suppression in approximately 80% to 90% of patients during the short term (235–240). There are currently no data on the preferred sequencing of NRTIs (18).

Susceptibility Testing

The susceptibility of a patient's HIV strain can be measured *in vitro* by a variety of methods: genotype, phenotype, or virtual phenotype (Table 13.11) (see Chapter **??**) (241). Within the past few years, resistance testing has gained widespread use in the management of HIV-infected patients despite the lack of long-term data demonstrating improved clinical outcome. However, data from several studies indicate that during the short-term (six to twelve months) basing treatment decisions on the results of resistance testing leads to a higher proportion of patients with viral load suppression than if such testing is not performed (242–244). However, not all studies demonstrate that resistance testing improves outcome as assessed by plasma viral load suppression (245). The ability of resistance testing to aid in successful drug selection is increasingly compromised as the number of prior failed regimens increase (246,247). By the time of the third failed ART regimen, resistance testing provides few options for devising new regimens (247).

Resistance testing has several noteworthy limitations: (1) Testing cannot be performed unless there are greater than approximately 500–1,000 viral copies/ml (248). Therefore, testing cannot be performed for patients with very early failure of an antiretroviral regimen. (2) Only the dominant viral strain at the time of testing is assayed. Strains that comprise < 10–20% of the viral population are not tested. (3) Strains that may be present in sequestered areas such as semen, vaginal secretions, the central nervous system or in non-replicating states in peripheral blood lymphocytes will not be assayed. (4) For resistance to antiretroviral drugs other that 3TC and NNRTIs, multiple mutations are required. Using the genotype assay, results may be difficult to interpret because the interplay among various mutations may lead to altered phenotypic expression of resistance or susceptibility in a manner not readily predicted. (5) Resistance to one agent may enhance sensitivity to another agent. This has been particularly well studied with the codon 184 mutation in the reverse transcriptase gene that leads to 3TC resistance but increases susceptibility to AZT. The genotype assay may not report this interaction. (6) Phenotypic assays use a threshold for defining susceptibility that may not always reflect antiretroviral drug concentrations, at least in part because of protein-drug interactions that occur *in vivo* but not *in vitro*. Threshold values have changed several times

in the past few years and are likely to change in the future as more is learned about the assay.

Despite the availability of resistance testing, it is still important for health care providers to take into consideration prior antiretroviral drug regimens. Drugs used in prior failing regimens must be used with caution. Resistance testing helps indicate which drugs should be avoided, but is less useful in determining which drugs should be included in a treatment regimen.

An unanswered question is whether to use resistance testing to determine what agents to use for initial drug therapy. Current guidelines do not strongly recommend such testing for chronically infected patients because data are limited regarding its utility (17). However, for newly infected patients (within six months of infection), resistance testing may be helpful because resistance to at least one antiretroviral drug can be found in up to 20% of cases (241,249–252). In contrast, in the chronically infected patient, it is more likely that the predominant HIV strain in the blood has reverted to wildtype (lacking resistance mutations) (253). A test demonstrating no resistance may lead to a false sense of security regarding the usefulness of various drugs.

Therapeutic Drug Monitoring

Therapeutic drug monitoring (TDM) is the terminology applied to the concept of measuring the plasma level of antiretroviral agents. It can be used to determine whether the level of a particular drug is in the therapeutic range as well as to determine potentially toxic levels of a drug. It is hoped that the use of TDM will explain some of the therapeutic failures among patients who are adherent to their medication regimens (254). TDM has not been tested in large clinical trials. Theoretically, its major role will be to measure the levels of drugs that have wide plasma ranges, particularly PIs (254). For instance, the trough level of indinavir is frequently below the therapeutic level needed to prevent HIV replication (255). Increasing the dose of indinavir or nelfinavir based upon a low trough level may help to improve viral suppression. In addition, TDM may be useful to both improve efficacy and decrease toxicity associated with efavirenz therapy, since treatment failure has been associated with low blood levels and toxicity with high blood levels of this drug (256). Because activity of NRTIs depends upon intracellular activation and because intracellular concentrations are more difficult to measure than plasma levels (18), TDM may have limited use with this class of antiretroviral drugs. Data are still emerging on how to account for the protein binding of various agents. Although TDM is commercially available, there is interlaboratory variability and the interpretation of results is still being formulated (254,256).

Practical Antiretroviral Drug Therapeutics

Despite susceptibility of HIV, some authorities are apprehensive about using a triple nucleoside regimen as first line therapy for patients with a very low CD4+ lymphocyte count (< 50 to 100 cells/mm^3) and high viral loads (> 100,000 copies/ml). Limited data have suggested a trend toward inferiority of the NRTI combination of AZT plus 3TC plus abacavir compared to AZT plus 3TC plus a PI (indinavir) in patients with a plasma HIV viral load of > 100,000 copies/ml (257). Because of concerns that PI containing regimens may predispose to adverse reactions such as lipodystrophy, hypertriglyceridemia, hypercholesterolemia, and glucose intolerance, some authorities will switch to a PI-sparing regimen when the viral load is stably suppressed on the PI-containing regimen. This appears to be effective, i.e. breakthrough viremia does not seem to occur in a higher proportion of patients whose therapy has been switched compared to those continued on the PI-containing regimen (258–260). Fig. 13.1a demonstrates the success of such a switch in a patient with lipoatrophy.

Preliminary data regarding the use of antiretroviral drug regimens with four and five agents have shown a more rapid decrease in viral load than with three-drug regimens (261), but are not currently recommended for initial therapy. It is of note that many regimens in use today with PI therapy use a low dose of ritonavir to "boost" the drug levels of the second PI. This allows for PIs to be given no more often than twice daily, with or without food, and with fewer pills. However, the ritonavir should not be considered a third or fourth drug when designing an antiretroviral regimen because the dose given for this purpose is usually not therapeutic for HIV.

Optimally, the goal of therapy is to reduce the plasma HIV viral load to undetectable levels (i.e. < 50 copies/ml). However, even a 0.5 log reduction (70%) in viral load leads to a decrease in the incidence of adverse HIV-related clinical endpoints (51,262), and this should be considered the minimally acceptable level of drug activity. By eight weeks of ART, a viral load reduction of at least 1 log is expected and by four to six months there should be no detectable virus.

In general, unless a patient develops drug toxicity, an antiretroviral drug regimen that has resulted in undetectable virus should be continued. Several randomized studies have tested whether "maintenance" therapy with fewer drugs could be used to simplify the therapeutic regimen after initial "induction" therapy with three (263–265) or four (267) drugs. Data from these studies in which one or more drugs were discontinued demonstrated that such patients had more frequent recurrence of HIV viral detection in plasma compared to those who continued the original regimen (263–266). Thus, this strategy is currently not recommended.

Despite rather remarkable decreases in viral load, increases in the CD4+ lymphocyte count can be more

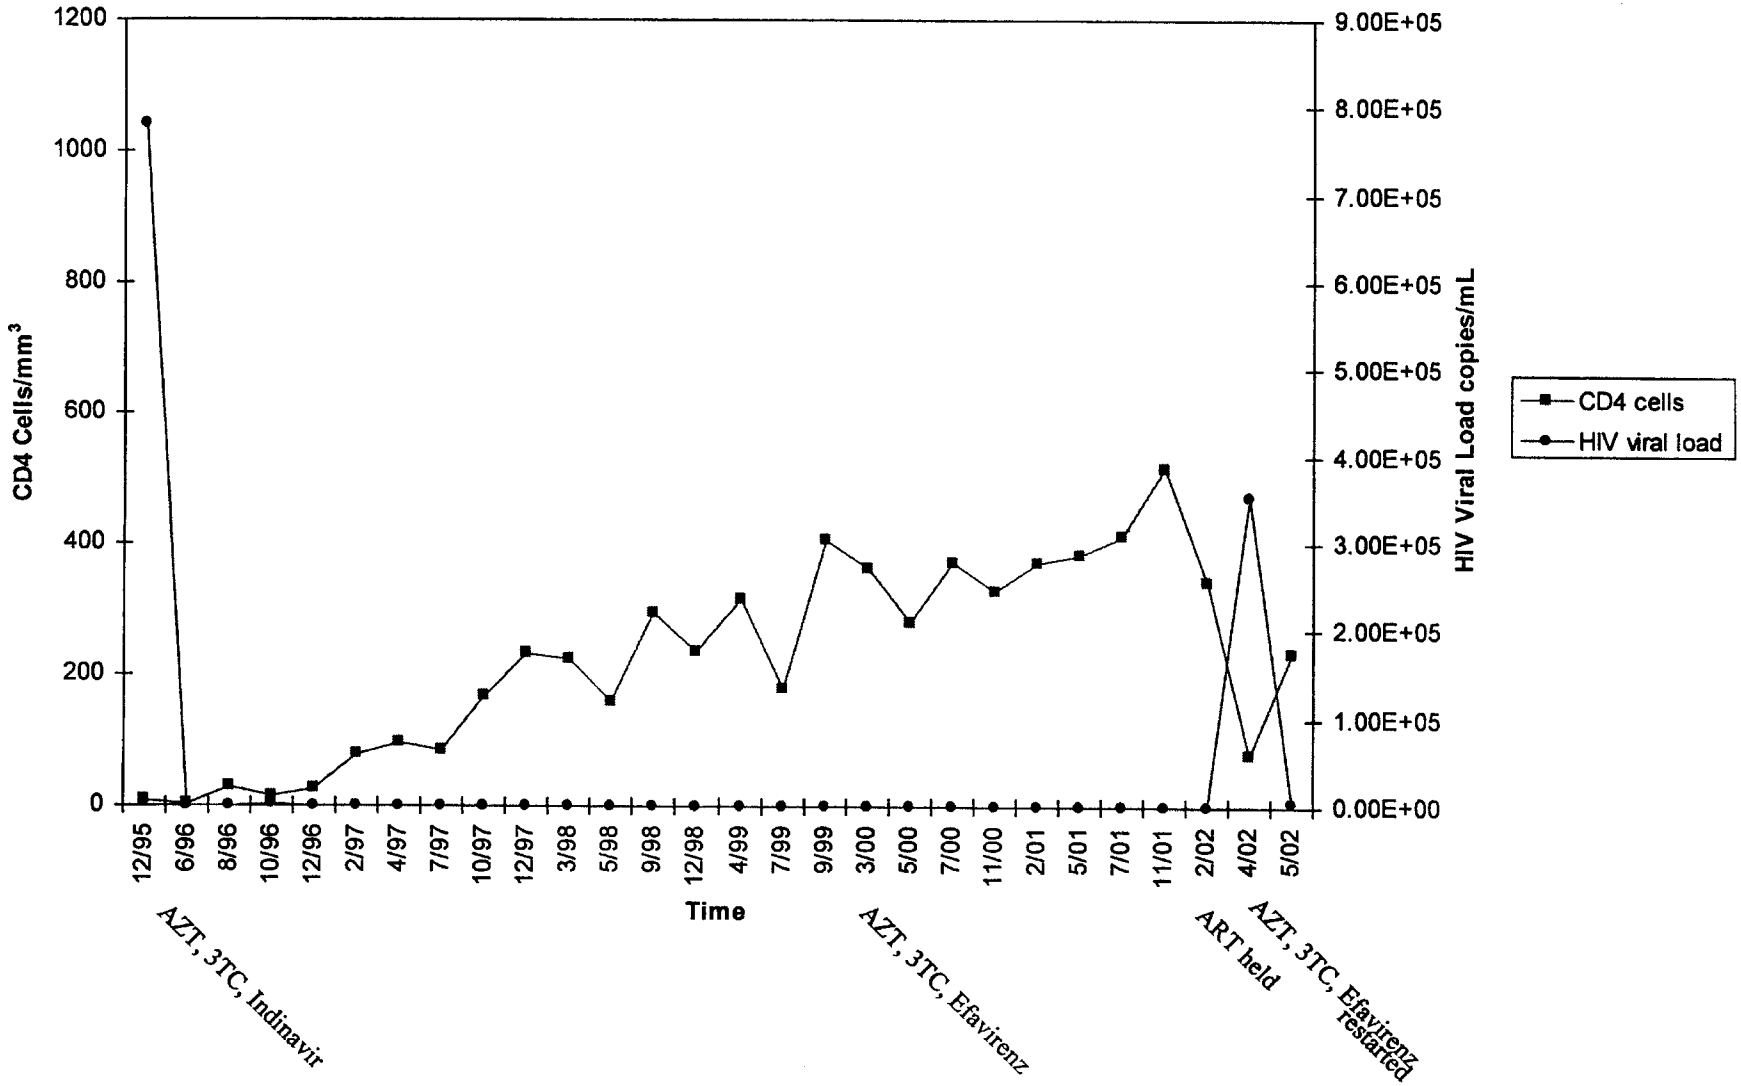

FIG. 13.1. Figures 1a and 1c demonstrate the rapid fall of CD4 + lymphocytes and rise in viral load that can occur when patients with previously very low CD4 + lymphocyte counts have therapy interrupted. Figure 1a also shows how reintroducing therapy can successfully re-suppress HIV and lead to a rise in CD4 + cells. Figure 1b demonstrates that the CD4 + lymphocyte count can be maintained after ART has been stopped despite viral load rebound in a patient who never had a low CD4 + cell count.
ART = antiretroviral therapy; AZT = zidovudine; D4T = stavudine; 3TC = lamivudine; ddI = didanosine.

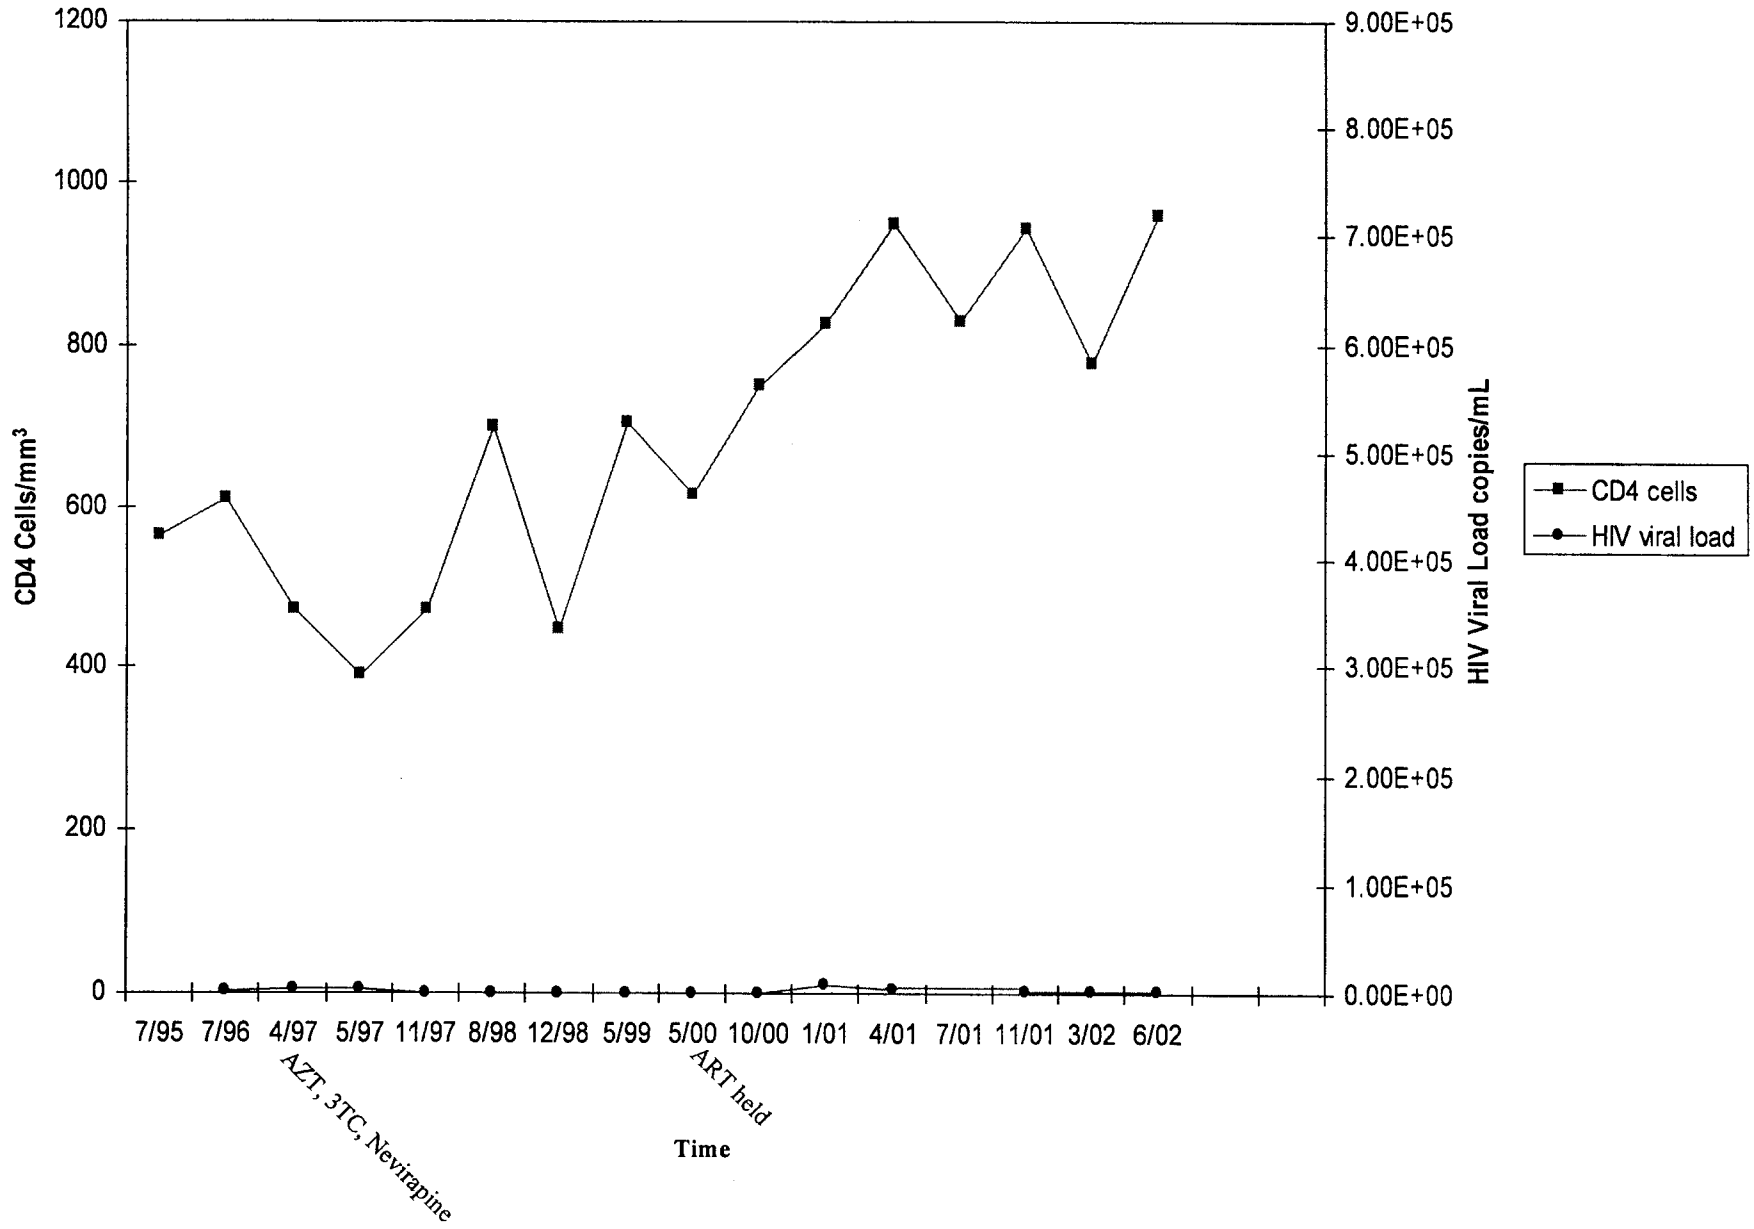

FIG. 13.1. continued.

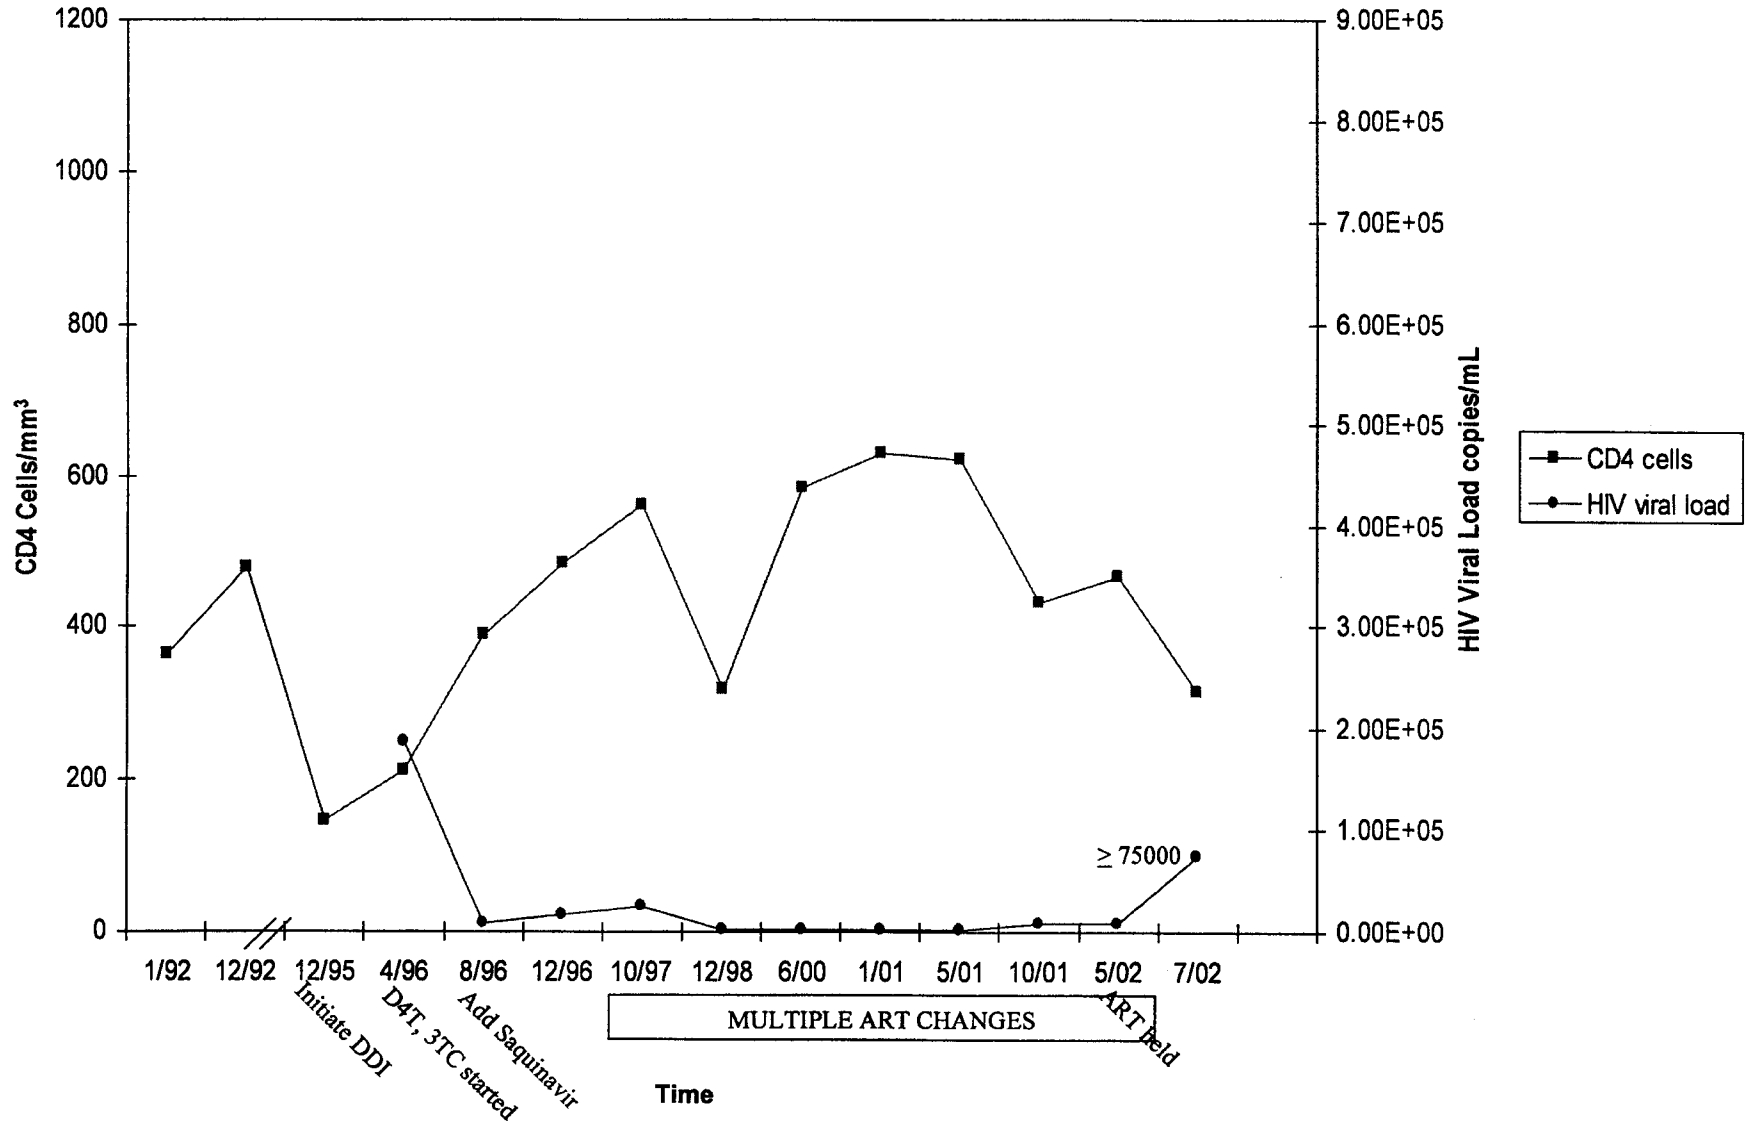

FIG. 13.1. continued.

TABLE 13.12. *Reasons to change antiretroviral therapy*

Failure to decrease viral load by □0.5 $\log_{10}$ within four weeks or 1 $\log_{10}$ by eight weeks after therapy initiation
Failure to decrease viral load to undetectable levels by four to six months of therapy[a]
Repeated detection of HIV after initial suppression to undetectable levels, possibly indicating resistance
Three-fold or greater increase in HIV load in plasma from nadir levels not attributable to other factors
Drug toxicity
Sustained and signi cant drop in CD4 + lymphocyte counts
Non-adherence (eg. high pill burden)
Clinical disease progression

[a] Patients with very high viral loads to begin with and those receiving salvage therapy may not suppress to undetectable levels. For these patients it is more realistic for health care providers to allow low (and sometimes even high levels depending upon the CD4 + lymphocyte count) of HIV in plasma without changing therapy.

TABLE 13.13. *Principles of changing antiretroviral drug therapy*

1.	Substitute □2 new drugs to a failing regimen
2.	For patients on antiretroviral therapy, resistance testing in combination with knowledge of prior therapy should be used to help in the design of a new regimen
3.	Single drug substitution is reasonable when HIV is suppressed and the change is made due to toxicity
4.	Changes for resistance between currently available NNRTIs is of doubtful bene t due to within class cross-resistance
5.	Switches are particularly problematic among patients who have been exposed to drugs from all three classes of antiretrovirals
6.	After a therapeutic change, drug-drug interactions and adverse reactions must be reevaluated
7.	Approximately four to six weeks after a change in therapy, ef cacy should be evaluated by a plasma viral load study
8.	If therapy is to be stopped for any reason, all drugs should be stopped
9.	For some patients who have received numerous drugs and have resistance to many antiretroviral agents and an increased CD4 + lymphocyte count despite active viral replication, continuing the current regimen may provide clinical bene t.
10.	When switches are made, particularly if a regimen is failing, reexamine adherence problems and solutions to these problems

NNRTI = Non-nucleoside reverse transcriptase inhibitor.

modest. The CD4 + cell count typically increases by more than 50 cells/mm^3 at four to eight weeks after starting an effective antiretroviral drug regimen, followed by an additional 50Ð100 cells/mm^3 per year thereafter (18,267Ð270). This point is demonstrated in Figs. 13.1a and 13.1b. Some patients have minimal initial CD4 + lymphocyte responses only to have marked increases years into treatment. In any one individual the maximum CD4 + cell response cannot be predicted. Individuals with a nadir CD4 + cell count that is extremely low (< 50 cells/mm^3), those with lack of optimal viral load suppression, or elderly patients may have more limited increases in CD4 + lymphocyte counts than others (271Ð274). Despite the fact that CD4 + cell increases are more likely to be sustained with optimal viral load suppression, relatively high CD4 + lymphocyte counts and clinical improvement may persist despite increases in viral load (termed discordant responder) (271,275Ð280). The patient results depicted in Fig. 1c (8/96Ð10/97) demonstrates this point. CD4 + lymphocyte counts may remain elevated for three years before they begin to decline. The marked decrease in OIs, and the ability to safely discontinue primary and secondary suppressive therapy for OIs among patients with CD4 + cell rises to > 200 CD4 + cells/mm^3 (9,281,282), suggests that these new CD4 + cells are functional (see below).

Changes in ART

Changes in ART are predicated on a variety of interrelated considerations. These include: drug tolerability, adverse reactions, clinical progression (evidenced by the development of new OIs), a declining CD4 + cell count, failure to suppress viral load adequately or viral load breakthrough after adequate suppression, and available options for treatment based upon prior therapy and resistance testing. At times it may be advisable to change therapy in order to improve adherence, i.e. decrease the number of pills or the frequency of dosing. Table 13.12 lists reasons to change therapy and Table 13.13 the principles that govern such changes.

Depending upon the reason for switching therapy, either a single drug substitution or a multiple drug change will be required. Patients with adequate viral suppression may need to have drugs changed because of a speci Þc toxicity. For instance, a patient placed on AZT, 3TC, and abacavir may develop an abacavir hypersensitivity reaction. In these instances, a single drug substitution is allowable. Rashes associated with NNRTI use also may require substitution of the NNRTI with an NRTI or PI. Other patients may develop adverse reactions to the PIs. In these instances, a simple switch of the PI to an NNRTI or a third NRTI may markedly improve glycemic control or help to

TABLE 13.14. *Adjustments in protease inhibitor doses when ritonavir enhancement is used*[a]

Drug dose[b]	Modi ed PI dose	Ritonavir dose
Saquinavir		
Invirase 600 mg TID	400 mg BID	400mg BID
Fortovase 1,200 mg TID	800–1,000 mg BID	100 mg BID
1,200 mg TID	1,600 mg QD 100 mg QD	100 mg QD
Indinavir 800 mg Q 8 hours[c]	800 mg BID—with food	100–200 mg BID
	400 mg BID—with food	400 mg BID
Amprenavir 1,200 mg BID	600 mg BID	100–200mg BID

BID = twice daily, TID = three times daily.
[a] Data on which these adjustments are based are limited; lopinavir is formulated with 100 mg ritonavir and prescribed daily (Kaletra).
[b] FDA approved non-enhanced dose.
[c] When taken without ritonavir should be taken on empty stomach or with light meal. However, when taken with ritonavir should be taken with food.

decrease elevated triglyceride or cholesterol levels (283). Unfortunately, to date, such a switch for lipoatrophy or lipohypertrophy does not appear to improve the situation (283–286).

Addition of a single drug to a three-drug regimen can be considered in several settings. In certain patients, ART may reduce viral loads to levels below 10,000 copies/ml, but not to undetectable levels. In this situation, ART "intensification", addition of a single drug in order to attempt to suppress the viral load completely, has been used by some investigators. Data for this strategy are limited (287–289), and more information on safety and efficacy are needed before this approach can be recommended.

Ritonavir, in lower than therapeutic doses, may also be added as a single drug to a multi-drug combination regimen. By inhibiting the CYP450 enzymes in the gastrointestinal tract and liver which are responsible for the metabolism of the PIs, ritonavir in doses as low as 100 mg twice daily can markedly increase drug levels of other PIs. This allows for a reduction in the frequency of administration and in the number of pills for PIs such as saquinavir, amprenavir, lopinavir, and indinavir (Table 13.14).

Addition of low-dose ritonavir to an indinavir-containing regimen may also be considered for patients who have an early HIV viral breakthrough after suppression, or for whom there was lack of complete suppression in the first place. Use of ritonavir to "intensify" therapy in this manner, before a multiple drug switch, has been shown to lead to viral suppression (288). The pharmacokinetics of indinavir are such that there is great variability in the trough level when 800 mg is given three times daily without ritonavir (290). When the indinavir concentration drops below the level necessary to inhibit the HIV strain, intermittent viral replication might occur until adequate levels are restored with the subsequent dose. Low trough indinavir levels have been associated with ART virologic failure (291). Low-dose ritonavir leads to higher and more constant blood levels of indinavir and avoids low trough levels (292), although the incidence of renal adverse effects of indinavir (eg stones, flank pain or hematuria) may be higher (293).

At least 50% of the time the reason for changing an antiretroviral regimen is due to failure to either reach or durably sustain viral load suppression (294). When changes are to be entertained for this reason, in most instances at least two new drugs to which the virus is susceptible should be included in the new regimen (17,18). The options for making such changes are numerous and no single regimen is "best" for all patients. In this particular area of therapy available study data are quite limited. Prior to making a switch, health care providers should try to ascertain which drugs the patient may have received earlier as part of a failing drug regimen, since the patient may harbor HIV strains resistant to these agents, that are not identified by drug susceptibility testing methods (see above) (241). Table 13.15 provides guidance regarding some of the changes to consider in this circumstance.

Other considerations to be kept in mind when making drug changes are prior intolerance of specific drug classes (such as NNRTI-induced rashes), co-existing illnesses (such as diabetes or pancreatitis), adherence problems, and prior reports of patient dissatisfaction with certain drugs. In some instances prescribing newer preparations of the same drug may make them much more tolerable. For instance, many patients in the past had an aversion to mixing ddI powder and taking it twice daily on an empty stomach. Now, a single pill can be taken daily. If ART failure is due to poor adherence, prior to switching medications, attempts should be made to ameliorate the problem.

Before making a change, it is important to assess the significance of the increased viral load. Among patients who have had adequate viral suppression, transient viremia may occur. Transient viremia is frequently low grade, i.e. <500 copies/ml, but can be higher. This phenomenon occurs in 35% to 40% of patients who have been suppressed to a level of <50 copies/ml (295). Although vaccination and intercurrent illness may be the etiology of transient viremia, frequently the cause is not known. The significance of such "blips" is not clear, but

TABLE 13.15. *Possible empiric changes in therapy for a failing regimen*[a]

If a 3 NRTI regimen has been unsuccessful consider:

switching 2 NRTIs (eg, AZT plus ddI to d4T plus 3TC; or d4T plus ddI to AZT plus 3TC) and adding an NNRTI or a PI (with or without ritonavir enhancement)

If a 2 NRTI plus NNRTI regimen has been unsuccessful consider:

switching 1 or both NRTIs (eg, AZT plus 3TC to ddI plus D4T; or d4T plus 3TC to AZT plus tenofovir) and switching the NNRTI to a PI (with or without ritonavir enhancement)

If a 2 NRTI plus PI regimen has been unsuccessful consider:

switching one or both NRTIs and
changing the PI to a NNRTI (if the patient has not been exposed to NNRTIs)

or

switching one or both NRTI's
and switching the PI (eg, saquinavir or nel navir to indinavir or lopinavir/ritonavir or amprenavir)

or

changing to a triple class regimen (if patient not exposed to NNRTIs)—switching one or both NRTI's and switching the PI and adding a NNRTI

[a] There are few data to recommend one speci c regimen over another when making such switches.
NRTI = Nucleoside reverse transcriptase inhibitor.
NNRTI = Non-nucleoside reverse transcriptase inhibitor.
PI = Protease inhibitor.
AZT = Zidovudine; ddI = didanosine; d4T = stavudine; 3TC = lamivudine.

patients who have frequent ÒblipsÓ to >400 copies/ml have an increased risk of eventually failing therapy (296Ð298).

Patients who are discordant responders (as described above) may also bene Þt from continuing their current regimen and not switching drugs, particularly if they have had prior problems with various drugs or failed other regimens, since the available antiretroviral drug options may be limited. These patients appear to have a reduced clinical progression of disease (277,278). It is hypothesized that the mutated virus that is replicating in the face of antiretroviral drugs is less ÒfitÓ (replicates more slowly) than wild-type virus (299). The decision regarding when to change therapy for these patients is complex and should be based upon available drug options and the patientÕs desire to make changes.

After changing ART it is advisable to obtain a complete blood count and blood chemistry studies (including liver function testing) approximately two to four weeks later to look for adverse effects that may not be clinically apparent. The viral load should be assessed between four and eight weeks after changing therapy.

Salvage Therapy

Some patients who have received numerous antiretroviral drugs will have persistently high or newly rising viral loads and either a poor CD4+ lymphocyte response or a falling CD4+ lymphocyte count. For these patients, the concept of salvage therapy (sometimes referred to as Òmega-HAARTÓ when four to Þve or more drugs are used) has entered the treatment lexicon. These regimens tend to be empiric due to broad antiretroviral drug resistance and sometimes consist of six or more drugs many of them recycled from prior use. There are few data to recommend any one of these regimens, many patients will not tolerate them for any prolonged length of time, and if viral load suppression is achieved, it is often short-lived (300Ð303). Furthermore, when changes are made at high viral loads i.e. >50,000 copies/ml, salvage therapy is more likely to fail (302). When devising a salvage regimen, it is advisable not to use new Òexpanded accessÓ drugs (drugs made available to health care providers under research protocols after completion of phase 3 studies while FDA approval is pending) unless other agents to which the HIV strain is susceptible can also be added at the same time, to avoid ÒwastingÓ potentially important and effective agents if they are used as monotherapy.

Even among patients with advanced disease who are not responding to therapy there seems to be an advantage to continuing therapy unless toxicity precludes doing so. However, there are some settings in which stopping therapy may be considered. Some patients with later stage disease choose to stop therapy to avoid taking medications when they are very ill. Some authorities also stop therapy for patients who were started on ART when their CD4+ lymphocyte count was >500 cells/mm^3 if the counts have been maintained at a high level. It is hoped that long-term toxicity will be avoided. When the CD4+ lymphocyte count falls to the threshold used to initiate ART, therapy is then restarted (17). Antiretroviral medications should be stopped and initiated together except in circumstances

when sequential initiation is used to determine which drug may be causing a particular toxicity.

Strategic Treatment Interruption

In recent years there has been a growing interest in intermittently stopping therapy, particularly for those patients with suppressed viral loads. The concept of strategic treatment interruption (STI) is that prolonged therapy may lead to unacceptable long-term adverse reactions. Furthermore, it is also hoped that stopping therapy will lead to a stronger immune response to the patientÕs HIV strain when the virus rebounds. Cost savings also would be considerable both due to lower expenditures for drugs and lower costs related to treating medication side effects.

Among chronically HIV-infected patients with prolonged viral suppression, the cell-mediated CD8+ anti-HIV immune response wanes (304,305). This can be boosted when the virus is allowed to replicate (304,306–308). There have been several small studies using differing strategies for stopping therapy (304). One is based upon a deÞned time period of drug discontinuation (for example, cycling one month on therapy then two months off). A second strategy is based upon the height of the viral load rebound (for example, therapy is restarted when the virus rebounds to a predeÞned level). It has been demonstrated that time to viral rebound increases in some patients with each drug treatment interruption (304,309). This supports the concept of Òself-immunizationÓ when therapy is stopped. However, the vast majority of patients still require intermittent treatment because the viral load eventually rises and the CD4+ lymphocyte count eventually falls when therapy is discontinued (309). Importantly, with re-initiation of therapy the virus is readily suppressed (304,306,308–310). Whether the hoped for decrease in toxicity can be realized using intermittent therapy, is an active area of investigation (311,312).

Among patients who have viral load suppression on ART, a syndrome that mimics the signs and symptoms of the acute antiretroviral syndrome may occur in a small percentage of patients when ART is stopped (see below) (313–315).

Treatment of Early HIV Infection

Patients with acute HIV infection and those infected within six months of diagnosis are two subgroups of patients whom many authorities would treat despite high CD4+ cell counts (17,316). Approximately 50% of patients with acute HIV infection manifest symptoms of the acute retroviral syndrome. This is manifested by an acute illness that has been characterized as mononucleosis-like (316,317). In fact, heterophile antibody studies may be positive (318). Common Þndings include: fever, lymphadenopathy, an erythematous maculopapular rash on the face and trunk, headaches, pharyngitis, myalgias and/or arthralgias (316,317,319). Although it is not common to make this diagnosis, physicians should consider it when encountering a patient from a high-risk population who presents with the above described illness.

At the time of the acute syndrome, antibodies to HIV are frequently negative (316,317). Diagnosis can be made by the p24 antigen assay or by Þnding HIV RNA in high levels in plasma (316). Although HIV RNA assays in general should not be used to make a diagnosis of HIV infection, in the setting of acute infection they may be helpful. Low levels of HIV in an HIV seronegative individual should be interpreted cautiously because of the potential for false positivity of HIV RNA assays (320). Among patients with a recent diagnosis of HIV infection who have high CD4+ cell counts, it is important to question when they may have most recently tested negative for HIV infection. In retrospect, these patients may recall a distinct exposure or illness compatible with acute HIV infection.

Data on the use of ART in early HIV infection are limited. However, preliminary data suggest that both disease progression and outcome are improved when therapy is begun during the acute antiretroviral infection or within the Þrst six months of infection (321–323). ART recommendations for these patients are similar to those outlined above for chronically infected patients, but should be based upon viral resistance testing (17). Patients should be informed that treatment is being offered based upon theoretical considerations with little scientiÞc data. It is hoped that early intervention will decrease viral dissemination, reduce viral load, alleviate the symptoms of the acute retroviral syndrome, and preserve immune function. The major risks for treating at this early time point are related to drug toxicities and their effect on quality of life among individuals who otherwise feel well. If the viral load cannot be adequately suppressed, resistance may limit antiretroviral options in the future when ART may be needed more.

If and when to stop therapy among these patients has not been Þrmly established. Some health care providers choose to treat indeÞnitely until new data are forthcoming. Others prefer to treat for 12 months before stopping therapy.

Treatment of Pregnant Women

The decision of when and with what drugs to treat HIV-infected pregnant women should be made in conjunction with an obstetrician, a health care provider well versed in the care of HIV-infected patients, and the patient. With some notable exceptions (see below), basic principles regarding treatment are similar for pregnant and non-pregnant HIV-infected individuals (324).

A nearly 70% reduction of HIV transmission from mother to infant can be achieved using monotherapy with

AZT, when the drug is given orally at 14 weeks of pregnancy, IV during labor, and then orally to the infant during the Þrst six weeks of life (325). However, more recent United States Public Health Service (U.S.PHS) task force guidelines (available at http://www.hivatis.org) recommend that health care providers discuss the use of combination antiretroviral drug therapies with their HIV-infected pregnant patients (326). In order to minimize the risk of vertical HIV transmission to the newborn, all HIV-infected pregnant women should receive ART regardless of CD4+ lymphocyte count and HIV viral load levels. Pregnant women must be counseled at length, however, about the lack of knowledge regarding toxicity to mother and child of multi-drug therapy. Pre-term delivery has been reported to be associated with combination antiretroviral therapy in one study (327), but not in others (328,329), and is probably not a major concern.

Due to limited enrollment of pregnant women in drug treatment trials, there are insufÞcient data concerning the effects of the physiologic and hormonal state of pregnancy on antiretroviral drug metabolism and distribution. However, based upon available data, combination ART appears safe in pregnant women (329) and can decrease the rate of vertical transmission of HIV to 1% to 5% (328,330,331). With the exceptions of ritonavir, saquinavir, nelÞnavir, and didanosine, which are category B (animal data fail to demonstrate a risk to the fetus, but human studies in pregnancy have not been done), all other approved antiretroviral drugs are category C (animal studies are either positive for fetal risk or have not been conducted, and safety in human pregnancy has not been determined) (17,324). Efavirenz, zalcitabine (ddC), and hydroxyurea should be avoided in pregnancy due to the development of fetal abnormalities in animal studies (17,326). The combination of D4T and ddI also should not be given to pregnant women, since this combination has caused severe lactic acidosis and death in three pregnant women (332).

Current recommendations for use of ART in pregnancy contemplate several potential scenarios (17). In all scenarios and regardless of the results of resistance testing to AZT, the three-part AZT regimen should be included if tolerated. HIV-infected pregnant women who have $<1{,}000$ copies/ml of plasma HIV and who have not previously received ART should be recommended to receive at least the three part AZT regimen described above beginning in the second trimester of pregnancy. Pregnant women without previous ART with $>1{,}000$ copies/ml of plasma HIV should receive three-drug combination therapy including, if tolerated, AZT. If an HIV-infected pregnant woman is already on ART and has $<1{,}000$ copies/ml, then the drug regimen may be continued with appropriate counseling about potential risks, unless it includes an agent contraindicated during pregnancy. HIV-infected pregnant women already on ART with $>1{,}000$ copies/ml HIV in plasma should have resistance testing done and changes made accordingly. The three part AZT regimen should be included when possible. If the patient is found to be HIV-infected while pregnant or is known to be HIV-infected but na•ve to ART, then therapy can be initiated immediately or deferred until the second trimester of pregnancy.

HIV-infected women who present in labor and are not taking ART present a special situation. Four options are recommended including: nevirapine (1 dose), AZT orally plus 3TC, intravenous AZT, or nevirapine (1 dose) plus intravenous AZT (326).

Cesarean section for delivery of infants of HIV-infected mothers combined with the use of AZT during pregnancy decreased the transmission of HIV from mother to infant to approximately 1% in one large French study (333). However, it is not clear that these rates are better than those achieved with combination therapy in the pregnant HIV-infected woman (328,330,331). Combination therapy without cesarean section avoids the potential morbidity and mortality associated with surgery (334,335). Among HIV-infected women undergoing cesarean section the risk of complications appears to be similar to that of non-HIV-infected women but is several fold higher than that for vaginal delivery (334,335).

Management of Adverse Effects of ART

Management of ART-related toxicity (Table 13.8) usually, but not uniformly, requires discontinuation of the medication. In many instances, complex decisions will need to be made regarding the beneÞts of continuing medication in order to maximize viral suppression and immune function versus stopping therapy. Some adverse reactions may be manifested by abnormal laboratory values such as anemia or elevated liver function studies that may not cause symptoms until the problem is severe. This is why most physicians monitor complete blood counts and blood chemistries including liver function studies at three-month intervals. Selected adverse-reactions and possible management approaches are listed in Table 13.16 (see Chapter **??**).

Adverse events can be categorized as follows. Symptomatic complaints that can occur with almost any drug are common with ART. These symptoms include nausea, vomiting, gastrointestinal discomfort, headaches, and fatigue, among others. They frequently occur early in treatment, are not life threatening, and may resolve without speciÞc treatment. Unless the problem is severe, it is worthwhile continuing the medication for several weeks to determine whether the symptoms improve. If not, then one or more medications will need to be changed. Unfortunately, if these problems occur after introduction of a new multi-drug regimen, it can be very difÞcult determining which drug caused the problem. At times, after stopping therapy, health care providers will need to reintroduce the medications sequentially in order to determine the offending drug.

Other adverse reactions tend to be more drug or drug-class speciÞc. Several NRTIs including ddI, d4T, and ddC

TABLE 13.16. *Selected adverse reactions and their treatments related to selected drugs used to treat HIV and HIV-related illnesses*

Adverse Reaction	Drugs	Evaluation and Treatment Options
Bone marrow suppression	AZT, cidofovir, cytotoxic chemotherapy, dapsone, ganciclovir, hydroxyurea, interferon, primaquine, pyrimethamine, ribavirin, sulfadiazine, TMP-SMX	Consider discontinuation of drug; Supportive therapy such as erythropoietin, G-CSF; Rule out other causes besides medication such as infection due to parvovirus or dMAC
Peripheral neuropathy	ddI, D4T, ddC, isoniazid	Consider discontinuation of drug; Rule out other causes such as vitamin B12 or folate de ciency; treat with analgesics, NSAIDS, tricyclics (e.g. nortriptyline, amitriptyline), gabapentin, phenytoin or carbamazepine; if severe, morphine sulfate or fentanyl patch; consider pain consult
Pancreatitis	ddI, pentamidine	Discontinue medication; Evaluate contributing factors such as hyperlipidemia, alcohol use or infections
Renal toxicity	indinavir, foscarnet, cidofovir, pentamidine, aminoglycosides, amphotericin B	Discontinue medication; Rule out HIVAN, other contributing medical conditions e.g. diabetes, hypertension, sepsis
Liver toxicity	NNRTIs[a], PIs, NRTIs, azole antifungals, rifampin, rifabutin, isoniazid, androgens	Consider drug substitution—NRTI for NNRTI or PI; or NRTI or PI for NNRTI; Switch from ritonavir-enhanced to non-enhanced ART; If HCV co-infection consider possible immune reconstitution if on new ART and continue medications; If severe, discontinue medications and evaluate for other medical causes and acute viral hepatitis
Rash	abacavir, PIs, NNRTIs, dapsone, TMP-SMX, sulfadiazine, clindamycin other drugs	If abacavir-related, stop drug and do not rechallenge[b]; If mild NNRTI-related rash, can observe closely and continue drug; Often must stop drug
Diarrhea	nel navir, ritonavir, lopinavir/ritonavir, amprenavir, clindamycin, among numerous other drugs	If severe and associated with a new PI containing regimen, consider switch of PI or change to another class of drugs; If mild and need or desire to continue drug then treat symptoms eg, loperamide If severe, evaluate for *Clostridium difÞcile* and other infections including OIs depending upon CD4 + cell count—likely will need to hold ART while evaluating; If evaluation negative, may need colonoscopy and symptomatic treatment
Hyperlipidemia	PIs[c], NNRTIs (less commonly)	Evaluate risk vs. bene t of continuing PI-based regimen; if HIV viral load suppressed consider switch to NRTI or NNRTI from PId If continue PI or after switch lipids remain elevated, treat according to guidelines with statins or brate,[e] dietary modi cation and exercise,[f]

TABLE 13.16. *continued*

Adverse Reaction	Drugs	Evaluation and Treatment Options
Fat maldistribution	PIs, NRTIs (particularly D4T)	Consider switch from PI to another class, particularly if associated with hyperlipidemia and HIV has been suppressed; Few data on successful management
Hyperglycemia	PIs[g]	Evaluate risk vs. bene t of continuing PI-based regimen; if viral load suppressed consider switch to NRTI or NNRTI from PI If elevated random blood glucose level, measure fasting blood glucose; Treat per diabetes guidelines
Lactic acidosis	NRTIs	Discontinue medications if symptoms
Nausea/vomiting	Any agent	If felt related to new ART regimen try to continue medications if mild and treat with antiemetics—problem may resolve within rst few weeks without need to stop medication; If severe, stop medications

g-CSF = granulocyte colony stimulating factor, TMP-SMX = trimethoprim-sulfamethoxazole, dMAC = disseminated *Mycobacterium avium* complex, NSAIDS = nonsteroidal anti-in ammatory drugs, HIVAN = HIV-associated nephropathy, NRTI = nucleoside reverse transcriptase inhibitor, NNRTI = nonnucleoside reverse transcriptase inhibitor, PI = protease inhibitor, ART = antiretroviral therapy, HCV = hepatitis C virus.

[a] although all NNRTIs can cause hepatotoxicity, nevirapine has been associated with severe liver disease.

[b] hypersensitivity reactions with the use of abacavir have been reported in up to 5% of patients, rechallenge has caused death in several patients; patients developing a rash on nevirapine frequently tolerate efavirenz.

[c] Hyperlipidemia most directly associated with PIs with the greatest incidence in patients taking ritonavir, even at low "boosting" doses but has been reported in patients taking NNRTIs regimens.

[d] Among patients with suppressed HIV viral loads, switching from a PI-based regimen to a NNRTI-based regimen appears to be safe with continued viral suppression.

[e] Statins and brates should be used in combination cautiously in HIV-infected patients, particularly if taking NRTIs due to concern about myopathy.

[f] Few data support these "lifestyle" changing measures but it seems advisable to use these in conjunction with other measures.

[g] Hyperglycemia occurs with all currently available PIs.

cause peripheral neuropathy (336). The distribution may be Ògglove and stockingÓ or may involve the lower extremities alone (337). NRTI-associated neuropathy may be mild or severe enough to interfere with activities of daily living. Other causes of peripheral neuropathy should be considered before attributing neuropathy to NRTI medications. If the inciting drug is stopped it can take months for the neuropathy to resolve. Some patients with neuropathy do not need medication for this problem. For those who do, initial management should include mild analgesic therapy and non-steroidal anti-inßammatory medications (336). Nortriptyline, amitriptyline, and gabapentin have been used with some success in a manner similar to the treatment of diabetic neuropathy (336). Some patients are in enough pain to warrant evaluation by a pain control service. An ascending Guillain-Barre-like polyneuropathy has been reported with D4T in rare instances (332) and ART should be stopped in patients who present with this syndrome.

Didanosine has been associated with pancreatitis. This drug should be stopped immediately if a patient has abdominal pain or symptoms consistent with this diagnosis, pending evaluation since this complication may be life-threatening.

Up to 3.7% of patients started on abacavir will develop a hypersensitivity reaction that includes such signs and symptoms as rash, fever, malaise, and abdominal complaints including diarrhea, nausea, vomiting, and pain (338). Recent data suggest that abacavir toxicity occurs predominantly among patients with HLA-B57 (339). However, routine screening for this HLA group is not recommended currently. In some instances respiratory symptoms such as cough, tachypnea, and pharyngitis may predominate (338). More than 90% of these reactions occur within the Þrst six weeks of therapy (338). Abacavir should be stopped if a patient is suspected of experiencing this syndrome (338). Due to the possibility of a severe reaction including death, patients who have had this reaction should never be rechallenged with abacavir (338).

Severe lactic acidosis is an infrequent adverse reaction associated with NRTIs alone or in combination, but may

be more frequent with D4T and ddI (340). This adverse reaction has been attributed to mitochondrial toxicity (341). The incidence of elevated lactic acid levels (8.7Ð14.5/1,000 patient-years) (181,183,342,343) exceeds that of symptomatic lactic acidosis (3.9/1,000 person-years) (178). Symptomatic lactic acidosis carries a high mortality rate (344); however, chronic mild, asymptomatic hyperlactatemia with levels in the range of 1.5 mmol/L to 3.5 mmol/L appears to be well tolerated (183). For lactate levels in the range of 2.1 mmol/L to 5.0 mmol/L, the lactate should be repeated, an arterial blood gas should be performed, and symptoms evaluated. If the patient becomes symptomatic, and the lactate level is persistently elevated, or the arterial pH is abnormal, ART should be stopped. Initial symptoms may be vague with complaints of fatigue most prominent. However, left untreated, patients may develop tachypnea, increasing fatigue, weight loss, nausea and vomiting, and abdominal pain (180,181). Laboratory studies reveal elevated lactate levels with a low serum bicarbonate with or without metabolic acidosis. CPK, ALT, and/or LDH all may be elevated (176). Hepatic steatosis is often demonstrated on liver biopsy. Discontinuation of therapy is critical, after which there may be slow resolution of the disease process over three to six months. Despite aggressive supportive therapy, patients frequently do not survive. Treatment for ART-associated lactic acidosis is supportive. Antioxidants such as riboßavin, carnitine, and ubiquinone have been suggested but data are limited regarding their efÞcacy (345). Once patients have improved, introduction of other NRTIs has been successful in some patients (180), but the safety of this approach has not been adequately studied.

All NNRTIs may cause rashes (346). This is particularly common in patients receiving nevirapine, occurring in nearly 20% of patients. If the rash is mild, therapy can be continued, and frequently the rash will resolve. However, patients must be observed carefully if therapy is continued; fatal Stevens-Johnson syndrome has been reported (347). Cross-reactivity between agents within this class occurs, but not in the majority of patients (347,348). Therefore, administration of a different NNRTI can be attempted but should be done cautiously. Use of corticosteroids, antihistamines, and/or desensitization techniques to decrease the incidence of skin rashes with nevirapine have met with variable results and cannot currently be recommended (349). Insomnia, dizziness, central nervous system irritability, and very vivid, often disturbing dreams have been associated with efavirenz (336,340,346). To reduce the risk for dizziness, the drug is usually taken at bedtime.

Diarrhea is a common problem with the PIs, especially ritonavir, amprenavir and nelÞnavir (340,346). Although this problem is generally mild, it can necessitate discontinuation of the medication. Drugs which slow gastrointestinal motility such as loperamide can be tried at the lowest dose that demonstrates efÞcacy after other more serious causes of diarrhea (such as infectious diarrhea) have been excluded.

Indinavir has two side effects peculiar to it: asymptomatic indirect hyperbilirubinemia that is of no consequence (340) and kidney disease including crystalluria, renal stones, and interstitial nephritis due to indinavir crystals (350,351). Renal stones can cause severe pain and hydronephrosis (350), while interstitial nephritis is frequently asymptomatic and leads to increased creatinine levels as a result of a reduction in kidney function (see Chapter **??**) (351). In order to prevent renal complications, at least two liters of ßuids should be drunk each day. Although indinavir does not necessarily need to be discontinued in the face of kidney stones, many authorities stop ART until the acute episode resolves. Afterwards, the health care provider and patient must decide whether to reintroduce indinavir and improve hydration. Indinavir should be stopped for patients with interstitial nephritis (351).

In some studies male sexual dysfunction has been associated with PI use (352) and has improved in most patients with discontinuation of the PI. Indinavir has been more strongly associated with this problem than other PIs (352).

Several metabolic adverse reactions that have been linked most closely with PI therapy, although they occur with non-PI containing regimens (175). These include lipohypertrophy, hyperlipidemia, and hyperglycemia (171) (see Chapter **??**). These metabolic abnormalities can occur together or separately and it is difÞcult if not impossible to predict which patients will develop any or all of these problems. The long-term consequences of these metabolic abnormalities such as coronary artery disease, peripheral vascular disease, and pancreatitis have been suspected, but data proving causation have not been consistent (353,354). This may in part be due to the fact that many HIV-infected patients who develop medical conditions such as coronary artery disease have other risk factors such as smoking. Another explanation for the lack of a clear association between PI therapy and consequences of metabolic problems is that the relatively brief duration of follow-up may be too short for development of clinically apparent disease.

Abnormal glucose metabolism among patients taking PIs has led to new onset diabetes, rarely with ketoacidosis, or exacerbation of pre-existing diabetes mellitus (139Ð141). It generally presents like type 2 diabetes. The mechanism for glucose dysregulation is not clear but may be multi-factorial. Some HIV-infected patients may be predisposed to diabetes mellitus because they are living longer. However, peripheral insulin resistance, pancreatic beta cell dysfunction, and accelerated conversion of proinsulin to insulin due to PI therapy are some of the proposed mechanisms for this problem (139Ð141). Fasting blood glucose levels should be monitored at three to four month intervals among patients taking PI-based ART. Glucose metabolism will improve in many patients if either ART is stopped or patients are switched to a non-PI-based regimen (283). If it is not possible to change therapy,

then patients should be managed according to the recommendations of the American Diabetes Association (284,355). Diet and exercise are important adjuncts to drug therapy. The indications for diabetic therapy and the agents that are chosen are similar to those for the non-HIV-infected patient with certain caveats. Health care providers must follow liver functions closely when biguanides and thiazolidinediones are used due to their potential to cause hepatotoxicity, especially among patients on ART or those with chronic underlying liver disease. These drug classes also may have beneÞcial effects upon lipid metabolism. Metformin, a biguanide, can also cause lactic acidosis. Careful symptomatic follow-up is required among patients taking NRTIs and metformin because lactic acidosis in this setting is often fatal.

Hyperlipidemia can be manifested by elevated cholesterol and/or elevated triglyceride levels in HIV-infected patients and has been associated with all PIs, in particular ritonavir. Fat maldistribution may or may not accompany hyperlipidemia. Co-morbid risks that may contribute to these problems such as smoking and alcohol use should be modiÞed. Factors such as liver disease, hypothyroidism, diabetes, and medications such as anabolic steroids and corticosteroids that may cause or exacerbate hyperlipidemia should also be addressed. When needed, medication for hyperlipidemia is similar to that of non-HIV-infected patients (356) except that several drugs must be avoided due to their metabolism by the CYP3A hepatic enzyme and the potential for elevated blood levels. Fluvastatin, lovastatin, and simvastatin should be avoided in patients receiving PIs, while atorvastatin and pravastatin can be used (17,357). Because levels of atorvastatin are increased six-fold, it is best to start at a low dose and then increase the dose as tolerated. Data regarding the efÞcacy of these agents are limited, and they may not be as effective as similar therapy in the non-HIV-infected patient. Statins are generally used for isolated high LDL cholesterol levels, a statin or Þbrate for high cholesterol and triglyceride levels, and Þbrates for isolated high triglyceride levels. Among non-HIV-infected patients when Þrst-line therapy fails or is not optimally successful, a member of the other drug class is added. However, the combination of a Þbrate and statin can lead to myopathy and should be used with extreme caution among patients on NRTIs. Diet and life-style changes incorporating more exercise are important adjuncts to medications for the treatment of hyperlipidemia.

Fat maldistribution sometimes termed ÒlipodystrophyÓ has been reported to occur in 17% to 75% of HIV-infected patients on ART (see Chapter **??**) depending upon how the syndrome is deÞned or ascertained and is often accompanied by hyperlipidemia and abnormal glucose metabolism (171,172,358,359). Although fat maldistribution is not in and of itself dangerous, it can be quite disabling due to the psychological impact associated with the patientÕs altered appearance. Patients may have lipohypertrophy and lipoatrophy simultaneously and all fat regions usually are not involved simultaneously.

To date, management of this problem has been difÞcult at best and no speciÞc therapies lead to consistent improvements. Discontinuation of all antiretroviral drugs can lead to minor improvement (17). Switching from a PI-based regimen to a NNRTI- or NRTI-based therapy rarely leads to signiÞcant improvement of body fat changes (360,361). Exercise, diet, and treatment of the lipid and glucose problems may help to avoid some of the body fat accumulation (284,346). Anabolic steroids, testosterone, and human growth hormone have been studied with modest effects (284,346). These therapies are expensive and have their own associated toxicity including glucose metabolism abnormalities, liver disease, and lipid disorders (346). Some patients have employed liposuction as a means of reducing fat accumulations while others have tried injections of collagen or collagen-like materials to augment facial fat loss. These are costly therapies that may not be covered by insurance policies. The long-term outcomes of such therapy are not known. In the short term, some improvement can be seen in the areas of the body that have had liposuction or injections (see Chapter **??**) (284,346).

Hepatocellular dysfunction may develop with the use of NNRTIs and PIs. In particular ritonavir and nevirapine have been associated with this problem (17,18). Fatal hepatic necrosis has been reported due to nevirapine in health care workers taking post-exposure prophylaxis and this drug is no longer indicated for that use (362). For mild liver function abnormalities, ART can generally be continued. If liver function studies rise to more than four to Þve times the upper limit of normal, health care providers should discontinue ART and consider a new regimen when the liver functions have normalized. In patients with HCV and HIV co-infection who are receiving a new ART regimen, the incidence of liver function abnormalities may be increased either because of drug toxicity (363) or because of an enhanced anti-HCV effect due to a stronger immune response, somewhat analogous to the immune reconstitution syndrome (see below). There is no deÞnitive way to distinguish between these two separate phenomena. Health care workers should therefore closely observe the patient with follow-up liver function studies. ART does not necessarily need to be withdrawn immediately.

Accelerated bone loss leading to osteopenia and osteoporosis has been reported to occur at an increased frequency in HIV-infected patients compared with the general population (364). The cause for this is not known. Although a relationship to ART has been hypothesized, this has not been established (364Ð368). When osteonecrosis (avascular necrosis) occurs, the femoral head is the most common site. However, avascular necrosis of the humeral head and multi-site disease also occurs. The association of ART and osteonecrosis is confounded by the fact that many patients have other risk factors such as

hyperlipidemia, alcoholism, pancreatitis, corticosteroids, smoking, and hypercoaguability (365,366). Patients who present with moderate to severe bone or joint pain should be evaluated for the presence of avascular necrosis. Magnetic resonance imaging is the most sensitive diagnostic test in the early stages of disease. Treatment of pain and physical therapy can help to reduce loss of mobility, and possibly the need for surgery. Whether management of osteoporosis should be similar to that of HIV-negative patients and include biphosphonates, raloxifene, calcium, calcitonin, and/or estrogens is not known at this time.

Two other adverse reactions associated with ART but not necessarily directly caused by these medications are galactorrhea and hyperprolactinemia (369), and gynecomastia among men (370). The former resolves with discontinuation of PIs.

The Immune Reconstitution Syndrome

Within weeks of starting ART, patients may become ill as new inßammation develops localizing to areas of preexisting infection (371,372). This unanticipated and unwanted consequence of ART results in troubling symptoms that occur because of the improved immune function. The frequency with which these problems arise is not known, but is probably less than 2%. Patients with inactive CMV retinitis can develop immune recovery vitritis (373,374). IntensiÞed immune responses causing symptoms in HIV-infected patients placed on ART have also been reported in patients with dMAC (375,376), herpes zoster (377), cryptococcal meningitis (378), toxoplasma encephalitis (379), tuberculosis (380,381), and progressive multifocal leukoencephalopathy (382,383). Although optimal treatment has not been deÞned, anecdotal treatment with anti-inßammatory agents such as steroids (local for vitritis or systemic for MAC) or nonsteroidal anti-inßammatory agents (MTb) plus speciÞc treatment of the inciting infection has been employed with some success. ART should not be stopped because of this problem.

The role of drugs with immunomodulating activity for use in conjunction with antiretroviral therapies is also under active investigation (384–388). Interleukin-2 administered by intravenous infusion or subcutaneously is the most well studied (389,390). No immunomodulating drug, however, can be recommended at present (see chapter). Continued changes in the approach to ART therapy can be expected over the next few years, representing perhaps the most dynamic area in clinical management.

CHEMOPROPHYLAXIS OF OPPORTUNISTIC INFECTIONS

As HIV induced immunodeÞciency advances and the CD4+ lymphocyte count falls to <200 cells/mm^3, patients become at risk for an increasing array of OIs including PCP, central nervous system toxoplasmosis, cryptococcosis, dMAC infection, oral and esophageal candidiasis, CMV retinitis, and many others (9). The CD4+ cell count is the single best indicator of when to offer and stop various preventive therapies (22–24). Unless the CD4+ lymphocyte count rises to levels at which it is safe to stop therapy, chemoprophylaxis should be continued indeÞnitely. Table 13.17 indicates the CD4+ lymphocyte levels at which primary prophylaxis should be started and stopped and the preferred antimicrobial choices for prophylaxis. Chemoprophylaxis can be considered primary (given to patients who never have had the particular infection) or secondary (given to patients who have had an episode of the infection).

If chemoprophylaxis is discontinued because of a rise in CD4+ cell count, it should be remembered that it may need to be resumed in the future if CD4+ cell counts decline. Discontinuation of chemoprophylaxis reduces: pill burden, potential drug-drug interactions, toxicity, potential for drug resistance to develop, and drug costs. HIV replication does not have to be completely suppressed in order to discontinue prophylaxis.

Primary prophylaxis is routinely recommended for prevention of infection due to: *P. carinii*, *T. gondii*, *Mycobacterium-avium* complex, and *M. tuberculosis*. For other infections, primary prophylaxis is not currently recommended.

Pneumocystis carinii Pneumonia (PCP) Chemoprophylaxis

Initiating prophylaxis

Without speciÞc chemoprophylaxis, it has been estimated that up to 75% of HIV-infected individuals will develop PCP when the CD4+ lymphocyte count falls to below 200 cells/mm^3 (23,391). Although PCP is rare among patients with a CD4+ lymphocyte count >200 cells/mm^3, approximately 5% have higher counts (22). Patients with CD4+ cell counts in the range of 200 to 250 cells/mm^3 with thrush or a CD4+ lymphocyte percentage of $<14\%$ are at higher risk for developing PCP and should receive PCP prophylaxis. The discovery that this form of pneumonia can be largely prevented by chemoprophylaxis was a major achievement in the care of HIV-infected patients (9,392–397).

The preferred agent for prophylaxis is trimethoprim-sulfamethoxazole (160 mg trimethoprim, 800 mg sulfamethoxazole) (TMP-SMX) given orally once per day, either daily, on alternate days or three times weekly (Table 13.17) (see Chapter **??**) (9,395–397). Daily therapy may be more effective than three times weekly (398) but is tolerated less-well than intermittent regimens (399). Advantages of TMP-SMX over other prophylactic therapies include greater efÞcacy, lower cost, convenience of

TABLE 13.17. *Prophylaxis of opportunistic infections*

Infection	Indication to start therapy	Duration of therapy[a]	Preferred regimen	Alternative regimen
Tuberculosis	Positive tuberculin skin test or recent contact with active case Mtb	Completion of course	INH 300 mg + pyridoxine 50 mg q.d. × 9 mo	INH 900mg + pyridoxine 100 mg BIW × 9 mo; Rifampin[b] 600 mg + pyrazinamide 15–20 mg/kg q.d. × 2 mo; Rifampin 600 mg q.d. × 4 mo
Suspected INH resistant *Mycobacterium tuberculosis*	As above	Completion of course	Rifampin[b] 600 mg + pyrazinamide 15–20 mg/kg q.d. × 2 mo	Rifampin 600 mg q.d. × 4 mo
Pneumocystis carinii	< 200 CD4 + cells/mm^3	Until CD4 + increases to 200–300 cells/mm^3	TMP-SMX DS q.d. or TIW TMP-SMX SS q.d.	Dapsone 100 mg q.d.; Atovaquone 1500 mg q.d. with meals; Dapsone 200 mg/wk + pyrimethamine 75 mg/wk + folinic acid 25 mg/wk; Dapsone 50 mg q.d. + pyrimethamine 50 mg/wk + folinic acid
Pneumocystis carinii				25 mg/wk; Pentamidine aerosol 300 mg q mo by Respirgard II$^{(TM)}$ nebulizer
Toxoplasma gondii	< 100 CD4 + cells/mm^3 and *T. gondii* IgG positive in serum	Until CD4 + increases to 200 cells/mm^3	TMP-SMX DS q.d. or TIW	TMP-SMZ SS q.d.; Dapsone 200 mg/wk + pyrimethamine 75 mg/wk + folinic acid 25 mg/wk; Dapsone 50 mg q.d. + pyrimethamine 50 mg/wk + folinic 25 mg/wk; Atovaquone 1500 mg q.d. with meals ± pyrimethamine 50 mg/wk + folinic acid 25 mg/wk
Mycobacterium avium complex	< 50 CD4 + cells/mm^3	Until CD4 + increases to 100 cells/mm^3	Azithromycin 1,200 mg/wk	Clarithromycin 500 mg b.i.d.; Rifabutin[b] 300 mg q.d.

INH = isoniazid; q.d. = daily; mo = months; TMP-SMX = trimethoprim-sulfamethoxazole; DS = double strength; SS = single strength; TIW = three times a week; wk = week, q = every.

[a] Time duration that CD4 + cell count should exceed the numbers given in this chart are not known but should be in the range of three to six months; If the CD4 + cell count drops to levels lower than the number for stopping medication, prophylaxis should be restarted.

[b] Rifampin should not be used concurrently with amprenavir, indinavir, nel navir, saquinavir, lopinavir/ritonavir, or delavirdine due to decreased levels of these drugs. If efavirenz is used with rifampin, the dose of efavirenz should be increased to 800 mg daily. Rifabutin should be considered in place of rifampin for patients on above drugs. When used with nel navir, indinavir, or amprenavir, the rifabutin dose is 150 mg daily or 300 mg two to three times per week; indinavir and nel navir dosages should be increased to 1,000 mg q 8 hours. With ritonavir-containing regimens, rifabutin should be decreased to 150 mg two to three times per week. Increase rifabutin to 450–600 mg daily when prescribed with efavirenz. Rifabutin should not be given with delavirdine and use with caution with saquinavir due to decreased saquinavir levels.

oral administration, and potential effectiveness in preventing extrapulmonary pneumocystosis and other infections such as salmonellosis, shigellosis, pneumococcal infection, *Haemophilus inßuenzae* infection, isospora infection, cyclospora infection, nocardiosis, and listeriosis (400). A particularly useful beneÞt of TMP-SMX is its effectiveness in preventing cerebral toxoplasmosis (401Ð403). The principal disadvantage of TMP-SMX is that it is not tolerated well by approximately 50% of patients. The most frequent causes of intolerance are hypersensitivity reactions, particularly rashes and fever (396,404).

There are a number of alternatives to TMP-SMX (9) (Table 13.17). Pentamidine by aerosol 300 mg per month by *Respirgard II* nebulizer (Maarquest, Englewood, Colorado) was widely used at the beginning of the HIV epidemic but has largely been replaced by oral regimens. Because dapsone provides systemic therapy and may provide some protection from reactivation of *T. gondii* infection (particularly when combined with pyrimethamine), it has become, for many physicians, the Þrst alternative to TMP-SMX (9,395,397,405). Although dapsone is a sulfone antibiotic with some structural similarity to sulfonamides, approximately 60% of patients who react to TMP-SMX will tolerate dapsone (406).

Several caveats should be noted when considering the use of dapsone. Any patient with a prior life-threatening reaction to a sulfonamide, such as anaphylaxis or Stevens-Johnson syndrome, should not be challenged with dapsone. Furthermore, before using dapsone, glucose-6-phosphate dehydrogenase (G-6-PD) levels should be measured to avoid the problem of hemolytic anemia that can occur in G-6-PD-deÞcient patients. Dapsone should be used with caution in patients who are concomitantly receiving rifampin or rifabutin due to hepatic microsomal enzyme induction by these drugs leading to a decrease in dapsone levels (407).

Atovaquone is an effective preventive therapy for PCP (408,409) and may be better tolerated than dapsone (409). However, it is markedly more expensive than dapsone and therefore some authorities reserve it for patients intolerant of dapsone (410). Use of dapsone in preference to atovaquone has been evaluated and felt to be cost-effective (411).

Aerosol pentamidine should probably be reserved for patients who are intolerant of TMP-SMX, dapsone, and atovaquone. It is more costly than TMP-SMX and dapsone but less than atovaquone. Major drawbacks to pentamidine therapy are that it requires special equipment, is less efÞcacious than other regimens (especially at CD4+ counts <100 cells/mm^3), is not systemic and therefore extrapulmonary *P. carinii* infection may occur, and it does not protect against *T. gondii* infection (397,412,413). Because of aerosolization, pentamidine treatment poses potential risks of transmission of respiratory tract pathogens such as *M. tuberculosis*. Bronchospasm and coughing, which occur in about one-third of patients during inhalation, are the most common toxicities of aerosolized pentamidine (392). These problems can largely be prevented by pretreatment with an inhaled beta-adrenergic agonist. Hypoglycemia (414) and pancreatitis (415,416) are much less common with aerosol pentamidine than with IV administration, but they may still rarely occur.

Pentamidine given IV at a dose of 300 mg once monthly also has been used successfully to prevent PCP (417). This regimen may be useful for hospitalized patients with TMP-SMX intolerance who cannot ingest oral medications.

Some authorities prefer to desensitize TMP-SMX-intolerant patients with the use of an escalating dosage regimen administered over a time period ranging from as short as Þve hours to as long as several weeks (418Ð420). Success rates of 50% to 80% have been reported based on small numbers of patients. Two regimens for desensitization are listed in Table 13.18. Patients who have experienced only liver function abnormalities or cytopenia with high dose intravenous TMP-SMX can usually tolerate the lower doses used for prophylaxis and desensitization is not required (396). After desensitization has been completed, it is important that the patient not interrupt the TMP-SMX regimen.

It is important to emphasize that when patients who are compliant with TMP-SMX prophylaxis develop respiratory tract symptoms and an abnormal chest roentgenogram, PCP is unlikely to be the cause. In contrast, PCP may develop in patients receiving aerosol pentamidine,

TABLE 13.18. *Examples of trimethoprim-sulfamethoxazole desensitization regimens*

Regimen		Trimethoprim-sulfamethoxazole
10-day		
Day	1	1 ml of 1:20 dilution pediatric suspension[a]
	2	2 ml of 1:20 dilution pediatric suspension
	3	4 ml of 1:20 dilution pediatric suspension
	4	8 ml of 1:20 dilution pediatric suspension
	5	1 ml of pediatric suspension
	6	2 ml of pediatric suspension
	7	4 ml of pediatric suspension
	8	8 ml of pediatric suspension
	9	1 tablet of single-strength[a]
	10	1 tablet of double-strength (DS)[b]
5-hour		
Hour	0	5 ml of 1:10,000 dilution pediatric suspension[a]
	1	5 ml of 1:1,000 dilution pediatric suspension
	2	5 ml of 1:100 dilution pediatric suspension
	3	5 ml of 1:10 dilution pediatric suspension
	4	5 ml of undiluted pediatric suspension
	5	1 tablet, double-strengt[b]

Adapted from Gluckstein and Ruskin, ref. 419, and Absar et al., ref. 420.

[a] Pediatric oral suspension has 40 mg trimethoprim-200 mg sulfamethoxazole per 5 ml; single strength tablet (80 mg trimethoprim/400 mg sulfamethoxazole).

[b] Thereafter, 1DS tablet of trimethoprim-sulfamethoxazole (160 mg trimethoprim/800 mg sulfamethoxazole) every other day or daily for *Pneumocystis carinii* pneumonia prophylaxis.

although the roentgenographic Þndings may be atypical for this form of pneumonia (eg, upper lobe inÞltrates) (421Ð423).

Discontinuation of prophylaxis

Several studies have now demonstrated the safety of discontinuing both primary (424Ð428) and secondary (427Ð428) PCP prophylaxis when the CD4+ lymphocyte count has risen to >200 cells/mm^3. Recent U.S.PHS/IDSA guidelines reßect this, recommending stopping therapy when the CD4+ lymphocyte count is stable for 3 months at a level >200 cells/mm^3 (9) (Table 13.17). Although the guidelines recommend stopping prophylaxis at 200 cells/mm^3, in the largest studies addressing this question, the mean CD4+ cell count was 350 cells/mm^3 at the time of stopping therapy (424Ð428). A simulation model of HIV infection evaluating various times to stop PCP prophylaxis found that waiting to discontinue prophylaxis at a CD4+ lymphocyte count of >300 cells/mm^3 instead of 200 cells/mm^3 was cost effective (411). If the CD4+ lymphocyte count falls to below 200 cells/mm^3 among patients who have stopped prophylaxis, then prophylaxis should be resumed.

Toxoplasma gondii Chemoprophylaxis

Initiating prophylaxis

The risk of developing cerebral toxoplasmosis among HIV-infected individuals with positive *T. gondii* serology (positive IgG) is estimated to be 25% to 50% (430,431), with the highest risk occurring in patients with a CD4+ lymphocyte count <100 cells/mm^3 (432). Patients with CD4+ lymphocytes <100 cells/mm^3 who demonstrate no prior exposure to *T. gondii* demonstrated by lack of seropositivity, do not need chemoprophylaxis. However, they should be intermittently tested for seroconversion and counseled on how to avoid acute infection.

Preventive chemotherapy is recommended for toxoplasma antibody seropositive patients with a CD4+ cell count <100 cells/mm^3 (9). TMP-SMX in doses of one double strength tablet daily or on alternating days has been demonstrated to be extremely effective for prevention of cerebral toxoplasmosis (Table 13.17) (401,402).

For the TMP-SMX intolerant patient, dapsone 50 mg daily plus pyrimethamine 50 mg weekly plus leucovorin 25 mg weekly or a once weekly regimen of dapsone 200 mg plus pyrimethamine 75 mg plus leucovorin 25 mg are also effective for prevention of toxoplasmosis (9,433,434). Atovaquone with or without the addition of pyrimethamine and leucovorin may also be considered for prevention of *T. gondii* reactivation (9). Although clindamycin plus pyrimethamine is less well studied as primary chemoprophylaxis for toxoplasmosis, it may well be effective because this is an alternative regimen for the treatment of cerebral toxoplasmosis (435,436). This regimen should be considered second-line due to the large number of pills that must be used, frequency of administration, and adverse reactions associated with clindamycin (437). In addition, clindamycin plus pyrimethamine is not protective against PCP infection.

Discontinuation of prophylaxis

Patients who have responded to ART with an increase in the CD4+ cell count to >200 cells/mm^3 for at least three months can have primary prophylaxis discontinued (9). These recommendations are supported by both observational (427,438Ð441) and randomized trials (442,443). Although the critical CD4+ lymphocyte count at which to begin therapy is 100 cells/mm^3, in the studies of prophylaxis discontinuation, most patients have had CD4+ lymphocyte counts >300 cells/mm^3.

It has been recommended that secondary prevention of *T. gondii* cerebral infection can be discontinued after the CD4+ lymphocyte count has risen to >200 cells/mm^3 and the patient has had more than six months of therapy (9). These recommendations, however, are based upon data from only a limited number of patients (427,429,444). Although uncommon, relapses can occur despite CD4+ lymphocyte counts above 200 cells/mm^3 (445). Prior to discontinuing therapy many authorities repeat a cranial imaging study to ensure that prior lesions have either completely resolved or are markedly smaller.

Primary and secondary prophylaxis should be reintroduced when the CD4+ lymphocyte counts drops to <200 cells/mm^3 (9). Although there are no published data regarding which drugs to restart for patients who have had secondary prophylaxis stopped, it is probably safe to treat with TMP-SMX alone for patients who tolerate this medication.

Disseminated *Mycobacterium-avium* complex (dMAC) chemoprophylaxis

Initiation of chemoprophylaxis

Disseminated *M. avium* complex (dMAC) infections are almost uniquely associated with AIDS patients as compared with other immunocompromised populations. In the United States, dMAC infections occur in up to 40% of HIV-infected patients who have CD4+ lymphocyte counts <100 cells/mm^3 (446). Because treatment of active infection requires a multi-drug regimen that provides only modest success, prevention is greatly preferred. *M. avium* complex organisms are ubiquitous in nature and most of the transmission probably occurs through exposure to contaminated water. Because there are no proven ways to predict who will develop dMAC, all patients who reach the

critical CD4+ lymphocyte count at which to begin prophylaxis should receive prophylaxis.

Current USPHS/IDSA guidelines recommend that chemoprophylaxis begin at a CD4+ lymphocyte count of <50 CD4+ cells/mm^3 (9). Three drugsÑ azithromycin, clarithromycin, and rifabutinÑ are FDA approved for prophylaxis of MAC infection on the basis of randomized multicenter studies (447,448) (Table 13.17). Azithromycin (1,200 mg weekly) is the drug of choice because it lacks several of the drug-drug interactions found with rifabutin or clarithromycin, can be taken once a week, is equally as effective as rifabutin or clarithromycin, and is less expensive. Clarithromycin is prescribed in doses of 500 mg twice daily and rifabutin at a dose of 300 mg daily (Table 13.17).

Combination therapy with azithromycin plus rifabutin may be more effective than azithromycin alone for prevention of dMAC (448). However, adverse reactions occur more commonly with this combination, there is greater potential for drug-drug interactions, and the costs are higher. Furthermore, there was no difference in survival between patients who received combination prophylaxis and those who received azithromycin monotherapy (448). Therefore, combination therapy is not recommended.

When initiating chemoprophylaxis for dMAC, many authorities Þrst exclude active dMAC infection by evaluating the patient clinically and obtaining mycobacterial blood cultures. For patients who are intolerant of macrolide antibiotics and are going to be prescribed rifabutin, infection with *M. tuberculosis* should be ruled out clinically, by PPD testing (if not previously already done) and by chest roentgenogram. This is to avoid giving rifabutin inadvertently as a single agent for active tuberculosis. This would pose a substantial risk for the emergence of drug resistance to both rifampin and rifabutin (449).

If clarithromycin is prescribed for chemoprophylaxis, several drug-drug interactions should be considered despite the fact that their clinical signiÞcance has not been proven. Clarithromycin levels are increased by PIs, while efavirenz decreases the levels of clarithromycin while increasing those of its active metabolite 14-OH (450).

Rifabutin has been relegated to the third option for dMAC prevention mainly because of the potential problem with *M. tuberculosis* resistance and because of numerous drug-drug interactions. Like rifampin, rifabutin may cause an orange-brown discoloration of the urine (which should be mentioned to the patient prior to starting the drug) and may induce hepatic microsomal enzymes, thereby affecting the metabolism of a wide array of drugs. When administered with PIs with the exception of saquinavir, the dose of rifabutin should be 150 mg daily. However, if rifabutin is prescribed with efavirenz, the dose should be increased to 450 mg daily.

Discontinuation of prophylaxis

When the CD4+ lymphocyte count has risen to >100 cells/mm^3, primary MAC prophylaxis can safely be stopped (9,438,451Ð453). Secondary prophylaxis (which is a multi-drug treatment regimen given for dMAC infection) can be discontinued when the CD4+ lymphocyte count has risen to >100 cells/mm^3 on ART for approximately six months and the patient has received >12 months of therapy for MAC (9). These recommendations are based upon relatively few patients who have stopped therapy (429, 444). Discontinuation of secondary prophylaxis has major advantages to the patient in terms of decreased pill burden, toxicity, and reduced drug-drug interactions.

If the CD4+ lymphocyte count drops below 100 cells/mm^3, then dMAC prophylaxis should be restarted (9). Data on what therapy to begin among patients who have been treated previously for dMAC is lacking. However, if the patient has already received >12 months of multi-drug therapy, single drug therapy is probably safe.

Cytomegalovirus Infection Chemoprophylaxis

Initiation of prophylaxis

Cytomegalovirus infection, in particular retinitis, was a devastating OI for HIV-infected patients in the pre-HAART era (454). Infection developed in severely immunocompromised patients with CD4+ lymphocyte counts <50 cells/mm^3 who had positive serology for prior exposure to CMV (454Ð456). At necropsy, $>80\%$ of patients with such low CD4+ cells could be demonstrated to have evidence of CMV infection, although many of these infections were not clinically apparent (456). Retinitis occurred in 25% to 40% of patients and gastrointestinal disease, encephalitis, polyradiculitis, and rarely pneumonia were also well described (456). Use of primary prophylaxis to prevent CMV was hampered by the lack of a well-tolerated oral agent that was effective and moderately priced.

Acyclovir was not effective for prevention of CMV retinitis among patients with AIDS (457,458) and valacyclovir led to increased deaths among persons with AIDS receiving this medication despite the fact that it was modestly effective in preventing CMV disease (459). Of the systemic agents approved by the FDA for treatment of CMV disease (ganciclovir, foscarnet sodium, and cidofovir), all require IV administration except for ganciclovir, which can be taken orally. All have signiÞcant toxicities. For prophylaxis, oral ganciclovir is extremely costly, requires pills to be taken three times daily, and is only modestly effective (460,461). Furthermore, patients who either develop CMV disease or have a recrudescence while taking oral ganciclovir may then have ganciclovir-resistant strains of virus (462).

Due to the toxicity and costs associated with CMV primary prevention, numerous studies were undertaken to identify a target population of AIDS patients at highest risk for developing CMV disease. Blood or urine cultures for CMV have limited utility because of their poor positive predictive value (463). On the other hand, several studies have suggested that detection of increasing amounts of CMV antigen or DNA in peripheral blood is predictive of those patients who will develop CMV disease (464–467). These tests are not well standardized and their role in selecting patients for prophylaxis has not been determined.

In 2001, the FDA approved valganciclovir, a prodrug of ganciclovir that is taken orally for the treatment of CMV disease. In a randomized trial it was as effective as IV ganciclovir for treatment of CMV retinitis (468). This drug can be taken twice daily and is well absorbed. There are no studies to document the efficacy of valganciclovir to prevent CMV disease in severely immunocompromised patients with AIDS. Furthermore, with the advent of ART, it is not likely that a large trial can be easily undertaken to demonstrate its utility.

USPHS/IDSA guidelines do not recommend primary chemoprophylaxis for CMV disease (9). It is recommended to educate patients with CD4+ lymphocytes < 50 cells/mm^3 about the early signs of CMV retinitis such as floaters and to have regular (at least yearly) funduscopic examinations. By employing this strategy, early disease can be detected and treated.

Secondary prophylaxis for CMV retinitis relies upon continuation of the initial medication used for treatment and must be continued indefinitely unless the CD4+ lymphocyte count improves on ART (Table 13.22). Unfortunately, except for the use of oral ganciclovir or valganciclovir, therapy with other agents requires either prolonged IV infusions (foscarnet or cidofovir), or repeated intravitreous injections with fomivirsen or intraocular implants with ganciclovir (9). Foscarnet and cidofovir are problematic to use due to renal toxicity. Unless the CD4+ cell count increases, even with secondary prevention, recrudescent disease is common (469–471). Limited data exist supporting the use of secondary prophylaxis for CMV infection of the gastrointestinal tract after an initial three weeks of treatment (472). Due to the toxicity of traditional therapies, however, secondary prophylaxis has not been recommended. With the advent of valganciclovir, longer therapy or secondary prophylaxis may be warranted for CMV gastroenterologic disease until ART leads to CD4+ cell increases.

Discontinuation of prophylaxis

Patients who have a rise in CD4+ lymphocyte counts to > 100–150 cells/mm^3 for > 6 months on ART can safely stop CMV treatment (429,444,473–476). When stopping therapy it is important to consider the extent of ocular damage, activity of disease, and vision in the contralateral eye. Patients who have had CMV retinitis should continue to have regular follow-up examinations by an ophthalmologist (9). CD4+ lymphocyte counts must be followed closely among patients who have had secondary prophylaxis discontinued. Relapse may occur when the CD4+ lymphocyte count drops to < 50 cells/mm^3 (444). Therefore, therapy should be restarted when the CD4+ lymphocyte count drops to < 100–150 cells/mm^3 (9). Patients who have recurrent symptoms after therapy has been stopped should be evaluated immediately because CMV retinitis has recurred in rare instances even when the CD4+ lymphocyte count was > 100 cells/mm^3 (477,478).

Mycobacterium tuberculosis Chemoprophylaxis

Initiation of prophylaxis

Part of the initial assessment of patients with HIV infection includes evaluation of a patient's current potential risk for exposure to *M. tuberculosis* (their occupational risks and risks related to habitation) as well as their prior exposure to *M. tuberculosis* (by history and prior PPD studies).

HIV-infected patients who warrant primary anti-tuberculous chemoprophylaxis include those who have: close contact with an individual with active tuberculosis; a positive skin test; a prior positive skin test; or chest roentgenogram findings consistent with old disease, if not previously treated (9) (Table 13.17). Although individuals from regions of the world with a high incidence of tuberculosis may have a higher risk of exposure to *M. tuberculosis*, if they are skin test negative, they do not need prophylaxis since preventive therapy has not been demonstrated to improve outcome (478–480). Patients who have had prior tuberculosis and were adequately treated do not need preventive therapy. Recommendations for prophylaxis are independent of CD4+ lymphocyte count and patient age (9,160).

Isoniazid 300 mg daily for nine months is the most commonly used prophylactic regimen, although intermittent regimens can be prescribed (9). Isoniazid has excellent efficacy in preventing tuberculosis in HIV-infected patients (481). Rifampin or rifabutin alone for four months or one of these agents plus pyrazinamide for two months should be considered for patients at high risk for isoniazid resistant *M. tuberculosis*. However, rifampin-based regimens are contraindicated in patients on certain antiretroviral agents, and doses of rifabutin as well as some PIs must be modified if taken concurrently (163). Due to the potential for hepatotoxicity, the two-month rifampin plus pyrazinamide regimen should not be considered a preferred regimen (482), although it may be as effective as a nine-month isoniazid regimen for preventing tuberculosis (483).

Health authorities should be consulted to develop an appropriate chemoprophylactic regimen among patients exposed to strains of multiply drug resistant *M. tuberculosis*.

Discontinuation of prophylaxis

The duration of chemoprophylaxis for tuberculosis depends upon the selected regimen as described in the preceding section (Table 13.17), not upon the CD4+ cell count.

Fungal Chemoprophylaxis

Initiation of prophylaxis

Infections caused by fungi are a major problem for HIV-infected patients. *Candida* species (particularly *Candida albicans*) cause recurrent mucocutaneous infections including thrush and esophagitis at some point in the majority of HIV-infected patients with advanced immunodeficiency (484). *Candida* vaginitis is also a considerable problem for women with AIDS (485,486).

Cryptococcus neoformans is responsible for meningitis in approximately 5% to 10% of HIV-infected patients with advanced immunodeficiency in the United States (487). The incidence of disseminated infection caused by *Histoplasma capsulatum* among AIDS patients has been reported to be as high as 27% in endemic areas such as the Mississippi and Ohio River valleys in the United States, Puerto Rico, and Central America (488). In endemic areas it is not certain whether the majority of patients with disseminated histoplasmosis have primary infection, reinfection, or reactivation of old disease. In nonendemic areas, histoplasmosis in AIDS patients appears to be reactivated from previous foci of infection (488). Disseminated infection due to *Coccidiodes immitis* is another fungal infection that generally occurs during later stage HIV infection (489). Patients living in or traveling to endemic regions, such as southwestern United States, are at risk for developing coccidioidomycosis.

There are no reliable serologic or skin test studies for fungi to guide selective therapy for higher-risk patients. It is important to counsel patients regarding the avoidance of exposure to these organisms when possible. For instance, patients should be warned about the risk of histoplasmosis in areas of building excavation or in caves or areas with heavy bird droppings and the risk for coccidiodomycosis in areas of building excavation (9).

Several studies have demonstrated the efficacy of long-term prophylaxis against recurrent oral or vaginal candidiasis using a variety of azole antifungal agents including ketoconazole, fluconazole, and itraconazole (490–493). A randomized trial comparing fluconazole (200 mg per day) to clotrimazole troches (10 mg five times per day) showed that invasive fungal infection was significantly reduced during a 35-month follow-up period from 10.9% in the clotrimazole arm to 4.1% in the fluconazole arm (490). The protective effect of fluconazole was most marked for prevention of cryptococcosis, but it was also found for esophageal and oropharyngeal candidiasis. The protective effect was greatest among patients with <50 CD4+ lymphocytes/mm^3. However, survival differences were not found between the two groups. Other studies have demonstrated that administration of fluconazole in doses varying from as little as 100 mg weekly to 100 mg to 200 mg per day significantly reduced the incidence of cryptococcal meningitis when compared with historical controls (494–496). This effect may be dose-related (497).

In another study, itraconazole at 200 mg per day significantly lowered the rates of histoplasmosis and cryptococcosis when compared with placebo (498). This effect was confined to the subset of patients with <100 CD4+ cells/mm^3. However, the frequency of recurrent or refractory oral or esophageal candidiasis was not altered, toxicities were higher in the itraconazole group, and there was no survival benefit to prophylaxis (498). Data regarding the use of antifungal drugs for prevention of coccidioidomycosis are lacking. However, the incidence of this infection appears to be considerably lower than that of cryptococcosis or histoplasmosis.

Although it is tempting to consider antifungal prophylaxis for patients with extremely low CD4+ cell counts, the emergence of resistance in *C. albicans* to fluconazole and superinfection with non-*albicans* candida fungal infections that are inherently resistant to fluconazole is cause for concern (484,499,500). Intravenous amphotericin B may be necessary for patients with azole-resistant *Candida* infections, thereby exposing patients to the inconvenience and hazards of long-term intravenous catheter use and to more toxic antifungal drugs. Primary prophylaxis for these fungal infections is currently not recommended (9) and generally should not be offered.

Secondary prophylaxis for candidal oropharyngeal or vaginal infection is not recommended for episodic disease. However, in some patients with very low CD4+ lymphocyte counts, recurrence can occur frequently enough that chronic suppressive therapy is warranted. Fluconazole 100 to 200 mg daily should be considered, recognizing the risk for developing azole-resistant disease.

Secondary prophylaxis, or maintenance therapy, is indicated for life for patients with cryptococcosis, histoplasmosis, or coccidioidomycosis unless the CD4+ cell count rises. For cryptococcosis, fluconazole is the preferred drug because of its excellent activity (501,502) and low risk for drug-drug interactions (compared to itraconazole). In addition, fluconazole is associated with a lower relapse rate than itraconazole (503). However, itraconazole is an acceptable alternative (9,503). Coccidioidomycosis can be treated chronically with either fluconazole 400 mg daily or itraconazole 200 mg twice daily (504). However,

ßuconazole should be considered the preferred agent due to the greater potential for drug-drug interactions with itraconazole. For histoplasmosis, itraconazole 200 mg per day is the recommended drug of choice (471).

Discontinuation of prophylaxis

Data regarding discontinuation of secondary prophylaxis are extremely limited for these infections. The most data are available for cryptococcosis. It appears that therapy can safely be stopped after six to twelve months of ART if the CD4+ cell count has risen to >100 to 200 CD4+ lymphocytes/mm^3 (444,505,506). Some authorities prefer to perform a spinal tap to ensure that CSF cultures are negative before stopping anti-cryptococcal therapy (9). Before considering stopping therapy, the health care provider must explain the lack of data and the need for prompt evaluation if symptoms recur. Discontinuation of prophylaxis for recurrent candidal esophagitis was safe for a small number of patients with a good CD4+ count response to ART (429). Data regarding the safety of stopping secondary prophylaxis for histoplasmosis and coccidioidomycosis are even more limited. Discontinuation can be considered if the patient has been treated for the fungal infection for six to twelve months, and while taking ART the CD4+ lymphocyte count has risen to >100 to 200 cells/mm^3. However, current U.S.PHS/IDSA guidelines do not recommend stopping therapy (9).

If the CD4+ lymphocyte count drops to <100 cells/mm^3, it is probably wise to reinitiate antifungal therapy despite the absence of data on this subject.

Chemoprophylaxis of Varicella-Zoster Virus (VZV) Infection

Data are limited on the efÞcacy and safety of the varicella-zoster vaccine in adults, and it is currently not recommended (9). HIV-infected patients who are susceptible to varicella, ie have not had varicella or shingles or who have no detectable antibody to VZV, should be given varicella-zoster immune globulin within 96 hours of exposure to an active case of varicella (varicella or shingles) (9). Use of acyclovir cannot be recommended after exposure due to lack of data demonstrating efÞcacy.

Primary chemoprophylaxis is not recommended regardless of CD4+ cell count (9). After an episode or recurrent episodes of shingles in an HIV-infected patient, secondary prophylaxis is not warranted when initial treatment is completed. Among HIV-infected patients, no drug has been proven to be effective in preventing recurrent disease.

Chemoprophylaxis of Herpes Simplex Virus (HSV) Infection

Primary prophylaxis for HSV infection is not recommended regardless of CD4+ lymphocyte count, even for HIV-infected patients potentially exposed to HSV (9). Secondary prevention is generally only offered to patients with severe, frequently recurrent disease. Daily suppressive therapy with acyclovir, famciclovir or valacyclovir should be considered in these situations (Table 13.19). These recommendations are similar to those for non-HIV-infected patients and are independent of CD4+ cell count.

TABLE 13.19. *General principles in the approach to the HIV-infected patient with fever*

Except for primary HIV infection, sustained fevers are due to causes other than HIV infection itself
Serious opportunistic infections usually Þrst occur in patients with CD4+ lymphocyte counts <200 cells/mm^3
Multiple opportunistic infections and neoplasia may occur simultaneously, even in the same organ or tissue
Serodiagnostic studies and tuberculin skin testing may be ambiguous
Growth of some opportunistic organisms, e.g. cytomegalovirus or *Mycobacterium avium* complex, from urine or sputum samples may not indicate active infection.

DRUG-DRUG INTERACTIONS

No chapter on the management of HIV-infected patients would be complete without some discussion of drug-drug interactions and their potential impact upon devising treatment regimens (see Chapter **??**). There is perhaps no area more complicated than this because of the lack of data upon which to base decisions. This is due at least in part to the numerous combinations of medications that may be prescribed for: (1) treatment of HIV, (2) complications related to both HIV and its treatment, (3) prevention and treatment of OIs, and (4) co-morbid illnesses such as psychiatric problems, drug use treatment, and HCV among others. HIV-infected patients also may use alternative therapies such as St. JohnÕs wart or garlic tablets that can directly impact upon drug levels because of drug-drug interactions. Because two different drugs may both interact with the same liver enzyme, it is often impossible to say how the interaction will affect the blood levels of each without direct measurements. Data in this Þeld are emerging rapidly (7,507). Some drug-drug interactions may actually be quite useful as for example in the boosting of PI levels with ritonavir. The major interactions to consider are those related to the effects of various drugs on the cytochrome p450 hepatic enzyme system by PIs, NNRTIs, rifamycins, and itraconzole. This enzyme system is involved in the metabolism of numerous drugs. Other drug interactions to consider are related to potential additive toxicities of two or more drugs.

Sources of information include drug package inserts, HIV-related periodicals, fax reports, and internet sites.

MANAGEMENT OF SELECTED SPECIFIC PROBLEMS

Most HIV-infected patients will develop fever at some point in the course of their illness. Aside from primary HIV infection, sustained fevers are rarely, if ever attributable to HIV infection itself and are usually due to serious but treatable superimposed infections (Table 13.19) (508–510). Management of the febrile HIV-infected patient is integrally related to establishing a specific etiology for the fever. Determining the source of fever, however, at times can be extremely challenging. Fever may be related to nonopportunistic infections presenting typically or atypically, opportunistic infections (sometimes multiple (511)), hypersensitivity reactions to medications and malignancies, particularly lymphomas. Furthermore, nosocomial infections from intravascular catheters, pressure sores, Clostridium difficile diarrhea, and urinary tract infections should not be overlooked in the hospitalized, febrile HIV-infected patient (508).

It is important at the outset to know whether the patient is highly immunocompromised (i.e. has a CD4+ lymphocyte count <200 cells/mm^3) and is thus predisposed to serious opportunistic infections. If not, evaluation may be directed toward the discovery of less unusual microbial pathogens and conditions, for example, sinusitis (512), herpes zoster infection (513), or tuberculosis (514). In patients who are highly immunocompromised, it is essential to determine which chemoprophylactic therapies were prescribed and the level of compliance. Infections related to granulocytopenia, such as bacteremia, also may occur in HIV-infected patients with low white blood cell counts and should be taken into consideration when prescribing empiric antibiotic therapy (515–517).

It is important to note epidemiologic clues that may help in identifying specific infectious risks (518). The etiology of fever in the various reported series was greatly dependent on where the study was performed (519–523). For example, Haitians, African natives, Southeast Asians, and other patients from the developing world, as well as intravenous drug users from major Western metropolitan areas, have an increased risk of tuberculosis (524,525). Patients from the southwestern United States (and occasionally those who have previously resided there) are at risk for disseminated *Coccidioides immitis* infection (526). Histoplasmosis may be a consideration in persons who have resided in areas endemic for this fungus in the United States (527) or elsewhere, including certain areas of the Caribbean (such as Puerto Rico), and Central America (528,529). Visceral leishmaniasis is endemic in parts of the Mediterranean basin and may be responsible for fever in patients who have lived in these areas (520).

An approach to the evaluation of fever in the HIV-infected patient with advanced immunodeficiency is found in Table 13.20. If the source of fever has not been identified on routine diagnostic studies, such as blood and urine cultures or chest roentgenogram, then further testing is necessary. Blood cultures for fungi and mycobacteria should be obtained (530) (two are sufficient (531)). Mycobacterial blood cultures should include lysis of the cellular fraction of the specimen, followed by plating on a standard solid mycobacterial culture medium or by liquid culture with radiometric detection (532). Multiple cultures of stool, urine, and sputum for mycobacteria also should be considered (533). Stool acid-fast smears and cultures are helpful in the diagnosis of dMAC infection because the intestinal tract is often involved in the disease process (532,534). Positive cultures from stool and sputum for nontuberculous mycobacteria my represent contamination or colonization, however, and not indicate true infection. Stool acid-fast cultures also may be useful in the diagnosis of *M. tuberculosis* infection, although usually the sputum is culture positive in these instances (524).

Although CMV infection may be a cause of fever in these patients, positive cultures for this virus from urine, pharynx, bronchial lavage fluid or even blood are so frequent that they cannot be relied on to pinpoint the cause

TABLE 13.20. *A diagnostic approach for evaluation of fever in HIV-infected patients*

Evaluate whether the patient falls into a group at high risk for serious opportunistic infections (i.e. CD4+ cell count <200 cells/mm^3)
Direct history to determine possible geographic, ethnic, or lifestyle risk factors for specific infections; pay particular attention to neurologic, respiratory, dermatologic, visual, and gastrointestinal complaints
Note medication list
Physical examination
Laboratory tests: complete blood count; chemistry profile, including liver function tests; urine analysis; cultures of blood, urine, and sputum for bacteria; chest roentgenogram; stool culture if diarrhea is present
If initial cultures are negative, culture blood, urine, sputum, and stool for mycobacteria and blood, urine, and sputum for fungi; serum cryptococcal antigen, toxoplasma titer, and VDRL; PPD with controls unless known to be anergic; sputum for IFA test for *Pneumocystis carinii*; urine for histoplasma antigen
If no source yet identified, consider: Gallium scan of lung Computed tomography of abdomen Examination by ophthalmologist for CMV retinitis Lymph node biopsy if enlarged node is accessible Bone marrow biopsy and aspiration (especially if anemic) Skin lesion biopsy (if lesion present) Lumbar puncture if clinical signs warrant Bronchoscopy with bronchial alveolar lavage and/or biopsy (if respiratory tract signs or abnormalities are present) Liver biopsy (if liver function studies are abnormal)

CMV, cytomegalovirus; IFA, immunofluorescent antibody; PPD, purified protein derivative (of tuberculin); VDRL, Venereal Disease Research Laboratory.

of fever (535–537). For the same reasons serology for CMV is also nondiagnostic (535,537a,537b). It is of utmost importance to attempt to establish the pathogenicity of an organism that has been cultured, as specific treatment of microorganisms such as CMV or MAC may be at best partially effective, potentially toxic, inconvenient (i.e. require multiple drugs or intravenous administration), or prolonged. Further, administration of ganciclovir for CMV infection may preclude the use of AZT because of potential additive bone marrow suppression (538).

Additional diagnostic studies should include a test for serum cryptococcal antigen, which is positive in 75% to 95% of HIV-infected patients with central nervous system cryptococcosis (539,540) (this test is less likely to be positive when cryptococcal infection is confined to the lungs (541)). Sputum should be obtained (induced if necessary) for detection of *P. carinii* using an immunofluorescent monoclonal antibody assay (542,543), especially in patients with respiratory complaints, an abnormal chest roentgenogram, or gallium-67 uptake by the lung on scintigraphy (544). If an induced sputum sample is nondiagnostic or unavailable, bronchoscopy for bronchial alveolar lavage or biopsy should be considered for patients with objective pulmonary signs or test abnormalities (545).

Serodiagnosis of *Histoplasma capsulatum* and *Coccidioides immitis* is helpful for selected patients (526,527). Also, Giemsa-stained preparations of the buffy coat of peripheral blood may be useful in the diagnosis of disseminated histoplasmosis (546). A test for histoplasma polysaccharide antigen in urine is commercially available and appears to have excellent sensitivity and specificity in AIDS patients with histoplasmosis (547).

A careful funduscopic examination by an ophthalmologist may help establish the diagnosis of disseminated CMV infection. Although the patient with CMV retinitis usually reports visual disturbances, this is not uniformly true, particularly in patients with an altered mental status (see Chapter **??**) (548).

Biopsies for culture, special stains, and histologic examination of sites such as bone marrow, lymph nodes, gastrointestinal tract, or skin lesions may be helpful in the diagnosis of disseminated fungal, mycobacterial, or CMV infection, bacillary epithelioid angiomatosis, lymphoma and Kaposi's sarcoma, when other modalities of diagnosis are either nondiagnostic or negative. Biopsies may provide a rapid presumptive diagnosis of a fungal or mycobacterial infection based on the staining characteristics of these microorganisms. It is particularly helpful to perform a lymph node biopsy in patients who have a single group of lymph nodes that are disproportionately enlarged or that have rapidly increased in size (549).

Computed tomography may be used to locate intra-abdominal masses or enlarged lymph nodes for biopsy. In patients with an elevated alkaline phosphatase level and fever, a liver biopsy for histologic examination and culture may be useful (530,550–552). This procedure is not often necessary, however, as other sources of culture material are usually diagnostic.

Before embarking on any biopsy procedure, it is important to determine whether the patient has a potential bleeding diathesis, such as thrombocytopenia. Platelet transfusions, intravenous infusions of immunoglobulin G (IgG) preparations or other measures to elevate the platelet count at least transiently may be required for patients with platelet counts below 50,000 to 100,000/mm^3, depending on the bleeding time and the type and urgency of the invasive procedure to be done. Partial thromboplastin times and (less often) prothrombin times may be prolonged in HIV-infected patients, usually due to the presence of a lupus-like anticoagulant, found in up to 70% of HIV-infected patients particularly those with opportunistic infections (553–555). The "anticoagulants" are immunoglobulins that interfere with several *in vitro* coagulation assays. The presence of these anticoagulants can be confirmed by several diagnostic tests, such as the $^1/_2 + ^1/_2$ correction of the Russell's viper venom time (556). Most patients who have these factors are not predisposed to bleeding unless the level of coagulation factors is abnormal or qualitative/quantitative platelet abnormalities coexist (553).

Empiric Treatment of Infection

The empiric use of broad-spectrum antibiotics is not routinely indicated for the febrile HIV-infected patient because these drugs may be toxic, lead to increasingly resistant organisms, or confound the diagnostic evaluation. If the patient is clinically unstable or profoundly granulocytopenic (< 500 granulocytes/mm^3), however, broad-spectrum antibiotics should be administered promptly. Certain other indications for empiric therapy are listed in Table 13.21.

When an opportunistic infection (or infections) is diagnosed, specific therapy should be initiated (Table 13.22) (160,163,166,208,539,540,557–702). It is important to note that treatment of opportunistic infections in HIV-infected patients is rarely curative (703,704). More often, chronic maintenance therapy (secondary prophylaxis) for an indefinite period is necessary after completion of the acute treatment, unless the CD4 cell count increases secondary to ART.

Rheumatologic Manifestations

Arthralgia, seronegative spondyloarthropathy, arthritis, and connective tissue-like disorders including various forms of vasculitis, a sicca syndrome, and numerous other autoimmune phenomena are the principal rheumatologic complications of HIV infection (Table 13.23) (705–712). Rheumatologic complications are more common in HIV-infected patients with advanced immunodeficiency (709,710,713). Consequently, for those patients with

TABLE 13.21. *Clinical situations in which empiric antimicrobial therapy may be useful in HIV-infected adults prior to conÞrmation of the diagnosis*

Condition	Microorganism to which therapy is directed	Recommended therapy
Clinically unstable (septic appearing) or profoundly neutropenic (< 500 PMNs/mm3) with fever	*Staphylococcus aureus* *Streptococcus pneumoniae* *Haemophilus inßuenzae* *Salmonella sp.* Aerobic gram-negative rods	Third or fourth generation cephalosporin with or without an aminoglycosidea[a]
Lobar pneumonia	*Streptococcus pneumoniae* *Haemophilus inßuenzae* *Moraxella catarrhalis* *Staphylococcus aureus* *Legionella sp.* *Klebsiella sp.* *Escherichia coli*	Third-generation cephalosporin plus erythromycin or a quinolone
Ring-enhancing mass lesion(s) on cranial MRI or CT, especially if serum toxoplasma titer is positive	*Toxoplasma gondii*	Pyrimethamine plus sulfadiazine plus folinic acid
Diffuse pulmonary in ltrates and hypoxia, especially if not on trimethoprim-sulfamethoxazole chemoprophylaxis	*Pneumocystis carinii*	Trimethoprim-sulfamethoxazole
Dysphagia or odynophagia	*Candida albicans*	Fluconazole
PPD + and ill-appearing, especially with abnormal chest roentgenogram (or if PPD-negative and anergic, but at high epidemiologic risk for tuberculosis)	*Mycobacterium tuberculosis*	Isoniazid, rifampin,[b] pyrazinamide, ethambutol

CT, computed tomography; MRI, magnetic resonance imaging; PPD, puri ed protein derivative (of tuberculin); PMN, polymorphonuclear leukocytes.

[a] A third or fourth generation cephalosporin, or extended spectrum penicillin, with *Pseudomonas aeruginosa* coverage (e.g. cefepime) is essential unless an aminoglycoside is included in the drug regimen.
Vancomycin should be added in patients with a central line or in other clinical situations in which methicillin resistant staphylococci are suspected.

[b] Note that there are many drug-drug interactions between rifampin and antiretroviral agents, particularly protease inhibitors and non-nucleoside reverse transcriptase inhibitors (9,17,163)—see Table 13.17.

access to effective ART, these manifestations are becoming less common, although other complications such as osteopenia, osteoporosis and avascular necrosis that appear to be associated with ART (see above), are being increasingly recognized (364Ð368,714).

Intermittent arthralgias without synovitis may occur during primary HIV infection and in up to 45% of patients at a later time (706,715,716). Although sometimes intensely painful (715), the cause is unknown and treatment is symptomatic.

Joint infections are surprisingly uncommon among HIV-infected adults. Anecdotally, we have seen a case due to *Staphylococcus aureus*, and other reported pathogens include *Sporothrix schenckii Cryptococcus neoformans*, *Histoplasma capsulatum*, *Pseudomonas sp*., *Neisseria gonorrhoeae*, *Nocardia asteroides*, *Mycobacterium haemophilum*, *Salmonella sp*., and *Campylobacter fetus* (706,708,710,713,717Ð722). *Helicobacter cinaedi* may cause multifocal cellulitis or arthritis (697,708). Microbiologic studies are an essential component in the evaluation of joint ßuid in the HIV-infected patient with arthritis.

Reactive arthritides and Reiterõs syndrome are the most frequently recognized forms of arthritis in HIV infection, occurring in 2Ð10% of adults depending on geographic area (705,706,715,723Ð725). The majority of Caucasian patients with Reiterõs syndrome have the human leukocyte antigen (HLA)-B27 allele (705). Organisms known to trigger reactive arthritis are, however, rarely discovered (717,726). It should be noted that reactive arthritis or Reiterõs syndrome may be the Þrst clinical manifestation of HIV infection. Psoriasis is also common in HIV infection occurring in 5Ð20% of patients and is complicated by psoriatic-like arthritis in up to one-half of cases (715,727). Since skin rashes may be extensive in HIV-infected patients with Reiterõs syndrome, it may be difÞcult in some cases to distinguish between Reiterõs syndrome and psoriasis (710).

A less etiologically well-deÞned type of oligoarthritis termed ÒHIV-associated arthritisÓ has been described, which is characterized by subacute painful involvement of the knees and ankles with fewer than 10,000 leukocytes/mm^3 on synovial ßuid analysis (705,706). Proposed

TABLE 13.22. *Guide to therapy of opportunistic infections in HIV-infected patients*

Infection	Speci c Treatment	Alternative Treatment	Maintenance Therapy	References
FUNGAL INFECTIONS				
Oral candidiasis (thrush)	Clotrimazole troches (10 mg) 5 × /day	Nystatin oral suspension 100,000μml, 5 ml QID swish/ swallow;or ketoconazole 200–400 mg/day; or uconazole 100 mg/day PO (may need to increase dose); or itraconazole 200–400 mg/ day PO; or amphotericin B oral solution 1 ml (100 mg) QID	Same as initial therapy but may reduce frequency of administration	557–562
Candida esophagitis	Fluconazole 100 mg/day PO or IV; may need to titrate upward to 400–800 mg if response slow	Ketoconazole 200–400 mg/day PO; or itraconazole 200–400 mg/day PO; or amphotericin B 15–25 mg IV/ day; or caspofungin 50 mg/kg IV daily	Same as initial therapy	557,563–566
Histoplasmosis	Amphotericin B □0.5 mg/kg/ day*; 2 gm total dose	Itraconazole 200 mg BID PO or 200 mg/day IV	Itraconazole 200 mg PO BID; or amphotericin B 1 mg/kg weekly	527,557,567–576
Cryptococcosis	Amphotericin B, 0.7 mg/kg/day plus ucytosine 100 mg/kg/ day × 2 weeks	Amphotericin B □0.5 mg/kg/ day*; or uconazole 400 mg PO or IV/day	Fluconazole 200–400 mg PO/day	539,540,557,576–584
Coccidioidomycosis	Amphotericin B, □0.5 mg/kg/ day*; □1 g total dose	Fluconazole 400 mg/day IV or PO; or itraconazole 200 mg BID PO or 200 mg/day IV	Fluconazole 400 mg PO/day; or itraconazole 200 mg PO BID; or amphotericin B 1 mg/kg IV weekly	557,568,576,585–588
Aspergillosis	Voriconazole 6 mg/kg IV Q12h × 2 doses, then 4 mg/ kg IV Q12h	Amphotericin B, 0.5–1.5 mg/kg IV/day*; or itraconazole 200 mg BID PO or 200 mg/ day IV	Voriconazole 200 mg PO Q12h	568,576,587,589–592
VIRAL INFECTIONS				
Localized herpes zoster	Acyclovir 800 mg PO 5 × 7–10 days × /day	Famciclovir 500 mg PO Q8h × 7–10 days	None	557,593–596
Disseminated varicella zoster	Acyclovir 10 mg/kg IV Q8h × 10 days	Foscarnet 40–60 mg/kg IV Q8h × 10 days	Consider high-dose oral acyclovir if recurrences are seen	557,596–598
Localized, nonhealing herpes simplex virus, nasal labial, genital, or perianal areas	Acyclovir 200 mg PO 5 × /day × ≥10 days	If suspect acyclovir resistance, foscarnet 40–60 mg/kg IV Q8h × □10 days	Acyclovir 200 mg PO TID or 400 mg PO BID; or famciclovir 250 mg PO BID; or valacyclovir 500 mg PO BID	557,599–604

TABLE 13.22. *continued*

Infection	Speci c Treatment	Alternative Treatment	Maintenance Therapy	References
Cytomegalovirus retinitis	Ganciclovir 5 mg/kg IV Q12h × 14–21 days; or valganciclovir 900 mg PO BID × 14–21 days	Foscarnet 60 mg/kg IV Q8h × 14–21 days; or cidofovir 5 mg/kg IV q week × 2 weeks, then every other week (with probenecid)	Ganciclovir 5 mg/kg IV Q24h; or valganciclovir 900 mg PO daily; or foscarnet 90–120 mg/kg IV Q24h; or cidofovir 5 mg/kg IV every other week (with probenecid); or oral ganciclovir 1 g PO Q8h; or ganciclovir ocular implant; or fomivirsen 330 mg by intravitreal injection every four weeks	557,562,605–618
Progressive multifocal leukoencephalopathy (JC virus infection)	None	None	None	619,620
Parvovirus B19	IgG IV 0.4 g/kg × 5 days	None	If relapse occurs within six months after initial treatment, give single day infusions of IgG 0.4 g/kg every four weeks	621
PROTOZOAL INFECTIONS *Pneumocystis carinii* pneumonia	Trimethoprim (15–20 mg/kg/day) with sulfamethoxazole (75–100 mg/kg/day) in 3–4 divided doses IV or PO × 21 days plus a tapering dose of corticosteroids if $PaO_2 < 70$ or A-a gradient > 35 mm Hg. One possible regimen is prednisone 40 mg PO BID × days 1–5, prednisone 40 mg PO daily × days 6–10, prednisone 20 mg daily × days 11–21	Pentamidine 3–4 mg/kg IV daily × 21 days; or trimethoprim 20 mg/kg/day PO in 4 divided doses plus dapsone 100 mg PO daily × 21 days; or atovaquone elixir 750 mg PO BID with meals × 21 days; or trimetrexate 45 mg/m^2 IV daily × 21 days plus folinic acid 20 mg/m^2 IV Q6h × 24 days; or clindamycin 600 mg IV Q6h plus primaquine 15 mg base PO daily × 21 days; plus steroids when indicated, for all the above regimens.	Trimethoprim (160 mg)-sulfamethoxazole (800 mg) PO TIW; or dapsone 100 mg PO daily (dapsone plus pyrimethamine regimens are preferred for toxoplasma antibody + patients, see Table 13.17); or atovaquone 1,500 mg PO/day; or aerosol pentamidine 300 mg once/month by the Respirgard II nebulizer	208,543,557,622–637

TABLE 13.22. *continued*

Infection	Speci c Treatment	Alternative Treatment	Maintenance Therapy	References
Cerebral toxoplasmosis	Pyrimethamine 50–100 mg/day PO with sulfadiazine 1 g PO QID plus folinic acid 5–20 mg/day PO, until resolution or stabilization, with improvement of clinical signs and CT abnormalities	Trimethoprim (10 mg/kg/day)—sulfamethoxazole (50 mg/kg/day) in two to three divided doses; or clindamycin up to 1,200 mg IV Q8h with pyrimethamine 50–100 mg/day PO with folinic acid 5–20 mg PO/day; or pyrimethamine plus folinic acid as above plus one of the following: clarithromycin 1gm PO Q12h; atovaqone elixir 750 mg PO Q12h; azithromycin 1,200–1,500 mg PO/day; dapsone 100 mg PO/day	Pyrimethamine 25 mg/day plus sulfadiazine 1 g/day plus folinic acid 5 mg/day	557,638–644
Microsporidial enteric infection	Albendazole 400 mg PO BID	Fumagillin 20 mg PO TID × 2 weeks (experimental)	? None	645–649
Cryptosporidiosis	Paromomycin 500–750 mg PO QID	Azithromycin 500–1250 mg/day; or nitazoxanide 1,000 to 2,000 mg/day (experimental)	Same as initial therapy	166,557,650,651,651a, 651b
Isospora belli enteric infection	Trimethoprim (160 mg) with sulfamethoxazole (800 mg) PO QID × 10 days	Pyrimethamine 75 mg/day PO and folinic acid 5 mg PO daily × 10 days; or cipro oxacin 500 mg PO BID × 10 days;	Same as initial therapy if response; or trimethroprim (160 mg) sulfamethoxazole (800 mg) TIW; or pyrimethamine 25 mg/day plus folinic acid 5 mg/day	166,652–655
Cyclospora	Trimethroprim (160 mg)—sulfamethoxazole (800 mg) PO QID × 10 days	Cipro oxacin 500 mg PO BID × 10 days	Trimethoprim (160 mg)—sulfamethoxazole (800 mg) PO TIW	166,655–657
HELMINTHIC INFECTION				
Strongyloides stercoralis	Ivermectin 200 r ~ glkg/day × 1–2 days	Thiabendazole 25 mg/kg Q12h x □2 days	None	166,658,659

TABLE 13.22. *continued*

Infection	Speci c Treatment	Alternative Treatment	Maintenance Therapy	References
BACTERIAL INFECTIONS				
Nocardiosis	Sul soxazole 1–2 g PO QID × 6 weeks	Minocyciine 100–200 mg PO BID; or other antimicrobials based on susceptibility testing	Continue therapy at 1 g sul soxazole PO QID	660–664
Salmonella bacteremia	Cipro oxacin 750 mg PO BID × 6 weeks	Amoxicillin 500 mg PO TID; or trimethoprim (160 mg)—sulfamethoxazole (800 mg) PO TID	? None, if cipro oxacin is used as primary therapy; otherwise, continue primary therapy	664–666
Mycobacterium tuberculosis	Isoniazid 300 mg PO daily with pyridoxine 50 mg PO daily, with rifampin 600 mg PO daily, with pyrazinamide 15–30 mg/kg per day PO (once daily or in 3–4 divided doses up to daily maximum of 2 g), with ethambutol 15–25 mg/kg daily; all × 2 months (if multiply resistant strain suspected, use 5 drugs)[D]	Same except may substitute streptomycin 20–40 mg/kg (maximum 1 g) IM daily for ethambutol	Isoniazid 300 mg PO daily withpyridoxine 50 mg PO daily, with rifampin 600 mg PO daily; both × 6 months total course (including initial two months)	160,163,524,667–670
Mycobactenum avium complex	Clarithromycin 500 mg PO BID with ethambutol 15–25 mg/kg PO daily (many experts use three-drug initial regimen)	Add or substitute rifabutin 300–600 mg PO daily, cipro oxacin 500–750 mg PO daily, amikacin 7.5 mg/kg IV Q12–24h	Continue initial therapy	557,671–689
Bacillary epithelioid angiomatosis	Erythromycin 500 mg PO QID x 2–4 weeks	Doxycycline 100 mg PO BID	None, unless relapse occur	690–695
Helicobacter cinaedi cellulitis and/or bacteremia	Doxycycline 100 mg PO or IV Q12h x 2–6 weeks	Gentamicin 3–5 mg/kg/day IV	None	696,697
*Rhodococcus equi*Vancomycin 15 mg/kg IV Q 12h plus rifampin 600 mg PO or IV/day × 4–8 weeks	Macrolide plus rifampin 600 mg IV or PO daily	Macrolide plus rifampin 600 mg PO daily	698–701	

[a] Recent evidence suggests that *Pneumocystis carinii* is a fungus (701a).
[D] Many drug-drug interactions can be expected when either rifampin or rifabutin are used in conjunction with anti-retroviral agents, particularly protease inhibitors and non-nucleoside reverse transcriptase inhibitors, see Table 13.17 for speci c recommendations and references 9, 17 and 163.
Q, every; PO, orally; IV, intravenous; BID, twice daily; TID, three times daily; QID, four times daily; IgG, immunoglobulin G; CT, computed tomography; IM, intramuscularly; CNS, central nervous system.
* If patients unable to tolerate amphotericin B due to nephrotoxicity, consideration should be given to substitution of a lipid preparation of amphotericin B (571,575,576).

TABLE 13.23. *Rheumatic manifestations in HIV infection (705–710,715)*

Arthralgias
Painful articular syndrome
Seronegative spondyloarthropathy
Reiter's syndrome
Reactive arthritis
Psoriatic arthritis

Systemic lupus erythematosus-like disease
Rheumatoid arthritis-like disease
Miscellaneous
Septic arthritis and other septic complications
Avascular bone necrosis
Osteopenia
Osteoporosis
Myalgias
Fibromyalgia

pathophysiologic mechanisms include direct HIV infection of joints (716,728–730), immune complex deposition (716,731,732), and an atypical form of reactive arthritis occurring in the absence of HLA-B27, antecedent genitourinary or enteric infections, and inßammatory synovial ßuid. In general, the process is transient lasting several weeks and is not destructive (710,711), although a polyarticular erosive form has been reported (708,710).

For patients with these forms of arthritis or with Reiter's syndrome, nonsteroidal antiinßammatory agents are the mainstay of treatment. A trial of sulfasalazine may be warranted in instances of sustained inßammation (706), but steroids, other immunosuppressive medications or etretinate are usually reserved for refractory cases (710,717,733).

A wide spectrum of inßammatory and non-inßammatory muscle disorders have been described in association with HIV infection (see Chapter **??**) (708–710). HIV associated polymyositis patients do not exhibit in their sera the autoantibodies described in the idiopathic forms (709).

Almost the entire clinical spectrum of vasculitides have been reported in HIV-infected patients (734–737), including those of the polyarteritis nodosa type (710,738,739). The latter patients present primarily with a peripheral sensory or sensorimotor neuropathy. The etiology for the vasculitis is unknown in most cases, although cytomegalovirus infection is one recognized cause (740,741). Polymyalgia rheumatica and temporal arteritis may also occur more commonly in HIV-infected patients (725).

A syndrome characterized by massive parotid enlargement and xerostomia that superficially resembles Sjögren's syndrome is a well-established but relatively infrequent complication of HIV infection (742,743). In adults the syndrome appears to have an immunogenetic basis and is found principally in blacks who have the DR5 allele (743). It is characterized by markedly elevated numbers of CD8+, CD29+ lymphocytes in blood that infiltrate various glandular and extraglandular tissues (728). Consequently, it has been designated as the "diffuse infiltrative lymphocytosis syndrome." Unlike classic Sjögren's syndrome, autoantibodies are usually absent. Extraglandular involvement may include the liver, lung, gastrointestinal tract, kidney, thymus, and nervous system (744). The possibility of HIV infection should always be considered in an individual with unexplained bilateral parotid enlargement. Anecdotally, we have observed striking resolution of parotid enlargement following irradiation of the gland.

Various other autoimmune phenomena have been associated with HIV infection including the production of autoantibodies (705). Aside from antiplatelet antibodies that may be responsible for thrombocytopenia (745,746), antibodies directed at other targets, including red blood cells, leukocytes, and nuclear and cardiolipin antigens, are usually clinically silent (705). The same can probably be said for the presence of circulating immune complexes (731,732) and cryoglobulins (747).

FUTURE PROSPECTS

Studies of novel chemotherapeutic and immunomodulatory agents to control HIV infection are likely to increase in the coming years. In particular, within the next several years, agents that target parts of the HIV lifecycle other than the reverse transcriptase and protease enzymes will probably become part of the armamentarium for treatment. The role of IL-2 as an immunomodulator will be better defined, and the role if any, of strategic drug interruptions will be defined. Further study will also help to better understand when to start and change antiretroviral therapy. Data from the numerous vaccine trials regarding preventive and therapeutic vaccines will be forthcoming and with hope the results will be promising. Better outcomes that may result from these advances in turn will further alter the natural history of HIV infection.

ACKNOWLEDGMENTS

The authors wish to thank Eleanor Bramesco, Lisa Giarratano, Diane Holmgren, Susan Bittker, Denise Cooper and Jennafer Carlin for their assistance.
