The histogenesis and pathogenesis of KS have been extensively studied but are poorly understood. The proposed cell of origin has included most cells of mesodermal origin, but recent research has focused on the vascular (capillary) endothelium, lymphatic endothelium, or a combination of both (260–264). Immunohistochemical comparisons between the AIDS-related KS and sporadic KS have shown no signiþcant differences between these two forms despite the marked clinical dissimilarities (263,265). The presence of angioproliferative changes of nonlesional skin from AIDS patients, diploid DNA content, multicentric nature, and occasional reversibility have led some investigators to hypothesize that KS is a reactive proliferation rather than a true sarcoma (266). A recently described virus, human herpesvirus 8 (HHV8), also known as KS associated herpesvirus, is present in KS lesions of both AIDS patients and all forms of HIV-negative KS (267). It has been suggested that HHV8 may be an etiologic agent of KS. HHV8 has also been detected in body cavity based lymphoma (also known as primary effusion lymphoma), a rare form of B cell AIDS-related lymphoma occurring in HIV patients, anaplastic large cell lymphoma, as well as in multicentric Castlemanõ disease (267,268).

Clinical Characteristics

Cutaneous lesions of KS are often þrst recognized on the face, oral cavity (especially hard palate), arms, and soles of feet, and can be quite subtle (269,270). They may present as asymptomatic pigmented pink to violaceous macules, papules or small angiomatoid nodules being mistaken for hemangioma, pyogenic granuloma, dermatoþbroma, melanoma, molluscum contagiosum, or lichen planus (271,272). Gastrointestinal KS may cause bleeding, obstruction, and perforation, but is more commonly asymptomatic (259,273,274). Pulmonary involvement can result in cough, shortness of breath, hemoptysis, and respiratory failure as a consequence of intra-alveolar hemorrhage, tracheal and bronchial obstruction, and hemorrhagic pleural effusions (275,276). Lymph node KS can be seen in a high proportion of cases with estimates varying from 30–95% (254). As lymph node enlargement from a variety of causes is commonly encountered in patients with AIDS, conþrmation of lymphadenopathic KS requires excisional biopsy.

Diagnosis

Aggressive diagnostic studies of patients who have this condition are essential as chemotherapy and radiation therapy may provide signiþcant palliation, particularly if used in conjunction with antiretroviral therapy (256). Any cutaneous or mucous membrane pigmented lesion in a member of a high-risk group for HIV infection should raise the suspicion of KS and prompt tissue biopsy to establish a histological diagnosis. In small biopsy specimens of early skin lesions, it may be necessary to examine multiple levels, and the diagnosis of patch KS should be make cautiously in the presence of healed ulceration or at sites of previous trauma (277). Gastrointestinal tract lesions can be seen with or without cutaneous disease and usually present as either small red macules with associated submucosal hemorrhage or violaceous nodules involving the stomach and duodenum most commonly (274). Endoscopic biopsies will sometimes yield diagnostic material, although yields tend to be low because of the submucosal location of these lesions (274). Pulmonary KS occurs in between 20% and 50% of cases and clinically can be difþcult to distinguish from opportunistic infections, especially *Pneumocystis carinii*, as both can have similar symptoms and show diffuse interstitial inþltrates. The bronchoscopic appearance is that of multiple discrete raised red to violaceous mucosal plaques of the trachea or bronchial tree. KS is usually conþrmed by bronchoscopy without biopsy, but involvement of the parenchyma in the absence of bronchial disease may require an open lung biopsy for conþrmation (275). Bone marrow involvement has rarely been reported in core biopsies (278). Fine-needle aspiration biopsies from a variety of sites infrequently yield diagnostic material (279).

Histopathology

The histopathologic appearance of AIDS-associated KS in skin does not differ signiþcantly from the classical, endemic, and allograft-associated types despite the marked differences in clinical behavior among these groups. Two microscopic features are seen in the lesions: vascular spaces and spindle cells. The basic histologic patterns as described by Ackerman (280) include the patch, plaque, and nodular types, although mixed patterns are commonly observed. In the early patch stage, anastomosing thin-walled vascular spaces with irregular outlines involve the upper dermis and dissect collagen bundles (281). The lining endothelial cells display little nuclear atypia, and luminal erythrocytes are infrequent. These lesions, resembling granulation tissue, reaction to trauma, or areas of recently healed ulceration, can be quite subtle and difþcult to diagnose. Thin-walled anastomosing angulated and

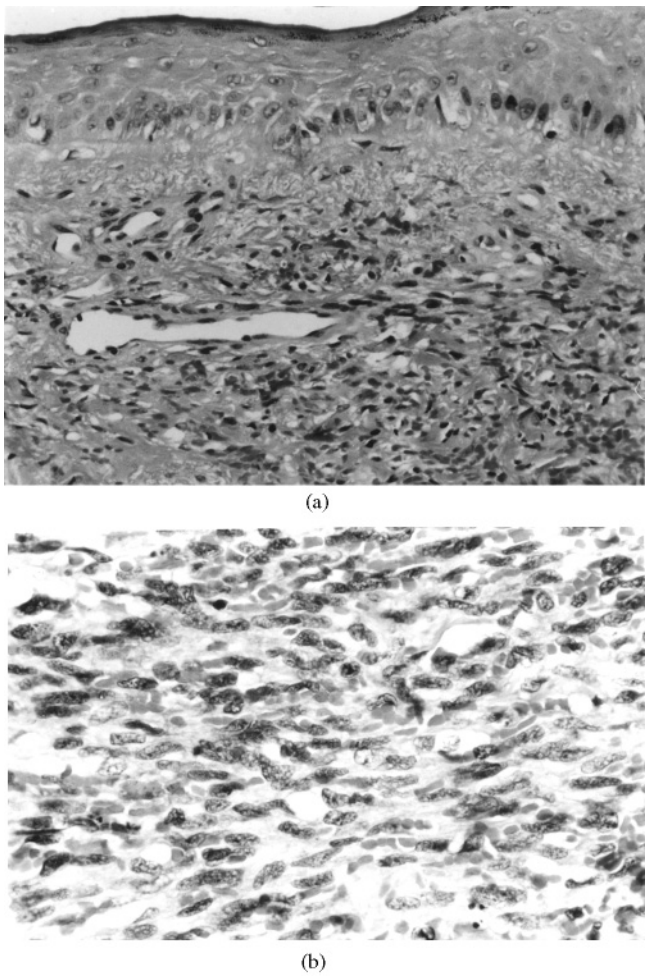

FIG. 27.19. Cutaneous Kaposi's sarcoma. a: Vascular spaces and spindle cells characterize the plaque lesion (hematoxylin and eosin, × 100). b: Late stage lesion with predominantly spindle cell proliferation and extravasated erythrocytes (hematoxylin and eosin, × 200).

irregularly outlined vascular spaces admixed with spindle cells are the hallmark of the plaque lesion (Fig. 27.19a). Nodular lesions contain a predominance of spindle-shaped cells, usually in well-deÞned aggregates that involve the dermis but may extend into the subcutaneous tissue (Fig. 27.19b). Vascular slits containing erythrocytes and hemosiderin deposits between the spindle cells help distinguish KS from other sarcomas. The spindle cells frequently show erythrophagocytosis and may contain eosinophilic inclusions, the latter shown ultrastructurally to represent lysosomal residual bodies (282). In the late stages, the histologic picture may resemble Þbrosarcoma with minimal nuclear atypia and occasional mitotic Þgures. Features said to be useful in differentiating KS from other vasoproliferative lesions include the promontory sign and the angiomatoid lesion. The former is a proliferation of jagged irregular endothelial lined spaces arising around a normal dermal vessel, while the latter is a collection of small vascular spaces lined by prominent ÒhobnailÓ endothelial cells surrounded by small numbers of proliferating spindle cells (277).

Extracutaneous KS

The histopathology of lymphadenopathic KS is that of a focal or diffuse expansion of the sinuses by a vascular and spindle cell proliferation, which may progress to the classic nodular pattern. The subcapsular sinusoids, medulla, and T cells zones are usually involved Þrst with eventual involvement of germinal centers. Eosinophilic globules can be found in macrophages or spindle cells. The lesions may co-exist with infectious processes, malignant lymphoma, and the various reactive patterns described in AIDS associated lymphadenopathy. The main differential diagnosis of early node involvement is with nodal angiomatosis.

AIDS associated bronchopulmonary KS may be the Þrst site of involvement recognized, but more commonly the diagnosis has been established by prior skin or oral biopsy. KS grows Þrst along lympathic pathways and involves intralobular septae, pleura, and forms distinct proliferations around bronchi and pulmonary vessels (275). The lesions consist predominantly of spindle cells and to a lesser extent, small vascular lumina and variable inßammation, that grow in a diffuse fashion rather than as nodules (283).

Endoscopic biopsies of the gastrointestinal tract can show diffuse mucosal plaque-like involvement or polypoid proliferations whose histologic appearance is similar to that described in skin. The tumors usually Þrst involve the submucosa but later intramucosal lesions also occur (Fig. 27.20). Involvement of the muscularis propria is uncommon (274).

Involvement of other organs including liver, spleen, heart, adrenal gland, and kidney is seen less frequently (284,285). The lesions can present as distinct parenchymal

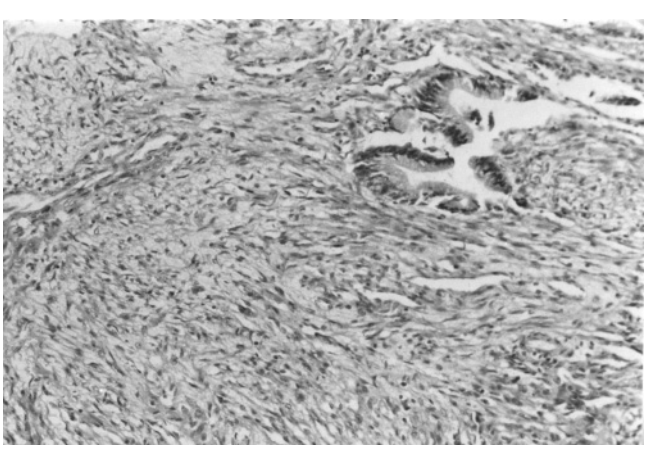

FIG. 27.20. Kaposi's sarcoma involving the stomach. The lamina propria is extensively in ltrated by a spindle cell proliferation with few vascular spaces. Residual gland is seen in upper right (hematoxylin and eosin, × 100).

nodules or inÞltrate along pre-existing lymphatic and vascular pathways. Microscopically, the classic mixture of spindle cells and vascular spaces are recapitulated regardless of the site of involvement.

Differential Diagnosis

Bacillary angiomatosis (BA) is a lesion occurring predominantly in AIDS patients that may be mistaken clinically and histologically for KS (285Ð287). BA can involve the skin, lymph nodes, mucosal surfaces including those of the gastrointestinal tract and respiratory tract, and causes peliosis of the spleen and liver (288). The cutaneous lesions usually present as erythematous papules, dome-shaped papules and nodules, indurated plaques or more deeply located circumscribed tumors. The majority of cases of BA are caused by *Bartonella henselae*, with a minority due to *B. quintana* (288). *B. henselae* is also the major cause of cat scratch disease. HHV8 has not been detected in the lesions of bacillary angiomatosis using polymerase chain reaction methods (289). Cutaneous BA is characterized histologically by lobular proliferations of capillaries lined by protuberant endothelial cells surrounded by neutophils, neutrophilic debris, macrophages and aggregates of gram-negative bacilli, visible on H and E stained section as granular, faintly basophilic material. The bacilli can be demonstrated in these lesions by the Warthin-Starry silver stain and by electron microscopy. The presence of neutrophils, granular debris, and clumps of bacteria in the absence of spindle cells, bizarrely shaped vascular channels, and eosinophilic inclusions help to distinguish BA from KS. The microscopic features of BA resemble the cutaneous form of bartonellosisÑÒverruga peruanaÓÑa benign cutaneous vascular proliferation associated with systemic infections with *Bartonella bacilliformis* (290). The differential diagnosis also includes angiosarcoma, pyogenic granuloma, hemangioma and angiolymphoid hyperplasia with eosinophilia. Angiosarcomas generally exhibit greater endothelial atypia and are less well circumscribed than BA. Hemangioma and pyogenic granuloma are usually more circumscribed, lack the neutrophilic debris and bacteria are not demonstrable. Accurate diagnosis of BA is important as treatment with erythromycin has resulted in complete and rapid resolution of the lesions (291). **Table 27.2???** highlights the important histologic features of BA and KS.

Malignant Lymphoma and Lymphadenopathy

AIDS-associated malignant lymphomas may be preceded by multifocal lymph node enlargement termed persistent generalized lymphadenopathy (PGL) (292,293). PGL is deÞned by the CDC as palpable lymphadenoopathy (>1.0 cm) at two or more extrainguinal sites persisting for more than three months in the absence of a concurrent illness or conditions other than HIV infection to explain the Þndings (294). Biopsies of lymph nodes from patients with PGL show three characteristic, although nonspeciÞc, histopathologic patterns of reaction (295,296). These patterns have been shown to correlate with the progression of immune dysfunction and the clinical course (297Ð299).

Histologic Patterns Seen in Lymphadenopathy

In ßorid follicular hyperplasia (type I or A pattern), the normal architecture is effaced by a marked proliferation of irregularly shaped follicles in the cortex and medulla. The follicles may show conßuence and attenuation of the mantle zones. The germinal centers contain a mixture of cell types, including large and small lymphocytes, immunoblasts, tingible body macrophages, nuclear debris, and numerous mitoses (Fig. 27.21). Invagination of mantle zone lymphocytes into the germinal centersÑ termed follicular lysis, results in islands of large transformed germinal center lymphocytes and disruption of follicles. Interfollicular zones show a prominent vasculature with a mixture of small lymphocytes, immunoblasts, plasma cells, and histiocytes. Neutrophilic aggregrates and multinucleated giant cells similar to the Warthin-Finkeldey giant cells of measles are frequently onserved. Changes resembling dermatopathic lymphadenitis and prominent histiocytic proliferation with erythrophagocytosis may also be seen.

Lymphoid depletion (type III or pattern C) shows atrophic Òburned outÓ follicles with depletion of lymphocytes, absent or vestigial germinal centers, and prominent vasculature. Interfollicular zones show loss of lymphocytes and excessive vascularization. Sinuses are dilated and usually contain numerous histiocytes, some of which show erythrophagocytosis. Multinucleated giant cells may also be seen. This pattern, which has the worst prognosis, is associated with the shortest intervals of progression to AIDS and the shortest patient survivals.

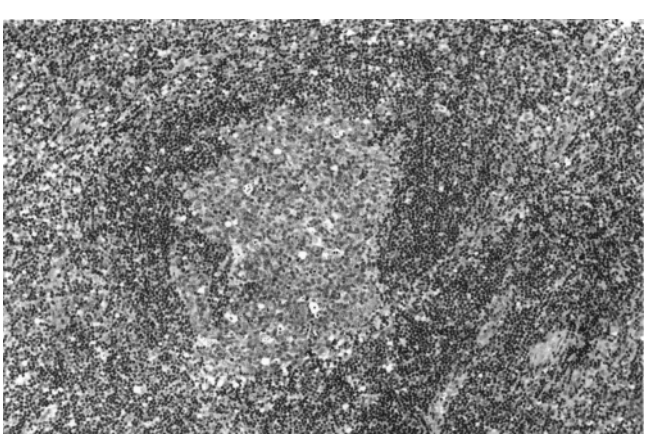

FIG. 27.21. Lymph node biopsy demonstrating marked follicular and interfollicular hyperplasia (type I pattern) (hematoxylin and eosin, $\times$ 100).

Mixed or intermediate patterns of reaction (type II or pattern B) include features of both ßorid hyperplasia and lymphoid depletion. This pattern is strongly associated with the impending development of AIDS (295,296).

At the present time lymph node biopsy is rarely done in HIV-infected patients with PGL. It is selectively performed to diagnose treatable opportunistic infections, lymphadenopathic Kaposi's sarcoma, and malignant lymphoma.

Malignant Lymphoma

It is estimated that 8–10% of HIV-infected individuals will develop a non-Hodgkin's lymphoma (NHL) (300). NHL is the second most common neoplasm associated with AIDS. Most cases have been reported in homosexual men, hemophiliacs, and intravenous drug abusers, although lymphomas can occur in individuals belonging to any AIDS risk group. PGL precedes the development of NHL in about one-third of patients (292,293). Most AIDS-associated NHL present with widely disseminated disease usually involving extranodal sites, particularly the gastrointestinal tract, central nervous system, liver, bone marrow, and skin. These tumors belong to the aggressive histopathologic subtypes: small cell noncleaved (Burkitt-type), large cell immunoblastic, and large cell noncleaved (Fig. 27.22) (301). However, a variety of low and intermediate-grade lymphomas including maltomas have also been reported.

About 95% of AIDS-associated NHL are of B-cell origin, and display various genetic lesions including Epstein-Barr virus infection, c-myc and bcl-6 gene rearrangements, ras gene mutations and p53 gene mutations/deletions (302,303,304). HIV does not appear to be directly involved in malignant transformation, as HIV DNA sequences have not been found in the genome of these neoplastic lymphoid cells (305). About one-third of AIDS-associated NHL have detectable Epstein-Barr virus DNA sequences or proteins (302,306). Body cavity-based lymphomas (BCBL), also known as primary effusion lymphomas, are a rare form of B-cell non-Hodgkin's lymphoma, which occur in HIV-infected patients and display a propensity to grow as ascites tumors in the pleural or peritoneal cavities (267). HHV8 has also been detected in cases of BCBL (267). Hodgkin's malignant lymphoma has been described in HIV-infected individuals, and like AIDS-associated NHL, the majority of patients present with extensive disseminated disease that often involves extranodal sites, including bone marrow, liver, skin, and soft tissues. In contrast with classic Hodgkin's disease, most patients with AIDS-associated Hodgkin's disease have an aggressive clinical course and a rapidly fatal outcome. The distribution of histopathologic categories includes mixed cellularity, nodular sclerosis, and lymphocyte-depleted types (Fig. 27.23) (301,307,308).

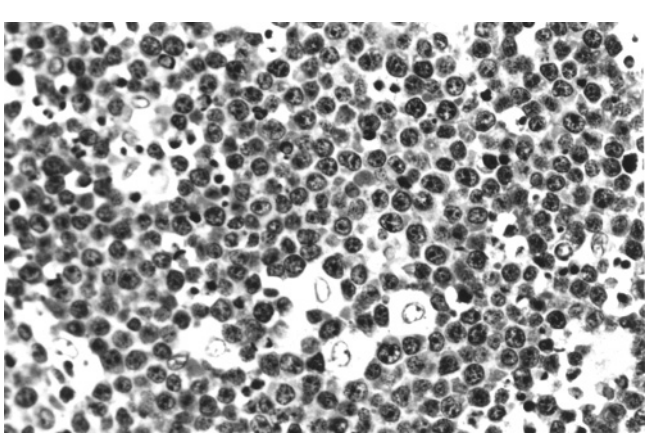

FIG. 27.22. AIDS-associated small noncleaved cell lymphoma involving lymph node. The presence of benign histiocytes within tumor imparts a "starry sky" appearance (hematoxylin and eosin, × 250).

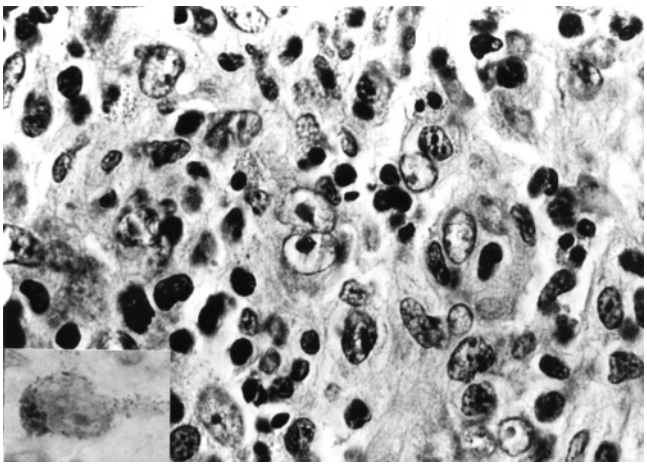

FIG. 27.23. AIDS-associated mixed cellularity Hodgkin's disease. Polymorphous in Itrate including the presence of Reed-Sternberg cell (hematoxylin and eosin, × 200). Inset is Leu M-1 (CD-15) immunoperoxidase stain of atypical mononuclear variant (Avidin-Biotin complex, hematoxylin counterstain, × 250).

Other Malignancies

Other hematopoietic and nonhematopoietic neoplasms have been reported in HIV-infected individuals (**Table 27.3**) (252,309–342). While the occurrence of many of these tumors is probably coincidental, some investigators believe tumor development is facilitated by the immunosuppression of HIV infection (343). These include low-grade B-cell NHL, T-cell leukemias and lymphomas, plasmacytomas, acute lymphoblastic leukemia, multiple myeloma, squamous cell carcinomas of several sites, adenocarcinomas of pancreas and colon, malignant melanomas, metastasizing basal cell carcinomas, thymomas, mesenchymal tumors including Þbrosarcomas, liposarcomas, leiomyosarcomas, leiomyomas, angiolipomas, and germ cell tumors including seminomas and embryonal

carcinomas. Anorectal squamous carcinomas and squamous cell carcinomas of the oral cavity are the most frequently reported malignancies after Kaposi's sarcoma and malignant lymphomas (309,310). Some of the squamous neoplasms have been associated with infections by human papillomavirus (313,341,343,344). A large National Cancer Institute study found that of a total of 38 malignant disorders other than KS and NHL, only angiosarcoma, Hodgkin's disease, multiple myeloma, brain cancer, and seminoma were increasing significantly from the pre-AIDS to the post-AIDS period (345).

POORLY UNDERSTOOD COMPLICATIONS OF AIDS

Cardiac Pathology

Early reports of cardiac pathology in autopsy studies focused on opportunistic infections and neoplasms involving the heart, and later reports focused on other cardiac lesions. Clinical studies subsequently established the presence of cardiac dysfunction in patients with HIV infection in the absence of opportunistic infection (346). The incidence of symptomatic heart disease in AIDS patients is estimated to be approximately 7% (347).

Infections and neoplastic involvement is usually seen in the setting of systemic disease. The findings of cardiac disease unrelated to opportunistic infections and neoplasia emerged in a report of dilated cardiomyopathy in 1986 (348). Since that report, several patterns of cardiac dysfunction in AIDS patients have been described that may be grouped into pericardial effusions and tamponade, dilated cardiomyopathy, heart failure without ventricular dilatation, refractory ventricular tachycardia, sudden death, and systemic disease (347).

Pericardial effusions are frequently detected in AIDS patients (349,350). Most often these effusions, which may result in cardiac tamponade, are seen in association with opportunistic infections (e.g. toxplasmosis, cytomegalovirus infection) and malignancies (e.g. Kaposi's sarcoma, malignant lymphoma) (72,351). When cardiac tamponade is present, infectious or neoplastic involvement is found in 88% of the reported cases.

AIDS-related dilated cardiomyopathy has been associated with ventricular dilatation and idiopathic myocarditis. It has been found that 6% of HIV-infected patients develop symptomatic cardiomyopathy (352). In one pediatric autopsy study, cardiac disease, including cardiomyopathy was a major contributor to mortality, being the underlying cause or an important contributing factor in almost one-third of patients (353). Ventricular dilatation may involve the left or right ventricles. Isolated right ventricular dilatation usually reflects severe pulmonary disease. The myocardium grossly appears normal in thickness, flaccid, and pale. Enlargement of valvular annuli is seen in biventricular dilatation. Cardiac hypertrophy (heart weight >400g) is usually absent. Microscopic findings, with the exclusion of cases with myocarditis, include enlarged myocyte nuclei with bizarre shapes, lipochrome pigment deposits, variable interstitial fibrosis, and edema (348,354). Myocyte fiber loss is variable.

Myocarditis, defined as myocyte degeneration or necrosis associated with adjacent inflammatory infiltrates, has been observed in some cases of dilated cardiomyopathy, ventricular tachycardia and sudden death, and pericardial effusions (354). Clinical symptoms were seen in 58% of the cases that were detected at autopsy (355). Idiopathic myocarditis was diagnosed by endomyocardial biopsy in a patient with refractory ventricular tachycardia (356). The cause of myocarditiis in HIV infection remains obscure in the majority of cases (354). No correlation has been found between therapy and the occurrence of myocarditis (354,355). Viral-induced injury either directly or by activation of latent viral infections by immunosuppression has been proposed. Acute global left ventricular dysfunction occurs infrequently in AIDS patients and can be associated with myocarditis or acute onset of cardiomyopathy, both of which have a uniformly fatal outcome, or can be associated with toxic myocardial damage, in which case it is potentially reversible (357).

Nonbacterial thrombotic endocarditis is usually a right-sided, asymptomatic finding at autopsy. The vegetations are small masses of fibrin and blood that collect on the valve leaflets along the lines of closure. Either side of the heart may be affected. The lesions are commonly seen in chronic debilitating conditions such as metastatic cancer, renal failure, or chronic sepsis. Their presence in AIDS patients probably reflects the underlying severe illness. Involvement of all four cardiac valves has been reported. Complications are rare, but one patient with cerebral infarctions has been reported (351).

HIV-Associated Enteropathy

Diarrhea, weight loss, and malabsorption have been recognized as major manifestations of HIV infection and may precede the AIDS-related complex (ARC) or AIDS stage of HIV infection (358). Mucosal injury may result from immunosuppression leading to the development of opportunistic infections or AIDS-associated malignancies. Some of the opportunistic infections, such as cryptosporidiosis, are primary for the gastrointestinal tract (86,180, 188,359). Alternatively, evidence for direct mucosal injury by HIV itself has been recognized as HIV-associated enteropathy (360).

HIV-associated enteropathy has been postulated in those patients who do not have a demonstrable specific infectious agent. HIV antigen and virus have been demonstrated in the lamina propria of intestinal biopsies (361,362). Diarrhea and malabsorption have been documented in 29% of patients who are HIV-seropositive but have negative stool cultures and other examinations for the

infectious agents common to AIDS patients (363). It is postulated that depletion of CD4+ T-cells leads to altered IgA B-cell development and decreased IgA production (364). HIV-infected patients have also been reported to have impaired gastric acid secretion which, together with reduced IgA production, may lead to bacterial overgrowth of the small intestine. These bacteria may contribute to mucosal inßammation, villous atrophy, and malabsorption (364). Duodenal mucosal biopsies in these patients may show nonspeciÞc changes of mucosal atrophy, normal crypt depth, and decreased mitotic activity (361). Jejunal biopsies have demonstrated an increase in intraepithelial lymphocytes over control subjects (363). Rectal Þndings include focal epithelial cell degeneration (apoptosis) with intranuclear virus inclusions (360). Electron microscopy studies demonstrate contact between intraepithelial lymphocytes and apoptotic cells, which suggests a cell-mediated immune response. Apoptosis is not a typical feature of infectious enteritides, but has been observed in acute graft-versus-host disease of the colon following bone marrow transplantation. It has been postulated that viral infection induces changes in the cell membranes that triggers a host response and apoptosis (360). In those patients with diarrhea the changes seen are most pronounced. Mucosal atrophy, crypt hyperplasia, and lymphoplasmacytic inÞltration of the lamina propria are not speciÞc for HIV enteropathy. Similar changes may be seen in other enteric infections (365).

Damage to autonomic nerve bundles in the jejunal mucosal lamina propria has been described and is similar to that reported in laxative abuse, diabetic autonomic neuropathy, inßammatory bowel disease, and amyloidosis (366).

The carrier rate for enteric pathogens increases for the population of HIV-infected patients with AIDS. In these patients with diarrhea and malabsorption, one-third will be found to have a treatable infection, which underscores the importance of searching for enteric pathogens.

Renal Pathology

The renal manifestations of HIV infection may be the result of indirect or direct mechanisms (367Ð369). These include acute tubular necrosis, allergic interstitial nephritis (AIN), immune complex-associated glomerulonephritis, focal segmental glomerulosclerosis/collapsing glomerulopathy, thrombotic microangiopathy, microbial infection from a variety of pathogens (370), and crystal nephropathy (371).

Acute tubular necrosis is not usually directly attributable to HIV but occurs as a result of episodes of hypovolemic shock and sepsis, or because of exposure to radiocontrast agents. Acute interstitial nephritis or acute tubular necrosis may be the result of therapy with trimethoprim-sulfamethoxazole, gentamicin, pentamidine, acyclovir, and amphotericin B. Biopsies are infrequently performed in the typical clinical setting of AIN but may reveal interstitial edema, epithelial damage, and inßammatory inÞltrates. Eosinophils may be present in variable numbers. Toxic or ischemic injuries occur in a clinical setting, which likewise infrequently lead to a biopsy. The histopathologic Þndings at biopsy include low ßattened tubular epithelium with sloughing, loss of brush border, dilatation of tubules, mild interstitial edema, and sparse cellular inÞltrates. The acute renal failure experienced by these patients often contributes to their death because of underlying serious illness.

Immune complex-mediated glomerulonephritis has been reported in sporadic cases, often related to various infectious diseases in these patients. Mesangial proliferation and diffuse proliferative glomerulonephritis have been described (372,373). Immunoglobulins and complement proteins are usually seen in the mesangial areas and along capillary loops by immunoßuorescence.

Fluid and electrolyte abnormalities are frequently seen in these critically ill patients, with hyponatremia being one of the most common. Gastrointestinal ßuid loss, before hospital admission, is the etiology of the hyponatremia in 40% of patients with AIDS. Mortality in hospitalized hyponatremic patients with AIDS is twice as high as in normonatremic patients (374).

HIV-Associated Nephropathy

In 1984, Rao and associates (375) recognized a renal disorder characterized by heavy proteinuria and progression to renal failure in AIDS patients. Since then, HIV-associated nephropathy has been recognized in many medical centers but has been controversial for several reasons (374). Initially, the lesion was described in AIDS patients with a high proportion of drug abuse cases. Controversy was spawned because some centers, notable those in San Francisco (376), did not see this lesion with the same frequency. Later, this renal lesion was shown to be present in children with AIDS, which strengthened the argument for a primary causal relationship (377). A second controversial point was whether this lesion was secondary to immunological changes that accompany AIDS or was just associated with HIV infection. Again, recently the lesion has been described in patients with HIV infection, but no manifestations of AIDS (378). So, in spite of initial controversies, acceptance of HIV nephropathy is generally agreed as valid.

The clinical features of HIV-associated nephropathy have the following characteristics. The lesion may be found in asymptomatic, HIV-infected patients or in patients with ARC and AIDS. Males are more frequently affected than females, with variations in incidence in different geographic areas (i.e. high in New York City, low in San Francisco). Black patients are affected more frequently than white. Proteinuria is always present and is usually heavy. The course is usually marked by early and

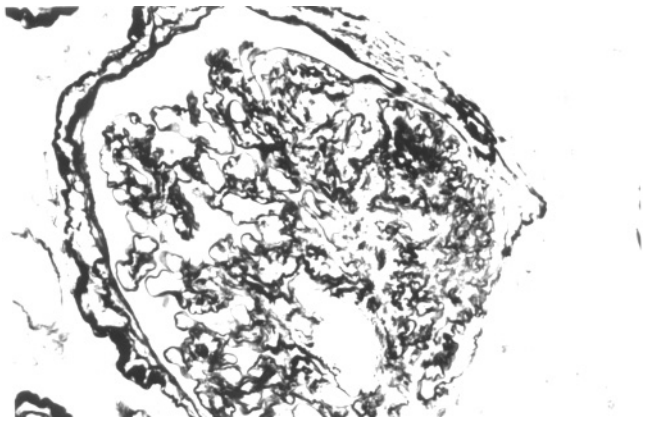

FIG. 27.24. Biopsy specimen from a patient with AIDS nephropathy. The glomerulus is segmentally sclerosed (Gomori's methenamine-silver, × 200).

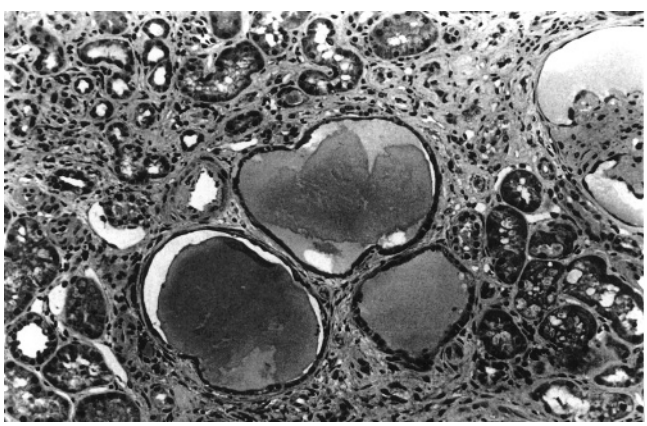

FIG. 27.25. Biopsy specimen from a patient with AIDS nephropathy. The interstitium is brotic and dilated tubules are present (hematoxylin and eosin, × 200).

rapidly progressive azotemia. Mild hypertension is present (379).

Morphologic manifestations of HIV-associated nephropathy are found in glomeruli, tubules, and interstitium (pan-nephropathy). The kidneys are usually enlarged. Progressive changes may be seen in the affected glomeruli. Initially, the epithelial cells become swollen and the underlying capillary loops are wrinkled or collapsed (collapsing variant of focal segmental glomerulosclerosis). Occasional intraluminal foam cells are seen. In the more advanced lesions the capillary loops are completely collapsed, with expansion of the mesangial matrix-basement membrane material (Fig. 27.24). Plasma proteins may accumulate within the capillary loops (hyalinosis). In far advanced lesions more glomeruli are involved and there is complete capillary obliteration.

Microcystic dilation and proteinaceous casts may be found in the tubules. Interstitial Þbrosis and tubular atrophy are seen as the glomerular lesion advances (Fig. 27.25). Interstitial inÞltrates contain lymphocytes, histiocytes, and plasma cells.

Ultrastructural studies demonstrate a diffuse effacement of epithelial foot processes and detachment of cells from the basement membranes. Inclusions of tubuloreticular bodies are almost always present in the vascular endothelium. Cytoplasmic inclusions of parallel stacks and cyclindrical confronting cisternae, also known as test tube and ring-shaped forms, have been described. Immuno-ßuorescence studies demonstrated C3, C1q, and IgM in the sclerotic segments. Granular deposits of these proteins may also be seen in mesangial areas. In situ hybridization techniques have demonstrated proviral HIV DNA in the tubular and glomerular epithelial cells.

PATHOLOGY OF AIDS IN CHILDREN

Since the Þrst published series of AIDS cases in children (380,381), it is estimated that at the end of 1999, 1.2 million children are living with HIV-1 infection and an additional 3.6 million children have died of the disease. In 1999 alone, 570,000 children became infected with HIV, primarily through mother-to-child transmission (382).

There are basic similarities between pediatric and adult AIDS in major clinical features and pathologic lesions. However, pediatric AIDS is different with respect to mode of transmission, frequency and types of certain clinical features, immunologic abnormalities and pathologic lesions. These differences will be highlighted and the pathologic lesions, which occur more frequently or predominantly in children, and perinatal pathology of HIV infection will be described in this section.

Mode of Transmission

There are two major modes of transmission (383): (a) Transplacental/perinatal transmission from the HIV-infected mother (the mother may or may not have symptomatic HIV infection or full blown AIDS) and (b) parenteral transmission through transfusion of infected blood or blood products (e.g. factor VIII). Of the two, the former is by far more common. Transmission can occur prenatally, during delivery, and postnatally via breast milk (384,385). Of these, transmission during delivery presents the greatest risk. The risk estimates of transmission of HIV from infected mothers to their infants vary greatly. Administration of antiretroviral agents during pregnancy and labor and to the infant after birth can decrease transmission rates to as low as 2% (386,387).

Clinical Features and Immunologic Abnormalities

Failure to thrive, fever, lymphadenopathy, respiratory symptoms and signs and neurologic abnormalities are among the most common clinical features (380,381,388). The immunologic features include both T and B cell

abnormalities such as cutaneous anergy, low absolute T helper cell counts, reversed T helper/suppressor cell ratio, lack of response to mitogens and polyclonal hypergammaglobulinemia. With longer survival due to early diagnosis and intensive therapy, cardiomyopathy, renal disease, neoplastic disorders, etc., are seen with increasing frequency.

Pathologic Lesions

All the lesions described in adults occur in children with AIDS. Although these lesions occur with different frequency, lesions of lymphoreticular, central nervous, respiratory and digestive systems, and heart and kidneys have all been reported in pediatric AIDS, as are various infections and malignancies (4,389). The following lesions are seen predominantly or more frequently in children with AIDS: (a) Thymic lesions (primary lesions), (b) Pulmonary lymphoid lesions (associated lesions), (c) Lymphoproliferative disorders, including lesions of mucosa associated lymphoid tissue (MALT), (d) Arteriopathy (lesion of undetermined pathogenesis), and (e) certain types of neoplastic lesions.

The lesions in the thymus and lungs, those related to the lymphoproliferative disorders, arteriopathy, and neoplastic lesions, will be discussed. Similarities, differences and frequency of these lesions in adults with AIDS will also be described.

Lesions of the Thymus

Three types of lesions have been noted in the biopsy and autopsy specimens of the thymus (4,389):

a. Precocious involution is characterized by marked depletion to virtual absence of lymphocytes, loss of corticomedullary differentiation, and microcystic dilation of Hassall's corpuscles (HC) which are present in normal numbers. Hyalinization of the cortex and medulla is present in some cases at autopsy. The location, conÞguration and the blood vessels of the thymus are normal. These features resemble age and stress related involutionary changes but occur prematurely and are out of proportion to the severity of stress. There is marked reduction in weight often to less than 1 g.
b. Dysinvolution (Fig. 27.26) is characterized by all the features noted above except that HC are virtually absent. Rare HC can be demonstrated in an occasional lobule by studying step serial sections of the thymus. These features particularly the virtual absence of HC resemble the dysplastic thymus seen in certain congenital immune deÞciency syndromesÑ hence the term dysinvolution.
c. Thymitis is characterized by one of the following features: Lymphoid follicles with germinal centers in the medulla, focal or diffuse lymphomononuclear or lymphoplasmacytic inÞltrate disrupting the normal architecture of the thymus or multinucleated giant cells in the medulla. Recently another reactive lesion, multilocular thymic cyst has been described in children with AIDS (390,391). This lesion should be considered in the differential diagnosis of a mediastinal mass in a child with AIDS.

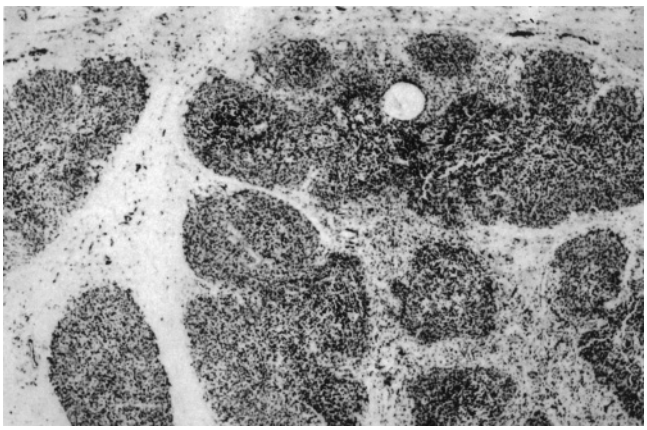

FIG. 27.26. Dysinvolution of thymus. Note loss of corticomedullary differentiation, lymphocytic depletion of both cortex and medulla and markedly reduced number of Hassall's corpuscles—only one of which is present in one of the lobules (hematoxylin and eosin, × 20).

The etiology and precise target cell in thymic injury are not known. However, it is possible that the thymic epithelial cells may be injured by HIV since: (a) HIV has been isolated from a thymic biopsy specimen in one of our cases and from the thymus of a 20-week fetus and (b) Simian immunodeÞciency virus (SIV) has been demonstrated by immunoperoxidase staining in the thymic epithelial cells in rhesus monkeys with an AIDS-like disease complex (4).

It is of interest to note that severe involutionary changes with thymic epithelial injury have been reported in adults with AIDS (392). Thymic enlargement with thymitis characterized by presence of lymphoid follicles with germinal centers and vascularized lymphoid follicles in the medulla resembling those seen in Castleman's disease has been observed in an adult with AIDS (393). Thymic injury in AIDS thus may lead to defective T cell differentiation and maturation and contribute to the immune deÞciency in AIDS both in children and adults.

Lesions of the Lungs

Pulmonary lesions associated with the frequently observed respiratory symptoms and signs in children with AIDS are listed in **Table 27.4**. Lesions related to pulmonary opportunistic and pathogenic bacterial infections are the same as in adults. The pulmonary lymphoid

lesions including the systemic lymphoproliferative disorder are seen much less frequently in adults.

Lymphoid Lesions

These are of two types: Pulmonary lymphoid hyperplasia/lymphoid interstitial pneumonitis complex (PLH/LIP complex) (394,395) and polyclonal polymorphic B cell lymphoproliferative disorder (PBLD). PBLD, a systemic disorder with prominent pulmonary involvement, will be described separately in the next section. PLH is characterized by peribronchiolar lymphoid nodules commonly with germinal centers (Fig. 27.27). The lymphoid nodules are composed of mature and immature lymphoid cells of the germinal center with plasma cells at the periphery. LIP is characterized by diffuse inÞltration of the alveolar septa by mature and immature lymphoid cells, plasmacytoid lymphocytes and plasma cells with occasional Russell bodies (Fig. 27.28). Nodular aggregates of lymphoid cells are seen in some foci. There is no involvement of blood vessels or destruction of bronchi. No viral inclusions are seen. Special stains for fungi, acid-fast bacilli, and *Pneumocystis carinii* are negative. Immunoperoxidase stains for kappa and lambda light chains of immunoglobulins show that the pulmonary lymphoid inÞltrates are polyclonal.

With experience of larger number of cases, the overlap between PLH and LIP was evidenced by (a) the variable degree of alveolar septal inÞltration in cases which could otherwise be labeled as PLH, (b) the presence of peribronchiolar lymphoid nodules in cases which could be labeled as LIP and (c) the gradual transition between (a) and (b) became more evident and of more common occurrence. Therefore, it was recommended that these lesions should be designated as PLH/LIP complex (395).

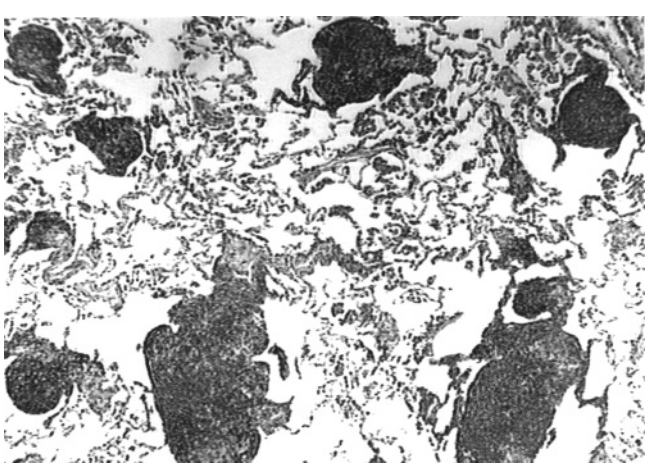

FIG. 27.27. Lung biopsy specimen showing lymphoid nodules around bronchioles. Note slight extension of lymphoid in ltrate into adjacent alveolar septa and germinal centers vaguely disconcernible at this magni cation (PLH/LIP complex) (hematoxylin and eosin, × 10).

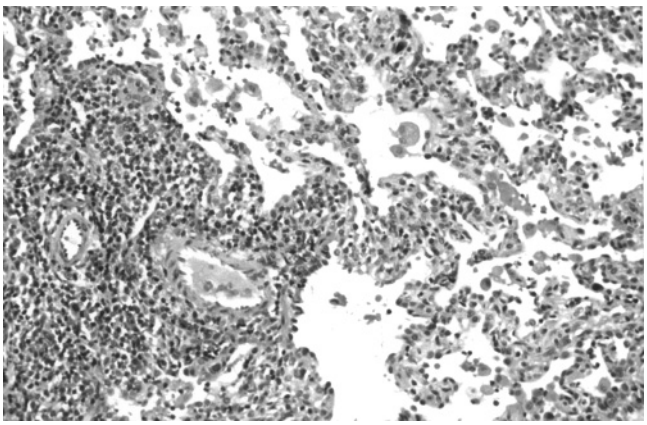

FIG. 27.28. Lung biopsy specimen showing dense in ltration of alveolar septa by lymphoid cells (PLH/LIP complex) (hematoxylin and eosin, × 100).

Besides B cells demonstrated by routine histologic methods and by immunoperoxidase stain for light chains, T cells are also present in the lesions of PLH/LIP complex shown by cell marker studies on bronchoalveolar lavage ßuid or the lung biopsy tissue. T_8 cells predominate in this T cell population.

Although infrequent, PLH/LIP complex has been described in adults with AIDS (57). However, the recent study by Guillon et al. (396) indicates that PLH/LIP complex diagnosed by lymphocytosis in bronchoalveolar lavage ßuid is more common in adults than generally thought. The lesion in adults has been labeled as LIP or lymphocytic alveolitis. Although detailed descriptions and illustrations are lacking, it is apparent from the limited accounts (57,396) that the lesion in adults represents PLH/LIP complex similar to that in children.

Pathogenesis: Although the pathogenesis of pulmonary lymphoid lesions is not yet established with certainty, there is evidence to suggest that both Epstein-Barr virus (EBV) and HIV may be etiologically related (4,397). In view of the concept of mucosa associated lymphoid tissue (MALT) of various organs such as the gastrointestinal tract, respiratory tract, etc. (398), the pulmonary lymphoid lesions can be considered to represent MALT lesions.

Diffuse Alveolar Damage (DAD): DAD is seen in both biopsy and autopsy specimens. The exudative phase is characterized by hyaline membrane formation, interstitial and alveolar edema, mild mixed interstitial inßammatory inÞltrate and focal intra-alveolar hemorrhage (Fig. 27.29). In the proliferative phase there is cuboidal metaplasia of alveolar epithelium, interstitial Þbroblastic proliferation and interstitial edema.

DAD is related to a variety of pathogenetic factors, which include oxygen toxicity, pulmonary infections, sepsis, and shock. One or more of these factors are operative in individual cases. DAD may obscure the infectious nature of the lesion. In adults, DAD related to similar factors is seen. However, in some cases of adult AIDS, features of DAD with proliferative changes in the

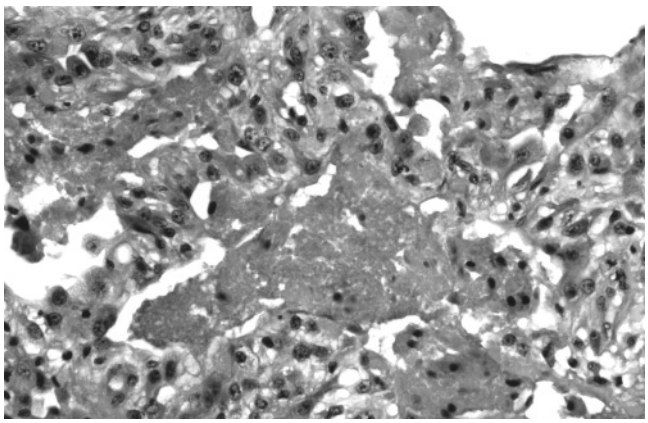

FIG. 27.29. Lung biopsy showing organizing diffuse alveolar damage. Note the hyaline membranes and alveolar foamy exudate (Gomori's methenamine silver stain revealed *Pneumocystis carinii*) (hematoxylin and eosin, × 400).

lung biopsy are present without any demonstrable pathogenetic factors (399).

In addition to these lesions occurring in children and adults, two inßammatory lesions viz. nonspeciÞc interstitial pneumonitis (NIP) (400) and lymphocytic bronchiolitis (LB) (401) have been described in isolated cases of AIDS in adults having respiratory symptoms and signs. In NIP, histologic features are essentially those of a combination of exudative and proliferative phases of DAD and consist of alveolar edema, Þbrin deposition, hyaline membranes, interstitial inßammation and loose and dense interstitial Þbrosis. The lesion is labeled as NIP presumably because the inßammatory component is more prominent (402). In most instances NIP is seen in association with or following other pulmonary lesions such as KS, experimental therapy, drug abuse or PCP and shows prominent Þbroproliferative changes. However, in a minority of the patients no associated factor or other pulmonary lesion is found. In this latter group, NIP is characterized by interstitial lymphoid cell aggregates and the absence of loose or dense interstitial Þbrosis. Hyaline membranes are seen in some cases. NIP with only interstitial lymphocytic inÞltrate without hyaline membranes has also been described in adults with AIDS having no respiratory symptoms or signs. The importance of recognition of NIP is related to similarities between the clinical features of NIP and of pulmonary opportunistic infections particularly PCP.

LB has been reported only in one case (401). It is characterized by an intense inÞltration of the wall of terminal and respiratory bronchioles by lymphocytes and plasma cells. Increased numbers of T_8 suppressor cells were found in the bronchoalveolar lavage specimen.

Both NIP and LB need to be further characterized with a detailed description and illustration of the pathologic features. It is possible that NIP and LB in adults are less severe variants of PLH/LIP complex described above in children.

Lymphoproliferative Disorders

Two types of these disorders occur in children: (1) systemic lymphoproliferative disorder and (2) spectrum of MALT lesions. In four children with AIDS a systemic lymphoproliferative disorder with prominent involvement of lungs and less severe involvement of liver, spleen, kidneys, other extranodal sites and lymph nodes, was seen (4) (Figs. 27.30 and 27.31). There was no involvement of the brain.

Histologically, the cellular inÞltrates in the various organs mentioned above and in skin, skeletal muscle, and salivary glands were polymorphic and consisted of an admixture of lymphocytes, plasma cells, plasmacytoid lymphocytes, and immature lymphoid cells or immunoblasts. The polyclonal nature of the lymphoid inÞltrates was demonstrated by the presence of both kappa and lambda light chain immunoglobulins in parafÞn sections of different organs stained by an immunoperoxidase method. In the kidneys and spleen, vascular invasion by the cellular inÞltrate was noted. It appears that this lymphoproliferative disorder is distinctive and was designated as polyclonal polymorphic B cell lymphoproliferative disorder (PBLD). It is considered to be intermediate between benign and full-ßedged malignant lymphoproliferations. In two cases PBLD appeared to represent a progression of PLH/LIP complex, while in other cases it seemed to arise *de novo*.

A spectrum of lymphoproliferation (follicular hyperplasia of lymph nodes, PLH/LIP complex, lymphoid hyperplasia of G.I. tract, lymphoid follicles in the thymus,

FIG. 27.30. Polyclonal polymorphic B-cell lymphoproliferative disorder (PBLD) involving the kidney. Whole mount of histologic section showing multinodular involvement of cortex with extracapsular extension (hematoxylin and eosin), × 5).

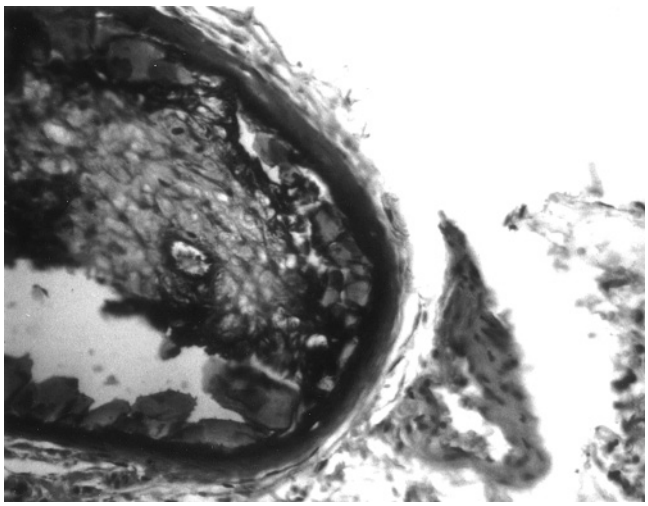

FIG. 27.31. Arteriopathy characterized by intimal brosis with calci cation and brosis of media of an artery. Note the markedly narrowed lumen (hematoxylin and eosin, × 25).

and nodal and extranodal malignant lymphoma) similar to that in children can also be proposed for adults with AIDS. Thus the following lymphoid lesions described in adults may belong to such a spectrum: Follicular hyperplasia of lymph nodes, adenoidal hypertrophy (403), PLH/LIP complex, EBV related lymphoproliferative disorder (404) similar to PBLD in children, and nodal and extranodal malignant lymphoma.

The other major category of lymphoproliferative lesions is the spectrum of MALT lesions (405,406). The spectrum includes: typical and atypical PLH/LIP complex, myoepithelial sialadenitis with or without focal lymphoma, low grade MALT lymphoma of parotoid gland and diffuse large cell lymphoma of parotid gland and of tonsil. MALT lymphomas respond to therapy and follow an indolent clinical course. Both EBV and HIV may be involved in the pathogensis of MALT lesions (407).

There is overlap between the systemic lymphoproliferative disorder and MALT lesions. The concept of MALT has been extended to include tissues and organs such as liver, thymus, genital tract, etc., besides the respiratory and digestive tracts (405). Therefore, it appears that most of the lesions seen in the systemic lymphoproliferative disorder described above belong to the spectrum of MALT lesions. We would like to suggest that since PLH/LIP complex, which is a MALT lesion, is considered one of the criteria for the diagnosis of AIDS in children, that the other reactive MALT lesions described above should also be included as criteria for the diagnosis of pediatric AIDS.

Arteriopathy

The lesion designated as arteriopathy is seen in small and medium sized arteries of different organs (heart, lungs, kidneys, spleen, intestine, brain) (4). It is characterized by intimal Þbrosis, fragmentation of elastic Þbers in the media, Þbrosis and calciÞcation of internal elastic lamina and media with variable luminal narrowing (Fig. 27.32). (Vasculitis seen only in the brain in association with progressive HIV encephalopathy is not considered as part of the arteriopathy described here.) Arterial aneurysms affecting young black patients occurring in atypical sites and with a tendency towards multiplicity have been described (408). In one case, fatal outcome resulted from aneurysms of the right coronary artery with thrombosis (**Fig. 27.33**) and myocardial infarction (4). Aneurysm formation of cerebral arteries has been reported in another case.

The pathogenesis of arteriopathy is not clear. Arteriopathy is therefore included under the category of lesions of undetermined pathogenesis. However, it is possible that repeated bacterial and opportunistic infections secondary to immunodeÞciency might result in increased exposure to endogenous and exogenous elastases. Elastic tissue damage, which is the striking feature of the arterial lesions, may be related to such an increased and repeated exposure.

The arteriopathy seen in children with AIDS appears to be distinctive. Similar arterial lesions have not been reported to occur in adults with AIDS, although we have seen similar ÞbrocalciÞc lesions of medial of small and medium sized arteries of thyroid, mesentery and kidney in a 30 year old male intravenous drug abuser who died of AIDS.

Recently, other types of vascular lesions have been described in children and adults with AIDS. These include: inßammatory lesions (mycotic aneurysms, systemic vasculitis, polyarteritis nodosa like vasculitis, hypersensitivity vasculitis), artherosclerosis, thomboembolic lesions, proliferative lesions (e.g. bacillary angiomatosis) and miscellaneous lesions (zidovudine induced leukocytoclastic vasculitis, etc.) (409).

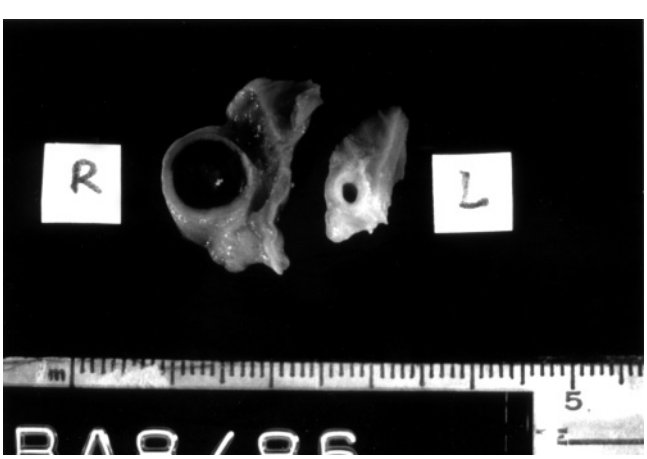

FIG. 27.32. Gross photograph of both coronaries. Note the aneurysmal dilatation with thrombotic occlusion of the lumen of right coronary artery.

PROLIFERATIVE AND NEOPLASTIC DISORDERS

Of the various neoplastic lesions described in association with pediatric AIDS, non-Hodgkin's lymphomas (NHLs) are the most common. There are no basic differences between NHL in adults described above and NHL in children with AIDS (410). Other neoplastic lesions in children include smooth muscle tumors, Kaposi's sarcoma, and leukemias. With the increasing incidence of human papilloma virus (HPV) infection and HIV infection in adolescent girls, it is conceivable that the incidence of HPV related genital lesions will increase in HIV-infected adolescent girls. These lesions, which include condyloma acuminatum with or without various grades of cervical intraepithelial neoplasia (CIN), can progress to invasive cervical carcinoma. Rapid progression of these lesions may occur due to immunosuppression in HIV infection. In fact a case of invasive cervical carcinoma has been reported in a 16 year old HIV-infected girl (411). Pediatricians should be alert to the possibility of HPV-related genital lesions and take steps for early diagnosis and treatment of these lesions so their progression is prevented.

It appears that smooth muscle tumors (SMTs) are the second most common neoplastic disorder in pediatric AIDS. Thirteen cases of SMTs involving GI tract, lungs, soft tissue, skin, and spleen (most of which are leiomyosarcomas and a few leiomomas) have been reported (412). Quantitative PCR done on the fresh frozen samples of the tumor tissue revealed 170 to 455 copies of EBV per 100,000 tumor cells. EBV receptor (CD21) was demonstrated in high concentration in the tumor cells by an immunoperoxidase method. In situ hybridization studies using an EBER probe showed the presence of EBV in tumor cells but not in the adjoining normal cells (413). These findings suggest that the EBV receptor may be upregulated in children with AIDS and EBV may enter the muscle cells and cause their transformation.

PERINATAL PATHOLOGY

Transplacental/perinatal transmission is by far the commonest route of transmission of HIV to children. Several large studies have demonstrated the ability of short-course antenatal/intrapartum prophylaxis with zidovudine or nevirapine to reduce perinatal HIV transmission dramatically (414,415). There are only a few systematic virologic and pathologic studies on placenta, abortuses, and stillborn fetuses from HIV-infected women to document intrauterine transplacental HIV transmission. HIV was isolated from amniotic fluid, thymus, lungs, spleen and brain of a 15- and a 20-week fetus, but pathologic description of the various fetal tissues and placenta was not given (416). Jauniaux, et al. (417) studied 49 placentas, seven fetuses and two stillbirths from Central African and European HIV-infected women with or without fully developed AIDS. No villitis was noted but irrespective of gestational age, the villi were coarse, cellular, hypovascularized and the intervillous spaces were narrow with fibrin deposition and calcification. There was a high incidence (43%) of chorioamnionitis, which was unrelated to HIV infection. The fetuses did not show any histologic lesions in the viscera. The two stillbirths had pneumonia (associated with chorioamnionitis) and nodular peribronchiolar and alveolar septal lymphocytic aggregates in the lungs. Ultrastructural studies in 13 placentas revealed isolated retrovirus-like particles with some morphologic similarities to HIV (100 nM in size, dense central or eccentric core) in the syncytiotrophoblasts, fibroblasts and endothelial cells in villous capillaries and free membranes. Other investigators have demonstrated the presence of HIV RNA and p24 protein in the trophoblasts, Hofbauer cells and endothelium of placentas from HIV-infected women (418,419). Systematic prospective virologic, immunologic, and pathologic studies of placenta, abortuses and stillborn fetuses of HIV-infected mothers with and without full-blown AIDS are needed to confirm the observations outlined above. Such studies on larger number of pregnant women in various stages of HIV infection would also provide data regarding timing of HIV infection of the fetus, the cell types and tissues of the fetus infected by HIV and the relationship of severity of HIV infection in the mother to that in the fetus.

Perinatal transmission, (i.e. transmission shortly before, during, or shortly after the process of birth) is probably far more common than intrauterine transplacental transmission. Findings in the cervical biopsy tissue of four HIV-infected women described by Pomerantz, et al. (420) and isolation of HIV from vaginal and cervical secretions reported by Wofsy, et al. (421) support the concept of perinatal transmission to the neonate (and also of heterosexual transmission of HIV). The findings described by Pomerantz, et al. (420) were as follows: Chronic cervicitis characterized by mononuclear cell infiltration and lymphoid aggregates in the mucosa and/or submucosal, isolation of HIV from cervical biopsy tissue and demonstration of HIV antigens in the monocytes, endothelial cells and lymphocytes in the cervical biopsy.

PATHOLOGY OF AIDS IN AFRICAN PATIENTS

The epidemiology and clinical spectrum of AIDS in Africa differ markedly from that in the United States and western European countries (422,423). Heterosexual activity, a history of prostitution or sexual contact with prostitutes, blood transfusion, the use of unsterilized needles in medical facilities, and vertical transmission from mother to infant are considered the primary modes of HIV transmission in African countries (424). Published histopathologic studies of AIDS in Africa are meager as a result of inadequacies of laboratory facilities in these

developing countries. Limited investigations have shown pathologic lesions similar to those described in western patients. However, the following differences in the frequencies and types of opportunistic infections and other lesions have been noted between these two groups (118,425–428): (1) MTB infections are more common, (2) MAI infections are infrequent, (3) Cryptosporidium and *Isospora belli* are frequently found in endoscopic biopsies, (4) PC pneumonitis is infrequent, (5) a generalized, pruritic, maculopapular dermatosis is seen in about 50% of patients as the initial disease presentation, and (6) growth retardation and chronic diarrhea are more frequently seen in African children with AIDS (118,429).

There are few studies comparing HIV-associated Kaposi's sarcoma and malignant lymphoma in African and western patients.

PREVENTING HIV TRANSMISSION IN THE CLINICAL LABORATORY

Occupational transmission of HIV to health care workers by sharps injuries or mucocutaneous contact is well reported (430–438); however, appropriate use of needle stick prevention devices, especially as part of a comprehensive prevention program, can significantly reduce the incidence of such injuries. Federal law now requires the use of sharps "devices to protect workers and many states have passed similar legislation.

To minimize exposure, microbiologic and other specimens requiring manipulation during processing should be handled under a laminar flow hood to control aerosol dispersion. Mechanical pipetting devices are routinely used and mouth pipetting strictly forbidden. Specimens requiring centrifugation are capped and placed in a centrifuge with a sealed dome. Accidental spillage of a specimen is promptly cleaned with a suitable disinfectant solution (439–442).

All laboratory work areas should be cleaned and sanitized at the end of each shift or at least daily using an appropriate chemical disinfectant such as 0.5% sodium hypochlorite (1:10 dilution of household bleach). Specimens leaking from their containers are discarded if specimen replacement is possible. Otherwise, the outside of the container is appropriately disinfected.

Tissue sent from the operating room for frozen section studies should be placed in leak-proof containers during transport and handled with latex or vinyl gloves to prevent inadvertent skin contamination. During cryostat cutting of specimens, the use of tissue-freezing aerosol is discouraged to prevent aerosolization. The cryostat and all cutting areas exposed to blood or body fluids should be decontaminated at frequent intervals with an appropriate germicide. Face shields or a facemask and goggles should be routinely worn during the gross examination and cutting of surgical specimens.

For health care workers, who are occupationally exposed to HIV, the U.S. Public Health Service issued guidelines for prevention and chemoprophylaxis in 1998. The exposure site should be washed with soap and water as soon as possible after exposure and then cleaned with sterile saline or disinfectant solution. Thorough irrigation should occur if the exposed area is mucus membrane. For post high-risk exposure, antiretroviral chemoprophylaxis should be offered (443). Agents used for post-exposure prophylaxis have had serious adverse effects, such as bone marrow suppression, peripheral neuropathy, nephrolithiasis, and hepatocellular injury. However, there are no reports of long-term sequela.

Autopsy Procedures

Currently, there is no documentation of an autopsy assistant or pathologist having contracted AIDS or seroconverting as a result of performing an autopsy on a patient with AIDS (444,445).

The autopsy recommendations of the National Committee of Clinical Laboratory Standards are for total-body barrier protection with water repellent protective clothing. This includes a hood that covers the hair, face shield, or safety goggles with mask to cover the nose and mouth, as well as water-protective boots, double surgical gloves, and, in certain instances, heavy overgloves (446). Aerosols generated by an oscillating electric saw (Stryker) can be minimized by the use of a plastic bag over the head and neck of the corpse and shielding the spray by keeping wet towels immediately adjacent to the blade. A circulating assistant outside the work area should be designated to perform tasks such as answering phones and pages and obtaining supplies. Some institutions, including ours, have elected to perform autopsies in special "isolation" rooms.

Following the autopsy, the closed body is washed with a detergent solution and then with dilute sodium hypochlorite, rinsed with water, and placed into a body bag. Tables, instruments, and floors are washed with a detergent to remove dried blood and fluids, and then decontaminated with a dilute solution of household bleach or other effective germicides. The prosector and assistant should discard all disposable materials into a specially marked bag for incineration. Reusable materials are cleaned and disinfected or autoclaved. Adequate washing or shower facilities should be available in the vicinity of the autopsy suite.

Recommendations for preventing nosocomially acquired HIV infection are designed to minimize the risk of mucosal or parenteral exposure to potentially infectious materials. This can be accomplished through the establishment of departmental protocols developed from known scientific, clinical, and epidemiologic information about HIV and its associated diseases. Special attention to inservice training of laboratory workers on the hazards posed by all specimens should diminish the risk of acquiring HIV in the clinical laboratory setting.

Chapter 28

Neuropathology of AIDS

Umberto De Girolami, Leroy R. Sharer, Dana Gabuzda and Ana Sotrel

HIV-1 causes neurologic dysfunction in as many as 20Ð30% of infected adults and children at some stage of their illness and can be isolated from the brain and cerebrospinal ßuid (CSF) of patients with neurologic syndromes (1Ð3). The spectrum of neurologic disorders includes HIV-1-associated dementia (HAD) and related cognitive and motor disorders (termed minor cognitive/motor disorder), vacuolar myelopathy, and peripheral neuromuscular disorders (1Ð5). The etiologic basis of these clinical syndromes is principally attributable to the direct and indirect effects of HIV-1 on the nervous system, to opportunistic infections, or neoplasms. It is well known that multiple etiologic agents may cause neurologic disease in any one affected individual.

The incidence of these disorders has declined remarkably since the introduction of combination highly active antiretroviral therapy (HAART) (6Ð11). However, neurologic disability continues to be an important complication of AIDS, since most current antiretroviral drugs have relatively poor central nervous system (CNS) penetration and the CNS is a reservoir for long-term viral persistence. In response to this challenge, through intensive research over the past decade, the mechanisms of injury of the nervous system are slowly beginning to be understood (3,12Ð19).

This review will discuss the range of neuropathologic abnormalities found in adults and children with AIDS.

NEUROPATHOLOGY OF AIDS

Post-mortem neuropathologic studies have demonstrated abnormalities in up to 80% of AIDS cases (see reviews (20Ð26)), though in the authors' recent personal experience and in that of published series (27), the percentage of cases in the various diagnostic categories listed below seems to be changing when the decades 1980Ð1990 and 1990Ð2000 are compared.

The neuropathologic abnormalities in adults can be subdivided into Þve categories: (1) direct and indirect effects of HIV-1 on the central nervous system (CNS)Ñ including HIV-1 encephalitis and vacuolar myelopathy; (2) opportunistic infections; (3) neoplasms, including primary CNS lymphoma and metastatic Kaposi sarcoma; (4) neuromuscular disorders; (5) AIDS-related illnesses in children and other less common conditions.

Direct and Indirect Effects of HIV-1 on the Central Nervous System in Adults

It was recognized early in the course of the study of AIDS, that some patients developed a unique encephalitic syndrome. The neurologic syndrome is characterized by a variably-progressive, subacutely-evolving dementia (including principally slowness of thought, loss of retentive memory, apathy and language disturbances) and is associated with motor dysfunction (incoordination of limbs, ataxia of gait, and eye movement abnormalities) and sphincteric disturbances (28,29). This syndrome has been termed *HIV-associated AIDS dementia complex* (ADC) (30).

Over a Þfteen year span, the possibility that HIV-1 could infect CNS cells was supported by isolating the virus from the cerebrospinal ßuid (CSF) of patients early in the

course of their disease and by identifying it in the neural tissues of patients with (and without) ADC, utilizing a variety of virological and molecular methods (31–34). Meanwhile, numerous autopsy studies of patients with AIDS, including thorough examinations of the CNS, were conducted in this country and in Europe (4,20,22,35–46). These post-mortem studies established the existence of a new form of viral encephalitis with the now generally accepted designation "*HIV-encephalitis*". Review of this large body of work indicates that the neuropathologic aspects of HIV encephalitis in adult patients differ considerably depending on the stage of evolution of the disease. These neuropathologic, and to some extent neurologic, stages can be grouped into three phases of the illness*: acute HIV-1 encephalitis, subacute HIV-1 encephalitis and late manifestations of HIV-1 encephalitis*.

Acute HIV-1 Encephalitis

Within one week of seroconversion patients may develop symptoms of meningitis and encephalopathy lasting several days or weeks. In these mildly symptomatic patients and in HIV-1 positive, neurologically asymptomatic people, antibodies to HIV-1 are detectable in the cerebrospinal fluid (CSF), and/or virus can be isolated from the CSF (31,47–49). Furthermore, in this population, there is radiologic imaging and clinical laboratory evidence of CNS injury in the acute stages of the disease (50–52). Individuals who have come to post-mortem examination at the time of this early phase of HIV-1 invasion, or shortly thereafter, having died of unrelated causes (e.g. accidental death, suicide, homicide) have been found to have mild to moderate meningeal lymphocytosis, focal cerebral white matter myelin damage, perivascular gliosis, and chronic inflammatory lesions in and around small blood vessels, principally in the white matter (23,24,32,53–56). Immunohistochemical studies with antibodies directed against the p24 HIV-1 viral antigen and PCR studies to detect HIV-1 DNA in paraffin-embedded human brain tissue have demonstrated the presence of the virus in HIV-positive asymptomatic cases (57).

Subacute/Late Manifestations of HIV-1 Encephalitis

The most complete post-mortem studies of patients dying of AIDS months or years after the onset of the disease, as reported from this country and Europe in the first decade of the study of the disease, described the histopathology of a unique viral encephalitis (4,20,22, 35–45). This newly recognized illness was called "*subacute encephalitis*" by Nielsen and coworkers (37), and the term retains validity today inasmuch as it emphasizes the cellular response of the inflammatory reaction in this phase of the disease. Subsequently, with further virological understanding of the etiologic basis of the illness, the term "*HIV-1 encephalitis*" became accepted in a "Consensus Report", 1991. For purposes of description, we like to indicate the stage of evolution of the illness, thereby integrating the original and the newer terminology.

In the majority of cases of acute or subacute HIV-1 encephalitis *macroscopic* external examination of the brain shows that the meninges are clear and that there is no evidence of cortical atrophy. Brain weight is also normal (20,22). Progressive loss of cerebral volume in AIDS patients has been reported in studies using magnetic resonance imaging methods (52). On imaging studies, sectioning of the formalin-fixed brain, or whole brain sections, in a minority of cases, there is ventricular dilatation and widening of the Sylvian fissures and adjacent cortical sulci (Fig. 28.1a and b). The cortical mantle is of normal thickness as established by quantitative measurements (58). Posterior fossa structures and the spinal cord are not remarkable.

By far the most careful neuropathologic *microscopic* studies of patients with AIDS have been carried out in individuals who have died within months or years of the onset of the illness. The full range of abnormalities which characterize subacute HIV-1 encephalitis has been defined in these cases. This distinctive spectrum of microscopic findings which has been found to affect both the white matter and gray matter will be described in detail.

The Inflammatory Lesion in the White and Gray Matter (Fig. 28.2a–c)

The earliest neuropathologic studies described the *microglial nodule* as a cardinal feature of subacute HIV-1 encephalitis. These are aggregates of nuclei of elongated or bean-shaped microglial cells that cluster around regions of tissue disruption (sometimes with foci of necrosis). The surrounding tissue shows reactive astrocytosis and slight pallor of myelin-staining. The nodules can occur diffusely throughout the brain, though the extent and density of lesions varies considerably, apparently irrespective of the clinical severity of neurologic manifestations. In the experience of Petito and co-workers (39), Kure and collaborators (59), and in our observations (22), microglial nodules occur most often in the subcortical white matter, though they also be seen in the diencephalon/basal ganglia and brainstem/cerebellum, but are ordinarily less common in the cerebral cortex.

Infiltrates of *macrophages,* characterized by abundant foamy (sometimes pigment-laden) cytoplasm, are often found in association with the microglial nodules, or they may occur in sizable collections perivascularly, especially in the white matter of the cerebral hemispheres and cerebellum. Diffuse microglial proliferation has also been noted, particularly in the late stages of the disease (see below).

Thirdly, an important component of the inflammatory lesion are the *multinucleated giant cells*. These are

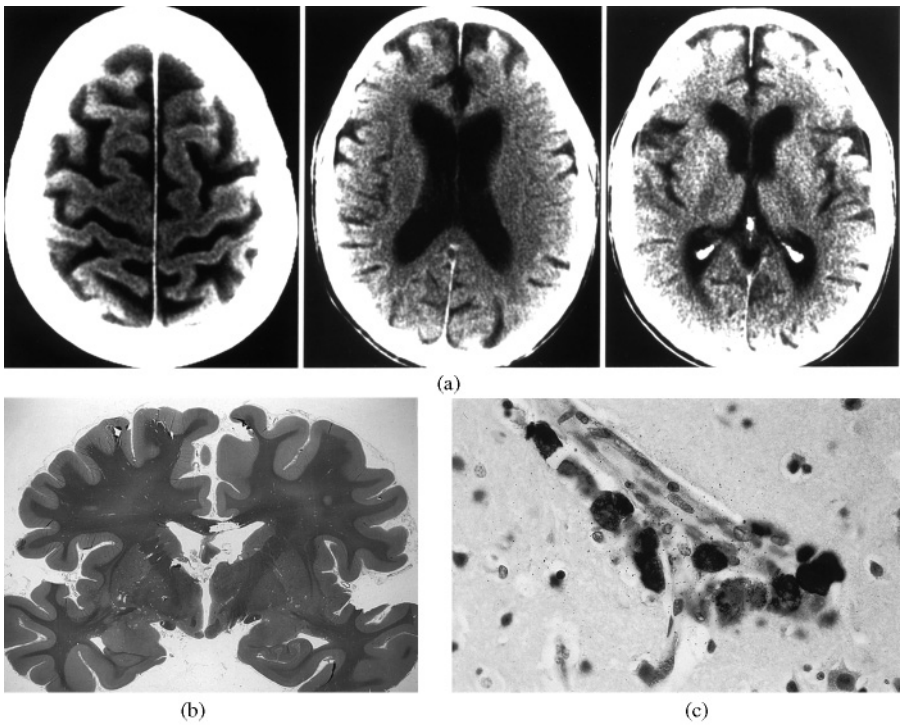

FIG. 28.1. HIV-1 encephalitis. (a) CT scan showing ventricular dilitation and sulcal widening in a 61 year old man with clinically progressive dementia and pathologically-proven HIV encephalopathy. (b) Whole brain section of paraf n-embedded brain at level of mammillary body showing some pallor of myelin staining in the centrum semiovale, mild ventricular dilatation, and widening of sulci (LFB stain for myelin).

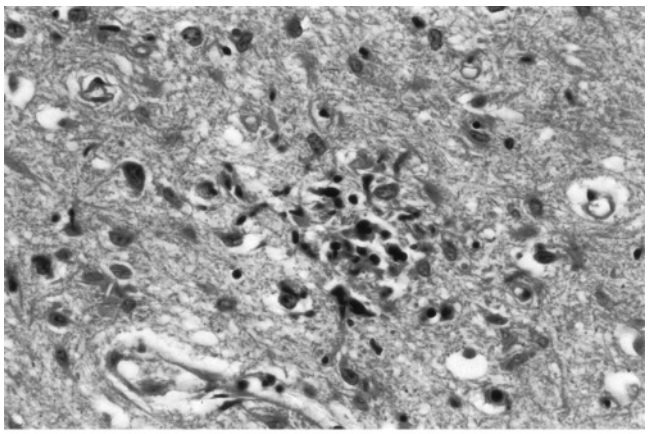
macrophage-derived cells with several nuclei either haphazardly-arranged or aggregated within a brightly eosinophilic, irregularly-shaped cytoplasm. They can occur admixed with other cells in microglial nodules or appear in isolated clusters in the parenchyma and perivascular spaces. They tend to occur in the same topographic distribution as the microglial nodules and macrophages. Multinucleated cells have been demonstrated to result from fusion of macrophages and have the same immunohistochemical properties as macrophages. The diagnostic importance of the multinucleated giant cells was Þrst emphasized by one of us (60), and other investigators have interpreted their presence as an essential component of the histopathologic picture (23,61,62). It is now apparent that their occurrence is characteristic of subacute HIV-1 encephalitis, as they are not often seen at either extreme of the illness (22,23,46).

Many studies, utilizing electron microscopy, anti-HIV-1 antibody immunocytochemistry, *in situ* hybridization, and polymerase chain reaction methods, have conclusively demonstrated the presence of HIV-1 in tissue sections of brain and spinal cord (20,25,63Ð72). HIV-1 has been found principally within the macrophages, multinucleated giant cells and microglial cells that characterize the lesion of subacute HIV-1 encephalitis as described above. These affected cells have been shown to be CD4-positive, which HIV uses as a binding site (73,74). Although there had been early speculation that the microglial nodules and multinucleated giant cells might be the result of non-HIV-related opportunistic viral infections, there seems to be no evidence of immunoreactivity to HSV, CMV and papovavirus antigens within microglial nodules containing HIV-positive mononuclear cells when these agents are searched for with immunohistochemical and electron microscopic methods (64,66,74,75).

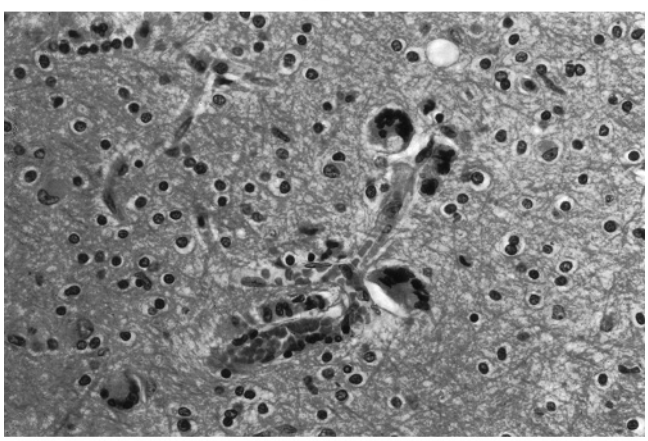
Until very recently, in spite of an assiduous search, there has been no incontrovertible evidence of HIV-1 infection of neurons or oligodendrocytes in human tissue (77,78). The work of Torres-Mu–oz and collaborators has demonstrated HIV-1 gene sequences in neurons in the CA3, CA4 and CA1 regions of the hippocampus utilizing laser capture microdissection methods on autopsy tissue; these investigators postulate non-productive latent infection of neurons (78). The implications of this interesting new Þnding in the pathogenesis of AIDS-associated dementia will be discussed below. Furthermore, recent evidence also suggests limited and nonproductive infection of astrocytes (57,72,79Ð81) particularly in the early stages of the disease. Endothelial cell infection by HIV-1 will be discussed below.

Lesions of the Microcirculation

The second striking abnormality seen in subacute HIV-1 encephalitis is evident in the intracerebral capillaries and venules (microcirculation). As mentioned above, an important manifestation of *acute* HIV-1 encephalitis consists of foci of perivascular and intravascular inßammation (24,56); recent evidence indicates HIV-1 infection of endothelial cells in this early phase of asymptomatic involvement of the CNS (57). In the *subacute* phase of the illness the inßammatory component subsides and the microcirculatory changes consist of thickening of the wall



(a)



(b)

of the blood vessels, increased cellularity, with enlargement and pleomorphism of endothelial cells (82). These vascular abnormalities are usually associated with prominent perivascular aggregates of HIV-1-positive monocytes and multinucleated cells (Fig. 28.3). Microcirculatory abnormalities are most commonly observed in the white matter of the centrum semiovale and in posterior fossa structures. A particularly interesting aspect of both the acute and subacute vascular lesions is that they are sometimes related to microinfarcts. The microinfarcts are characterized by small regions of white matter necrosis and prominent axonal swelling with little inßammatory reaction. The brain microinfarcts are histologically identical to those seen in the nerve Þber layer of the retina, recognized clinically as cotton wool spots (Fig. 28.4a and b). Cotton wool spots are an important and characteristic funduscopic abnormality in patients with AIDS and have an established relationship with the retinal microcirculation (83).

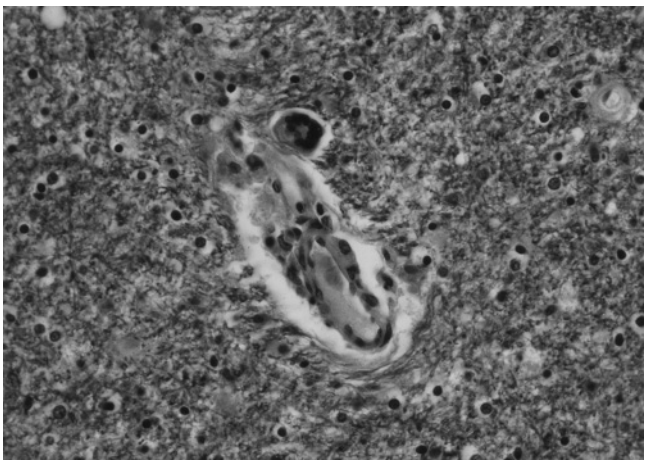

FIG. 28.3. Thickening of blood vessel in the white matter and perivascular multinucleated giant cell (LFB stain for myelin).

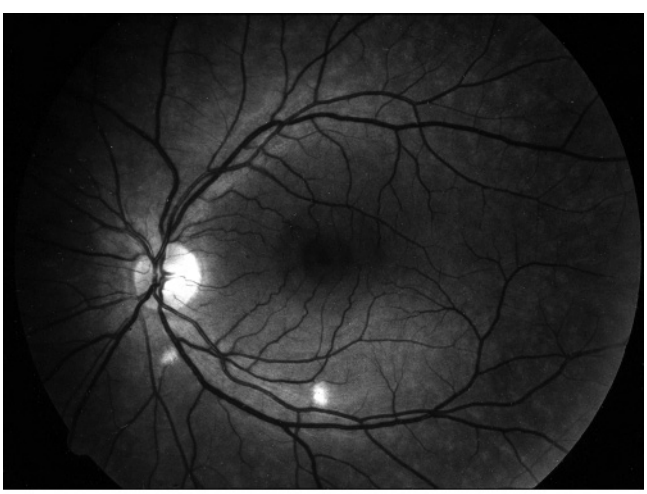
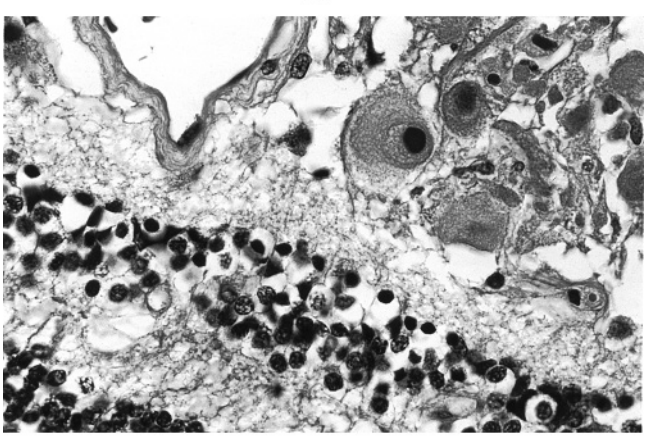


(a)



(b)

FIG. 28.4. Cotton-wool spots. (a) Funduscopic image of uffy super cial exudates. (b) Microscopic section through lesion in nerve ber layer, next to vessel, showing multiple concentric cores within axonal swelling (H&E).

The pathogenesis of these lesions of the microcirculation could well be related to infection of cerebral endothelial cells by HIV-1 as reported by some investigators (57,66,72); there are also reports demonstrating infection of retinal endothelial cells (84,85). These abnormalities of the microcirculation were at Þrst postulated to give rise to altered vascular permeability (82). Leakage of ßuid and plasma proteins around the perivascular extracellular spaces was subsequently demonstrated by Rhodes (86), Petito et al. (87), Power et al. (88), and Dallasta et al. (89). There has been no systematic neuropathologic study of the topographic distribution of these sites of increased vascular permeability over the course of the disease, although neuroradiologic studies indicate the basal ganglia have increased early enhancement suggesting disruption of the BBB in these regions over other areas of the brain (90).

The sequence of events that leads to penetration of HIV-1 into the human brain are unknown (13,15,16,21,91). At the time of initial viremia it is speculated that the endothelial cells of cerebral microcirculation may well become transiently infected; indeed there is now evidence of infection of the brain endothelial cells of HIV-1-positive asymptomatic individuals who died of unrelated causes (57). The considerable numbers of circulating, latently-HIV-infected monocytes (77) may then adhere to the damaged endothelial cells and perivascular astrocytes and be transported across the blood-brain barrier (BBB) (92,93).

The potential injurious effect of this BBB breakdown on the surrounding white and gray matter is discussed below.

Demyelinating Lesions

One of the truly remarkable aspects of the disease, which was especially evident to us upon examination of whole brain sections embedded in celloidin or in paraÞn and stained with conventional myelin stains, is the presence of a multifocal, poorly-circumscribed or diffuse faint pallor of myelin staining which involves primarily the centrum semiovale but also less often affects the white matter of the cerebellum and the brain stem. At high magniÞcation the typical white matter lesions consist of poorly deÞned regions of tissue rarefaction wherein there is a moderate reduction in the number of myelinated Þbers, scattered macrophages/microglial cells, few reactive astrocytes, relative sparing of axons, and virtual absence of any other inßammatory cell. Microglial nodules and/or multinucleated giant cells are sparse or absent within these lesions. Less severe forms of this process (perhaps early lesions) are characterized by focal, often angiocentric regions of myelin loss often around microcirculatory abnormalities as described above. Transitions between the focal and more diffuse white matter lesions are frequent. Very severe examples (late lesions) show extensive destruction of myelinated Þbers, conspicuous axonal damage with axonal spheroids in the centrum semiovale, and secondary degeneration. In patients with long-standing disease, on macroscopic examination, the white matter of the centrum semiovale appears unusually Þrm (20,94). Giometto et al. (95) and Raja and co-authors (96) have documented axonal injury within areas of demyelination using an antibody to b-amyloid precursor protein. This leukoencephalopathy has been studied in detail by several workers (38,39,62,82,88,96Ð98).

The pathogenesis of these white matter abnormalities is uncertain. Some investigators (40,99) have noted alterations in the number and size of oligodendrocytic nuclei within areas of myelin pallor, while others have not (100). Thus far, conclusive evidence of HIV infection of oligodendroglial cells in human tissue has been lacking.

Alterations in BBB permeability as discussed above could cause accumulation of edema ßuid within the extracellular space as well as allow various circulating macromolecules to enter the cerebral parenchyma which could cause injury to myelinated Þbers.

Other as yet hypothetical causes for the white matter degeneration include the destruction of myelin and axons by soluble substances elaborated by HIV-infected monocytes or autoimmune-associated demyelination. In experimental models, HIV-1-infected monocytes are believed to migrate through the BBB (101Ð103), and recent work by Dallasta and co-workers has provided structural evidence that BBB tight-junction proteins are affected in HIV-1 encephalitis. Viral replication within the transformed macrophages might then follow, with a release of virions and subsequently, infection of other cells which express CD4 receptors on their surface (i.e. macrophages and microglial cells) through the binding of the HIV envelope glycoprotein gp120 to the CD4 receptor. Cytokines released by the infected cells might then diffuse into the extracellular spaces of the white matter and cause damage to myelin and axons.

Neuronal injury and apoptosis

A particularly elusive and troublesome issue in the understating of the effects of HIV-1 on the CNS has been the issue of neuronal injury. This has been an especially critical issue to resolve because, as mentioned above, one of the cardinal clinical neurologic manifestations of the disease is dementia, a neurologic abnormality ordinarily associated with structural, physiological and biochemical abnormalities of neurons.

It is now believed by most workers in this Þeld that the neuropathologic substrate of ADC is *subacute HIV-1 encephalitis* as described above (104,105). However, as mentioned above, light microscopic evidence of neuronal injury is not a prominent feature of the illness. To address this issue, workers have postulated that indeed there is neuronal damage in HIV-1 encephalitis, but that the injury requires specialized techniques to demonstrate it morphologically and that perhaps the nature of the injury is a

physiologic/molecular dysfunction of the neuron, rather than an overt destruction of the cell.

There is considerable evidence that the brain serves as a reservoir of large quantities of proviral unintegrated DNA which apparently is predominantly localized to selective regions, including basal ganglia and hippocampus (34,106). While some quantitative studies suggest that brain viral burden correlates with the severity of ADC (25,107), others reach opposite conclusion (33). We have already reviewed above which CNS cells seem to be primarily infected with the virus. What then might the mechanisms of HIV-1 neuronal injury?

A number of workers have suggested that the neuronal dysfunction is due to indirect neurotoxic effects. Cytokines, including tumor necrosis factor and other soluble factors or proteoloytic enzymes, liberated by the inßammatory cells (largely macrophages and microglial cells) which permeate the brain in subacute HIV-1 encephalitis, have been shown to be toxic to both neurons and their processes and to glia (108Ð112) (see also review (16)). The work of Glass et al. (113) has shown that the severity of the ADC in the patients analyzed correlated best with postmortem brain tissue density of macrophages and microglial cells, as identiÞed by immunohistochemical methods, rather than with the viral burden within the infected macrophages and microglial cells. This fact has led to the speculation that control of systemic HIV replication might limit the development of the dementia (114). According to the *in vitro* studies of Lipton (115,116), another mechanism of impairment of neuronal function involves the HIV-1 envelope glycoprotein gp120, or a fragment of this protein, which was shown to be toxic to rodent neurons by inducing an inßux of intraneuronal free calcium. This toxicity was later shown to be mediated through the participation of macrophage/microglial cell-derived factors which acted via NMDA receptors (117,118). It was also demonstrated that neurons poor in calcium-binding proteins (parvalbumin and calbindin), located in the cerebral cortex, are relatively vulnerable to injury, whereas those rich in these proteins (basal ganglia and hippocampus) are unaffected (119,120). Further evidence of the participation of infected inßammatory cells in mediating neuronal toxicity comes from the experimental study of Tardieu and collaborators (121) who have shown neuronal cell injury only after adhesion between HIV-infected monocytes and neurons. Cell-cell interactions have also been shown to exist between HIV-infected macrophages and astrocytes (13,79,93). Finally, Dallasta and collaborators have reported that the disruption in the BBB which occurs in the brains of patients with HIV-1 encephalitis and ADC is associated with HIV-infected macrophages (89), again suggesting that it is the infected macrophage which is the key culprit in causing neuronal injury.

The relationship between these neurotoxic factors and the development of neuronal and glial injury currently under active investigation (see reviews (15,46,93,122, 123)). Morphologic evidence of neuronal injury, possibly caused by the release of macrophage-derived neurotoxic factors or other mechanisms, has been presented by several laboratories in an attempt to explain the clinical syndrome of ADC. This evidence rests on the demonstration of quantitative neuronal loss in the cerebral cortex, reduction in cell size, and/or dendritic injury in cortical neurons (119,124Ð130). On the other hand, in a prospective study of six patients with HIV-associated dementia compared with six controls (non-demented, non-AIDS) there was no statistically signiÞcant difference in the number of cortical neurons (Brodmann areas 4, 9, 40) in the two groups (58). Other methods of determining cell death utilizing the TUNEL technique to detect apoptosis have documented both neuronal and astrocytic injury in HIV-encephalitis, though careful quantitation of this phenomenon correlated with morphometric cell-counting has not yet been accomplished (81,131Ð135).

Still, in spite of all the cited studies, a plausible pathogenesis for the ADC has remained elusive. It remains a complete mystery how the putative neurotoxic substances could be acting on neurons of the cerebral cortex and elsewhere when systematic neuropathologic examinations in a number of laboratories have shown relatively few microglial nodules, multinucleated giant cells and macrophages/microglia in patients with clinical evidence of severe dementia. Quantitative assessments of neuronal injury or death have not uncovered damage of such magnitude that would easily explain the clinical syndrome. The abnormalities of the microcirculation described above are rare in the cortex. Possibly, the white matter injury caused by a breakdown of the BBB might be giving rise to a sub-cortical dementia, though often enough the neuropathologic changes do not appear to be so severe to afford a reasonable explanation for the dementia in most cases.

Vacuolar Myelopathy and Vacuolar Encephalopathy (Fig. 28.5a and b)

In early 1985 two separate groups of investigators (5,136) described the clinical and pathologic aspects of a previously unrecognized disorder of the spinal cord in patients with AIDS, occurring late in the course of their disease. The disease, named vacuolar myelopathy by Petito and collaborators, was characterized neuropathologically by multiple 10Ð100 μm vacuoles within the white matter of the posterior and lateral columns of the lower thoracic cord. They also stressed the importance of Þnding foamy macrophages in association with these vacuolar lesions so as to be certain to rule out artifactual changes. In the twenty cases recorded, the severity of the lesions was graded (I-mild, II-moderate, III-severe) and transition forms between the prototypes were frequent. In subsequent large studies (39,76,137Ð140), the disorder has been estimated to be demonstrable at post-mortem in

20–30% of unselected patients with AIDS in the Western hemisphere; less often in Europe. It has also been noted that, although extensive reactive gliosis is rare, microglial nodules and multinucleated giant cells may be seen in the cord away from the zones of vacuolar myelopathy. Ultrastructural studies indicate both axonal and myelin injury (141,142).

The etiology/pathogenesis of vacuolar myelopathy is unknown (143). The early reports pointed out the striking resemblance of the cord lesions to those of Vitamin B12 deficiency (subacute combined degeneration) but this etiology was negated by appropriate serum assays (5). The pathogenetic role of HIV-1 in vacuolar myelopathy has been controversial. Ho et al. (31) were able to isolate the virus from CSF and post-mortem spinal cord tissue in a patient with clinical manifestations indicative of a myelopathy. Budka et al. (144), Maier et al. (145), and Eilbott et al. (146) have demonstrated by immunohistochemistry and in situ hybridization that the macrophages and multinucleated giant cells in the vicinity of the vacuoles are HIV positive suggesting that the cause of vacuolar myelopathy is HIV. On the other hand strong evidence has been adduced to demonstrate just the opposite viewpoint. Kamin and Petito (147) reported 12 cases of vacuolar myelopathy in immunosuppressed patients without AIDS. Rosenblum et al. (148) demonstrated, in a comprehensive study combining immunohistochemistry (p24), in situ hybridization (DNA), and HIV isolation, that the presence of the virus correlated not with the presence of vacuolar myelopathy but with an inflammatory myelitis which was in every way similar to subacute HIV-1 encephalitis as described above. Grafe and Wiley (138) also showed a complete lack of association between immunocytologic localization of HIV antigens and vacuolar myelopathy. Shepherd and colleagues (140) studied the spinal cords of 90 patients with AIDS and found no evidence that proximity of productive HIV-1 (as assessed by quantitative PCR) infection is implicated in the pathogenesis of vacuolar myelopathy. Our own experience with a series of cases from Paris and Boston agrees with these findings (76). Similarly, the reports of neuropathologic observations of the spinal cords of children with AIDS again dispute the assertion that vacuolar myelopathy is caused by HIV-1 (149,150). Finally, there has been some interest in the role of s-adenosyl methionine deficiency or malutilization in the pathogenesis of vacuolar myelopathy which has resulted in clinical trials (151,152). Similar lesions have been described in the cerebrum (multifocal vacuolar leukoencephalopathy) (153). When they occur in the basis pontis, (multifocal pontine leukoencephalopathy) (154) they can to a large extent be necrotizing and demonstrate focal calcification.

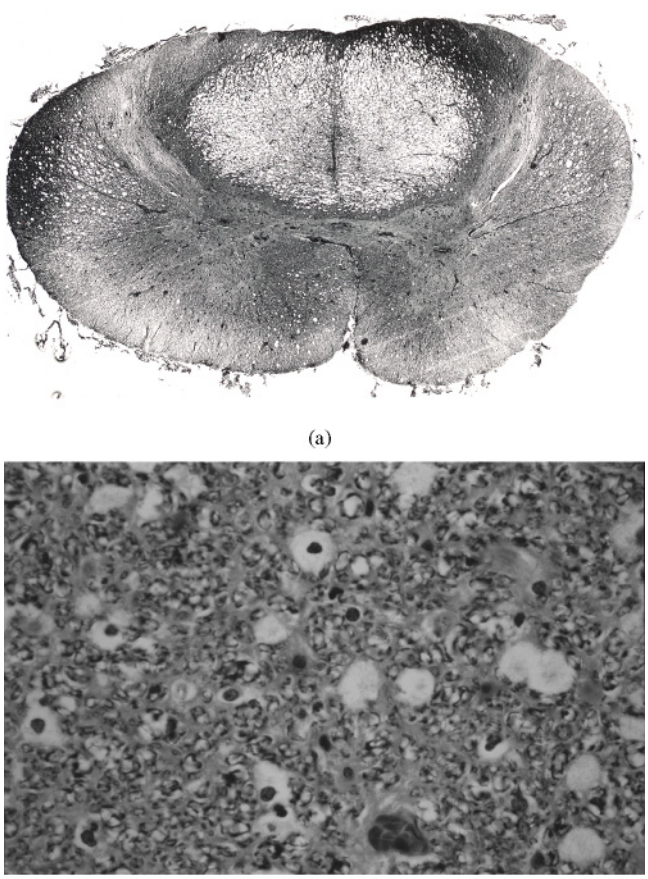


FIG. 28.5. Vacuolar myelopathy of AIDS. (a) Transverse section through high lumbar cord. Note extensive vacuolization of myelin in posterior columns and lateral corticospinal tracts (LFB stain for myelin). (b) High magnification view of posterior column abnormality showing numerous macrophages (LFB stain for myelin).

It can now be concluded that AIDS-associated vacuolar myelopathy is probably not related directly to HIV-1 infection of the spinal cord. Available evidence suggests that it may be the result of a yet unidentified indirect effect, possibly a myelinolytic cytokine (155). The report by Goudreau et al. (156), in which transgenic animals expressing HIV genome in oligodendroglia were found to develop vacuolar changes in the white matter of the spinal cord lends credence to the speculation there is an indirect role for HIV in the pathogenesis of vacuolar myelopathy.

The spinal cord has also been reported to be the site of "degenerative" changes to the corticospinal tracts or the posterior columns. Such changes have been attributed to secondary Wallerian degeneration consequent to proximal injury in either the pyramidal system or the dorsal root ganglia (97,157).

OPPORTUNISTIC INFECTIONS

In the early days of the AIDS epidemic in the United States and Western Europe, opportunistic infections (OIs) of the central nervous system (CNS) were a major cause of morbidity and mortality. Since that time, there has been improved recognition and medical management of these conditions. In addition, the incidence of many of CNS OIs

has declined in people who have been treated with highly active antiretroviral therapy (HAART). Several parameters affect the occurrence of various OIÕ in the CNS of patients with AIDS, including:

1. The severity of immune deÞciency.
2. The age of the patient (adult, child).
3. The geographical location where the patient resides.
4. The effectiveness of control of HIV-1 infection in a particular patient.

Much information about CNS OIs is derived from older data, from the 1980s and early 1990s, prior to the availability of HAART, which became the standard of care in the U.S. from 1996 onwards. However, CNS OIs continue to occur in people living in countries like the U.S., for several reasons:

1. Patient compliance with complex antiretroviral treatment regimens may be poor.
2. People with limited access to medical care may have unrecognized, and hence untreated, HIV-1 infection.
3. The development of resistance mutations of HIV-1 can lessen the effectiveness of antiretroviral therapy.

In countries where HAART and adequate prophylaxis of OIs are largely unavailable, the incidence of CNS OIs is startlingly similar to what was observed in the pre-HAART era in the U.S., as has for example been reported from India 158).

The common CNS OIs in AIDS will be described below, beginning with viruses, and continuing through parasites, bacteria, and fungi. It should be recalled that patients with AIDS may have more than one type of CNS pathology, and more than one OI of the CNS (159).

Viral Opportunistic Infections

Cytomegalovirus (Fig. 28.6aÐd)

In patients who are either untreated or inadequately treated with antiretroviral agents, cytomegalovirus (CMV) is the most common cause of OI in the CNS, according to published autopsy studies from the U.S. (39). Despite this high incidence, the diagnosis of CMV encephalitis during life is difÞcult to make, since this entity has few clinically distinguishing characteristics. This is not surprising, given the pathology of this disorder, in which there are widely scattered glial-microglial nodules, usually with no large lesions that would be apparent with radiographic imaging techniques. A pathological variant, seen in up to 10% of cases (160), exhibits involvement of the ependymal surfaces of the ventricles termed ÒventriculofugalÓ (66). This periventricular pattern is reminiscent of the congenital form of CMV that occurs in newborn infants. On microscopical examination of both the glial-microglial nodule form and the periventricular form, one Þnds typical, enlarged cells containing large, dark, intranuclear inclusions that are virtually pathognomonic of CMV. On immunohistochemical examination, using an antibody that recognizes CMV antigen, both the intranuclear inclusion and the cytoplasm are positive.

Clinically, patients with CMV encephalitis often manifest a non-speciÞc, subacute encephalopathy that is difÞcult to distinguish from either HIV-associated dementia or a metabolic encephalopathy. The clinical diagnosis can be assisted by the Þnding of speciÞc CMV nucleic acid sequences in cerebrospinal ßuid (CSF), as determined by polymerase chain reaction (PCR) (161). The CSF examination is otherwise not speciÞc, except in those relatively rare cases of CMV lumbrosacral polyradiculitis, in which polymorphonuclear leukocytes may be seen, in the absence of bacteria or fungi (162).

CMV is the most frequent OI of the CNS in children with AIDS (163). HIV-1-infected children have a higher incidence of developing non-congenital CMV infection than do non-HIV-1-infected children, and CMV infection is a risk factor for poor outcome in young children with AIDS (164). Young HIV-1-infected children who are co-infected with CMV have a higher incidence of neurological deterioration, including impaired brain growth and progressive motor deÞcits (164), probably due to synergistic deleterious effects of CMV and HIV-1 on the brain and spinal cord.

Progressive Multifocal Leukoencephalopathy (PML) (Fig. 28.7aÐd)

PML is an opportunistic viral infection of the CNS that is caused by the papova virus JC (165). In the earliest reports of this disease, prior to its identiÞcation as a viral OI, PML was noted to be associated with either immune deÞciency or immune suppression (166). Thus it was not surprising that this disease should be reported in patients with AIDS (167). JC virus has particular tropism for oligodendrocytes, the cells that produce and support CNS myelin; this accounts for the main clinical and pathological features of PML, which is characterized by multiple white matter lesions. There is some tropism for astrocytes as well (168), which can result in enlarged, bizarre astrocytes in late stages of the lesions, a histopathological change that can be mistaken for astrocytoma.

JC virus has high seroprevalence in adults, with seroconversion usually occurring during late childhood (169). For this reason, PML is uncommon in children with AIDS (170), although it can be expected to occur in adolescents. There is evidence from *in vitro* studies that HIV-1 infection can exacerbate JC virus infection, since the HIV-1 gene product *tat* can transactivate the JC virus promoter (171).

Grossly, the lesions of PML are highly characteristic, with scattered, patchy, granular zones of loss of white matter, with relative sparing of gray matter. On microscopical examination, evolving lesions of PML contain enlarged oligodendroglial nuclei that contain dark intranuclear inclusions that Þll the nucleus, although in some instances they resemble Cowdry type A inclusions, with a space between the inclusion and the thickened nuclear membrane. These inclusions can be shown to harbor papova virus antigen by immunocytochemistry and characteristic papova virus particles by electron microscopy (169), as well as speciÞc JC virus nucleic acid sequences by in situ hybridization (168). More longstanding lesions, which may extend focally into gray matter, are associated with loss of myelin and axis cylinders, with few or no intranuclear inclusions, since the oligodendrocytes have largely been destroyed. These late lesions contain bizarre astrocytes, and they may be associated with gross atrophy of both white and gray matter structures.

The occurrence of PML in people with AIDS who are not on adequate antiretroviral therapy is associated with a poor prognosis (172). Since the introduction of HAART, the ÒnaturalÓ history of PML in these patients has changed, with improved survival and quality of life (173). However, the incidence of PML in patients on HAART has declined less than that of other OIs of the CNS. PML can be reliably diagnosed by Þnding characteristic, multiple white matter lesions on MRI scans, combined with detection of speciÞc JC virus sequences in CSF by PCR, thereby obviating the need for brain biopsy in most instances (174,175). The Þrst reported randomized treatment protocol for PML found that cytosine arabinoside was ineffective for this

disorder (172), and no other therapy has as yet proved to be useful. One study has suggested that cidofovir may improve survival in people with AIDS and PML who are on HAART (176), but another European study has not supported these Þndings (177).

Herpes Virus Infection

The most common opportunistic herpes virus infection of the CNS is that due to varicella-zoster virus (VZV). Diagnosis of this virus infection can be difÞcult, since it has protean manifestations. However, the combination of skin lesions and spinal cord involvement should raise suspicion of VZV (178,179). Diagnosis during life is most reliably accomplished by identifying speciÞc VZV nucleic acid sequences in CSF by PCR. Patients with AIDS may have necrotizing myelitis, meningoencephalitis, brain and spinal cord infarcts, or giant cell arteritis (178,180). Pathologically, the diagnosis can be facilitated by Þnding eosinophilic Cowdry type A intranuclear inclusions, which however may be difÞcult to locate and which are identical to those of herpes simplex virus (HSV). Immunocytochemistry and in situ hybridization are necessary for conÞrmation of VZV infection in tissue, in most cases.

A small number of cases of HSV infection, mainly HSV-1, has been diagnosed by pathologists in autopsies of people with HIV-1 infection and AIDS. It is not clear if

this infection occurs more frequently in this patient population than it does in the general population, since HSV encephalitis is uncommon in both. Such cases in patients with AIDS may be atypical, with absence of both CSF pleocytosis and of typical imaging studies of temporal lobe involvement. Pathologically, there may be a necrotizing encephalitis without typical inßammatory features, rendering the clinical diagnosis difÞcult (181,182) From a pathological point of view, HSV encephalitis is characterized by eosinophilic Cowdry type A intranuclear inclusions, which are positive for HSV antigens on immunocytochemistry. However, by current standards, this technique cannot differentiate HSV-1, which has been reported to cause brain infection in patients with AIDS, from HSV-2, which has been reported to cause myelitis; such a distinction needs to be made by either PCR or in situ hybridization (183).

Parasitic Infections

Toxoplasmosis (Fig. 28.8aÐc)

Encephalitis or brain ÒabscessesÓ due to *Toxoplasma gondii* are common in people who have low CD4 counts and high HIV-1 viral loads. In the U.S., toxoplasmosis has classically been the most common cause of a mass or space-occupying lesion in the brains of people with AIDS. CNS toxoplasmosis in people with AIDS is more common in people who live in France and Germany than in people who live in the United States or the United Kingdom (184). It is also a common occurrence in people with AIDS in sub-Saharan Africa, South America, and India (158,185,186).

Pathologically, the diagnosis of toxoplasmosis can be suspected in lesions with abundant necrosis, with a variable inßammatory response, including polymorphs and perivascular lymphocytic cuffs that mimic the angiocentric pattern of primary brain lymphoma (PBL) (187). Diagnostic accuracy is enhanced by the use of immunocytochemistry, since organisms, particularly scattered, free tachyzoites, can be difÞcult to distinguish from cellular debris (188). The Þnding of encysted bradyzoites along with free tachyzoites on routine hematoxylin and eosin-stained sections is highly suggestive of toxoplasmosis, but this appearance is less sensitive for the diagnosis than is immunocytochemistry.

In the mid-1980s, clinicians in the U.S. developed an algorithm for patients with CNS mass lesions, with a recommendation for treatment for 10 days to two weeks using antibiotics directed against *T. gondii* (189). If the lesions regressed during the period of therapy, a presumptive diagnosis of toxoplasmosis was made. If, however, the lesions progressed either clinically or radiographically, the patient would require other diagnostic modalities, including brain biopsy, for diagnosis. The most common alternate cause of CNS mass lesion in patients with AIDS is primary brain lymphoma (PBL), which clinically and pathologically can be confused with toxoplasmosis. Since resistance of *T. gondii* to antibiotics has apparently not developed, treatment failure would rule

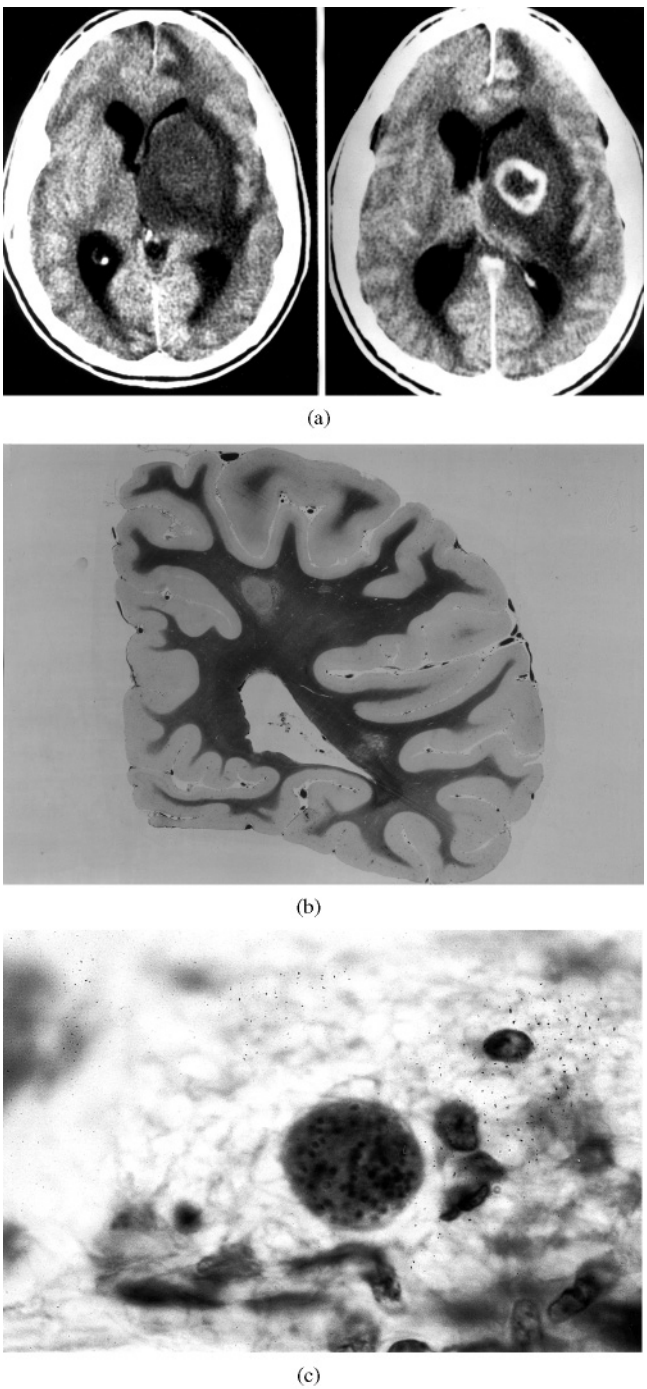

FIG. 28.8. Toxoplasmosis. (a) Computed tomography scan (CT scan) before (left) and after (right) contrast enhancement in a 32 year old patient with AIDS and toxoplasmosis. Note hypodense space-occupying mass with edema and contrast-enhancement. (b) Whole-brain coronal section through occipital lobe showing multiple discrete lesions (Loyez stain for myelin). (c) Bradyzoite of *Toxoplasma gondii* (H&E).

out toxoplasmosis, in most instances. As is the case with HAART, it is important to assess whether the patient has been compliant with anti-toxoplasmosis therapy or not. This was vividly illustrated recently for one of us (LRS), when a brain biopsy on a patient who was alleged to have been treated for toxoplasmosis for two weeks had readily demonstrable *T. gondii* organisms. In retrospect, it was recognized that this patient had indeed not been compliant with his medication and was therefore inadequately treated.

In the U.S., clinicians continue to see patients who have HIV-1 infection that has not been previously diagnosed and who present with CNS mass lesions. The Þnding of *T. gondii* organisms on biopsy of a brain lesion should prompt the physician to evaluate the patient for HIV-1 infection, which in most jurisdictions requires the patientÕs consent. One of us (LRS, unpublished) recently encountered a patient with recurrent hemangioblastoma of the cerebellum who developed new, multiple, rapidly progressing cerebral lesions, after treatment with corticosteroids for edema associated with the recurrent tumor. Biopsy of one of the new lesions revealed toxoplasmosis with numerous free tachyzoites, as seen on immunocytochemistry using an anti-Toxoplasma antibody. This patient was not known to have either HIV-1 infection or a risk factor for acquisition of this virus, but post-biopsy studies demonstrated that he was indeed infected. He succumbed before adequate anti-*Toxoplasma* therapy could be initiated.

In contrast to the situation in adults with AIDS, CNS toxoplasmosis is distinctly unusual in children in the U.S. In our experience, the most common cause of CNS mass lesions in children with AIDS is PBL. For this reason, we have recommended that a child with AIDS who develops a CNS mass lesion should be considered to have PBL until proven otherwise, and this will usually require brain biopsy (190). Children with AIDS who reside in or come from developing countries, on the other hand, may develop CNS toxoplasmosis, as for example was recently reported in a clinical study from Brazil (191).

The decline in incidence of OIÕs in patients treated with HAART has extended to CNS toxoplasmosis. A recent report (192) has suggested that the incidence of PBL may becoming more frequent in these people, leading to the recommendation of study of brain mass lesions with thallium single-photon emission computed tomography (SPECT) and CSF PCR examination for speciÞc Epstein-Barr virus (EBV) nucleic acid sequences, both of which can be helpful in the clinical diagnosis of PBL. Brain biopsy is not without signiÞcant risk in this patient population (1998).

Other Parasitic Infections

A few parasitic infections can resemble CNS toxoplasmosis, on histological examination. Among these is *Trypanosoma cruzii*, or Chagas disease, which can cause brain infection in people with AIDS who either live in or come from endemic areas. Brain involvement with this organism can be seen in acute infection (194) as well as in reactivated infection (195) In addition, microsporidia have also been reported in the CNS in people with AIDS (198), and these organisms also bear some resemblance to the free tachyzoites of *T. gondii*. Immunocytochemical differentiation of these organisms from *T. gondii* is essential, particularly in biopsy tissue.

Bacterial Infections

Bacteria are uncommon causes of CNS OIs in patients with AIDS. Of increasing importance is *Streptococcus pneumoniae*, which has been reported to cause acute leptomeningitis (197). Gram-positive cocci have been reported in brain abscesses (197), and this is an especially important complication in people who self-administer drugs of abuse by the intravenous route, in whom there may be concomitant endocarditis. Although infrequent, *Nocardia* sp. should be considered in the differential diagnosis, when biopsy reveals an acute brain abscess in a patient with AIDS (Sharer, unpublished). A diagnosis of *Nocardia* in biopsy tissue may be facilitated by Gram stain and methenamine silver stain for fungi, which may reveal organisms before they are reported by the microbiology laboratory.

By contrast with bacteria, mycobacterial infections are relatively frequent in the CNS of people with AIDS, especially leptomeningitis due to *Mycobacterium tuberculosis*. Other types of infection with this organism can be seen, including tuberculoma and tuberculous abscess (198). CNS tuberculosis can be expected in regions of the world where both *M. tuberculosis* and HIV-1 infection are common, such as sub-Saharan Africa, as well as in certain populations in the U.S., for example in incarcerated individuals (197). Tuberculous leptomeningitis in AIDS has a poor prognosis (198), and it may also be complicated by vasculopathy (199). Treatment is often unsuccessful, even with strains of the organism that are sensitive to anti-tuberculous therapy.

Mycobacterium avium/intracellulare, or *M. avium* complex (MAC), is a common OI in people with AIDS. However, clinically important CNS involvement with atypical mycobacteria is rare (200) (Fig. 28.9).

Fungal Infections

Cryptococcus (Fig. 28.10a and b)

Cryptococcal meningitis, due to the yeast *Cryptococcus neoformans*, the most common opportunistic CNS fungal infection in general, is also the most common CNS fungal infection in patients with AIDS (187) in whom it may be

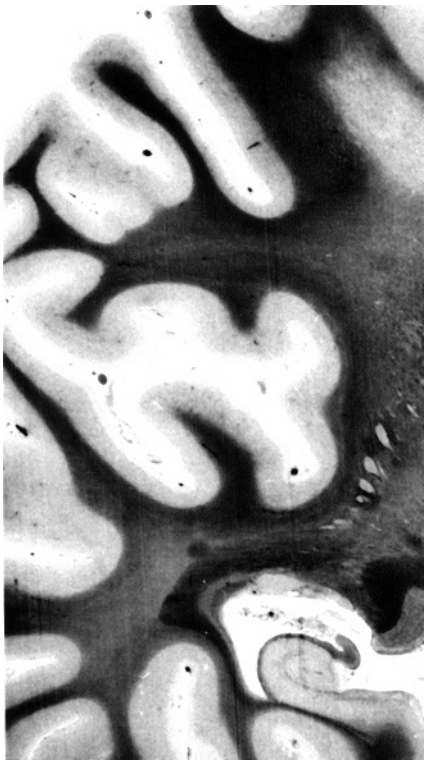

FIG. 28.9. Mycobacterium avium intracellulare. Note small patch of myelin destruction in centrum semiovale (Loyez stain for myelin).

the presenting manifestation of both HIV-1 infection and AIDS. This organism can be successfully treated with oral ßuconazole, if the diagnosis is made before the lesions become too advanced. The use of HAART has rendered the occurrence of this infection less common than it formerly was, with autopsy studies from the mid-1980s showing an incidence of cryptococcal meningitis in up to 6% of cases (39). HAART has also made the management of the disease much easier.

In AIDS, cryptococcal meningitis typically has minimal inßammation in the CSF compartment, although this can vary, from no inßammatory cells at all to well-developed granulomas (189). The organisms also have a propensity to grow in the Virchow-Robin spaces about blood vessels, particularly in the basal ganglia, where large numbers of them can form gelatinous masses that are readily seen on imaging (201) and that can be appreciated grossly at autopsy. For the most part, the organisms do not invade through the pia into the brain parenchyma, and there is usually minimal astrocytic reaction around the masses of organisms surrounding the vessels. However, on rare occasion the organisms can invade the brain, where they can cause hemorrhage and necrosis (Sharer, unpublished).

Cryptococcal meningitis is unusual in children, as are most OIs of the CNS, probably due to low exposure of children to opportunistic and other pathogens, with this exposure increasing with time and therefore with age. Although cases have been reported in children (202,203), we have seen no cases of cryptococcal meningitis at postmortem in our own autopsy series (163), which now numbers 80 cases.

Other Fungal Infections

Aspergillus sp. infections can occur in people who have disseminated aspergillosis, including people with AIDS. The lesions in brain are frequently hemorrhagic, because of the propensity for the fungus to destroy blood vessel walls. Patients with AIDS are no more likely to have

FIG. 28.10. Cryptococcosis. dissemination of *Aspergillus* infection to the CNS than are other immunocompromised patients with disseminated disease (204).

CNS OIs have been reported with *Histoplasma capsulatum* and *Coccidioides immitis* (205), either in areas where these infections are endemic, or in people who have lived in those areas. Clinically both of these fungal infections in patients with AIDS can be confused with infection due to *M. tuberculosis*. On pathological examination of tissue specimens, *C. immitis* can be readily identified, due to the large size (up to 100 μm or more) and characteristic morphology of the spherules (206). Special stains for fungi, such as PAS and Gomori methenamine sliver, are useful for identification of both of these agents, with small forms, 2–4 μm in diameter, often intracellular, for *H. capsulatum* (207).

NEUROMUSCULAR DISEASES

Neuropathies (Fig. 28.11a–c)

Patients with AIDS are susceptible to a wide range of cranial and peripheral nerve disturbances (4,62,208–214) see also reviews (210–212,215–218). The most commonly reported clinical syndromes include: (1) acute and chronic inflammatory demyelinating polyneuropathy (AIDP, CIDP); (2) distal painful sensory polyneuropathy; (3) polyradiculopathy; (4) autonomic neuropathy; and (5) mononeuritis multiplex. A sensory "ataxic" neuropathy due to ganglioneuronitis has also been described (157,219). The histopathologic findings observed in most of these cases include segmental demyelination, axonal degeneration, and epi- and endoneurial mononuclear cell inflammation. The etiology of these AIDS-associated neuropathies is undoubtedly multifactorial and often obscure. HIV has been cultured from the nerve in some cases of AIDS-associated neuropathy (31,64,212); however, in a series of 24 cases the virus could not be demonstrated by immunohistochemistry within Schwann cells or elsewhere in the nerve (139). In one patient reported by Bailey et al. (210), electron microscopy demonstrated retrovirus-like particles within peripheral nerve axoplasm. Necrotizing arteritis has been reported in some cases of AIDS-associated neuropathy (220). In the two patients described by Gherardi et al. (220) HIV replication was demonstrated by in situ hybridization

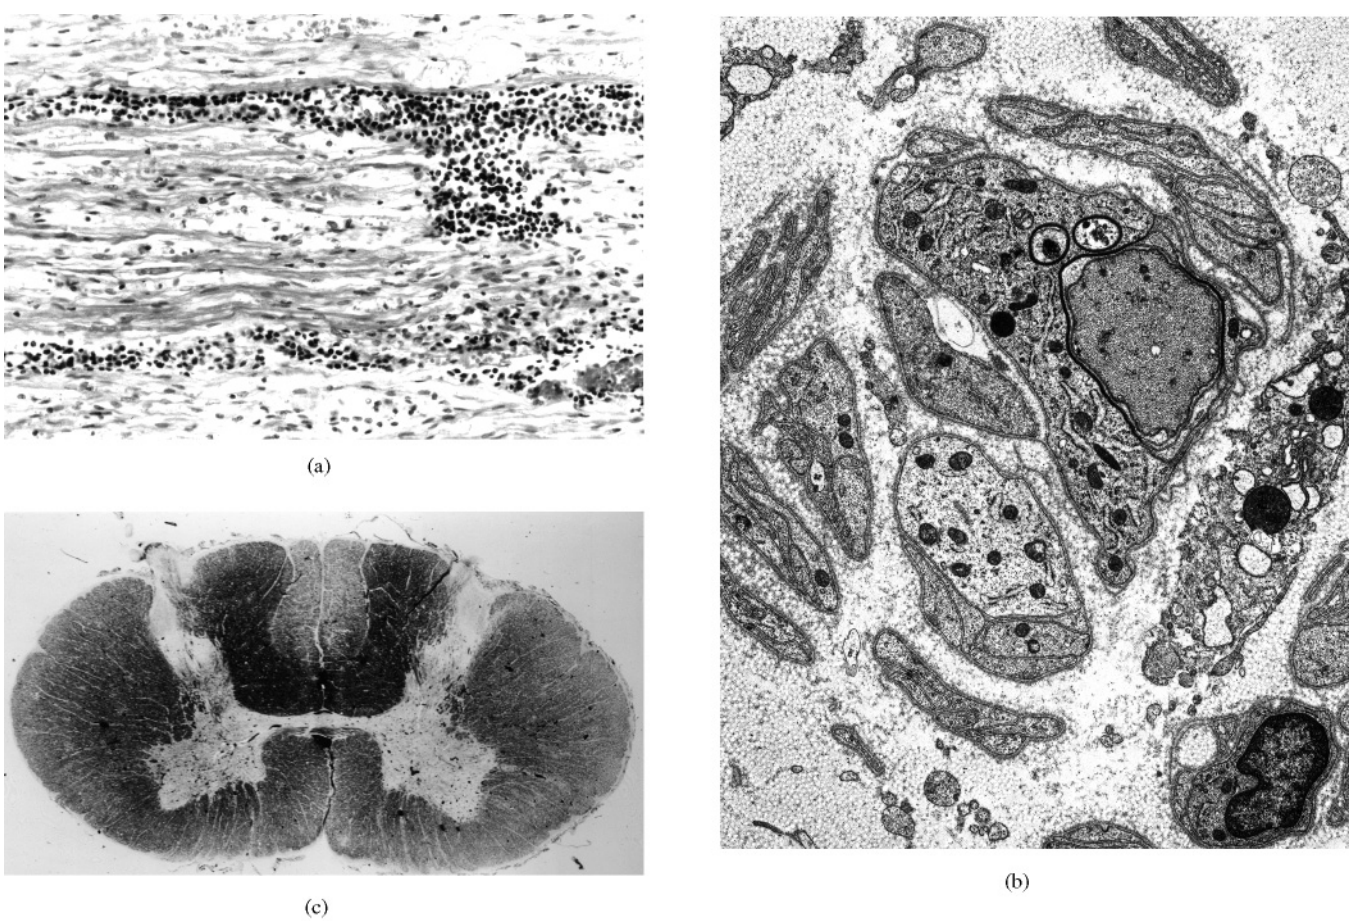

FIG. 28.11. Nerve. Demyelinating polyneuropathy. Note chronic inflammatory cells (a) in longitudinal section of nerve (H&E stain) and ultrastructural image of thinly myelinated fiber (b). (c) Transverse section of cervical spinal cord showing posterior column degeneration in fasciculus gracilis secondary to injure of dorsal root ganglion cells. (Woelke for myelin).

within mononuclear cells inÞltrating the vessels. Other infectious agents may cause a neuropathy in some HIV-infected individuals. In the patients reported by Bishopric et al. (221), Eidelberg et al. (222), and Behar et al. (223) a Guillain-BarrŽ-like syndrome was related to CMV. Lanska et al. (224) described a HIV-positive patient with syphilitic polyradiculopathy. Other possible causes for AIDS-related neuropathies include immune-mediated attack against peripheral nerve components triggered by HIV or other viruses, or by the immunodeÞciency state itself; various toxic, metabolic, and nutritional factors, and inÞltration of nerves and/or roots by neoplasm (e.g. lymphoma).

Myopathies (Fig. 28.12a and b)

Inßammatory myopathy has been the most frequently described skeletal muscle disorder in patients with AIDS or ARC (215,218,225Ð236). The disease is characterized by the subacute onset of proximal weakness, sometimes pain, and elevated serum creatine kinase. The histologic Þndings in these cases have included muscle Þber necrosis and phagocytosis, T-cell lymphocytosis and interstitial inÞltration with HIV-positive macrophages, and in a few cases cytoplasmic bodies and nemaline rods (215,229, 231). There have been no reports of direct viral invasion of skeletal muscle cells. An inßammatory myopathy has also been described in simian AIDS (237). Wiley et al. (238) reported a patient with polymyositis who was seropositive for both HTLV-I and HIV. Using in situ hybridization and immunocytochemistry, they observed direct infection of muscle Þbers by HTLV-I but no evidence of HIV in muscle or inßammatory cells.

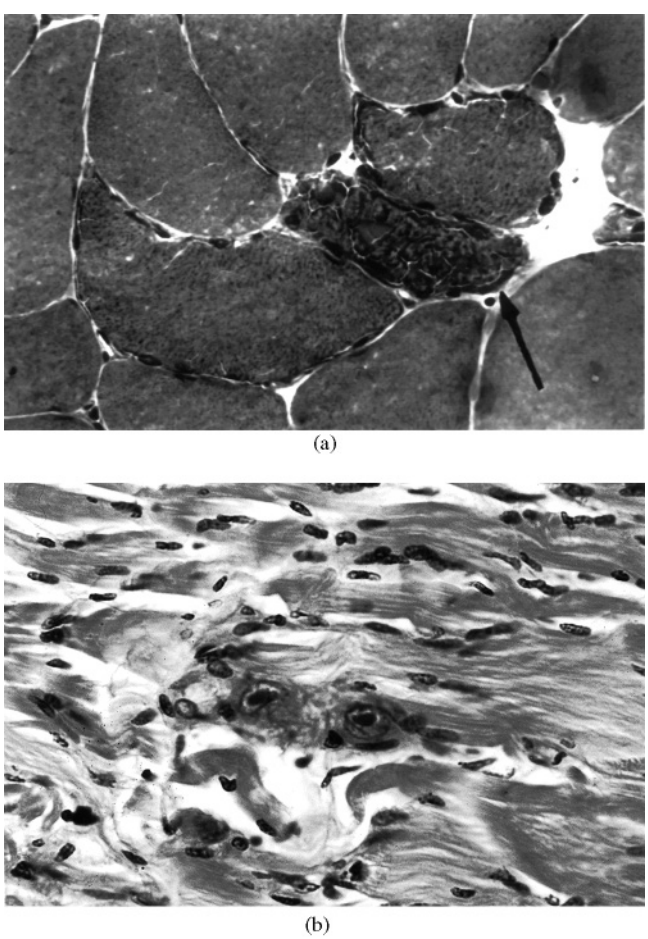

FIG. 28.12. Muscle. (a) Ragged-red ber. (modi ed Gomori trichrome stain on frozen muscle). (b) CMV involving skeletal muscle (H&E stain).

The pathogenesis of the inßammatory myopathy is not clear. The hypothesis that skeletal muscle cells are a primary target of HIV has not been borne out by tissue culture, ultrastructural or viral localization studies. An alternate possibility is that there is an attack on skeletal muscle cells by immune effector cells or that an opportunistic infectious agent alters muscle membranes rendering them the target of an autoimmune reaction akin to idiopathic polymyositis. In a case of HIV-associated myopathy which we have studied, we suggested that the virus might localize to the vascular bed of skeletal muscle, whether or not skeletal muscle is itself a target cell (239). The hypothesis was based on the presence of structural abnormalities of the microcirculation, immunocytochemical localization of the virus within monocytes around vessel walls, and evidence of altered vascular permeability (extravasation of red blood cells, iron pigment-laden macrophages). Such regional distribution of viruses has been proposed as one possible mechanism of viral tropism.

There have also been several reports of an acute toxic myopathy with myoglobinuria developing in AIDS patients treated with zidovudine (AZT) (235,240,241). These cases seem to illustrate a different pathologic process from the inßammatory myopathy described above. In several subsequent series (241,242), muscle biopsies demonstrated the presence of numerous Òragged redÓ Þbers (Þbers containing abnormal mitochondria with paracrystalline inclusions) which suggested the presence of a toxic mitochondrial myopathy. Some patients with AIDS may develop proximal muscle weakness with normal creatine kinase, with severe type II Þber atrophy seen on muscle biopsy (215,243). This condition may be related to poor nutrition, rapid weight loss, prolonged bed rest, or remote effect of malignancy. Instances of infectious myositis due to CMV and toxoplasmosis are also on record (242).

AIDS-RELATED ILLNESSES IN CHILDREN AND OTHER LESS COMMON CONDITIONS (Fig. 28.13)

The neuropathologic abnormalities encountered in children with AIDS, although somewhat different from those in adults, will be brießy reviewed. Up to the advent of intensive antiretroviral treatment of HIV-positive expectant mothers, neurologic disease was reported to be

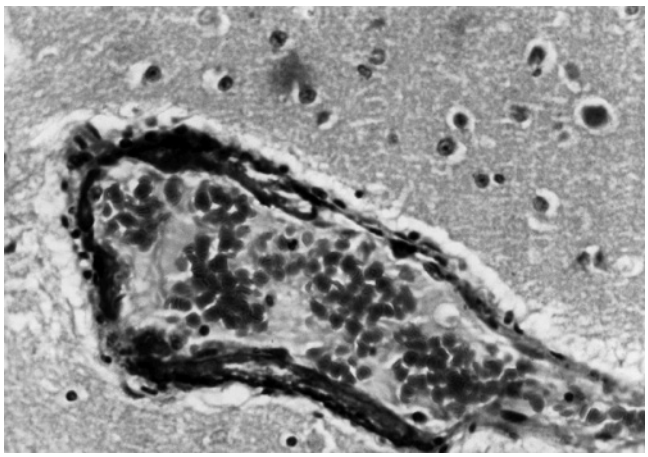

FIG. 28.13. Pediatric HIV-1 encephalitis. Note plate-like mineralization in large vessel of basal ganglion (H&E).

common in children with AIDS (244–246). Clinical manifestations of neurologic dysfunction are evident by the first years of life and include microcephaly with mental retardation and motor developmental delay with long tract signs. The presence of progressive HIV encephalopathy in children with untreated HIV-1 infection indicates a poor prognosis for survival, especially for younger children.

The neuropathologic features of AIDS in children have been discussed in a few comprehensive reports and reviews (21,38,247–256). The most frequently reported macroscopic abnormalities are calcific deposits within the basal ganglia and deep cerebral white matter, micrencephaly and diffuse firmness of the supratentorial white matter. These findings are demonstrable with radiologic studies (246,257). Histopathologically, the characteristic findings include lesions of the medium-sized and small blood vessels of the basal ganglia and subcortical white matter characterized by mineralization of the vessel wall and narrowing of its lumen without associated inflammatory changes of any great severity. Calcific deposits may also be found scattered throughout the white matter and in association with destructive lesions. Many patients have also had histopathological changes of HIV-1 encephalitis, similar to those seen in adults, including characteristic multinucleated giant cells. The severity of the encephalitis in children is often greater than seen in adults, with more numerous lesions and more widespread involvement of the CNS (163). Immunocytochemical and ultrastructural studies of children with HIV encephalitis have also demonstrated the same abnormalities as noted in adults (256,258). Studies have suggested amelioration of some of the lesions of HIV-1 encephalitis by antiretroviral therapy, particularly with zidovudine, with reduction in the percentage of cases having multinucleated giant cells. This change in pathology was not noted for calcifications, however. There have been no detailed quantitative studies of neuronal injury, but neuronal apoptosis has been recorded (259). Also remarkable in children has been the extent of white matter damage in the cerebral hemispheres and cerebellum, which often show extensive pallor of myelin staining, reactive astrocytosis, and evidence of axonal injury.

As mentioned above, CNS OIs are less frequent in the brains of children with AIDS than in the brains of adults (163). The most obvious explanation for this phenomenon is that children have less time to become exposed to the common opportunistic pathogens than do adults. This information should direct the management of children with AIDS, particularly those with expansile lesions in the brain, since, in the United States, these are much more likely to be due to primary brain lymphoma than to toxoplasmosis (190). Vacuolar myelopathy is also encountered in the spinal cords of children with AIDS much less often than it is in adults, for reasons that are not apparent (163).

The introduction of HAART has affected children as well as adults with AIDS. The Pediatric AIDS Clinical Trial Group has recently reported, in PACTG 219, reduction of mortality in children, from 5.3% in 1996, to 0.7% in 1999, following the introduction of HAART. Although the effect of HAART on neurological function was not addressed in this report, other recent studies have noted improved growth and immune function in treated children. Indeed, complete cessation of HIV-1 replication can be achieved by combination therapy given during the first three months of life, an effect that can be expected to cut dramatically the incidence of progressive HIV-1 encephalopathy in children.

Lesions of large blood vessels (macrocirculation) are known to occur in patients with AIDS; these may or may not be associated with HIV encephalitis and include instances of embolic cerebral infarction, hemorrhages at various sites of the gray and white matter, intimal thickening with narrowing of the vascular lumen, and vasculitis (4,260–265).

Rare instances of fulminating multiple sclerosis-like leukoencephalopathy occurring at almost any stage of AIDS have been described in several clinicopathologic studies. The neuropathology of these lesions closely approximates acute disseminated encephalomyelitis or multiple sclerosis-like syndromes (266–269). In this context, some cases showing plaque-like demyelinating lesions have been found to be due to opportunistic infection with herpes viruses (270–273).

NEOPLASMS

Patients with AIDS have a high risk of developing systemic and CNS malignancies, but this trend appears to be subsiding. A recent collaborative study (276, and the National Cancer Institute/AIDS-Cancer Match Registry) that compared the records of 98,336 AIDS patients to that of 1,125,098 non-AIDS cancer patients, revealed that 7% of AIDS patients had Kaposi's sarcoma (KS). This represents 310-fold increase in relative risk (RR) of

developing KS compared to non-AIDS patients; 2% (113-fold) had non-Hodgkin lymphoma (NHL). Moreover, 712 AIDS patients (1%), had other types of cancer, at the incidence rate that was on an average 2-fold higher than that of the general population. These included: angiosarcoma (37-fold); anal and cervical human papilloma virus (HPV)-related cancers (277) (32-fold); Hodgkin disease (8-fold); malignant astrocytic CNS tumors 3.5-fold. The most noteworthy Þgures appeared recently in the National Center for Health Statistics report on cancer death rate associated with HIV-infection in USA (278). Their analysis of death certiÞcates from 1990Ð1995, of AIDS patients aged 25Ð44 years, revealed 22,275 deaths caused by a combined HIV-infection and cancer; 55% had KS, 38% had NHL and about 2% had both.

Kaposi Sarcoma (KS) (Fig. 28.14)

KS-associated with AIDS is an aggressive polyclonal, angioproliferative, usually multifocal disorder, caused by a persistent infection of the endothelial progenitor cells by human herpes virus-8 (HHV-8) also known as KS associated herpes virus (KSHV). The virus induces uncontrollable proliferation of infected cells and neoangiogenesis (277). The incidence of KS has decreased since the introduction of HAART (278). Between 1988 and 1998, KS was diagnosed as an AIDS-deÞning illness, in 9.6% of all Western European AIDS patients; however, there was a signiÞcant decline from 13% in 1988 to 6% in 1998 (275). Likewise, the International Collaboration on HIV and Cancer (ICHC), including 23 cohort studies in developed countries, reported a decline in the incidence rate of KS from 15.2% in 1992 to 4.9% in 1999 (ICHC, 2000). In the CNS KS has been exceptionally rare and invariably as a consequence of metastases from systemic sites (279,280).

FIG. 28.14. Kaposi sarcoma. Note eshy lesion of conjunctiva.

Lymphoproliferative Disorders (LPD) and AIDS

There are two relatively rare forms of LPD that occur in the patients with AIDS, both causally related to KSHV-HHV-8. One is the primary effusion lymphoma (PEL), also known as a ßuid-Þlled body cavities (peritoneal, pleural, pericardial)-based, large cell type B-lymphoma; the other is a plasmacytic variant of multicentric Castleman disease (MCD) (280,281). Far more commonly, patients with AIDS develop LPD that are pathogenetically linked to Epstein-Barr virus (EBV). This category includes a relatively rare, mostly systemic, aggressive variant of H, and NHL.

AIDS-associated NHL (75Ð95% are extranodal) are classiÞed as: (a) systemic, diffuse Burkitt type lymphoma (BL); (b) systemic, diffuse large cell (DLCL) and LC-immunoblastic lymphoma subtypes; (c) primary CNS lymphoma (PCNSL) (282). According to one study, NHL have increased in all European countries from an average of 3.6% in 1994 to 5.3% in 1998 (283). However, there has been an overall decline in the worldwide incidence rates of NHL from 6.2 prior, to 3.6 following the introduction of HAART (284). The pathogenesis of AIDS-related systemic NHL is yet to be fully understood. Postulated pathogenetic mechanisms include virally-mediated oncogenesis, cytokine dysregulation, and oncogene activation or loss of tumor suppressor genes (285). For the most part, these are phenotypically B-cell tumors that are biologically and genetically heterogeneous with a variable rate of EBV infection (range from 30% in BL to 80% in DLCL) (286).

Nervous System Lymphoma-Associated with AIDS

A 1994 Southeast England study of trends in the incidence of PCNSL, independent of age, gender, or HIV status (287), demonstrated a nine-fold increase in PCNSL over the preceding Þve years. This did not seem to be related to AIDS epidemic, although HIV status was known for only 39 of 210 PCNL patients, of whom eight were HIV-positive. Likewise, another 1995 epidemiological study of AIDS-related CNSL (288), demonstrated an increase in frequency of CNSL over the previous decade; 40% of AIDS patients with systemic NHL also had secondary leptomeningeal tumorous involvement, and 7.6% of autopsied AIDS patients had highly malignant B-cell CNSL.

Secondary meningeal lymphoma, also known as lymphomatous meningitis (LM), most commonly represents a complication of an immunoblastic, or large cell subtype of a B-cell systemic NHL. According to one study (289), detectable EBV infection of the systemic NHL is predictive of the secondary CNS involvement; presence of EBV-DNA in CSF often precedes clinical and neuroradiological signs of a CNS spread. Furthermore, about 7% of PCNSL-s develop CSF-borne dissemination of tumor cells

resulting in LM. PCNSL in non-AIDS patients develop leptomeningeal and subependymal dissemination in 42% of cases at presentation and in 41% at the time of recurrence (290), indicating that the incidence of LM secondary to AIDS-related PCNSL, may be underestimated. CSF obtained through lumbar puncture from all patients with LM contains diagnostic tumor cells (291). For an exhaustive discussion of the clinical presentation (frequently reßecting involvement of cranial nerves), imaging, modes of treatment and outcome of LM see (291). Large B-cell type lymphoma has rarely been reported to originate primarily in the peripheral nerves (292).

Primary CNS Lymphoma (PCNSL) (Fig. 28.15aÐe)

AIDS-associated NHL almost always presents as an extranodal disorder manifesting as a PCNSL in 23% to 25% of all NHL cases (293Ð295). Some studies report no statistically-signiÞcant decline in the incidence of PCNSL as a result of extensive use of HAART (296); others have detected an unequivocal decrease in PCNSL between 1995Ð1999 (297).

A recent Multicenter AIDS Cohort prospective study (MACS) of the natural history of HIV infection among homosexual men in Baltimore, Pittsburgh, Chicago and Los Angeles (298), recorded the most dramatic and statistically signiÞcant decrease in the mean incidence rate (no./1,000 person-years) of AIDS-associated PCNSLs. This went from 4.3, during the 1993Ð1995 predominant employment of combination therapy without protease inhibitors, to 0.4 in the 1996Ð1998 of HAART time (298).

Although pathogenesis of PCNSLs in AIDS may in part be related to presently undeÞned genetic alterations, EBV is considered to be the major etiologic factor. This is based on the virtually omnipresent infection of PCNSLs by EBV, and an expression of EBV-encoded transforming latent membrane protein antigen LMP-1 by about 50% of cases (286). Whereas still speculative, most believe that PCNSL in AIDS arises from EBV-infected and subsequently immortalized B-cells that enter CNS and continue to grow unchecked because of T-cell deÞciency and limited natural killer-cell activity at such an ÒimmunoprivilegedÓ site (293,308).

Presenting neurological signs and symptoms reßect PCNSL propensity for supratentorial location and multicentricity. Involvement of eyes occurs in 5Ð20% of cases (299), whereas spinal cord lesions are rare. Signs of increased intracranial pressure and focal neurological deÞcits are most common. This may include: progressive headache, altered mental status, hemiparesis, aphasia, memory impairment and partial epilepsy. In PCNSLs with meningeal or periventricular dissemination, headache, cognitive decline and cranial nerve palsies may be predominant signs (291,300,301).

Diagnosis of PCNSLs associated with AIDS is usually made by a series of tests that may involve:

a. Neuroradiologic studies (CT&MRI) that detect a solitary lesion in 29% of cases, or multicentric tumors in 50Ð70% of patients (300,301). The most common anatomical sites of PCNSL-s include basal ganglia and frontal lobes, followed by parietal, temporal and occipital lobes. Corpus callosum and periventricular white matter are affected in about 20% of cases; both supra and infratentorial lesions are seen in about 18% of cases; isolated cerebellar or brainstem lesions are very rare; MRI detects more lesions than CT (291). By CT most lesions are of low density; with contrast more than 80% show either rim or irregular peripheral enhancement (IPE); likewise, most contrast-enhanced T1-weighted MRI images show either ring or IPE. Multifocal tumor tissue necrosis is the pathologic correlate of heterogeneous, patchy enhancement; peripherally enhancing lesions, pathohistologically have an extensively necrotic center, surrounded by an abundance of newly-formed vessels cuffed by viable tumor cells. Normal CT images of an affected brain most likely correspond to a diffusely inÞltrative, perivascular, inßammatory-like pattern of tumor growth. Structural imaging tools, CT and MRI, cannot reliably separate PCNSL from a potentially treatable, infectious mass-like lesion, such as toxoplasmosis. Functional imaging tools, such as FDG-PET (302,303), or SPECT (304,305), appear to be more reliable in differentiating actively proliferating mass lesions, such as PCNSLs, from largely necrotic indolent-infectious lesions caused by toxoplasma or other organisms. This is based on a signiÞcantly higher FDG uptake by the metabolically active tumor cells; similarly, radioactive tracers, such as thalium-201 (or technetium-MIBI) used in SPECT studies, become actively incorporated only into living cells by utilizing their Na/K/ATP-ase transmembranous system.
b. Examination of the CSF usually reveals an increased protein, a normal or decreased glucose level and pleocytosis in about 50% of cases. The reported percentage of PCNSL-s cases with diagnostic cytology of the tumor cells, differs widely from one study to the next ranging from 10Ð30% (291,300,301). It has been repeatedly demonstrated (306,309), that EBV-DNA ampliÞcation in CSF is positive in about 85% of all biopsy/autopsy-proven PCNSLs. Most importantly, a combination of a positive CSF-EBV-DNA with a hyperactive SPECT-detectable CNS lesion, is considered diagnostic of PCNSL at 100% level of speciÞcity (305); these diagnostic procedures may eliminate the need for a more invasive brain biopsy.
c. Stereotactic brain biopsy, although invasive, is considered to be Òsafe and effectiveÓ, but less invasive, yet highly speciÞc diagnostic tools (305,313), may presently have better Ònet survival advantage.Ó

Pathohistologically, PCNSLs, that share the same cell of origin with their nodal and extranodal counterparts, are classiÞed according to the working formulation for systemic NHLs (301,306,307). Nonetheless, some argue that such a classiÞcation Òis not reliable and clinically not relevant for PCNSLÓ (308). Rather, on the basis of their biological behavior, frequently atypical morphology, and Òlocation in an organ devoid of lymphatics, PCNSLs

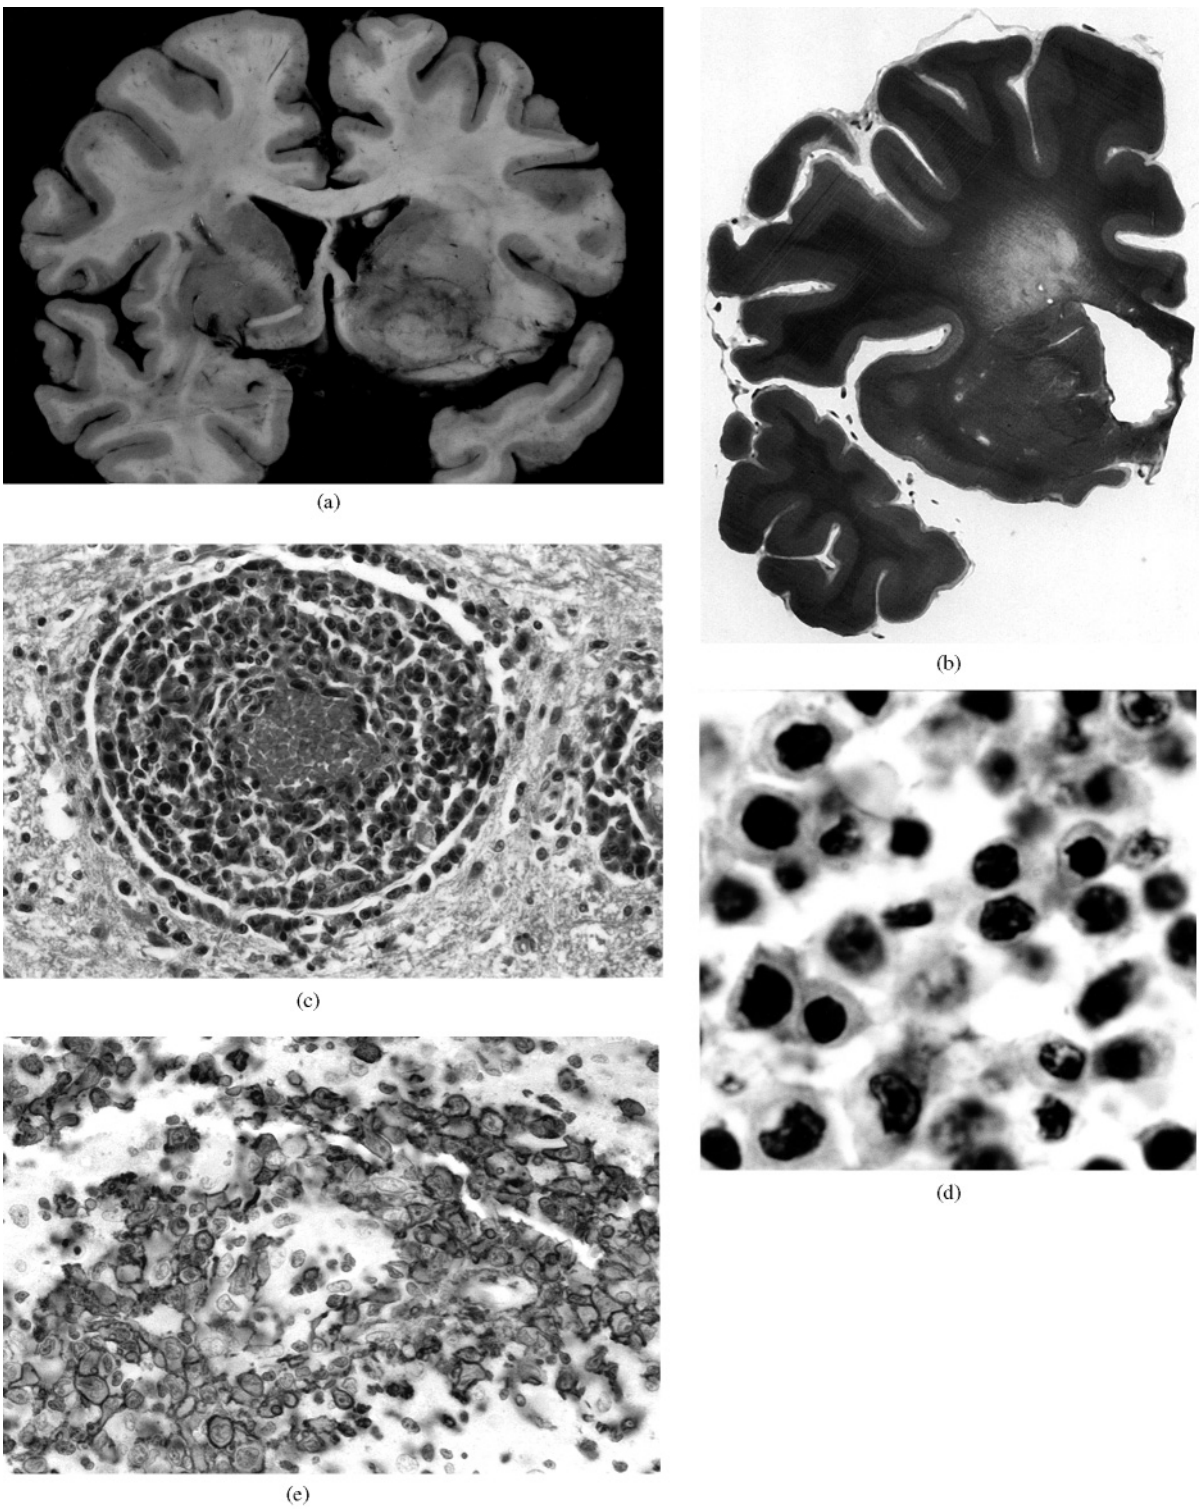

FIG. 28.15. Lymphoma. (a) Coronal section of formalin- xed brain at level of anterior commisure showing discrete whitish lesion in basal forebrain. (b) Whole brain section through frontal lobe showing destruction of tissue and in ltrating lesion in centrum semiovale. (c) Microscopic appearance of lesion characterized by perivascular collections of tumor cells (c) and pleomorphic nuclei (d) (H&E stain); the tumor is a B-cell lymphoma (e) (immunoperoxidase stain for B-cells).

constitute a disease entity unto its ownÓ (307), that in many instances may not be readily classiÞable (301,308). In about 98% of cases PCNL tumor cells express B-cell antigens (CD20); only 2% are T-cell lymphomas, and all other subtypes are exceptionally rare (308). Taken together, most studies of PCNSLs associated with AIDS, have reported a preponderance of the more aggressive large-cell immunoblastic and large non-cleaved-cell subtypes of NHL (280,295,309Ð312). Some are composites of mixed large-cell subtypes, as well as mixed large and small cleaved cell variants, or only the latter (301). Our own experience in patients with AIDS parallels that of others in that PCNSLs are usually highly malignant, morphologically polymorphous and extensively necrotic; routine histopathological work-up almost always demonstrates positive reticulin staining. Treatment of PCNSLs involves one or, more frequently, a combination of the following modalities: whole brain irradiation, chemotherapy, HAART and interleukin-2 (313). With some exceptions, the overall prognosis is still poor.

Chapter 29

Infection Control Considerations to Prevent HIV Transmission in Healthcare Settings

Linda A. Chiarello, Adelisa L. Panlilio and Denise M. Cardo

Transmission of human immunodeÞciency virus (HIV) from patients to healthcare personnel (HCP), from HCP to patients, and from one patient to another can occur in healthcare settings. Similar to other bloodborne pathogens, HIV is more likely to be transmitted from patients to HCP than from HCP to patients. Needle punctures or other similar percutaneous injuries inßicted by contaminated sharp instruments account for most cases of occupational HIV infection. Transmission from an infected healthcare provider to a patient is unusual, but possible, e.g. when an infected provider is injured by a sharp object, which then recontacts a patientÕs tissues. Transmission between patients is usually attributable to breaches in infection control practices such as reuse of contaminated equipment or injection of contaminated materials. Fortunately, all these modes of transmission are rare and can be prevented. In this chapter, we discuss the epidemiology and prevention of HIV transmission in healthcare settings.

OCCUPATIONAL HIV TRANSMISSION

Occupational exposures to blood and certain other body substances (e.g. cerebrospinal ßuid, amniotic ßuid) pose a risk of HIV transmission. Important determinants of the risk of occupational HIV transmission are the prevalence of infection in the patient population, the likelihood of acquiring infection after a single blood contact from an infected patient, and the nature and frequency of blood contact. These factors have been assessed by seroprevalence studies, prospective studies of HCP after occupational exposure to HIV, and observational studies of occupational contact with blood and other body ßuids.

In prospective studies of HCP, the average risk of HIV transmission after a percutaneous exposure to HIV-infected blood has been estimated to be approximately 0.3% (95% conÞdence interval (CI) = 0.2%Ð0.5%) and after a mucous membrane exposure, approximately 0.09% (95% CI = 0.006%Ð0.5%) (1,2).Although episodes of HIV transmission after nonintact skin exposure have been documented (3), the average risk for transmission by this route has not been precisely quantiÞed but is estimated to be less than the risk for mucous membrane exposures (4). The risk of transmission after intact skin exposures has not been quantiÞed precisely, but is believed to be even smaller; no cases of HIV transmission after exposure to intact skin have been documented (3). The risk of transmission after exposure to ßuids or tissues other than HIV-infected blood also has not been quantiÞed.

As of June 2001, the Centers for Disease Control and Prevention (CDC) had received reports of 57 U.S. HCP with documented HIV seroconversion temporally associated with an occupational HIV exposure (5 and CDC unpublished data). In addition, the CDC has received reports of 137 HCP (one worker was reclassiÞed) with possible occupationally acquired HIV infections; each of these workers reported that his or her infection was occupationally acquired and no other risk for HIV infection was identiÞed, but transmission of infection after a speciÞc exposure was not documented. Of the 57 documented episodes, 49 involved exposure to HIV-infected blood; one to a visibly bloody body ßuid; four to unspeciÞed ßuids; and three to concentrated virus in a laboratory. Forty-eight HCP had percutaneous exposures, Þve mucocutaneous, and two both percutaneous and mucocutaneous; the route for two exposures is uncertain (5).

Linda A. Chiarello, Adelisa L. Panlilio and Denise M. Cardo: Division of Healthcare Quality Promotion, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, GA, 30333.

The 51 percutaneous exposures involved a hollow-bore needle (45), broken glass vial (two), scalpel (two), or an unknown sharp object (two).

Factors associated with transmission risk have been evaluated in a retrospective case-control study of percutaneous exposure to HIV among HCP (6). The risk for HIV infection was increased with exposure to a larger quantity of blood from the source patient as indicated by a device visibly contaminated with the patientÕs blood, a procedure that involved a needle placed directly in a vein or artery, or a deep injury. The risk also was increased for exposure to blood from source patients with terminal illness, possibly reßecting the higher titer of HIV in blood late in the course of acquired immunodeÞciency syndrome (AIDS) or other factors, such as the presence of syncytia-inducing strains of HIV. A laboratory study that demonstrated that more blood is transferred by deeper injuries and hollow-bore needles lends further support for the observed variation in risk related to blood quantity (7).

HEALTHCARE PROVIDER-TO-PATIENT HIV TRANSMISSION

Since the onset of the AIDS epidemic, only three episodes of HIV transmission from an infected healthcare provider to patients have been reported: one in the U.S. (1990) and two in France (1997) (8Ð11). The episode in the U.S. involved a cluster of six patients whose HIV infections were linked epidemiologically and genetically to a dentist with AIDS (8). Although the investigation indicated that HIV transmission occurred during ofÞce visits for dental care, and was most likely from dentist to patient rather than from patient to patient, the precise event(s) resulting in transmission could not be determined.

The second episode of HIV transmission from an infected healthcare provider involved an orthopedic surgeon in France whose HIV transmission to one patient was conÞrmed through DNA sequence analysis of viral isolates obtained from the surgeon and the patient (9). The surgeon in this case most likely became infected by an occupational injury sustained during a surgical procedure in 1983. However, the surgeon was not aware of his infection until AIDS was diagnosed in 1994. A retrospective (Òlook-back)Óinvestigation of 3,004 patients who had undergone at least one invasive procedure performed by the infected surgeon since 1983 was initiated. One patient, who had a negative HIV antibody test before undergoing the Þrst of three procedures performed by the index surgeon, was found to be infected with HIV when she underwent preoperative testing before a third procedure. Although the precise mechanism of transmission is unknown, the duration of the procedure (10 hours), procedure-related opportunities for percutaneous injury to the healthcare provider, and possible high viral titer in the surgeon are hypothesized as contributing factors. No breaches in recommended infection control practice were identiÞed.

The third report of transmission of HIV from a nurse to single patient in France, conÞrmed by phylogenetic analyses, was published in 2000 (10). The nurse was co-infected with HCV; however, the patient was found to be infected with HIV only. Nursing duties involved monitoring the patient post-operatively and giving two subcutaneous injections. No circumstances that could have contributed to HIV transmission were identiÞed. A lookback investigation of more that 2,300 patients who may have been exposed to the nurse found no other case of nurse-to-patient HIV transmission (11).

Data from retrospective investigations of HCP infected with HIV for the purpose of assessing the risk for HCP-to-patient transmission did not detect any transmission among 22,759 patients treated by 53 infected HCP (12). Despite the limitations of retrospective studies, these data are consistent with previous assessments that the risk for HIV transmission from infected HCP is extremely low.

PATIENT-TO-PATIENT HIV TRANSMISSION

Episodes of HIV transmission from one patient to another have been reported in hospitals and out-patient healthcare settings in the U.S. and other countries; the majority have involved breaches in protocol, improper infection control practices, and/or inadequate disinfection procedures. Reuse of blood-contaminated hypodermic needles was linked to HIV transmission to at least 41 hospitalized children in the Soviet Union and may be responsible for as many as 400 HIV infections in hospitalized children in Libya that occurred in 1998 (13,14). Similar opportunities for such transmission have been reported during immunizations in the U.S. (15).

In three separate incidents (two in the U.S. and one in the Netherlands), patients were inadvertently injected with blood from an HIV-infected patient during nuclear medicine procedures (16). These procedures involved withdrawal of the patientÕs blood, labeling with a radioactive isotope, and then reinjection of the blood. In these reported instances, system errors in identiÞcation of patients and/or materials to be injected contributed to exposure.

In Australia, Þve patients who underwent minor out-patient surgical procedures performed on the same day by an HIV-negative surgeon were subsequently found to be HIV positive (17). Four of these patients had no identiÞable source of infection; the Þfth patient had known risk factors for HIV, was subsequently found to be HIV positive, and is the probable source of infection. Although the mechanism of transmission was not identiÞed, contamination of multi-dose medication vials was hypothesized as a possible vehicle for transmission in this outbreak.

Transmission of hepatitis B and C viruses is well documented in the hemodialysis setting; rarely, HIV transmission has been associated with this procedure (18).

No case of patient-to-patient transmission of HIV during dialysis has been reported in the U.S. However, HIV transmission to at least nine patients in a hemodialysis center in Colombia has been reported and was attributed to inadequate disinfection and reuse of contaminated vascular access devices; similar cases have been reported from Argentina and Egypt (19–21).

There are few reports where HIV transmission from patient-to-patient was suspected but not confirmed. One report from the U.S. involved an infant with AIDS whose source of infection was unknown but was possibly related to exposure to another HIV-infected patient during medical care (22). In Denmark, a child was reported to have acquired HIV during a hospital stay that overlapped 15 days with an HIV-positive child; genotypes of the two viruses were similar (23). Although no mechanism of transmission was identified in this case, a needle disposal box was accessible in the infected child's room. It was hypothesized that an unnoticed needlestick occurred to the second child during an unobserved visit to the source patient's room.

In most cases, these transmissions could have been avoided through adherence to standard infection control practices. These include aseptic technique, cleaning and disinfecting or sterilizing equipment between patients, safe injection practices, and appropriate handling of single-use or single-patient-use devices and equipment.

Epidemiology of Blood Exposures in Healthcare Personnel

Epidemiological data on blood exposure are important for targeting and prioritizing prevention efforts. Aggregate data from more than 50 hospitals participating in the CDC National Surveillance System for Healthcare Workers (NaSH) show that the majority (82%) of reported blood exposures are the result of a percutaneous injury (e.g. needlestick or other sharp object injury) followed by exposures to mucous membranes (14%), non-intact skin (3%), and human bites (1%) (CDC unpublished data).

NaSH data on percutaneous injury demonstrate that a few types of devices are associated with the majority (74%) of injuries, although a large variety of sharps injure HCP (CDC unpublished data). Among these devices are disposable syringes, which account for 29% of injuries, suture needles (17%), winged-steel needles (12%), scalpel blades (7%), intravenous (IV) catheter stylets (6%), and phlebotomy needles (3%). Many of these devices are hollow-bore needles that have been used in a vein or artery that may contain residual blood.

Injuries can occur at multiple points in the course of handling a needle or other sharp device. NaSH data show overall that 39% of injuries occur during use on the patient, 41% occur after use and before disposal, and 16% occur during or after disposal (CDC unpublished data). Table 29.1 lists possible injury mechanisms during each of these time periods and demonstrates the multiple factors that contribute to injuries.

TABLE 29.1. *Common mechanisms of percutaneous injury to healthcare personnel*

While manipulating patient or needle/sharp
Patient moved and jarred device
During needle insertion, manipulation, or withdrawal from a patient or intravenous line
Passing or transferring equipment during use
Handling equipment or specimens
Handling equipment on a tray or stand
Transferring specimens into a container
Recapping
Disassembling device or equipment
During clean-up
In transit to disposal
Collision with other person or sharp device
Disposal-related
Placed sharp in container
Injured by sharp sticking out of container
Over- lled or punctured sharps container
Sharp in unusual location
Found in trash, linen/laundry
Left on tray/table
Left in bed/mattress
Placed in pocket/clothing

Mucocutaneous exposures generally reflect either noncompliance with recommendations for using protective barriers, failure of protective equipment to provide an adequate barrier, or unanticipated circumstances in which the HCW was unable to prepare for the patient interaction. Of the mucocutaneous exposures reported to NaSH, 68% were to the eyes (CDC unpublished data). This is most likely due in part to a reporting bias, since an eye exposure is dramatically apparent to a healthcare worker and is therefore more likely to be reported (24). In 89% of eye exposures, the healthcare worker wore no protective eye wear (e.g. goggles, face shield). That exposures occurred in some instances despite the use of protective eye wear suggests a problem with either the selection or the design of the protective device in use.

Reported nonintact skin blood contacts often involve the hands, arms, and/or face/head and frequently include exposure of a mucous membrane. The distribution of these exposures suggests that in addition to better eye protection, more consistent protection of the hands and arms is needed, including overlap between gloves and the cuffs of cover garments to eliminate the problem of "wrist gap" (24,25).

Prevention Strategies

The strategies for preventing transmission of other pathogens to patients in healthcare settings also prevent transmission of bloodborne viruses to patients. These

include handwashing, using aseptic technique, wearing gloves and other barriers when contact with blood and other body ßuids is anticipated, and cleaning, disinfecting, and sterilizing patient care equipment, instruments, and other devices in accordance with recommendations issued by various authorities (26Ð30).

Healthcare personnel must be educated and trained in the modes of disease transmission and the basic principles and practices of infection control to protect patients during provision of healthcare. Written policies and procedures help guide correct practice and prevent system errors. However, many situations with the potential for disease transmission are not covered by written guidelines and procedures. In these situations, HCP who understand and are able to apply the fundamentals of prevention in a variety of circumstances are best equipped to protect their patients and themselves.

UNIVERSAL AND STANDARD PRECAUTIONS

In 1987, CDC issued recommendations for Òuniversal precautionsÓ based on the concept that all blood and certain body ßuids should be treated as infectious, since it is not possible to know who may be carrying a bloodborne virus (26). Accordingly, CDC recommended that all HCP anticipate the extent of blood contact that is likely, based on the speciÞc type of patient interaction, and use preventive practices. These include careful handling and disposal of sharp devices, positioning patients and using other procedural techniques to avoid or limit blood splashes and using appropriate barriers (e.g. gloves, gowns, eye protection) to provide optimal protection of skin and mucous membrane.

Universal precautions was initially conceived as a strategy for HCP protection from bloodborne virus exposure. However, its relevance to other aspects of patient care was soon recognized and, in 1996, universal precautions was incorporated as a key component of a more comprehensive prevention strategy, designated as standard precautions (27). Standard precautions integrates and expands the elements of universal precautions into a standard of care designed to protect both patients and HCP from pathogens that may be spread by blood, or by enteric and contact routes of transmission.

PREVENTION OF OCCUPATIONAL EXPOSURES

To prevent bloodborne virus transmission to HCP, attention must focus on preventing blood exposure, in particular, percutaneous injuries. This can be accomplished by approaching all blood as potentially infectious and using a combination of strategies, i.e. engineering controls (e.g. safety devices), work practice controls, and personal protective equipment to prevent injury and direct contact with blood (31).

Several strategies can be used to prevent percutaneous injuries to HCP. These include:

- minimizing needle use (e.g. using alternate routes for medication delivery and specimen collection where appropriate and safe for patient care, consolidating specimen collection and implementing needle-free intravenous delivery systems);
- using devices with engineered sharps injury prevention features (e.g. safety IV catheters, hypodermic needles/syringes, and blood collection equipment);
- ensuring safe sharps disposal (e.g. puncture-resistant sharps containers available at the point of use and systems for removing containers before they become overÞlled); and
- promoting injury prevention work practices (e.g. not recapping needles or, if recapping is necessary, using a one-handed scoop technique; keeping the hands behind the sharp; maintaining awareness of the presence of an exposed sharp).

The importance of implementing such measures has been the focus of regulatory and legislative activity since 1991, when OSHA Þrst issued its Bloodborne Pathogens Standard to protect HCP from such exposures (32). The initial focus of this standard was the use of barriers to prevent blood contact. However, as the scientiÞc understanding of bloodborne pathogen transmission from sharp devices increased, attention turned to making safer devices in order to prevent percutaneous injuries; state and federal legislation and regulations now require the use of safety devices to prevent needlesticks.

Hand Protection

Hands are the primary site of cutaneous blood exposure. Gloves serve the dual purpose of protecting patients from pathogens that may be on the hands of HCP and also protecting providersÕhands in situations where blood and body ßuid contact can be anticipated (26,27). The type and number of gloves used should be determined by the procedure being performed.

For most clinical situations that require nonsterile gloves, a single pair of good quality medical gloves that Þt comfortably will provide ample protection. Questions have arisen regarding differences in barrier properties between latex, vinyl, and, more recently, nitrile gloves. Data comparing latex and vinyl gloves have consistently shown that latex is superior to vinyl in distension leak tests (33Ð35) and that sterile surgeonsÕgloves are superior to nonsterile gloves (36). However, differences in failure rates among gloves from different manufacturers were apparent in these studies, suggesting that a good quality vinyl glove sometimes will provide better barrier protection than a poorer quality latex glove. In recent years, concerns about latex allergies have inßuenced glove selection. As a result, gloves made of nitrile, neoprene, and various polymers are now being manufactured for clinical use. One in-use study of barrier performance has found nitrile gloves comparable to latex (37).

Body, Face and Eye Protection

The use of barriers to protect the eyes, face, and other exposed areas of skin during procedures when blood contamination can be reasonably anticipated is recommended (26,27). The type of equipment needed should be appropriate to the procedure being performed (38). Eye protection minimally requires the use of goggles, as neither contact lenses nor glasses provide sufficient protection. Face shields often are used when more extensive splashing might occur. Cover garments protect the arms, torso, and legs in situations where blood contact is likely. The effectiveness of garment barriers depends on their design and the level of liquid resistance of the material of which they are made. Garments should have a high neck and long sleeves and should close in the back or have a well-sealed front closure. The conventional "lab coat" should not be considered a protective garment for preventing blood and body fluid exposures since its front opening, V-neck, and loose cuffs do not provide sufficient coverage of body areas that might be exposed. In addition, the cotton-blend fabric of the lab coat and the traditional reusable cloth or disposable isolation gown generally lack the protective qualities necessary for preventing penetration of blood or body fluids.

PREVENTION OF HIV TRANSMISSION TO PATIENTS

Episodes of patient-to-patient transmission of bloodborne viruses, including HIV, serve as sentinel events for the detection of breaches in infection control practice and are reminders that such lapses have important public health implications. Such transmissions occur indirectly through lack of adherence to infection control by HCP and to date have not involved direct contact between two or more patients/persons. Almost all of the transmissions reported are preventable through adherence to recommended practices for infection control (Table 29.2).

SPECIAL SETTINGS: OPERATING ROOMS

Among NaSH hospitals, the operating room (OR) is a common location where sharps injuries occur, accounting for 27% of reported percutaneous injuries; 39% of OR injuries are reported by residents (24%) and surgeons (15%) (CDC unpublished data). However, this most likely underestimates the true incidence of injuries among surgeons; surveys performed by NaSH hospitals between 1996 and 1998 found that surgeons reported only 25% of their exposures, compared to other physicians and nurses who respectively reported 45% and 48% of their exposures (39).

The epidemiology of sharps injuries in the OR differs from that in other hospital locations. Observational studies of operative procedures have recorded some type of blood exposure in 7–50% of cases; in 2–15% of cases, the event is a percutaneous injury, usually from a suture needle (40–44). Aggregate data from reported injuries among OR staff in nine hospitals also reflect the importance of suture needles, which in this study accounted for 43% of the injuries in the OR (45). Most suture needle injuries occur when palpating a needle tip being drawn through tissue, loading or unloading a needle holder, and/or passing a

TABLE 29.2. *Measures to prevent patient-to-patient HIV transmission*

Safe injection practices
use only single-use disposable needles/syringes
use single-dose vials when available and cost-effective
use aseptic technique when handling injection equipment
prevent contamination of multidose vials; never reenter a vial with needle/syringe used on one patient if that vial will be used to withdraw medication for a subsequent patient
prepare medications in clean areas, physically separated from areas where blood and other body fluids are handled
Gloves and hand hygiene
wear gloves for procedures where blood contact is reasonably anticipated
change gloves between patients
wash hands if visibly soiled with blood
perform hand hygiene (washing hands or using a waterless hand hygiene agent) after changing gloves
Environmental practices
use barriers as appropriate to protect equipment that may become blood contaminated
avoid touching clean equipment and surfaces with blood contaminated hands or gloves
follow recommended procedures for cleaning, disinfection, or sterilization of reusable equipment and instruments and blood-contaminated surfaces
maintain a physical separation between "clean" and "contaminated" equipment and supplies
Other practices
assign equipment with potential for blood contamination (e.g. reusable spring-loaded lancet devices) to individual patients
evaluate new devices and equipment for cross-contamination potential; establish procedures to ensure proper between-patient handling

suture needle to someone else (43–45). Other injuries unique to this environment involve wires, scalpels, and bone spurs. These injuries have additional implications as they may result in recontact with the patient's tissue and patient exposure to a healthcare provider's blood (44).

Observational studies in surgical and obstetrical settings have found that 71–92% of blood contacts are mucocutaneous (40–46). In these studies, most of the observed blood contacts involved intact skin and therefore theoretically did not pose a risk for bloodborne virus transmission. In contrast, of the mucocutaneous exposures reported to surveillance systems, 80–83% involve a mucous membrane or nonintact skin and therefore might pose a risk for bloodborne virus transmission (38, CDC unpublished data).

Prevention of sharps injuries during surgery requires a comprehensive approach that includes eliminating the unnecessary use of needles and other sharp instruments and using safer devices and preventive work practices. The least invasive surgical approach that will achieve the desired patient outcome is preferable. For example, fiberoptic techniques usually pose a lower risk of injury and blood exposure than do more invasive surgical approaches. Likewise, when patient safety permits, alternatives to needles and other sharps (e.g. use of adhesive tape, staples, or tissue glue rather than sutures, or use of blunt electrocautery rather than scalpels) should be used (47,48).

The protective effect of wearing two pair of gloves in reducing percutaneous injury and blood contamination during surgery has been reported (40,51–56). When perforation rates are compared, rates for outer double gloves and single gloves are remarkably similar; however, inner double glove perforation rates are much lower. In these studies, wearing double gloves reduced inner glove perforation between 55% and 84%. In addition, double gloves were shown to reduce blood contamination of surgeons' hands (43,57).

Despite concerns about comfort, sensitivity, and dexterity (58,59), the majority of surgeons who wear double gloves find them acceptable and do not report that tactile sense is significantly impaired (60). While double gloving appears to have important implications for preventing blood contact and has been shown to be acceptable for use during many types of surgical procedures, the impact of this intervention on disease transmission has not been determined.

SPECIAL SETTING: DIALYSIS

When AIDS was described in 1981 and its epidemiology was subsequently determined to be similar to that of hepatitis B, concern increased for transmission of HIV in the dialysis settings. However, as the AIDS/HIV epidemic progressed, it became evident that HIV was less efficiently transmitted than HBV, presumably because of the substantial difference in the amount of infectious virus circulating in the blood of infected individuals. Thus, standard infection control strategies using basic barrier precautions could be used to prevent transmission of HIV from patients to staff members and from patient to patient in the dialysis setting (61,62). From 1985 to 1997, the percentage of centers that reported providing dialysis for patients with HIV infection increased from 11% to 39%. The percentage of patients receiving dialysis who were known to be infected with HIV increased from 0.3% in 1985 to 1.3% in 1997 (63). An HIV serosurvey among hemodialysis patients at 28 dialysis centers found that none of 254 HIV-seronegative patients became HIV positive during a one-year follow-up period (64).

Routine testing of dialysis patients or staff members for anti-HIV for is not necessary for infection control. Patients with HIV infection can be treated with either hemodialysis or peritoneal dialysis and they need not be isolated from other patients, either in separate rooms or by using dedicated machines. The type of dialysis treatment should be based on the needs of the patient and not on the presence or absence of HIV infection. The infection control precautions recommended for dialysis centers are sufficient to prevent HIV transmission between patients. These include the use of both standard precautions and additional measures that are specific for the hemodialysis setting (18,65). These precautions include the routine use of gloves, handwashing, and cleaning and disinfection of external surfaces of dialysis machines and other environmental surfaces. Disinfection and sterilization strategies routinely practiced in dialysis centers are adequate to prevent HIV transmission. In addition, patients who are HIV-positive may participate in dialyzer reuse programs. Because HIV is not transmitted efficiently through occupational exposures, reprocessing dialyzers from HIV-positive patients should not place staff members at increased risk for infection.

PROTECTION OF PATIENTS INFECTED WITH HIV

Patients with HIV vary in the degree to which their immune system is compromised. However, no special measures during any stage of HIV disease are indicated to protect these patients from acquiring other diseases during hospital care (27). The use of standard precautions for all patients and appropriate isolation of patients who have diseases that pose a risk for transmission should protect HIV-infected patients from acquisition of institutionally acquired pathogens from other patients and environments.

MANAGEMENT OF HEALTHCARE PERSONNEL INFECTED WITH HIV

HCP infected with HIV should follow the same precautions to prevent exposure to transmissible agents

recommended for all other personnel (27). There are no recommendations for modifying the work environment to protect these workers from exposure. However, as with anyone who may be immunocompromised, referral to personnel health professionals who can provide individual counseling on the worker's job-related infection risks is advised (66).

The risk of HCP-to-patient transmission of HIV is extremely low. Guidelines for the management of HCP infected with HIV and other bloodborne viruses have been published (67,68). The focus of these recommendations is on HCP who perform a subset of highly invasive procedures where a percutaneous injury to the provider could result in patient exposure to the healthcare provider's blood. Healthcare organizations are advised to develop comprehensive occupational health programs to manage impaired workers, including evaluation of personnel fitness for duty based on competence, ability to perform routine duties, and compliance with established guidelines and procedures. Restriction of an infected provider is rarely indicated. Recommended strategies to prevent blood exposure during surgery, especially percutaneous injuries, should be emphasized.

SUMMARY

The prevention of HIV transmission in healthcare settings requires the use of strategies to prevent blood exposures. All blood should be considered potentially infectious and appropriate barriers and personal protective equipment should be used to prevent blood contact between patients and HCP. Percutaneous injuries from contaminated needles and other sharp devices pose a particular risk for HIV transmission to HCP; during certain invasive procedures, such injuries can also result in blood exposure to both a HCP and patient. The prevention of percutaneous injuries is therefore a high priority. In recent years, devices with engineered sharps injury prevention features have been developed to reduce percutaneous injuries. These devices, in combination with the elimination of unnecessary needle use, use of safe work practices, and organizational efforts to promote a culture of safety are necessary to reduce percutaneous injuries effectively during the provision of healthcare.

Strategies to protect patients rely on the basic principles and practices of infection control, including standard precautions; aseptic technique; handwashing or hand hygiene; use of gloves and other barriers to prevent blood contact; and the cleaning and disinfection or sterilization of equipment and environmental surfaces. Using care to prevent patient-to-patient blood contact when handling injection equipment and multidose vials is particularly important.

Chapter 30

HIV Era Occupational Exposures and Risks

Stanley H. Weiss and Judith D. Leschek

The initial recognition in 1981 of the acquired immunodeÞciency syndrome (AIDS) epidemic was based on the recognition by clinicians and the conÞrmation by epidemiologists of the unusual occurrence of a few cases of Kaposiõ sarcoma and *Pneumocystis carinii* pneumonia (1Ð6). An infectious etiology was supported by cases of unusual infections in intravenous drug abusers, children of drug abusers, and blood transfusion recipients that were judged likely to be related to the illnesses occurring in homosexual men (7Ð10).The Þrst occupational guidelines were formulated on the premise that the agent might be similar enough to the hepatitis B virus (HBV), known to be a highly infectious bloodborne pathogen that was also common among homosexual men, that guidelines based on our knowledge of HBV epidemiology would be sufÞcient for interim protection. In 1982 (just a year after the Þrst report of AIDS), and again in 1983, guidelines were formulated and widely disseminated (11Ð13).

U.S Public Health Service (USPHS) guidelines have since been revised many times, most recently (as of this writing) on June 29, 2001 (14). These guidelines highlight the potential risk of parenteral exposure to blood and other body ßuids that might contain HBV, hepatitis C virus (HCV) or the human immunodeÞciency virus (HIV). These major bloodborne pathogens are transmitted sexually as well. The risks of percutaneous acquisition for these three agents vary by more than 100-fold (Table 30.1). The initial section of this chapter focuses on HIV, with the other major bloodborne pathogens of concern for the modern health care worker covered in the latter portion.

THE HIV ERA

Building upon the isolation and culturing of HIV type 1 (HIV-1) in 1983Ð1984 (22Ð24), reliable serological screening for HIV became available in 1985 (25Ð27).The HIV antibody test also helped to establish a convincing etiologic connection between HIV and AIDS (27,28).

These discoveries subsequently led to the realization that the magnitude of the epidemic was far greater than had been imagined, with the early numbers of AIDS cases dwarfed by the prevalence of (number of persons infected with) HIV (25). This meant that in the United States transmission of HIV had silently occurred during the 1970s with continuing, extensive spread in the ensuing decades. Thus, in the early years of the epidemic healthcare and laboratory workers were unknowingly in routine contact with the blood or body ßuids of a great many more patients infected with HIV than those recognized to have AIDS.

During the early 1980s, few workers took precautions against blood-borne agents, with a somewhat cavalier

attitude reinforced by the reassurance that no worker had (yet) become infected with AIDS/HIV as a result of an occupational exposure and an under-appreciation of the risks from the hepatitis viruses. At that time, the standard infection control precautions were disease specific and aimed at prevention of exposure of staff and other patients with regard to a limited set of diagnosed or suspected diseases. There were some fearful workers who heavily garbed to protect themselves from AIDS patients. These efforts were misplaced as well, representing both an over-reaction with AIDS patients (excessive, unnecessary precautions) and an under-reaction (as no protection at all was used with the even greater number of patients who were HIV-infected but had not been identified as having AIDS).

It became increasingly evident that most persons with bloodborne pathogens were, in fact, not visibly "sick" and thus not recognized to be infected and infectious. (This recognition underlies the development of universal and standard precautions.) Needlestick injuries in the medical setting occurred frequently (29) but were infrequently reported or documented. Sharps injuries continued to occur (30) after the risks of sharps exposure had been documented (21) and despite the implementation of standard precautions, giving the impetus for safer devices and safer work practices.

DIAGNOSIS OF HIV INFECTION

The mainstay of HIV diagnosis is testing for antibodies ("seropositivity") (confer Chapter **00**, "Laboratory **Diagnosis** of Retroviral Infection," for a more complete discussion), connoting chronic, persistent infection (as opposed to protection). In the "window" period that exists before antibody becomes detectable but after exposure and infection with HIV, other tests such as p24 antigen (p24Ag, with and without immune complex disassociation), nucleic acid amplification tests (NAT) and viral load measures, or immunologic tests may be positive (31–35). These tests have some specific applications in various sections of the "window" period, discussed in detail in that portion of Chapter **00** (the LAB chapter). These additional tests are not routinely used in the clinical evaluation of persons with an exposure to HIV, in part related to the costs involved, the low pre-test probability of HIV infection leading to a limited positive predictive value), questions concerning the specificity of the tests, and the lack of standards.

Available data have been consistent with the picture painted by HIV antibody testing alone (36–38). Antigen and nucleic acid amplification assays, on the average, detect HIV only a few days before standard antibody tests (31), are expensive, and results are usually not immediately available. Some have not been licensed as screening tools in the clinical setting. In contrast, tests for screening for HIV antibody are commonly available, a confirmed result can be obtained shortly afterwards, and rapid screening tests were licensed in 2002 (39,40).

In a person with possible acute retroviral seroconversion syndrome, for whom the pre-test probability of true positivity rises, there is justification for use of alternative tests, since an unconfirmed positive research assay has an increased likelihood of ultimately being a true positive (see Chapter **00**, "Laboratory **Diagnosis** of Retroviral Infection"). It is believed that most persons who acquire HIV from an exposure will demonstrate antibodies to HIV within six months, although exceptions occur (see Chapter **00**, "Laboratory **Diagnoses** of Retroviral Infection"). The data are sparse with regard to how frequent these longer latency exceptions might be, but anecdotal cases of prolonged seroconversion intervals continue to be reported sporadically, with varying levels of documentation (41–43).

HISTORICAL DISCOVERY OF HIV OCCUPATIONAL RISKS FOR THE WORKER

By early 1985, there were some clues that HIV infection was a chronic disease, with long latency (25,44). The demonstration of a long incubation period between first acquiring HIV and developing AIDS or other severe clinical sequelae involved the use of both prospective epidemiologic data and tests for the causative agent (45). It was, at least theoretically, possible that many healthcare workers might have (unknowingly) become infected with HIV and feel and look perfectly well; the initial studies of occupational risk could conceivably have failed to detect widespread transmission.

It was therefore quite reassuring in January 1985 when two groups found HIV antibody to be absent serologically in a combined total of 273 persons drawn from institutions and laboratories where AIDS and HIV, respectively, were routinely encountered (15,27,46).

The CDC subsequently reported on 40 healthcare workers, representing persons who had specific potential HIV exposures. These exposures included 29 needlestick injuries, five cuts, five mucosal exposures, and five skin exposures (47). No worker was seropositive, with a median follow-up period of eight months. Additionally, the T-cell subsets were normal and HIV clinical sequelae were absent among over 200 workers followed prospectively (47). This reinforced the message that the initial U.S.PHS guidelines for AIDS had been reasonable initial measures. These data, however, still did not exclude the statistical possibility of a substantial public health risk (48), since needlestick transmission rates for HIV exceeding 1% were within the 95% upper confidence bounds given that limited observation base. The transmission by a needlestick injury from an AIDS patient of HBV, *without* transmission of HIV (49), suggested that transmission of HBV was more likely compared to HIV (21). These findings supported the tendency to offer reassurances to a somewhat nervous

work force, but also tended to instill a sense of complacency in many institutions. The medical community largely ignored the limitations of the data.

In late 1984 a nurse in Great Britain became infected with HIV as a consequence of injection of fresh blood from an arterial blood gas syringe in an intensive care unit setting (50). The source patient was known to have AIDS. Healthcare workers could no longer deny that they were at some risk for occupational acquisition of HIV.

Needlestick transmission was next documented in early 1985 in a cross-sectional study of high risk hospital workers in the United States (21), conducted before the commercial availability of any HIV tests. One (2.4%) of 42 persons who had reported parenteral exposure to patient(s) with AIDS was HIV seropositive, with no other risk identified in a prospective questionnaire that had been completed prior to initial phlebotomy nor after a thorough investigation, which included assessment of her seronegative heterosexual spouse. Two other seropositive healthcare workers with nosocomial parenteral exposure but no other risk factors were simultaneously reported (21), further cementing the reality of risk.

First positive reports not infrequently overestimate the magnitude of risk, as negative data from other studies do not enter the denominator. It is not surprising that current estimates of risk (see Table 30.1) are significantly lower than the 2.4% transmission risk above. The actual rate remains high from a public health viewpoint. Several other large studies as of that time had not yet observed any unexplained HIV infection or seroconversions among exposed workers (27,51,52). Numerous authorities thus chose to continue to interpret incorrectly the risk to workers as minimal, awaiting future reports. Given the clear evidence of other types of parenteral transmission from other settings, such viewpoints may have reflected more a political assessment than a balanced scientific assessment.

In retrospect, it is clear that most summary analyses systematically tended to underestimate risk, the flaw in part reflecting methodological biases. For example, health care workers with non-occupational risks were excluded from the numerator (i.e. from the cases of occupational transmission), on the assumption that the other risks were the responsible factor(s) (or, at best, that such factors were not easily excluded). However, workers with these risk factors were nevertheless still included in the denominator (reflecting all those considered to be at risk), artifactually reducing the risk estimates. Indeed, only a single review (15) addressed (and adjusted for) this type of methodological bias.

Documentation of HIV transmission to healthcare and laboratory workers by multiple investigators around the world has since occurred (15,53–65), leading to a broader acknowledgement that infectious risks in the workplace deserve attention. This apparent change in viewpoint by some infection control experts led some physicians, particularly surgeons at high risk of percutaneous injury, to feel they had been misled and even betrayed by earlier advice and reassurances. A few retreated from active clinical practice because of their concerns, and some attracted national publicity in doing so.

The American Medical Association, through its insurance agency, by the late 1980s had developed and promulgated an insurance policy for HIV negative physicians who were concerned about the risk of contracting HIV infection and its consequences. The cost of the insurance policy is fairly high compared to the low risk of occupational acquisition for most workers. However, this insurance coverage was apparently not limited to workplace risks, which account for very few of the incident HIV infections among workers. Thus, the worker is insured against possible loss of income irrespective of the cause of infection. Furthermore, the issue of demonstrating mode of acquisition, which might become the subject of litigation and dispute, is removed from consideration in obtaining benefits. There is reason for concern about the possibility of work restrictions for healthcare workers in the event of HIV infection, as discussed below. Thus, a professional who is physically well enough to work (and thus ineligible for standard disability policy benefits) might nevertheless be suffering loss of income and incurring substantial medical expenses. This "HIV insurance" is probably most useful, and on a cost-benefit basis practical, for those with high sexual risk and for workers in high HIV prevalence areas who suffer many parenteral injuries.

IS THERE A RISK OF TRANSMISSION TO THE PATIENT?

Given the theoretical possibility that HIV might be transmitted to a patient and recurrent inquiries to the New Jersey Board of Medical Examiners for advice, a multidisciplinary conference was convened in 1990 to explore what the risks to patients might be (66). Interest was subsequently heightened by the CDC investigation of the practice of a dentist in Florida (67), in which purported HIV transmission from a health care provider to multiple patients gained notoriety. This initially led to a public outcry for further regulation. This reflected an environment in which only absolutely zero risk in the medical care setting was to be tolerated.

As we struggle to protect patients and healthcare providers and to render appropriate care despite limited resources, compromises shall occur that may have long-standing impact on the delivery of healthcare services. As the quantitative risks and costs continue to be weighed by the medical community, public policy is likely to continue to evolve on this issue. It is unclear how lawyers, politicians and others will ultimately weigh such data.

Developing Institutional Policies

This chapter discusses the magnitude of risks to workers and to patients in perspective, and outlines key medical issues involved in the development of institutional policies. Periodic policy review at individual institutions by a multidisciplinary committee will be useful. Members of the committee might include an epidemiologist, an occupational health professional knowledgeable about nosocomial risks, an infectious diseases expert knowledgeable about HIV and its treatment, an infection control professional, administrative and legal staff representatives, a bioethicist and a patient advocate.

HIV OCCUPATIONAL RISK TO THE WORKER

Anecdotal case reports are important in describing modes of transmission, but these cannot be used to calculate the magnitude of risk from those speciÞc types of exposure. HIV transmission to healthcare workers has been documented from several types of HIV exposure: parenteral injury from contaminated sharps (particularly hollow bore needles) and other cuts, mucosal splashes, and skin contact. Even persons rendering home health care are at some risk (68,69). Despite common perceptions to the contrary, transmission of HIV has occurred with needlestick injuries involving only limited blood infusion or relatively superÞcial injury. However, one study has reported Þnding evidence of a dose-response with sharps injury exposures (70)Ñ greater exposure to HIV increasing risk of transmissionÑ consistent with our expectations.

The reported frequency of cutaneous injury with sharp instruments in various surgical procedures is 1.5Ð15%, with an average risk of Þve injuries per 100 procedures (71Ð73). However, injuries from needlesticks may be even more common than suggested by institutional reports (74Ð77). Over 70% of U.S. resident physicians in one study reported at least one needlestick injury (78,79). In a longitudinal study of medical students, the percentage exposed to blood increased from 45 to 65% over the seven-year study period 1990Ð1996 at teaching hospitals afÞliated with the University of California San Francisco School of Medicine (80). The risks outside the Unites States are likely to be at least as great. In a Pakistani study of operating room personnel, 59% reported more than four needlestick injuries per year, 37% reported one to three per year, and only 4.4% reported no needlestick injury in the prior Þve years (81). A British survey of house ofÞcers and senior house ofÞcers in 1996 found that 68% reported at least one needlestick injury (82).

The cumulative number of needlesticks, and the ensuing exposure risk from parenteral agents, can therefore be quite substantial (83Ð86).

Historically, it was also the impression that the majority of injuries were never reported. With increasing attention by OSHA and focused efforts by individual institutions, there are anecdotal reports of improvement. The International Healthcare Worker Safety Center of the University of Virginia, led by Dr. Janine Jagger, estimated that an average of 30 percutaneous and blood and body ßuid exposures occur per 100 occupied hospital beds each year, and that only 39% of all exposure injuries are never reported (87). Other types of occupational exposure are also common in the healthcare environment (88,89). Analysis of where and what causes sharps injuries can help assist in focusing injury prevention programs on speciÞc devices and departments (90).

In a study of percutaneous injuries in 1993Ð1995, nearly 40% of the cases of HIV transmission in the healthcare workplace were associated with phlebotomy procedures (91). The magnitude of the needlestick problem was thus considerable (30). Instruction in universal precautions and clinical procedures is not sufÞcient to prevent exposures to blood (80,92). These data highlight the potential role for modern safety devices and safe work practices (87,93,94). Safety improvements at the phlebotomy service at the Mayo Clinic succeeded in reducing accidental needlestick exposures from 1.5/10,000 venipunctures in 1985 to 0.2/10,000 in 1996 (95,96).

Surgeons reacted beginning in the late 1980s to these risks of HIV with greater attention to the potentials for occupational exposure. Changes in surgical techniques have been recommended (91,94,97Ð100). An example of one of the early, effective safety attempts was the use of blunt suture needles during gynecologic surgical procedures, which reduced the risk of suture-related percutaneous injuries to healthcare workers (94). Many efforts to re-engineer medical products to reduce the risk of injury are ongoing; vascular access ports are a typical example (101). Comprehensive education programs may be needed to introduce successfully and gain acceptance of new devices (102). A cross-sectional study reported a reduced injury rate among surgeons in 1993 as compared to 1988 (103).

Although HIV has been detected in many body ßuids (28,104), strong epidemiologic evidence of HIV transmission has only been demonstrated in association with blood, semen, cervicovaginal secretions and breast milk. There are other potentially infectious material (OPIM). Those OPIM currently deemed to pose a potential risk for HIV include (105):

a. Human body ßuids: any other body ßuid or tissue containing visible blood, cerebrospinal ßuid, synovial ßuid, pleural ßuid, pericardial ßuid, amniotic ßuid, saliva in dental procedures, and all body ßuids in situations where it is difÞcult or impossible to differentiate between body ßuids;
b. any unÞxed tissue or organ (other than intact skin) from a human (living or dead);
c. HIV-containing cell or tissue cultures, organ cultures, and HIV-containing culture medium or solutions; and

d. blood, organs, or other tissues from experimental animals infected with HIV.

The importance, if any, of saliva is unclear. In the dental setting, saliva is invariably contaminated with blood and thus viewed as infectious. Persons with AIDS are also more likely to have bloody saliva, due to hematological disorders (106). In the initial case report that suggested HIV transmission by a human bite (107), the skin was not broken and neither temporal seroconversion information nor viral strain comparison data was available. In a second case report (108), some question remained as one sexual partner (a "one-night stand," who thus might be from a pool of higher risk partners) of the healthcare worker was never tested for HIV. No other cases of transmission by bite were reported (109) leaving transmission by bite uncertain until a well-documented report in 1996 (110). Similarly, one report of female-to-male HIV transmission implicating saliva exposure during fellatio (111) was questioned (112) and the initial report was partially retracted in a follow-up by the authors, but some risk does exist (106,110,113,114). The magnitude of risk from orogenital sex is controversial (115–117). Household transmission has occurred (118,119). In summary, saliva alone has generally not been included among the body fluids posing a high risk of HIV transmission. However, saliva or other body fluids that are contaminated by blood should generally be treated in the same manner as blood itself (120).

The CDC periodically publishes tables summarizing "documented" and "suspected" cases of occupational HIV transmission within the United States. These reports highlight the diversity of jobs where workers have become infected, and some of the non-needlestick transmission routes. The actual total number of transmissions is unknown, but likely greatly exceeds these CDC tabulations. Anecdotal cases of cutaneous and mucocutaneous transmission have been reported (121) and represent acknowledged sources of risk (14).

The risk of HIV transmission is thought to be related to the mode and dose of exposure, but the data to substantiate this are sparse, especially since measures of HIV infectivity and even surrogate measures such as viral load (122) have generally not been utilized in prospective transmission studies. Specimens with high p24 antigen titers or a detectable viral load are believed to have increased infectivity (risk of transmission) (110). Host susceptibility factors to HIV and immunologic defenses remain important areas of investigation (33,38,123–131). It is also possible that some HIV genetic strains may have altered virulence. Superinfection with a genetically different HIV can occur during the course of established HIV-1 infection (128,132). These issues may help explain the lack of a clear relationship between magnitude of blood exposure and risk of transmission to workers. Nevertheless, virtually all transfusion recipients of HIV-positive blood do acquire HIV infection. Thus, at some exposure dose HIV transmission clearly becomes very likely, notwithstanding some specific form of resistance such as absence of a necessary chemokine receptor molecule (124,126).

Within an individual patient infected with HIV, the titer of HIV will vary over the course of infection, so that a given person's infectiousness likely varies, perhaps considerably, over time. In terminal AIDS patients, the HIV viral load often rises—evidenced in early studies by the re-emergence of measurable p24Ag titers. In an epidemiologic study, the CDC found that several clinical surrogate markers of dose exposure, including deep injury, visible blood on a device, a procedure involving a needle in an artery or vein, and terminal illness in a source patient (defined as disease leading to death from AIDS within two months of the exposure) were significant predictors of HIV percutaneous transmission to health care workers (70).

During the "window" before seroconversion, the plasma HIV titers, and hence the potential for infection, may be particularly high (133). This risky situation would be devoid of protection if clinical precautions were taken only for patients with known, documented infection. Some occupational exposures to blood and bodily fluids occur where the HIV status of the source patient is unknown, and many such patients may refuse HIV testing even in the setting where a worker has been exposed (134). These considerations are part of the rationale behind the concepts of "universal precautions" and "standard precautions" (135–137), and are especially important in regions where the incidence of seroconversion remains high. Policies to deal with these situations, which balance the worker's right to a safe workplace against the privacy rights of an individual, are essential for all health care facilities.

The many epidemiologic studies of occupational transmission risk provide numerators for cases of work-related acquisition and denominators for persons-exposed and specific exposures. Within these studies, persons who have had parenteral exposure have the greatest risk: roughly about 0.3% per parenteral exposure (see Table 30.1) (14,138). In other words, the vast majority of exposures do not lead to infection. Among research laboratory workers who handle highly concentrated HIV, the annual risk of HIV acquisition is about 0.3% (58). Three persons working in research laboratories were reported to have acquired HIV infection occupationally (59).

Several studies have sought to quantify level of exposure and other risks (89,139–142). Only one prospective study, by Ippolito et al. in Italy, has so far observed a risk with mucosal membrane or cutaneous HIV exposures (143). The limited number of persons in the denominator still leads to wide statistical confidence limits concerning the specific level of risk (144). A CDC summary cited a risk estimate for a mucosal membrane or cutaneous HIV exposure of 0.09%, with a 95% upper confidence bound of 0.5% while the lower bound was just 0.006% (14). This estimate is apparently based on the

single case noted above by Ippolito (1/158, 0.63%, 95% CI 0.018%–3.47%), with adjustment of the denominator with data from other studies (which were negative). The existence of multiple anecdotal cases confirms that such exposures convey some risk (142). While it can sometimes be difficult to pinpoint the precise mode of HIV acquisition (142), the evolving tools of molecular epidemiology hold some promise for verification (58) as well as elimination of suspected transmission (112). The interpretation of these research tests remains uncertain, given the newness of the techniques and applications, the complexity of HIV and its host interactions, and the very limited data from controls (confer below, and also Chapter **00**, Laboratory Diagnosis). Further complicating the picture is that coinfection by multiple HIV-1 strains can occur *in vivo* (145), and pre-existing infection does not prevent super-infection with another strain (128,132).

STANDARD PRECAUTIONS

The initial CDC recommendations called for blood and body fluid precautions when a patient was known or suspected to be infected with bloodborne pathogens (13). In August 1987 the CDC and OSHA called for "Universal Precautions" (UP) to be consistently used all the time, regardless of the apparent blood-borne infection status of a given patient (146). UP applied to blood, to body fluids that had been implicated in the transmission of blood-borne infections (i.e. semen and vaginal secretions), to body fluids from which the risk of transmission was unknown (i.e. amniotic, cerebrospinal, pericardial, peritoneal, pleural, and synovial fluids), and to any other body fluid visibly contaminated with blood. Feces, nasal secretions, sputum, sweat, tears, urine and vomitus were not included unless they were visibly contaminated with blood. At the same time (1987), a new system of isolation called Body Substance Isolation (BSI) was developed by infection control personnel in Seattle, Washington and San Diego, California, as an alternative to diagnosis-driven isolation precautions. BSI focused on the isolation of all moist body substances with the exception of tears and perspiration (120). BSI and UP shared many similar features and thus became the basis for "Standard Precautions." Standard Precautions reduces the risk of transmission of blood-borne and other pathogens. Standard Precautions applies to all body fluids and body substances with the exception of perspiration. Standard Precautions are used with all patient's body fluids/body substances in all situations where contact is, or can be, reasonably anticipated.

Since it was acknowledged that available medical and laboratory data might not always identify those persons and specimens with blood-borne pathogens, Universal and subsequently Standard Precautions in effect eliminate the "need to know" and provide broader safety and infection risk reduction for patients and healthcare workers. Implementation of Standard Precautions is currently the primary strategy for successful nosocomial infection control (120). Barrier precautions and hand washing are among the mainstays of Standard Precautions (147).

A century ago, surgical gloves were introduced to practice as part of the new antiseptic technique and originally to protect the hands of the surgeon and his assistants from the harmful dermatological effects of powerful antiseptics (e.g. carbolic acid) in use at that time (148). Since then, the wearing of gloves during surgery has been standard practice. Furthermore, the protection value of surgical gloves in preventing cross-infection has stood the test of time.

The estimated prevalence of HIV infection within the U.S., projected from mathematical models, is under one million persons (25,149,150). There is wide geographic variation in HIV seroprevalence. In some hospitals, e.g. public hospitals in San Francisco, New York City or Newark, a very high proportion of patients are infected (151). In such locations a person of unknown HIV status has a high probability of seropositivity, as highlighted by a study of emergency room patients in Baltimore (152). The incidence of new infections (community seroconversion rates) may also be sufficiently high that HIV seronegativity cannot be relied upon to rule out HIV infection. The implementation of "Standard Precautions" for blood, body fluids, and body substances, once controversial in such settings, is now commonly used and well accepted. Nevertheless, many professionals still express the desire to "know" their patient's status.

Universal and Standard Precautions certainly do not have perfect efficacy in removing all risks (140,153–163). Gloves are not expected to prevent needlestick or other penetrating sharps injuries (164–168). However, gloves may exert some protective effect (169). In a study of simulated needlestick injury, glove material reduced the transferred blood volume by 46% to 86% in two models (169). After standard pre-operative hand preparation, glove perforations were found to be of no clinical significance to the patient, but the high incidence of perforations suggested that a main indication for preoperative change of damaged gloves was for protection of surgeons against pathogens transmissible during surgery (170). These data lend further support to the recommendation that gloves be worn whenever sharps are to be handled.

Since gloves can tear (168), and breaks may not even be recognized by the worker, hand washing should be routinely performed whenever gloves are removed (147). The risk of glove perforation during surgery may be higher than generally appreciated (171,172). The quality of disposable (and of sterile) gloves can be variable (173–176). Latex gloves appear preferable to poly-vinylchloride, since the rates of perforation in latex gloves are generally lower than those made from poly-vinylchloride and latex gloves tend to fit better, improving tactile sensation and reducing injury risks (154,165,173,177–180). It has been suggested that increased government

supervision may be needed world-wide in monitoring the quality of surgical gloves (181), beyond that of current FDA approval (182).

Data suggest that the powder used in gloves may increase bacterial environmental contamination. In animal models, corn starch (a material used as a glove powder) promotes wound infection (183). Talc also may elicit tissue toxicity (184,185). As discussed below, concerns related to latex allergy have further led to promotion of powder-free gloves. Infection control teams should support switching from use of powdered to powder free gloves.

Gloves may reduce dexterity and thereby increase the risk of percutaneous injury (186). In one study of dentists, latex glove wear was associated with a 16-fold increase in percutaneous injury with endodontic Þle manipulation compared to when the same group was tested barehanded. Dynamometer tests showed a 36% decrease in light-touch proprioception when the dentists were gloved as compared to scores when they were tested barehanded. In a study of surgeons, statistically signiÞcant differences in moving two-point discrimination for the dominant hand index Þnger were found for no gloves versus double gloves ($p = 0.05$) and single versus double gloves ($p = 0.02$) (187).

The advent of newer gloves which can provide an excellent Þt and improved dexterity compared to products in the past, such as some current nitrile, polyurethane and other polymer gloves, may now offer possible alternatives to latex (180,188Ð190).

During a surgical operation when an overt sharps injury occurs, the aseptic barrier is broken and except under emergency circumstances the injured worker leaves the operating Þeld and returns upon the re-establishment of asepsis. Thus, the primary risk in these circumstances is generally from patient to worker (170). Inapparent barrier breakdown, however, appears to be common (77,191). If a single glove is worn, surveys have found frequent gross contamination of the hands (192). With double gloving, such gross contamination is greatly reduced (192), which led to the suggestion of double gloving for surgeons (193). Some surgeons went further, including a thin cloth glove between the two latex gloves, in an effort to impede minor needlestick injuries. The problem with double gloving can be a loss of dexterity. A study of vascular surgeons recommended against double gloving, Þnding that the loss of dexterity led to an actual increase in glove perforation rates for the operating room surgeon and scrub nurse (194). Similarly, an analysis of the routine dental treatment of HIV-infected patients concluded that there was unlikely any signiÞcant beneÞt from the use of a double-gloving technique, or of a glove perforation detection system (195). Other analyses have favored double gloving, particularly with deep surgical procedures (172,196,197). Further complicating the picture are studies in which methodological problems and biases may exist (193). In summary, the relative merits of double gloving are controversial, so that recommendations will continue to need to be adapted to the particular specialty and speciÞc procedures based upon available evidence.

One study found that over half of needlestick injuries occurred to the index Þnger of the non-dominant hand (83). Thus, the addition of reinforcement to this portion of the glove or the routine use of a thimble-equivalent could dramatically reduce occupational exposures. Various safety devices to guard against needlesticks and sharps injuries have been marketed (198,199). Although these can add signiÞcant costs to the workplace, this is offset by risk reduction, and the unit costs may be reduced with increased use and production efÞciencies of scale. Training in the use of all new devices is essential. The Final Rule from OSHA in 2001 detailed some of the dilemmas and costs (200).

The Needlestick Safety and Prevention Act of 2000 and the 2001 revised Blood-borne Pathogens Standard require health care facilities to maintain a sharps injury log. The log must include, at a minimum, the type and brand of device involved in the exposure incident, the department where the exposure occurred, and an explanation of how it occurred. Among the proprietary systems developed for such purposes is the Exposure Prevention Information Network (EPINet[a]), which was developed by Dr. Janine Jagger and colleagues in 1991 to provide standardized methods for recording and tracking percutaneous injuries and blood and body ßuid contacts (http://hsc.virginia.edu/medcntr/centers/epinet/). The EPINet[a] system consists of a series of report forms and software for entering and analyzing the data from the forms, and has been utilized by a wide variety of institutions. Data from EPINet[a] and other sources have been used to estimate the number of annual percutaneous injuries in the U.S. (201). Although the extent of reduction in needlestick injury rates with initial protective devices had been questioned (202), beneÞts have since been establishedÑ although cost-efÞcacy issues remain (203,204). With increasing production of devices and expected concomitant reduction in unit cost, the cost-beneÞt balance can be expected to improve further.

Healthcare workers are at greatest risk of exposure to blood-borne pathogens when handling contaminated sharps. More than half a million sharps related injuries occur each year, according to OSHA.

The International Healthcare Worker Safety Center of the University of Virginia estimates that an average of 30 percutaneous and blood and body ßuid exposures occur per 100 occupied beds each year. It is estimated that 39% of all exposure injuries are never reported. Annually, this could potentially cause 18 to 35 new cases of HIV infection, about 400 new cases of hepatitis B infection, and 39 to 1,967 new cases of hepatitis C infection. It is commonly accepted, based on evolving studies, that sharps safety devices signiÞcantly reduce the risk of injury during procedures. Studies have demonstrated that safer intravenous systems have reduced needlesticks associated with

piggy-back tubing and intravenous medication administration (87). Needlestick injuries which carry the highest risk of HIV, HBV and HCV transmission are those associated with the hollow-bore needles used in intravenous catheters, phlebotomy, and injecting medications; further evaluation of the efficacy of risk reduction and safety improvement are needed (87). It should be noted that for a few safety devices, because of design flaws, the risk of injuries increased – for example, safety features that are clumsy or difficult (and therefore never activated by the worker). Thus, implementing the use of safer sharps products alone will not eliminate all blood and body fluid exposures. Safer work practices much be reinforced in all work areas.

Safety devices include needleless systems, engineered protective devices for needles and other sharps as well as breakage resistant capillary tubes to decrease exposure. General guidelines for sharps safety rules are as follows: (1) use of a safety needle device or needleless system for withdrawal of body fluids, accessing a vein or artery or administering medications or fluids; (2) use of either a needleless system or a needle with engineered sharps protection for any other procedure requiring needle devices when available; and (3) use of a non-needle sharps with engineered sharps protection when available. When using sharps, always follow effective, safe handling techniques to prevent injury. Bending, breaking, manipulating, shearing or recapping contaminated needles or sharps are prohibited, except in specific procedures when recapping is procedurally required and then only a resheathing recapping device or a one-handed "scoop" method may be used.

Disposable sharps are not to be reused. Contaminated broken glass should always be picked up using a broom and dustpan, forceps or tongs and never ones' hands. Sharps safety includes discarding contaminated sharps immediately or at "point-of-use" in an appropriate, puncture-resistant, color-coded container. NIOSH suggests this risk can be decreased by placing sharps containers within easy reach – slightly below eye level, and not allowing containers to overfill. These safe work practices may reduce needlestick or sharps exposure.

Continued refinements and improvements towards injury reduction, which can protect both patient and worker, include safer work practices, engineering controls, improvement of the design and organization of jobs and tasks, and facilitation and reinforcement of safer behavior by institutions (161). Sharps injuries and fluid splashes will not be eliminated by simply buying and using sharps with engineered safety protection. Many types of injury occur during use and will not be prevented by safety mechanisms. There will also remain unpredictable elements both within the facility and from patients. The system envisioned under the OSHA regulations seeks to minimize the risks by systematic safer work practices and safer devices. All of this needs to be documented and evaluated for efficacy; the safety logs mandated by OSHA will be valuable in ongoing assessments by individual facilities and in research studies.

Latex Sensitivities and Allergies

Exposure to latex and latex products has greatly increased over the last two decades. With the advent of universal precautions, latex glove usage greatly increased. Standard precautions has maintained that practice for bloodborne pathogens, but has further expanded the overall use of gloves to include contact with any body fluid or body substance (except for perspiration). Other exposures to latex products have also significantly increased in the population as a whole over this time period, including the use of condoms for safer sex (205–207).

There has emerged a recognition of latex-related allergic phenomena (208–215). A wide variety of products contain latex: medical supplies, personal protective equipment (PPE), and numerous household objects (214). A recent study by the National Institute for Occupational Safety and Health found no significant difference in work-related symptoms between latex sensitized and non-sensitized workers (216). Environmental concentrations of latex were higher in the work areas of the non-sensitized workers, and higher in the clinical than in the non-clinical areas. Occupational latex glove use was judged not to be a risk factor for latex sensitization (216).

Within health care facilities, powdered latex gloves represent one of the largest sources of latex antigen. Glove powder (cornstarch) can function as a carrier for latex allergens (217,218); antigens may be carried in association with the powder and liberated into the air when gloves are applied or removed (211). Once airborne, the antigen may be inhaled or come into contact with mucous membranes. Powder-free gloves, with reduced latex protein content, are thus now preferable if using latex. Significant reductions in the airborne latex antigen can be accomplished by using low-allergen-containing latex gloves or latex-free gloves (such as polyurethane or nitrile gloves). Low-allergen latex gloves are now comparable in price to high-allergen-containing latex gloves. Cost remains a major concern of institutions when moving to latex-free gloves. Some workers complain of increased sweating when using nitrile gloves, with attendant personal complaints. Also, tactile sensation may be better with latex gloves, and thus may reduce the risk of sharps injuries. Thus, when dealing with possibly infectious fluids or materials, low-allergen latex gloves are often still recommended as the preferred product.

It has been recommended that high-allergen-containing latex gloves be replaced, at the least, in places such as the operating room, to protect both patients and health care workers but primarily to reduce exposure in general and thereby reduce the incidence of latex allergies. These and other efforts, such as frequent cleaning of ventilation filters and vacuum bags (which attract such particles) and

frequent cleaning of areas contaminated with latex (such as upholstery, carpets, ventilation ducts, and plenums) to reduce the amount of allergen-laden dust in the environment should be employed when possible (214).

Education of personnel is important. All workers should avoid using oil-based hand creams when wearing latex gloves, since these can cause glove deterioration and increase latex sensitization. For activities that are not likely to involve contact with infectious materials, such as in food preparation, routine housekeeping, maintenance, and so on, non-latex gloves are preferred in the workplace.

OSHA currently requires that the employer provide PPE in appropriate sizes and accessible locations (219). In addition, "hypoallergenic" gloves, glove liners, powderless gloves, or other similar alternatives must now be readily available and accessible at no cost to those employees who are allergic to the gloves normally provided (219). (The FDA, as of September 30, 1998, prohibited products that contain natural rubber from being labeled as "hypoallergic.") It has been suggested that it may be beneficial for a worker with latex sensitivity to work during the earliest part of the day, before workplace antigen levels begin to rise higher. Workers with true immediate hypersensitivity-type reactions to latex should avoid exposure to latex, and may need to be reassigned to other roles in the health care facility. Workers with latex sensitivities may also already have, or develop, cross-sensitization with other substances (212). Cross-reactivities may lead to impaired specificity in diagnostic testing when trying to determine specific allergic propensities.

Although life-threatening anaphylaxis has occurred in patients invasively exposed to latex (220,221), no deaths attributable to latex exposure have occurred among health care workers. This may in part reflect the significant exposure differences between an invasive procedure and routine occupational exposure with respect to route and dose. A recent review concluded that "increased risk of (latex) sensitization was not clearly associated with the duration of work in health care, the time spent wearing latex gloves, the frequency of exposure, the specific job categories, the use of powdered versus non-powdered latex gloves, the use of latex versus non-latex gloves, or any measurements of ambient exposure to latex proteins. The epidemiologic studies do not support a conclusion that health care workers are at clearly increased risk of latex sensitization and type I allergies compared to other occupations in the United States" (222). Others have argued that workers are at risk (223,224). Further epidemiologic studies, especially prospective studies, are needed that "include measured exposures to latex antigens, that compare health care workers to appropriate referent groups, and that address confounding by atopy, age, sex and race" (222) and avoid methodological biases.

These matters raise issues in terms of workplace regulations, modifications of the environment, and the cost-benefit analyses of universal precautions. Further studies concerning risk reduction, efficacy, and economic assessments also will aid in continuing the development, implementation and assessment of policies.

Compliance and Costs

Universal precautions are expensive, both for materials (such as gloves) as well as the educational effort required. Studies that have assessed efficacy are mixed in their results (77,137,160–162,191,225–233), and the effort may not be cost effective (202,234). Compliance correlates with the perception of risk and extent of knowledge. Adherence to guidelines may be greater when employee compliance is monitored. Institutions may find it useful to work with employee unions to effect meaningful changes that enhance workplace safety.

With the first U.S. documentation of occupational transmission of HIV to a healthcare worker (a woman in a residency program), it was recommended that attention to structured education was important to reduce the risks (21). Other studies have since clearly delineated the significant risks to students and others in training (89,235–243). The need to strengthen our prevention efforts remains (74,162). Enhanced attention to education of those at risk, and in particular those with limited prior experience, is of the utmost importance (21,162).

POST-HIV EXPOSURE PROPHYLAXIS— A HISTORICAL INTRODUCTION

The time period immediately following an occupational exposure is a difficult one for both the exposed worker and his physician or occupational health service. The low statistical risk of acquisition of a deadly infection provides limited comfort. It is helpful to have a comprehensive program in place to deal with the anticipated accidental exposures (53,244,245).

Early on, researchers pondered the potential value of treatment in the event of a significant exposure event. In a multi-institutional prospective study initiated in 1985 by investigators at the National Institutes of Health of workers at high risk for HIV occupational exposure, consideration was given to post-exposure prophylaxis in the very trial design, at a time when all therapies were strictly experimental (58) (and S. H. Weiss, unpublished data).

Around the time of FDA approval of the first antiretroviral agent for treatment of HIV, zidovudine (246), the manufacturer (then the Burroughs-Welcome Company) sponsored a randomized trial offering zidovudine to workers exposed to HIV (247). Given the low risk of seroconversion, it was unlikely that a sufficient sample size could ever have been accrued for this clinical trial to prove efficacy. Furthermore, the ready availability of the

approved drug, worker apprehensions, and the delay in drug access through the trial led few to enroll. The trial was abandoned after very limited enrollment. A decade later, a new effort to enroll exposed workers so as to monitor for possible drug toxicity was undertaken (the HIV Post Exposure Prophylaxis Registry) with much fanfare, but it had no greater success at enrollment, and was abandoned without having accomplished its primary objective (248).

Evidence from animal studies suggesting that zidovudine might be useful (249–251) prompted the USPHS to formulate guidelines concerning post-exposure prophylaxis (252). Zidovudine does have some toxicity in this setting, sometimes severe (253–256). Data, on otherwise healthy workers given a limited course of zidovudine, found a worker whose neutrophil count declined to 500/mm^3 (257), a level at which serious infections might occur. Due to considerable side effects, a very high proportion of workers discontinue zidovudine prophylaxis even in the context of research studies (255). There is also concern about the potential for delayed mutagenicity or carcinogenicity (258). Embryonic toxicity in mice at high zidovudine doses has been demonstrated (259). The initial USPHS judgment was that it could "not make a recommendation for or against the use of zidovudine for this (post-exposure prophylaxis) purpose because of the limitations of current knowledge" (252). Nucleoside analog drugs are known to induce mitochondrial dysfunction. Concerns for toxicity exist for other anti-retroviral drugs as well (258).

In the absence of demonstration of high clinical efficacy in the post-exposure setting, some clinicians have questioned the wisdom of administration. Since some laboratory data suggest that administration of zidovudine within an hour or two may be requisite to achieve a substantial likelihood of prophylactic efficacy (260), mechanisms for rapid decision making and initiation of therapy are important if zidovudine or other anti-retroviral therapy is to be given at all.

A decision analysis study concerning the issue of post-exposure prophylaxis (PEP) for needlestick exposures to HIV concluded that even a very low zidovudine efficacy (of 3–8%) might warrant its use (261). On the other hand, subsequent laboratory data suggest a limitation to its usefulness (260,262,263). Zidovudine benefits do not clearly outweigh the risks after exposure to blood of unknown serologic status, or if there is a delay in starting therapy (261,264–266). Furthermore, multiple documented instances of seroconversion in which prophylactic zidovudine was given, and sometimes initiated extremely rapidly, demonstrate it is not 100% efficacious (141,267–275,275–278).

In December 2000, two instances of life-threatening hepatotoxicity were published concerning health-care workers in Chicago who had been taking nevirapine (NVP) for postexposure prophylaxis after occupational HIV exposure (279,280). In one case, a 43 year old female healthcare worker required liver transplantation after developing fulminant hepatitis and end-stage hepatic failure while taking NVP, zidovudine, and lamivudine as PEP following a needlestick injury. In the second case, a 38 year old male physician was hospitalized with life-threatening fulminant hepatitis while taking NVP, zidovudine, and lamivudine as PEP following a mucous membrane exposure.

Based on these anecdotal case reports, the CDC and FDA reviewed MedWatch reports of serious adverse events in persons taking NVP for postexposure prophylaxis received by FDA to better characterize NVP-associated postexposure prophylaxis toxicity (281). (MedWatch, under the aegis of the FDA, **passively** accrues toxicity data as part of routine post-licensure and marketing surveillance.) Including the two case reports of fulminant hepatitis, FDA had received reports of 22 cases of serious adverse events related to NVP taken for postexposure prophylaxis from March 1997 through September 2000. These 22 events included hepatotoxicity (12), skin reaction (14), and rhabdomyolysis (one); four cases involved both hepatotoxicity and skin reaction, and one case involved both rhabdomyolysis and skin reaction. In the CDC HIV postexposure prophylaxis registry, which collected data on occupational HIV postexposure prophylaxis use from October 1995 through March 1999, six cases of serious adverse events related to postexposure prophylaxis were found retrospectively among 492 registered participants; a severe skin reaction occurred in one of 11 health-care workers taking a regimen that included NVP.

Their analysis indicated that healthy persons taking abbreviated four-week NVP regimens for postexposure prophylaxis were at risk for serious adverse events. Because most occupational HIV exposures do not result in transmission of HIV, the USPHS recommended that clinicians considering prescribing postexposure prophylaxis for exposed persons must balance the risk for HIV transmission represented by the exposure and the exposure source against the potential toxicity of the specific agent(s) used. When postexposure prophylaxis is prescribed, the manufacturer's package insert should be consulted for dosing instructions, possible side effects, and potential drug interactions. In many circumstances, the risks associated with NVP as part of a postexposure prophylaxis regimen outweighed the anticipated benefits (281).

Thus, whether to administer zidovudine or other post-exposure therapy depends upon the individual circumstances, including the nature of the exposure, documentation of the likelihood that the source was infected with HIV and any surrogate measures of infective titer, the risk-taking perceptions of the exposed worker, and the availability of alternative experimental therapies. The issues of pregnancy and contraception are also relevant related to safety issues. Some workers may reasonably decide to "take their chances." Others who have a particularly high risk of seroconversion (e.g. an

inoculation with a substantial amount of blood) might decide to try experimental combination chemotherapy in consultation with an infectious disease expert, rather than zidovudine alone. These issues were addressed in part by provisional guidelines released in 1996 (282), although variations in approach are appropriately being debated, as discussed further below (255,256,283–286).

POST-EXPOSURE PROPHYLAXIS—CURRENT GUIDELINES

In late 1995, the CDC reported in summary form in *MMWR* an analysis of 31 selected healthcare workers who seroconverted to HIV as a consequence of well-documented occupational exposures (278). A full report, extended to 33 seroconverters, was published in 1997 (70). These data on seroconverters include critical details that were collected only retrospectively. These data were then compared with prospectively collected data from 665 (679 in *MMWR*) healthcare workers who had participated in CDC studies of occupational exposure but who were not known to have seroconverted ("controls"). Thus, although case-control in design, the sources and types of bias in the two study groups (seroconverters and "controls") differ.

The results were consistent with an increased risk of HIV transmission from exposure events where high viral load exposure was likely, such as visible contamination of a device with an HIV-infected patient's blood, deep injury, or the patient being terminally ill.

In the univariate analyses (in Cardo's Table 1), there was no evidence of protection against seroconversion by prophylaxis with zidovudine (95% confidence interval for the odds ratio was 0.3 to 1.4, p = not significant). In contrast, in a multivariate model zidovudine prophylaxis was statistically significant in terms of reduction in risk (70). This unusual and surprising biostatistical situation sometimes can arise where statistical confounding exists.

However, this multivariate model included many variables (five) despite only a limited number of outcomes (33 seroconverters). In such situations, the robustness of the multivariate model is highly questionable from a statistical viewpoint. As pointed out by Concato and colleagues in a 1993 general biostatistics critique, "risk estimates may be unreliable if the multivariable data contain too few outcome events relative to the number of independent variables" (287). Multivariate methods of analysis can yield problematic results when methodological guidelines and mathematical assumptions are ignored (288). "In general, the results of models having fewer than 10 outcome events per independent variable are thought to have questionable accuracy and the usual tests of statistical significance may be invalid" (287). This guideline would permit a maximum of only three variables in Cardo's logistic regression model. Simulation work concerning the number of events per variable in logistic regression analysis have confirmed these guidelines (288–293). "The key issue in the overfitting is an ample number of outcome events, not just a large sample size. When numerous variables are included in an attempt to "control" or "adjust" the data, accuracy of results can be threatened by overfitting or by other mechanisms. The number of variables selected for analysis should therefore be parsimonious, based on clinical sensibility and suitable data quality" (287).

Although the report by Cardo et al. has been widely cited as demonstrating that zidovudine post-exposure prophylaxis is 79% efficacious and as a key justification for its routine use, these claims in fact represent a gross overstatement of our current knowledge base. There is no convincing evidence for any protection at all, and the claim for protection resides only in an over-analysis that is questionable statistically. It must be noted that the absence of proof that prophylaxis provides protection does *not* rule out the possibility that there may be some protection. But, all post-exposure prophylaxis policy recommendations are best considered tentative. Thus, as the USPHS guidelines presented in Tables 30.2 and 30.3 presume efficacy of post-exposure prophylaxis, there is adequate reason to consider alternative guidelines.

Given the widespread use of zidovudine and, more recently, other therapies among patients, the issue of primary resistance to zidovudine or to combination chemotherapy regimens is a valid concern (294). Indeed, multi-drug clinical trials have demonstrated increasingly subsets of patients with primary HIV infection in whom underlying zidovudine as well as other anti-retroviral drug resistance exists (295). This phenomenon may even have somewhat limited the ability to detect postexposure prophylaxis protection from zidovudine in the Cardo study, and supports the theoretical basis for using combination therapy in this setting.

In light of the expectation that HIV strains resistant to combination therapy would arise (296), it was predictable that a case would eventually be reported in a prominent journal of HIV transmission to a healthcare worker despite full and prompt recommended "prophylaxis" (14,297,297,298). However, anecdotal case reports do not necessarily undermine the concept. They serve as a reminder of the necessity of continually reassessing guidelines and of the complexity of HIV and of the pandemic. Indeed, genotypic analysis of HIV-1 isolates to identify antiretroviral resistance mutations from source patients involved in health care worker occupational exposures has been proposed (299). In one small study, the majority of HIV-exposed workers who remained virologically and serologically negative demonstrated transient cellular immune responses to HIV-specific peptides in temporal association with their HIV exposures (32,123). As these responses may have been to non-infectious particles, such data do not prove widespread transient infection, but merely demonstrate the mounting of an immunologic response. Others have reported finding autoantibodies against CD4 significantly before sero-conversion (300). A

TABLE 30.2. *The 2001 update of the U.S. Public Health Service recommendations for basic and expanded HIV postexposure prophylaxis (PEP) regimens*

1. BASIC REGIMEN
   - Zidovudine (RETROVIR™; ZDV; AZT) + Lamivudine (EPIVIR™; 3TC); available as COMBIVIR™
   – ZDV: 600 mg per day, in two or three divided doses, and
   – 3TC: 150 mg twice daily.

   Advantages
   – ZDV is associated with decreased risk of HIV transmission in the CDC case-control study of occupational HIV infection.
   – ZDV has been used more than the other drugs for PEP in HCP.
   – Serious toxicity is rare when used for PEP.
   – Side effects are predictable and manageable with antimotility and antiemetic agents.
   – Probably a safe regimen for pregnant HCP.
   – Can be given as a single tablet (COMBIVIR™) twice daily.

   Disadvantages
   – Side effects are common and might result in low adherence.
   – Source patient virus might have resistance to this regimen.
   – Potential for delayed toxicity (oncogenic/teratogenic) is unknown.

2. ALTERNATE BASIC REGIMENS
   - Lamivudine (3TC) + Stavudine (ZERIT™; d4T)
   – 3TC: 150 mg twice daily, and
   – d4T: 40 mg (if body weight is < 60 kg, 30 mg twice daily) twice daily.

   Advantages
   – well tolerated in patients with HIV infection, resulting in good adherence,
   – serious toxicity appears to be rare, and
   – twice daily dosing might improve adherence.

   Disadvantages
   – Source patient virus might be resistant to this regimen.
   – Potential for delayed toxicity (oncogenic/teratogenic) is unknown.
   - Didanosine (VIDEX™, chewable/dispersible buffered tablet; VIDEX™ EC, delayed-release capsule; ddI) + Stavudine (d4T)
   – ddI: 400 mg (if body weight is < 60 kg, 125 mg twice daily) daily, on an empty stomach.
   – d4T: 40 mg (if body weight is < 60 kg, 30 mg twice daily) twice daily.

   Advantages
   – Likely to be effective against HIV strains from source patients who are taking ZDV and 3TC.

   Disadvantages
   – ddI is dif cult to administer and unpalatable.
   – Chewable/dispersible buffered tablet formulation of ddI interferes with absorption of some drugs (e.g. quinolone antibiotics, and indinavir).
   – Serious toxicity (e.g. neuropathy, pancreatitis, or hepatitis) can occur. Fatal and nonfatal pancreatitis has occurred in HIV-positive, treatment-naive patients. Patients taking ddI and d4T should be carefully assessed and closely monitored for pancreatitis, lactic acidosis, and hepatitis.
   – Side effects are common; anticipate diarrhea and low adherence.
   – Potential for delayed toxicity (oncogenic/teratogenic) is unknown.

3. EXPANDED REGIMEN
   Basic regimen plus *one* of the following:
   - Indinavir (CRIXIVAN™; IDV)
   – 800 mg every eight hours, on an empty stomach.

   Advantages
   – Potent HIV inhibitor.

   Disadvantages
   – Serious toxicity (e.g. nephrolithiasis) can occur; must take eight glasses of uid per day.
   – Hyperbilirubinemia common; must avoid this drug during late pregnancy.
   – Requires acid for absorption and cannot be taken simultaneously with ddI in chewable/dispersible buffered tablet formulation (doses must be separated by at least one hour).
   – Concomitant use of astemizole, terfenadine, dihydroergotamine, ergotamine, ergonovine, methylergonovine, rifampin, cisapride, St. John's Wort, lovastatin, simvastatin, pimozide, midazolam, or triazolam is not recommended.
   – Potential for delayed toxicity (oncogenic/teratogenic) is unknown.

TABLE 30.2. *Continued.*

- Nel navir (VIRACEPT™; NFV)
  - 750 mg three times daily, with meals or snack, or
  - 1250 mg twice daily, with meals or snack.

Advantages
- potent HIV inhibitor, and
- twice dosing per day might improve adherence.

Disadvantages
- Concomitant use of astemizole, terfenadine, dihydroergotamine, ergotamine, ergonovine, methylergonovine, rifampin, cisapride, St. John's Wort, lovastatin, simvastatin, pimozide, midazolam, or triazolam is not recommended.
- Might accelerate the clearance of certain drugs, including oral contraceptives (requiring alternative or additional contraceptive measures for women taking these drugs).
- Potential for delayed toxicity (oncogenic/teratogenic) is unknown.

- Efavirenz (SUSTIVA™; EFV)
  - 600 mg daily, at bedtime.

Advantages
- Does not require phosphorylation before activation and might be active earlier than other antiretroviral agents (note: this might be only a theoretical advantage of no clinical bene t.)
- One dose daily might improve adherence.

Disadvantages
- Drug is associated with rash (early onset) that can be severe and might rarely progress to Stevens-Johnson syndrome.
- Differentiating between early drug-associated rash and acute seroconversion can be dif cult and cause extraordinary concern for the exposed person.
- Nervous system side effects (e.g. dizziness, somnolence, insomnia, and/or abnormal dreaming) are common. Severe psychiatric symptoms are possible (dosing before bedtime might minimize these side effects).
- Should not be used during pregnancy because of concerns about teratogenicity.
- Concomitant use of astemizole, cisapride, midazolam, triazolam, ergot derivatives, or St. John's Wort is not recommended because inhibition of the metabolism of these drugs could create the potential for serious and/or life-threatening adverse events (e.g. cardiac arrhythmias, prolonged sedation, or respiratory depression).
- Potential for oncogenic toxicity is unknown.

- Abacavir (ZIAGEN™; ABC); available as TRIZIVIR™, a combination of ZDV, 3TC, and ABC
  - 300 mg twice daily.

Advantages
- potent HIV inhibitor, and
- well tolerated in patients with HIV infection.

Disadvantages
- Severe hypersensitivity reactions can occur, usually within the rst six weeks of treatment.
- Potential for delayed toxicity (oncogenic/teratogenic) is unknown.

4. ANTIRETROVIRAL AGENTS FOR USE AS PEP ONLY WITH EXPERT CONSULTATION
   - Ritonavir (NORVIR™; RTV)

Disadvantages
- dif cult to take (requires dose escalation),
- poor tolerability, and
- many drug interactions.

- Saquinavir (FORTOVASE™, soft-gel formulation; SQV)

Disadvantages
- Bioavailability is relatively poor, even with new formulation.

- Amprenavir (AGENERASE™; AMP)

Disadvantages
- Dosage consists of eight large pills taken twice daily.
- Many drug interactions.

- Delavirdine (RESCRIPTOR™; DLV)

Disadvantages
- Drug is associated with rash (early onset) that can be severe and progress to Stevens-Johnson syndrome.
- Many drug interactions.

TABLE 30.2. *Continued.*

- Lopinavir/Ritonavir (KALETRA™)
  – 400/100 mg twice daily.

Advantages
– potent HIV inhibitor, and
– well tolerated in patients with HIV infection.

Disadvantages
– Concomitant use of ecainide, propafenone, astemizole, terfenadine, dihydroergotamine, ergotamine, ergonovine, methylergonovine, rifampin, cisapride, St. John's Wort, lovastatin, simvastatin, pimozide, midazolam, or triazolam is not recommended because inhibition of the metabolism of these drugs could create the potential for serious and/or life-threatening adverse events (e.g. cardiac arrhythmias, prolonged sedation, or respiratory depression).
– May accelerate the clearance of certain drugs, including oral contraceptives (requiring alternative or additional contraceptive measures for women taking these drugs).
– Potential for delayed toxicity (oncogenic/teratogenic) is unknown.

5. ANTIRETROVIRAL AGENTS GENERALLY NOT RECOMMENDED FOR USE AS PEP
   - Nevirapine (VIRAMUNE™; NVP)
     – 200 mg daily for two weeks, then 200 mg twice daily.

   Disadvantages
   – Associated with severe hepatotoxicity (including at least one case of liver failure requiring liver transplantation in an exposed person taking PEP),
   – Associated with rash (early onset) that can be severe and progress to Stevens-Johnson syndrome,
   – Differentiating between early drug-associated rash and acute seroconversion can be dif cult and cause extraordinary concern for the exposed person, and
   – Concomitant use of St. John's Wort is not recommended because this might result in suboptimal antiretroviral drug concentrations.

speculative possibility is that low level, active replication (infection) does occur in some instances and that cellular immune responses play a role in controlling this initial, early infection Ðto the point of eradication or to inducing latency (with residual, unmeasurable infection). The rare cases of delayed seroconversion might then reßect instances of delayed escape from such control.

If active replication occurs in a sizeable proportion of those who do not seroconvert, the rationale for control by aggressive treatment with multiple anti-retroviral drugs is enhanced; the object of this being to reduce viral load at the earliest possible stage and maximize the chances for immune control. The tradeoff is treating many persons with potentially toxic drugs who do not need them (since most workers do not seroconvert) versus waiting, with close monitoring, until some sign or symptom of HIV infection (either clinical or virologic) occurs before initiating treatment. In the absence of animal studies that demonstrate the efÞcacy of therapy for protection in the post-exposure situation, if not human clinical trials, post-exposure therapy must still be considered experimental.

The CDC developed an interagency working group to explore these issues, culminating in guidelines concerning chemoprophylaxis (282) that tried to characterize degree of risk, and stratify suggested prophylaxis into Òrecommend,ÓÒoffer,Óand Ònot offer.ÓKey aspects to consider in assessing an exposure are summarized in Table 30.4.

In 2001, the USPHS guidelines were further revised (14). The number of drugs to be offered or recommended varies with the circumstances (Table 30.3). In the highest risk scenarios, where the expected risk of seroconversion can be far greater than the overall summary estimate, there is clearly strong theoretical support for intervention with multi-drug therapy. It is likely that the provisional guidelines in Tables 30.2 and 30.3 will continue to be modiÞed periodically, so the sources discussed below should be routinely consulted for updates in conjunction with experts in the Þeld.

Concordant with the above guidelines, some clinics, ofÞces and hospitals stock these drugs for potential immediate use in postexposure prophylaxis and others arrange for emergency prescriptions to be Þlled. It is not widely recognized that the labeling for these drugs in the FDA approved package inserts has not included post-exposure prophylaxis as one of the Òapproved indications.Ó (For example, Merck Òdoes not recommend the use of its products in any manner other than described in the prescribing informationÓ(Personal communication, David Horn, M.D., Merck Director of Medical Services, November 5, 1996).) The joint FDA and USPHS promulgation of postexposure therapy is a notable (and perhaps a sole) exception to standard FDA policies regarding promulgation of off-label uses of prescription pharmaceuticals.

One of the remaining difÞculties is the absence of toxicity and safety information for these regimens among healthy adults. An anonymous registry set up to assess postexposure prophylaxis drug use and toxicity closed in

TABLE 30.3. *Recommended HIV postexposure prophylaxis for percutaneous injuries (from the CDC, 2001 (14))*

	Infection status of source				
Exposure type	HIV-Positive Class 1*	HIV-Positive Class 2*	Source of unknown HIV status†[1]	Unknown source	HIV-Negative
Less severe[1]	Recommend basic 2-drug PEP	Recommend expanded 3-drug PEP	Generally, no PEP warranted; however, consider basic 2-drug PEP** for source with HIV risk factors	Generally, no pEP warranted, however, consider basic 2-drug PEP** in settings where exposure to HIV-infected persons is likely	No PEP warranted
More severe	Recommend expanded 3-drug PEP	Recommend expanded 3-drug PEP	Generally, no PEP warranted; however, consider basic 2-drug PEP** for source with HIV risk factors	Generally, no PEP warranted; however, consider basic 2-drug PEP** in settings where exposure to HIV-infected persons is likely	No PEP warranted

* HIV-Positive, Class 1—asymptomatic HIV infection or known low viral load (e.g. < 1,500 RNA copies/mL). HIV-Positive, Class 2—symptomatic HIV infection, AIDS, acute seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation or postexposure prophylaxis (PEP) should not be delayed pending expert consultation, and, because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.
? Source of unknown HIV status (e.g. deceased source person with no samples available for HIV testing).
? Unknown source (e.g. needle from a sharps disposal container).
[1] Less severe (e.g. solid needle and super cial injury).
** The designation "consider PEP" indicates that PEP is optional and should be based on an individual decision between the exposed person and the treating clinician.
?? If PEP is offered and taken and the source is later determined to be HIV-negative, PEP should be discontinued.
?? More severe (e.g. large-bore hollow needle, deep puncture, visible blood on device, or needle used in patient's artery or vein).

1999 (248). That registry was largely a failure due to a paucity of participants, which biases results from a potentially skewed sample and provided insuf Þcient statistical power for many types of analyses. Although the CDCÕ9 World Wide Web home page on the Internet was expected to carry updated information so as to broadly disseminate results of this monitoring, this never came to fruition. The CDC site (http://www.cdc.gov) can also be consulted for updates on USPHS guidelines. As with any drug, any unusual or severe toxicity should also be reported to the respective manufacturers as well as the Food and Drug Administration (800-332-1088).

The issue of post-exposure prophylaxis for non-occupational HIV exposure has also been raised, e.g. after a sexual exposure or an inadvertent transfusion of contaminated product. Although the published guidelines speci Þcally refrain from extension of these recommendations to other types of exposure, study and recommendations are warranted.

All exposed persons must be counseled regarding the risks of transmission to others, particularly sexual partners, and the need for follow-up past the seronegative window. For those persons who unfortunately acquire HIV infection, the period just prior to the appearance of antibodies (i.e. their blood test is misleadingly still negative) is likely to be a time of particularly high circulating viral loadÑ conveying a high risk of transmission to others through the conventional HIV transmission routes (122).

RISKS TO OUR PATIENTS?

There have been a limited number of clusters of HBV transmission from dentists and surgeons to patients (301), including very rare instances of recurrent HBV transmission despite attempts to improve the professionalÕ9 infection control techniques. Such risks from professionals to patients were not perceived as a major issue, as no such clusters of HBV transmission were reported from 1987 through 1991.

The 1989 provisional guidelines published by the Occupational Safety and Health Administration (OSHA) are oriented towards the protection of both worker and patient (302). However, injuries remained commonplace (77,303). The cumulative HIV risk to some providers, such as trauma and orthopedic surgeons in regions of high HIV prevalence, may be substantial. In summary, the cumulative career risk of occupational infection with HIV may vary widely based on individual circumstances and the population served (304).

With the widespread publicity concerning the CDC investigation of a dental practice in Florida (67,305,306),

TABLE 30.4. *(form the CDC, 2001 (14))*

Factors to consider in assessing the need for follow-up of occupational exposures

- Type of exposure
  - Percutaneous injury
  - Mucous membrane exposure
  - Nonintect skin exposure
  - Bites resulting in blood exposure to either person invloved
- Type and amount of uid/tissue
  - Blood
  - Fluids containing blood
  - Potentially infectious uid or tissue (semen; vaginal secretions; and cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic uids)
  - Direct contact with concentrated virus
- Infectious status of source
  - Presence of HBsAg
  - Presence of HCV antibody
  - Presence of HIV antibody
- Susceptibility of exposed person
  - Hepatitis B vaccine and vaccine response status
  - HBV, HCV, and HIV immune status

Evaluation of occupational exposure sources

Known sources

- Test known sources for HBsAg, anti-HCV, and HIV antibody
  - Direct virus assays for routine screening of source patients are recommended
  - Consider using a rapid HIV-antibody test
  - If the source person is **not** infected with a blood-borne pathogen, baseline testing or further follow-up of the exposed person is **not** necessary
- For sources whose infection status remains unknown (e.g. the source person refuses testing), consider medical diagnoses, clinical symptoms, and history of risk behaviors
- Do not test discarded needles for blood-borne pathogens

Unknown sources

- For unknown sources, evaluate the likelihood of exposure to a source at high risk for infection
- Consider likelihood of blood-borne pathogen infection among patients in the exposure setting

much attention was focused for a while on a related issue: the potential for transmission of HIV from healthcare workers to their patients and the risk of acquisition related to the healthcare environment.

In previous studies, no evidence of risk of AIDS or HIV transmission to patients was found (307Ð311). Several other subsequent investigations failed to reveal any new evidence of transmission risk, and comparative assessments based on the epidemiology of hepatitis B virus have been made.

In the Florida investigation, several patients who had a history of invasive dental procedures were found to be HIV seropositive. Molecular studies suggested the possibility of transmission from the dentist, who died with AIDS, based on the degree of strain similarity. However, limited data on the degree of homology within epidemiologic clusters exist (67). Some studies suggest extremely little variation in such clusters (312Ð314)Ñ raising the possibility that the changes observed by the CDC may be in excess of that associated with immediate (direct or indirect) transmission. Also, the period from Þrst dental visit to AIDS in one person (patient ÒA)Ówas less that two years. This would be an exceptionally short latency period, raising the question of possible earlier acquisition from an unidentiÞed source outside the dental practice (315).

Investigations of the Florida dental practice indicate general (although not absolute) compliance with the CDC recommendations for infection control in dentistry (316), and the CDC has not concluded how transmission might have taken place (315). This is problematic, since the public health implications of transmission to patient(s) via a direct blood-blood transfer versus an indirect route (e.g. faulty decontamination) differ considerably. Nevertheless, revised guidelines for dentistry were issued (317).

Mathematical models of direct transmission suggest a very low risk even with invasive procedures (304,318, 319). When the HIV status of a surgeon is unknown, the overall likelihood of reverse HIV transmission (to the patient) is about one chance in 21 million hours of surgery, with an upper bound 95% risk of one in four million (319). If the surgeon were known to be HIV seropositive, the estimate is one chance in 83,000 hours of surgery. These risks are of about the same magnitude as fatal injury to the patient on the way to the hospital (319). Risks have been similarly estimated for radiologists. If the radiologist is HIV-positive, the risk of transmission to a patient was estimated (by modeling) to be 7.5 per million procedures (95% upper conÞdence interval 15.3 per million) (304). These data would imply limited need to restrict the work of persons infected with HIV (304).

A meeting held by the CDC in February 1991 explored many related issues (320). Should the practices of HIV-infected surgeons and dentists engaged in invasive procedures be restricted? What procedures are ÒinvasiveÓ or Òexposure-prone"? Who, if anyone, and under what conditions, should be tested for HIV? The guidelines from the CDC issued in July 1991 concerning these matters (321) focused on several of these key issues, but left many questions unresolved. Subsequently, some proposals were found to be unworkable and quietly discarded (317,322).

Spurred by public apprehensions, new studies looking back at over 25,000 former patients of healthcare workers known to be HIV seropositive, have been conducted (323). It has even been suggested that in general look-back ventures may not be worth their considerable cost (324) and that they perhaps should only be conducted when there is a clearly identiÞable risk of transmission (324). Multiple additional studies also failed to document any evidence of HIV transmission from workers to any patients (304,325Ð327). These data led some medical groups to reappraise the scientiÞc rationale of the CDC recommendations (320) and to recommend that implementation of policy decisions should await further data or that global restrictions were not warranted (304,323). Other groups seized upon these issues, utilizing them as a surrogate for mobilizing public reaction amid long-standing fears, with the debate becoming charged and politicized.

Revised position papers on the issue of healthcare workers infected with blood-borne pathogens are being developed by organizations such as the Society for Healthcare Epidemiology of America, Inc. (SHEA) (323). The draft 1997 SHEA paper concluded that Òno blanket restriction on the performance of any procedure should be recommended for HIV positive healthcare workersÓ (323).

However, two reports from Europe in 1997 Ð one concerning HIV and one concerning HBV Ðwill undoubtedly lead to further discussion of the issue of possible disease transmission from healthcare professionals to their patients and policy guidelines.

According to press accounts, a French orthopedic surgeon reportedly acquired HIV occupationally in 1983, but did not have his infection diagnosed until 1994 when he developed multiple bouts of unidentiÞed illness (328Ð330). The French Health Ministry subsequently contacted 5,000 persons on whom he had operated since 1983. Of 936 tested, only one patient reportedly tested positive for HIV. The preliminary news reports suggest this female patient had no other risk factors and that analysis of the sequences of viruses from the surgeon and this patient were consistent with probable transmission of HIV from the surgeon to her. Given the complexities of such genetic analyses and the large number of studies conducted, it will be important to critically review any research reports that are published and to ascertain the statistical robustness and the adequacy of the controls utilized. It is conceivable that an apparent relationship might be detected as a chance occurrence given the universe of a large number of (negative) studies, and the issues discussed above concerning the Florida dental case remain pertinent to scientiÞc assessments.

These preliminary data reopened a debate in France concerning whether doctors and/or patients should be tested for HIV before surgery, and the issues of disclosure of HIV status. The French National Council for the Order of Physicians (Conseil National de lÕOrdre des Medcins), which sets standards for the medical profession in France, has considered asking surgeons infected with HIV to voluntarily stop performing some activities, although peer pressures and hospital managers might also inßuence individual responses.

In the United States, some HIV-infected workers concerned about possible loss of employment have not disclosed their HIV status to their employer. Evolving U.S. case law suggests that the anti-discrimination laws may not offer protection to such employees, even though HIV is considered a Òdisability.Ó However, in the event of notiÞcation the terms of employment may change. In short, the issues surrounding both disclosure and non-disclosure remain extremely complicated legally, medically and emotionally, and necessitate expert counsel for both employer and employee.

There have been sporadic, infrequent reports of clustered HBV transmission from surgeons and dentists to patients (331) with instances of abrogation of spread when routine glove use has been implemented (331Ð333). Transmission of HBV is signiÞcantly more likely when the index person is e antigen (HBeAg) positive and HBV also poses a greater risk for transmission than HIV does (21,333Ð335). Since healthcare workers infected with the hepatitis B virus who are ÒeÓ antigen positive (21) who perform certain types of invasive procedures may pose limited but heightened risk to their patients that is insufÞciently ameliorated with the use of gloves, it has been recommended that such workers may need to entirely refrain from such activities (323).

Molecular epidemiologic approaches have been applied to HBV clusters (336). Of interest is a 1997 analysis using molecular approaches that implicates four different surgeons in transmitting HBV to their patients, despite each of the surgeons being HBeAg negative (337). This report raises new concerns about the adequacy of standard precautions and testing procedures.

Hepatitis C virus can be transmitted by percutaneous exposure to blood (338,339). Hepatitis C virus is approximately 10 times more infectious than HIV by percutaneous blood exposure to small volumes of blood (340). (In contrast, HIV is more transmissible than HCV between heterosexual partners and from a mother to her infant (340).) An anesthesiologist who acquired HCV from a patient is believed to have transmitted the infection to another patient, based on molecular analyses of quasi-species sequences and the clinical histories (341). An HCV

outbreak in an ambulatory surgical center has been linked to a technician with chronic HCV who was involved in narcotic tampering (342). An anesthesiologist addicted to opioids was similarly linked to transmitting HCV to over 217 patients in Spain (343).

In summary, further attention to the improvement of workplace safety, which offers bilateral enhancement of protection to both the worker and the patient, remains critical.

OTHER WORKPLACE TRANSMISSION ISSUES

Other Retroviruses

Several studies have examined laboratory workers who work with human T-cell lymphotropic viruses (HTLV-I and HTLV-II), but no evidence of occupationally-related transmission was documented (58,344,345). In a survey of California blood donors (346), one HTLV-II carrier was identified who had no known traditional risk factors for HTLV-II (347) but who was a dentist. Similarly, a Belgian study found a midwife infected with HTLV-I who had no standard risk factors (348). A history of an accidental needlestick or cut was recently linked in a U.S. study of blood donors with their HTLV-I and HTLV-II infections (349). However, no prospectively documented instance of occupational acquisition of HTLV has so far been reported.

In contrast, the CDC reported transmission of the simian immunodeficiency virus (SIV) to two workers related to workplace exposure (350,351). The guidelines for handling these agents, as well as HTLV, are the same as for HIV.

Blood-Borne Pathogens: HBV and HCV

The other possibly infectious materials (OPIM) (see above) that may pose a risk for HBV and HCV include all those noted above for HIV, with the caveat that HBV or HIV, respectively, be substituted in the descriptions of fluids, tissues or cultures that may harbor these agents (105). The early report of transmission of HBV but not HIV after a needlestick injury from an AIDS patient demonstrated the apparent higher infectivity of HBV (Table 30.1) (49). Simultaneous exposures to HIV and HCV leading to transmission have been reported (41), including a case in which there was delayed seroconversion to both HIV and HCV (41).

The hepatitis B vaccination status and the vaccine-response status (if known) of an exposed person should be reviewed (14). A summary of the USPHS guidelines for HBV prophylaxis recommendations for percutaneous or mucosal exposure to blood according to the HBsAg status of the exposure source and the vaccination and vaccine-response status of the exposed person are summarized in Table 30.5. When HBIG is indicated, it should be administered as soon as possible after exposure (preferably within 24 hours). The effectiveness of HBIG when administered >7 days after exposure is unknown. When hepatitis B vaccine is indicated, it should also be administered as soon as possible (preferably within 24 hours) and can be administered simultaneously with HBIG at a separate site (vaccine should always be administered in the deltoid muscle).

The source patient should also be tested for anti-HCV (14). Indeed, some source patients, such as any person with a history of injection drug use after (about) 1970, may be at high risk for HCV and be an as yet undiagnosed carrier. Studies have reported serologically confirmed HCV prevalences in drug users ranging as high as 99% (352).

For the person exposed to an HCV-positive source, the USPHS recommends baseline testing for anti-HCV and ALT activity; and follow-up testing (e.g. at four to six months) for anti-HCV and ALT activity (if earlier diagnosis of HCV infection is desired, testing for HCV RNA may be performed at four to six weeks). All anti-HCV results reported positive by enzyme immunoassay should be confirmed using supplemental anti-HCV testing (e.g. recombinant immunoblot assay (RIBA[a])).

Healthcare professionals who provide care to persons exposed to HCV in the occupational setting should be knowledgeable regarding the risk for HCV infection and appropriate counseling, testing, and medical follow-up. Immunoglobulin and antiviral agents are not recommended for postexposure prophylaxis after exposure to HCV-positive blood. In addition, no guidelines exist for administration of therapy during the acute phase of HCV infection. However, limited data indicate that antiviral therapy might be beneficial when started early in the course of HCV infection. When HCV infection is identified early, the person should be referred for medical management to a specialist knowledgeable in this area.

Other Agents

The immune system impairment that results from infection with HIV leads to an inability to control some infectious organisms, including some pathogens such as *Mycobacterium tuberculosis* that are causing increasing burdens of disease in association with HIV (353–358). This has also led to secondary transmission within urban communities as well as in hospitals, since *M. tuberculosis* (unlike HIV) can be highly infectious through aerosol transmission routes (359). Close-contact spread has been compounded by the crack cocaine epidemic (360), the existence of anergy in HIV-infected persons (leading to delay in diagnosis of new infection with *M. tuberculosis* as well as diagnosis of active tuberculosis) (361–363), and reduced physician prescription of isoniazid prophylaxis (due to hepatotoxicity concerns) during the 1980s

TABLE 30.5. *Recommended postexposure prophylaxis for exposure to hepatitis B virus*

Vaccination and antibory response status of exposed workers*	Treatment		
	Source HBsAG† positive	Source HBsAg† negative	Source unknown or not available for testing
Unvaccinated	HBIG§ × 1 and initiate HB vaccine series¶	Initiate HB vaccine series	Initiate HB vaccine series
Previously vaccinated			
Known responder**	No treatment	No treatment	No treatment
Known nonresponder#	HBIG§ × 1 and initiate revaccination or HBIG × 2	No treatment	If known high risk source, treat as if source were HBsAg positive
Antibody response unknown	Test exposed person for anti-HBs 1. If adequate,** no treatment is necessary 2. If inadequate, administer HBIG × 1 and vaccine booster	No treatment	Test exposed person for anti-HBs 1. If adequate,¶ no treatment is necessary 2. If inadequate,¶ administer vaccine booster and recheck titer in one to two months

* Persons who have previously been infected with HBV are immune to reinfection and do not require postexposure prophylaxis.
† Hepatitis B surface antigen.
§ Hepatitis B immune globulin; dose is 0.06 mL/kg intranuscularly.
¶ Hepatitis B vaccine.
** A repsponder is a person with adequate levels of serum antibody to HBsAg (i.e. anti-HBs □10 mlU/mL).
? A nonresponder is a person with inadequate response to the vaccination (i.e. serum anti-HBs < 10 mlU/mL).
? The option of giving one dose of HBIG and reinitiating the vaccine series is preferred for nonresponders who have not completed a second 3-dose vaccine series. For persons who previously completed a second vaccine series but failed to reposnd, two doses of HBIG are preferred.
? Antibody to HBsAg.

(364Ð366). In addition, multiply-drug resistant strains of *M. tuberculosis* have been described, particularly in HIV seropositive prisoners and intravenous drug users (367,368). A death of a healthcare worker (who had an underlying malignancy and worked in close contact with infected prisoners) attributed to occupational acquisition of multiply-drug resistant tuberculosis highlighted the risks (368).

These issues have important ramiÞcations regarding implementation of respiratory precautions, as well as the design and adequacy of ventilation systems in many types of medical institutions (369). Some buildings are clearly inadequate in terms of the availability of private rooms with appropriate ventilation, and the cost would be great to correct these deÞciencies. Initial OSHA regulations, and in particular those related to respirator use (including type of device and Þt) (370), were revised in response to public comment and vigorous actions by multiple medical groups (371Ð373). Occupational risks in the healthcare setting due to airborne organisms have been reviewed (374). Practices concerning the use of masks and other respiratory personal protective equipment have been evolving (375,376).

Infections by classic pyogenic pathogens also occur in HIV-infected persons (377,378), including pneumococcal infections (379). Reports of antibiotic resistant strains in some common bacteria (380) suggest a possible, future problem arising regarding nosocomial spread of such agents either to other patients or to workers, as the epidemic progresses and new resistance patterns emerge. The possibility of nosocomial spread of *Pneumocystis carinii* has been raised (381Ð384). However, since this agent has not yet been cultured *in vitro*, the genetic (and possible antibiotic resistance) variability has been difÞcult to study and the question difÞcult to address and resolve.

Nosocomial outbreaks of other highly infectious agents, such as measles (385), have also been described. Among laboratory workers and animal care handlers, the speciÞc agents with which they work and to which they might be exposed further broadens the spectrum of occupational risks (58,59,350,386Ð388). A high clinical index of suspicion and adherence to infection control guidelines can be expected to minimize these problems, and re-assessment of the biosafety level of precaution may sometimes be necessary (388).

Other occupationally acquired infections transmitted by blood-borne routes (e.g. hemorrhagic fever viruses such as Ebola virus (389)), organisms spread through the fecal-oral route (salmonella species, hepatitis A virus), and organisms spread by direct contact (herpes simplex virus, *Sarcoptes scabiei*) have been reviewed elsewhere (390). Violation of at least one of three basic infection control principles was noted to be associated with most instances of transmission: hand washing, vaccination of the workers,

or the prompt placement of infectious patients into appropriate isolation (390).

In the aftermath of the terrorism events of September 11, 2001 and the anthrax cases thereafter, there are intensiÞed concerns about bioterrorist threats. Healthcare and laboratory workers would be in the forefront of the Þrst responders to such agents, so new issues continue to ariseÑ such as vaccination status of workers and the persistence of protection for agents such as smallpox, as well as plans for decontamination and surveillance (391Ð399). It will be important for public health professionals, epidemiologists, infection control and infectious disease experts to be integral in the development and implementation of plans, with dissemination of this information at the local level, to maximize our ability to cope if there is an ÒeventÓ while minimizing the substantial risks to workers (399).

SUMMARY

The perception of degree of risk can vary markedly from actual risk. About 5% of the cases of AIDS and HIV infection in the U.S. have occurred in healthcare workers, a percentage that has remained stable over time. Nearly all of these infections are related to lifestyle factors, not occupational risk. The primary occupational risk for HIV is related to percutaneous exposures. The risk to patients appears to be very much smaller, but has received even more publicity. Apprehension exists concerning the future framework of our medical care delivery system, and who will care for whom (400,401). The sensitive handling of legitimate fears and the balancing of conßicting risks will continue to be a challenging task in the decades ahead.

Chapter 31

Antiretroviral Chemotherapy

Robert T. Schooley

The past seven years have witnessed an unprecedented reduction in morbidity and mortality due to HIV-1 in areas of the world in which antiretroviral chemotherapy has been routinely available (1). During this period an ongoing discovery and development effort has resulted in the introduction of additional antiretroviral agents to the point that over 15 are now available and several more are on the verge of approval. These agents have made it increasingly possible to apply a set of principles of antiretroviral chemotherapy that were derived from a series of clinical trials and translational research efforts undertaken in the preceding Þve years. This chapter outlines a current approach to antiretroviral chemotherapy and provides insight into the directions likely to be followed by the Þeld over the next several years.

ANTIRETROVIRAL CHEMOTHERAPEUTIC AGENTS

The rational development of antiretroviral chemotherapy compounds is based on the development of agents that are directed at aspects of the viral replicative cycle that are not shared by the host. In the case of HIV-1, additional complexity is added by the wide variety of cell types in which the virus replicates, artifacts that are introduced by the *in vitro* cultivation of the virus in continuous cell lines and the highly error-prone process of reverse transcription. The high rate of errors introduced into the replicative process results in major strain diversity at the population level and in a propensity in individual patients for the emergence of strains with reduced susceptibility to antiretroviral agents following prolonged exposure to antiviral drugs unless near complete suppression of viral replication is achieved with combination chemotherapy. Finally, HIV-1 poses unique problems of drug delivery, both in terms of general pharmacokinetic principles, which must take into account the need for the continuous maintenance of therapeutic levels of drug, the need for penetration of the central nervous system, and the need to be active in each of the intracellular sites in which the virus replicates.

The initial step in replication of HIV-1 involves its use of the CD4 molecule as its major ligand for interaction of the viral envelope of glycoprotein, gp120, with susceptible cells. This high-afÞnity interaction, which accounts for much of the selectivity of the virus for cells of the CD4 surface phenotype, led to initial efforts directed at interfering with gp120-CD4 binding with soluble forms of the extracellular domain of the CD4 molecule (2). These efforts failed because it had not yet been recognized that CD4 binding was just the Þrst in a series of interactions between the viral envelope and the cell that greatly increased the afÞnity of the virus for the cell (3,4). The interactions that follow CD4 binding include binding with one of two chemokine receptors, CCR5 or CXCR4 (5Ð7). Each viral particle has a tropism for one or both of these ligands that is determined by a short region in the viral envelope and that determines, in part, the tropism of the virus for lymphocytes, monocytes or both types of cells. The viral quasispecies that generally emerges during primary infection is primarily of the CCR5 or monocyte-preferring lineage. As the disease progresses, the virus evolves to the CXCR4-binding subtype in an increasing fraction of patients. CXCR4-binding virus tends to grow preferentially in activated CD4 cells and grows at a more rapid rate *in vitro* than CCR5-binding virus. Emergence of virus of the CXCR4-binding phenotype often signals a more rapid CD4 cell decline and is associated with a more rapid clinical course (8). Recently inhibitors of viral envelope binding to chemokine receptors have been developed, and proof of their activity *in vivo* has been demonstrated (9,10). Each chemokine receptor binding inhibitor is speciÞc for its own viral quasispecies class, i.e. inhibitors of envelope binding to the CCR5 receptor block the growth of CCR5-utilizing virus and those that inhibit

Robert T. Schooley: Infectious Disease Division, University of Colorado Health Sciences Center, Denver, Colorado 80262.

binding to the CXCR4 receptor inhibit replication of CXCR4-utilizing virus.

After chemokine receptor binding, the viral envelope undergoes a change in conformation and the hydrophobic gp41 domain of the envelope fuses with the cell membrane allowing viral entry into the cell. This step, too, has been shown to be amenable to inhibition with fusion inhibitors that mimic one of the strands of the heptad formed in the process of conformational reorganization of the viral envelope that precedes fusion.

After gaining entry into a susceptible cell, the virus is confronted with the problem of converting its genetic information, which is contained in two identical strands of single-stranded RNA, into double-stranded DNA. This conversion requires reverse transcription of the viral genomic RNA in the cellular cytoplasm by an RNA-dependent DNA polymerase known as reverse transcriptase. This enzyme has served as a major target for antiretroviral drug development. Inhibition of reverse transcription is the mechanism of action for all the currently approved nucleoside analogues or nucleotides (zidovudine (AZT), didanosine (ddI), zalcitabine (ddC), stavudine (D4T), lamivudine (3TC), abacavir and tenofovir), as well as for the class of allosteric inhibitors known as non- nucleoside reverse transcriptase inhibitors (NNRTIs).

The double-stranded DNA that results from reverse transcription may exist in a free form within the cytoplasm of the cell, or it may be integrated into host cell DNA. Cellular activation favors integration, which is catalyzed by another viral enzyme termed integrase. Systems were developed to screen for inhibitors of integrase activity several years ago, but only recently have compounds emerged from these screening attempts into later stages of drug development (11,12). After integration, the virus may remain within the host cell in latent form for long periods of time. Viral transcription is controlled by the long terminal repeat (LTR) sequence of the virus. Activation of the viral LTR sequence is, like integration, favored by cellular activation. HIV-1 has evolved a complex regulatory strategy to control its replication. This regulatory process includes several HIV-1 gene products that interact to control splicing and intracellular traffcking of viral RNA. Tat is an 86-kd protein that binds to a short segment of viral messenger RNAs. Binding of these segments by tat protein enhances the effciency of viral replication by several thousand-fold. Rev is another regulatory gene of HIV-1 that plays a critical role in determining the success of the virus in production of its structural genes, especially the viral envelope. Rev encodes a protein that binds to messenger RNA encoding the viral envelope and that is required for efficient translation of the viral envelope mRNA. Several other viral genes including nef, vif, vpu, and vpr with regulatory properties or properties affecting effciency of cell-to-cell transmission of HIV have also been identified. No prototypic drugs have yet been developed that inhibit the action of these regulatory proteins. At this point several investigative groups are attempting to delineate in more detail the function of these genes using molecular biologic approaches.

Translation of the viral gag-pol messenger RNA results in a large fusion polyprotein that must be cleaved into separate gag and pol proteins. This cleavage is mediated by a viral proteinase, which is located within the polyprotein near the gag-pol junction. This proteinase activity, which cleaves the large gag-pol fusion polyprotein into the polymerase component and into four separate gag polypeptides, is essential for the production of viral structural proteins that are capable of maturation into infectious viral particles. Compounds that are capable of inhibiting the viral proteinase with a high degree of selectivity were introduced into clinical use in the mid-1990s and essentially ushered in the current era of antiretroviral chemotherapy.

Thus many potential steps in the viral replicative cycle have been identified that might serve as excellent candidates for the rational development of effective antiretroviral agents. This chapter focuses primarily on approaches that have progressed to clinical trials and practice, namely, inhibition of binding or entry, reverse transcription and viral protease activity.

Inhibitors of Reverse Transcription

Initial success in the development of antiretroviral drugs came from agents directed at inhibiting reverse transcription. The prototype drug in this class, zidovudine (AZT, Retrovir), made its debut as an antineoplastic agent in the 1960s and was resurrected as an antiretroviral drug in 1985. Zidovudine and the other nucleoside analogues currently in clinical use serve as competitive inhibitors of reverse transcription. In each case these nucleoside analogues are taken up by cells susceptible to HIV-1 infection and phosphorylated by kinases of the host cell to triphosphate derivatives of the parent compound. These nucleotides are incorporated by the reverse transcriptase enzyme as the viral RNA template is used to construct complementary DNA. Tenofovir is an exception in this class in that it is administered as a nucleotide and does not require intracellular phosphorylation. Incorporation of these competitive inhibitors prevents further elongation of the DNA and terminates reverse transcription. Because such agents serve primarily to protect susceptible cells from initial infection with HIV, these agents have no effect on previously infected cells.

Zidovudine

Zidovudine was initially found to have antiretroviral activity against murine retroviruses in the 1960s. Zidovudine inhibits HIV replication in cell lines at concentrations in the range of 0.1 μM. Broder and his colleagues initiated

a small phase I escalating dose tolerance trial of zidovudine in individuals with advanced HIV infection in 1985 (13). Subsequent large scale blinded, placebo-controlled randomized trials demonstrated the clinical efficacy of zidovudine in individuals with moderate to advanced HIV-1 infection (14–16). This drug remains in widespread clinical use nearly 20 years after its initial introduction. The major dose-limiting toxicity of AZT was bone marrow toxicity but the use of the drug in lower doses than initially studied in combination with other antiretroviral agents to more fully suppress viral replication has greatly reduced this side effect. Zidovudine is also associated with several subjective complaints. In the initial randomized placebo-controlled trial of zidovudine, anorexia, mild to moderate headaches and insomnia were reported significantly more frequently by zidovudine recipients than by those receiving placebo. In practice, anorexia and headache are the subjective complaints that most frequently trouble patients to the extent that discontinuation of the drug is contemplated. In most cases these symptoms subside despite continuation of the drug over the first two to three weeks of therapy. In situations in which anorexia, nausea, or headache are particularly troublesome, symptomatic relief may be offered with antiemetics, aspirin, or nonsteroidal antiinflammatory agents.

ddC (Zalcitabine)

Zalcitabine (ddC) is another nucleoside analogue with selective antiretroviral activity that was developed shortly after zidovudine. The agent is roughly ten-fold more active against HIV-1 *in vitro* than is zidovudine but a narrow therapeutic index imposed by neurotoxicity and the development of several more potent and better-tolerated drugs in this class has rendered ddC primarily a drug of historical interest (17).

ddI (Didanosine)

Didanosine (ddI) followed zidovudine and ddC into clinical trials in 1988 (18,19). ddI has a serum half-life of 30 to 90 min, but the intracellular half-life of the active metabolite of ddI, dideoxyadenosine triphosphate, allows q24 hourly dosing. Pancreatitis and neuropathy are the major toxicities of ddI that require discontinuation of therapy. The initially unpalatable buffered form of the drug has recently been replaced with an enteric-coated formulation that has resulted in a major improvement in its tolerability. The drug exhibits antiviral activity *in vivo* of roughly the same magnitude (0.6–0.7 $\log_{10}$) as that of zidovudine in previously untreated individuals.

D4T (Stavudine)

D4T (Stavudine) exhibits antiretroviral activity *in vitro* of a magnitude that is similar to either zidovudine or ddI and is less cytotoxic to bone marrow progenitor cells *in vitro* than is zidovudine. From the subjective standpoint, the drug is extremely well tolerated by most individuals. A recently developed extended release formulation has made daily dosing possible. The major toxicities that have been reported with D4T are peripheral neuropathy and hepatitis, both of which occur in 15% to 20% of individuals. Each of these toxicitites may be exacerbated by the simultaneous administration of ddI and both are generally reversible if recognized early. Of particular concern, however, these two agents appear to be the most prone of the nucleoside analogs to cause lactic acidosis and hepatic failure (20–24). The presentation of this syndrome may be subtle and the results of missing the diagnosis may be serious. Patients on nucleoside analogs, especially those taking either D4T or ddI should be followed carefully for symptoms of lactic acidosis that may include lethargy, fatigue, anorexia, weight loss and exercise intolerance. Patients exhibiting any of these symptoms should undergo serum lactic acid monitoring, and the drugs must be discontinued if symptomatic lactic acidosis is noted. The apparent propensity of these two agents to be associated with the increasingly appreciated syndrome of lipodystrophy has also tempered the enthusiasm for their use in the past two years. The use of D4T in combination with AZT is discouraged in that D4T utilizes the same intracellular kinases as zidovudine for phosphorylation and, thus, antagonizes the antiviral activity of zidovudine (25).

3TC, Lamivudine (Epivir)

3TC is a nucleoside with potent antiretroviral activity ($\sim$1.5 $\log_{10}$) that is extremely well tolerated. The major difficulty with 3TC lies in the rapid rate at which viral isolates with reduced 3TC susceptibility arise both *in vitro* and *in vivo* if the drug is not used in combinations that suppress viral RNA below the limits of detectability in the serum (26,27). The mutation induced by 3TC at position 184 of the reverse transcriptase sensitizes the virus to AZT and tenofovir (28,29). This finding, coupled with the excellent tolerability of the drug, has resulted in widespread use of the drug in combination regimens, especially those containing zidovudine or tenofovir that allow one to take advantage of this resistance interaction.

Abacavir (Ziagen)

Abacavir is almost an ideal antiretroviral agent. Antiviral potency in untreated patients is in the range of 1.5 $\log_{10}$; the emergence of high-level resistance requires selection of two or more mutations; and the drug is well tolerated by most patients (30). The only significant problem with the drug is the occurrence of a hypersensitivity reaction in 3–5% of individuals in whom the

drug is used (31). The hypersensitivity reaction usually manifests itself in the Þrst three weeks of drug exposure and is characterized by a multisystem syndrome that may include fever, rash, gastrointestinal and/or pulmonary symptoms. If the drug is continued, the symptoms generally progress and may become severe. In general, these symptoms resolve quickly without residua if the drug is discontinued promptly at the time the syndrome is recognized. If, however, the drug is discontinued and the symptoms are allowed to resolve, a rechallenge with the drug may result in an accelerated recurrence of syndrome that can be fatal. The mechanism of the syndrome is not clear but an association with a speciÞc HLA type (B57) has recently been demonstrated in two small studies involving primarily Caucasians in approximately two-thirds of cases (32,33).

Tenofovir (Viread)

Tenofovir is a nucleotide reverse transcriptase inhibitor and, as such, does not require intracellular phosphorylation to form the active drug moiety (34). It has several ideal properties including potency (~1.25–1.5 $\log_{10}$ of plasmaviral RNA suppression in untreated individuals), convenience (once daily dosing), a relatively unique resistance proÞle and excellent tolerability (35). Tenofovir was initially approved by the FDA on the basis of its action in "salvage" situations in which its addition to failing drug regimens added approximately a half $\log_{10}$ of viral suppression in heavily pre-treated individuals (35–37). In these studies that demonstrated durable activity of up to 48 weeks duration, minimal toxicity was observed and little drug resistance developed, even in patients with incompletely suppressed viral replication. There is a certain degree of cross resistance between tenofovir and thymidine-based nucleoside analogs but the cross resistance is not complete and, as noted earlier, the presence of an M184V mutation induced by exposure to 3TC actually sensitizes the virus to tenofovir (38–40). Recently the drug has been studied in a large trial of previously untreated individuals and found to be as effective as D4T in reducing viral replication in a three-drug regimen including 3TC and efavirenz in addition to either tenofovir or D4T (41). In contrast to D4T, however, tenofovir did not elevate levels of cholesterol or triglycerides above the changes caused by the background drugs in the regimen. This study has Þrmly established tenofovir as an agent that is attractive for use in previously untreated individuals in addition to being useful in patients with multidrug resistant virus.

Nonnucleoside-Based Reverse Transcriptase Inhibitors

Several investigative groups have independently discovered a series of nonnucleoside compounds that exhibit potent inhibitory activity against the HIV-1, but not the HIV-2, reverse transcriptase enzyme. The agents are collectively known as nonnucleoside reverse transcriptase inhibitors (NNRTIs). These compounds are superÞcially quite dissimilar in terms of structure but exert antiretroviral activity by the same allosteric mechanism of action. Each group of agents is extremely selective for HIV-1. The agents exhibit activity against strains of HIV-1 that show reduced susceptibility to nucleoside analog reverse transcriptase inhibitors. NNRTIs exhibit synergistic antiretroviral activity with nucleoside analogue antiretroviral agents. The major difÞculty with the use of these agents resides in the rapid emergence of resistance both *in vitro* and *in vivo* if they are employed in incompletely suppressive regimens. The excellent pharmacokinetic proÞle, relatively good tolerability and inexpensive cost of manufacture of this class of drugs has made them extremely important in the management of HIV-1 infection.

Nevirapine (Viramune)

Nevirapine was the Þrst member of this class to enter clinical trials but the failure to appreciate the need to use it in fully suppressive regimens greatly delayed demonstration of its clinical utility. With the realization that antiviral activity can be prolonged indeÞnitely if used in completely suppressive combination regimens, nevirapine has become an important antiretroviral agent in worldwide use (42). Because of its tolerability and its relatively low cost of manufacture, nevirapine has become an important component of regimens designed to reduce maternofetal transmission of HIV-1 (43). The half-life of the drug allows once daily dosing; *in vivo* antiviral activity is in the range of 1.5 $\log_{10}$ of plasma viral RNA suppression. The major toxicities of the drug include rash that may result in drug discontinuation in as many as 15% of patients and a syndrome of fever and hepatitis that can be fatal if not recognized and managed by drug discontinuation.

Delavirdine

Delavirdine is slightly less potent than nevirapine *in vivo* and shares many of the same toxicities. It has been shown to be active both as a single agent and in the context of combination regimens. The initial formulation of this agent imposed a high pill burden on patients, but a new formulation has signiÞcantly improved the convenience of the drug. Because of the potency and convenience issues, delavirdine has not enjoyed as much commercial success as nevirapine but one advantage that it does exhibit is that it more consistently enhances serum levels of HIV-1 proteinase inhibitors than does nevirapine.

Efavirenz (Sustiva, Stokrin)

Efavirenz has become the dominant agent in this class. It has an *in vivo* potency of 1.5–2.0 $\log_{10}$ and has an extremely prolonged serum half-life that easily supports once daily dosing. As with other members of the class, efavirenz administration may be associated with a rash. The major unique toxicity of efavirenz is its propensity to cause CNS toxicity manifest by somnolence and/or by vivid dreams that can interrupt sleep. This toxicity is dose limiting in up to 15% of patients and is directly related to serum drug levels. Most patients prefer to take the drug at bedtime to minimize the effects of somnolence on their daily pattern of living. Combination regimens consisting of efavirenz and two nucleoside analogs such as zidovudine, D4T or tenofovir and 3TC can be expected to reduce HIV-1 RNA levels to below the limit of detection in more than 80% of previously untreated patients (44).

HIV-1 PROTEASE (PROTEINASE) INHIBITORS

As noted earlier, the HIV-1 gag-pol fusion polyprotein is cleaved by a viral proteinase (protease) that is contained within the gag-pol polyprotein. The viral proteinase enzyme has been expressed in *Escherichi coli* and found to be a dimeric aspartic protease. The deÞnition of structure-activity relationships for the viral protease has greatly enhanced insights into mechanisms of action of this enzyme, and into directed approaches to the development of inhibitors. The introduction of HIV-1 protease inhibitors into clinical trials represented the initial phase of the current revolution in antiretroviral chemotherapy.

Saquinavir (Invirase or Fortovase)

Saquinavir was the Þrst member of this class to enter clinical development. The initial formulation of saquinavir as a hard gel capsule (Invirase) was less than optimal in that it had limited bioavailability because of high Þrst pass metabolism. This formulation exhibits *in vitro* activity that is only slightly greater than zidovudine (45). Despite this relatively limited activity, a clinical endpoint trial demonstrated clear clinical beneÞt of this compound (45a), thus establishing the clinical utility of this class of drugs. The hard gel formulation of saquinavir was so limited in its bioavailability that a soft gel formulation (Fortovase) was developed (46). This formulation was much more bioavailable and exhibited antiviral activity *in vivo* in the range of slightly less than 1.5 $\log_{10}$, but its use has been largely supplanted by the use of the ritonavir/saquinavir combination that provides much more certainty with respect to drug levels and a lower pill burden (47). When combined with ritonavir, the hard gel formulation is preferable to fortovase.

Ritonavir (Norvir)

Ritonavir was the Þrst truly potent protease inhibitor to enter clinical practice and formed the basis of many of the initial studies that demonstrated the extremely high daily production rates of HIV-1 (48). The dose (600 mg twice daily) required to achieve its full antiviral activity *in vivo* ($\sim$1.5 $\log_{10}$) is only marginally palatable, and many patients are unable to tolerate this dose for an appreciable length of time because of gastrointestinal side effects. The major use of ritonavir at this point is as a pharmacologic enhancer in which it is used to retard the Þrst pass metabolism of other protease inhibitors, thereby providing longer dosing intervals, reducing food restrictions and raising achievable trough serum concentrations (47). Even in this clinical application, there is a trade-off between the pharmacological enhancing activity of ritonavir and its side effects with respect to tolerability and its propensity to raise serum levels of cholesterol and triglycerides.

Indinavir (Crixivan)

Indinavir is a potent protease inhibitor with *in vivo* activity in the range of 1.5 $\log_{10}$ (49,50). The drug is better tolerated by most patients than is ritonavir but its short half-life and signiÞcant food interactions greatly decrease the convenience of the agent when used as it was initially developed at a dose of 800 mg every eight hours. This shortcoming is largely overcome when indinavir is pharmacologically enhanced with ritonavir that allows twice daily dosing and removes the requirement that the drug be given on an empty stomach. This greatly improves the convenience of indinavir but does not eliminate the other three limitations of the drugÑ the propensity to cause renal stones, gastrointestinal disturbance and abnormalities with nails and other epidermal tissues. Despite these side effects, the combination of ritonavir and indinavir remains a widely used combinationÑ especially in salvage situations in which the addition of ritonavir greatly enhances trough serum levels (51). Although there have been a number of pharmacologically oriented studies to determine the optimal dosing combination of ritonavir and indinavir, there remains some controversy as to the best strategy. Many experts advocate the use of 100 mg of ritonavir and 800 mg of indinavir twice daily when the combination is used in individuals in which resistance testing does not indicate that indinavir resistance is present and the use of a 200 mg ritonavir dose in the presence of reduced susceptibility to indinavir.

NelÞnavir (Viracept)

Until recently nelÞnavir was the most widely prescribed drug in this class (52,53). The drug is generally well tolerated and can be administered twice daily (at 1,250 mg

bid). Major side effects include gastrointestinal intolerance and elevation of cholesterol and triglycerides. Although the *in vivo* antiviral activity is approximately 1.5 $\log_{10}$, it performs slightly less well in head to head comparisons with lopinavir/ritonavir or efavirenz when durability of viral suppression is compared in an intention to treat analysis (54). Combined dosing with ritonavir is not a viable strategy because of the two-way interactions between nelfnavir and ritonavir; thus, it is the only current protease inhibitor that is usually dosed without ritonavir enhancement. Despite these limitations, many clinicians and patients continue to use the drug because of its resistance profile in which the mutation (D30N) that is usually initially induced has few implications for other protease inhibitors, thus providing an opportunity for the use of other protease inhibitors after nelfnavir failure (55).

Amprenavir (Agenerase)

Amprenavir is a well-tolerated agent that, like nelfnavir, has a resistance profile that overlaps less extensively with other agents in the class (56–59). Because the drug is heavily protein bound, initial hopes that it would exhibit potency *in vivo* superior to other first generation protease inhibitors were not realized (57). The high lipid solubility of the compound has required that it be formulated in a large capsule in which 150 mg of amprenavir is emulsified with vitamin E to enhance bioavailability. This has resulted in the need to administer the drug in a very inconvenient dosing regimen of eight capsules twice dailyÑ a regimen that few patients are willing to tolerate. Amprenavir is, however, pharmacologically enhanced by ritonavir and it is now usually administered at a dose of 900 mg in combination with 100 or 200 mg of ritonavir twice daily. Amprenavir, like atazanavir, appears to be less likely than other currently available protease inhibitors to induce lipid abnormalities. Another unique property of amprenavir is the fact that the N88S mutation that can be induced by several other protease inhibitors renders the virus hypersusceptible to amprenavir (60). There are indications that these variants are particularly likely to respond to amprenavir therapy *in vivo* (61). A more conveniently dosed phosphonate formulation of the drug (now termed Ò908Ó) is in late stages of clinical development and will likely replace amprenavir over the next 12 months.

Ritonavir/Lopinavir (Kaletra)

Lopinavir is structurally similar to ritonavir but has limited bioavailability when administered by itself. In combination with ritonavir, however, it achieves much higher and more sustained serum levels and exhibits potency that is probably slightly greater than other currently used protease inhibitors. Because of the dependence upon ritonavir for bioavailability, it is co-formulated with ritonavir in a single capsule as a fixed dose combination and marketed as Kaletra. This agent is currently the most widely used member of the protease class and has been very well studied both as initial therapy and in salvage situations. The major toxicities of the drug are gastrointestinal intolerance and the induction of hypertriglyceridemia and hypercholesterolemia (62,63). It has been demonstrated to be an extremely potent protease inhibitor and significantly outperformed nelfnavir in a recently published head-to-head comparison in antiretroviral naïve patients (54).

Atazanavir

Atazanivir is a generally well-tolerated, once-daily protease inhibitor that appears less likely than currently available agents in this class to elevate cholesterol and triglycerides (64). As in the case of amprenavir, atazanavir has a resistance profile that overlaps less extensively with other agents in this class (65). The major unique toxicity of atazanavir is its propensity to cause a GilbertsÕlike hyperbilirubinemia. This toxicity is related to serum drug levels and is reversible with dose reduction or discontinuation of therapy. The ultimate niche for this drug has not yet been fully delineated but a recently completed trial comparing it to efavirenz in initial therapy (65a) and its Òlipid sparingÓ profile suggests it will be more widely used than initially assumed.

ENTRY INHIBITORS

Over the past several years a much better understanding of the molecular interactions between the virus and host cell surface proteins has been developed. Although initial hopes that interfering with the binding of the viral envelope to the CD4 molecule could lead to effective antiretroviral therapy were not realized (3), interference with subsequent steps of the viral cellular entry sequence has demonstrated significant promise (3,4). Since the experience with recombinant soluble CD4, it has been learned that the viral envelope binds to a second set of cellular proteins termed chemokine receptors before undergoing a structural change that facilitates fusion of one of its hydrophobic domains to the cell membrane (66). Interference with either of these steps has been demonstrated to inhibit viral replication *in vitro* and *in vivo* and FDA approval of the first entry inhibitor appears likely within the next 24–36 months (67).

Chemokine Receptor Antagonists

As outlined in more detail above, following binding of the viral envelope to the CD4 molecule on the surface of

the cell both the CD4 molecule and the viral envelope undergo secondary structural changes that allow binding of another portion of the viral envelope to one of two chemokine receptors (CXCR4 or CCR5) (66). These receptors are present in different amounts on monocytes and activated lymphocytes with the CCR5 molecule being most heavily expressed by monocytes and the CXCR4 molecule being most heavily expressed on activated lymphocytes. Which of the two chemokine receptors is most efficiently bound by a given viral particle is determined by a short sequence of amino acids within the third hypervariable loop of the gp120 viral envelope glycoprotein. In early disease, virus of the CCR5 binding type usually predominates; later in disease a more rapidly growing and more pathogenic quasispecies of CXCR4-preferring viral particles often emerges (68–70). Specific inhibitors for each of these types of virus have been developed and have been studied in clinical trials.

Inhibitors of binding of HIV-1 to the CCR5 receptor have advanced the most in clinical trials because several companies have developed agents that are orally bioavailable (67). The proof of concept that blocking this interaction between HIV-1 and the CCR5 molecule inhibits viral replication *in vivo* has been demonstrated in Phase I/II trials of a compound (Schering ÒCCÓ) that appears to reduce viral replication by over 1.0 $\log_{10}$ (71). Clinical development of the compound was delayed for a period while concerns about its propensity to cause QT segment prolongation were evaluated. Resumption of development of this compound was allowed by the FDA when the QT segment prolongations were found to be related to peak levels of compound in the serum and a twice daily dosing schedule was substituted for daily dosing. CXCR4 antagonism has also been shown to reduce HIV-1 replication *in vitro* and *in vivo*, but the reduction is limited to viral quasispecies of the X4 phenotype (72). Development of X4 antagonists has been further limited by the fact that the only compounds studied to date have not been orally bioavailable and have required intravenous administration.

Fusion Inhibitors

Following chemokine receptor binding the gp41 component of the viral envelope changes configuration and aligns a six-stranded segment of amino acids that fuse with the cellular membraneÑ thereby allowing viral entry into the cell. This process can be inhibited by mimics of these amino acid segments that interfere with this hexamerization. A thirty-six amino acid protein that has been given the name of ÒT20Ó or enfuvirtide has been shown to reduce viral replication by up to 1.5 $\log_{10}$ *in vivo* in a series of Phase I/II studies. Recently reported Phase II/III trials conducted in the U.S. and in Europe have confirmed these findings and have set the stage for FDA approval of this compound early 2003 (73,74). T20 is a clear demonstration that this approach is viable clinically but is greatly limited as a drug both by its high cost of manufacture and by the requirement that it be administered parenterally because of its lack of oral bioavailability. It will likely prove to be a critical agent for patients in salvage situations with limited therapeutic options but the cost and inconvenience of administration will greatly limit its clinical utility.

Integrase Inhibitors

Following reverse transcription, the DNA copy of the HIV-1 RNA must be integrated into the host cell DNA. This process is facilitated by a viral encoded integrase that enters the cell with the viral particle. Inhibitors of this enzyme have only recently entered clinical trials, and it is premature to speculate about the potential clinical utility of this approach since *in vivo* activity against HIV-1 has not yet been demonstrated (12,75).

PRINCIPLES OF ANTIRETROVIRAL CHEMOTHERAPY

The principles of antiretroviral chemotherapy have become increasingly well delineated. The ability to deliver antiretroviral drugs in accordance with these principles has steadily improved as a wider variety of agents have appeared. This rapid development of new agents is both enormously exciting and desperately needed. The pace of this evolution, however, poses a significant challenge to physicians in that antiretroviral chemotherapeutic agents are often widely available at significantly earlier stages of development than in the case of drugs used in other illnesses. This, coupled with the need for a deep understanding of the pathogenesis of HIV-1 infection, requires that clinicians stay abreast of a wide body of data, and necessitates therapeutic decisions that are based on fewer data from formal clinical trials than in the case of more traditional infectious diseases. Given the complexity of the disease process and the wide variety of objective and subjective factors that must be considered in therapeutic decision-making, a rigid algorithm for making therapeutic decisions that is valid in all situations cannot be recommended in HIV medicine. Nonetheless, from the available data, a general pathogenesis-based approach to antiviral chemotherapy has been developed that provides a reasonable framework from which to base therapeutic decisions in individual patients.

These principles are based on the premise that HIV-1 replication is the major driving force in the deterioration of the immune response that ultimately leads to most HIV-1 associated morbidity and mortality. HIV-1 replicates at an extremely high rate with the production of over a billion viral particles daily in the infected host (76–78) (Fig. 31.1). Approximately 99% of viral replication occurs in activated CD4 cells, thus accounting for the preferential

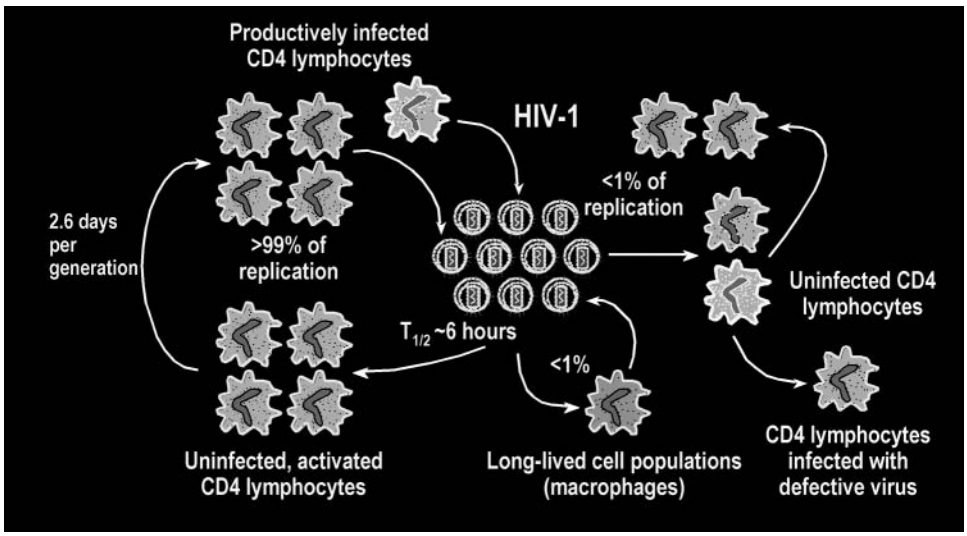

FIG. 31.1. Immunologic damage is mediated by viral replication.

depletion of this subset of immune cells. The remaining 1% of viral replication occurs in resting CD4 cells and in cells of the macrophage/monocyte lineage. Viral replication in this immunologic compartment is less important from the standpoint of inducing immunologic dysfunction but it is a critical component of the ability of the virus to retain a foothold within the host even when viral replication is nearly totally inhibited in the activated CD4 cell compartment. The rate of development of immunologic dysfunction is directly related to the rate of viral replication. Partial or complete inhibition of HIV-1 replication facilitates immune reconstitution. Because reverse transcription is error prone, the selection of drug resistant mutants is rapid if virus is allowed to replicate in the presence of incompletely effective antiretroviral drugs. With this set of principles in mind, a rational approach to antiretroviral therapy can be developed that must be adapted to Þt the individual patient.

Starting Therapy

The optimal time to initiate therapy must be determined by weighing the degree and rate of development of immunologic dysfunction, potential complications of the speciÞc drugs to be used and the willingness of the patient to initiate therapy. This determination is a complex one that varies from patient to patient and has changed over time as information has been developed about the pathogenesis of the disease and as new agents have been developed. Over the past several years, increased concerns about potential long-term toxicities of the agents utilized to treat the disease coupled with the realization that immunologic dysfunction is highly reversible in many patients even when therapy is delayed until late in the disease process have resulted in a tendency for many practitioners and patients to delay the initiation of therapy until CD4 cell counts have declined to lower levels than were tolerated in the past. Since it is also apparent that the plasma viral RNA level is mainly germane from the standpoint of the rate at which immunologic dysfunction develops and that the correlation between plasma HIV-1 RNA levels and the likelihood of viral suppression is relatively limited, most clinicians rely primarily on the CD4 cell count to determine when to recommend the initiation of therapy. At this writing most clinicians recommend starting therapy in the range of 350 CD4 cells/mm^3. This downward trend in the CD4 cell count at which therapy is recommended will likely to reverse with the advent of better tolerated and more convenient drug regimens and with the realizations that the lipodystrophic Þndings initially ascribed to antiretroviral therapy (especially protease inhibitors) are both drug and disease related and that the extent to which these complications occur is highly inßuenced by the CD4 cell count nadir. Patients with lower CD4 cell counts at the time of therapy initiation are much more likely to manifest these complications.

Selection of the Initial Drug Regimen

As in the case of when to initiate therapy, the speciÞc regimen with which to start therapy is one that must be individualized. Once started the goals of therapy are to reduce viral replication to a level at which HIV-1 RNA cannot be detected in the plasma with the most sensitive available assays (e.g. 20Ð50 copies/ml) with the least degree of toxicity and inconvenience for the patient. The ultimate success of a given antiviral regimen requires that it be potent, well-tolerated, convenient and that it require the virus to make multiple genetic changes to replicate successfully in its presence. At this writing there are several regimens that will accomplish this in a signiÞcant majority of patients.

Most current initial regimens include at least two nucleoside analogs to provide a high genetic barrier for

TABLE 31.1. *Options for initial therapy*

Nucleoside backbone	
Preferred regimens	*Comments*
Zidovudine and lamivudine (AZT/3TC)	Extensive clinical experience; available in co-formulated tablet; generally well tolerated.
Tenofovir and lamivudine (Tenofovir/3TC)	More limited clinical experience; highly ef cacious; well tolerated, low toxicity.
Alternative regimens	
Stavudine and 3TC	Extensive clinical experience; well tolerated symptomatically but D4T component contributes to neurotoxicity and hyperlipidemia.
Stavudine and didanosine	Extensive clinical experience; relatively dif cult resistance barrier; D4T and ddI interact to cause neurotoxiticy.
Abacavir/3TC	Limited clinical experience but theoretically a reasonable nucleoside combination.
Combinations that should not be used	
Stavudine and zidovudine	Antiviral antagonism
Potent "Third" Drug	
Preferred agents	
Efavirenz	Extensive clinical experience; highly ef cacious when combined with either of the preferred nucleoside backbone combinations; CNS toxicity limits use in 5–15% of patients.
Abacavir	Available in a tablet co-formulated zidovudine and 3TC allowing a compact one-pill, twice daily regimen; likely less ef cacious at HIV-1 RNA levels > 100,000 copies/ml.
Alternative agents	
Nevirapine	Acceptable alternative to efavirenz when CNS toxicity or baseline psychiatric abnormalities make use problematic; potential for hepatotoxicity should be monitored closely.
Nel navir	Extensive clinical experience but longer-term toxicities associated with protease inhibitors make PI's less attractive in treatment naïve patients.
Atazanavir	Recently completed clinical trials support its ef cacy and indicate less toxicity related to lipid abnormalities.
Lopinavir/ritonavir Indinavir/ritonavir Saquinavir/ritonavir Amprenavir/ritonavir	Potent regimens but side effects of ritonavir-forti ed protease inhibitor based regimens make these regimens more attractive in more experienced patients.

resistance and at least one additional agent (a "third" drug) to maximize potency (Table 31.1). Although many nucleoside combinations are possible, clinicians are increasingly using combinations of zidovudine and 3TC as their nucleoside backbone although the combination of tenofovir and 3TC also has been shown to have signi cant merit (41). Two recently completed studies (ACTG 384 and Gilead 903) have demonstrated the utility of these regimens (79,80). Based on currently available information, the combination of zidovudine and 3TC or tenofovir and 3TC should be offered to most patients as the initial nucleoside options. With the accumulating evidence that D4T is more likely than AZT to be associated with lipodystrophy, the previously heavily used nucleoside backbones of D4T and 3TC or D4T and ddI should be preserved for those who experience toxicities or are unable to tolerate one of the primary regimens.

Efavirenz is the most frequently used "third" drug at this writing but it is not the ideal agent for all patients and exibility in the selection of this component of the regimen is critical. Efavirenz has the advantage of once-daily dosing and is now available in a 600 mg tablet allowing this dose to be given as a single pill. When combined with AZT and 3TC (which can be administered in the xed dose formulation of Combivir), a highly potent regimen can be administered that requires the patient to

take only one pill in the morning and two at night. Especially in patients with lower baseline plasma HIV-1 RNA levels, abacavir is a very attractive third drug as well because of its tolerability and its compact dosing proÞle. With the development of Trizavir (a co-formulation of abacavir, AZT and 3TC), a daily regimen that consists of only one pill twice daily is now available. Although Þrst-line use of protease inhibitors as the ÒthirdÓ drug is also a very viable initial strategy, concerns about the longer-term effects of this class of drugs on cholesterol, triglycerides and body habitus have greatly reduced the tendency of clinicians and patients to use these agents in the initial regimen.

Although many arguments can be made about which regimen is the ÒbestÓ initial regimen, it is clear that no single regimen is best for all patients and that in the individual patient, one of the most important considerations is ßexibility. At this point, it should be expected that the initially selected regimen will drive HIV-1 RNA below the limit of detection in over 80% of patients. It is critical to communicate to patients the most likely side effects of the regimen chosen and to indicate to them that it is equally critical that they communicate to you any difÞculties they encounter with this regimen. If patients are made aware that the side effects of a speciÞc regimen may be difÞcult to predict in a given patient and that it is almost always possible to make an adjustment to the regimen, it is relatively easy to assure them that a regimen that they will tolerate with minimal toxicity can be developed in the vast majority of patients.

When to Switch Therapy

Once therapy is started the goal should remain to suppress viral replication to the point that HIV-1 RNA is not detectable in plasma with as little toxicity to the patient as possible. The two main reasons for changing therapy are a failure of the regimen to achieve or to maintain control of viral replication (virologic failure) or the occurrence of unacceptable toxicity. Virologic failure is best deÞned as the conÞrmed presence of detectable levels of HIV-1 RNA in plasma. Whether or not one should change therapy immediately when viral RNA is detected in plasma depends both on the reasons for failure and upon the therapeutic options remaining. In general, the Þrst detection of HIV-1 RNA in the plasma should trigger a return visit to the clinic and a discussion as to whether the patient had been adherent to the prescribed regimen during the period of time just prior to the phlebotomy. If a lapse of adherence is detected, a discussion should ensue as to whether the lack of adherence is due to either subjective side effects of the regimen or to the fact that the regimen is unduly complicated. If either of these factors can be addressed, this would be the time to do so. If the patient is adhering to the regimen and if viral RNA is detected on a repeat determination, it is usually prudent to change the drug regimen to one that will fully suppress viral replication although patients often do well clinically and immunologically for a prolonged period of time despite measurable amounts of virus in plasma. The main reason for changing therapy when possible is that if the regimen is not changed, selective pressure will inevitably lead to an increasing amount of drug resistanceÑ further limiting eventual treatment options.

There are clearly circumstances during which there are no treatment options likely to restore full control of viral replication. Under these circumstances, the physician must weigh the ongoing clinical and immunological beneÞt of partial suppression of viral replication against the damage done by broadened resistance to any remaining antiviral agents. It is clear from a number of contemporary studies as well as from studies conducted prior to the availability of potent combination regimens that any measurable reduction in viral replication from baseline reduces morbidity and mortality over the short to intermediate term. It is also clear that the problem of drug resistance worsens with ongoing viral replication in the presence of partially effective antiretroviral drugs. Although there is no speciÞc point at which antiretroviral therapy must be changed in all patients, one of the more common errors made by treating physicians is to stay with a failing regimen because the patient is immunologically and clinically stable at the expense of downstream treatment options. The physician should tolerate much less viral replication when there are many remaining treatment options than in the case of patients who already have multidrug resistant virus and, thus, have less likelihood of achieving virologic control with changes in the treatment regimen.

What Drugs to Change the Regimen to in the Case of Regimen Failure

In the past it was fashionable to speculate about a magic sequence of drug regimens that would be most efÞcacious for the majority of patients. It has become apparent that the selection of regimens after the failure of one or more treatment regimens is even more complex than the selection of the initial regimen. With each regimen failure, considerations related to drug susceptibility become increasingly important. The prior dictum that regimen failure mandates the change of as many of the drugs in the prior regimen as possible has given way to the concept that drug resistance testing is the key component in choice of subsequent regimens. This change in thinking has arisen with the realization that drugs in treatment regimens fail sequentially rather than simultaneously and with the wider availability and appreciation of the role of resistance testing. Although generalizations in this regard are dangerous, the sequence with which drugs fail follows a general pattern that drugs with the most potency and the least number of mutations required to develop high-level

TABLE 31.2. *Comparison of attributes of genotypic and phenotypic testing methodologies*

Genotypic testing
Advantages
Turn-around time ~ 1 week
Generally less expensive
Disadvantages
Interpretation dif cult except in experienced hands
Not quantitative
Not predictive of phenotypic susceptibility in some viral isolates—especially those with multiple mutations
Phenotypic Testing
Advantages
Quantitative
Interpretation more straightforward
Not affected in unpredictable ways by complex genetic interactions
Disadvantages
Turnaround time 14–21 days
More expensive than genotypic testing in most settings

resistance are the most vulnerable when regimens initially fail. This would include Òone mutationÓdrugs such as 3TC and the NNRTIs as compared to protease inhibitors and drugs such as abacavir. If a regimen is continued after resistance to these drugs has developed, it is highly likely that the stepwise selection of broader resistance to other agents in the regimen will follow.

A full understanding of resistance testing is a required component of contemporary management of antiretroviral chemotherapy. Resistance testing should be undertaken each time a regimen fails, and in situations in which the transmission of drug resistant virus is common (> 5% of isolates), when therapy is initiated for the Þrst time (81). Viral characterization as it relates to drug susceptibility may be undertaken by either genotypic or phenotypic techniques (Table 31.2). Genotypic approaches rely on associations between previously deÞned mutations in speciÞc locations and drug susceptibility; phenotypic testing actually measures drug susceptibility of the virus in question to available agents. Genotypic testing is usually less expensive and usually has a more rapid turnaround time than phenotypic testing but it does not provide quantitative data and it is increasingly limited with the evolution of the more complex viruses that emerge after exposure to sequential drug regimens. Although genotypic testing is adequate in patients with limited drug exposure, this approach becomes increasingly limited in its predictive capabilities in patients in whom it matters the mostÑ namely in those with fewer treatment options. Under ideal circumstances, physicians would use both approaches in all patients because the information provided by the two techniques is complementary. Considerations of cost often require the physician to choose one approach or the other in a speciÞc circumstance. In general, it is acceptable to use genotypic testing in patients with relatively limited treatment experience and to increasingly use phenotypic testing as patients have more treatment experience.

Chapter 32

Discovery and Development of New HIV Medicines

Edward P Garvey, Karen R. Romines and Lawrence R. Boone

The success of current HIV chemotherapy and the research that supported it has created both opportunities and hurdles for the development of new medicines to combat this infection. The opportunities range from novel molecular targets to avenues for overcoming drug resistance or undesired side effects of current drugs. However, because of the many drug approvals (16 to date) and the emergence of generic versions of existing drugs in the near future, a new drugÕ attributes must be striking to play a signiÞcant role in standard care and be commercially viable. Because many patients will proceed through multiple regimens during their course of treatment, and there is widespread acceptance of the drugs in the initial lines of therapy, many new drugs may be limited to later treatment regimens. This chapter will discuss speciÞc opportunities and hurdles in the development of new antiretroviral agents in the context of the broader difÞculty of developing any new drug.

The chapter will focus on the discovery and development of small organic molecules for treatment of HIV infection. DNA or RNA-based therapies have been and will continue to be examined in clinical trials (1,2), and the 36mer peptide T20 (3) most likely will be FDA approved. However, the preference for small molecules is supported by the molecular weight range for compounds approved to date for HIV therapyÑbetween approximately 300 for nucleoside analogs and 700Ð800 for protease inhibitors, with non-nucleoside reverse transcriptase inhibitors falling in between. In addition, among the approved HIV drugs, those with higher molecular weights usually have poorer pharmacokinetic and oral absorption properties, a common observation within drug development in general (4). Some of the desired properties of a new drug and various approaches to predict achieving the product proÞle are listed in Table 32.1.

The drug discovery and development process begins with a hypothesis and ends with approval to sell a drug for speciÞc indications. For organizational purposes, the entire process is sometimes divided into three broad research efforts: generation of a lead molecule, preclinical development of that lead, and clinical development of the drug candidate. Even though the possibility exists for a *fast track* approval by the USFDA (which can reduce the clinical process by one to two years), the entire process usually takes at least ten years. For example, the viral entry inhibitor peptide T20 was Þrst described in the scientiÞc literature in 1994 (5), and even with a fast track designation, the soonest that it will be approved will be 2003. Furthermore, new drugs targeted against HIV integrase will take even longer due to the difÞculty of generating leads for this particular target. Integrase was cloned and expressed in 1990 (6), and the Þrst inhibitors described in 1993 (7). However, the Þrst molecules with cellular antiviral activity proven to be due to inhibition of integrase (8,9) have only just recently entered Phase I trials. Thus, at best, the process will take at least 15 years for integrase. Figure 32.1 provides a graphic look at the magnitude of the effort from screening to launch of a new drug. Because of the length and expense of this overall process, pharmaceutical companies spend considerable time evaluating particular targets before any work commences. The speciÞcs of this exercise will be reviewed in this chapter.

TABLE 32.1. *Predicting the desired properties*

Property	Preclinical Predictors
Effective	Biochemical assays, cell-based assays, animal models
Safe	Selectivity assays, receptor panel screening, toxicology studies
Convenient (small oral pill, QD)	Solubility, cell permeability, *in vitro* metabolic stability, pharmacokinetics in animals
Financially viable	Differentiated from competition
	Low dose, simple synthesis

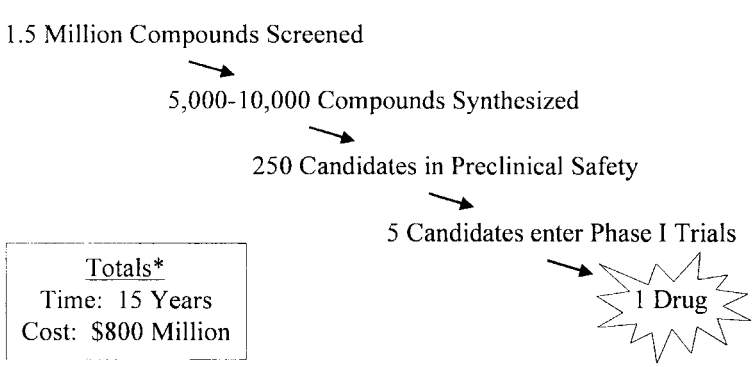
TARGET TRACTABILITY AND VALIDATION

To decrease the attrition rate of drug discovery projects, targets are analyzed prior to commencing research for their tractability (the chances of developing a desired modulator of that target) and validity (the certainty that the target plays an essential role in the disease in question). Such analyses do not give an absolute score of attractiveness, but can lead to a relative ranking of many targets. We will highlight the various components considered in these exercises, and then describe the tractability and validity of the proteins encoded in the HIV genome as an example.

In judging tractability, the most important question is what is known about the proposed binding site for small molecule modulators. This understanding can range from very high with a binding site of a well studied class of enzymes with many structural classes of modulators already identiÞed (e.g. the ATP pocket of protein kinases (10,11)) to non-existent for a protein-protein interaction where no structural information is available. In general, enzymes or receptors that bind small biomolecules as substrates or ligands are more tractable than enzymes or receptors that bind other macromolecules. The least tractable targets are macromolecular interactions of relatively large surfaces. However, if this interaction is dominated by a relatively small number of residues (e.g. the RGD pocket of integrins (12)), small drug-like molecules could mimic those residues. In addition, there are examples of small molecules modulating macromolecular interactions through noncompetitive mechanisms (e.g. modulators of G protein-coupled receptors that bind small proteins/large peptides). The existence of such noncompetitive binding sites cannot be predicted *a priori* and may be identiÞed through random screening. Obviously, such targets are given relatively low tractability scores.

Aside from knowledge of the potential small molecule pocket, each of the speciÞc steps that make up the drug discovery process can be accessed for the likelihood of success. The following questions and answers enumerate some of the major steps.

1. If necessary, can the molecular target be cloned, expressed, and puriÞed? Possible difÞculties are the size of the protein, and post-translational modiÞcations, membrane-bound nature of the protein, and overexpression of protein being toxic to cells. Solutions may include truncations or mutations, and thus the biological relevance of the altered construct must be considered.
2. If random screening is required, can a biologically relevant high throughput assay be developed? It is relatively easy to envision and develop an enzyme or binding assay that can be used to screen hundreds of thousands of compounds in a few weeks. However, there are many examples of difÞculties in establishing biological relevance (for example, wrong ÒformÓ of the enzyme, missing componentsÑ either macromolecular or small molecule, incorrect concentrations relative to *in vivo* environment). Alternatively, cell-based assays can sometimes be considered. However, such assays often produce relatively high response rates or biological activity with unclear mechanism.
3. If structure-base design is desired, is the target obtainable in high quantity and purity, and can crystals



*Source: PhRMA

FIG. 32.1. Finding new drugs: an exercise in beating the odds.

of both apo and higher order complexes be grown? This is hard to predict, with answers empirically determined. Obviously, large proteins of over 100 kD in size and membrane-bound proteins are usually problematic.

4. Can small molecule starting points be identiÞed? (See discussion above on small molecule pockets.)
5. Can secondary assays be developed to progress starting points into clinical candidates? Minimally, a cell-based assay is required to test whether compounds that are active *in vitro* are also active in a cell-based assay, especially if the target is intracellular. If the target is not fully validated (see below), such assays can also provide further evidence for disease association.
6. Can chemical starting points be progressed to clinical candidates? Many hurdles need to be overcome with speciÞc goals often conßicting with one another: increase in potency and selectivity, appropriate oral bioavailability, favorable *in vivo* pharmacokinetics, and metabolism proÞles, no or low *in vivo* toxicity. Usually, these issues do not weigh heavily in determining initial target tractability. However, knowledge may be available to give conÞdence or cause concerns.
7. Have biological patents of the target or compound patents describing modulators of the target been issued? Though not a scientiÞc issue, it is critical in starting a drug discovery program within a pharmaceutical company that research directions are not blocked by issued patents.
8. How easy or difÞcult will it be to monitor modulation of the proposed target in clinical trials? Again, it is not critical to know the details of the answer at the time of target evaluation. However, the earlier details are known, the sooner preclinical experiments can be devised to support clinical trials. It should be stressed that clinical trials of antiviral agents to treat HIV infection have a major advantage in the relative ease of assessing efÞcacyÑ the reduction of viral load in plasma samples.

Separate from target tractability is the evaluation of target validation. Target validation rests on the hypothesis that the target plays a critical if not essential role in the given disease. If true, modulation of the target will improve the disease state. Compared to complicated metabolic diseases such as type 2 diabetes, validation of microbial infection targets is relatively straightforward if the microbe is well characterized and a cell culture system is established. This is certainly true of HIV. Through any number of genetic or biochemical techniques, selective disruption of speciÞc HIV genes or gene products can and have demonstrated that particular gene products are essential to the viral lifecycle. Genetic techniques include deletion or mutation of the gene in question, or blocking transcription or translation of the genetic information into protein via antisense, RNAi, or ribozyme nucleic acids introduced transiently into the infected cell. Alternatively, protein reagents such as antibodies or dominant negative forms of a protein can block the target proteinÕs function.

Although biological reagents can probe for the microbeÕs dependency on a particular protein, there can be a subtle difference between using such tools and knowing for certain that a small molecule can clinically modulate the target. With some biological tools, the target is not made, which results in two subtle differences compared to small molecule modulation. (1) The protein in question may have an unknown secondary function that could also impact the lifecycle. (2) The microbeÕs dependency on the target could be absolute and inhibition of the lifecycle only obtained by 100% alteration of the targeted function. Because of intracellular concentrations of target, substrates, ligands, or inhibitors, a small molecule may not achieve complete modulation. Usually, biological validation does predict clinical success of a small molecule. However, the highest degree of target validation is *clinical* data demonstrating efÞcacy with a small molecule modulator.

Finally, target validation has a second component in addition to conÞrmation of efÞcacy, that is determination of whether speciÞc modulation of the target would induce toxicity. With microbial targets, unless there is a highly homologous host counterpart, target-based toxicity is usually not a concern. (It should be emphasized that this issue is not the same as compound-based toxicity that is always a concern until proven otherwise.) However, lifecycles of microbes often depend on host proteins. Because a host protein may be demonstrated to be essential and also be viewed as tractable, host proteins such as the chemokine receptors have become attractive targets for new HIV therapies. However, such proteins may also play critical roles in normal human physiology, and thus modulation may lead to target-based toxicity.

Using the above descriptions, the proteins encoded by the HIV genome have been ranked in terms of their *relative* attractiveness (Table 32.2). This analysis should not be viewed as a deÞnitive description of the likelihood of developing drugs targeted against each protein, but rather as a vehicle for exemplifying the issues outlined above. This exercise will not include descriptions of the structure and function of the HIV proteins; recent reviews can be referred to for such details (13,14).

Reverse transcriptase and protease are clearly in the top bracket when evaluating HIV targets. The three small molecule pockets for nucleoside reverse transcriptase inhibitors (NRTIs) (15), nonnucleoside reverse transcriptase inhibitors (NNRTIs) (16) and protease inhibitors (PIs) (17) within these two proteins are well characterized, and mutant proteins that lead to drug-resistant virus are now targets for second-generation drugs. Both enzymes have the highest validation as several inhibitor series for both have been approved based on robust efÞcacy in suppressing viral replication in patients. All components of the lead generation process mentioned above have been in place for years. However, even proven targets such as RT

TABLE 32.2. *Relative ranking of HIV proteins as potential targets for development of small molecule antiviral therapy*

Target	Likelihood of Small Molecule Drug	Target Tractability			Target Validation	
		Precedence	Relevant Assay	Structural Data	Biological	Small Molecule
RT	Very High	approved drugs	yes	pockets well de ned	High	approved drugs
Protease	Very High	approved drugs	yes	pocket well de ned	High	approved drugs
Integrase	High	clinical trials ongoing	yes	apo protein	High	*in vitro* resistance
Rev/RRE	Medium	little (aminoglycosides)	probably relevant	pocket w/in RRE	High	none
Tat/TAR	Medium	little (aminoglycosides)	probably relevant	pocket w/in TAR	High	none
RNase H	Medium	little (no antivirals)	possibly relevant	unbound to duplex	High	none
gp41	Med/Low	large peptide	possibly relevant	not encouraging	High	T20 approval expected
gp120	Low	none	possibly relevant	not encouraging	High	CCR5 inhibitors; sol CD4
Gag	Low	none	no	not encouraging	High	PIs; Zn ejectors; cyclosporin
Nef	Low	none	unknown relevance	unknown relevance	LTNP	none
Vpu	Low	none	no	none	accessory	amantadine (by analogy)
Vif	Very Low	none	no	none	accessory	none
Vpr	Very Low	none	no	none	accessory	none

and protease contain inherent weaknesses. NRTIs (and their anabolized phosporylated forms) are close analogs of many naturally occurring metabolites (i.e. nucleosides and nucleotides), and thus may interfere in many critical cellular pathways. The pocket that NNRTIs bind is near to but separate from the active site of RT. Amino acid residues that are critical in binding the inhibitors are not as critical to the normal function of the enzyme compared to active site residues, and therefore resistance arises more rapidly for this drug class. The broad pocket that binds the protein substrates of HIV protease dictates that relatively large small molecules are required for sufficient potency. This in turn has led to relatively poor oral bioavailability and difficulties in formulation. However, these issues are more challenges than obstacles, and RT and protease remain the most attractive molecular targets for new HIV drug development.

HIV integrase resides alone between the targets successfully attacked and all other HIV proteins. This ranking is due to the strength of both tractability and validation for integrase, whereas the other targets are all relatively weak in their perceived tractability. Research on integrase has been ongoing for nearly as long of RT and protease, with most of the components for lead generation in place by the early 1990s. Integrase catalyzes two reactions (reviewed in 18)Ñ hydrolysis of terminal dinucleotides at both 3′-ends of the viral DNA (3′-processing) and insertion of both new 3′-hydroxyls into host cell DNA (strand transfer). Early assays were developed similar to most enzymatic assaysÑ integrase was added *last* in its free or apo form. Inhibitors found using such assays were inactive against the form of the enzyme isolated from virally infected cells (bound in the preintegration complex, or PIC) (19) and were inactive in cellular antiviral assays. Because PICs contain the viral DNA tightly bound to integrase (in addition to other viral proteins), assays were subsequently developed (20) where the oligo substrate that mimics the viral DNA was prebound to integrase. The strand transfer reaction was then initiated by addition of the oligo substrate that mimics host DNA. Such assays identified 4-aryl-2,4-diketobutanoic acids that inhibit integrase within the PIC and HIV replication in cell assays (21). Additionally, the mechanism of antiviral activity has been demonstrated to be inhibition of integrase (21,22), and structure-activity relationship studies have demonstrated a tight correlation between enzyme and cellular potencies (23). Thus, there is little doubt that integrase is fully validated, awaiting clinical data as final proof.

The other four proteins listed under medium attractiveness all have strong biological validation, but concerns exist surrounding the likelihood of finding small molecule modulators. The transmembrane gp41 protein has the highest validationÑ it is the target of the fusion inhibitor peptide T20 which has potent antiviral activity in clinical trials (24). However, there are serious concerns in finding small molecules that could circumvent the difficulties of delivering a large peptide. T20 is derived from gp41 itself and blocks the formation of the fusogenic state of gp41 by competing with the analogous stretch of peptide within gp41. When T20 (a 36mer) is truncated by more than six amino acids, its potency decreases by greater than 1,000-fold (25). Thus, it is difficult to imagine how a small molecule could mimic this peptide. Consistent with this concern is that the crystal structure of the proposed fusogenic conformation (26) shows no obvious pocket in which a small molecule could bind and effectively block the formation of that state. Assays have been developed to monitor the formation of the fusogenic conformation (27,28), but no identification of small molecule inhibitors has been reported.

The other three targets in this section (RNase H, Rev, and Tat) all have strong biological data supporting HIVÕs essential dependence on their function. However, no small molecule modulator has been developed against these targets which has antiviral activity. Thus, they lack definitive validation. The tractability of RNase H is similar to that of integrase prior to the key findings that led to changes in assay format for integrase. Like integrase, RNase H binds nucleic acid as its substrate in a relatively shallow groove (29). In addition, initial RNase H assays were simple RNase assays where cleavage of RNA within RNA/DNA duplexes was monitored. Inhibitors were identified but had no observable antiviral activity in cells and were often toxic most likely due to nonspecific inhibition of RNases. Recently, more sophisticated assays have been described (30) that appear to better recapitulate RNase HÕs function *in vivo* (31). However, no selective HIV RNase H inhibitors have been reported to date.

The final targets within this section are the two essential viral protein/RNA interactionsÑ Rev/RRE and Tat/TAR. The Tat/TAR interaction is required for robust transcription of the integrated viral DNA into viral mRNA. The Rev/RRE interaction is the essential switch between the translation of early and late viral proteins. Because of the many similarities between these targets, comments will be focused on Rev/RRE. This interaction has been demonstrated by use of a variety of different biological reagents (32,33), and has also been validated by natural occurrences of low viral infectivity in association with suppression of Rev function (34,35). Concerns regarding this target mainly reside with its tractability. The only small molecule inhibitor of this interaction with antiviral activity has been neomycin B (36), an aminoglycoside that binds in the major groove of a stem loop of RRE. However, no mechanistic studies were reported to demonstrate that inhibition of viral replication was due to inhibition of Rev/RRE. The antiviral IC_{50} value was in the hundreds of micromoles (36), and neomycin B binds to structured host RNAs at much lower concentrations (37). Although the NMR structure of a critical helical peptide from the Rev protein bound to the stem loop RRE pocket was solved in 1996 (38), no Rev/RRE inhibitor has been reported through a structure-based approach. Alternatively, a high throughput screen of Rev/RRE did identify modulators

(39). However, no antiviral activity was observed, leading again to the question of whether the *in vitro* assay accurately reproduced the *in vivo* interaction. For example, the concentrations of target inside the nucleus of the infected cell may be much higher than the nanomolar concentrations of Rev and RRE used in the screen, leading to too sensitive of a system. Alternatively, unknown components could be missing in the binding assays. To circumvent such issues, cell-based assays where expression of a reporter gene is dependent on Rev/RRE have been developed (40), although no screens using such assays have been reported.

There are enough concerns regarding the remaining seven HIV proteins listed in Table 32.2 to make drug discovery research extremely risky. Whereas there is little doubt that functional modulation of gp120 or the gag proteins would lead to clinical efficacy, there are significant reservations surrounding validation of the last four proteins listed in Table 32.2 (Nef, Vpu, Vif, and Vpr). Compounding these concerns are the low tractability of these four targets. Within this analysis, ranking is still relative and Nef could be considered more tractable than Vif or Vpr. Most likely Nef's function is tied to its binding of cellular SH3 domains (41), although what aspect of Nef's function is due to binding what particular SH3 domain is not clear. There is even less clarity as to the interactions that drive the functions of Vif and Vpr. Because these proteins are not essential to viral replication, there are no cell assays to use in the progression of lead molecules into clinical candidates. Additionally, how modulators of these accessory proteins would be used and their effects monitored in clinical trials is questionable.

Finally, the structural HIV proteins gp120 and gag (matrix, capsid, and nucleocapsid) fall into the low priority ranking due solely to their low tractability. Each protein's function results from complicated macromolecular interactions. For example, gp120 interacts with three proteins—CD4, a chemokine receptor (either CCR5 or CXCR4), and gp41. The limited structural understanding of its interactions with CD4 and the chemokine receptors (42) does not suggest that small molecule pockets exist. Although binding assays have been developed to measure the interaction of gp120 and CD4 (43), only recently have small molecule antivirals been identified (43a). Furthermore, there are no published reports of a possibly more relevant ternary complex assay. Matrix, capsid, and nucleocapsid have equal if not greater tractability concerns. For example, the interaction that appears to be critical for capsid function is capsid dimerization where the structure is dependent on a large subunit surface (44). Such a molecular target is simply not conducive for drug discovery.

DRUG DISCOVERY

Once a target is selected for a drug discovery effort, the first step is to find a starting point for the drug discovery and optimization process. Two useful, yet quite different approaches are broad screening and structure-based drug design.

Broad screening is not unlike playing the lottery, in the sense that discovering an appropriate starting point, often referred to as a "hit," involves an element of luck. Assuming that finding a hit is a random event, the more compounds you screen, the better your chances are of finding a good hit. This provides scientists with an incentive to seek access to very large collections—the equivalent of buying multiple lottery tickets rather than just one. Broad screening, however, is not a completely random exercise since compound libraries contain bias. Most large compound collections are owned by pharmaceutical companies who have accumulated them over a number of years, and the primary source is former projects within the company. Since the number of structural analogs required to find a single drug candidate is usually well over 5,000, a single drug discovery project may contribute a significant number of high quality specimens to corporate collection over the life of a project. Since many of these compounds are likely to be closely related, however, the structural diversity contributed to the collection may be surprisingly low. This, consequently, is the source of the collection bias. This can be an advantage if a company is attempting to start working with a target that is structurally similar to the target of an existing research project. For example, in the early days of HIV protease research, a number of companies with renin inhibitor research programs were able to easily find hits. Since renin and HIV protease are quite similar, collections of renin inhibitors were fertile hunting ground for the HIV scientists. Of course, the disadvantage of this bias is that it can add an additional hurdle to companies attempting to start work in a novel target area.

Most companies attempt to compensate for bias in their compound libraries by supplementing from outside sources. This may be done in a deliberate fashion, by analyzing the library for gaps in its chemical diversity and making or purchasing structures that fill those gaps, or it may be done in a more opportunistic fashion, by simply buying compounds that become available from commercial or academic sources.

The compound collection is not the only necessary component for a broad screening strategy. One must also develop an assay that is amenable to high throughput screening. Much of this screening is now automated and done on 384-well plates. The automated approaches obviously will have some constraints on assay conditions, but do offer the advantage of evaluating hundreds of thousand of compounds in the space of a few days. As mentioned previously, it is vital that the *in vitro* screening assay recapitulate the *in vivo* situation as closely as possible.

Once a data set has been generated by a high throughput screen, the next step is hit selection. A high throughput screen typically generates a percent activity (usually

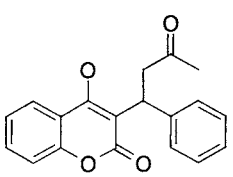
inhibition) of target at a single concentration of compound. The Þrst step is usually to conÞrm the activity of the most promising compounds by generating titration curves. Once the activity is conÞrmed, structures for optimization will be chosen based on both activity in the assay and chemical tractability. It is of particular importance to gain a sense of structure activity relationships (SAR). Medicinal chemists will look for patterns of structural changes, which correlate with varying degrees of target inhibition, to gain conÞdence that the compound is modulating the assay via the intended mechanism of action.

An example of broad screening used to generate a novel lead can be found in the HIV protease discovery process. As mentioned above, peptidomimetic renin inhibitors were expected to generate HIV protease hits, and as will be discussed in more detail later, those hits generated some excellent drugs. In this situation, however, a broad screen found the coumarin derivative warfarin (**x**). Warfarin was a known anti-coagulant, but scientists at Upjohn were able to separate the antiviral activity from the anti-coagulant activity during optimization of the structure, and this research effort produced tipranavir. It is not coincidental that tipranavir has a unique resistance proÞleÑ starting from a different hit than the other protease inhibitors gave it an advantage in this respect (Fig. 32.2) (45,46).

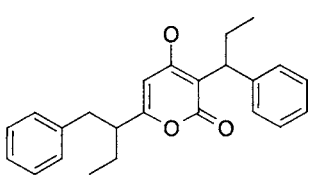
The second approach for identifying a hit is structure-based drug design. This approach is much more elegant than the broad screening approach, but limitations in our knowledge of target make it harder to implement. In this approach, knowledge of the structure of a particular target is used to design effective inhibitors. Some of the best examples are found in the HIV protease literature. As discussed, structural features of the protease were known to be similar to renin, a familiar target to many in the pharmaceutical industry. For example, scientists at Merck screened their renin inhibitor collection to Þnd a starting point for the design of HIV protease inhibitors. Through a series of structural modiÞcations, which were guided by molecular modeling and X-ray crystal structures of the inhibited enzyme complex, they were able to produce indinavir, one of the HIV protease inhibitors which helped achieve prolonged viral load suppression through combination therapy in the early 1990s (Fig. 32.3) (47,48).

It is important to note that broad screening and structure based drug design approaches are by no means exclusive. Using them together can be an extremely powerful approach. Note in Fig. 32.2 that the coumarin structure warfarin underwent signiÞcant structural alteration on its way to tipranavir. Scientists working on this project got many clues about improving the binding afÞnity of the compounds by studying X-ray crystal structures of warfarin and subsequent analogs in the HIV program bound to the HIV protease.

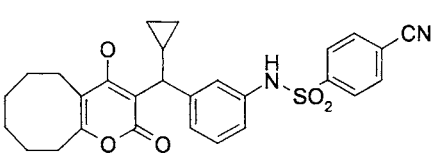
Once a hit has been identiÞed, either through broad screening or design work, the next step is to optimize the structure to contain all of the desired properties and none of the undesired properties. This is very much an iterative process: medicinal chemists make novel compounds



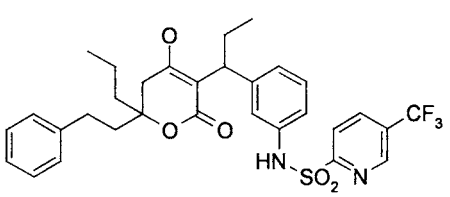
1, Warfarin



2, PNU-96988

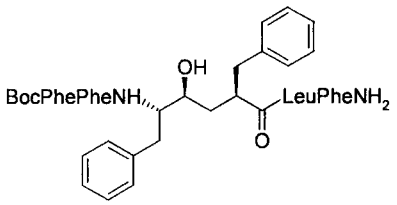


3, PNU-103017

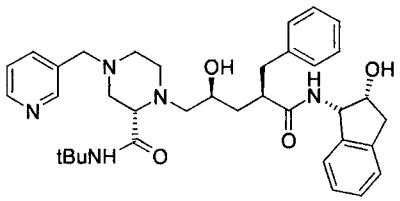


4, Tipranavir

FIG. 32.2. Compound **1**, the anticoagulant warfarin was identi ed through broad screening against HIV protease. Warfarin had minimal activity; the IC_{50} value against HIV protease was ca. 30 μM, and there was no sign of activity in cell culture. Optimization of this screening hit originally focused on increasing inhibition of the HIV protease and decreasing anti-coagulant activity, both of which were achieved with **2**, the rst generation clinical candidate from this series (ED_{50} in HIV-1_{IIIB} infected MT4 cells was 3 μM). Additional optimization resulted in the preparation of more potent compounds, including the second generation clinical candidate **3** (ED_{50} = 1.5 μM) and tipranavir (ED_{50} = 0.03 μM), which is currently in Phase III clinical trials. Early data indicate that tipranavir has very promising clinical ef cacy against viral strains resistant to current approved HIV protease inhibitors (45).



5, L-364,505



6, Indinavir

FIG. 32.3. Peptide derivative **5** was identi ed through screening of a renin inhibitor collection. Compound **5** was quite potent against HIV-1 protease (IC_{50} = 1 nM) and showed some selectivity over renin (IC_{50} = 73 nM), but it had activity against HIV in cell culture only at high micromolar concentrations (47). Extensive modi cation, guided by molecular modeling and X-ray crystal structures, led to the discovery of indinavir, an extremely potent HIV protease inhibitor (IC_{50} = 0.52 nM against HIV-1 protease; no inhibition of human proteases, including renin; and complete inhibition of HIV-1 $_{IIIB}$ spread in cell culture at 50 nM) (48).

which are designed to have the desired properties, these compounds are evaluated in biological assays, then the chemists use these results to guide structural modiÞcations and a new set of analogs are made. This exercise generally takes at least a couple of years, in part, because a number of properties must be optimized. In addition to potency, the scientists on the team need to design compounds that have favorable physical properties (e.g. solubility), good pharmacokinetics, excellent selectivity, and a structure amenable to efÞcient synthesis to keep cost of goods low (Fig. 32.4).

Generally, the Þrst aspect of a lead structure that is optimized is the *in vitro* potency in the primary assay. One of the challenges of this part of the optimization effort is knowing when the compoundÕs potency is sufÞcient for clinical efÞcacy. The clinical efÞcacy will, of course, depend on both the intrinsic potency (which is ideally measured by the primary assay) and the exposure levels achieved *in vivo*. Recent examples in the chemokine receptor Þeld illustrate this concept. Schering has developed a CCR5 antagonist, SCH-C, with excellent activity in assays measuring RANTES binding (Ki = 2 nM) and in antiviral assays (mean IC50 = 2 nM against range of M-tropic viral isolates in PBMC cells). In rats, SCH-C had a half life of Þve hours and an oral bioavailability of 63% (49). Recently, clinical studies showed that this preclinical proÞle translated into promising viral load reductions, even at a dose of 50 mg of SCH-C twice a day. At this dose, 10/12 subjects had at least a 0.5 log drop in viral load over the study period of 10 days (50). In contrast, AMD-3100, which is also a nM inhibitor of HIV replication *in vitro* (EC50 = 4 nM against T-tropic virus), performed much poorer in a clinical setting. In a dose-escalating study of 40 patients, only one patient achieved a viral load drop of more than one log (51). There are at least two major differences between these two studies. First, the pharmacokinetic proÞles of the two compounds are quite different, although dosing of AMD-3100 intravenously would overcome some of the exposure differential. The second difference is in the targets. Although both CCR5 and CXCR4 are both chemokine receptors which are necessary for HIV entry, the CCR5- and CXCR4-tropic viruses exhibit differences in both prevalence and pathogenicity.

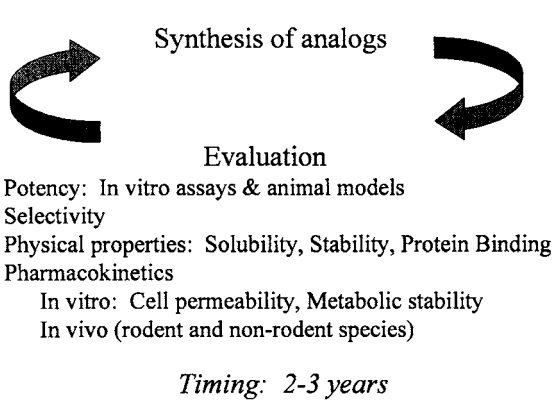


FIG. 32.4. Lead optimization.

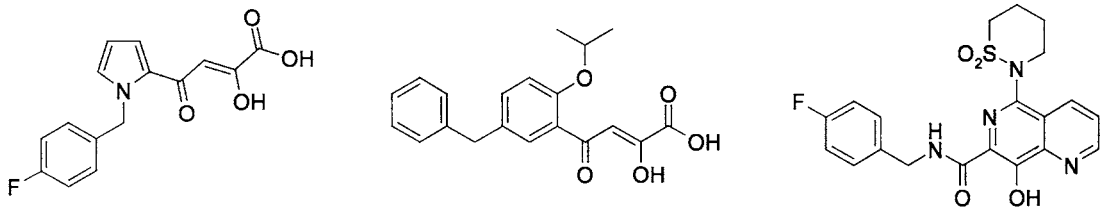
As mentioned above, potency is not the only criterion considered in the optimization stage. One elegant example of optimization to improve metabolic stability is found in MerckÕs HIV integrase inhibitors. As mentioned in the earlier section, Merck identiÞed 4-aryl-2,4-diketobutanoic acids in early screening, and they were able to signiÞcantly improve the antiviral activity of this series by modifying the aryl portion of the molecule (23). Although the *in vitro* potency of the modiÞed compound was over 100-fold better than the initial lead compound, the modiÞed agent still had metabolic liabilities that restricted its utility as a drug. Replacement of the acid with an isostere, followed by replacement of the resulting 1,3-diketone with a 1,6-naphtyridine produced compounds such as L-870,810, which has both potency and metabolic stability (Fig. 32.5). This compound also demonstrates good pharmacokinetics in three species (52).

Optimization culminates in selection of a candidate, but there is still signiÞcant work to do before that candidate can enter clinical trials. The focus at this stage is on preclinical developability and safety.



7, L-731,988 **8** **9**, L-870,810

FIG. 32.5. The original integrase inhibitor lead **7** (IC_{95} = 9.6 μM in HIV-1 $_{IIIB}$ infected MT4 cells), was modi ed to improve potency, resulting in compound **8** (IC_{95} = 0.10 μM). Further modi cation of this structural template led to the discovery of clinical candidate **9**, which has both improved potency (IC_{95} = 0.019 μM) and metabolic stability, relative to earlier structures in this class (52).

Developability refers to characteristics of a new drug that are necessary for efficient manufacture and *in vivo* delivery. At this point, stable crystal forms of the drug candidate will be identified and the synthetic route will be optimized for efficient manufacturing. Stability of the drug candidate will be evaluated, and formulation work will begin in earnest.

Preclinical safety work also begins in earnest once a candidate is selected. The potential for mechanism-based toxicities were addressed at target selection stage, but compound-based toxicities are difficult to predict and remain a potential issue until proven otherwise. Before beginning animal studies, scientists will use any available *in vitro* screening methods, such as broad panels of receptors, to look for potential difficulties. Of course, toxicity studies in at least two species are required before clinical trials can begin.

For some classes of compounds or targets, a potential safety liability has been identified, and scientists can attempt to screen for this at the preclinical safety stage, or even earlier during compound optimization. For example, HIV nucleoside reverse transcriptase inhibitors have been associated with symptoms of mitochondrial toxicity, such as peripheral neuropathy, in the clinic. The mitochondria employ a γ-polymerase, and *in vitro* studies have shown differential γ-polymerase inhibition by different nucleoside triphosphates (53). Correlating the *in vitro* profile with clinical side effects over time can be an important clue for designing safer drugs. Since mitochondrial toxicity is both quite serious and difficult to detect in animal models, such information can be quite valuable.

Toxicity and side effects are not a black and white issue. The level of undesired effects a drug candidate can have will depend on several factors, including the severity of the adverse events relative to the severity of the disease being treated and the ability to control adverse events with other drugs. The success of pharmaceutical scientists in controlling HIV infection with HAART has allowed current drug discovery efforts to focus more on both the long term toxicities associated with chronic HAART and the convenience of drug regimens that can promote adherence. For example, although atazanavir, a protease inhibitor in late stage development, does not have significantly better *in vitro* potency than other available protease inhibitors, its once a day dosing and lack of effect on patient lipid profiles are creating significant enthusiasm (54).

CLINICAL DEVELOPMENT

The final step in the drug development process is clinical evaluation. This will involve an initial safety study (Phase I), usually in healthy volunteers, a small-scale efficacy study (Phase II), and large registration trials to evaluate both safety and efficacy in a broad population (Phase III). In HIV infection, the endpoints of these studies are usually based on viral load, but it is important to note that this is a surrogate marker. Registration of the early HIV drugs was based on clinical endpoints, such as progression to an AIDS-defining illness or death. Although viral load surrogate markers are widely used and readily accepted by the regulatory agencies, clinical endpoints are still the gold standard and may be appropriate in some cases. A recent example where viral load measures may not have told the whole story was the AMD3100 study cited above. Although only one patient reached the goal of a □1 log drop in viral load, a closer look at the data indicated a dose dependent shifting of viral populations from X4/R5 dual-tropic to R5-tropic. In other words, the X4-tropic population was reduced below the limits of detection (55). Since X4-tropic disease has been associated with increased viral pathogenesis, there may still be some benefit to a drug with this profile. Of course, a clinical endpoint trial would be required to prove any such benefit.

Given all of the potential issues cited above, it should not come as a surprise that despite the best efforts of scientists to predict clinical success, only approximately 20% of drugs which enter Phase I trials make it to registration. We have already noted the challenges of predicting clinical efficacy and safety based on pre-clinical data, especially for novel targets and new chemical classes. For these reasons, it is routine for large pharmaceutical companies to bring forward multiple drug

candidates. For example, we have already noted that for tipranavir there had been two earlier generation protease inhibitors which entered the clinic. Even though initial efficacy studies with SCH-C are very promising, Schering-Plough has begun development of a second generation compound, SCH-D (56). Although it may be somewhat discouraging to need multiple attempts to get a good drug to patients, the initial failures often yield valuable information for design and development of the drug candidate which is ultimately successful.

Following a successful phase I study where safety and tolerability and drug exposure levels are determined, Phase II studies are designed to provide evidence of efficacy. Early efficacy studies of novel agents face many challenges. ÒProof of ConceptÓstudies are relatively small and begin to provide data as to whether the compound is likely to meet a desired product profile. These studies may not be adequate for regulatory submission but provide data to reduce some of the risks inherent in committing to a full-scale clinical development program. Time and resource pressures usually make it imperative that Proof of Concept is achieved as quickly as possible. It is particularly important to decide in what patient population a new agent is most likely to show efficacy. This population is not necessarily the one that is the ultimate target population based on medical need and commercial viability. For example, it may be appropriate and expedient for early Phase II studies to be conducted in anti-retroviral na•ve subjects who have progressed to a stage where initiation of therapy is recommended based on current guidelines. This may not be the ultimate target population if, for example, the drug is intended to treat drug-resistant strains of HIV. The advantage may be an opportunity to enroll volunteers and complete the trial more rapidly but the tradeoff is the risk that efficacy in the trial population may not translate to efficacy in a more difficult-to-treat population chosen for the Phase III study. Recruitment for these studies may also be a challenge as patients who are on effective regimens are often less likely to be willing to switch to a regimen with a novel drug in early development where the Proof of Concept has not been met. These patients may be more willing to participate in Phase III studies where there exists some evidence of efficacy. At the other extreme are salvage patients who have few therapy options remaining. For many new agents this is the target population and Proof of Concept studies are conducted in this population straight away. The most straightforward way to demonstrate antiviral activity of a novel agent is to test it as a single agent for a short period of time. The duration of treatment in monotherapy is typically from a few days to one or two weeks. Based on what is known about current HIV drugs, monotherapy will almost certainly be sub-optimum. Thus, if monotherapy is used, it should be limited to short duration especially if there is a low genetic barrier to drug resistance for the target and resistance is expected to occur rapidly. Furthermore, it is important to consider whether such resistant virus is likely to be cross-resistant to other members of the class (if the novel agent is a member of a current target class). Another consideration is what therapy is appropriate for the subjects following the short duration testing with the novel agent. Here again, one is confronted with several options. If the new agent is shown to be effective in this short duration monotherapy study, one could add two or more current drugs to constitute a regimen and continue the trial along with an appropriate comparator arm without the novel agent. The toxicology studies for the novel agent must be of sufficient duration to match the duration of human exposure in order to continue such a trial. Often in early development such toxicology is not available and following short exposure to the novel agent, subjects may switch to a standard first line or other appropriate regimen depending on their treatment history. Additional, longer term clinical studies are designed based on the data from the short duration studies, and they may be initiated when sufficient toxicology coverage is available. The timing of preclinical and clinical study results is quite important to ensure rapid and uninterrupted development of the new agent.

While monotherapy may a straightforward way to demonstrate activity of a drug in an early Proof of Concept study, it is not the standard of care and novel drugs must be tested in combination with other drugs. Indeed, in the vast majority of Phase II studies a novel agent is tested in combination with one, two or three other agents. Preclinical studies can give some guidance on the suitability of certain combinations, especially if antagonism is suspected. Regulatory agencies often request *in vitro* combination studies of the new agent with approved agents.

For the larger, longer term Phase III studies it is very important to conduct the appropriate studies to ensure that the desired indication for the new drug is achieved. Given the large number of approved anti-retroviral drugs and the massive number of possible combinations, it can be a daunting task to design a well-controlled study to determine the efficacy of a new drug in a combination regimen. Close interaction between the sponsor and the regulatory agency is essential as this phase of development requires significant investment in time and resources and volunteer subject commitment. Following regulatory approval of a drug, the greatly expanded use outside of the carefully controlled clinical trial setting often brings more information about safety. Continued monitoring by drug company sponsors in Phase IV is important in capturing and interpreting this information. Furthermore, as long term use of drugs continues, long term side effects are revealed. For examples, mitochondrial toxicity mentioned previously and lipodystrophy syndrome have emerged as serious side effects of HAART (also discussed elsewhere in this volume (Chapter 00). A better understanding of the etiology of the metabolic complications of HAART could lead to development of preclinical models and assay

systems for next generation drug discovery and development. For example, PI inhibition of adipocyte differentiation (57,58), NRTI effects on mitochondrial function and the associated lactic acidosis (59) and CCR5 inhibitor QTc prolongation (60), provide some tools and benchmarks to apply to progressing new compounds.

CONCLUSIONS

There are indeed many challenges to drug discovery and development as outlined in this chapter. However, it is likely that the coming years will see new safe and effective drugs to treat HIV-infected patients. Viral gene products will remain the best drug targets and integrase is likely to be the most important new target for drug development. Although after integrase, additional viral targets will represent large challenges. There is a shift in the perception of acceptability of host cellular targets and the chemokine co-receptors are expected to constitute another area likely to be successful. Drug resistance and side effects to currently approved agents will continue to drive discovery efforts to Þnd improved drugs to the well-validated targets. Improvements in preclinical assessments to reduce attrition of drug candidates is a constant goal of the pharmaceutical industry and this will be especially important for HIV infection, as this area becomes even more crowded with approved drugs and the hurdles to initiate new programs gets higher and higher.

Chapter 33

Toxicities of Antiretroviral Therapy

Patrick W. G. Mallon, David A. Cooper, Andrew Carr

Recognition of HIV as the pathogen behind the AIDS epidemic in the 1980s led to an intensive effort within medical, research and pharmaceutical establishments to develop therapies that could delay progression of disease and possibly eradicate the infection. Due to the signiÞcant morbidity and mortality associated with AIDS, it was imperative to move potentially life-saving therapies quickly from the laboratory to the clinic. For example, it took only two years from the initial recognition of zidovudineÕs (AZT) antiretroviral effect *in vitro* for the drug to receive FDA approval for general clinical use in March 1987 (1). The development of nucleoside reverse transcriptase inhibitors (NRTI) delayed progression and improved mortality in many cases, but it was not until the introduction of protease inhibitors (PI), and the recognition that eradication of HIV was not a realistic treatment outcome (2), that HIV-infection, in developed countries, was widely regarded as a chronic disease requiring long-term management strategies.

Many phase II and III trials of new antiretroviral medications identiÞed potential immediate and short-term side effects of the drugs. Many side effects were avoidable with appropriate patient monitoring and alteration of dose, or were of a severity where continued treatment was thought to be beneÞcial compared to the dangers from untreated disease (3). In many cases, pre-licensing data regarding the medium to long-term side effects of speciÞc drugs or drug combinations was not readily available. Consequently, within several years of the use of combination highly active antiretroviral treatment (HAART) involving PIs and NRTIs, the emergence of metabolic abnormalities, chießy related to lipid metabolism, and changes in body shape were described (4,5). These have since been grouped together under the umbrella of HIV-associated lipodystrophy (HIVLD). Of all the side effects of antiretrovirals, this condition has drawn most attention due to its impact on the general appearance of affected patients, as well as the possibility of increased cardiovascular disease associated with the metabolic abnormalities (6).

As treated HIV-infected patients live longer, grow older, and cope with more co-morbidities, such as concurrent chronic viral hepatitis infection, so the spectrum of toxicities is evolving. In addition to HIVLD, concerns have arisen with regard to osteoporosis and hepatotoxicity associated with long-term antiretroviral treatment. This chapter will aim to address issues of toxicity, concentrating on HIVLD. In addition to prevalence of speciÞc side effects and risk factors associated with their development, possible pathogenic mechanisms behind the abnormalities will be discussed. The text will also provide an insight into current and future management strategies to cope with these problems.

HIV-ASSOCIATED LIPODYSTROPHY

Description

Lipodystrophies have been described as far back as the late 19th century (7), although prior to the recognition of HIVLD, lipodystrophy was conÞned to relatively rare congenital and acquired disorders (8). HIVLD is characterised by the development of morphological and metabolic abnormalities associated with the use of antiretroviral medications (ARV). Morphological abnormalities revolve around adipose (fat) tissue, hence the term Ôlipodystrophy.Õ Wasting of subcutaneous adipose tissue

from the peripheries (4), and accumulation of adipose tissue in the intra-abdominal space, the dorsocervical regions and the breasts are hallmarks of the condition (4,5) (Fig. 33.1) although discreet lipomata have also been described (9). Metabolic abnormalities include hyperlipidemia, insulin resistance, diabetes mellitus and lactic acidemia (4,10).

These morphological and metabolic abnormalities share similarities with previously described congenital and acquired lipodystrophies (8) (Table 33.1). Mechanisms underlying these conditions have been used as models in the investigation of the pathogenesis of HIVLD (11). What is emerging is that the aetiology of HIVLD is complex, with genetic, environmental and drug factors all playing a signiÞcant role.

When a cohort of anti-retroviral na•ve patients was studied after starting their Þrst antiretroviral regimen, an initial increase in body fat in general was observed, associated with an increase in lean mass, increases in CD4 count and decreases in viral load (12). This may represent recovery from the chronic active viral state and the associated catabolic metabolism. After six months of treatment, a selective loss of limb fat tissue occurred, which likely reßects the lipoatrophy described in HIVLD.

Risk Factors

Many complex medical disorders have multifactorial aetiology, involving genetic factors, which predispose an individual to a certain condition, environmental factors, which alter the severity of or susceptibility to the condition, and triggers, which bring the condition to the fore. This is true for diseases such as diabetes (13) and Crohnõ disease (14) and evidence exists to support such a model for HIVLD.

The HIVLD phenotype exhibits marked heterogeneity with some individuals experiencing predominantly peripheral lipoatrophy rather than central adiposity, while others develop metabolic abnormalities before any morphological changes become apparent. This may reßect a combination of environmental and genetic factors contributing to the condition. Certain genetic polymorphisms in fat related genes may result in variations in the severity of

FIG. 33.1. Morphological features of lipodystrophy. (a) Facial and upper limb lipoatrophy with accumulation of central abdominal fat leading to a ‘pot belly’ appearance. (b) Lower limb lipoatrophy resulting in prominence of super cial veins.

HIVLD (15,16) with additive and protective effects described.

Numerous cross sectional cohorts and one prospective cohort have been analysed to determine the effect of multiple environmental factors, factors such as age and sex, and triggers such as antiretroviral treatment on the presence of HIVLD (10,17–24) (Table 33.2). Major associations include prior or continuing use of PIs and/or NRTIs, and increasing age. Minor associations include male sex, AIDS diagnosis and greater CD4 and HIV RNA response to treatment. A signiÞcant role for non-nucleoside reverse transcriptase inhibitors (NNRTIs) was not apparent. The use of combinations including NRTIs and PIs seems to have a synergistic effect with regard to the severity of HIVLD (25).

Pathogenesis

There are complex interactions between adipose tissue, serum lipids, lipids in cells other than fat cells, such as muscle and liver, and insulin resistance. Balanced interactions, under hormonal control, are required for the normal handling of fats within the body (Fig. 33.2) (26). This delicate homeostasis can be upset by numerous factors, including both genetic factors, such as those seen in familial hyperlipidemia and congenital lipodystrophies, and environmental factors, such as diet or drugs.

Lipoatrophy

Lipoatrophy of subcutaneous adipose tissue (SAT) was among the Þrst recognised manifestations of HIVLD and often proves most distressing to patients, explaining much of the apprehension many patients in the developed world feel about starting treatment. Three factors inßuence the mass of SAT. These are differentiation of preadipocytes to mature adipocytes, adipocyte death, either by apoptosis or necrosis, and adipocyte size. Evidence exists supporting a role for each of these factors in the lipoatrophy seen in HIVLD.

$$\text{SAT mass} \propto \frac{\chi[\text{rate of differentiation}].\gamma[\text{adipocyte size}]}{\kappa[\text{rate of adipocyte death}]}$$

Adipocyte Differentiation

Differentiation of adipocytes takes place in two stages. An initial cell mitotic phase (normally two cell divisions from day 0 to day 2) is followed by a differentiation phase (day 2 to day 6–8). This process is regulated by intracellular transcription factors such as the CCAAT/enhancer-binding proteins (C/EBPα & C/EBPβ), sterol regulatory element-binding protein-1 (SREBP-1) and peroxisome proliferator-activated receptor gamma (PPARτ) (27). Changes in levels of these factors during differentiation are illustrated in Fig. 33.3. *In vitro*, protease inhibitors have been shown to decrease the intracellular levels of these transcription factors, resulting in abnormal differentiation of the pre-adipocytes to mature adipocytes (27,28). Similar changes in expression have also been reported *in vivo* (29).

SREBP-1 is thought to be a particularly important factor in the regulation of fat differentiation and metabolism (26). It resides in the cytoplasm before migrating to the nucleus where it stimulates expression of genes involved in lipogenesis and adipogenesis. There are three stages at which its action can be affectedÑ at the transcription phase, limiting the amount of immature SREBP-1 produced, in the cytoplasm where immature SREBP-1 is cleaved to produce an mature fragment that passes into the nucleus, and at the nuclear membrane where the ability of the mature molecule to cross the membrane into the nucleus can be affected (30). Protease inhibitors have been shown *in vitro* to result in accumulation of SREBP-1 outside the nucleus of adipocytes (28), presumably affecting nuclear localisation and subsequent function. Whether they do this by inhibiting the proteases involved in cleavage of immature SREBP-1 to mature SREBP-1, or whether they affect the structure of the nuclear membrane, thereby affecting transport of SREBP-1into the nucleus, remains to be resolved. Interestingly, abnormalities in lamins, structural proteins within nuclear membranes, have been identiÞed in a congenital lipodystrophy called familial partial lipodystrophy FPLD (31,32). This form of lipodystrophy shares many features with HIVLD (Table 33.1).

Additional research has suggested a possible genetic contribution to the function of SREBP-1. Recent identiÞcation of a single nucleotide polymorphism (3Õ22C/G) in SREBP-1c (16) and its association with antiretroviral induced hyperlipidaemia support a scenario where certain individuals may have molecular defects which under normal circumstances do not cause signiÞcant disadvantage, but which place them at higher risk of developing morphological and metabolic abnormalities when combined with added insults to adipose tissue function from antiretroviral therapy. Further population based research in HIV-infected, treated individuals is required to verify such mechanisms.

Adipocyte Death

Increased apoptosisÑ or programmed cell deathÑ has been sought in fat biopsies from individuals with HIVLD (33) and in adipocyte cultures exposed to antiretrovirals (27). The terminal deoxynucleotidyl transferase dUTP-digoxigenin nick end labelling (TUNEL) assay was used to demonstrate apoptosis. In adipocyte cultures, increased TUNEL reactivity was detected after as little as 48 hours

TABLE 33.2. *Factors associated with presence of HIVLD*

Cohort	N	↑Age	Sex	PI now	PI duration	NRTI now	NRTI duration	NNRTI	ARV duration	CD4 count	HIV RNA	AIDS diagnosis	↑Lactate	↑Lipids	Insulin Resistance

" + " = positive correlation with development of HIVLD. "–" = negative correlation with development of HIVLD. ns = not studied. D4T = stavudine. IDV = indinavir. NRTI = nucleoside reverse transcriptase inhibitor. NNRTI = non-nucleoside reverse transcriptase inhibitor. PI = protease inhibitor. LA = association with development of predominant lipoatrophy. LH = association with the development of predominant lipohypertrophy. PI/NRTI "now" = subject on PI/NRTI containing regimen at time of study. PI/NRTI "duration" = total length of exposure to stated class of drug. HOPS = HIV Outpatients Study. ↑ = increase. ↓ = decrease. ♂ = male. ♀ = female.

exposure to PIs (27), while in fat biopsies, mild to moderately increased TUNEL reactivity was seen (33). In addition to apoptosis, other causes of cell death such as necrosis can also result in increased TUNEL reactivity (34). Other speciÞc markers of apoptosis such as procaspase 9 cleavage and DNA laddering were not detected in the cell culture models (27). Therefore, although evidence exists for increased apoptosis in HIVLD, it is by no means conclusive. Nevertheless, evidence exists for increased cell death in HIVLD, whether by apoptosis or necrosis.

Tumour necrosis factor alpha (TNF-α), a molecule released by numerous types of cells within the body, particularly in response to stress, has been implicated in the pathogenesis of HIVLD especially in relation to adipocyte death. It is hypothesised that increased levels, which could be produced in response to HIV infection, could contribute to lipolysis (35,36). Excess TNF-α is known to lead to changes in body composition, as seen in the generalised wasting seen in other aggressive conditions such as metastatic disease (37). However, when plasma TNFα levels were examined in a cross sectional cohort of HIV-infected individuals, neither PI use or lipodystrophy were associated with signiÞcant differences in TNFα concentration (38).

Adipocyte Size

Size of adipocytes is largely determined by the size of the intracellular lipid reservoir. Intracellular lipid reservoirs are depleted in cells exposed to PIs (27,28). Cross sectional analysis of subcutaneous fat from individuals with HIVLD has show marked heterogeneity in the size of adipocytes (33). Obviously the accumulation of lipids within adipocytes will depend on adipocyte function. In addition to the PI effects on transcription factors such SREBP-1 and PPARγ, much interest has been directed at the effect of NRTIs on mitochondria within fat cells.

Mitochondria are essential for the normal physiological function of cells, including the production of acetyl coenzyme A (acetyl CoA) from glucose. Production of acetyl CoA is vital to normal cellular functionsÑ it is the main substrate for the citric acid cycles and the electron transport chain reactions that provide a cell with almost all of its energy requirements (39). Excess acetyl CoA can be stored for later energy use as lipid within a cell and is an important substrate for lipogenesis within adipocytes (26). Mitochondrial dysfunction, resulting in decreased acetyl-CoA, could starve the cell of energy and also prevent an adipocyte from accumulating fat within the cell. Without this energy source, the cell is forced to metabolise

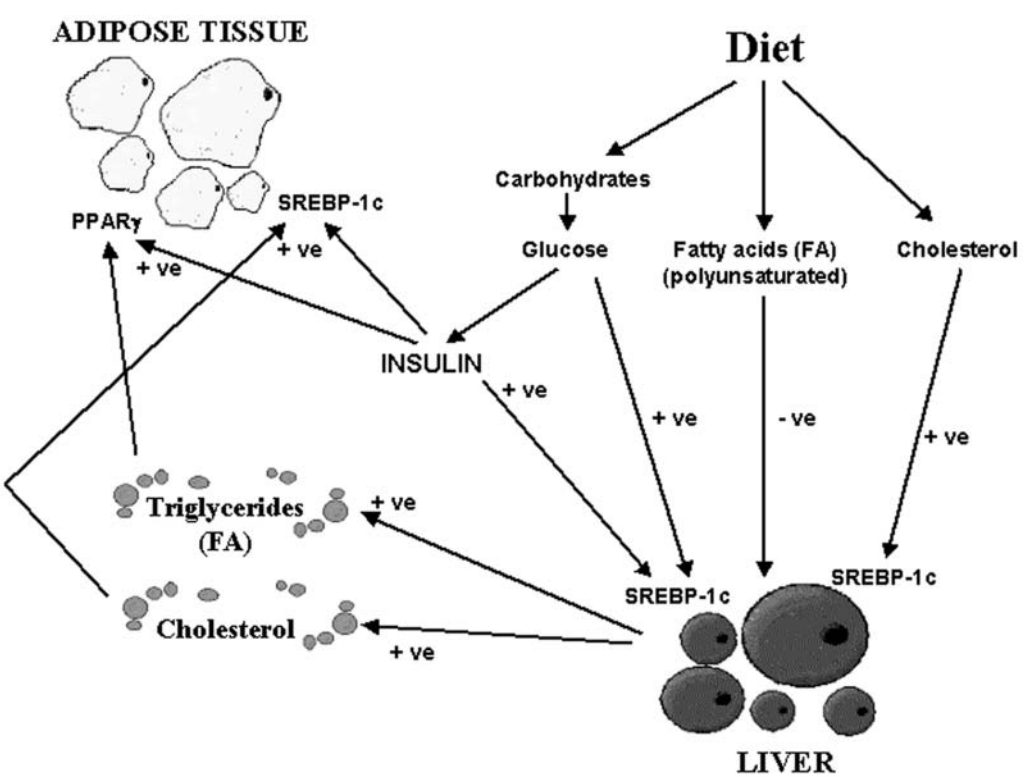

FIG. 33.2. Handling of dietary lipids. Dietary cholesterol and glucose stimulate lipogenesis (production of lipids) in liver. Glucose does this directly, by acting as a substrate for lipogenesis, and indirectly via insulin action. Polyunsaturated fatty acids inhibit lipogenesis. Both serum and intracellular lipid levels and insulin action also in uence lipogenesis in adipose cells. SREBP-1 (sterol regulatory element-binding protein-1) and PPARγ (peroxisome proliferator-activated receptor gamma) are thought to be two important intracellular molecules through which various factors exert their actions (26).

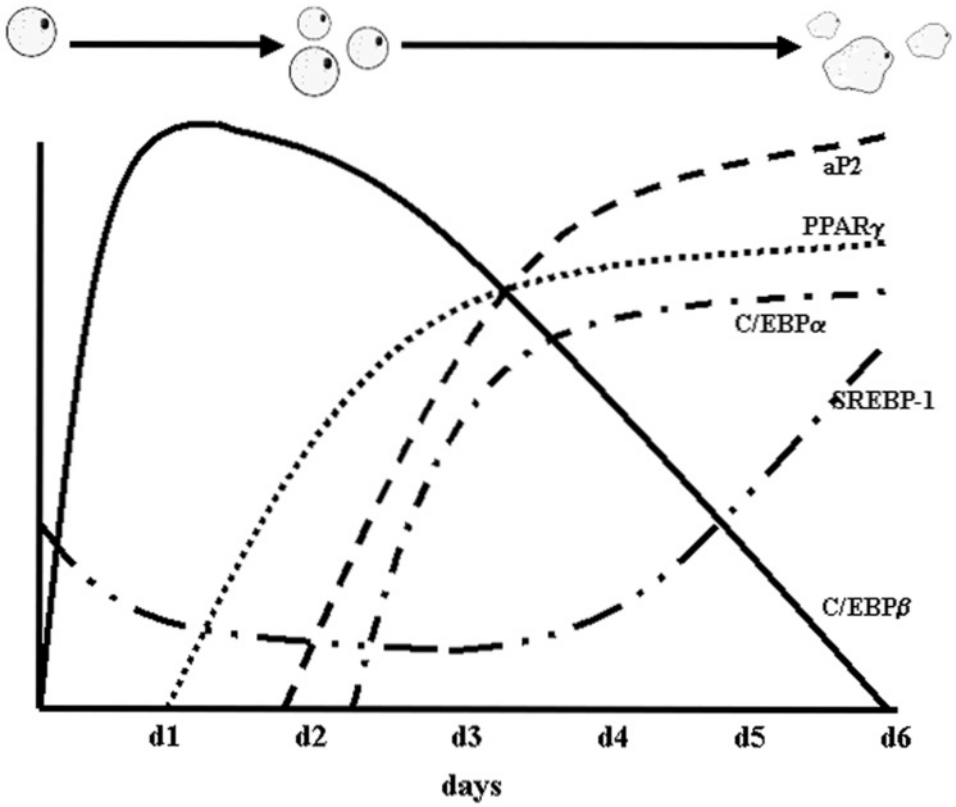

FIG. 33.3. Regulation of adipocyte differentiation. Slow decline in levels of C/EBPβ towards the end of the cell division phase correlate to increasing levels of C/EBPα and PPARγ. Levels of SREBP-1 drop initially but increase towards the end of the differentiation phase. As levels of PPARγ and C/EBPα increase, so do levels of the aP2 protein, the expression of which is regulated by these two transcription factors. C/EBPα and C/EBPβ = CCAAT/enhancer-binding proteins alpha and beta, SREBP-1 = sterol regulatory element-binding protein-1, PPARγ = peroxisome proliferator-activated receptor gamma (27).

pyruvate to lactate, a much less efficient energy creating process (39).

NRTIs exert their effect by incorporating themselves into nucleic acid during gene transcription resulting in the inhibition of polymerases, such as viral reverse transcriptase, thereby causing the termination of transcription. NRTIs may adversely affect mitochondrial function in adipocytes by inhibiting the function of DNA polymerase γ, the major DNA polymerase active in mitochondria, which is susceptible to such inhibition (40). This would almost certainly affect the normal function of adipose tissue, which has a high concentration of mitochondria. Evidence exists to support a role for NRTI induced mitochondrial toxicity in HIVLD. Some individuals develop HIVLD with exposure to NRTIs alone (10). These cases are often characterized by high serum lactate levels suggestive of mitochondrial toxicity. In addition, subcutaneous fat from individuals with HIVLD has revealed decreased levels of mitochondrial DNA (41). This toxicity could result in smaller size of adipocytes.

Fat Accumulation

Accumulation of visceral fat (VAT) and lipomatosis are features of HIVLD (5,10,42). The mechanism whereby VAT accumulates is poorly understood. It has been suggested that, in addition to genetic predisposition (15), shunting of dietary fats towards the visceral compartment due to increased production of lipids (which will be discussed later) and relative loss of the subcutaneous fat compartment may explain the gains seen (42). Visceral fat is significantly different metabolically from SAT, therefore exposure to antiretrovirals may not have as great an effect on its function (43). Prospective data have shown that gain in central fat occurs relatively early into treatment, at the same time when individuals also gain limb fat and lean mass, but is maintained over the period where limb fat mass is lost (12). This could reflect a general improvement in nutrition. A combination of nutritional improvements, decreased energy requirements resulting from treated HIV infection, and shunting of serum lipids away from depleted subcutaneous stores to the visceral compartment could go a considerable way to explaining the persistent increases in VAT seen in HIVLD.

Insulin Resistance

Insulin resistance has been described in both HIV associated and non-HIV associated lipodystrophies (4,8).

Insulin resistance has been related to the fat content within tissues such as muscle, and liver, and has also been associated with abdominal obesity (44Ð46). In HIVLD, its pathogenesis is complex and involves actions by antiretrovirals on several organs (Fig. 33.4).

Insulin, acting through the insulin receptor (IR), activates an intracellular messenger cascade, resulting in the redistribution of an intracellular glucose transport molecule (GLUT4) to the cell surface to facilitate glucose uptake by the cell. GLUT4 is the principal molecule involved in glucose uptake from plasma by adipose and muscle cells in response to insulin (47). Abnormalities in GLUT4 expression affect insulin resistance. These effects may not be tissue speciÞc. Experimental models have shown that decreases in GLUT4 expression in a speciÞc organ results in insulin resistance in other organs with normal GLUT4 expression (48). Abnormalities in the function of GLUT-4 and decreased expression of the IR as a result of PI exposure have both been proposed as possible additional mechanisms for the insulin resistance seen in HIVLD (28,47), although the exact nature of the abnormalities remains unclear.

The etiology of insulin resistance in HIVLD is obviously complex, involving interactions with insulin action and fat metabolism, and a probable role for molecules synthesized in one tissue having an effect on the insulin sensitivity of other tissues (49). One such molecule, the hormone leptin, is secreted by adipocytes. In congenital lipodystrophies, where there is a lack of SAT, levels of leptin are low and are associated with severe insulin resistance (8). In animal models of lipodystrophy, leptin infusions improved insulin sensitivity (50). In contrast high levels of leptin are seen in cases of obesity related insulin resistance (51). In one HIV study, signiÞcantly lower levels of leptin were seen in patients on PIs and correlated with total body fat (34), suggesting that low leptin concentrations may be a consequence rather than a cause of HIVLD. Therefore, a lack of leptin under such circumstances, may contribute to insulin resistance. In obesity, adipose tissue produces excess leptin in an unsuccessful attempt to overcome insulin resistance. A possible explanation is that intracellular lipid concentrations have a dominant effect on insulin resistance, with attempted compensation by increased leptin levels unable to overcome the effect. In lipoatrophic patients, however, leptin replacement may have a beneÞcial effect on insulin resistance (52).

Hyperlipidemia

Accumulation of excess lipids in the serum is thought to be, in part, the result of increase in production of lipids, primarily by the liver (53), and a decrease in the removal and storage of circulating lipids by depleted adipose tissue stores. Loss of SAT affects the bodyÕs ability to adequately store excess circulating lipids. The amount of residual functioning adipose tissue and its capacity to store lipids will vary between individuals, explaining the heterogeneity of lipid proÞles seen in HIVLD.

In vitro work has shown that hepatoma cells exposed to PIs produce excess apolipoprotein B (ApoB) lipoproteins (54). This is thought to be due to a combination of PIs causing inhibition of the proteasome, preventing the normal breakdown of ApoB molecules within the cell, and hypersecretion of these molecules following stimulation from increased intracellular levels of fatty acids (54). This

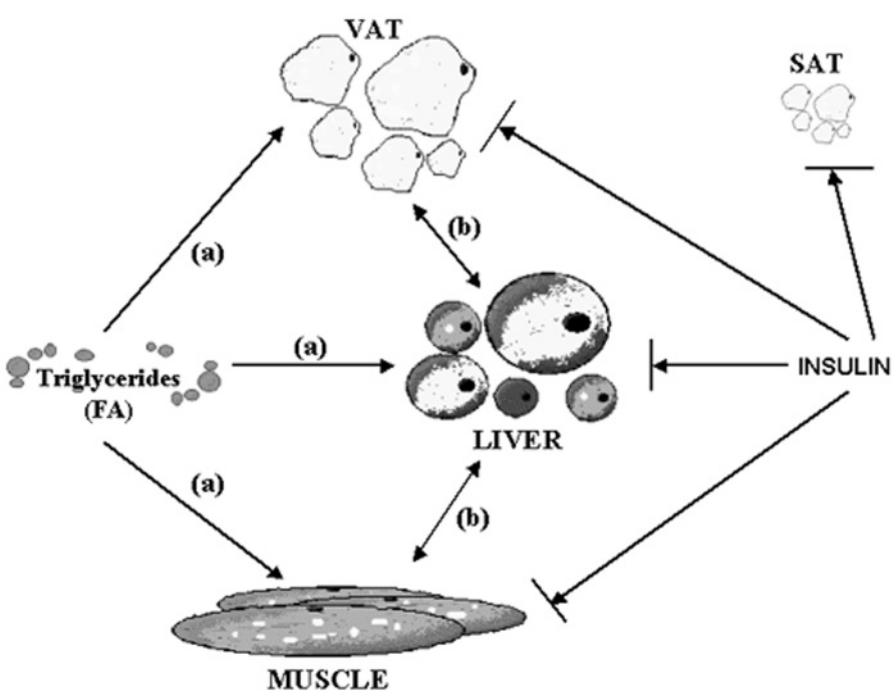

FIG. 33.4. Tissue lipid accumulation and insulin resistance. In HIVLD, as in congenital lipodystrophies, lipid accumulates in tissues such as muscle, liver and visceral fat (a). Lipid accumulation within these tissues is associated with increased insulin resistance (IR). Decreased expression of the insulin receptor gene and abnormalities in the function of GLUT-4 have both been shown with exposure to protease inhibitors (PIs). This could contribute to insulin resistance. Abnormalities of GLUT-4 in one tissue can also lead to insulin resistance in other tissues (b) suggesting a role for other molecules in the regulation of GLUT-4 and insulin resistance (8,42,44,45,47, 48).

combination of events could explain the observation of increased hepatic lipid production in HIVLD (53), resulting in hyperlipidemia and contributing to the insulin resistance seen in HIVLD.

In HIV negative populations, increase in VAT is associated with increased insulin resistance (44). In HIVLD, abdominal fat accumulation correlated with increased intramyocellular lipid levels, which in turn was associated with insulin resistance (42). In addition, increased VAT in those with HIVLD has also been associated with reduced bone mineral density (55).

Lactic acidemia

Associations between the increased frequency of elevated lactate levels seen in treated HIV-infected individuals and the development and severity of HIVLD have been described. Higher serum lactate concentrations have been observed in antiretroviral treated HIV-infected subjects (24). Its pathogenesis is thought to be further reßection of mitochondrial dysfunction. A subgroup of treated individuals with lactic acidemia was seen to suffer from accelerated lipodystrophy, which was of greater severity when compared to those with normal serum lactate concentrations (10). This may either reßect a more severe mitochondrial disturbance in these individuals, or a separate pathogenic effect of lactic acid on adipose metabolism. Lactic acidosis, referring to symptomatic lactic acidemia, will be discussed in more detail later in this chapter.

Complications

Of principal concern is that the metabolic abnormalities seen in those treated with antiretrovirals will result in premature cardiovascular disease (CVD) over the long term. Hyperlipidemia, hyperinsulinemia and central obesity are associated with increased risk of CVD in settings other than HIV infection (56,57). In addition, factors such as increased oxidative stress and cytokine production associated with HIV infection can independently contribute to accelerated atherosclerosis (58). Various techniques have been used to determine an individualÕs risk of cardiovascular disease. Changes in measurements of endothelial function, scans to detect asymptomatic vascular plaques and measurements of increased intimal thickness of blood vessels are thought to correlate well with cardiovascular risk (59).

Although there have been reports of premature cardiovascular disease in HIV-infected individuals on treatment, at present these episodes are associated more with classical cardiovascular risk factors, such as smoking, hypertension and positive family history, than the use of antiretrovirals (60). Risk of cardiovascular disease is usually expressed as a percentage increased risk of a clinical cardiovascular event (such as myocardial infarction) over a 10-year period (61). Subsequently, current increased risk developing from the use of antiretroviral medications may not become clinically apparent for a number of years to come.

Changes in vascular function, such as increased vessel intima thickness and abnormal endothelial function, predate clinical cardiovascular events and therefore may give a more accurate, early indication of the effects of antiretrovirals on cardiovascular risk (59). Abnormalities in endothelial function have been detected in individuals taking PI-containing antiretroviral regimens (62). In addition, in a group of HIV-infected subjects, elevations in systolic and diastolic blood pressure, contributors to cardiovascular risk, were also shown to be more prevalent in those with HIVLD, correlating with increased abdominal girth (63). Several abnormalities may combine to result in signiÞcant increased risk in individuals with HIVLD. This risk will be magniÞed in those with non-HIV speciÞc risk factors such as smoking and a positive family history. There are currently several large observational cohort studies underway to monitor HIV-infected populations to determine if these risks do translate to increased cardiovascular events.

Treatment

Numerous interventions have been investigated as possible treatment options for speciÞc metabolic abnormalities associated with HIVLD (64Ð76), with varying degrees of success. The major interventions and their outcomes are listed in Table 33.3. Overall, many of the interventions, considered effective at rectifying metabolic abnormalities in the HIV-uninfected population, are much less effective in those with HIVLD.

There are several possible explanations. First, in the presence of continuing insult from antiretrovirals, these interventions may not be as potent as in the settings in which they are normally used. Secondly, some of the interventions may beneÞt some aspects of the syndrome while making other features worse. Examples include recombinant human growth hormone, which can reverse visceral fat accumulation but which may exacerbate lipoatrophy and insulin resistance (72), or metformin, which at high dose can help with insulin resistance but can result in further lipoatrophy (68). On the other hand, thiazolidinediones, which act as PPARγ agonists, are the subject of intense investigation, as a side effect of their use in the general population was gain in peripheral fat in addition to its antidiabetic effect (74). In the setting of HIVLD, this would result in an overall beneÞt. Lastly, many of the interventional drugs are metabolised by the same metabolic pathways as antiretrovirals, resulting in altered serum levels of drugs, such as that seen with the use of some lipid lowering drugs from the statin class.

A treatment strategy that has received much attention is that of changing regimens or ÔswitchingÕ away from drugs

TABLE 33.3. *Interventions used in the treatment of HIVLD*

Q = quality of evidence. I = evidence from at least one RCT. II = evidence from at least one randomised trial, dramatic results from uncontrolled trial, or cohort or case control trial. III = evidence from respected authorities or expert committee reports. * = evidence from trials involving HIV-infected subjects. ψ = evidence from trials of HIV-uninfected subjects. Adapted from revised ISDA rating system (76). ↑ = increase. ↓ = decrease. HDL = high density lipoprotein. LDL = low density lipoprotein. Δ = change. NRTI = nucleoside reverse transcriptase inhibitor. PI = protease inhibitor. NNRTI = non-nucleoside reverse transcriptase inhibitor. P450 = hepatic cytochrome P450 enzyme system.

suspected of contributing to HIVLD to ones with more metabolically friendly proÞles. Numerous Ôswitch studiesÕ have been conducted. Most involved in switching from a PI based regimen to a non-PI based regimen (65Ð67,75). The results have varied greatly with some improvement in metabolic abnormalities, but little change or an exacerbation of body composition changes (75).

Augmentation of diet and exercise certainly has an important role to play in the general management of HIVLD. It is a role that is often overlooked in the search for an effective pharmacological treatment. With concerns regarding increased cardiovascular disease risk, cessation of smoking, and maintaining regular exercise are essential in that they counterbalance independent risk factors for CVD, and it is possible to modify these risks even in the setting of HIV infection and ongoing ARV treatment.

Summary

With considerable research into the etiology and pathogenesis of HIVLD continuing, the mechanisms behind the syndrome are starting to unravel. The overall picture is a complex one, with multiple insults from various medications resulting in the phenotype observed. By increasing our understanding of fat metabolism, this research has also helped us to realise the important role of adipose tissue function, not only in the setting of HIV infection, with essential roles for fat in many of the bodyÕs functions such as lipid and glucose homeostasis. The complex nature of HIVLD is reßected in the difÞculties experienced and the relative lack of success seen in treatment strategies for the condition. The eventual effect of these abnormalities on long-term incidence of CVD remains to be ascertained.

OTHER TOXICITIES

Lactic Acidemia

As discussed in the previous section (HIVLDÑ lactic acidemia), use of nucleoside reverse transcriptase inhibitors (NRTIs), particularly the synthetic thymidine analogues, has been associated with increases in serum lactate concentrations (24). The underlying mechanism is thought to be NRTI inhibition of the enzyme DNA polymerase gamma, the principal polymerase active in mitochondria (11,24). Evidence to support this includes *in vivo* studies demonstrating decreased mitochondrial DNA content of adipocytes in patients treated with NRTIs (41), thought to represent decreased functioning capacity of the organelles within these cells. Decreased mitochondrial function leads to disruption of intracellular oxidative capacity, leaving the cell unable to meet its energy needs adequately through aerobic metabolism alone. Under such circumstances, cells tend to revert to anaerobic metabolism, the end product of which is lactate, which is usually cleared from the circulation by the liver.

On rare occasions, build-up of serum lactate can become symptomatic (lactic acidosis). This may occur as a result of increased lactate production resulting from mitochondrial dysfunction. Once metabolic decompensation occurs with lactic acidosis, multiple end-organ damage follows rapidly, resulting in a high incidence of mortality (77).

The symptoms of lactic acidosis are non-speciÞc. Occasionally, the condition is preceded by a period of fatigue, weight loss and rapidly progressive peripheral lipoatrophy (10,77). Those presenting with overt acidosis may complain of symptoms such as nausea, vomiting, abdominal distension, tachypnea and occasionally myopathy or neuropathy, developing anywhere from days to several weeks prior to presentation.

Diagnosis is based on demonstration of high lactate levels, anion gap metabolic acidosis, and relevant clinical symptomatology in an individual being treated with NRTIs. Although often deranged, liver function tests may be deceptively normal, as the predominant histopathological lesion appears to be hepatic steatosis rather than hepatitis (77). Management involves the immediate cessation of antiretoviral medications, along with treatment of the metabolic acidosis. Despite intensive treatment and early detection, mortality remains high, quoted at 42% in one study (77).

The use of intermittent measurements of serum lactate as a screening tool remains controversial. The incidence of stable, chronic hyperlactatemia is relatively high (> 8%) in patients treated with antiretrovirals (24) but the development of lactic acidosis is rare (3.9Ð14.5 cases/1,000 patient years) (78,79). However, serum lactate helps identify a subset of individuals who may be at risk of severe lipoatrophy, osteopenia, peripheral neuropathy and insulin resistance (10,24,80), allowing for identiÞcation and closer monitoring of these conditions. Monitoring of lactic concentrations should also be performed in situations where there is a higher risk of lactic acidosis, such as during pregnancy or during concurrent treatment with ribavirin.

Abnormalities of Bone

Osteoporosis, osteopenia, avascular necrosis (osteonecrosis) and pathological fractures have all been reported in adult males and females, and children treated with antiretrovirals (81Ð88). With the exception of avascular necrosis, these abnormalities result from abnormalities in bone metabolism. Avascular necrosis is better explained by abnormalities in vascular function (for example secondary to hyperlipidemia).

Osteopenia

Cross sectional cohorts report a prevalence of osteopenia between 20Ð50% (80Ð82). Decreases in BMD have

been described in antiretroviral-experienced adults (82) and children (85) compared to those who were antiretroviral naïve. Hormonal, HIV and antiretroviral-related factors have all been implicated (80,81,83,84). The underlying defect results in uncoupling of the equilibrium normally existing between bone formation by osteoblasts and bone resorption by osteoclasts (83,84) with increases in markers of bone resorption detected in several studies (84,85). The nature of the underlying defect(s) is unclear but a multifactorial etiology is likely. Currently, principal areas of interest are effects of protease inhibitors, effect of nucleoside reverse transcriptase inhibitors, effects of changes in body composition on bone metabolism and the effect of pre-morbid body composition (eg wasting).

HIV-infected individuals taking protease inhibitor containing regimens may be at higher risk of osteopenia and osteoporosis (81,82). However, one study has demonstrated stable bone mineral density over time in individuals taking protease inhibitor-containing regimens (82).

Mitochondrial toxicity, induced by NRTI, can also lead to loss of bone mineral density. Osteopenia could occur as a by-product of lactic acidemia, resulting from NRTI use. Chronic metabolic acidosis, like that seen with lactic acidemia results in mobilization of calcium from bone, used to buffer high serum acid prior to its excretion by the kidneys. Lactic acidemia has been shown to be an independent risk factor for the presence of osteopenia in HIV-infected, antiretroviral-treated individuals (80). The duration and magnitude of lactic acidemia is thought to play a major role in loss of bone mineral density.

The association between HIV associated lipodystrophy (HIVLD) and reduced bone mineral density is unclear at present. Although reduced BMD has been demonstrated in groups of adults with HIV wasting and those on treatment (82,89), one cross-sectional study found no relationship between body composition changes and osteopenia (80). A smaller cross-sectional study revealed a significant association between increases in central abdominal fat and reduced bone mineral density (55). In this study, no other component of treatment or body composition had a similar association.

Case reports have described the use of bisphosphonates for the treatment of antiretroviral-induced osteopenia or osteoporosis, although randomized controlled trials of their efficacy and safety in this situation have not been published, and concerns regarding possible drug interactions with antiretrovirals persist (90).

Avascular Necrosis (Osteonecrosis)

Bilateral avascular necrosis of the femoral head has been described with increasing frequency in antiretroviral treated adults and children (86,87), many of whom had evidence of lipodystrophy and insulin resistance. Diabetes, insulin resistance and hypertriglyceridemia, all recognized side effects of antiretroviral treatment, are recognized risk factors for avascular necrosis in the general population, although similar risk factors in the HIV-infected population have yet to be identified.

Hepatotoxicity

Many factors contribute to liver dysfunction in the setting of HIV-infection. All antiretroviral medications have the potential for hepatotoxicity. In addition, HIV associated factors that are not drug-related such as opportunistic infections (especially CMV and MAC) can contribute to liver dysfunction, and co-infection with hepatitis viruses such as hepatitis B (HBV) and hepatitis C (HCV) also play an ever greater role in hepatotoxicity. Hepatotoxicity is becoming increasingly more important in the management of HIV infection as it results in considerable morbidity and mortality. It is, in itself, a large topic and therefore this chapter will deal only with antiretroviral related hepatotoxicity.

Antiretroviral related hepatotoxicity can be classified as early (occurring within 1 to 6 weeks of starting therapy) or late (after six weeks) (Table 33.4). Early hepatotoxicity usually occurs either as a result of hypersensitivity to a drug, or as a component of immune recovery (sometimes referred to as immune reconstitution). Hypersensitivity hepatotoxicity, has been described with the use of all PI and NNRTI drugs, with much interest directed against the NNRTI, nevirapine. Use of nevirapine results in hepatitis in approximately 6% of cases irrespective of CD4 count (91) and has rarely ($<1\%$) resulted in fulminant hepatitis in both HIV negative and HIV positive individuals (92,93). Incidence of hepatotoxicity was increased in subjects co-infected with HCV, in those with higher baseline transaminases, and in those with longer exposure to antiretrovirals. The condition usually resolves with discontinuation of the drug, but can rarely be fatal if not recognised early.

Immune recovery against infections such as HBV, HCV, CMV and *Mycobacterium avium complex* (MAC), especially in those with lower CD4 counts pre-treatment, can give rise to an acute and often self-limiting hepatitis, thought to be secondary to immune mediated injury. This hepatitis can be more severe in those with HBV or HCV co-infection but is usually self-limiting (94).

Late hepatotoxicity is usually independent of immune status but is associated with long-term exposure to antiretroviral medications. In such individuals, co-infection with either HBV or HCV can result in increased severity of toxicity. Drugs implicated include the thymidine analogue NRTIs didanosine and stavudine, the NNRTI nevirapine, and certain protease inhibitors. The predominant lesions are steatosis and cirrhosis rather than hepatitis (95–97). NRTI-induced mitochondrial toxicity may contribute to hepatic steatosis, apoptosis and fibrosis, while PI-induced hyperlipidaemia and insulin resistance can also result in steatosis, as seen in cases of congenital

TABLE 33.4. *Liver dysfunction associated with antiretroviral therapy*

	Lactic acidemia	Hyper-sensitivity	Isolated hepatitis	Immune reactivation	HBV reactivation
Antiretroviral (class)	NRTIs	NNRTIs, Abacavir	NNRTIs and PIs	All Classes	None
Speci c ARVs	stavudine-didanosine	nevirapine	ritonavir, nevirapine	any	lamivudine
Onset[a]	late	early	early/late	early	early
Risk Factors (possible in italics)	*NRTI duration* *Pregnancy* *HCV treatment (ribavirin)*	*Female*	HCV/HBV co-infection ↑ ALT pre-therapy	CD4 + < 100 cells/μL pre-ARVs, *MAC bacteremia*	HBV DNA + pre-lamivudine or n*t*RTI
Clinical Features					
Fever	No	Common	Occasional	Yes	Yes
Jaundice	No	Occasional	Occasional	Common	Common
Dyspnea	Common	No	No	No	No
Rash	No	Common	No	No	No
Fulminant Hepatic Failure*	Occasional	1%–2%	Unknown	Relatively common	Relatively common
Chronic Liver Failure	Rare	Not described	2° to HCV/HBV	Not described	Not described
Laboratory Features					
ALT > 10 x ULN	rare	common	common	common	common
lactate > 2 mmol/L	Yes	no	no	no	no
Therapy	cease nRTIs if lactate > 5 mmol/L or symptomatic	cease NNRTI if symptomatic	cease drugs and treat HBV/HCV	cease ARVs until underlying OI treated	restart HBV therapy (usually lamivudine)
Prognosis	mortality 80% if lactate > 10 mmol/L	good	good	good if OI treated effectively	risk of lamivudine resistance

Abbreviations: ALT = alanine aminotransferase. ARV = antiretroviral. HBV = hepatitis B virus infection. HCV = hepatitis C virus infection. MAC = *Mycobacterium avium* complex. NNRTI = nonnucleoside reverse transcriptase inhibitor. NRTI = nucleoside reverse transcriptase inhibitor. n*t*RTI = nucleotide reverse transcriptase inhibitor. OI = opportunistic infection. PI = protease inhibitor. ULN = upper limit of normal. * Features of acute liver failure are peripheral edema, ascites, encephalopathy, hypoalbuminemia, and prolonged clotting times. [a] early onset is de ned as within six weeks of starting the medication.

lipodystrophy, in which severe insulin resistance and hepatic steatosis co-exist (8). Although toxicity is often reversible, or slower to progress upon switching regimens to those with less potential for hepatotoxicity, liver failure and death have been reported (95,96), in some cases several years after drug cessation (95).

Co-infection with HIV and HCV is increasing worldwide, with a reported 25% of those infected with HIV also co-infected with HCV. In this setting, drug associated hepatotoxicity often occurs with increased frequency, with an estimated 21-fold increased incidence of cirrhosis in patients with HIV/HCV co-infection. HCV is a treatable condition and eradication of the infection is achievable in many cases using newer combination regimens of ribavirin (a nucleoside analogue) and pegylated interferon (98). Treatment of HCV concurrently with the use of antiretrovirals has raised concerns with respect to side effects, which could limit the effectiveness of either the HCV or HIV treatments. For that reason, many now consider delaying the introduction of antiretrovirals, providing the patientÕs CD4 count is compatible, until treatment and eradication of HCV infection is complete.

In those co-infected with HBV, antiretroviral treatment with drugs active against HBV, such as lamivudine, can provide added beneÞt. Rebound hepatitis has been reported in several cases where lamivudine was withdrawn for reasons related to failure of HIV therapy (99).

Management of hepatotoxicity in the setting of HIV-infection should include vaccination against viral hepatitis, preventive strategies to avoid exposure to HCV, treatment of concurrent viral hepatitis, careful monitoring of liver function tests while receiving antiretroviral therapy, and cessation of suspected agents in cases of derangement of liver function.

Chapter 34

HIV Drug Susceptibility Testing

Joseph K. Wong, Davey Smith and Douglas Richman

Resistance of clinical HIV isolates to the Þrst antiretroviral drug, the nucleoside analogue azidothymidine (zidovudine, ZDV), was identiÞed in 1989 soon after its introduction into clinical trials (1Ð3). These studies utilized standard methods of virus isolation and *in vitro* assays for susceptibility based on measurement of inhibition of viral replication by varying concentrations of drug. The following year, the genotypic basis for ZDV resistance was deÞned (4) and opened the Þeld of HIV drug susceptibility testing based on viral genetic sequence determination.

Since that time, the introduction of each new antiretroviral agent has been quickly followed by the recognition of resistance. HIV drug resistance is both a cause and an effect of incomplete viral suppression, but it is not the only impediment to effective, long-term antiretroviral therapy (discussed in Chapter **00**). A number of techniques have been developed to diagnose and study HIV drug resistance, each with particular strengths and weaknesses, but the testing strategies that may be most clinically effective still need to be determined. Based on current data: circumstances that merit drug resistance testing include patients who need to switch therapy due to drug failure, patients with primary HIV infection, patients with established infection from regions where the prevalence of primary resistance is known to be high who are about to initiate therapy and pregnant patients starting long term treatment or perinatal prophylaxis. (5,6).

The apparent ease with which HIV evades both pharmacologic inhibition and immune control through sequence change is explained by the massive scale of HIV replication (7Ð9) and by the high mutational rates characteristic of replication of RNA viruses, which lack proof-reading mechanisms (10). These circumstances result in the random generation on a daily basis of viral variants bearing every single mutation (and many double mutations) along the 9kb HIV genome (11,12). Therefore, the genetically complex population (termed quasispecies) at any given time has a high likelihood of containing viral variants that harbor mutations that can contribute to resistance. Incomplete suppression of viral replication in the presence of antiviral drug(s) results in the selective outgrowth of these variants with reduced susceptibility. For some drugs, single mutations can render mutants fully resistant (13,14), while for other drugs and for combinations of drugs the evolution of high level drug resistance requires iterative events during successive viral generations that result in the accumulation of multiple mutations (15,16). Genetic recombination among viral quasispecies may facilitate the emergence of multi-drug resistant virus (17Ð19).

Joseph K. Wong, Davey Smith and Douglas Richman: University of California San Diego and VA San Diego Healthcare System.

OVERVIEW OF RESISTANCE TESTING

Most clinical resistance testing is now performed on HIV RNA in plasma (or serum). This has the advantage of sampling contemporaneous virus because the HIV population in plasma turns over rapidly (8,9). Additionally, the typically large concentrations of free virus in plasma from untreated patients or from those failing treatment with high level drug resistance increases the likelihood that the sampling will be more representative and less susceptible to sampling artifact (8,20,21). Alternatively, peripheral blood mononuclear cells (PBMC) can be used for virus isolation as well as direct molecular studies. However, this viral compartment turns over relatively slowly and may not provide an accurate picture of the most recent evolutionary events (22,23). Drug resistance can be detected in cell free virion RNA weeks and even months before their appearance in PBMC DNA (8,24Ð27). In addition, direct molecular assays targeting HIV DNA in PBMC risk over sampling the relatively large numbers of Òreplication defectiveÓ genomes known to exist in PBMC (28,29), which may not accurately reßect the replicating virus pool.

Two categories of resistance testing are available. Phenotypic assays determine drug susceptibility by directly measuring viral growth rates or biochemical activity of the viral molecular target in the presence of varying concentrations of a particular inhibitor. Genotypic assays assess resistance based on the absence or presence of mutations or combinations of mutations known to confer reduced susceptibility to a particular drug or class of drugs.

Some considerations and caveats are generic to all resistance testing methods. Plasma collected for resistance testing should be stored at -70¡C to minimize degradation of viral RNA prior to processing. Methods that include polymerase chain reaction (PCR) amplification are very susceptible to contamination because of the exquisite sensitivity of these amplification procedures. Where these methods are used, active measures to prevent and survey for cross contamination should be employed. This includes separate dedicated areas for specimen processing, PCR set up and post PCR processing, the inclusion of negative controls with all assays, and adjunctive measures to limit aerosol formation during processing such as positive displacement or plugged pipet tips. Additionally, when sequences are generated, each new sequence should be compared to known laboratory strains and previously generated sequences for unexpected similarities or differences.

Another generic issue is the timing of resistance testing. For patients who undergo resistance testing because of a failing drug regimen, sampling should ideally be performed while the patient is still on treatment or as soon after stopping therapy as possible. Most drug resistance mutations result in selective advantage for the virus only in the presence of drug and stopping treatment will result in their replacement by wildtype, drug susceptible virus. However, this does not indicate that all traces of the drug resistant variants will have been eliminated. On the contrary, resumption of therapy results in the rapid re-emergence of drug resistant virus that lingers in latently infected cells (30). This highlights another potential weakness in drug resistance testing as resistance may have developed in response to treatment received in the remote past and is unlikely to be detected with standard assays. An exception may be certain "reversion" mutations that are seen when patients have previously had resistance to ZDV (31). Because of this, drug selection should not be based solely on the most recent drug resistance data but should take into account treatment history and prior resistance test data when available.

GENOTYPIC ASSAYS

Cycle Sequencing

The most broadly available resistance testing strategy is based on sequencing the viral genes that are targeted by individual inhibitor drugs. The utility of genotypic testing is dependent on the accuracy and completeness of existing inventories of resistance associated mutations (32,33). Such inventories are constantly updated, but many of the key (major) and secondary resistance associated mutations are well described for most of the available antiretroviral drugs. The identification of individual mutations as possibly conferring drug resistance is made when mutations reproducibly arise during the use of a drug *in vivo* or when virus is passaged in the presence of the drug *in vitro*. Establishing the relationship of mutations or groups of mutations conclusively to drug resistance depends on the demonstration that the viral isolate has a reduced susceptibility to the drug in phenotype assays *in vitro* and that site directed mutation(s) can confer reduced susceptibility.

Genetic sequencing for resistance testing begins with isolation of RNA from cell free virus in plasma which is used to generate complementary DNA (cDNA) by *in vitro* reverse transcription (RT) or by isolation of total DNA from cells, which contain viral DNA (see earlier discussion of comparative relevance of RNA and DNA sequences). Next, the target sequence is amplified by polymerase chain reaction (PCR), a repetitive procedure of annealing, extension and denaturation, which approximately doubles the amount of the sequence target with every cycle. Both the RT and PCR steps require the presence of primers which have high homology to the targeted genes. The amplified products are separated from unincorporated primers and deoxynucleotides, and can be cloned to generate individual clonal sequences that can be individually sequenced or, more typically, the entire mixture of products can be sequenced as a "population".

The most common sequencing methods are based on the Sanger chain termination strategy (34). Denatured amplicons are annealed to sequencing primers in the presence of one or more DNA dependent DNA polymerases and both unlabelled dNTP and individual 2′, 3′-dideoxy, chain terminating nucleotides. The iterative steps of annealing, extention and denaturation results in generation of chain terminated products of varying lengths in process known as "cycle sequencing." The use of fluorescently ("dye") labeled dideoxy chain terminators (or in some cases of dye labeled primers) and automated genetic analyzers has greatly simplified this method of nucleotide sequencing (Fig. 34.1). The labeled single stranded DNA fragments are separated by electrophoresis and the individual fragments detected as they migrate past a laser source. The raw data from "automated sequencing" are interpreted by base calling software. A chromatogram consisting of a series of peaks representing the pattern of individual fluorescently labeled fragments is generated (Fig. 34.2a). This approach is the basis of both commercial genotyping kits (TrueGene[a] , Bayer Diagnotics; Viroseq[a] , Celera Diagnostics) as well as many "in-house" genotypic assays.

Because HIV exists *in vivo* as a complex genetic mix, more than one base may be present at each position when

bulk sequencing is performed. This is observed as multiple peaks at a single location on the chromatogram (Fig. 34.2b and 34.2c). The threshold for identifying a base position as mutant is set with the base-calling software of the sequencing system (typically >20–30%). Most sequencing protocols involve sequencing both strands of DNA and comparing these results for consistency. In many sequencing laboratories, some manual inspection and editing is also done. In order to screen for sequences that may be the result of contamination by exogenous sequences during PCR amplification, many laboratories perform additional quality assurance procedures by comparing every newly

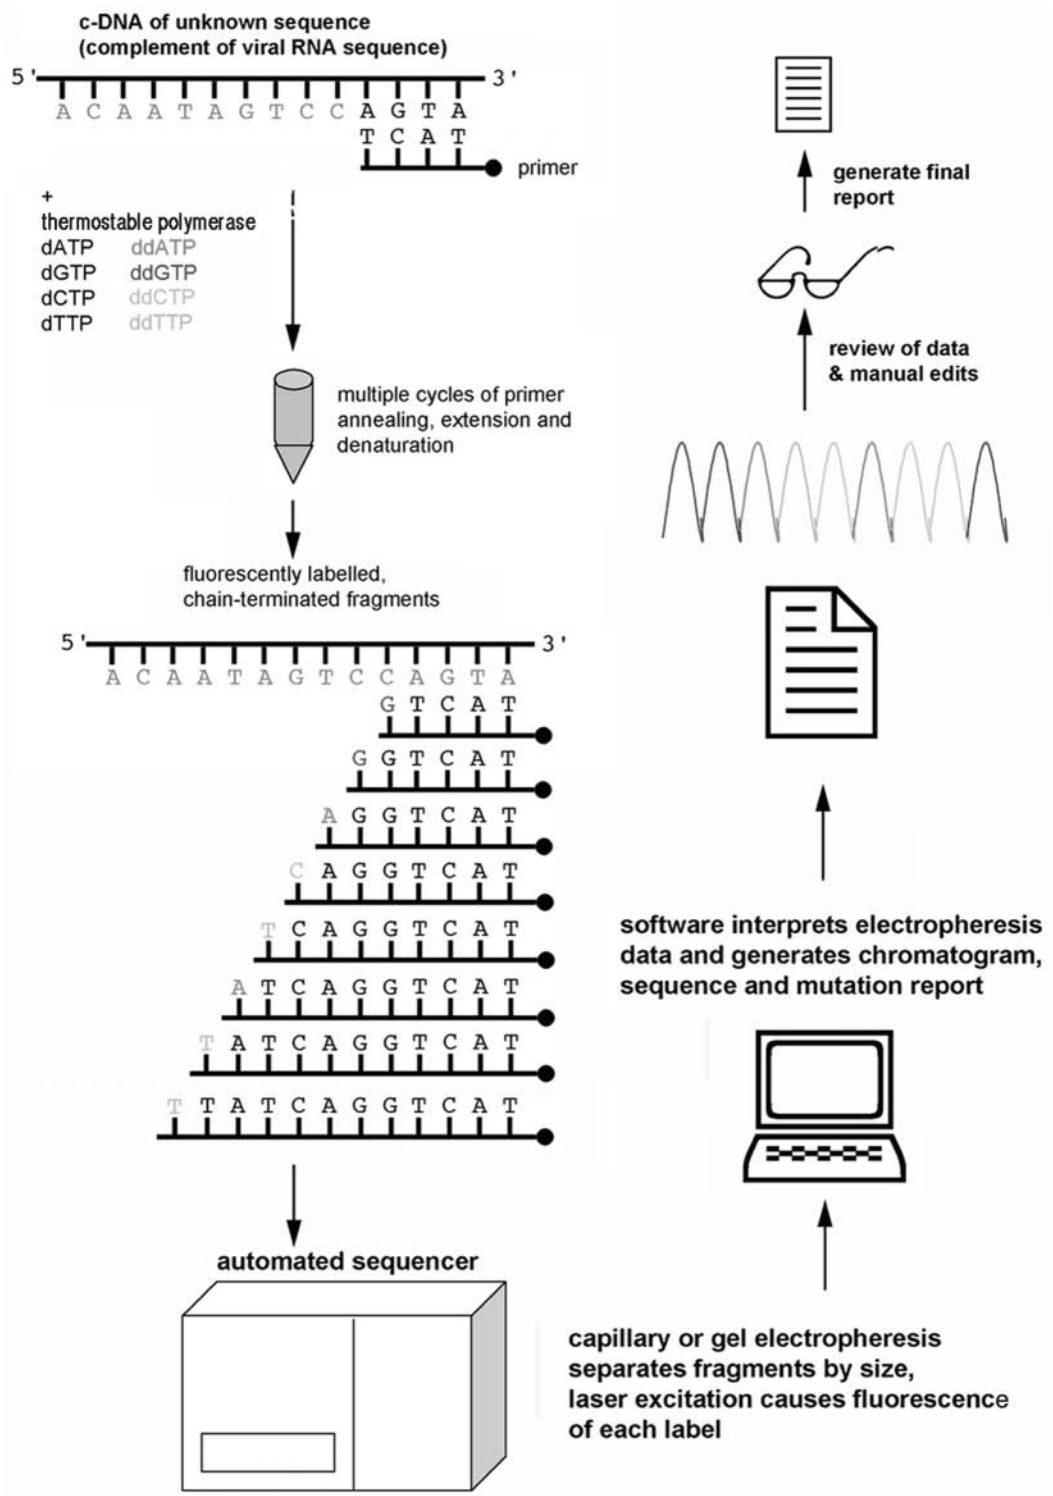

FIG. 34.1.

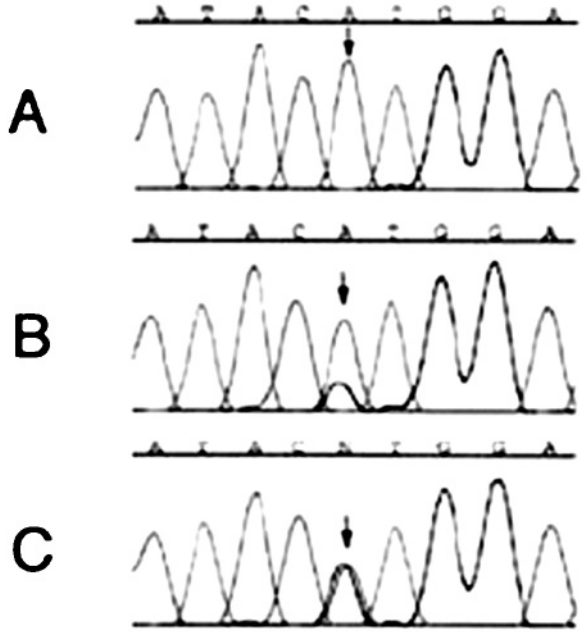

FIG. 34.2.

generated sample sequence with laboratory strain HIV sequences and sequences generated from other patient samples by phylogenetic reconstruction and BLAST searching against sequence databases (35,36). The sample sequence is then compared with a reference Òwild-typeÓ sequence to generate a summary of mutations which can be annotated with information on whether the position is associated with resistance to one or more drugs. (Fig. 34.3).

Hybridization Sequencing: GeneChip

Sequencing the entire length of HIV protease and the relevant 5′ portion of the HIV RT can be performed by large scale hybridization to gene arrays. In one such approach, phosphoramidite chemistry and lithography are used to Þx arrays of probe oligonucleotides based on wildtype and mutant HIV pol sequences to a silicon wafer (37Ð39). These oligonucleotides include various permutations of wildtype and mutant codons together with polymorphisms in the ßanking sequences. The arrays are designed with many redundant probes for each position interrogated. RT PCR is performed to generate complementary DNA (c-DNA) templates, and the inclusion of RNA polymerase promoter sequences in the ampliÞcation primers permits the generation of complementary RNA (c-RNA). These labeled c-RNAs are partially fragmented to generate short oligomers of varying lengths and hybridized to the ÒGeneChipÓ(39). These arrays contain many more probes than can be tested using conventional southern blotting or even the line probe approach. In general, the agreement of this method of resistance testing with cycle sequencing approaches is high (>96% concordance); however, even this method may not be able to detect novel (previously unrecognized) resistance mutations or clusters of mutations and sequence regions with extensive polymorphisms. An example of this limitation are the recently identiÞed insertion mutants between codon 69 and 70 (40,41).

Oligonucleotide Hybridization

An alternatives to long range sequencing are hybridization based assays that inspect only select positions known to confer drug resistance. These assays detect the presence or absence of mutations in the viral genome by the use of individual oligonucleotides that are either complementary to the wildtype (drug sensitive) or the mutant (drug resistant) sequence. The oligonucleotides are used to directly probe for the presence of mutant or wildtype sequences by hybridization under stringent conditions (temperature and salt conditions that prevent annealing unless the probe and template are a perfect match) or to prime ligation or extention reactions that are dependent on annealing of the oligonucleotide to the viral target ÒtemplateÓ Hybridization assays function best to detect well characterized and predictable mutation patterns, but they may yield an indeterminate result when there are ßanking sequence polymorphisms around the interrogated site which affect probe or primer binding. These assays are generally easier to perform with less instrumentation than required for the long range sequencing methods, but they are not designed for discovery of new resistance associated mutations.

Line Probe Assay (LiPA)

The line probe assay (LiPA, Innogenetics) uses oligonucleotide probes that are Þxed onto membrane strips (42). Biotinylated primers are used in RT-PCR ampliÞcation on RNA extracted from plasma and the ampliÞed products are allowed to anneal to the probe strips, washed and treated with streptavidin-alkaline phosphatase conjugate and nitroblue tetrazolium substrate to detect hybridization. Like other hybridization based assays, the applicability of the system depends on well deÞned resistance mutations hence only known resistance mutations can be detected. In addition, binding of the ampliÞed products to the probe strips is also affected by sequences ßanking the codon of interest therefore highly polymorphic regions can be problematic (43). Where high-throughput examination of one or a few resistance codons in well-conserved regions is the principal goal, the time savings with LiPA is appealing. An important feature of the LiPA system is its relative independence from sophisticated instrumentation following the PCR step. Thus, this system may have advantages when a fully equipped molecular diagnostic laboratory is unavailable. The LiPA also appears capable

FIG. 34.3.

of detecting minor resistant mutant populations that make up as little as 5–10% of the total population. In addition to HIV resistance testing, it has been adapted for hepatitis B resistance testing and hepatitis C genotyping (44,45).

Primer Extension and Primer Ligase Assays

The ability of primers, that match either wild-type or resistant sequence, to anneal and prime a PCR amplification reaction has also been used for mutation detection either with conventional detection of product following electrophoresis (46,47) or for use in real-time PCR assays (48,49). These latter assays can be exquisitely sensitive and can be used to detect minority populations $< 0.1\%$. However, each assay is directed at a single codon and not all positions and mutational patterns may be amenable to this approach because of polymorphisms flanking the positions of interest. These assays are currently limited to research applications.

Other assays have been described that use primers whose 3′ ends terminate at the site of the position to be studied. This is the basis of both the Point-mutation Assay (50) and the Oligo-ligase assay (51). In the former, RT-PCR generated template are tested in duplicate polymerase extension assays with either a wild-type or mutant primer and labeled dNTPs. The incorporation of label (originally described with radioactive labeling) in each reaction is proportional to the match between templates to each primer. Minority populations as low as 10% can be detected with this assay but only assays for NRTIs have been described. In the Oligo-ligase assay, mutant is distinguished from wildtype sequence by the ability of respective primers that are differentially modified to anneal to template and become ligated to a third common oligonucleotide (51,52). This system has been used to study NRTI, NNRTI and PI resistance. Sensitivity for detecting minority species approaches 5% which is important because a resistant variant may exist as a minority species, especially when certain drug pressure is not present, but then become the major variant when this drug pressure is reinstated.

Interpretation of Resistance Data

Mutations associated with HIV drug resistance have been classified as primary or secondary. Typical characteristics of primary resistance associated mutations include their ability to alter susceptibility of the virus to the antiviral compound, their early appearance and their relative specificity for one or a class of drugs. Secondary mutations typically accumulate in virus that has already developed primary mutations. By definition, secondary mutations confer little or no reduction in drug susceptibility. However, secondary mutations can increase the level of resistance of virus that already possess primary resistance associated mutations and can also restore or augment the replication capacity of such virus. Secondary mutations that have this latter effect are also called compensatory mutations. The identification of a mutation as important for drug resistance is usually supported by one or more lines of evidence. First, before drugs enter human trials, cell culture passage of virus in the presence of escalating concentrations of drugs can select for mutations *in vitro* that can be detected by sequencing. Virus isolates can then be tested in growth assays (as described in IV. phenotypic assays) for their drug susceptibility in comparison with the parental virus. Further confirmation that particular mutations confer the resistance phenotype can be obtained by creating the individual or groups of mutations in molecular viral clone and testing these "site directed mutants." Second, virus can be recovered from patients on a particular drug and these viruses can be similarly tested. The resistance mutations selected *in vivo* do not always correlate with resistance patterns selected *in vitro*. Finally, some mutations may be consistently observed in the setting of treatment failure with or without the simultaneous development of known drug resistance conferring mutations. The secondary role that such mutations play in enhancing resistance or in restoring replication fitness can be established in some but not all cases.

While a comprehensive inventory of all primary and secondary RAM is beyond the scope of this chapter, a summary of important resistance associated mutations is provided in Figs. 34.4a–c and a discussion of mechanisms of resistance relating to some key mutations concludes this chapter. Comprehensive, updated databases describing known drug resistance genotypic patterns are accessible on the Web at http://resdb.lanl.gov/Resist_DB and http://hivdb.stanford.edu. Additional information can be obtained through the International AIDS Society (http://www.ias.se/).

The standard nomenclature to describe mutations is to use the single letter abbreviation for the wild-type or reference strain amino acid, according to the International Union of Pure and Applied Chemistry (IUPAC) followed by the location of the codon in question followed by the single letter amino acid abbreviation of the new amino acid of the mutant. For example, K103N represents a mutation at the 103rd codon of the RT gene from a Lysine (K) to an Asparagine (N). It is commonly associated with high-grade resistance to NNRTIs (53).

PHENOTYPIC ASSAYS

Inhibition of Virus Replication in PBMC and Cell Lines

A consensus PBMC assay has been described that assesses the phenotypic drug susceptibility of clinical isolates of HIV to AZT by determining the drug concentration necessary to inhibit virus replication *in vitro* (54). The

assay uses virus isolated from co-cultivation of stimulated patient PBMC with sero-negative donor PBMC. The titered virus is then used to infect seronegative donor cells in the presence of varying concentrations of drug. The concentration of drug that reduces the amount of viral p24 production is called the inhibitory concentration 50 or IC_{50}. The fold change in drug concentration for the sample virus to a ÒwildtypeÓ drug sensitive control virus provides a measure of susceptibility. Adaptations of this assay have been used to assess the susceptibility to other antiretroviral drugs as well (55–60). Because of the requirement for virus isolation and titration of the viral stock prior to performance of the actual drug susceptibility tests, this approach is too time consuming and labor intensive for routine clinical monitoring. Furthermore, there are concerns that the process of virus isolation itself can alter the makeup of the viral population and that virus recovered from PBMC may overly represent archival viral forms and

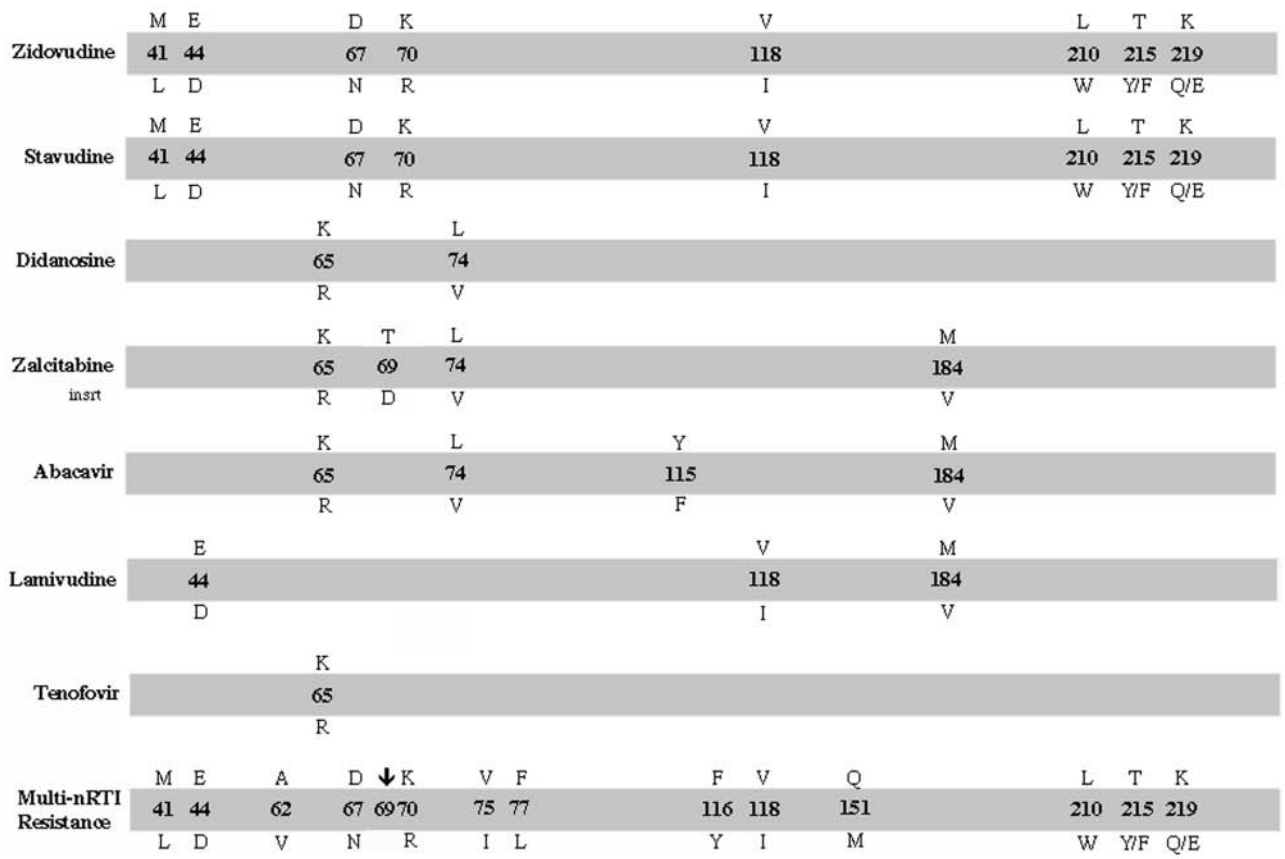

FIG. 34.4a.

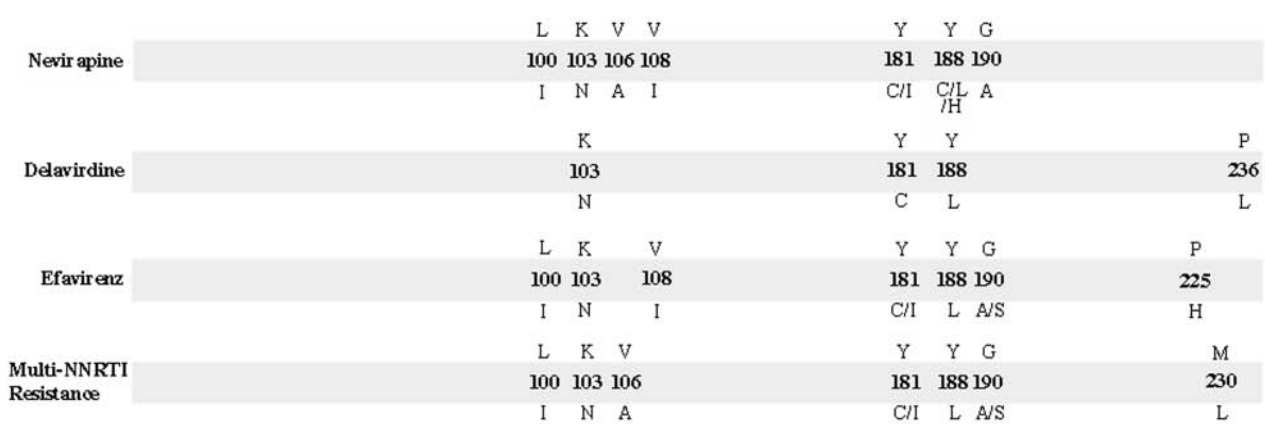

FIG. 34.4b.

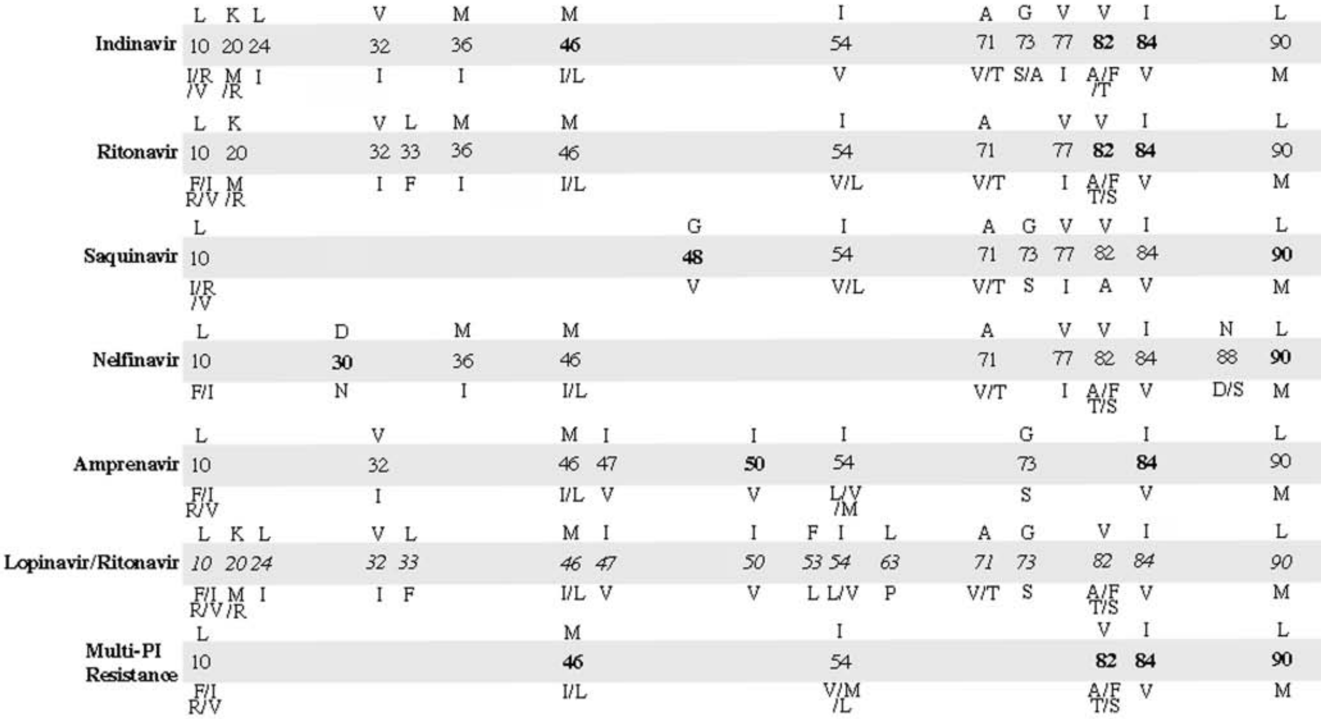

FIG. 34.4c.

therefore not reßect the contemporaneous replicating viral population in plasma (25,61). However, some data suggest that this may not be major problem in practice (53).

A related assay utilizes HeLa cells, which have been engineered to express CD4, to test drug susceptibility (1,62). It scores the amount of HIV infection of HeLa cells by counting syncitial plaques formed by infected cells. Like the PBMC assay, a titered viral isolate must be prepared. However, the readout for infection is relatively simple and less expensive than quantifying p24 production. Because HeLa cells are more homogeneous than donor PBMC, the reproducibility of the assay tends to be better. However, this assay can only be performed with syncitia inducing virus (i.e. those that use the CXCR4 co-receptor) and hence has limited utility for primary virus isolates, which more often do not induce syncitia.

Recombinant Virus Assays

The large time requirement of conventional phenotypic drug susceptibility testing has led to the development of Òrecombinant-virusÓ assays that measure *in vitro* phenotypic susceptibility but can be performed rapidly enough to have clinical utility (63Ð67). These assays utilize virus chimeras that are created from the target gene(s) of interest from clinical specimens using molecular techniques. These assays have advantages over conventional phenotypic assays since they do not require time consuming viral isolation and they minimize the potential for alteration of viral characteristics during *in vitro* cell culturing that can occur during virus isolation (25,61). Several commercial assays have been developed using this strategy.

In one recombinant virus assay, the Phenosense[a] (Virologic, South San Francisco) the HIV gene(s) of interest (in current application, the HIV protease and Þrst 340 bases of the RT) are cloned into a vector which encodes an indicator gene, the Þreßy enzyme, luciferase, under the transcriptional control of the HIV-1 LTR. This chimeric construct and a separate vector that provides the murine leukemia virus envelope (a-MLV) are co-transfected into a cell line, which permits production of pseudotyped virions (Figs. 34.5aÐc). These virions are

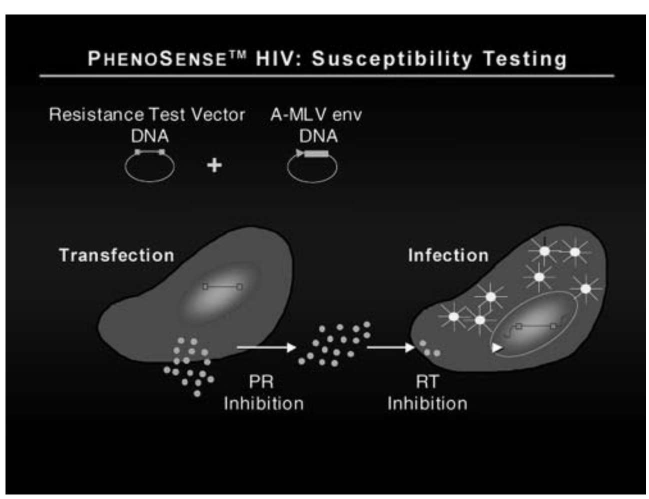

FIG. 34.5a.

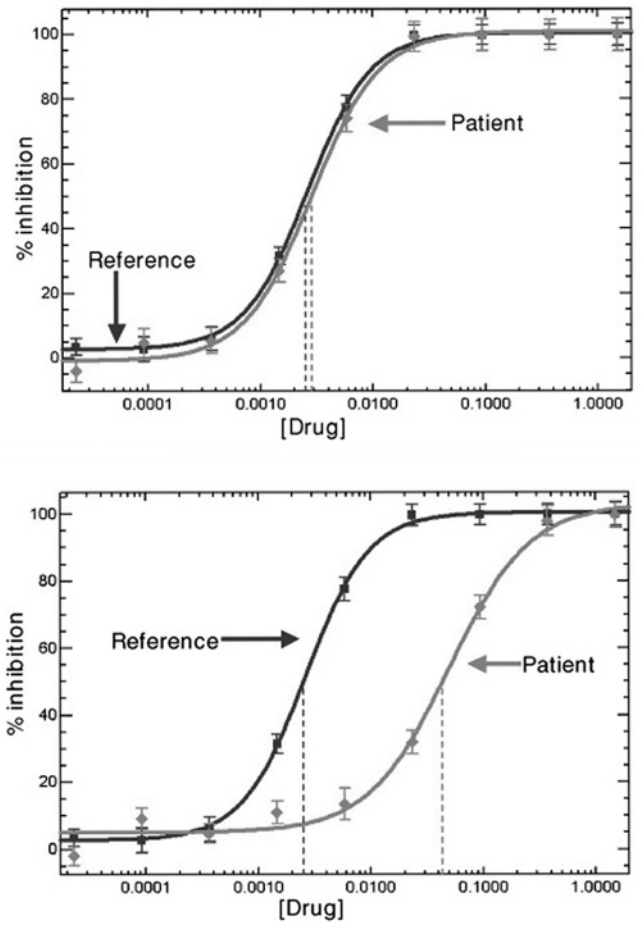

FIG. 34.5b.

either produced in the presence of drugs (protease inhibitors) or are exposed to inhibitors during the infection step (reverse transcriptase inhibitors). Successful infection of a second cell line is quantitatively assayed by detection of luciferase activity in cell lysates. These are compared with no-drug controls and are used to calculate drug concentrations where 50% or 90% of virus replication is inhibited, the inhibitory concentration$_{50}$ (I.C.$_{50}$) or inhibitory concentration$_{90}$ (I.C.$_{95}$). Comparisons with values for wildtype virus are used for calculation of a fold change over wildtype. (Figs. 34.6a and b showing readout from Phenosense assay and inhibition curves) (67). The two other commercial phenotypic assays, the Antivirogram[a] (Tibotec-Virco, Belgium) (63,65,68) and the Phenoscript[a] (Bioalliance, Paris) (68,69) differ from the Phenosense[a] in that they use homologous recombination rather than cloning to construct the recombinant viruses. cDNA corresponding to the viral protease and Þrst 3 to 400 codons of RT derived from the patient sample is co-transfected into a cell line along with a vector containing a laboratory clone of HIV missing the corresponding region in the HIV pol. A complete viral genome is reconstituted by homologous recombination within the target cell by the cellular machinery and results in virus production. The virus is harvested and used in assays of infectivity and virus growth at varying concentrations of drugs. Calculation of I.C.$_{50}$ and I.C.$_{95}$ and fold-change in drug susceptibility are similarly calculated (Fig. 34.6).

Interpretation of these phenotypic assays depends on three assay characteristics: assay reliability, biologic measures and clinical measures. Cutoffs for reliability are determined by observations on assay to assay variability (i.e. consistency of replicate assays on the same sample). Biologic cutoffs are based on the range of results on samples from patients not receiving therapy. Clinical cutoffs are based on relationship between change in I.C.$_{50}$ for a drug and the likelihood of a clinical response. This last and arguably most important cutoff has been determined for some but not all drugs.

The automation of these assays now permits their rapid and reproducible performance and simultaneous testing against all 16 of the licensed antiretroviral agents available in the U.S. Such studies using conventional approaches for phenotypic testing would be hard to perform in a timely manner. However, commercial phenotypic assays are expensive compared to genotypic assays with costs ranging from three to four times more. It remains to be determined when phenotypic testing carries sufficient advantages over genotyping to be indicated. Scenarios where phenotypic testing may provide potentially useful information for clinical management include cases of highly experienced patients whose viral genotypes indicate no available therapeutic alternatives. In such cases, phenotypic testing with precise endpoints may be able to distinguish drugs with little or no effect from drugs that retain some activity. Furthermore, subtle increases in I.C.$_{50}$ for some drugs such as didanosine, stavudine and possibly tenofovir appear to correlate with loss of *in vivo* inhibitory activity even when genotypic resistance is not apparent (70,71). In other cases, mutations to one drug may enhance susceptibility to another rendering genotypically resistant virus phenotypically susceptible. Finally, phenotypic assays can indicate loss of susceptibility to drugs due to novel mutations or combinations of resistance mutations not yet characterized.

Biochemical Assays

Other phenotypic assays, which do not depend on measures of viral infection, assess the biochemical activity of RT in the presence of varying concentrations of inhibitor (72–74). In the system described by Heinene and colleagues, HIV RT present in virions from patient plasma are used to reverse transcribe a heterologous RNA template belonging to the encephalomyocarditis virus (ECMV) in the presence of varying concentrations of RT inhibitors (73). Like genotypic assays and recombinant phenotype assays, the biochemical assays have the advantage that virus isolation is unnecessary, saving time. This assay has an additional advantage in that minor populations of resistant virus in frequencies as low as 10% can be

Replication capacity (RC) indicates the ability of the virus to replicate in the absence of drug. Range represents 95% confidence interval around RC measurement. 100% =median RC of wild-type viruses.
Phenotype/Genotype Comments (clinical significance may vary)
3 - IC50 reduced: Phenotypic measurement reflects possible enhanced susceptibility due to M184I or V.
6 - M184V: Prediction of susceptibility based on genotype does not match measured phenotype; mutations in addition to M184I or V may be required for phenotypic resistance.
13 - NNRTI HS: NRTI resistance may confer increased NNRTI susceptibility or hypersusceptibility (HS).
16 - Unexplained discordance: Genotypic correlates of susceptibility not accounted for by current rules.
This test was developed and its performance characteristics determined by ViroLogic, Inc. It has not been cleared or approved by the U.S. Food and Drug Administration.

detected. Furthermore, the assay is independent of sequence type so it is theoretically adaptable to divergent viral forms such as non-B subtype and O group viruses. However, there are a limited number of drugs for which this test has been validated (Nevirapine and 3TC) and some drugs for which this approach does not work (ZDV). Finally, the levels of viremia required are typically higher than for assays that include a genetic amplification step.

Virtual Phenotype

The difficulties with interpretation of genotypic data and the cost and time requirement of many phenotypic assays have led to the examination of large databases of simultaneous genotypes and phenotypes to generate algorithms for predicting phenotype from genetic sequence (Vircogen Virtual Phenotype; Virco) (75,76). In a study of clinical specimens, virtual phenotype and actual phenotype have been found to be in agreement in most but not all cases (77). Prospective comparisons between virtual and actual phenotype are needed to determine clinical utility. Further refinement of the prediction algorithms may be possible by the accumulation of additional "learning" data. Finally, the updating of databases with actual phenotypes for virus with new genotypic resistance patterns developing in response to new and new combinations of antiretroviral drugs will need to be continued.

ROLE OF RESISTANCE TESTING IN CLINICAL PRACTICE

Predictive Value and Clinical Utility

Support for resistance testing in clinical practice is mounting although precise guidelines for which assays to use and how best to use them are not yet available. Abundant retrospective data clearly show the predictive value of the presence of individual and categories of resistance mutations to NRTI (78–85), NNRTI (83,86–88) and PI (76,85,89) on treatment responses and outcomes. These observations suggest the utility of resistance testing in choosing antiretroviral drugs when switching therapy.

Evidence from prospective studies is less clear. Some but not all prospective studies performed to date provide support for the short term benefits of resistance testing. The VIRADAPT study randomly assigned 108 treatment experienced patients either to receive treatment based on genotypic resistance testing or to standard of care (90). By 12 weeks, mean change in plasma RNA was significantly greater in the genotyping arm (–1.04log vs. –0.46log) as was the proportion of patients achieving viral loads <200 copies/ml (29% vs. 14%). Similar results were maintained to the conclusion of the study at six months. In the CPCRA 046 study, genotypic testing along with expert interpretation and recommendations was compared to standard of care in 153 patients failing dual NRTI plus PI therapy (91). Reduction of plasma RNA was greater in the genotype arm than in the standard of care arm (–1.19 log vs. –0.61 log) and the proportion with plasma VL $<$ 500 copies/ml was also greater (55% vs. 25%) (at week 8). However, the difference was no longer statistically significant at week 12 (34% vs. 22%).

Similar results studying phenotypic assays have been reported. In a study of 273 ARV experienced patients randomized to treatment based on a recombinant phenotypic assay (Antivirogram, Virco) or to standard of care, viral load decrease (–1.23 log vs. –0.89 log) and proportion of patients with undetectable viral load (<400 copies/ml) (59% vs. 42%) were significantly better with phenotyping at week 16 (92). However, another study using the same assay reported benefits at week 4 that were lost by week 16 (93). Meynard and colleagues found no overall benefit to either phenotypic or genotypic testing in a study of 541 patients randomized to standard of care, genotyping or phenotyping (in-house assay) at week 12 but in a subset of patients experiencing failure on their first PI regimen, genotyping appeared superior (94). In another study using the Phenosense[a] assay, Haubrich and colleagues noted that baseline phenotype was indeed strongly predictive of outcomes however, at months 6 and 12, viral suppression was similar for those randomized to phenotype and those randomized to standard of care (95). These investigators stressed the need to refine the cutoff values for some drugs such as stavudine and didanosine.

Several important conclusions can be drawn from these prospective studies. First is the need for expert interpretation of resistance data for optimal benefit from resistance testing. In the one study where expert interpretation of resistance data and recommendations were not provided to clinicians, neither genotype nor phenotype provided convincing benefit (94). Computerized algorthims have also been advocated for the interpretation of resistance data, but it remains to be seen how these compare with results based on the recommendations of experienced clinicians and virologists. Another factor that appears to affect the utility of resistance testing is the range of treatment options available to patients failing therapy. Patients with many treatment options based on treatment history and those with no options may receive less benefit from resistance testing than would patients who are in between these extremes (6,94,95). The development of appropriate clinical cutoffs for each drug should also enhance the benefits from resistance testing.

IAS Consensus Recommendations

The International AIDS Society expert panel has recently recommended the use of resistance testing to help guide the selection of new drugs following treatment failure and for the selection of drugs for HIV infected, pregnant women. The panel also recommends consideration of resistance testing of drug naïve chronically infected

patients prior to initiation of therapy in areas where the prevalence of drug resistance is high. Finally, testing is strongly advocated in patients with primary HIV-1 infection who are about to undergo treatment because of the increasing incidence of primary drug resistance (96).

Viral Resistance in Tissues

Drug resistance testing of virus in blood is currently the only commonly employed clinical strategy. Because the vast majority of virus in blood arises from active viral replication and production lymphoid tissue, it is not surprising that drug susceptibility of virus in blood and lymphoid tissues correlate quite well (97,98). However, virus in other anatomic compartments such as the CNS and genital tract has been shown in small studies to comprise distinct genetic sub-populations (99–102). In the absence of treatment, this may reflect the selective effects of differences in target cell availability and host immune response (reviewed in Blankson) (103). With therapy, variation in drug penetration into different anatomical sites may result in suboptimal drug levels, promoting the evolution of resistance (104), or when no significant drug penetration occurs, give rise to sanctuary sites that permit the replication of drug susceptible virus (25,105–110). The discordance of resistance genotypes between virus in plasma and CSF has been noted in two recent studies (106 107). The clinical significance of these observations has not been determined.

EPIDEMIOLOGY OF DRUG RESISTANCE

Through analysis of samples derived from clinical trials and population-based surveys of resistance in treated patients, the risks of emergence of resistance in those receiving specific drug combinations have been well documented. The largest such database to date has been presented by the Virco group, who assessed the prevalence of specific mutations and phenotypic resistance in over 11,000 samples submitted for routine clinical testing in the U.S. (111). These data demonstrate that less than 25% of patients had a wild type phenotype and over 20% had reduced susceptibility to drugs within all three classes of currently available antiretroviral drugs. In nearly 50% of patients, plasma virus carrying M184V in reverse transcriptase could be detected, representing high level resistance to lamivudine, and a large proportion also had the zidovudine resistance-associated mutations at positions 215, 70, 67 and 41 of reverse transcriptase (Fig. 34.7). Multinucleoside resistance mutations (Q151M and 69 insertions) were only rarely detected, although this may rise as patients become more treatment-experienced. Of note, around 30% of patients also had at least one of the nonnucleoside analog and/or one of the key protease inhibitor resistance mutations.

In the U.K., the Public Health Laboratory Service started monitoring the prevalence of HIV drug resistance in 1998, recruiting patients on a random basis, who were receiving antiretroviral drugs with a viral load > 5,000 copies/mL. Results from the first year identified nearly 50% of 100 patients with resistance to drugs within at least one class of drugs, and approximately 20% having demonstrable resistance to drugs within all three classes. The most common mutations were associated with reduced susceptibility to the nucleoside analogs. These results, from a much smaller data set, are remarkably similar to those from the U.S. discussed above, and demonstrate the problems faced in choosing effective antiretroviral therapies for patients failing treatment.

There is also increasing concern about the possible transmission of drug resistant HIV, so called "primary drug resistance" (112–115). In many developed countries, the incidence of HIV/AIDS related mortality fell dramatically since the mid-1990s, coincident with the introduction of HAART while the number of new HIV diagnoses has remained constant. It is therefore unsurprising that some of these individuals have been infected with resistant virus, with prevalences of 5–20% being reported from Europe, Australia, and the U.S. (112–116).

MECHANSIMS OF ANTIRETROVIRAL RESISTANCE

Antiretroviral resistance develops as viral replication is allowed to continue in the presence of drug selective pressure. For some agents (such as lamivudine and the non-nucleoside agents), a single point mutation induces high-grade phenotypic resistance in a predictable manner. For others (such as zidovudine, abacavir and most of the protease inhibitors), high-grade phenotypic resistance requires the serial accumulation of multiple mutations, and is thus much slower to emerge. A final group of drugs (including didanosine and stavudine) is only associated with low-grade phenotypic resistance, despite the presence of one or more key mutations. Although it was originally thought that this could be associated with persistent *in vivo* efficacy of these agents, clinical trial data now show that this is not the case, and the cut-off for phenotypic resistance to didanosine and stavudine has been lowered to reflect this.

Despite the fact that many antiretroviral agents are available for use, the phenomenon of cross-resistance among drugs in a same class limits the options for second and third-line therapy. For protease inhibitors, it appears that a primary resistance mutation develops, which leads to an increase in drug resistance at a cost of decreased viral replicative capacity or "fitness". As an example, isolates carrying the D30N or M46I mutation in the protease gene may be as much as 20% less fit. The majority of isolates resistant to PIs demonstrate alterations in substrate specificity, which in theory, could be exploited to design

novel protease inhibitors (117) that would retain activity against these less Þt isolates. However, the subsequent accumulation of secondary mutations (such as at codons 46 and 63) may restore Þtness and allow the strain to replicate and persist. Recent data show that these strains (with multiple primary and secondary mutations in the protease and reverse transcriptase genes) can be transmitted, and persist for many years in the absence of drug pressure. It is likely that this phenomenon is not fully explained by changes in the target genes themselves, as interesting experiments have shown that if multi-resistant protease genes are cloned into recombinant backgrounds, they appear much less Þt than when wild-type protease genes are cloned into recombinant backgrounds (118). However, the Þtness of resistant viruses may not parallel that of wild-type isolates, as the persistence of this resistance tended to be associated with more favorable virologic and immunologic set points (30).

The sequential use of PIs is based on the fact that a number of agents in this class have unique primary resistance mutations. This is particularly true of nelÞnavir and amprenavir. Indeed, the I50V amprenavir resistance mutation alters the hydrophobic interaction with the substrate without altering the binding of other drugs in this class (119). This advantage may be lost if the isolates are allowed to continue to replicate under drug pressure, and develop secondary mutations. These would, at the very least, hasten the development of the primary mutations to other agents in the class. One agent that seems to retain activity in this setting is lopinavir/ritonavir, due to the high circulating drug concentrations that are achieved. It may thus retain activity in a situation where other protease inhibitors are no longer effective. Finally, protease cleavage site mutations may be more important than previously appreciated. In one study of drug na•ve patients such mutations were present in 77/473 individuals and were associated with a poorer therapeutic response to protease inhibitor-based HAART (120).

Although most of the mutations associated with NRTI resistance are not at the active site of the enzyme, they do lead to conformational changes that propagate to the active site (121). The fact that the mutations occur in two separate domains leads to two speciÞc mechanisms for resistance: decreased substrate binding and increases

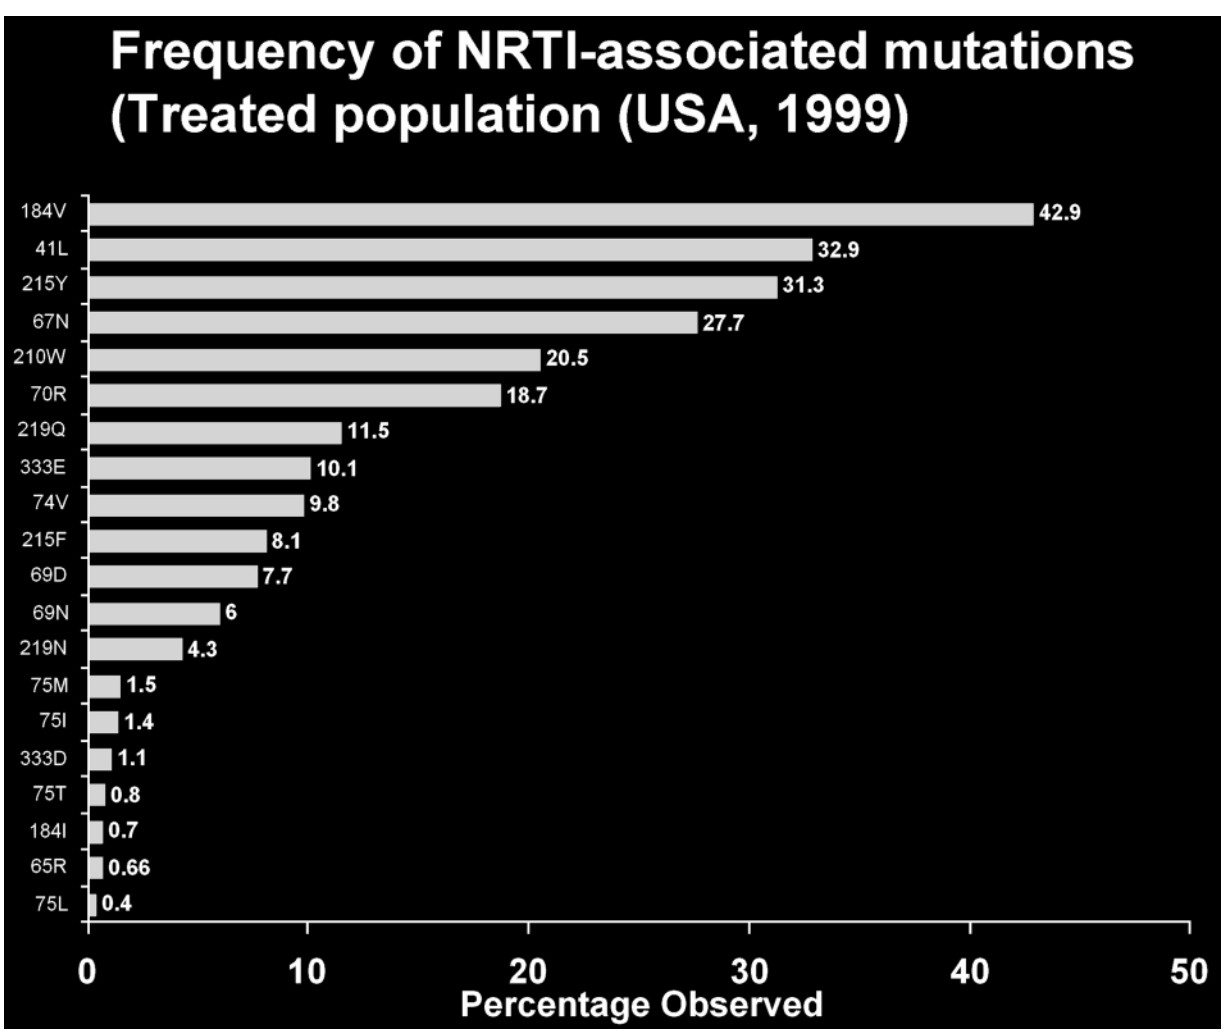

FIG. 34.7.

pyrophosphorolysis, leading to a net decrease in chain termination (122). Resistance to another agent, phospohonoformic acid, reduces pyrophosphorolysis, and partially restores zidovudine susceptibility of resistant isolates, conÞrming the importance of both mechanisms in high-grade zidovudine resistance. For multi-drug resistance three patterns have been identiÞed. Two of these are associated with an inability of the reverse transcriptase enzyme to incorporate ATP and the third (the Q151M complex) leads to substrate-independent inhibition of enzyme function (123). Further, the insertion of a dipeptide between codons 69 and 70 has been shown to enhance the removal of the terminal nucleotide and enhance extension of the unblocked primer (124). These data provide a biochemical explanation as to why the latter pattern is most readily associated with multi-drug resistance within the class. It is worrisome that these isolates may be more Þt than corresponding wild type strains *in vivo*. This is also true of certain strains carrying other multi-drug resistant mutations in the reverse transcriptase genes, suggesting the need to intervene in the course of therapy before such progressive genetic changes occur. A new nucleotide agent, tenofovir, has preserved activity against many isolates carrying multi-nucleoside resistance mutations, but seems less active against those carrying K65R, the T69S insertion or four or more resistance associated mutations (79). The small size of the molecule and its ability to interact with its substrate in multiple conformations likely explain its retained activity against most resistant isolates (125).

The K103N mutation confers resistance to all currently available NNRTIs, presumably by stabilizing the closed pocket form of the enzyme, thus inhibiting the binding of the drug to its substrate (126). The fact that all agents in this class bind to the same area explains the broad pattern of cross-resistance, and should prompt the development of new agents that would interact with this side chain more favorably. Although mutations at codons 181 and 188 confer high-grade resistance to certain drugs in this class such as nevirapine, this is not generalized to newer drugs such as efavirenz, which is a more compact molecule, and these changes do not alter the binding to its substrate (127). Therefore, cross-resistance across this class is not absolute. In practice, as many as 20% or more of patients developing nevirapine resistance will still have isolates that are sensitive to efavirenz (53,128). Although it may be that subsequent exposure to efavirenz will lead to a more rapid development of resistance, than if the baseline isolate were wild-type, which limits the possibility of sequencing of drugs within this class.

Certain mutations may confer resistance to one drug and enhanced susceptibility to another, such as M184V (129,130) and L74V (131), associated with resistance to lamivudine and didanosine respectively, which leads to enhanced sensitivity to zidovudine. M184V may also restore susceptibility to stavudine and adefovir (132,133). Isolates carrying these single changes have been consistently shown to be less Þt. It has been postulated that isolates with M184V mutations have increased Þdelity, thereby decreasing their ability to accumulate new resistance mutations (134). They may also lead to a decrease in pyrophosphorolysis, further enhancing zidovudine susceptibility (135). Indeed in early studies of the combination of zidovudine and lamivudine as double therapy, the development of zidovudine resistance was considerably delayed (129). Based on these data, it has been suggested that the use of lamivudine in salvage therapy settings could help reduce the development of resistance to other agents and enhance the efÞcacy of the overall regimen, a fact that remains to be proven in clinical trials.

Enhanced susceptibility to NNRTIs has been described in association with multiple mutations conferring broad cross-resistance to nucleoside analogues. It now appears that this phenomenon has biological signiÞcance, since its presence enhances the response to efavirenz-based therapy in both uncontrolled (136) and controlled (137) trials. However, the presence of hyper-susceptibility did not appear to delay the emergence of delavirdine resistance in one controlled salvage therapy study (138). This phenomenon may also extend to protease inhibitors, with mutations at codons 30 and 88 possibly conferring hyper susceptibility to amprenavir and ritonavir (139).

Some preliminary data suggest that non-B HIV isolates may have a reduced response to HAART. This may be due to natural polymorphisms in the protease gene, such as M36I, with or without additional changes at codons 71 and 77 (140,141). Secondary mutations that are more frequent in subtype C isolates exposed to protease inhibitors appear to be unique, a Þnding of unclear clinical signiÞcance (142). Additionally, it appears that subtype G isolates develop nelÞnavir resistance through the L90M rather than the D30N pathway, a difference that would confer different patterns of cross-resistance to other agents in this class than we are used to seeing (143). *In vitro* data exist to suggest that subtype C isolates develop resistance to NNRTIs more rapidly (144,145).

FUTURE DIRECTIONS

Clinical Outcomes with Resistance Testing

While available data strongly suggest a role for resistance testing in clinical practice, they also suggest that we currently underestimate the degree of cross-resistance (in particular with NRTIs) and that more accurate clinical cutoffs need to be established for all drugs. Additionally, the most cost effective approach to resistance testing remains to be deÞned and given the rapid pace of new drug development and the ever growing complexity of drug resistance is an issue that will require continued review and revision.

Early Detection of Resistance

In research applications, sequences of individual viral RNA molecules or proviral DNA sequences can be obtained by performing a cloning step (105,146) Such procedures can permit detection of minor populations of drug resistant virus when the bulk sequences only reßect the major variant. How important this might be to clinical practice is not known.

Hypersusceptibility

The precision of some of the automated phenotypic assays have permitted the identiÞcation of genetic polymorphisms of HIV from some patients that exhibit greater susceptibility to drugs than the control susceptible or Òwild-typeÓ strains (136,147Ð150). Some of these polymorphisms represent resistance mutations to other drugs or classes of drugs and are elicited by prior treatment while others appear to be naturally occurring. Whether treatment with drugs for which a patientÕs virus is hypersusceptible translates to a better clinical outcome remains to be determined but these observations suggest an additional potential beneÞt of drug susceptibility assessment to guide drug selection.

Viral Fitness

The recent observation that some drug resistant virus may exhibit attenuated virulence properties (30,151Ð153) adds additional complexity to therapeutic decisions based on drug resistance testing. Continued treatment with drugs against which resistance has developed can still provide some residual viral inhibition and also serves to maintain drug resistant viral populations that may be associated with lower viral replication Þtness and virulence compared to Òwild-typeÓ virus. In net, continued treatment can be associated with prolonged immunologic beneÞt. Under circumstances where therapeutic options are limited, the potential beneÞts of continued treatment need to be weighed against the possibility that continued treatment will result in selection of viral variants with greater resistance and replication Þtness (154,155).

Resistance to New Drug Classes

Inhibitors of the HIV-1 integrase are now in clinical trials and resistance to these agents will doubtless be recognized in the near future. The investigational fusion inhibitor enfuviritide (156,157) is already under review by the FDA and resistance to this drug appears to develop in the gp41 coding region (20, 158). This and future progress in drug development against new viral targets will necessitate the development of new tests for resistance and the adaptation of existing resistance testing methods.

Non-Clade B Resistance

While the Þeld of HIV drug resistance testing has largely been restricted to the study of subtype-B virus, three issues make increased attention to drug resistance in non-B viruses important. First, drug therapy is being introduced into areas of the world where the predominant subtypes are non-B (159,160). While there remain serious Þnancial and other logistical barriers to antiretroviral therapy in the developing world (160,161), the need to begin to build the infrastructure to support treatment in these areas of the world is acknowledged to be great and is a major goal of many governmental and non-governmental agencies. Second, some non-B viruses exhibit natural polymorphisms that appear to confer intrinsic resistance to certain drugs. The need for pre-treatment screening may therefore be greater under these circumstances. Third, the genetic background of these viruses may theoretically result in mutational patterns not previously encountered with clade B virus (162). Because many of the existing assays were developed and reÞned speciÞcally for type B virus, their performance for the testing of non-B virus is only recently being explored (163,164).

CONCLUSION

HIV drug resistance testing is a rapidly evolving Þeld. Technical advances and reÞnement of testing modalities are matched by the growing complexity of therapeutic options and the complex resistance patterns that result. A further challenge will be the application of resistance testing to non-subtype B virus as therapy is introduced into areas outside North America and Europe. Ultimately, analyses of large data bases relating genetic resistance patterns to phenotypic susceptibility, drug treatment and clinical outcomes will be needed to fully optimize and deÞne the use of resistance testing in clinical care. In the meantime, the standard of care for HIV infected patients includes the judicious use of resistance testing along with expert interpretation. Resistance testing has been advocated when switching patients from a failing drug regimen, for choosing drugs for pregnant patients and should be considered in all patients with primary HIV infection or any patient about to embark on therapy in areas where the prevalence of drug resistance is high.

Chapter 35

The Analysis of HIV Dynamics Using Mathematical Models

Ruy M. Ribeiro and Alan S. Perelson

The use of mathematical modeling and computer simulation in the study of infectious disease and, in particular HIV infection, has proven quite fruitful. The study of the dynamics of HIV infection represents a paradigm of success in the application of mathematical models to further our knowledge of disease pathogenesis (1,2). With these analyses, it was possible to quantify the rapidity of HIV infection and replication, the rate of virion clearance, the lifespan of productively infected cells (3Ð5), and predict the impact of treatment and the appearance of drug resistant mutations (6). Moreover, models have helped clarify controversial issues relating to the mechanism of T cell depletion in HIV infection and motivated new experimental and clinical studies.

In this chapter we will introduce the basic model for the analysis of HIV viral load decay under treatment, and explain the quantitative results obtained by these models when compared with experimental data. In later sections we will discuss extensions of this basic model to the analysis of viral reservoirs, primary infection and immune responses. Finally, we will consider models of cellular turnover, which are closely related to pathogenesis of HIV infection.

BASIC MODEL OF HIV INFECTION

Throughout most of the asymptomatic phase of HIV infection the plasma viral load remains approximately constant, at the set point reached after primary infection. This observation implies that the total amounts of virus produced and cleared in the body are balanced, i.e. production = clearance. If one of the processes in that equation dominated the other, than we would either have uncontrollable growth of virus (if production > clearance), or the virus would be eradicated (if production < clearance). This is a very powerful observation, because it means that by perturbing one side of the equation we can gain insight into the other. Thus, if we decrease the production rate, for example with antiretroviral therapy, then clearance dominates and the viral load decreases. This is exactly what is observed. Importantly, the magnitude and speed of the decrease allows the calculation of the clearance rate. Moreover, once the clearance rate is estimated, then the baseline production rate before therapy was initiated can also be estimated since at baseline, production = clearance. To obtain these estimates we need appropriate models, because the proÞle of the viral decay curve depends on several factors such as the clearance rate, the efÞcacy of the drug, and the death rate of virus producing cells. These models, based on the lifecycle of the virus, can then be used to Þt quantitative data about viral decay under antiretroviral therapy.

We begin by considering a model of the viral lifecycle. Although HIV infects different types of cells, with variable replication rates, there is a consensus that the bulk of HIV production occurs in activated CD4 + T-cells (7). Thus a basic model of HIV infection only includes activated cells (T), productively infected cells (T^*), and free virus (V). It is assumed that cells become activated at constant rate λ, and die at rate d per cell. In the uninfected individual, for most of the time, there is a steady level of these cells, which is given by λ/d. However, in infected patients these cells are susceptible to infection by HIV at a rate proportional to the available numbers of uninfected cells and free virus, with rate constant k. Thus cells become infected at rate kVT, which corresponds to a mass-action term, common in chemical kinetics. Infected cells are created at this same rate, and die at rate δ per cell,

Ruy M. Ribeiro and Alan S. Perelson: Theoretical Biology and Biophysics Group, Theoretical Division, Los Alamos National Laboratory, Los Alamos, NM 87545.

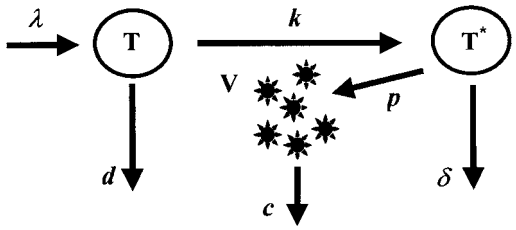

FIG. 35.1. Model used to analyze the dynamics of HIV-1 infection. See text for a full description.

which may be different from the death rate of uninfected cells (d), possibly higher. Finally, the virus is produced from the infected cells at rate p, and it is cleared from the circulation at rate c. Figure 35.1 represents this system in schematic form, and the corresponding equations are:

$$\frac{dT}{dt} = \lambda - dT - kVT \tag{1}$$

$$\frac{dT^*}{dt} = kVT - \delta T^* \tag{2}$$

$$\frac{dV}{dt} = pT^* - cV \tag{3}$$

We note that these terms and rates represent abstractions of possibly many different biological processes. Thus, for example, the clearance rate, c, indicates how fast virus is cleared from the circulation, whatever the mechanismsÑ Þltration by the reticuloendothelial system, opsonization, binding to follicular dendritic cells, phagocytosis, etc.

During the long asymptomatic phase of untreated HIV infection the viral load remains unchanged (8). This suggested initially that HIV replicated slowly. However, there was no quantitative way of measuring the viral turnover. Eqs. (1)Ð(3) show that the viral load can be at a steady state, i.e. unchanged in time ($dV/dt = 0$), as long as the production of virus (pT^*) and the clearance (cV) are balanced ($pT^* = cV$). However, this balance may occur for many different sets of parameters, and thus viral production could be high, if clearance was also large, or those rates could both be small. Knowledge of the rate of production also indicates the burden imposed on the immune system and the opportunity for the virus to mutate.

Treatment of HIV Infection

When treatments with potent antiretroviral drugs, either protease inhibitors or a combination of a protease inhibitor and reverse transcriptase inhibitors, were administered to HIV-1 infected patients, a 1 to 2 log drop in the viral load was observed over the Þrst one to two weeks of therapy. This observation allowed the quantiÞcation of the dynamics of virus production and clearance, using model (1)Ð(3) (3Ð5). Indeed, drug treatment represents a perturbation of the equilibrium by stopping the production of new virus, and the observed changes in viral load with time (dV/dt) are an indirect measurement of the clearance rate of free virions.

To analyze such drug treatment experiments, a slight modiÞcation of model (1)Ð(3) is necessary. The drugs belonging to the class of reverse trancriptase inhibitors (RTI) reduce the ability of the virus to infect new cells, by interfering with the necessary process of reverse transcription of viral RNA into proviral DNA. Thus if the efÞcacy of these drugs is ε_{RT}, then only a proportion $1 - \varepsilon_{RT}$ of new infections will be productive and the infection terms in Eqs. (1)Ð(3), kVT, have to be reduced to $(1 - \varepsilon_{RT})kVT$. On the other hand, drugs belonging to the class of protease inhibitors (PI) interfere with the maturation of new virions, rendering them non-infectious. However, these non-infectious viral particles are still quantiÞed by the commonly used RT-PCR based assays of viral load. Thus, it is important to follow the dynamics of these non-infections particles (V_{NI}). If the protease inhibitor efÞcacy is ε_{PI}, then only a proportion $1 - \varepsilon_{PI}$ of new viruses will be infectious, and a proportion, ε_{PI}, of viral particles will be non-infectious. The equations for the analysis of drug treatment data are then (Fig. 35.2):

$$\frac{dT}{dt} = \lambda - dT - (1 - \varepsilon_{RT})kV_1T \tag{4}$$

$$\frac{dT^*}{dt} = (1 - \varepsilon_{RT})kV_1T - \delta T^* \tag{5}$$

$$\frac{dV_1}{dt} = (1 - \varepsilon_{PI})pT^* - cV_1 \tag{6}$$

$$\frac{dV_{NI}}{dt} = \varepsilon_{PI}pT^* - cV_{NI} \tag{7}$$

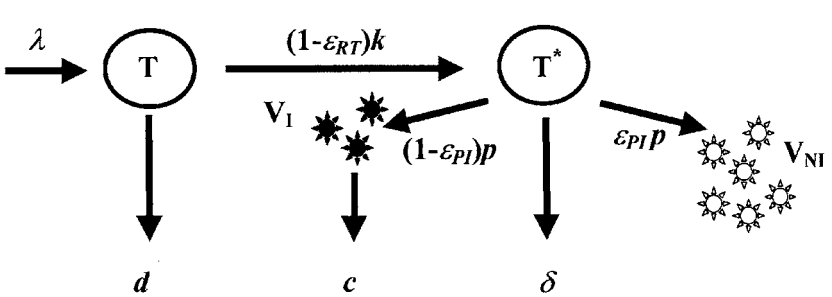

FIG. 35.2. Adaptation of the model in Fig. 1 to the study of antiretroviral drug therapy in HIV-1 infection.

where V_I represents infectious (or more precisely mature protease inhibitor untreated) virus, and V_{NI} represents non-infectious (or immature) virus.

With Eqs. (4)–(7) it is in principle possible to estimate the decay rate of free virus (c) and infected cells (δ), and from these the respective half-lives: $\ln(2)/c$ and $\ln(2)/\delta$. (Here $\ln(2)$ represents the natural logarithm of 2 and it is approximately 0.693.) It may also be possible to estimate the efficacies of the drugs, ε_{RT} and ε_{PI}. However, estimates of all these parameters demand frequent sampling of viral loads, from the start of therapy, which is not always possible due to ethical considerations.

Experimental Results

The model in Eqs. (4)–(7) was used to fit experimental data of viral decay under drug treatment in HIV infection. With a 100% effective PI regimen, and assuming that the uninfected cells (T) remain constant during the short period of analysis, the number of viral particles ($V_I + V_{NI}$) per ml of blood decays as:

$$V(t) = V_0 e^{-ct} + \frac{cV_0}{c-\delta}\left[\frac{cV_0}{c-\delta}(e^{-\delta t} - e^{-ct}) - \delta t e^{-ct}\right] \quad (8)$$

where V_0 is the pre-treatment (baseline) steady state viral load.

Estimates obtained by this method indicated that the half-life of free virus is less than 6 h, and that of infected cells is less than 1.6 days (3). The estimates are upper bounds because they are based on the assumption that drug therapy was 100% effective. In reality therapy is not so effective and residual viral production occurs. Thus, residual virus that is not accounted for in the model must also be cleared, and hence the true rates of virus and infected cell loss must be higher than is estimated by assuming a perfect drug. In Fig. 35.3 we show typical fits of the model solution, given by Eq. (8), to data for three patients. Since the virus is cleared rapidly, frequent sampling is needed at the initiation of treatment. Indeed for this experiment blood samples were initially obtained every 2 h, and still the estimated half-life of 6 h is approximately the limit of detection since it depends on so few initial data points, and is in fact just an upper bound.

The half-life of free virus has also been estimated using a different experimental method: plasma apheresis (9). In this method plasma with suspended viral particles is removed from the patient, and the same volume of fluid is re-infused. This technique again induces a perturbation of the equilibrium, since the clearance of HIV is no longer just cV, as in model (1)–(3), but larger due to the apheresis process. Frequent measurements of the decline in viral load with knowledge of the rate of removal of the virus by apheresis allow the estimate of c, and thus the half-life of free virus. This method yielded half-lives of about 1h, i.e. even shorter than those estimated by application of drug therapy.

A half-life can be biologically interpreted as the time it takes for 50% of the free virus (infected cells) to be removed from circulation. Since before treatment, the viral load is in equilibrium, it follows that the viral (infected cell) production has to equal the removal rate. Thus a half-life of 1 h indicates that a typical individual with a set-point viral load of 10^5 HIV RNA copies/ml (or equivalently 1.5×10^9 HIV RNA in the 15 liters of body water in a 70 kg person) has a total body daily production of between 10^{10} and 10^{11} viruses. The total body load of productively CD4+ T-cells was estimated to be about 4×10^7 (10). If these cells have a half-life of 1.0 day, then 4×10^7 CD4+ T-cells are destroyed and produced each day. (This half-life of one day is a recent estimate obtained with a very potent four-drug protocol (11).)

These large turnovers have implications for the generation of mutations in the viral genome. The estimated mutation rate of HIV is 3.4×10^{-5} mutations per base per replication cycle (12), and the viral genome is about 104 bases. Thus, it can be estimated that, on average, all one-point mutations will be produced many times each day, and that a proportion of all viable two-point mutations will also be produced. Depending on the selective disadvantage of these mutants, many will be present at low levels in the patient's viral population, allowing for further accumulation of mutations (13,14). This explains the quasi-species nature of HIV and its rapid evolution *in vivo*. One consequence of this evolution is the rapid generation of viral variants resistant to all the available drugs when used alone, and this provides a rationale for combination therapy.

Potent combination antiretroviral therapy leads to a sustained viral decay over long periods of time until the viral load becomes undetectable by conventional assays. However, after the first week or two, the decay slows down and it no longer corresponds to the decline of short-lived productively infected cells, which have a half-life of about 1.0 day.

MODELS FOR THE SECOND PHASE OF DECAY

In the basic model (Section 1) HIV is only produced from productively infected CD4+ T-cells. However, to understand the second phase of decline observed in patients undergoing HAART, models with additional sources of HIV had to be developed (15). After productively infected CD4+ T-cells are removed by treatment, these other sources would become dominant and their slower clearance leads to the observed slower decline in the levels of HIV RNA. Different possible putative sources were considered in the context of modeling: long-lived productively infected cells, latently infected cells, and tissue reservoirs, such as follicular dendritic cells (FDC) or drug sanctuaries (i.e. cell

populations or tissues where drug penetration is sub-optimal).

Data Þtting to HIV RNA decline cannot distinguish between those possible sources, since the Þts for different models are equally good. For example, one can not distinguish between long-lived productively infected cells or latently infected cells being the source of second phase of decay. However, Þtting HIV RNA and infected cell decay simultaneously indicates that the second phase of decay is more likely due to long-lived productively infected cells. These cells were estimated to have an average half-life of about 14 days (16), whereas latently infected cells without integrated provirus were estimated to have a half-life of about 8.5 days (16). With these estimates, we have calculated that productively infected cells contribute 93Ð99% of the virions produced at steady state, before therapy, whereas long-lived infected cells contribute only 1Ð7%, and latently infected cells less than 1% (16). HIV infects not only CD4 + T-cells but also other cell types such as macrophages and dendritic cells, which are candidates for the long-lived productively infected cell pool. However, it is difÞcult to eliminate other contributions to the second phase of decline, and instead of a long-lived infected cell pool the second phase of decay

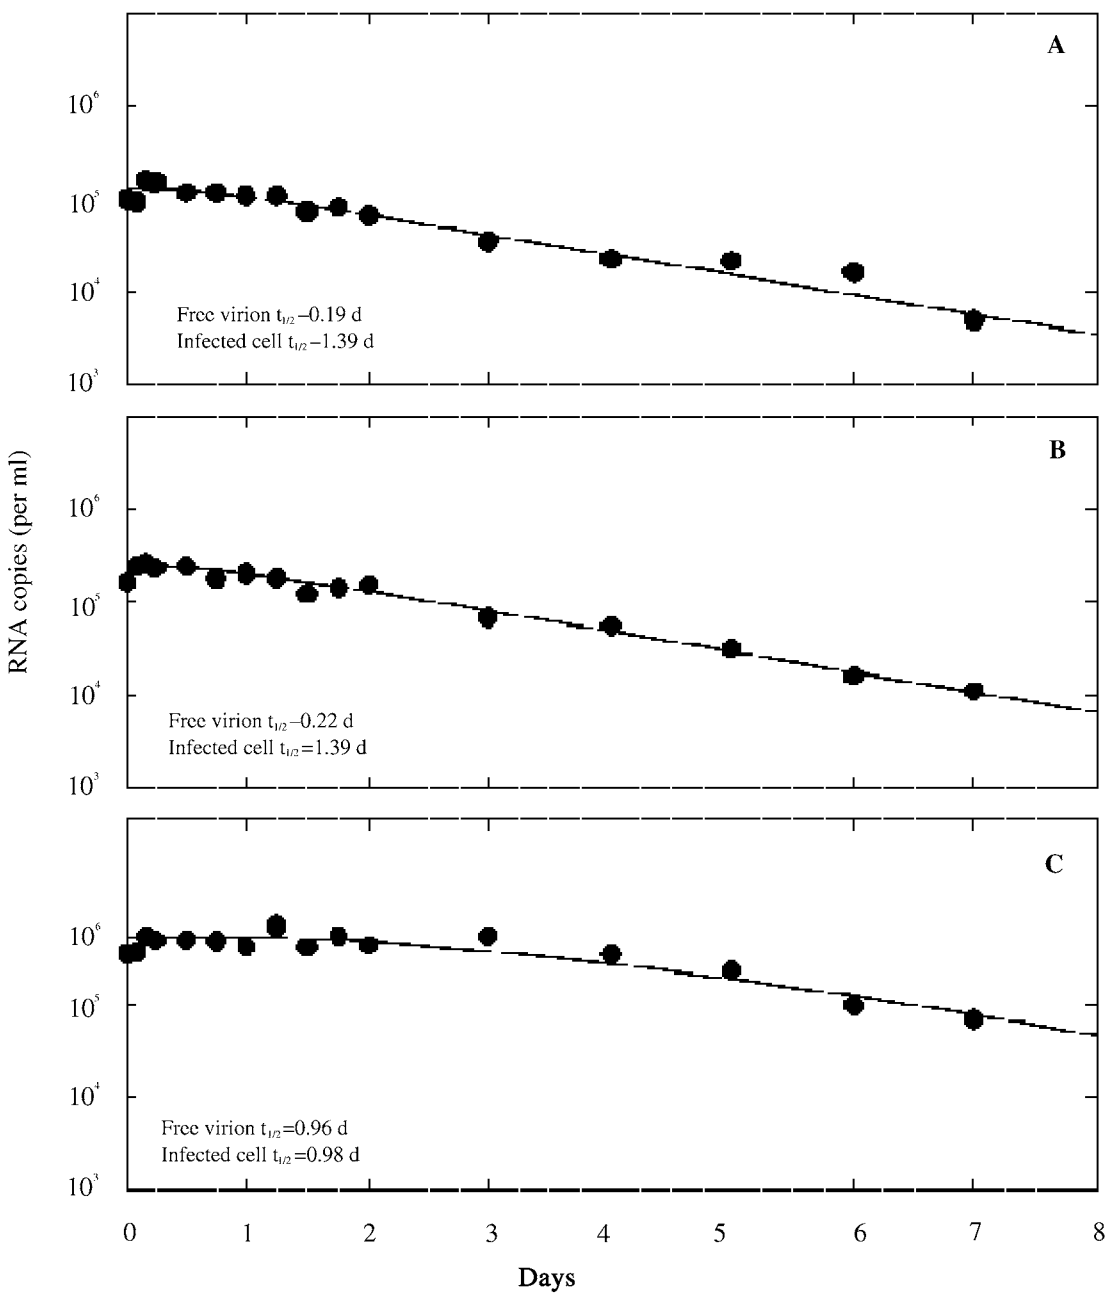

FIG. 35.3. Fit of Eq. (8) to data of HIV-1 treatment, for three individuals (A, B, C), studied in (3). The black dots are the data-points and the solid lines the theoretical ts, from Eq. (8).

could actually correspond to release of virions trapped on follicular dendritic cells (FDC) (17) (Fig. 35.4).

There are large amounts of potentially infectious virions attached to FDC, and these may be released in a biphasic mode, if binding is reversible and multivalent (18). Thus, it is conceivable that these virions are an important source of HIV RNA during drug treatment (19). If this is the case, then the estimates of viral clearance and infected cell death rates would have to be revised upward, because these rates would have to compensate not only for the residual production of virus from infected cells, but also for the release of virus from FDC. Moreover, virus may remain bound to FDC for prolonged periods of time, perhaps decades (18). If they maintain their infectiousness, then they represent a serious obstacle to current therapies, since they could re-seed a productive infection as soon as therapy is stopped.

Finally, detailed measurements of HIV provirus integrated in resting memory CD4+ T-cells indicate that this cell population can constitute an inducible long-lived latent reservoir (20–23). Measurements of the decay of PBMC infectiousness by limiting dilution analysis suggests that this reservoir could lead to a third, even slower, phase of decay of plasma HIV RNA. Analysis of the decay of the latent reservoir in patients treated with potent combination therapy, with models that assume exponential decay of the reservoir, show that the half-life of cells carrying replication competent viral genomes varies between six and 44 months (20–23). Since, it is possible that this latent pool is replenished whenever there is active production of virus, for example due to temporary incomplete suppression of replication by the drug regimen, it is unclear whether the long half-lives in this range represent the true rate of decay of the reservoir or are artificially raised due to reseeding of the reservoir.

EXTENSIONS OF THE BASIC MODEL

Most of the models used to analyze HIV RNA decay do not take into account the immune response mounted against the virus. However, several lines of evidence point to the importance of cytotoxic T lymphocyte (CTL) control of the virus. These include viral evolution and escape under CTL pressure (24), the rise of viremia in CD8+ T-cell depletion studies in macaques (25,26), and the concomitant appearance of a HIV-specific CTL response and the decline of virus in primary infection (27).

It is worth pointing out that models without an immune response can account for the general dynamics of virus during primary infection (28,29). In these models, the viral load increase and subsequent decrease is controlled by the availability of target CD4+ T-cells for the virus to infect and spread (28). However, when data are analyzed over periods longer than 100 days after infection, in some patients the predicted viral set point by the basic model is larger than observed, suggesting an effect of immune control. A way to model immune control by CTL-mediated cytolysis is simply to assume that the death rate of infected cells (δ) in Eq. (2) is not constant (29). For example, Stafford et al. (29) modeled δ as the sum of a constant part, δ_0, and a part, $\delta_1(V)$, that increases with viral (antigen) load, i.e. $\delta = \delta_0 + \delta_1(V)$. The use of models that allowed an immune response provided a better fit to the viral load data obtained from some but not all primary infection patients studied by Stafford et al. (29). Changing the rate of death of productive infected cells is only one of a number of possible implementations of the effect of the immune response. Another possibility is that the antiviral effect of CD8+ T cells is due to secretion of soluble factors that inhibit viral production (30). In this case, it is the production of virus by infected cells, p, in Eq. (3) that

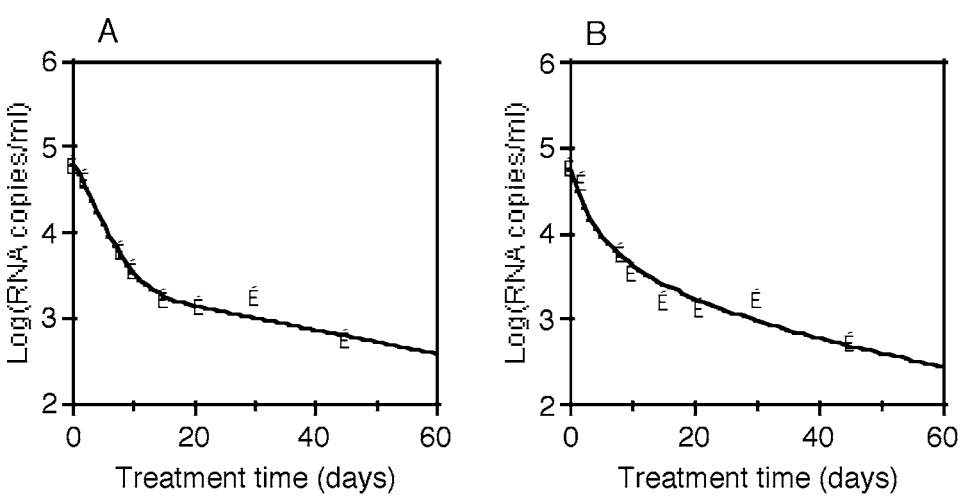

FIG. 35.4. Fit of data from the same patient with two different models. (A) A model assuming a population of long lived infected cells (15), and (B) A model that takes into account the decay of FDC bound virions during treatment (17). The circles are the data-points and the solid lines the theoretical fits. Notice that both models fit the data equally well.

is not constant, but rather decreases as CD8+ T cells increase (1,29).

Models of immune response in HIV infection have also been developed in other contexts. For example, to explain the two phase initial decay of viral load under therapy (31), to explore the cytopathicity of HIV (32), to explain HIV pathology and pathogenesis (33), to study viral evolution and diversification (34), and the role of CD4+ T-cell help in maintaining the immune response (35).

MODELS OF T-LYMPHOCYTE DYNAMICS

An important question in HIV infection has been what is the effect of infection in T-lymphocyte turnover. Several experimental methods have been used to try to look at this question (36–43). For the quantitative interpretation of these experimental results, the use of mathematical models became crucial. Here we will only refer to two methods, which attempt to directly quantify turnover of T-cells. Both involve the incorporation of a label into the DNA of replicating T-cells. In one the label used is bromodeoxyuridine (BrdU), and in the other it is deuterated glucose (D-glucose).

The most informative way to use these labels is in pulse-chase experiments with frequent measurements to assess the kinetics of acquisition and loss of label. For modeling purposes, these methods differ mainly in the way measurements are taken. In the BrdU case, the fraction of labeled cells is measured, whereas in the deuterated glucose case, the fraction of labeled DNA is measured (44). This subtle difference has important implications in the definition of the model. For example, the pool of unlabeled cells is reduced both by proliferation (cell acquires label) and death (cell is removed), when one measures cell labeling with BrdU (45). However, if one uses DNA labeling, then death of a cell will reduce the pool of unlabeled DNA, but proliferation of a cell does not reduce the pool of unlabeled DNA. This is because replication of DNA is accomplished by copying the original unlabeled DNA strand template, which thus is still present in the progeny (46). Thus, when an unlabeled DNA strand, U, is copied, the result is one unlabeled and one labeled, $U+L$ strand (Fig. 35.5). This difference between the two methods is easily seen in the equations used to analyze each of the experiments (see Table 35.1).

In Table 35.1, in the BrdU method, U and L refer to unlabeled and labeled cells; and in the D-glucose method, the same letters refer to unlabeled and labeled DNA, respectively. In these equations, d and p are the death and proliferation rates of lymphocytes, whereas s_U and s_L represent potential sources of unlabeled and labeled material (cells or DNA) into the proliferating pool, where measurements are taken. As can be seen in Table 35.1, the equations to describe D-glucose labeling can be reduced to expressions involving only the death rate d and the sources, whereas in the BrdU expressions both death and proliferation rates are present, in addition to the sources. Thus the D-glucose data can be fitted with a model with fewer parameters. Both models assume that the cell population being labeled is at steady state (T), so that the total number of cells and total amount of DNA is constant. Thus, for each method $U+L=$ constant and the fraction labeled, $f_L(t)$, can be determined from either $U(t)$ or $L(t)$, as shown in Table 35.2. In this table, T_0 represents the total number of cells in the BrdU method, and the total amount of DNA in the case of D-glucose labeling.

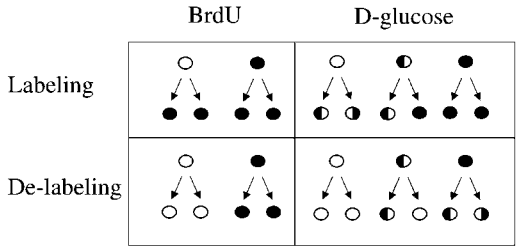

FIG. 35.5. Diagram of the labeling of T-cells under two protocols: BrdU labeling of dividing cells, and D-glucose labeling of the DNA of dividing cells. Labeled cells or both strands of DNA labeled are shown as filled circles, and half-filled circles indicate that only half of the DNA strands are labeled. Notice that in the D-glucose case the amount of unlabeled/labeled DNA remains constant with division during the labeling/de-labeling period, respectively.

The use of these types of models has shown that in untreated HIV infection the average proliferation and death rates are increased threefold or more, and that treatment reduces these rates (40–43). Moreover, this reduction is dependent on the time since the initiation of treatment and after one year of antiretroviral therapy, the values for the proliferation and death rates are nearly equal to those of uninfected subjects (41).

One drawback of these models is that to obtain good agreement with the data one needs to assume a source of unlabeled cells (DNA) into the labeling population. However, the exact nature of this source is not known, and it is indeed controversial (40,41,47). We have built a more realistic model, based on two populations of resting and dividing T-cells, to study this issue (46,47). In this model, resting T-cells can be activated into the dividing pool, and the death and proliferation rates in the activated population are the same. In this way, the model allows for the differentiation between the dynamics of proliferation and

death, and the dynamics of activation. Surprisingly, the same model applied to data on CD4+ and CD8+ T-cells, that look similar leads to very different conclusions. The analysis shows that in the CD8+ T-cells the fraction of activated cells is increased in relation to healthy individuals, even though the proliferation and death rates of activated CD8+ T-cells are the same in infected and uninfected people. On the other hand, in the CD4+ T-cell compartment the proliferation and death rates of activated cells are increased in relation to healthy individuals. Even though these short-term experiments that assume equilibrium cannot explain the long-term dynamics of T-cells in HIV infection, this result helps explain why CD4+ and CD8+ T-cells show different behavior during the course of infection.

CONCLUSIONS

Modeling has become an important tool in the analysis and interpretation of experiments in HIV research. The use of these models has allowed the estimation of important kinetic parameters that allow us to understand the rapidity of HIV infection, to test hypotheses, and to make new predictions. Overall, the use of models has resulted in a signiÞcantly better understanding of viral dynamics, the appearance of drug resistant mutations, and the pathogenesis of infection (49). In the future, collaborations between experimentalists and modelers should lead to new ways to plan, conduct, and analyze experiments.

ACKNOWLEDGMENTS

This work was performed under the auspices of the U.S. Department of Energy and supported by N.I.H. grants RR06555, AI28433, and AI40387. Most of the experiments reported here were done in collaboration with David D. Ho, Martin Markowitz, and Hiroshi Mohri, Aaron Diamond AIDS Research Center, Rockefeller University, NY. Without these experiments and the intellectual collaboration of David Ho this work would never have been done.

Chapter 36

Practical Therapeutics

Stephen C. Piscitelli, Scott R. Penzak and Charles Flexner

Treatment regimens for HIV infection have evolved dramatically over the past 15 years. In 1985, treatment was limited to management of opportunistic infections, prophylactic trimethoprim-sulfamethoxazole, and zidovudine monotherapy. Clinicians now have an arsenal of sixteen antiretroviral drugs to choose from along with a variety of adjunctive and supportive medications. However, increases in therapeutic options have come at the price of regimens that are increasingly complex. Food restrictions, drug interactions, scheduling, adherence and overlapping side effects have become important factors to consider when constructing an antiretroviral regimen. Keeping abreast of this information can be overwhelming for the clinician. This chapter will outline a number of practical considerations in the construction of an antiretroviral regimen.

SCHEDULING

Food Restrictions and Spacing of Medications

Scheduling medication intake around meals remains one of the most common complaints of HIV-infected patients. SpeciÞc food restrictions, whether they be with meals or on an empty stomach, have a large impact on quality of life. Food may dramatically affect the systemic availability of several drugs commonly used in HIV-infected patients. Nonadherence with food restrictions or requirements can lead to suboptimal or excessive plasma concentrations; reduced efÞcacy or increased toxicity may result. Most nucleoside reverse transcriptase inhibitors (NRTIs) can be taken without regard to food. However, didanosine tablets and sachets are formulated with a buffer that requires administration on an empty stomach because a low gastric pH leads to degradation of the drug (1). Although not buffered, didanosine enteric coated capsules also must be given on an empty stomach since administration with food decreases the Cmax and AUC of the drug by 46% and 19%, respectively (2). Bioavailability of the other nucleosides is not signiÞcantly affected by food, although peak absorption may be delayed. For example, a high-fat (3) or high-protein (4) meal slows the rate of absorption of zidovudine and may reduce its maximum concentration; however, the extent of zidovudine absorption is unaltered, making this interaction clinically inconsequential.

Several protease inhibitor regimens are particularly problematic in terms of food effects. When used alone, indinavir must be given on an empty stomach or with a light meal containing less than 2 gm of fat (5). When combined with ritonavir, indinavir can be administered without regard to food (6). Conversely, the bioavailability of both formulations of saquinavir (Invirase¨ and F ortovase¨) is impro ved with high-calorie, high-fat foods, and these drugs must be given within two hours of a full meal. Both Lopinavir-ritonavir (Kaletra¨) and nelÞna vir also require administration with food for optimal absorption. While ritonavir capsule absorption is only somewhat increased in the presence of food, administration with a meal is recommended to decrease its gastrointestinal side effects (7).

In general, food does not markedly affect the systemic availability of non-nucleoside reverse transcriptase inhibitors (8). Neither nevirapine nor delavirdine plasma concentrations are appreciably altered by food. Antacids, however, may impair delavirdine absorption and the two medications should be separated by at least one hour. Efavirenz plasma concentrations are increased approximately 50% (11Ð126%) when administered after a high fat meal (1070 Kcal; 82 g of fat) (9). Because enhanced efavirenz exposure may predispose patients to increased central nervous system side effects, efavirenz should not

TABLE 36.1. *Food-drug interactions with HIV-related medications*

Drug	Food Effect	Recommendation
Atovaquone	High-fat meal may increase bioavailability up to 3-fold	Administer with food
Didanosine (tabs)	Administration with food results in 55% decrease in AUC	Administer on empty stomach at least 30 min before a meal
Didanosine (caps)	Administration with food results in 20–25% decrease in AUC	Administer on empty stomach at least 30 min before a meal
Ganciclovir (caps)	High-fat meal results in 22% increase in AUC	Administer with food
Indinavir	High-fat caloric meal results in 77% decrease in AUC	Administer on empty stomach or with low-fat, light meal
Itraconazole (caps)	Signi cant increase in bioavailability when taken with a full meal	Administer with food
Itraconazole (solution)	Maximal absorption when taken under fasting conditions	Recommended without food if possible
Nel navir	AUC 2- to 3-fold higher when given with food	Administer with meal or light snack
Ritonavir	Food results in 15% increase in AUC	Recommended to be taken with meals
Saquinavir	Marked increase in AUC following high-fat meal	Administer within 2 hr after a full meal
Saquinavir	Grapefruit juice increases AUC by 50–200%	Use caution or avoid coadministration
Efavirenz	High-fat meal results in 50% increase in AUC	Avoid taking after high-fat meals
Amprenavir	High-fat meal results in 21% decrease in AUC	Avoid taking after high-fat meals
Lopinavir-r (caps)	Moderate fat meal results in 48% increase in AUC	Administer with food
Lopinavir-r (solution)	Moderate fat meal results in 80% increase in AUC	Administer with food
Tenofovir DF	Food enhances bioavailability from 27% to 40%	Administer with food

AUC, area under the concentration-time curve.

be taken along withÑ or immediately after, a high fat meal. In summary, a variety of HIV-related medications have speciÞc food restrictions stemming from the possibility of increased or decreased absorption from the gastrointestinal tract; these restrictions are summarized in Table 36.1. A review of food restrictions should be an important part of patient counseling for a new or modiÞed drug regimen.

Certain antiretrovirals cannot be taken concomitantly and require separation. For example, the antacids in didanosine tablets and sachets may decrease the absorption of indinavir and delavirdine (10). Thus, a minimum 30-minute separation is required between didanosine tablets or sachets and indinavir; one hour separation is required for delavirdine. In the case of indinavir and didanosine tablets (or sachets), both agents are generally taken on an empty stomach and the patient may have to wait several hours before a full meal can be eaten. Such regimens are particularly difÞcult for patients to take and may result in nonadherence with the regimen. Didanosine is currently FDA-approved for once-daily dosing, and this schedule may alleviate the problem. The new enteric coated formulation of didanosine does not alter indinavirÕs absorption and can be given concomitantly.

Concentrations of some protease inhibitors in dual combination may differ depending on whether they are given concomitantly or in a staggered fashion. A study in healthy volunteers evaluated single doses of dual combination of protease inhibitors (saquinavir, ritonavir, or nelÞnavir) given either simultaneously or when separated by four hours. The AUC of saquinavir was markedly lower when given four hours before ritonavir or nelÞnavir, as compared to simultaneous dosing. NelÞnavir and ritonavir exposure did not appear to be affected by separation (11). As such, the simultaneous administration of protease inhibitor combinations is currently being exploited to enhance the pharmacokinetic proÞle of one of the coadministered agents (usually the non-ritonavir protease inhibitor).

A number of dual protease inhibitor combinations are being evaluated for once daily dosing (12,13) Such regimens may be particularly useful in selected populations such as prison inmates, patients enrolled in methadone maintenance programs, and those requiring directly observed therapy. Although these regimens would be more convenient, they might also require perfect adherence, since protease inhibitor concentrations at the end of the 24-hour dosing interval may be near the IC50 value for the patientÕs virus. Therefore, a missed dose would result in suboptimal plasma concentrations for a prolonged period, leading to increased risk of recurrent viral replication and drug resistance. Furthermore, because most protease inhibitors exhibit large inter-patient pharmacokinetic variability, a small proportion of patients may

present with inadequate plasma concentrations for durable viral suppression despite optimal adherence (5).

DRUG INTERACTIONS

The management of drug interactions in HIV-infected patients has signiÞcantly changed in the past few years. When protease inhibitors and non-nucleoside reverse transcriptase inhibitors became available, interactions were a concern that had to be addressed.

A number of medications used in HIV-infected patients can produce adverse drug interactions (14). A review of product information for the 16 available antiretrovirals reveals over 200 potential drug interactions (2,9,10, 15Ð27). Some common antiretroviral drug interactions are shown in Table 36.2. Although many of these interactions may be minor in nature, some are potentially serious, leading to severe toxicity or treatment failure. Fortunately, most interactions can be easily recognized, prevented, and corrected. In addition, some of the drugs that caused life-threatening interactions have been removed from the U.S. market. Minor alterations in scheduling or selection of an appropriate alternative are usually all that is required to avoid a potential interaction. On the other hand, some interactions increase the systemic exposure of antiretroviral medications and are therapeutically beneÞcial.

Drug interactions can generally be classiÞed as pharmacokinetic, that is, affecting drug concentrations, or pharmacodynamic, that is, affecting drug activity. Pharmacokinetic interactions involve changes in absorption, distribution, metabolism, or excretion, whereas pharmacodynamic interactions may involve additive, synergistic, or antagonistic effects.

TABLE 36.2. *Clinically signiÞcant drug interactions in HIV-infected patients*

Affected Drug	Interacting Drug(s)	Effect	Recommendations
APV IDV RTV NFV SQV	Rifampin	Protease inhibitor AUC decreased by 70–92%	Avoid concomitant use
NFV IDV RTV NFV SQV LPV/RTV	Phenytoin Carbamazepine	Protease inhibitor concentrations potentially decreased; phenytoin and carbamazepine concentrations potentially increased or decreased	Monitor anticonvulsant levels; consider measurement of protease inhibitor levels
APV IDV SQV LPV/RTV	Nevirapine Efavirenz	Protease inhibitor AUC decreased by 28–62%	Use with ritonavir or increase dose
Methadone	Efavirenz Nevirapine	Methadone concentrations decreased	Monitor for symptoms of opiate withdrawal and adjust dose if necessary
	Ritonavir	Methadone concentrations possibly decreased	Monitor for symptoms of opiate withdrawal and adjust dose if necessary
	Nel navir	Methadone concentrations possibly decreased	Monitor for symptoms of opiate withdrawaland adjust dose if necessary
Rifabutin	APV IDV NFV	Rifabutin AUC increased two to three-fold	Decrease dose to 150 mg/day, increase IDV dose to 1000 mg tid
Atorvastatin	RTV/SQV LPV/RTV	Atorvastatin AUC increased four to ve-fold	Use low dose and increase with caution
Simvastatin	RTV/SQV	Simvastatin AUC increased 32-fold	Avoid concomitant use
Pravastatin	RTV/SQV	Minimal change in pravastatin AUC	No dose adjustment necessary
Sildena l	IDV SQV RTV	Sildena l AUC increased 2 to 11-fold	Use 25 mg dose, with ritonavir do not repeat for 48 hours
MDMA (Ecstasy)	RTV	Potential Increase in MDMA concentrations	Avoid concomitant use
GHB (hydroxy butyrate)	RTV RTV/SQV	Potential increase in GHB concentrations	Avoid concomitant use

AUC, area under the concentration-time curve; APV, amprenavir; IDV, indinavir, NFV, nel navir; RTV, ritonavir, SQV, saquinavir; LPV, lopinavir.

Pharmacokinetic Interactions

Altered Drug Absorption

Impairment of drug absorption can lead to a marked reduction in the bioavailability of certain agents. One of the most common interactions affecting drug absorption is chelation, the binding of drugs to substances in the gastrointestinal tract. The concomitant administration of a ßuoroquinolone antibiotic with a di- or trivalent cation such as calcium, magnesium, aluminum, or iron results in a greater than 90% decrease in the area under the concentration-time curve (AUC) of the ßuoroquinolone, possibly leading to therapeutic failure (28Ð30). Didanosine formulations with a calcium and magnesium buffer (tablets) or citrate-phosphate buffer (sachet) can alter ßuoroquinolone disposition. Concomitant administration of didanosine with ciproßoxacin has been shown to decrease the ciproßoxacin AUC from 15.5 to 0.26 μg/hr/ml (31). A similar interaction would be expected with other products such as antacids, sucralfate, or iron preparations. Administration of these agents should be separated from the ßuoroquinolone by at least two hours, and the ßuoroquinolone should be administered Þrst, followed by the cation, to ensure adequate absorption. The newer enteric coated formulation of didanosine does not alter ciproßoxacin pharmacokinetics and can be given concomitantly (2).

A change in gastric pH may affect the absorption of azole antifungals such as ketoconazole and itraconazole. An acidic environment is required for absorption of ketoconazole; thus its administration should be avoided with concomitant histamine-2 antagonists, proton pump inhibitors, and antacids (32,33). Administration of ketoconazole with sodium bicarbonate and cimetidine resulted in therapeutic failure in a patient with cryptococcal infection (34). If clinically appropriate, ßuconazole may be an acceptable alternative in patients requiring agents that raise gastric pH, or in those with achlorhydria; this is because ßuconazole absorption is not dependent on gastric pH (35). For itraconazole capsules, the presence of food is the most important determinant of drug absorption, while low gastric pH is also beneÞcial. If itraconazole capsules cannot be coadministered with food, an acidic beverage such as Coca-Cola¨ may be given to improve absorption (36). Counterintuitively, acidic citrus juices such as orange juice and grapefruit juice do not enhance the absorption of itraconazole capsules (37,38). The oral solution of itraconazole is best absorbed on an empty stomach (39).

Altered Drug Metabolism

Intestinal Metabolism and P-Glycoprotein

The cytochrome P-450 (CYP) enzyme system consists of at least 12 families of enzymes common to all mammals, and represents the major enzyme system involved in drug metabolism (40). In humans, the CYP1, CYP2, and CYP3 families are primarily responsible for drug metabolism, with the CYP3A subfamily involved in the metabolism of the largest number of drugs including most available protease inhibitors. CYP-mediated metabolism takes place primarily in the liver, although CYP enzymes are also present in other sites including enterocytes in the intestinal wall (40). Thus, inhibitors of CYP3A4 may alter drug absorption or hepatic metabolism. The 20-fold increase in plasma concentrations of saquinavir produced by ritonavir is likely caused by inhibition of CYP3A4 at both sites (41). Grapefruit juice contains various substances that inhibit CYP3A4- mediated metabolism in the gut wall, mainly by selective down regulation of the CYP3A4 protein (40). In quantities normally consumed by the public (< 6 glasses daily), CYP3A4 inhibition by grapefruit juice occurs solely at the intestinal level; larger quantities and highly concentrated preparations of grapefruit juice may also inhibit hepatic CYP3A4 (42). The area under the curve for saquinavir is increased by 1.5 to 2.5-fold during concomitant administration of grapefruit juice (19). Conversely, grapefruit juice does not appreciably alter the pharmacokinetics of indinavir (43,44). As such, grapefruit juice cannot be relied upon to increase the plasma concentrations of protease inhibitors because the amounts of P450 inhibitors in the juice vary widely between brands and are affected by factors such as how much and how often the juice is consumed (42).

P-glycoproteins (P-gp) is the product of the *mdr1* gene Þrst described as a mediator of resistance to cancer chemotherapy. Enterocytes in the intestinal mucosa are a major site for expression of P-gp, one of several membrane-bound proteins that increase efßux of drugs from cells (45). P-gp appears to contribute to the low bioavailability of some drugs, including certain PIs. P-gp in the brush border cells of the intestine can pump drug back into the gastrointestinal lumen, decreasing absorption. In the liver, P-gp pumps drug into bile; it is also present in the blood-brain barrier, where it can limit the uptake of drugs into the central nervous system. Lastly, P-gp is also expressed in hematopoietic progenitor cells, lymphocytes, and macrophages, where it may inßuence intracellular drug exposure and/or immunologic and virologic response to antiretroviral treatment (46).

Several protease inhibitors are substrates for and inhibitors of P-gp. In theory, inhibiting P-gp could be used to increase protease inhibitor concentrations in target sites such as the CNS (47). However, P-gp expression has a profound negative impact on HIV replication. In two separate sets of experiments, cells expressing P-gp produced at least 40- to 70-fold less HIV, than control cells. This was thought to be primarily due to inhibition of HIV entry and/or membrane fusion (48,49). Recently, patients with low P-gp expression (TT genotype) were found to have a greater rise in CD4+ cells compared to patients with high P-gp expression (CC genotype) six months after

beginning antiretroviral treatment; this occurred despite lower plasma antiretroviral concentrations among patients with the TT genotype (50). The clinical implications of these Þndings highlight a dilemma regarding how (or whether) P-gp should be altered in HIV-infected patients, particularly since the inßuence of P-gp expression on drug exposure, HIV replication, immune recovery, and the interrelationship between these factors, is not fully understood.

In the intestine and liver, cytochrome P450 enzymes and P-glycoprotein can present a barrier to oral drug absorption and contribute to interactions between medications. The overlap of tissue distribution and substrate speciÞcity of CYP3A4 and P-glycoprotein complicates deÞnition of the speciÞc mechanisms of some drug interactions. Many drugs that are modulators of P-glycoprotein are also inhibitors of CYP3A4 (51). The effect of these two pathways on antiretroviral drug concentrations remains a fertile area for additional research.

Enzyme Induction

CYP enzyme inducers increase the rate of hepatic metabolism, usually through increased transcription of mRNA, and decrease serum concentrations of other drugs metabolized by the same hepatic isoenzyme. Rifampin and rifabutin are classic examples of enzyme inducers that decrease plasma concentrations of coadministered CYP substrates. Both drugs can decrease concentrations of protease inhibitors. The Centers for Disease Control and Prevention have issued guidelines for concomitant use of rifampin or rifabutin with HIV protease inhibitors in patients with tuberculosis (52). Rifampin should be avoided with all single protease inhibitors but may be used with caution in patients receiving saquinavir plus ritonavir (52). Patients receiving indinavir or nelÞnavir should receive a reduced dose of rifabutin and a slightly increased PI dose (52,53). With regard to non-nucleoside reverse transcriptase inhibitors, rifampin should be avoided in patients receiving nevirapine and delavirdine (52). Rifampin may, however, be coadministered with efavirenz although some clinicians advocate giving a higher efavirenz dose in patients receiving this combination (52,54). Rifabutin may be taken along with nevirapine without dosage adjustment of either agent; however, its use with delavirdine is not recommended. Higher rifabutin doses are necessary when the drug is given concurrently with efavirenz, however efavirenz dose-adjustment is unnecessary (9,52,54).

Nevirapine is a mild to moderate hepatic enzyme inducer, and decreases the AUC of saquinavir and indinavir by 27% and 28%, respectively, but has a minimal effect on ritonavir and nelÞnavir (55,56). It is currently recommended that the indinavir dose be increased to 1,000 mg q8h with nevirapine, although clinical studies have not veriÞed the effect of this combination on surrogate markers or clinical endpoints. Efavirenz is a mixed inducer/inhibitor that decreases concentrations of amprenavir, saquinavir, and indinavir, necessitating increased doses of these drugs or the addition of ritonavir (57).

Ritonavir and nelÞnavir are also moderate enzyme inducers, and can increase hepatic glucuronidation as well as CYP activity. The AUC of the oral contraceptive ethinyl estradiol is decreased by approximately 40% with these agents (and also with the lopinavir-ritonavir combination product (Kaletra¨)), necessitating an alternative form of birth control (25,58). Ritonavir is also an inducer of CYP1A2 which is involved in the metabolism of theophylline and the antipsychotic medications clozapine and olanzapine (59,60). Concomitant administration of ritonavir was noted to reduce theophylline and olanzapine AUCs by 43% and 53%, respectively (59,60). Patients receiving these drugs in combination with ritonavir should be warned to watch for symptoms of reduced therapeutic effects with theophylline and olanzapine; theophylline levels should be monitored.

Enzyme Inhibition

There are a number of inhibitors of CYP that decrease the rate of hepatic metabolism and increase plasma concentrations of other drugs metabolized by the same isoenzyme. HIV protease inhibitors can be both CYP inhibitors and substrates, increasing concentrations of some metabolized drugs and having their own concentrations increased by other CYP inhibitors. Most of the currently available protease inhibitors are primarily metabolized by CYP3A4 (5). These agents differ in the number and magnitude of potential drug interactions. Ritonavir is associated with the greatest number of drug interactions, while saquinavir is the weakest enzyme inhibitor and, has less propensity to alter concentrations of other drugs. In general, the combination of lopinavir and ritonavir has a similar drug interaction proÞle to that of ritonavir (25). Amprenavir, nelÞnavir, and indinavir inhibit CYP3A4 metabolism to a lesser extent than ritonavir. For example, all three drugs increase the rifabutin AUC approximately two-fold, necessitating a 50% reduction in the rifabutin dose (14). Ritonavir increases the rifabutin AUC by four-fold, necessitating a marked reduction in the rifabutin dose when these agents are coadministered (61,62). Nonetheless, although dosage adjustments are necessary, rifabutin can usually be safely coadministered with protease inhibitors in patients requiring the drug for anti-tuberculosis therapy.

In patients in whom MAC prophylaxis is required, clarithromycin or azithromycin are commonly prescribed. The clarithromycin AUC is increased 77% with ritonavir and 53% with indinavir, although a dosage adjustment is unnecessary in patients with normal renal function (63). Azithromycin is primarily excreted by the biliary route and does not interact with inhibitors of CYP (64).

Deleterious Drug Interactions

Historically, the most serious potential interactions with CYP inhibitors involved concomitant administration with certain metabolized drugs such as terfenadine and cisapride, antiarrhythmics, and ergot alkaloids. Terfenadine and cisapride have been removed from the U.S. market and a number of non-sedating antihistamines without drug interaction potential are now available. In the case of cisapride and terfenadine, these combinations led to cardiotoxicity, with the potential for life-threatening arrhythmias (65). Administration of protease inhibitors with some benzodiazepine sedative-hypnotics can result in exaggerated side effects such as oversedation, but serious adverse effects such as respiratory depression are unlikely.

BeneÞcial Drug Interactions

Drug interactions were initially viewed as a complication to be avoided in HIV-infected patients. The concept of using two protease inhibitors concomitantly to increase plasma concentrations or improve convenience was Þrst recognized with the combination of saquinavir and ritonavir. Simultaneous administration of two protease inhibitors takes advantage of beneÞcial pharmacokinetic interactions, and may circumvent many of the drugsÕ undesirable pharmacologic properties (6). In addition, dual protease inhibitors decrease inter-patient variability, making drug concentrations more predictable. Dual protease inhibitor regimens have now been widely prescribed and are included in published treatment guidelines despite not being FDA approved. A number of potentially beneÞcial metabolic drug interactions exist for combinations of two HIV protease inhibitors. One drug is used to inhibit the metabolism of the second agent, producing increased bioavailability, decreased clearance, or both. Two-way interactions also exist, in which the pharmacokinetic proÞle of each drug is enhanced.

Ritonavir-Saquinavir

Administered as a single protease inhibitor, saquinavir possesses a number of disadvantages including poor bioavailability, three times daily dosing, and a pill burden of 18 capsules per day. However, when combined with even small doses of ritonavir, there is a marked increase in saquinavir bioavailability and a decrease in clearance, allowing twice daily dosing and a decreased dose from 1800 mg T.I.D. to 400 mg B.I.D. In a single-dose, crossover study in healthy volunteers, ritonavir increased the saquinavir AUC by 50- to 132-fold, and increased the saquinavir Cmax by 23- to 35-fold (66). Since ritonavir is a P450 inducer and undergoes autoinduction during the Þrst 10Ð14 days of therapy (67), steady-state concentrations of saquinavir should be lower when these two drugs are combined. Indeed, multiple-dose pharmacokinetic interaction studies found that the steady-state saquinavir AUC was increased only 20- to 30-fold (68). Nonetheless, this increase in saquinavir exposure remains sufÞcient to be pharmacologically beneÞcial.

The effect of ritonavir dose on saquinavir plasma levels was evaluated in 120 patients receiving various saquinavir/ritonavir combinations (69). Data from two dose-ranging trials of saquinavir/ritonavir given either twice daily or once daily were included in the analysis. A wide range of saquinavir doses (400Ð1,800 mg) and ritonavir doses (100Ð400 mg) were evaluated. The investigators used multivariate linear and nonlinear regression to correlate steady-state saquinavir pharmacokinetic parameters (Cmin, Cmax, and half-life) with saquinavir and ritonavir doses. This model showed a strong effect of ritonavir on saquinavir Cmax and Cmin; however, these parameters were correlated only with saquinavir dosage, and the increase in saquinavir concentrations was similar for ritonavir dosages over the range of 100Ð400 mg twice daily. In this analysis there was not a dose-dependent effect of ritonavir on saquinavir concentrations.

The poor oral bioavailability of saquinavir (1Ð12%, depending on formulation and conditions) likely reßects extensive Þrst-pass metabolism rather than poor absorption. The increase in saquinavir concentrations with ritonavir is the result of improved bioavailability, perhaps to as much as 100%, with little effect on post-absorptive systemic clearance. The large magnitude of ritonavirÕs effect on the oral bioavailability of saquinavir may be accounted for by ritonavirÕs dual inhibitory effects on intestinal CYP3A4 and P-gp, which are involved in the presystemic metabolism and transport of saquinavir, respectively (70).

Although the doses of 400 mg ritonavir/400 mg saquinavir twice daily have been commonly used for a number of years, additional dosing regimens are under evaluation that employ a lower dose of ritonavir to improve tolerability and reduce effects on plasma lipids. One single-dose study in healthy volunteers found that combining 200 mg of ritonavir with 600 mg saquinavir increased the saquinavir AUC by an average of 74-fold, an effect similar to that seen with 400 mg ritonavir plus 400 mg saquinavir (66). Clinically, doses of 1000 mg saquinavir/ 100 mg ritonavir B.I.D. are being evaluated as well as 1600 mg saquinavir/100 mg ritonavir administered once daily (12,13).

RitonavirÑIndinavir

When used as a sole protease inhibitor, indinavir possesses a number of limitations including an every-eight-hour dosing regimen, food restrictions, hydration requirements, and large inter-individual pharmacokinetic variability (5). The combination of indinavir, even with small doses of ritonavir, alleviates many of these disadvantages.

In a steady-state pharmacokinetic interaction study in healthy volunteers involving 14 days of ritonavir treatment, the combination of 200 or 400 mg ritonavir with 400 or 600 mg indinavir increased the indinavir AUC by three- to six-fold compared to indinavir 800 mg alone (71). This mechanism primarily involves inhibition of hepatic CYP 3A4 with reduced Þrst-pass metabolism making a minor contribution. Ritonavir increased the indinavir Cmax up to two-fold, and increased the indinavir concentration eight hours after dosing by 11- to 33-fold (71). Decreased ritonavir dose and increased indinavir dose were examined in a separate study. In healthy volunteers administered ritonavir for 14 days, the 24-hour indinavir AUC with a 100 mg B.I.D. ritonavir/800 mg B.I.D. indinavir regimen was four-fold higher than with 800 mg q8h indinavir alone. In the same study, the 24-hour AUC of indinavir with a 400/400 B.I.D. ritonavir-indinavir regimen was 40% lower than with the 100/800 regimen and 55% lower than with a 200/800 regimen (72). However, the mean 12-hour trough concentrations of the 400/400 regimen and the 100/800 regimen were nearly the same.

In two studies, co-administration of ritonavir and indinavir abolished the effect of food on indinavir bioavailability. A high-fat meal reduced the bioavailability of oral indinavir by up to 85% (72). Doses of 100, 200, or 400 mg of ritonavir B.I.D. reversed the effect of a high- or low-fat meal on indinavir pharmacokinetics, as compared to 800 mg indinavir given in the fasted state (72). In theory, ritonavir could enhance indinavir oral bioavailability in the presence of food through inhibition of intestinal cytochrome P450 or drug transporters such as P-glycoprotein. However, the respective roles of P-gp and intestinal CYP3A4 in limiting the oral availability of indinavir appear to be minimal (73), suggesting that inhibition if these enterocyte proteins by ritonavir does not signiÞcantly alter the Þrst-pass metabolism of indinavir (6).

There is some concern that the high peak concentrations achieved with indinavirÐritonavir combinations may lead to an increased risk of nephrolithiasis. In patients taking indinavir 800 mg q8h, a higher AUC and Cmax were associated with increased risk of IDV nephrotoxicity in one study (74). Increasing indinavir Cmax and Cmin were associated with an increase in nephrolithiasis in patients taking indinavir/ritonavir B.I.D. combinations of 400/100, 400/400, 600/100, or 800/100 mg; these regimens were associated with short-term nephrotoxicity risks of 0, 2, 6, or 10%, respectively (75). In 17 Thai patients receiving indinavir 800 mg plus ritonavir 100 mg every 12 hours, a 12-hour indinavir AUC > 60 mg*hr/L and Cmax > 13 mg/L were associated with nephrotoxicity (76). Indinavir/ritonavir regimens of 400/400 mg B.I.D. were not associated with an increased incidence of nephrolithiasis compared to indinavir 800 mg q8h without ritonavir, although tolerability may be an issue with the higher ritonavir dose (77). Of note, one study found that indinavir Cmax > 7 mg/L was associated with increased CD4+ cell response, perhaps due to inhibition of CD4+ cell apoptosis with higher indinavir Cmax; further study is warranted to conÞrm this theory (78).

The inßuence of efavirenz on indinavir disposition was analyzed under steady-state conditions in 18 healthy male volunteers receiving indinavir 800 mg plus ritonavir 100 mg twice daily (79). Efavirenz co-administration resulted in a 19% reduction in the indinavir AUC and a 48% reduction in Cmin. Based on these results, ritonavir should be administered at doses 200 mg twice daily when used in combination with indinavir and efavirenz; this is particularly true in treatment-experienced patients who no longer harbor wild-type HIV virus.

LopinavirÐRitonavir

Lopinavir-ritonavir (Kaletra¨) represents the Þrst use of ritonavir in a co-formulated product to increase concentrations of a second protease inhibitor. Each dose of Kaletra¨ contains 400 mg of lopinavir along with 100 mg of ritonavir (133/33 mg capsules × 3 caps) which is given twice daily. Lopinavir is a highly active protease inhibitor but its bioavailability is low and its clearance rapid when given alone. However, in combination with low doses of ritonavir, lopinavirÕs AUC is increased by greater than 100-fold (80) due to inhibition of the drugÕs CYP3A4-mediated metabolism in the liver and gastrointestinal tract. RitonavirÕs effect on the lopinavir AUC was several-fold greater than ritonavirÕs effect on the saquinavir AUC (6).

This beneÞcial pharmacokinetic interaction was conÞrmed in human volunteers; when dosed at 12-hour intervals (q12h) with ritonavir, mean trough concentrations of lopinavir were approximately 30-fold higher than the *in vitro* IC50 for HIV (81). In 101 HIV-infected patients taking lopinavir 200 or 400 mg B.I.D. with ritonavir 100 or 200 mg B.I.D. plus two nucleoside analogs for 48 weeks, HIV viral load was suppressed to < 400 copies/mL in 93Ð100% of patients and to < 50 copies/mL in 83Ð86% (82).

The addition of efavirenz to lopinavirÐritonavir results in a decrease of 40% in the lopinavir AUC (83). Although concentrations are still relatively high despite this reduction, the manufacturer suggests the dose be increased to 533/133 (four capsules) mg B.I.D. when combined with efavirenz or nevirapine in order to offset the enzyme induction effects of the NNRTIs, especially if the patient is treatment-experienced and resistance is suspected (25).

AmprenavirÐRitonavir

Amprenavir is a twice daily protease inhibitor but has the disadvantage of an oral formulation requiring 16 capsules per day. The combination of amprenavir with varying ritonavir doses has been evaluated in a number of pharmacokinetic studies in patients and healthy volunteers. Administration of amprenavir with low-dose

ritonavir increases the amprenavir AUC two- to three-fold and increases the trough concentration by approximately 5-fold (84). In one study, patients received amprenavir 1200 mg B.I.D. with either 200 mg or 500 mg B.I.D. of ritonavir. The patients receiving the higher ritonavir dose did not achieve higher amprenavir concentrations (84). Thus increasing the ritonavir above 200 mg likely will only be associated with more adverse effects and will not provide higher plasma concentrations.

A number of amprenavirÐritonavir regimens have been proposed based on pharmacokinetic studies in volunteers and simulation of plasma concentrations (85). Although clinical data are lacking, many clinicians employ a 600/100 mg amprenavir/ritonavir B.I.D. regimen, although the amprenavir dose may need to be increased in treatment-experienced patients with suspected resistance. However, in patients also receiving nevirapine or efavirenz, 100 mg B.I.D. of ritonavir does not appear to prevent a decrease in amprenavir concentrations from the enzyme inducing properties of these NNRTIs. In a small study, patients receiving 450 mg of amprenavir with 200 mg B.I.D. of ritonavir were switched to a 600 /100 mg regimen and amprenavir trough values were decreased by 80% (86). A separate study demonstrated no decrease in amprenavir Cmin when efavirenz was added to an amprenavir/ritonavir regimen containing 200 mg B.I.D. of ritonavir (84). Thus, there appears to be a threshold dose of at least 200 mg of ritonavir that is required to prevent NNRTI-induced drug interactions.

Once daily dosing regimens of 1200 mg amprenavir/ 200 mg ritonavir have been recently evaluated in HIV-infected patients. At the end of a 24-hour dosing interval, amprenavir concentrations were approximately 3-fold higher with this regimen than with amprenavir1200 mg B.I.D. alone (87).

RitonavirÐNelÞnavir

Originally marketed as a T.I.D. regimen, nelÞnavir was studied in combination with ritonavir to reduce its dosing frequency, and the potential for once-a-day dosing. While ritonavir does increase nelÞnavir concentrations modestly, this combination is generally not widely used because of poor tolerability. Dose limiting diarrhea or gastrointestinal adverse effects make this regimen less attractive than other dual protease inhibitor combinations.

A single-dose drug interaction study in healthy volunteers showed that ritonavir increased the nelÞnavir AUC by 152%, while nelÞnavir increased ritonavirÕs AUC by only 9% (22). A steady-state pharmacokinetic interaction study in HIV-infected volunteers evaluated the combination of 400 mg ritonavir B.I.D. with 500 or 750 mg nelÞnavir B.I.D. After Þve weeks of dosing, ritonavir use was associated with a 162% increase in the 500 mg nelÞnavir 24-hour AUC (dose-normalized), and a 62% increase in the 750 mg AUC, as compared to historical controls taking only nelÞnavir 750 mg T.I.D. (88). At the same time, the change in ritonavirÕs dose-normalized 24-hour AUC was +13% with nelÞnavir 500 mg, and Ð13% with the 750 mg regimen.

This pharmacokinetic interaction is more complicated than others, because both drugs are CYP450 inducers as well as inhibitors (6). The fact that nelÞnavirÕs AUC did not increase signiÞcantly when the dose was increased from 500 to 750 mg B.I.D. may reßect increased induction with the higher nelÞnavir dose. In addition, there was a trend for nelÞnavir to reduce ritonavirÕs trough concentrations at the higher 750 mg nelÞnavir dose (88). This may have decreased the magnitude of ritonavirÕs beneÞcial impact on nelÞnavir pharmacokinetics.

NelÞnavir is the only HIV protease inhibitor known to produce an active metabolite, the hydroxy-butylamide M8 (AG1402), which is the major metabolite of nelÞnavir in humans and has equipotent anti-HIV activity *in vitro* (89). Ritonavir had a more signiÞcant beneÞcial impact on the pharmacokinetics of M8 than on nelÞnavir itself. After Þve weeks of dosing, ritonavir use was associated with a 430% increase in the 500 mg M8 24-hour AUC, and a 370% increase in the 750 mg M8 AUC, as compared to historical controls taking nelÞnavir 750 mg T.I.D. alone (6). This is likely due to impaired CYP-mediated metabolism of M8 by ritonavir, as opposed to increased production of the metabolite.

A recent study evaluated the effect of low-dose ritonavir (100 or 200 mg B.I.D.) on nelÞnavir pharmacokinetics in healthy volunteers (90). Overall, the AUC of nelÞnavir was increased by approximately 30% in both ritonavir dosing groups. The morning steady-state pre-dose concentrations of nelÞnavir were increased substantially in a dose-dependent fashion with a 45% and 90% increase in the 100-mg and 200-mg arms, respectively. The half-life of nelÞnavir was not altered by ritonavir, and the active nelÞnavir M8 metabolite was increased by approximately 75% for Cmax and 90% for AUC. The magnitude of the M8 increase was similar for both ritonavir doses (90).

NelÞnavirÐSaquinavir

In single-dose pharmacokinetic interaction studies, nelÞnavir increased the saquinavir AUC by up to Þve-fold, with no effect of saquinavir on nelÞnavir concentrations (5). However, nelÞnavir is an inducer of CYP450 3A, and at steady-state the magnitude of this interaction was substantially reduced. Combining nelÞnavir 750 mg T.I.D. with 800 mg T.I.D. of the soft-gel formulation of saquinavir produced a saquinavir AUC equivalent to 1200 mg T.I.D. at steady-state (91). This combination was well-tolerated and was highly active against HIV in patients who were also taking two nucleoside analogs (92). However, this combination lacks many of the pharmacologic and clinical beneÞts of other dual protease inhibitor combinations. With a trend to convert all protease inhibitor

regimens to B.I.D., the T.I.D. dosing regimens of nelfinavir and saquinavir appear to be less relevant to clinical practice.

Nelfinavir–Indinavir

Combining nelfinavir with indinavir produced a 50% increase in the indinavir AUC and an 80% increase in the nelfinavir AUC in single-dose studies in healthy volunteers (5). However, when these two drugs were administered to patients in a B.I.D. steady-state regimen, there was little pharmacokinetic enhancement and a disappointing anti-HIV effect, with only 10 of 21 patients suppressing their plasma HIV RNA to <400 copies/mL (the lower limit of quantification) after 32 weeks (93). Presumably hepatic enzyme induction by nelfinavir resulted in reduced concentrations of both drugs, and no real pharmacokinetic benefits.

Indinavir–Saquinavir

This combination was reported to be antagonistic when used to inhibit HIV replication *in vitro* (94). While the clinical relevance of this finding is unknown, this combination has not been pursued further *in vivo*, even though indinavir increased saquinavir concentrations by five-fold in single dose studies (5).

Lopinavir/Ritonavir–Other Protease Inhibitors

Drug interaction studies between lopinavir-ritonavir and other protease inhibitors have generally been conducted in healthy volunteers under non-steady-state conditions (25). Because of these limitations in study design, it is not possible to make definitive dosing recommendations for lopinavir–ritonavir in combination with other protease inhibitors. Nonetheless, based on the data that is available, the Kaletra® manufacturer recommends reduced doses of indinavir, saquinavir, and amprenavir when these drugs are coadministered with lopinavir–ritonavir (400 mg/100 mg twice daily) (25). Recent data suggest that plasma concentrations of both amprenavir and lopinavir may be reduced when they are coadministered; however, limitations in study design mandate that these results be confirmed before they are widely accepted (95).

Other Antiretroviral Combinations

Another strategy for increasing concentrations of protease inhibitors through enzyme inhibition includes administration of the CYP3A4 inhibitor delavirdine. Delavirdine significantly increased the AUC of saquinavir by 520%, indinavir by 72%, and nelfinavir by 92% (96,97). Other CYP3A4 inhibitors evaluated for their ability to increase plasma protease inhibitor concentrations include ketoconazole, itraconazole, and erythromycin. Despite encouraging data in healthy subjects, ketoconazole and erythromycin increased saquinavir concentrations only modestly (69% and 99%, respectively) in patients with HIV infection (98). In a separate study in HIV-infected patients, saquinavir concentrations were not appreciably altered by concurrent itraconazole administration (99).

Interactions with Herbal Therapies

Herbal remedies and nutritional supplements are widely used in HIV-infected patients although little attention has been paid to the pharmacokinetic effects of these compounds since they are considered benign. An increasing number of studies have shown that certain alternative therapies may cause drug interactions with agents used in the treatment of HIV infection. In healthy volunteers, St. John's wort decreased the AUC of indinavir by over 50% (100). In a case series of five HIV-infected patients, St. John's wort appeared to increase nevirapine clearance by 35% (101). The mechanism of these interactions is complex and appears to be mediated by both induction of CYP3A4 and P-glycoprotein (102,103). This herb should be avoided in patients taking protease inhibitors and non-nucleoside reverse transcriptase inhibitors, although there currently are no data on whether ritonavir can reverse this interaction.

Garlic supplements are sometimes used by HIV-infected patients because of their touted effects on lowering cholesterol. Raw garlic and garlic supplements inhibit the activity of CYP3A4 in vitro and in animals, and case reports have documented ritonavir-related gastrointestinal toxicity in two people after they ingested uncooked garlic preparations with ritonavir (104). However, a study in healthy volunteers showed that garlic capsules taken B.I.D. for three weeks led to a mean decrease in saquinavir concentrations of approximately 50% probably as a consequence of reduced bioavailibility (105). Even after a 10-day washout period, AUC values returned to only 60–70% of baseline suggesting a prolonged effect. In contrast to the findings with garlic and St. John's wort, silymarin, (milk thistle) did not significantly alter the pharmacokinetics of indinavir in healthy volunteers (106). Other herbs with reported in vitro effects on CYP450-mediated metabolism include ginseng and skullcap although clinical data are lacking (107). Clinicians need to include alternative medicines in their drug histories and consider them when adverse effects or treatment failure appear with no other cause.

Drug-Cytokine Interactions

The effect of cytokines on antiretroviral drug concentrations has received recent attention with the advent of immune-based therapies for HIV infection. Cytokines may

be either synthesized recombinantly and administered as therapy or they may be produced *in vivo*. Pro-inßammatory cytokines including interleukin (IL)Ð6, IL-1, and tumor necrosis factor (TNF)Ðα are released during periods of stress, trauma, or infection. A number of in vitro and clinical studies have shown that IL-6 and TNF-α inhibit cytochrome P450-mediated metabolism. This mechanism is not competitive but is a metabolic interaction at the level of transcription of cytochrome P450 messenger RNA (108).

Several immunodulating agents are being evaluated for the treatment of HIV-infection. One of the best studied is IL-2. Its exogenous administration has been shown to increase CD4 cells, but results in a profound release of pro-inßammatory cytokines that are one likely cause of its problematic side effect proÞle. In HIV-infected patients receiving a Þve-day continuous infusion of IL-2, indinavir clearance signiÞcantly decreased and the area under the curve increased 88% as compared with baseline values before IL-2 adminsitration (109). The short term administration (Þve days) of IL-2 makes this interaction less clinically signiÞcant, although drug-cytokine interactions should be considered as additional investigational agents are used in a more chronic fashion; this rings particularly true since recent data suggest that, in addition to CYP3A4, IL-2 may also down-regulate CYP1A2, CYP2C, and CYP2E1, increasing the likelihood of drug interactions with this cytokine (110).

Altered Excretion

Drug interactions may also be caused by alterations in renal elimination, although in general these interactions are not often clinically signiÞcant for antiretrovirals. This can be a consequence of either inhibition of tubular secretion or impairment of renal function. Probenecid and trimethoprim are inhibitors of renal tubular secretion, which may increase concentrations of some renally cleared drugs. The lamivudine AUC is increased by 44% with concomitant trimethoprim-sulfamethoxazole (111). The acyclovir AUC is increased 40% with concomitant probenecid (112). Recently, the AUC of didanosine, administered in tablet form, was found to be increased by 44% with concurrent administration of the nucleotide reverse transcriptase inhibitor, tenofovir (113). Although the mechanism of this interaction is unknown, it is hypothesized to result from impaired renal excretion of didanosine by tenofovir. Inhibition of renal secretion may be a useful strategy to increase plasma concentrations of antimicrobials such as acyclovir, to increase the likelihood of a successful response or to offset poor oral absorption.

Intracellular Interactions

The nucleoside reverse transcriptase inhibitors are prodrugs that must undergo phosphorylation intracellularly to their active forms. While these drugs are not generally affected by CYP450 interactions, there may be competition for intracellular activation pathways that result in clinically relevant drug interactions. Ribavirin decreases the phosphorylation of zidovudine and stavudine in vitro, resulting in decreased concentrations of the active compound (114,115). AIDS patients with hepatitis C may be treated with Rebetron¨ , a ribavirin-interferon combination formulation that may result in decreased efÞcacy of zidovudine. Similarly, zidovudine may impair the intracellular phosphorylation of stavudine (115), and this combination is associated with unfavorable clinical outcomes as compared with other regimens containing two nucleoside reverse transcriptase inhibitors (116). Lamivudine inhibits zalcitabine phosphorylation and this combination should be avoided (117).

Penetration of HIV protease inhibitors into CD4+ cells and macrophages may be regulated in-part by P-gp. As such, compounds that inhibit P-gp may modulate intracellular protease inhibitor concentrations and enhance their antiretroviral activity. Ritonavir, a potent P-gp inhibitor, was recently shown to signiÞcantly raise intracellular amprenavir concentrations above those achieved when amprenavir was administered by itself (118). Whether higher intracellular protease inhibitor concentrations are associated with improved virologic and/or immunologic response is unknown and requires further study.

Recognizing and Circumventing Drug Interactions

Strategies for recognizing and avoiding drug interactions are shown in Table 36.3. A careful review of the patientÕs medication proÞle is essential to monitor for drug interactions. Patients should be asked to disclose all their medications, because they may often seek treatment from more than one health care provider. In addition, a medication history should include both prescription and nonprescription drugs, as well as any herbal, investigational, or alternative therapies. Clinicians should be

TABLE 36.3. *Strategies for recognition and avoidance of drug interactions*

Thorough review of patient medication pro les
Include over-the-counter, herbal therapies, investigational drugs, alternative medications
Counsel patients to discuss with clinician before starting new prescriptions
Recognition of “red ag” drugs with high interaction potential
Protease inhibitors, azole antifungals, NNRTIs, rifampin, etc.
Recognition of drugs with overlapping toxicities
Selection of alternative regimen if possible
Use of supportive medications for treatment of toxicity
Proper staggering and scheduling of medications
Counseling of dietary restrictions with certain medications
Selection of agents with fewer drug interactions if clinically appropriate

familiar with those agents most commonly associated with drug interactions. Any patient receiving Ò red ßagÓ drugs such as rifampin, ritonavir, or ketoconazole requires extra attention, and patients should be given a list of drugs that should not be administered concomitantly.

Finally, drug interactions can be avoided by simplifying drug regimens whenever possible. Selection of a therapeutically equivalent agent with fewer drug interactions may be wise. Azithromycin could be substituted for erythromycin or clarithromycin if appropriate for the clinical situation. Similarly, it may be advantageous to replace ritonavir with another protease inhibitor for patients requiring medications with the potential for serious interactions. Care provider and patient need to work together to develop a tolerable regimen that meets therapeutic goals.

OVERLAPPING SIDE EFFECTS

Many of the drugs used in the HIV-infected patient share similar toxicity proÞles. Some common examples are shown in Table 36.4. Although it would be ideal to prescribe drugs with non-overlapping adverse effects, the limited choices for antiretroviral therapy and opportunistic infection treatment often preclude this. In the nucleoside analog class, stavudine, didanosine, and zalcitabine are all associated with the development of peripheral neuropathy. However, a clinical study examining the combination of stavudine and didanosine showed that only two patients developed peripheral neuropathy after one year of therapy (119). Regardless, patients receiving these drugs should be counseled on the signs and symptoms of peripheral neuropathy. Other examples include a ßu-like syndrome with some recombinant cytokines (interferon, interleukin-2) or pancreatitis with didanosine and pentamidine. When the use of these combinations is unavoidable, reduced dosages or supportive medications (i.e. antidiarrheals, antiemetics) should be considered to lessen certain adverse effects.

A common dilemma is trying to identify which drug is actually causing an adverse effect. For example, ritonavir, zidovudine, and didanosine are all associated with nausea and other gastrointestinal side effects. One strategy would involve stopping all medications until the side effects resolve and adding drugs back sequentially as tolerated. Note that this strategy may be unwise for patients taking combination antiretroviral therapy. Alternatively, single drugs could be removed and/or substituted in the regimen to see if the gastrointestinal symptoms resolve. This situation may be more difÞcult in the case of neutropenia, in which the adverse effect could be caused either by medications (Table 36.4) or by disease processes such as *M. avium* infection. For particularly toxic combinations such as zidovudine and ganciclovir, supportive care with granulocyte colony-stimulating factor may be a useful adjunctive therapy to allow continuation of the regimen. Another common adverse effect that crosses multiple drugs and classes is rash. The clinician again must consider treating through the rash or guessing which agent is causing the problem and discontinuing the proposed offending agent. As some rashes can be serious in nature, this involves close monitoring of the patient.

TABLE 36.4. *Common examples of overlapping toxicities of HIV-related medications*

Rash
Abacavir
Amprenavir
Delavirdine
Efavirenz
Nevirapine
Bone Marrow Suppression
Cytotoxic chemotherapy (i.e. doxorubicin, cyclophosphamide, vinblastine, etc.)
Dapsone
Flucytosine
Ganciclovir
Interferon-□
Pentamidine
Sulfadiazine/pyrimethamine
Trimetrexate
Trimethoprim sulfamethoxazole
Peripheral Neuropathy
Didanosine
Isoniazid
Stavudine
Zalcitabine

MEDICATION ADHERENCE

Health care providers generally assume that patients take most or all of their prescribed medication. Numerous studies indicate that adherence to prescribed medication regimens varies greatly, and that few patients take all of their prescribed doses of drug. Imperfect adherence has probably been a medical fact of life since the dawn of civilization.

Using the most accurate means available to assess adherence, studies with single drugs suggest that fewer than 10% of patients take all prescribed doses of medication. Most patients are moderately compliant, taking between 70% and 90% of prescribed doses. About one third of patients take less than 60% of prescribed doses (120,121). These adherence estimates hold true in HIV-infected patients taking combination antiretroviral therapy (122). or treatment for opportunistic infections (123). Adherence assessment of combination regimens is far more complicated because adherence behavior may be different for different agents prescribed at the same time (124).

Even intelligent and highly motivated individuals with medical backgrounds have difÞculty with adherence. A

study in 36 medical students randomized to receive a B.I.D. or T.I.D. placebo for 14 days found that the mean number of doses taken was only 71% of those prescribed (125), a result similar to that seen in AIDS or epilepsy patients. Furthermore, less than 30% of dosing intervals were correct, regardless of assigned regimen. The two most common reasons cited for improper compliance in this study were "hectic schedule" and "irregular routine."

Health care providers cannot with great precision predict which patients will be adherent and which will not. Patient self-report and pill count also provide unreliable and inaccurate information (121,126,127). Socioeconomic factors, racial and ethnic background, and disease state, which seem as if they ought to be related to degree of adherence, generally are not (128). Depression and active substance abuse, however, are frequently recognized as barriers to adherence (129,130). Therefore, care providers need to anticipate noncompliance and whenever possible avert any problems it may cause.

Recent studies suggest that poor adherence may be a major factor in the development of resistance to HIV protease inhibitors (131). Overall adherence rates of less than 80% were associated with a significant increase in the risk of treatment failure (132,133). The risk of treatment failure increased with decreasing adherence rate in patients taking protease inhibitors plus two nucleoside analogs (133). In one study, 78% of patients taking 95% or more of prescribed protease inhibitor doses had undetectable viral loads, while only 20% of those taking less than 80% of prescribed doses had undetectable viral loads (133). Viral suppression dropped off substantially with each decile fall in adherence rate (133). It should be noted that most subjects evaluated in these studies were taking only a single protease inhibitor without ritonavir enhancement, and therefore most were using a T.I.D. regimen. Whether similar stringent adherence requirements would occur with simplified dual protease inhibitor regimens remains to be demonstrated.

A number of interventions can promote better adherence (122). Regimens involving fewer daily doses and fewer agents are easier to take. Once-a-day regimens promote adherence best; B.I.D. regimens are only marginally better than T.I.D. regimens in recently published studies (121,124,125), although these studies were conducted in patients taking only a single medication. An additional consideration is that the consequences of noncompliance are more severe for agents dosed infrequently. For example, if a drug is dosed T.I.D., then the daily therapeutic coverage is reduced by 33% if a single dose is missed; however, if a drug is dosed qd, then daily therapeutic coverage is reduced 100% if a single dose is missed.

Effective pharmacotherapy for AIDS in the future may benefit from incorporation into medical practice of means of improving adherence. Previous studies in patients with epilepsy and hypertension show that adherence can often be improved by modifying the drug regimen, physician practice, and patient behavior. Steps include increasing recognition of the problem, counseling and educating the patient about the importance of good adherence and the dangers of poor adherence, providing environmental cues to habituate the taking of medicines, incorporating medication taking into established routines, monitoring outcomes and providing feedback to reinforce success, minimizing polypharmacy, and using B.I.D. or qd regimens whenever possible.

THERAPEUTIC DRUG MONITORING

Therapeutic Drug Monitoring (TDM) refers to the adjustment of drug doses based on measured plasma concentrations to attain values within a "therapeutic window." While TDM has been used for years for drugs such as cyclosporin and digoxin, the concept has generally not been used for chronic infectious diseases. TDM may be useful in HIV infection since HIV is lifelong and treatment options can rapidly decrease with the development of resistance. A monitoring tool that can assure optimal plasma concentrations would help clinicians in constructing an effective regimen. Some antiretrovirals share many of the characteristics of drugs that require monitoring of plasma levels, including variable intersubject pharmacokinetics, serious consequences if there is a lack of effect or drug toxicity, and documented relationships between concentration and effect or toxicity. Assays for antiretrovirals are available but need to be sent to a reference laboratory for analysis. A number of other inherent problems must be resolved before TDM becomes a standard practice.

It is clear that there are relationships between antiretroviral drug concentrations and antiviral effect (134–140). What is less certain is whether adjustment of patient doses can lead to improved outcomes. Results from two prospective, randomized trials of TDM in HIV infected patients have been reported. ATHENA is an ongoing study of 600 patients randomized to TDM or no TDM. In treatment-naïve patients, indinavir and nelfinavir doses were adjusted based on the "concentration ratio," a measure of the patient's drug level compared to the mean expected drug level in the population at any time during the dosage interval. The TDM group had a significantly improved clinical outcome at one year as defined by a viral load < 500 copies; those who discontinued the drug were also considered treatment failures (141,142). Improved outcome with TDM for indinavir was primarily driven by reduced toxicity leading to fewer discontinuations, while improved outcome with TDM of nelfinavir was primarily due to improved efficacy. Results in treatment-experienced patients are not yet available. Conversely, PHARMADAPT, which used trough plasma PI concentrations to modify salvage therapy, did not show a significant improvement in virologic outcomes at 12 weeks (143). Modification of PI therapy occurred for only 22% of

patients receiving PI TDM and dosage modiÞcations did not occur until eight weeks into therapy. In addition, wild type IC_{50}s were used as target concentrations in PHARMADAPT, and this target may have been too low in this antiretroviral-experienced population.

Recent studies have evaluated the phenotype or Òvirtual Óphenotype used along with the plasma concentration as a potential tool to optimize drug therapy. The ratio of the Cmin (trough level) to the protein-adjusted IC_{50} is often called the Inhibitory Quotient or IQ. Preliminary trials demonstrate a correlation between the IQ and virologic outcome as measured by VL after 24 to 48 weeks, but larger, longer term studies are needed to validate this approach (144Ð146). These studies suggest that integration of the drug level and virus susceptibility to the drug may provide more complete information than either measurement used alone. Ongoing trials will evaluate if the IQ ratio will be a useful monitoring tool in HIV-infected patients.

A number of practical and logistical challenges may limit the widespread use of TDM for antiretroviral therapy. A primary limitation of TDM is that it does not provide information on long term adherence. A patient could not have taken their drugs correctly for weeks but may do so for the two to three days immediately before their clinic appointment if they know a TDM sample will be taken. The drug concentration in such a patient would appear to be adequate although the patient may be failing therapy due to nonadherence. It is important that any TDM program be combined with adherence counseling and monitoring so that results can be easily interpretable. Intrapatient variability also appears to be large for some antiretrovirals, suggesting that clinical decisions should be made only after two or more trough levels are collected and not after a single determination. The deÞnition of a true Òtherapeutic rangeÓ will also need to be determined for each drug, knowing that the target value may be very different for na•ve and treatment-experienced patients. Finally, accurate sample collection, timely processing, storage and shipping of plasma, and rapid turnaround times for assay results must be assured.

FORMULATION AND STORAGE ISSUES

Despite improved formulations of several antiretrovirals, many of the current drugs remain less than optimal in terms of patient convenience. A major problem is the actual number of capsules or tablets that must be swallowed through the course of the day. Approved protease inhibitor regimens vary from 6 capsules per day for indinavir or (Kaletra¨) to 18 capsules per day with saquinavir (Fortovase¨ formulation). Table 36.5 lists the number of pills for some common anti-HIV regimens. In patients taking two or more protease inhibitors, the number of pills per day can be quite large. Some recent improvements in formulation include the combination of zidovudine (300 mg) with lamivudine (150 mg; Combivir¨), and the combination of zidovudine, lamivudine and abacavir (Trizivir¨). This product represents the Þrst triple combination HAART regimen that requires only two tablets per day. This dramatically decreases the number of pills compared to taking these drugs separately.

TABLE 36.5. *Number of pills in combination regimens using standard doses*

Regimen per day	No. of Pills
Trizivir	2
COMB, NVP	4
COMB, EFV	5
COMB, IDV 800/RTV100	8
COMB, LPV/RTV	8
ZDV, d4T, LPV/RTV	10
COMB, NFV (bid)	12
ZDV, d4T, IDV 800/RTV 100, EFV	13
ZDV, d4T, APV 600, RTV 100	14
COMB, SQV 400, RTV 400, EFV	17

COMB, Combivir; d4T, stavudine; IDV, indinavir; LPV/RTV, lopinavir + ritonavir; NFV, nel navir; RTV, ritonavir; SQV, saquinavir (Fortovase); ZDV, zidovudine, EFV, efavirenz, NVP, nevirapine.

Didanosine is now available in a 200 mg tablet, and two of these tablets can be taken once daily. Didanosine can also be administered as an enteric coated capsule given once daily. A signiÞcant problem with the previous formulation of nelÞnavir was that it was difÞcult to swallow; the new Þlm coated tablet has generally alleviated this problem (22). Of note, ritonavir formulations contain ethanol and should be used with caution in patients receiving disulÞram, or drugs that can precipitate disulÞram-like reactions (e.g. metronidazole and certain cephalosporins) (20). A formulation consideration with amprenavir is that the capsules each contain 109 IU of vitamin E. As such, patients should be instructed to avoid vitamin E supplements and to exercise caution when taking the amprenavir along with anticoagulants. Amprenavir also contains a sulfonamide moiety and should be used with caution in patients with a history of sulfonamide allergy (24). Finally, amprenavir capsules and solution are not interchangeable on a milligram per milligram basis due to differences in formulation between the two products (24).

Two different combination products exist for the treatment of tuberculosis. Rifamate¨ is a product containing 300 mg of rifampin and 150 mg of isoniazid, while Rifater¨ contains 120 mg of rifampin, 50 mg of isoniazid, and 300 mg of pyrazinamide. The use of these combination products provides a simple and convenient alternative if clinically warranted.

Many products are available in liquid formulations for use in pediatric patients or in adults with dysphagia. Antiretrovirals with liquid or reconstitutable formulations include didanosine, stavudine, zidovudine, lamivudine, ritonavir, amprenavir and nelÞnavir. The taste of the

ritonavir and amprenavir solutions are often described as unpleasant, and may cause administration problems. Ritonavir can be mixed with chocolate milk, Advera¨ , or Ensure¨ to mask the taste. In addition, many of the medications for opportunistic infections, such as azithromycin, clarithromycin, and trimethoprim-sulfamethoxazole, are available as liquids.

Table 36.6 lists the storage requirements and stability of the Food and Drug Administration-approved antiretrovirals. Clinicians should remind patients to follow general precautions regarding storage of all medications (147). Drugs should be kept out of the reach of children and outdated medications should be discarded. In the absence of speciÞc storage recommendations, medications should

TABLE 36.6. *Storage and stability of antiretrovirals*

Drug	Trade Name	Dosage Form	Storage and Stability
Abacavir	Ziagen	Tablets	Store at room temperature
		Solution	Store at room temperature. May refrigerate, do not freeze.
Amprenavir	Agenerase	Capsules	Store at room temperature
		Solution	Store at room temperature
Delavirdine	Rescriptor	Tablets	Store in tightly closed containers at room temperature. Protect from high humidity. If dispersion in 3 oz water is prepared, consume within 1/2 hr.
Didanosine	Videx	Tablets	Store at room temperature in tightly closed bottles. If dispersed in water or apple juice, stable for 1 hr at room temperature.
		EC caps	Store at room temperature
		Sachet	Store packets at room temperature. If dissolved in water, stable for 4 hr at room temperature.
		Suspension	Store bottles at room temperature. After mixing with antacid, store in refrigerator in tightly closed container for up to 30 d.
Efavirenz	Sustiva	Capsules	Store at room temperature
Indinavir	Crixivan	Capsules	Sensitive to moisture; must be stored and dispensed in original container with desiccant.
Lamivudine	Epivir	Tablets	Store at room temperature in tightly closed bottles.
		Solution	Store at room temperature in tightly closed bottles.
Lopinavir/ritonavir Kaletra		Capsules	If refrigerated, stable until expiration date. At room temperature, use within two months
		Solution	If refrigerated, stable until expiration date. At room temperature, use within two months
Nel navir	Viracept	Tablets	Store at room temperature.
		Oral powder	Store at room temperature. Once mixed with liquid, use within 6 hr.
Nevirapine	Viramune	Tablets	Store at room temperature in tightly closed bottles.
Ritonavir	Norvir	Capsules	Store in refrigerator, protect from light. Discard if left at room temperature for > 12 hr.
		Solution	Storage in refrigerator recommended but not required if used within 30 d and stored at room temperature. Keep in tightly closed, original container away from excessive heat.
Saquinavir	Fortovase	Capsules	Stored in refrigerator in pharmacy until dispensed. For patients, refrigerated capsules stable until expiration date on label. If stored at room temperature, stable for up to 3 mo.
Saquinavir	Invirase	Capsules	Store at room temperature in tightly closed bottles.
Stavudine	Zerit	Capsules	Store at room temperature in tightly closed bottles.
		Suspension	After reconstitution with water, store in refrigerator in tightly closed, original container for up to 30 d.
Tenofovir DF	Viread	Tablets	Store at room temperature.
Zalcitabine	Hivid	Tablets	Store at room temperature in tightly closed bottles.
Zidovudine	Retrovir	Capsules	Store at room temperature and protect from moisture.
		Tablets	Store at room temperature.
		Solution	Store at room temperature.
Zidovudine/ lamivudine	Combivir	Tablets	Store at room temperature.

be kept in a cool, dry area, away from excessive heat, light, and moisture. They should not be stored in places that may be damp, such as the bathroom or near the kitchen sink.

SUMMARY

Antiretroviral regimens must be individualized to the patient. An understanding of the patientÕs lifestyle, work day, eating habits, and level of adherence is important when constructing a treatment plan. Counseling of the patient is critical to treatment success and even the simplest of regimens require a detailed explanation of food effects, potential drug interactions, adherence and scheduling.

Chapter 37

Immune-based Therapies for HIV Infection

Maria C. Allende and H. Clifford Lane

Due to the introduction of highly active antiretroviral therapy (HAART), HIV infection is no longer the often fatal disease that it was a decade earlier. Cessation of virus-induced immune system dysfunction and clinically relevant immune system improvement are responsible for HAARTÕs success.

Despite these successes there are still many challenges. One cannot achieve complete eradication of HIV nor total restoration of immune system function. Virological rebound invariably occurs following discontinuation of antiretrovirals, even after prolonged viral suppression with the most potent drug regimens (1Ð3).

SigniÞcant progress has been made in understanding the mechanisms of immune dysfunction in HIV infection over the last decade. HIV infection leads to a state of immune deÞciency caused by progressive loss of CD4+ T cells (a main target of the virus) coupled with a generalized immune activation that results in immune suppression (4). A number of qualitative and quantitative immunologic abnormalities occur in the setting of HIV infection that are potentially amenable to direct therapeutic intervention. These include strategies aimed at expanding or restoring the CD4+ T cell pool; strategies designed to counteract immune system activation/immunosuppression and strategies to enhance HIV-speciÞc immunity (Table 37.1). The current article will review the progress made in these areas over the last year.

IMMUNOLOGIC ABNORMALITIES IN PATIENTS WITH HIV INFECTION POTENTIALLY AMENABLE TO IMMUNE BASED THERAPIES

The immunodeÞciency state in HIV infection is characterized by a decline in the CD4+ T-lymphocyte count. The correlation between the CD4+ T cell count and the level of immunodeÞciency is illustrated by the association of lower CD4+ T cell counts with an increased frequency of opportunistic infections. While the level of HIV RNA in plasma is the strongest predictor of long-term clinical outcomes in HIV infection, the CD4+ T cell count is the best marker of immunodeÞciency and the best tool to use as a guide in the initiation or discontinuation of prophylaxis against opportunistic infections. Treatment with highly active antiretroviral therapy (HAART) leads to increases in CD4+ T cell counts due to a combination of redistribution and expansion of T cells. Genetic analyses of T cell receptor repertoire and studies of immune responsiveness to neoantigens, however, have revealed evidence of incomplete recovery of the immune system in HIV-infected patients treated with HAART. In one study some HIV-infected patients treated with HAART demonstrated abnormal *in vivo* CD4+ T cell responses after immunization with the primary antigen Bacteriophage Phix 174, suggesting the persistence of some degree of immunodeÞciency (5). The therapeutic strategies that

TABLE 37.1. *Immunologic approaches to the treatment of patients with HIV-1 infection*

I. Strategies to increase the CD4+ T cell pool
A. Cytokines: IL-2; IL-7, IL-15, CSFs
B. Adoptive transfer of CD4+ T cells
II. Strategies to reverse immune system activation
A. Corticosteroids
B. Cyclosporin A
C. Mycophenolate mofetil
D. Hydroxyurea
E. Thalidomide
F. IL-10
III. Strategies to enhance HIV-speci c immune responses
A. Immunization with HIV vaccine candidates
B. Adoptive transfer of HIV speci c T cells or antibodies
C. Structured treatment interruptions

Note: CSF – colony stimulating factor.
IL – interleukin.

Maria C. Allende, MD: Clinical and Molecular Retrovirology Section, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD 20892.
H. Clifford Lane, MD: Clinical and Molecular Retrovirology Section, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD 20892.

target the CD4+ lymphopenia component of HIV infection include cytokines such as interleukin-2 and T-cell transfers.

The immune systems of patients with HIV infection are also characterized by a profound polyclonal activation of T cells and B cells. This immune activation in turn enhances HIV replication and leads to increased destruction of CD4+ T cells. Rates of CD4(+) and CD8(+) T cell turnover are directly correlated with changes in viral load. In a recent study, rates of T cell turnover increased four-fold Þve weeks after termination of HAART and declined to pre-HAART-termination levels eight weeks after reinitiation of therapy (3,6). These data are consistent with the hypothesis that HIV-1 infection induces a viral burden-related, global activation of the immune system. Lack of proliferation of antigen-speciÞc CD4+ T cells in response to antigen is also seen as a consequence of high viral load and immune system activation. This rapidly reverses when levels of virus are suppressed (7). The rapid improvement in pre-existing opportunistic infections as well as the immune reactivation syndromes seen following the institution of HAART also suggest that HIV-associated immune system activation is associated with immunosuppression. Among the interventions that have been studied clinically to reduce immune activation are steroids, cyclosporin A, thalidomide, hydroxyurea, mycophenolate mofetil, and interleukin-10.

HIV-speciÞc CD4+ and CD8+ T cell responses are elicited in response to HIV infection. Their precise role in containment of HIV infection remains unclear. While it may seem logical to assume the higher the number of circulating HIV-speciÞc cells the better the control of virus, this logical assumption may not be correct. Conßicting results appear in the literature. Most recently, a study of 21 long-term non-progressors, determined that the frequency of CD8+ T cell HIV-speciÞc responses did not correlate with plasma viral load (8). There is strong evidence from other systems that virus-speciÞc CD8+ cytotoxic lymphocytes are crucial in controlling virus replication and that the optimal function of these cells requires a robust virus-speciÞc CD4+ T cell pool. Strategies explored in order to increase HIV-speciÞc immune responses include structured treatment interruptions, vaccines, and adoptive transfer of HIV-speciÞc T cells or antibodies.

Cytokines

Interleukin-2

IL-2 is a glycoprotein produced mainly by human CD4+T-lymphocytes and also by some CD8+T cells and natural killer (NK) cells following mitogen or antigen activation (9). IL-2 is known to play a central role in the generation of immune responses. It induces proliferation and differentiation of T-lymphocytes, natural killer cells and B-cells. IL-2 induces the production of other cytokines including γ-interferon (γIF), IL-1β, IL-5, IL-6, IL-10, TNF α, GM-CSF and M-CSF(10) and acts synergistically with TNF α, IFN γ, IL-1 and IL-6 to activate cytotoxic lymphocytes. IL-2 is licensed for treatment of metastatic renal cell carcinoma and melanoma in 45 countries. The doses approved for these indications are very different from the doses used in the setting of HIV infection.

The initial rationale for investigating the use of IL-2 in HIV infection came from the *in vitro* observation that IL-2 could augment natural killer cell cytotoxicity and cytotoxicity towards CMV infected cells by PBMC from patients with AIDS (11). In addition, IL-2 seemed a logical choice as a therapeutic candidate in patients with CD4+ T cell depletion due to its potential for *in vivo* T cell expansion. Despite the fact that the CD4+ T cell pool of patients with HIV infection shows approximately a three-fold increase in the rate of T cell turnover when compared to cells from healthy controls, this increased rate is not enough to compensate for the increased CD4+ T cell loss induced by HIV infection.

Phase I studies of IL-2 in patients with HIV-1 infection were initiated in 1983. Treatment modalities explored since then include daily SQ IL-2 in doses <3.0 MIU/d, intermittent IV or SQ IL-2 in doses ranging 6Ð18 MIU/d in cycles of three to Þve days every four to eight weeks, and PEG IL-2 in single or multiple infusions cycles, IV or SQ. A summary of recent studies is provided in Table 37.2.

A single randomized, controlled trial in 115 HIV infected patients examined the effects of daily SQ IL-2 at doses of 1.2 MIU/m2/d (12). Fifty-six asymptomatic HIV infected patients with <300 CD4+T cell counts and stable viral load received IL-2, while Þfty-nine patients received HAART alone. There was a statistically signiÞcant increase at week 26 in the mean percentage of CD4+ T cells (3.52% increase) when compared to control patients (1.33% increase) (p=0.001). This included a preferential expansion of the naïve phenotype (CD45RA+) component of the CD4+ T cell pool. The differences in total CD4+ T cell count between treatment groups did not reach statistical signiÞcance. The most common side effects of IL-2 were injection site reactions (73% of patients), asthenia (53%), ßu syndrome (46%), nausea (36%) and diarrhea (27%). Less than 13% of patients in the control group experienced these adverse events.

Fifteen randomized, controlled phase II studies of intermittent IL-2 therapy for HIV infection have been conducted over the last Þve years. These studies have documented a series of critical Þndings. The conclusions from these studies can be summarized as follows:

- A dose of 7.5 MIU BID is more efÞcacious than 1.5MIU BID(3) in increasing the CD4+ T cell counts.
- Patients with higher baseline counts appear to have a greater CD4 cell response to sc IL-2 therapy (13).

TABLE 37.2. *Randomized, controlled trials of Interleukin-2 plus antiretroviral agents in HIV infected patients performed over the past six years*

Stage of HIV infection	Study Authors, Year	Patient characteristics at study entry: CD4 count	Patient characteristics at study entry: Viral load	N-Number of patients: Treatment arms with IL-2 starting dose and schedule*	Change in CD4 + cell count Mean or **Median**: 6 months	Change in CD4 + cell count Mean or **Median**: 1 year	Change in viral load	Notes: P value for CD4 counts (IL-2 vs. control)

* All studies included intermittent IL-2 with the exception of the Lalezari study, which used once daily infusions.
Key:
ART = antiretroviral therapy
CIV = continuous intravenous
MIU = million international units
SQ = subcutaneous
PI = protease inhibitor

- Five-day treatment cycles are more effective than three-day cycles (14) in raising CD4+ T cell counts.
- Intervals of eight weeks seem preferable to four weeks since they have similar efficacy and less toxicity (3).
- Cycles of more than five days are not better than five days due to the tachyphylaxis observed beyond this duration (15).
- PEG IL-2 has not shown similar activity (16,17)
- There are no clinically significant changes in viral load.
- Administration of IL-2 is associated with a series of predictable, often dose-related side effects.

Most of these trials have compared IL-2 with antiretrovirals with a control arm treated with antiretrovirals alone. The follow up of 157 patients from the first three randomized controlled trials of this approach revealed a statistically significant long term reduction of HIV viral load (mean change from baseline HIV RNA −0.98 vs. −0.63 log/copies/mL, $p = 0.004$) in patients randomized to the IL-2 arm. The median followup was 31 months for the IL-2 group (range 4–44) and 28 months for the control group (range 9–42) (18). The results of seven recent randomized controlled studies, four of which were done in patients with <350 CD4+ T cell counts, show no statistically significant differences in viral load measurements between study groups at one year follow-up. An eighth study (19) revealed a slightly lower viral load in the IL-2 treated group (Table 37.2).

A study of 36 HIV-infected patients that were randomized to receive IL-2 without antiretrovirals at doses of 4.5 MIU or 7.5 MIU BID ($n = 24$) for five days every eight weeks or no treatment ($n = 12$) was presented at an international conference (20). Patients were treatment naïve and had CD4+ counts >350 cells/mm^3. At six months, a CD4+ count increase of 108 cells/mm^3 was observed in the IL-2 arm. Control patients received neither antiretroviral therapy nor IL-2 and exhibited an increase in CD4+ count of 11 cells/mm^3 ($P = 0.002$). IL-2 did not cause a sustained or significant increase in HIV replication in this study. Further studies of this type will be useful in evaluating IL-2 therapy alone or with pulse antiretrovirals as an alternative to chronic antiretroviral treatment.

In the pre-HAART era, the use of intermittent IL-2 in patients with lower baseline CD4 counts produced smaller CD4+ T cell count increases and greater toxicity (21). Three randomized, controlled studies of intermittent IL-2 done during the HAART era in HIV-infected patients with CD4+ T cell counts of <350 (22–24) have revealed that IL-2 is safely tolerated by patients with lower CD4+ T cell counts and stable, controlled viral loads and can lead to CD4+ T cell expansions (Table 37.2).

In vivo, IL-2 produces an immediate polyclonal T-cell proliferation with expansion of both naïve and memory cells. It also leads to an immediate mean increased cell death as reflected in rates of apoptosis of CD4 and CD8 T lymphocytes (25). In a study of apoptosis in HIV-infected patients treated with antiretrovirals and IL-2, cytofluorographic determination of DNA breaks ("TUNEL" assay) was used to examine the impact of IL-2 on cell death. In contrast to what is seen during the administration of IL-2, at the end of the treatment period (24 weeks) the percentage of PBMCs undergoing apoptosis was significantly decreased in the IL-2 treated group (26). These observations suggest that IL-2 induces a proliferation of the CD4+ T cell pool that is accompanied early by increased apoptosis but later results in decreased (normalized) immune activation.

The ability of IL-2 to activate the T cell pool led some investigators to postulate that IL-2 could be used to "flush" the reservoirs of latently infected T cells by promoting their activation, proliferation and death. A study of 18 HIV-infected patients with CD4(+) T cell counts >350 cells/microliter and viral load below the limits of detection for >1 year while on HAART revealed that all 18 patients developed viral loads >50 copies following discontinuation of therapy. Twelve of these 18 patients had previously received IL-2 and viral load rebound occurred despite prior IL-2 treatment (2,3). This approach was also tested in at least two other studies. In one study, 18 months of five antiretroviral agents, three cycles of IL-2 and two courses of γIFN, failed to prevent an increase in plasma HIV RNA levels after therapy interruption (27). In another study, treatment with IL-2 plus OKT3, combined with a five-drug HAART regimen (28) led to induction of viral replication and depletion of the CD4 pool. Thus, a consistent result from several studies is that high-level T cell stimulation in the setting of HAART has failed to reduce viral reservoirs.

To better understand the nature of the transient "viral burst" associated with IL-2 therapy, a detailed virological evaluation was performed in 11 patients undergoing intermittent IL-2 treatments for a year in the pre-HAART era (29). Six patients showed a >0.5 log increase in plasma HIV during at least one cycle. These increases were transient with levels returning to baseline within 7–10 days. Quasi species analysis from plasma and tissue in a separate cohort demonstrated that the virus induced by IL-2 most commonly resembled pre-IL-2 plasma quasi species. Thus, intermittent IL-2 therapy induced viremia does not result in sustained increases in plasma or tissue levels of HIV and does not produce a sustained expression of a previously silent quasispecies.

As noted above, five-day cycles of IL-2, spaced by at least four weeks, lead to prominent and sustained polyclonal increases in CD4+ T cell counts. This selective expansion of the CD4 pool appears to be associated with a selective induction of the alpha chain of the IL-2 receptor (CD25) on CD4+ T lymphocytes and is associated with immediate increases in rates of cell growth and cell death. Increased delayed-type hypersensitivity responses to tetanus and tuberculosis antigens were seen in patients that had weaker but present responses before IL-2 therapy (16). No new antigen-specific responses were generated with

IL-2 treatment, suggesting that deleted clones were not recovered. In a randomized, controlled trial, proliferative responses to tuberculin and CMV improved to a greater degree in the IL-2 treated patients than in the control group (24). Clinical endpoint studies with longer followup will determine if these observations will translate into clinical beneÞt.

In 1999, two large phase III clinical endpoint studies of IL-2 in HIV-infected patients were open to enrollment. ESPRIT (Evaluation of Subcutaneous Proleukins¨ in a Randomized International Trial) is a six-year study that will enroll a total of 4,000 patients with CD4 counts >300. SILCAAT (A Study of IL-2 with Low CD4 counts on Active Anti-HIV Therapy will enroll and follow for four years 1,400 patients with CD4 counts between 50 and 200. It is hoped that these studies will answer the question of the therapeutic role, if any, of IL-2 in patients with HIV infection. The websites for these studies are: www.e-spritstudy.org and www.silcaat.com.

Other Cytokines

G-CSF is capable of increasing neutrophil number in patients with HIV-infection and can allow treatment with higher doses of myelosuppressive agents in HIV-infected patients by minimizing the resulting neutropenia (30). A randomized, multicenter controlled trial (31) of 258 patients with HIV infection and ANC between 750–1000 showed that G-CSF treated patients had 31% fewer bacterial infections and 54% fewer severe bacterial infections than the control group. Another randomized, placebo-controlled trial examined the long term effects of 300mcg G-CSF three times a week on 30 HIV-infected patients treated for 12 weeks. SigniÞcant increases in absolute numbers of CD34+ cells and total white count were detected in the treated group. There was a small but statistically signiÞcant increase in CD4+ T cell count in the G-CSF treated group at week 12 (+58 vs +3, $p=0.03$). No correlation was seen between the numbers of myeloid progenitors and the CD34 counts. Thus, G-CSF appeared to be acting by increasing the number and differentiation of myeloid progenitors (32) ; rather than by expanding the pool of stem cells. No increases in HIV replication were seen with G-CSF administration. In contrast, a randomized, double blind, controlled study of G-CSF plus HAART in treatment na•ve HIV infected patients with <300 CD4+ counts was terminated prematurely after a case of severe encephalopathy occurred in the G-CSF group. At the time the study was closed, the G-CSF plus HAART treated group showed a less pronounced decrease in plasma HIV RNA of about 1 log ($p=0.02$) compared to the placebo plus HAART group. All patients reported bone pain. Thus, the use of G-CSF as a treatment for HIV infection remains controversial (33).

Compared to placebo, GM-CSF reduced the incidence of overall infections (78% vs. 67%, $p=0.03$) and the time to Þrst infection (56 days vs. 97 days, $p=0.04$) in a phase III randomized, double-blind, placebo-controlled trial of 309 subjects with no prior AIDS-deÞning illness and CD4 cell counts ≤ 50, or a prior AIDS-deÞning illness and CD4 cell counts ≤ 100. All patients were on stable antiretroviral therapy (34). No statistical difference in the cumulative number of opportunistic infections was observed between groups. In this study, GM-CSF signiÞcantly increased CD4 T cell counts with a mean change from baseline of approximately 40 vs. 20 cells ($p=0.004$). Neutrophil counts increased (median increase of 800×10^6 cells/l at two weeks vs. no increase in the control group) and there was a decrease in virological breakthroughs and overall infection rate in subjects with advanced HIV disease during the followup period of 24 weeks. Changes in viral load were not signiÞcantly different between the groups. Another use of GM-CSF in HIV infection was explored by Herranz and colleagues (35). Three patients with recurrent aphthous ulcerations who had failed to respond to other treatments (two of whom had contraindications for thalidomide use) underwent therapy with an oral solution containing recombinant human granulocyte-macrophage colony-stimulating factor (GM-CSF, 400 microg in 5% glucose 200 mL). All three patients experienced marked improvement and showed no relapses on a prolonged followup. GM-CSF appears capable of increasing neutrophil counts without adversely affecting HIV viral load in patients on HAART.

IL-10 use has been explored in HIV infection because of its inhibitory effects on proinßammatory cytokines (IL-1 α, IL-1 β, TNF α and IL-6) that increase HIV replication *in vitro* and are overexpressed in uncontrolled HIV infection. A prospective, randomized, double-blind and placebo-controlled trial of 39 HIV infected subjects was done with four different doses of IL-10 subcutaneously three times a week for four weeks (36). The follow-up was done up to four weeks after completion of therapy. Compared to baseline, no changes in CD4+ or viral load were seen in any of the groups. These results do not encourage the development of IL-10 as an immune therapy for HIV infection.

IL-12 is essential in the generation of CTL responses and induces IFN γ production by macrophages. IL-12 production by macrophages in response to antigen stimulation has been shown to be reduced in HIV infection (37). A phase I study of a single dose of recombinant human IL-12 (rhIL-12) in 47 HIV-infected patients with CD4+ counts between 100–500 (38) revealed no effects of rhIL-12 on plasma HIV RNA or absolute CD4(+) T cell counts. Dose-related increases in absolute CD8(+) T and NK cells were observed in subjects assigned to rhIL-12 doses of 30–300 ng/kg. Single rhIL-12 doses of 30–300 ng/kg were well tolerated. In an *in vitro* study, CD40 ligand trimer (CD40LT) and IL-12 were shown to enhance CD4+ T cell proliferation and production of IFN γ in response to p24 by PBMCs of HIV infected individuals

(39). CD40LT exerted its effect through B7-CD28 dependent and IL-12 and IL-15 independent mechanisms. These findings indicate the potential for CD40LT and IL-12 as immune-based therapies for HIV infection. Clinical studies need to be developed to followup on these findings.

Interferon-α is approved in some countries for treatment of hepatitis C and for therapy of Kaposi's sarcoma. Its use in HIV infection has been explored in followup of *in vitro* evidence of its ability to block HIV replication. In the treatment of Kaposi's sarcoma, the correlation between higher CD4+ counts and successful clinical outcome suggests that the effects of IFN α treatment are due to immunomodulation rather than direct anti tumor effects. In a seeming paradox, high levels of IFN α have been found in patients with advanced disease and some authors have suggested a pathogenic role for IFN α in HIV infection. In one study, HAART led to marked decreases in levels of IFN α and IFN-inducible protein 10 (40).

A randomized trial of IFN α was performed in 256 HIV infected subjects with CD4+ counts between 300–500/ml and not more than 14 weeks of prior antiretroviral therapy. All subjects received AZT and ddC and half of the subjects also received IFN α (3MIU SQ/day) (41). Evaluation at 48 weeks demonstrated that IFN-α inhibited HIV-1 replication but attenuated the CD4+ cell response to dual therapy with AZT and ddC. The mean HIV RNA changes from baseline at week 48 were −0.65 and −1.12 log 10 copies/ml for the control and IFN group respectively ($p = 0.01$). The use of IFN α with ribavirin for hepatitis C led to no significant changes in mean HIV plasma RNA levels irrespective of the hepatitis C response to treatment (42).

PEG*ylated* IFN α is a polyethylene glycol derivative of recombinant IFN α. It was studied in a multiple-dose clinical trial in HIV-infected patients with suboptimal viral suppression during antiretroviral therapy. Thirty subjects with CD4+ counts $>200/mm^3$ were enrolled to receive SQ PEG-IFN (1, 1.5, 2.25 or 3.5 mcg/kg) weekly for eight weeks (43). HIV viremia decreased by a median of 0.92 log^{10} at week 8, from a baseline median viral load of 4.47log^{10}. The responses were poorer in HIV-infected individuals with higher baseline activation markers (CD38+CD8 cells >40%). Future trials will be needed to assess the role of IFN α in HIV infection in combination with other agents.

IFN γ during the mid 1980s did not show clinical benefit in AIDS patients. Its potential use in adults has not been pursued. It has been the focus of one recent report in pediatric patients (44). Nineteen HIV+children receiving AZT or ddI were treated with $50mcg/m^2$ of recombinant IFN-γ subcutaneously three times a week for 12 weeks, and with twice that dose in same schedule during weeks 13 to 24 in a phase I/II trial. In this study, IFN-γ was well tolerated, however, it produced no changes in viral load or CD4 counts. No changes were noted *in vivo* in neutrophil bactericidal activity. There is little continued enthusiasm for the study of this cytokine in HIV-1 infection at this time.

Interleukin-7 may play an important role in T-cell immune reconstitution. A study evaluated plasma IL-7 levels and noted a correlation among IL-7 levels, thymic mass on computed tomography scan, HIV viral load and subpopulations of T cells in 175 HIV-infected individuals (45). Higher levels of IL-7 were seen with higher viral loads, lower thymic mass and lower CD4 counts, suggesting a positive feedback on thymopoiesis in patients with lower CD4 counts due to HIV infection. An *in vitro* study showed that IL-7 can increase bcl-2 expression and inhibit apoptosis in peripheral blood mononuclear cells (46). Based on these data, IL-7 would seem a promising agent for future clinical trials.

Interleukin-15 has similar effects to IL-2, using a different alpha chain in its high-affinity receptor while sharing the beta and gamma chains. *In vitro*, it has been shown to enhance neutrophil chemotaxis and fungicidal ability (47) and to enhance survival and expansion of NK cells from HIV-infected patients (48). IL-15 priming of pathogen stimulated PBMCs did not lead to increased IL-12 and IFN γ in HIV positive patients as it did in HIV negative ones (49). This suggests that IL-15 alone may be insufficient to correct the cellular defects seen in HIV infection. IL-15 has also been shown to reduce apoptosis of lymphocytes of HIV-infected patients by suppressing the down-modulation of Bcl-2 (50). IL-15, as IL-2, has failed to inhibit CD95 induced lymphocyte apoptosis *in vitro* (51). When compared with IL-2 effects *in vitro*, increases in lymphocyte survival were greater with equivalent doses of IL-15 (52). These data provide a preclinical basis for IL-15 immunotherapy in HIV infection.

Interleukin-16 is a proinßammatory cytokine synthesized mainly by CD8+ cells. IL-16 binds to the CD4 receptor; however, CD4 expression is not required for IL-16 to exert its actions (53). IL-16 leads to enhanced expression of the alpha and beta chains of the IL-2 receptor and enhances T cell proliferation in response to IL-2 or IL-15. *In vitro*, IL-16 was found to have an inhibitory effect on HIV replication at the level of viral transmission (54). T cells responding to IL-16 become unresponsive to antigen and less susceptible to activation-induced cell death. Lower *in vivo* levels of IL-16 correlated with advanced HIV disease (55). The enhancing effects on IL-2 and IL-15-induced proliferation, as well as its antiviral effects and ability to decrease activation-induced cell death make IL-16 an attractive molecule to be studied further in HIV infection.

Cell Transfers

Autologous CD4+ and/or CD8+ T cells expanded *in vitro* have been given to HIV+ patients in a variety of different clinical trials. Ex-vivo expansion of CD4+ T cells from infected patients using anti-CD3/CD28 antibodies has been more effective than using anti-CD3 alone.

This technique increases T-cell numbers in a polyclonal fashion. The resulting cell preparations are relatively resistant to HIV infection due to chemokine receptor downregulation. In a recent study by Bernstein et al. (56), eight patients received a mean of Þve infusions of autologous ex-vivo expanded anti-CD3CD28 co-stimulated CD4+ T cells. Doses started at 3×10^9 cells with a six week interval between infusions. The patients had a median baseline CD4 count of 442 cells/mm^3. The median viral load in the four of the eight patients with detectable levels was 24,000 copies/ml. At the end of the study, there were no changes in viral load. A median CD4+ T cell increase of 38% were seen in seven of the eight patients. All patients were taking antiretroviral agents.

Transfers of HIV-speciÞc CTLs between HIV-discordant syngeneic twins and autologous, expanded CD8+ T-cell transfers have also been attempted. One study assessed the survival of HIV-speciÞc CD8+ T cells and their *in vivo* migration using both a quantitative ßuorescent probe technique and PCR in situ hybridization (57). The cells were gene-modiÞed to contain a neomycin phosphotransferase gene. The number of circulating CD8+ T cells ranged from 1.6Ð3.5% shortly following infusion to $< 0.5\%$ (< 1 per 200) two weeks later. Concurrent analysis of blood and lymph node by these two techniques showed that modiÞed CTL were present in the lymph node at a 4.5- to 11-fold higher levels in lymph node than peripheral blood. The gene-marked CTL localized within parafollicular regions of the lymph node adjacent to cells expressing tat-env fusion transcripts, a correlate of virus replication. Thus, it appears that HIV-speciÞc CD8+ T cells expanded ex-vivo are capable of homing to sites of viral replication *in vivo*.

In an attempt to create CD4+ T cells resistant to HIV infection, studies have been carried out using genes that can disrupt the HIV life cycle by interfering with regulatory or structural genes of HIV. Inhibitors of HIV genes can be RNA-based or protein-based. RNA-based strategies include anti-sense trans-activation response (TAR) element inhibitors and ribozymes engineered to cleave speciÞc sites in the HIV genome (58). Ribozymes targeted to the HIV-1 tat gene have been shown to inhibit HIV-1 replication in tissue cultures. A phase I study(59) using an anti-tat ribozyme has been carried out. In this study cells from four healthy twins were transduced with an anti-tat ribozyme and infused into the corresponding HIV negative twin. Results at 10 months showed persistence of the transduced cells (with two different vectors) in all four twin pairs. There were no signiÞcant changes in CD4+ counts or viral load and no serious toxicities. Protein-based inhibitors include a dominant-negative mutant Rev protein (RevM10), engineered intracellular antibodies, and chemokines that bind and sequester speciÞc cellular coreceptors (60). A report from an ongoing study utilizing an antisense TAR (trans-activation response element) along with a transdominant rev noted that transduced cells have remained present in the circulation three years after infusion. These cells have shown a survival advantage compared to cells infused at the same time and marked with a control gene (61).

In an attempt to increase the number of CD4+ and CD8+ T cells capable of binding to HIV-infected cells, studies have been carried out in which a second T cell receptor consisting of the CD3 zeta chain of the T cell receptor fused to the sp120-binding portion of CD4 has been inserted to confer binding to HIV gp120. Genetically engineered CD4+ and CD8+ autologous T cells, modiÞed with the insertion of this fusion protein (CD4-zeta) were infused into 24 subjects (62), with or without IL-2 at a dose of 6MIU/day for Þve days. All patients were on stable antiretroviral therapy for more than eight weeks, had CD4+ counts □50 and HIV viral loads of □1,000 copies/mL. The T cells were autologous and had been stimulated ex vivo with anti-CD3/CD28 and expanded for approximately two weeks. CD4zeta was detected in 1Ð3% of blood mononuclear cells at eight weeks and 0.1% at one year. There were no signiÞcant changes in plasma HIV RNA or blood proviral DNA in either treatment arm. An increase of CD4+ counts of 73 cells/microL was noticed at eight weeks in the group receiving IL-2.

In a similar study CD4+ and CD8+ lymphocytes were obtained from healthy HIV negative syngeneic twins and transduced with the chimeric T cell receptor gene (CD4/CD3-zeta) mentioned above. These cells were then infused to the HIV+ twin (63). Transduced cells peaked in the circulation by 24Ð48 hs (10^4 to $10^5/10^6$ cells) and decreased by 2Ð3 logs in eight weeks. Sustained fractions of approximately 10^3 to 10^4 modiÞed cells/10^6 total CD4(+) or CD8(+) cells persisted for at least one year. Lymphoid tissue biopsies revealed the presence of modiÞed cells in proportions equivalent to or below those in the circulation. There were no signiÞcant changes in CD4 count or viral load in these patients. Transduction techniques used in these cell transfers have an efÞciency of 15Ð30%, which limits the efÞcacy of this kind of treatment and creates the need for a higher number of transfusions. The number of cells infused and the intervals used has varied among these studies, making comparisons difÞcult. Thus far, none of these approaches has achieved signiÞcant increases in CD4 or decreases in viral load. Higher numbers of cells, more frequent infusions and/or different targets are needed. One of the limitations of this area of research has been the development of immune responses directed towards the new genes.

Several groups have studied the potential role of genetic modiÞcation of stem cells as a way of creating T cells resistant to HIV infection. This area faces several hurdles, including poor transduction efÞciencies and limited differentiation via T cell pathways. The *in vivo* survival of transduced stem cells of HIV-infected subjects was evaluated in one study (64). Approximately 10^8 PBSC (from mobilized HIV-1 infected patients after leukopheresis and enrichment of the CD34+ cell population) were transduced with HGTV-43, a retrovirus-based vector,

followed by autologous infusion without host conditioning. The transduced cells were expressing an HIV-1 antisense RNA and were resistant to HIV infection *in vitro*. Measurements of the antisense RNA was performed using real-time RT-PCR of PBMC RNA. Antisense RNA was observed in CD4+ cells at six months. This observation is an example of the survival of transduced hematopoietic cells in nonablated human subjects.

Immunosuppressants

Corticosteroids

Corticosteroids have been evaluated in HIV infection as a temporary treatment directed to reduce the state of immune activation and inßammation that accompanies HIV disease. Their use is recommended as an adjunct to speciÞc antimicrobial therapy in patients with severe *Pneumocystis carinii* pneumonia (PCP). Among the actions of corticosteroids of possible beneÞt in HIV infection are a decrease in the levels of proinßammatory cytokines leading to a decrease in HIV replication and protection of CD4+ T cells from activation-induced cell death (65). In an early study, oral prednisolone at 0.5mg/kg for six months given to patients with CD4+ counts between 200Ð799 cells/ml produced increases in CD4+ T cells (median increase at one year, 119 cells/microL) with no changes in viral load after one year (66). Another study, done on four patients with HIV wasting syndrome, demonstrated a mean weight increase of 3.5 kg along with a transient decrease in viral load (67). A controlled study, designed to evaluate the effects of corticosteroids on IL-2 induced toxicities, found that although side effects were signiÞcantly decreased, the rise in CD4+ T cells was diminished (61). Recent studies describing an increased incidence of avascular hip necrosis in HIV-infected patients and identifying corticosteroids as a signiÞcant risk factor (68), as well as the growing evidence of insulin resistance and lipid metabolism abnormalities found with HAART, have created additional doubt as to the role of corticosteroids as a maintenance therapy in patients with HIV infection (69).

Hydroxyurea

Hydroxyurea (HU) inhibits ribonucleotide reductase, the rate-limiting enzyme for dNTP synthesis. HU decreases intracellular dNTPs, which are essential for cell division as well as HIV replication. This action creates a competitive advantage for the incorporation of nucleoside reverse transcriptase inhibitors in the HIV replication cycle. Thus, HU has both antiviral and cytostatic properties. It has been postulated that the cytostatic effects might control the dissemination of HIV early in primary infection. HUÕs predominant combination with didanosine rather than other nucleoside analogues in clinical trials is based on HUÕs ability to deplete deoxyadenosine triphosphates to a greater extent than deoxythymidine triphosphates. This likely increases intracellular concentrations of ddI metabolites relative to concentrations of dATP. The use of hydroxyurea at 1,000 mg/day in patients with CD4 counts between 100Ð350 that were on didanosine monotherapy resulted in a viral load reduction of 0.6 log10 after four weeks of treatment. No increases in CD4 counts were seen (70). A randomized study of 144 patients compared ddI plus d4T plus hydroxyurea to ddI plus d4T plus placebo. After 12 weeks of therapy, patients in the HU group had greater decreases in viral load (2.3 log10 vs 1.7 log10) with an increase in the CD4 count of 28cells/ml compared to 38cells/ml in the placebo group. A variety of side effects (neutropenia, thrombocytopenia, diarrhea and neuropathy) were increased in the HU group (71).

Interest in the potential role of HU in patients with HIV infection increased with the report of the ÒBerlin patientÓ (72). This patient was started on therapy with HU, ddI and indinavir two months after acquiring HIV infection. Treatment was then discontinued on two occasions. The plasma viral load was < 50 copies/ml 17 months after the last discontinuation of therapy. In follow-up of these Þndings, a 19 patient study was carried out in patients with primary HIV infection comparing four-drug HAART not containing HU with four-drug HAART that contained HU (73). At 36 weeks of therapy, the antiretroviral potency as well as the changes in CD4 were similar in both regimens.

More recently, a randomized trial of more than 200 patients (ACTG5025) compared ddI-d4T-indinavir with Hu to ddI-d4T-indinavir without HU. After 24 weeks of follow-up, patients in the HU arm had signiÞcantly higher treatment-limiting toxicities, particularly neuropathy, with two fatalities due to pancreatitis. It is unclear if these side effects were due to interactions with ddI and/or d4T exclusively or if the addition of indinavir might have produced additional interactions that resulted in increased toxicity in the HU group. In view of these toxic interactions and the fact that HU combination regimens do not seem to be superior to other HAART combinations in efÞcacy for primary infection treatment, the role of HU in HIV infection remains unclear.

Mycophenolate mofetil

Mycophenolate mofetil is the prodrug of mycophenolic acid (MA). This drug limits the *de novo* synthesis of guanosine nucleotides by reversibly inhibiting inosine monophosphate dehydrogenase. Thus, proliferation of monocytes and lymphocytes, which are dependent on de novo synthesis of purines, is inhibited by mycophenolic acid. MA also induces apoptosis of activated T cells (74). MA can directly inhibit HIV-1 replication *in vitro* at concentrations that are lower than those used for organ transplantation (75). This antiviral effect is obtained by

depleting one of the substrates (deoxy guanosine triphosphate) required for reverse transcription. By increasing the ratio of drug : native substrate, MA potentiates the antiviral activity of abacavir, a guanosine analogue. In contrast, the combination of MA with the thymidine analogues zidovudine or stavudine was antagonistic *in vitro*. A non-randomized controlled clinical study assessed the effects of mycophenolate mofetil (MM) in eight HIV-infected patients with viral loads <5 copies/ml treated with abacavir and amprenavir. No liver or renal toxicities were noted. MM induced a rapid decrease of both CD4 and CD8 T cell production. Daily CD4+ T cell production was suppressed by approximately 60% compared to that of HIV negative subjects. Therefore, MM may substantially reduce the number of dividing CD4+ T cells *in vivo* (74). Randomized clinical trials with long-term followup are needed to delineate the clinical effects of mycophenolate mofetil and its interactions with reverse transcriptase inhibitors. In transplant patients this agent has been associated with the development of Kaposiõ sarcoma, cytomegalovirus and fungal infections.

Cyclosporin-A

Cyclosporin-A (CyA) reduces T-cell activation by inhibiting IL-2 release. In this way, HIV replication is reduced at the expense of a reduction in T cell number. Initial studies before HAART and using higher doses (7.5mg/kg/day) had disappointing results in HIV-infected patients. In one early study no signiÞcant changes in CD4 count (440 vs. 404, $p=0.1$) and a signiÞcant increase in HIV p24 antigen levels (62 vs. 275, $p=0.001$) were found after one year of CyA treatment (76). While the CD4 decline was more rapid following the discontinuation of cyclosporin A it is difÞcult to assess the importance of this in the absence of a control group. More recently, two studies were presented at international meetings. Rizzardi et al. (77) treated nine patients with primary HIV infection with CyA at the lower dose of 0.6Ð1.2 mg/kg/day for eight weeks in combination with HAART and compared virologic and immunologic responses with 29 patients treated with the same HAART regimen without CyA. At week 24, the viral load reduction was similar in both groups, although the proportion of patients with viral loads <50 was higher in the CyA group (88% vs. 55%, $p=0.05$). A striking Þnding in this study was a sustained and marked increase in CD4 counts in the CyA treated group at week 64 (1,443 vs. 712 cells/mm^3). A randomized and placebo controlled study, ACTG 334, evaluated the use of 4mg/kg/day of CyA for 12 weeks in 28 patients treated with no antiretrovirals ($n=15$) or stable dual nucleoside therapy ($n=13$). Overall, therapy was safely tolerated. Total CD4+ and CD8+ lymphocytes numbers did not differ between the groups. No major differences were noted in viral load in preliminary analysis. A formal analysis is still pending (78). These studies support the further evaluation of CyA at low doses along with HAART in patients with HIV infection. HIV infected patients with autoimmune diseases or undergoing organ transplantation may be good candidates for future studies.

Thalidomide

Thalidomide was initially evaluated in HIV infection due to its ability to interfere with the production of TNF-α, a proinßammatory cytokine that can enhance HIV replication *in vitro*. The only current FDA-approved indication for thalidomide is for the treatment of erythema nodosum leprosum. A previous randomized, placebo-controlled trial (79) supported the use of thalidomide in the treatment of HIV-associated oral ulcers at a dose of 200mg/day. Sixteen of 29 patients in the thalidomide group (55%) had complete healing of their aphthous ulcers after four weeks, as compared with only two of 28 patients in the placebo group (7%; odds ratio, 15; 95% conÞdence interval after adjustment for group sequential testing, 1.8 to 499; unadjusted $P<0.001$).Unexpectedly in this study, this clinical beneÞt on oral ulcers was accompanied by increases in viral load that were statistically signiÞcant in comparison with the control group (0.42log10 vs. 0.05log10, $p=0.04$) and increases in serum TNF levels. More recently, a multicenter, double-blind, randomized, placebo-controlled study was conducted to determine the safety and efÞcacy of reduced, intermittent doses of thalidomide for preventing recurrences of oral and esophageal aphthous ulcers in HIV-infected patients (80). Forty-nine HIV-infected patients whose ulcers previously had healed as a result of thalidomide therapy were randomly assigned to receive either 100 mg of oral thalidomide or placebo three times per week for six months. Ulcers recurred in 61% of thalidomide-treated patients compared to 42% of placebo treated patients. The time to recurrence was not signiÞcantly different between groups. A randomized, placebo-controlled trial of thalidomide in 103 patients with HIV-associated cachexia (81) at doses of 100mg/day or 200mg/day for eight weeks demonstrated a signiÞcant increase in weight (2.2kg, $p=0.008$ and 1.5kg, $p=0.019$, respectively), in each thalidomide group compared to controls. Approximately half of this weight gain was fat-free body mass (bioimpedance analysis). There was an increase in viral load in the treatment group compared to controls, with no signiÞcant changes in CD4+ or CD8+ cell counts. More recently, other uses of thalidomide have been explored. Thalidomide was not able to decrease the toxicities or transient viral load increases seen with IL-2 (82). In another study, twenty patients aged 29 to 49 years with a median CD4 count of 246 cells/mm^3 (range, 14 to 646 cells/mm^3) and taking antiretroviral therapy were enrolled in a phase II dose-escalation study of oral thalidomide in Kaposiõ sarcoma (KS) (83). The median thalidomide dose at the time of response was 500 mg/d (range, 400 to 1,000 mg/d). Oral thalidomide was tolerated in this population at doses up to 1,000 mg/d for as long as 12

months. The median duration of drug treatment was 6.3 months, and the median time to progression was 7.3 months. Partial anti-KS responses were noted in eight of 17 evaluable patients (47%).

Overall, thalidomide appears to have a role in the treatment of HIV-associated oral ulcers. Additional work is needed to determine if there is beneÞt in other settings in HIV-infected patients. ThalidomideÕs serious teratogenic effects and its effect on the viral load require a careful selection of patients as well as frequent follow-up.

Therapeutic Vaccines

Among the candidate vaccines that have been evaluated in HIV-infected individuals are a series of recombinant envelope and gag proteins; killed virus; recombinant viruses and DNA vaccines. Vaccine research for HIV has two potential areas of application: prevention and therapy of HIV infection. Therapeutic vaccines for HIV infection are intended to promote HIV-speciÞc responses that would theoretically lead to better immunologic control of the disease and hopefully reduce the need for antiretrovirals in individuals already infected with HIV.

Recombinant Envelope Proteins

Several candidate envelope vaccines have been evaluated in HIV infected patients. In most cases, HIV-speciÞc proliferative T cell responses were induced. However, clinical beneÞt measured by disease progression, or signiÞcant drop in viral loadÑ the only surrogate marker of antiviral activity validated so farÑ has not been observed.

A large phase II efÞcacy trial with HIV-1 recombinant envelope glycoprotein gp160 (rgp 160) in 608 HIV-infected, asymptomatic individuals with CD4+ T cell counts >400 cells/mm^3 was reported this past year. This trial was multicenter, randomized, placebo-controlled and double blind, with a Þve year follow-up. It was designed to evaluate the time to AIDS deÞning events and/or mortality. The vaccine was given intramuscularly at days 0, 7 and then monthly at months 1, 2, 4 and 6 initially and every four months thereafter (84). Previous use of AZT for >1 year or within three months of study entry were exclusion criteria. After day 240, all approved antiretroviral drugs could be used. There were no signiÞcant differences in time to antiretroviral use between groups. Even though the study had a 17% loss of follow-up, there was sufÞcient power (90%) to detect 50% reduction in the primary clinical outcomes at the conclusion of the study. There was no statistically signiÞcant difference in time to primary endpoint between vaccine and placebo groups ($p=0.94$). Time to secondary endpoints (30% decline in mean on-study CD4+ T cell count from baseline) was not signiÞcantly different between arms ($p=0.23$). While increases in median viral load were noted for the whole cohort (3.91 to 4.22 logs over the observation period, $p=0.0001$ compared to baseline), there were no differences between study arms at any time point. Cellular immune responses, measured by lymphoproliferative assays, increased in the vaccine group from 31% at baseline to 88% at the end of year 1. Cellular reactivity was unchanged in the placebo arm. Overall, the vaccine was well tolerated without signiÞcant serious adverse events. Two other large phase II placebo controlled randomized studies of rpg160 have also been recently reported. One included 278 subjects with CD4 counts >500. The majority of them were on no antiretroviral therapy. Approximately 20% of subjects in each group were receiving AZT monotherapy (85). The other study involved 835 HIV-1-infected patients with CD4 counts >200. In this study, approximately 50% of subjects in each group were receiving antiretroviral therapy (86). The Þrst study showed no differences in the rate of CD4 decline, plasma RNA viral load, incidence of opportunistic infections or death at two year follow-up. The second study showed a higher CD4 count among vaccine recipients at six months than at baseline compared to those in the placebo group and there was a reduction in mortality at the two year follow-up in the vaccinees. However, results at the three-year follow-up failed to reveal this advantage. There were no differences in the rate of CD4 cell count decline, progression to AIDS or HIV viral load at that point.

In a recent review, the results from two studies, ACTG 209 and ACTG 214 (87), were reported. These studies were designed to compare the safety and immunogenicity of several candidate recombinant HIV-1 envelope vaccines and adjuvants. They were conducted between 1993 and 1995. Overall, immunogenicity was detected in $<30\%$ of subjects and there were no signiÞcant differences with placebo arms regarding disease progression. In most patients there was evidence of ongoing viral replication. A correlation between the baseline plasma HIV-1 RNA and the ability to elicit new cellular immune responses was demonstrated in these studies. In view of the partial immune restoration and improved T cell homeostasis achieved with HAART there is renewed interest in these approaches in patients with sustained viral load suppression.

A new approach to develop more potent and broadly directed antibodies is the generation of ÒfusionÓ-competentÓ immunogens (88). These have been generated by Þxing cells in the transient stage of fusion, involving the interaction of envelope, CD4 and coreceptor. In murine studies, high levels of cross-reactive neutralizing antibodies have been elicited. No clinical studies in humans have been developed yet.

Remune

One of the most extensively studied therapeutic vaccine candidates is the HIV-1 Immunogen, *Remune*, a gp120

depleted whole virus vaccine. Initial studies demonstrated enhanced HIV-p24-speciÞc lymphocyte blast transformation responses in HIV-infected patients immunized with Remune. Unfortunately, a phase III clinical endpoint trial of this candidate vaccine failed to prove differences in clinical progression or death between the treatment arm and placebo controls (89). This study was designed to assess the immune effects of the addition of HIV-1 Immunogen to patients on antiretroviral therapy by comparison with a antiretroviral-only treated control group receiving placebo injections. A total of 2,527 patients were randomized (1,262 received Immunogen and 1,263, IFA placebo). Entry CD4 T cell counts ranged between 300Ð549 x 10^6/L. There were no viral load entry criteria. The primary endpoint was AIDS-free survival (time to development of AIDS deÞning illnesses or death). At the time of randomization, 27% of the subjects were not receiving antiretrovirals, 5% were on monotherapy, 37% on dual therapy and 31% were on a protease inhibitor. During the course of the study the use of PIs increased from 31% to 59%. Changes in antiretroviral therapy were similar between treatment groups. Up to 13 vaccinations were administered intramuscularly at 12 weeks intervals. The mean followup was 119 weeks in the treatment group and 121 in the placebo group. The loss to follow-up was similar for both groups (approximately 18%). Even though the HIV-1 Immunogen elicited at least a Þve-fold increase in the lymphocyte proliferation assay to HIV-1 p24 antigen at week 24 and week 48 (45% and 34% of patients randomized to HIV-1 Immunogen, respectively, compared with 1% and 1% in the control group, ($p = < 0.001$ for both comparisons), there were no signiÞcance differences between the HIV-1 Immunogen and control group with respect to changes in viral load ($p = 0.59$) or clinical progression (53 events in each group, $p = 0.89$). There was a statistically signiÞcant increase of 10 CD4 T cells at 48 weeks in the treatment group compared to the control group ($p = 0.02$). A total of 42 subjects died, 23 in the HIV-1 Immunogen group and 19 in the control group ($p = 0.49$). While it failed to demonstrate a beneÞt of therapeutic immunization, this study provided important new information on the rate of disease progression after the introduction of protease inhibitors. The rate of 1.8 per 100 person-years was one-third of what had been previously reported in the literature and has important implications for ongoing studies with clinical endpoints in patients with early disease. Several additional trials of HIV-1 Immunogen with a modiÞed design are either in progress or planned to reassess the efÞcacy of this approach.

Poxvirus Vaccines

Recombinant Canarypox vectors, which are similar to vaccinia virus but have a limited ability to replicate in human cells, are being evaluated in human trials. The vectors may express sequences from env, gag and pol and CTL epitopes from nef and pol. Data on immunogenicity or viral load are yet available. Studies in HIV negative persons have shown that these vectors are able to induce CD4 and CTL responses as well as antibodies and that these responses are more robust in regimens that include a boost with recombinant protein vaccines (90).

Polypeptide Vaccines

This vaccine design strategy involves the use of polypeptide sequences from HIV-1 selected for their capacity to induce CTL responses and/or neutralizing antibodies. At least two vaccine candidates in this category, PCLUS and C4-V3 PV, are being studied in phase I trials for safety and immunogenicity. PCLUS are synthetic envelope cluster peptides. In a study of eight HIV-infected patients who received six subcutaneous injections, HIV-speciÞc T helper responses increased greater than four fold in four of eight patients, with smaller increases in three other patients at 36 weeks (adjusted $p < 0.05$) (91). Serum HIV-1 MN-neutralizing antibody titers increased in each of the three patients who had low titers prior to immunization. Plasma HIV RNA levels and CD4 cell counts did not change signiÞcantly during the study period.

C4-V3 PV is an immunogen that consists of four peptides containing T-helper epitopes from the fourth constant region (C4) of gp120 of the HIV-1 MN virus and B-cell neutralizing epitopes from the gp120 third variable region (V3) of four clade B viruses. In one study of 10 HIV-1-infected patients, (92) follow-up at 52 weeks showed a four-fold rise in serum neutralizing antibody titers in four out of eight subjects that received the vaccine. Five out of eight had a Þve-fold rise in peripheral blood mononuclear cells lymphocyte blast transformation assays. No signiÞcant changes in CD4 T cell counts or viral load were observed during this follow-up.

p24 VLP

The immunogen p24 VLP, contains codons 100Ð308 of the gag component of HIV-1. This agent has been studied in a phase II randomized, double-blind placebo controlled phase II trial (93). Sixty-one patients with CD4 > 400 received vaccinations with or without AZT monotherapy. At both 24 and 52 weeks there were no signiÞcant differences between the treatment groups in terms of antibody responses to p24, CD4 T cell counts or viral load, despite induction of antibody and proliferative responses to the carrier protein of the vaccine.

DNA Vaccines

DNA vaccines are currently being studied in phase I trials. The potential advantage of this strategy over others is that it allows expression of whole proteins from HIV

(gag, pol, tat, nef and rev, for example) by the body's own cells and thus facilitate processing via MHC I pathways. A large number of epitopes (small peptides) can be encoded in these plasmids and thus be available to produce a stronger immune response with a prolonged persistence of the antigens. Human trials of a DNA-based vaccine have been conducted in small groups of patients. In one study, (94) nine HIV-1-infected asymptomatic patients were immunized with DNA constructs containing the nef, rev or tat genes of HIV-1. The same vaccine was used in another study of nine patients, four of whom received concomitant HAART (95). Both studies have shown enhanced specific lymphocyte proliferative and cytotoxicity functions in the vaccinees, without significant changes in viral load or CD4 counts. Larger studies are needed to assess these responses and the impact of the use of HAART. DNA vectors that encode regulating cytokines as well as immunogenes are also being studied as a strategy to enhance immune responses.

Recombinant live attenuated bacterial or viral vectors, such as BCG, salmonella and rabies, can be engineered to contain fragments of HIV that are recognized by T cells during vector replication *in vivo*. This approach would potentially increase the number of epitopes available and the time of antigen exposure. These vaccines are currently in preclinical phases of development. Whether or not the exogenous administration of antigens will lead to a better immune resposne than that elicited during the course of natural infection remains to be determined.

Chapter 38

Immunizations, Vaccine-Preventable Diseases, and HIV Infection

Allyn K. Nakashima and Ida M. Onorato

Advances in antiretroviral therapy for human immunodeÞciency virus (HIV) infection have delayed progression to the acquired immunodeÞciency syndrome (AIDS) and reduced mortality (1). There is evidence of partial immune restoration after therapy, and this may have impact on response to immunizations (2Ð4).As HIV infection takes on the characteristics of a chronic disease and the incidence of AIDS and opportunistic infections declines, other causes of morbidity and mortality, including vaccine-preventable diseases, may become more important.

Immunization is generally thought to be safe and beneÞcial for persons infected with HIV. The Þrst recommendations for immunization for HIV-infected children and young adults were published in 1986 (5) and revised in 1993 (6). Current recommendations for routine immunization of children including those infected with HIV have been recently updated and are shown in Table 38.1 (7,8). This chapter focuses on recommendations for adults. The American College of Physicians and the Advisory Committee on Immunization Practices (ACIP) have published recommendations for immunization of adults, including those who are HIV-infected (6,9,10). In addition, the U.S. Public Health Service and Infectious Diseases Society of America Prevention of Opportunistic Infections Working Group has updated recommendations for prevention of opportunistic infections, including those that are vaccine preventable (11). Generally recommended vaccines at present for HIV-infected adults and adolescents include 23-valent polysaccharide pneumococcal vaccine, inactivated trivalent inßuenza virus vaccine, hepatitis A vaccine, and hepatitis B vaccine.

Allyn K. Nakashima: Division of HIV/AIDS Prevention, National Center for HIV, STD and TB Prevention, Centers for Disease Control and Prevention, 1600 Clifton Rd., Mailstop D-21, Atlanta, GA 30333. Email: ANakashima@cdc.gov

TABLE 38.1. *Recommendations for routine immunization of children with HIV infection, United States**

Vaccine	Recommended
DTaP	Yes
OPV	No
IPV	Yes
MMR	Yes[a]
Hib	Yes
Pneumococcal	Yes
In uenza	Yes
Hepatitis B	Yes
Hepatitis A	Yes[b]
Varicella	Possibly[c]
BCG	No

* See References 7 and 8. DTaP, diphtheria and tetanus toxoids and acellular pertussis vaccine; OPV, poliovirus live oral, trivalent: contains poliovirus types 1, 2, and 3 (OPV is no longer recommended for routine immunization of any children in the United States.); IPV, inactivated poliovirus vaccine: contains poliovirus types 1, 2, 3; MMR, measles, mumps, and rubella virus vaccine; Hib, *Haemophilus inßuenzae*, type b; BCG, bacille Calmette-Guérin vaccine.

[a] The Advisory Committee on Immunization Practices (ACIP) currently recommends withholding measles vaccine from HIV-infected persons with severe immunosuppression, de ned as 1) CD4 T-lymphocyte counts < 750 for children aged < 12 months, < 500 for children aged 1–5 years, or < 200 for persons aged □6 years; or 2) CD4 T-lymphocytes constituting < 15% of total lymphocytes for children aged < 13 years or < 14% for □13 years. MMR is recommended for HIV-infected persons without evidence of measles immunity who are not severely immunocompromised (25).

[b] ACIP recommends hepatitis A vaccine for routine use in some states and regions and for persons in certain high risk groups (e.g. travelers to endemic areas) (7).

[c] ACIP recommends that varicella vaccine should not be administered to persons who have cellular immunode ciencies, including HIV. However, after weighing potential risks and bene ts, varicella vaccine should be considered for asymptomatic or mildly symptomatic HIV-infected children in CDC class N1 or A1 with age-speci c CD4 + T-lymphocyte percentages > 25% (252).

In spite of the substantial morbidity and mortality of hepatitis B, inßuenza, and pneumococcal disease in older age groups, immunization levels of recommended vaccines for adults in general have been low (12). Immunization coverage among HIV-infected persons and those at risk for HIV is also low. In a study conducted during 1994Ð1998, only 9% of 3,432 MSM aged 15Ð22 years, a group for whom hepatitis B vaccine has been recommended since 1982, had been immunized (13). An ongoing medical record review study of HIV-infected adults and adolescents in care in over 100 health care settings found that only 14% of 13,012 persons had received >1 dose of hepatitis B vaccine (14). In other analyses from the same surveillance cohort, 40% of 19,081 persons had received inßuenza vaccination during follow-up (15) and 38% of 30,086 persons had documented receipt of pneumococcal vaccine (16); there was no temporal trend in vaccination rates. The increasing numbers of persons living with HIV infection in the United States (17) and their prolonged life expectancy necessitate an understanding of the epidemiology of vaccine-preventable diseases in this group and a renewed priority on immunization.

Several concerns about immunizing HIV-infected persons have been raised: the safety of the vaccines themselves; potential adverse effects on the progression of HIV infection; the indications for vaccines; and the immunogenicity and efÞcacy of vaccines in this population. These issues are reviewed in this chapter.

SAFETY OF IMMUNIZATION OF HIV-INFECTED PERSONS

Historically, live virus (e.g. oral poliovaccine (OPV); measles, mumps, and rubella (MMR) vaccine; smallpox vaccine) and live bacterial (i.e. Bacille Calmette-GuŽrin (BCG)) vaccines have not been recommended for immunocompromised persons because replication of live, attenuated agents may be enhanced, while inactivated bacterial and viral vaccines (e.g. diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP), inßuenza vaccine, pneumococcal vaccine, *Haemophilus inßuenzae* type b vaccine (Hib), inactivated poliovaccine (IPV), hepatitis A vaccine (HAV), and hepatitis B vaccine (HBV)) are recommended. In the 1960s, for example, a child with leukemia immunized with a less attenuated strain of measles vaccine than is used in the United States today developed measles pneumonia (18).

Vaccine-associated poliomyelitis, like infection with wild poliovirus, is more frequent and severe in persons with immunologic abnormalities (e.g. severe combined immunodeÞciency syndrome, agammaglobulinemia, or hypogammaglobulinemia) (19,20). However, only two cases of vaccine-associated paralytic poliomyelitis in HIV-infected children have been documented in the literature (21,22), and a case-control study in Zaire suggested that HIV infection may not be a risk factor for paralytic poliomyelitis (23). Current guidelines recommend that OPV not be administered to persons with immune systems compromised by HIV, or given to their healthy household contacts (24). In addition, as poliomyelitis control has been achieved in the United States, the ACIP has recommended exclusive use of the inactivated vaccine (IPV) essentially eliminating the problem of vaccine-associated paralytic poliomyelitis in this country (24). (OPV is recommended only under certain circumstances, e.g. outbreak control.) In contrast, extensive experience has shown that the attenuated viruses in MMR are not transmissible to close contacts. Therefore, all family and other close contacts of HIV-infected persons should be vaccinated with MMR vaccine, unless they have been previously immunized (25).

A corollary concern is the risk of vaccine-associated poliomyelitis in HIV-infected household contacts of recently immunized children. Because most HIV-infected children acquire HIV prenatally, their mothers are infected as well. Vaccine poliovirus strains are excreted by healthy vaccinees for up to eight weeks, but viral shedding may persist for years in some immunodeÞcient persons (26). Liste et al., in a study of HIV-infected children in Venezuela, although they concluded that there was Òno evidence of prolonged excretion of poliovirusÓ, two of 11 HIV-infected children who had received OPV were excreting poliovirus Þve to nine months after their last dose of OPV (27). Studies are being conducted to further assess the likelihood of prolonged poliovirus excretion in HIV-infected children and adults in countries where OPV continues to be used (28).

The safety of immunization in HIV infection has been studied mostly in children. The New York City Department of Health conducted a retrospective survey of 221 HIV-infected children with valid immunization records to evaluate the frequency of vaccine-associated adverse events (29). No adverse reactions were noted after receipt of a total of 468 doses of OPV and 70 doses of MMR or measles vaccine, some of which were given after the onset of AIDS. Prospective studies of cohorts of children born to HIV-infected mothers in Africa, the United States, and other countries provide further evidence of the safety of vaccines in HIV-infected children. For example, in the best studied cohorts in Zaire and Rwanda, 656 children with HIV infection and 1,088 non-infected children were vaccinated with BCG, DTP, OPV, and/or measles vaccine and observed for adverse events (30,31). Rates of common adverse reactions, speciÞcally fever and rash, were similar in both groups of children and no serious reactions were noted. National surveillance in the United States for adverse reactions to immunizations noted no increase in serious adverse events due to measles vaccine and no cases of vaccine-associated poliomyelitis in HIV-infected persons in the United States (CDC, unpublished data). An investigation has documented progressive vaccine-associated measles pneumonitis in a 20 year old AIDS patient

who received a second dose of measles vaccine to fulfill college requirements (32,33). The patient was severely immunosuppressed (CD4 T-lymphocytes "too few to enumerate"), although he was asymptomatic at the time of his vaccination one year earlier. The measles virus isolate recovered from the patient's lung tissue was genetically identical to the Moraten vaccine strain that he had received. Because of this case, evidence of diminished antibody response to measles vaccine among severely immunocompromised HIV-infected persons, and morbidity related to measles vaccination of severely immunosuppressed persons without HIV, the ACIP does not recommend measles vaccine for severely immunosuppressed HIV-infected persons (25). Severely immunocompromised patients and other symptomatic HIV-infected patients who are exposed to measles should received immune globulin prophylaxis regardless of vaccination status because they may not be protected by the vaccine (25). Serious illness associated with administration of rubella or mumps vaccines to HIV-infected persons has not been reported (25).

Adverse effects from vaccination have occurred in HIV-infected adults receiving vaccines not currently recommended for general use in the United States. An asymptomatic HIV-infected military recruit who received smallpox vaccine during basic training, later developed disseminated vaccinia and AIDS (34). Disseminated *Mycobacterium bovis*-BCG disease and regional lymphadenitis have occurred in persons with HIV infection who received BCG (35–38).

HIV-infected adults have been immunized with influenza and pneumococcal vaccines, as well as multiple other simultaneous vaccines, in a number of prospective studies. No unusual or more frequent adverse reactions have been observed in the immediate postvaccination period among HIV-infected persons (39–41). However, a recent large randomized, double-blind, placebo-controlled study of 23-valent pneumococcal vaccine in 1,392 HIV-infected adults in Uganda showed excess pneumonias in the vaccine recipients, including pneumonias with vaccine serotypes, and concluded that the vaccine should not be recommended in sub-Saharan Africa (42). The authors suggested a direct harmful effect of pneumococcal polysaccharides on polysaccharide-responsive B-cell clones as a possible cause. The HIV-infected population in sub-Saharan Africa where antiretroviral therapy is generally unavailable may be substantially different from the HIV-infected population in the United States. In addition, observational or case-control studies in the United States have not shown increased risk of pneumonias associated with pneumococcal vaccination and have shown benefit in HIV-infected populations with variable access to antiretroviral therapy (16,43,44). Therefore, most experts in this country believe the potential benefit of pneumococcal vaccination outweighs the risk and continue to recommend its use (7,11).

Data suggest that chronic hepatitis B surface antigen (HBsAg) carriage may be an unexpected consequence of hepatitis B vaccine in HIV-infected adults. In one study, HIV-infected men who received vaccine at the time they developed new hepatitis B infection were at increased risk of developing chronic HBsAg carriage compared to exposed unvaccinated HIV-infected men (45). Eighty percent of those who received their first dose and 56% of those who received a second dose at the time of hepatitis B infection became carriers compared with 21% of exposed unvaccinated men. This suggests that hepatitis B vaccine may temporarily impair the immune response to hepatitis B virus infection in HIV-infected men.

INFLUENCE OF VACCINATION ON HIV REPLICATION AND DISEASE PROGRESSION

Concern has been expressed that simultaneous administration of multiple antigens (even inactivated vaccines) may accelerate the progression of HIV disease by increasing HIV replication and activating CD4 cells (46,47). Retrospective review of clinical disease in a group of HIV-infected children who had received routine immunizations did not reveal any correlation between the number of vaccines received and subsequent progression to AIDS (29). Historically, prospective follow-up of HIV-infected men immunized with influenza and pneumococcal vaccines who received multiple simultaneous vaccines showed no clinical deterioration, although the observation periods were short (one to six months) for the majority of vaccinees (39,41,48,49). A cohort of 489 homosexual men enrolled in hepatitis B vaccine trials in 1978–1980 were retrospectively studied to determine progression to AIDS following hepatitis B infection or vaccination after seroconversion to HIV. When controlling for duration of HIV infection, there were no significant differences between 30 HBsAg carriers and non-carriers, 22 hepatitis B-infected and non-infected men or 56 hepatitis B vaccine recipients versus unvaccinated men in rates of progression to AIDS (50).

Laboratory indicators of increased HIV replication or adverse effect on immune function following vaccination have been studied by many investigators. Vaccination of 13 HIV-infected adults with a booster dose of tetanus toxoid resulted in activation of the immune system and transient increase in the expression of the HIV (47). Increases in HIV viral load following hepatitis B vaccination were not seen in ten patients who had moderate-to-severe immunosuppression (51). However, in another study, 20 patients with CD4 cell counts $>200/\mu l$ and receiving antiretroviral therapy were given standard hepatitis B vaccination (three doses), which was repeated (additional three doses) if they did not respond to the initial vaccination; transient viral load increase was seen in three patients, and a sustained increase in two patients (52). Increases in HIV viral load have been noted after

inßuenza or pneumococcal vaccination by some investigators (53Ð58). A double-blind trial of 47 HIV-infected patients randomized to receive inßuenza vaccine or saline placebo showed that Þve of 23 vaccine recipients had clinically signiÞcant increases in viral load compared with only one of 24 placebo recipients in at least one follow-up measurement up to one month after vaccination (58). However, a later trial by the same group that included 102 HIV-infected patients found no effect of inßuenza vaccination on plasma HIV-1 RNA levels or CD4+ cell counts (59). Other investigators have also found no increases in viral load following pneumococcal or inßuenza immunization (60Ð66). Viral load increases, when observed, appeared to be transient in most patients and did not appear to affect disease progression (55,64,65). More recent studies of HIV-infected patients undergoing highly active antiretroviral therapy (HAART) suggest that inßuenza (67Ð70) and pneumococcal (71) vaccination is safe and does not appear to induce any clinical deterioration. For example, Kroon et al. showed that viral load measured before, and nine and 30 days after, inßuenza vaccination was not increased in 13 of 17 patients on HAART with baseline viral loads of <400 copies/ml; of the remaining four, none had signiÞcant clinical change after administration of inßuenza vaccine (67). However, one study of 34 patients with undetectable viral loads at the time of inßuenza vaccination showed that seven had increased viral load after vaccination. Two of these patients had evidence of mutational changes in the HIV viral genome that might have contributed to resistance to antiretroviral therapy, and one patient failed therapy after vaccination (72). Although the effect on viral load of one immunization may be minimal, another concern has been the safety of reimmunization. A study of reimmunization with pneumococcal vaccine did not show changes in CD4+ cell counts or increases in viral load (73). A study of immune response to varicella vaccine in HIV-infected persons (who never had CD4+ cell counts <400) previously infected with varicella, found live attenuated varicella vaccine to be safe (74).

Similar concerns have been raised about reduction in CD4+ cell counts or increase in frequency of HIV-infected CD4+ cells following vaccination. Nine of 10 HIV-infected persons had a transient increase in frequency of infected CD4+ cells two weeks after inßuenza vaccination, which was greater in persons with high viral loads (75). A one-year prospective study of 90 HIV-infected men who received hepatitis A vaccine compared with 90 HIV-infected men (matched for CD4+ lymphocyte percentage at baseline) who were not vaccinated showed no differences in development of AIDS, deaths, or mean decline in CD4+ cell counts (76). Some studies have shown declines in CD4+ counts in HIV-infected adults vaccinated with pneumococcal or inßuenza vaccine (54,58), while others have not (57,59,61Ð66). A large observational cohort study of more than 36,000 HIV-infected persons showed no negative long-term effect of inßuenza vaccine on CD4 counts, HIV RNA levels, or progression to AIDS or death (15). They concluded that physicians should not withhold inßuenza vaccine because of concerns about long-term detrimental effects on disease progression.

In summary, transient viral load increases and CD4 declines shortly after immunization with some vaccines might be expected as a part of the normal immunologic response to antigenic stimuli and may be variably detected depending on the timing of follow-up examinations. At present, the effect on disease progression appears minimal. Nevertheless, vaccines may cause harm to HIV-infected persons. Therefore, the risks and beneÞts must be carefully weighed; in doing so, most experts and the ACIP continue to recommend inßuenza, pneumococcal, hepatitis A, hepatitis B, diphtheria, and tetanus as safe for most HIV-infected adults (11,77Ð81).

VACCINE-PREVENTABLE DISEASES IN HIV-INFECTED ADULTS

HIV infection is associated with profound defects in cell-mediated and humoral immunity, resulting in increased susceptibility to a variety of infectious agents.

Pneumococcus and *Haemophilus inßuenzae*

Polyclonal activation of B cells caused by HIV and the resulting decreases in speciÞc antibody responses and opsonization render HIV-infected persons susceptible to infection with the encapsulated bacteria, *Streptococcus pneumoniae* and *Haemophilus inßuenzae*. The increased incidence and severity of these infections in HIV-infected adults have been documented by examining mortality reports and pneumonia and inßuenza surveillance data. U.S. death rates for pneumonia and inßuenza (excluding *Pneumocystis carinii* pneumonia) in men 25Ð44 years had been declining for two decades until 1981. After 1981, rates increased each year with a 176% increase in deaths attributable to pneumonia or inßuenza in cities with the highest AIDS incidence (82). Pneumococcal and *H. inßuenzae* pneumonias were reported in homosexual men and intravenous drug users with AIDS early in the epidemic (83Ð85). The Þrst case reports of invasive pneumococcal disease in persons with AIDS, in 1984, also raised a question about the efÞcacy of pneumococcal vaccine in AIDS patients since one of the Þve cases had recently been immunized (83). Estimates of the annual incidence of community-acquired pneumococcal pneumonia in patients with symptomatic HIV infection were 17.9/1,000, 45.5/1,000, and 95/1,000 in three hospital-based clinical case series (83,86,87). These rates were several-fold higher than those in the general population or in non-AIDS patients admitted to the same hospitals (75,78,82). AIDS patients in San Francisco also had a

higher rate of pneumococcal bacteremia (9.4/1,000 person-years) than splenectomized patients (0.92–2.1/1,000 person-years), adults with sickle-cell disease (0.86/1,000 person-years), or community-based rates reported before the AIDS epidemic (7.5–16.4/100,000) (88). In New Jersey, the annual rate of invasive pneumococcal infections among persons 25–44 years was 0.0033% for the general population, 0.53% for persons developing AIDS within three years and 1.07% among AIDS patients (89). It is estimated that the rate of pneumococcal bacteremia among hospitalized patients with AIDS may be more than 100 times higher than that found in age-matched populations (90). Among a cohort of methadone-maintenance clients followed prospectively for one year, asymptomatic HIV-infected clients were five times as likely to be hospitalized with pneumococcal or *H. inßuenzae* pneumonia than HIV-seronegative drug users (91).

Since the advent of HAART, the incidence of invasive pneumococcal disease may have declined. A study of AIDS patients in San Francisco showed a decline in incidence from 10.6 to 4.2 cases of invasive pneumococcal disease per 1,000 person-years between October 1994 and June 1997; the incidence among persons without known HIV infection remained relatively stable during this time period at about 0.2 cases per 1,000 person-years (92). In this study, however, persons with HIV infection accounted for 54% of patients aged 18 to 64 years who had pneumococcal disease, and the risk for invasive pneumococcal disease for persons with AIDS was 46 times higher than for persons without known HIV infection. A study in Baltimore, Maryland, of 1,898 HIV-infected persons with CD4+ cell counts $<200/\mu L$ showed a decreased incidence of bacterial pneumonia from 22.7 episodes/100 person-years in 1993 to 9.1 episodes/100 person-years in 1997; use of protease-inhibitor containing antiretroviral regimens was associated with a decreased risk of bacterial pneumonia (93). In New York City, a study of hospitalization rates of HIV-infected persons showed that the incidence of hospitalizations with bacterial pneumonia decreased steadily between 1995–2001 from nearly 14 to three diagnoses per 100 patient-years (94). A study conducted in a hospital in Australia between 1996 and 2000 among HIV-infected patients, most of whom were on antiretroviral therapy, showed an incidence of invasive pneumococcal disease of only 1.9 per 1,000 person years. Because of low incidence and low vaccine efficacy (16 of 34 patients with invasive, presumptive or possible pneumococcal disease had been vaccinated), the authors suggested that the recommendation for routine pneumococcal vaccination of HIV-infected persons in Australia should be re-examined (95). In contrast, a large study of HIV-infected persons in care in the United States, showed an incidence of invasive pneumococcal disease of 8.2/1,000 person-years during 1990–1998, a period that spans the introduction of HAART; no significant decline in incidence was seen between 1994 and 1998 (16,96). Factors associated with an increased risk for invasive pneumococcal disease in that study included injection drug use, blood transfusion, black race, AIDS, and alcoholism; factors associated with a decreased risk included antiretroviral therapy and pneumococcal vaccination. A retrospective review of charts of HIV-infected patients seen in a pulmonary and critical care medical service showed that overall visits declined and *Pneumocystis carinii* pneumonia was less commonly diagnosed in persons taking HAART compared to the pre-HAART era (18% vs. 36%), while bacterial pneumonia was more common (47% vs. 29%) (97). In an Italian study comparing community-acquired bacterial pneumonia pathogens from 149 HIV-infected patients in the pre-HAART era (1995–1996) to 130 HIV-infected patients in the post-HAART era (1997–1998), both *H. inßuenzae* (4.7% vs. 6.1%) and *S. pneumoniae* (3.4% vs. 6.9%) were more commonly isolated post-HAART, although these differences were not statistically significant (98). In a county-level analysis of data from the Centers for Disease Control and Prevention's Active Bacterial Core Surveillance of Emerging Infections Program Network, the number of cases of invasive pneumococcal disease among adults 18–64 years of age, was directly associated with higher number of AIDS patients and larger total black population (99).

Two population-based studies have reported annual cumulative incidence rates of *H. inßuenzae* disease in HIV-infected persons. The study conducted in San Francisco reported rates of 79.2/100,000 in men with AIDS and 14.6/100,000 in those with HIV infection that had not progressed to AIDS (100). A study conducted in Atlanta reported an annual incidence of 41/100,000 in HIV-infected men regardless of AIDS status (the corresponding rate from the San Francisco study was 22.7/100,000) (101). The observed rate of 79.2/100,000 in men with AIDS in San Francisco is approximately 100 times the rate of invasive *H. inßuenzae* disease in the general adult population (102,103). Serotyping of isolates from the San Francisco study revealed that 33% were type b, and thus potentially preventable by current vaccines. In a study of 26 HIV-infected patients with *H. inßuenzae* pneumonia, 73.1% had a CD4+ cell count $<100/\mu L$ and mortality was 11.5% (104).

Clinical complications and recurrent infections are also more frequent in HIV-infected persons. In one study, AIDS patients with pneumococcal pneumonia had a survival rate of less that 50% compared to 75% for patients without HIV infection (105). Pneumonia due to penicillin-resistant pneumococci has also been reported (106, 107). In a study of colonization by *S. pneumoniae,* 25 of 34 isolates from 102 HIV-infected persons were penicillin-resistant compared with one of eight isolates from 39 non-HIV-infected controls (108). Mortality following invasive pneumococcal disease may be increased in HIV-infected persons depending on degree of immunosuppression. In a study of patients with pneumococcal bacteremia, 44 of 111 men and three of 41 women seen between 1989 and 1994 were

HIV-infected; 8.5% of HIV-infected patients and 3.8% of other patients died (109). A study of mortality from invasive pneumococcal pneumonia during 1995–1997 showed that AIDS (but not HIV infection without AIDS) was among the underlying diseases associated with elevated mortality; mortality was not elevated in most infections with β-lactam-resistant pneumococci (110). In contrast, a review of 153 episodes of invasive pneumococcal disease showed that HIV-infected persons had an increased rate of recurrence (15% vs. <1%); overall mortality was 12%, but this did not vary by HIV serostatus (111). An examination of U.S. death certificates showed dramatic overall declines in deaths with HIV or AIDS diagnoses after 1995 but found that the proportion of these deaths with unspecified pneumonia (non-*Pneumocystis carinii*) remained stable at about 14% (1% was specified as bacterial pneumonia) (112).

Thus, although the incidence of invasive disease due to *S. pneumoniae* and *H. influenzae* may be declining in the era of HAART, these infections remain an important cause of morbidity and mortality for HIV-infected persons. Effective prevention (if possible) of pneumococcal and *H. influenzae* infections would substantially decrease morbidity and mortality (83–86,90,103–115).

Pertussis, Influenza

Although *Bordetella pertussis* is increasingly recognized as a cause of respiratory illness in adults, and immunocompromised persons are known to be at risk of complications of influenza, these pathogens have rarely been reported in HIV-infected patients (116,117). Several case reports document the isolation of *B. pertussis* from HIV-infected persons with persistent cough which initially was incorrectly attributed to other respiratory pathogens (118–120). However, despite the increasing recognition of *B. pertussis* as a cause of respiratory disease in adults, pertussis appears to be rarely diagnosed in HIV-infected adults. In addition, HIV-infected persons do not appear to be a persistent reservoir for *B. pertussis* in the community. Among 60 HIV-infected adults, of whom 20 had a cough illness lasting >14 days, none had a positive isolation of *B. pertussis* from nasopharyngeal swabs (121).

Influenza viruses have also been isolated from HIV-infected patients initially suspected of having *Pneumocystis carinii* pneumonia (116,122,123). The increases in mortality in pneumonia and influenza surveillance data noted above occurred in the winter, concurrent with influenza activity, but the relative contributions of influenza and bacterial pneumonia are not known. Case series of HIV-infected patients diagnosed with influenza have been described (124,125). A series of 12 HIV-infected patients followed for five months after influenza was diagnosed showed no negative impact on CD4+ cell count, viral load, or clinical progression (125). Recent studies of HIV-infected persons with influenza showed no unusual clinical manifestations, although the hospitalization rate was higher than for HIV-negative persons (126,127). In a study of women aged 15–64 years, Neuzil et al. found influenza incidence rates and excess acute cardiopulmonary events requiring hospitalization higher among those who were HIV-infected (128). Excess mortality due to pneumonia or influenza has been found during influenza seasons among persons with AIDS (129).

Measles

Measles is known to be severe in immunocompromised persons with defects in cell-mediated immunity, including HIV-infected children both in the United States and in developing countries (130–132). Severe complications of measles include pneumonitis, measles-associated neurologic disorders (acute and subacute encephalitis), and myelopathy (133–137). Measles and measles-associated deaths in HIV-infected adults have been reported (133–138). Seven of 19 persons who died from measles complications in New York City during 1990–1991 were HIV-infected (138). A review of measles in HIV-infected persons reported the absence of rash in 27% of cases, and documented a case-fatality rate of 33% (136).

Because of the current epidemiology of measles in the United States, characterized by recurrent outbreaks of measles in inner city areas, HIV-infected persons may be at increased risk of exposure to measles. In 2000, 86 measles cases were reported in the United States; 57% were reported from three states—New York, California, and Nevada (139). Most cases were epidemiologically linked to international sources and the majority were in persons ≥5 years of age. In a review of seroprevalence studies of measles in HIV-infected adults, detectable measles antibody prevalence ranged from 79% to 99%, indicating that in those with pre-existing measles immunity, antibody is not lost despite progressive HIV-induced immunosuppression (140). Globally, the HIV epidemic has important implications for the control and eradication of measles because of primary and secondary failure of measles vaccine in HIV-infected children and adults, and issues of safety of vaccine for HIV-infected persons, including the theoretical risk that HIV-infected persons could become chronic carriers of measles (140,141).

An interesting phenomenon was recently reported by Moss et al. in a prospective study of 33 HIV-infected children hospitalized with acute measles in Zambia; they found that the median HIV RNA level was 5,339 copies/mL at entry, 60,121 copies/mL at discharge, and 387,148 copies/mL at one-month follow-up, and concluded that HIV replication was transiently suppressed in these children during acute measles (142).

Poliomyelitis

The Western hemisphere has been certified to be free of indigenous poliovirus since 1994, and substantial progress towards eradication has been reported from all regions (28). In the United States, except for religious communities opposed to vaccination, immunity to poliomyelitis is high among adults due to either vaccinations or natural infection, and no cases of poliomyelitis have been reported among HIV-infected adults. However, exposure to poliovirus could occur through reintroduction by visitors to the United States or travel to the developing world. In an outbreak of wild type 1 poliovirus among predominantly unvaccinated gypsy children in Romania in 1991, four (31%) of 13 paralytic cases occurred among HIV-infected children (143). In addition, the first published report of vaccine-associated paralytic poliomyelitis in an HIV-infected child was from Romania in 1993 (21); only one other subsequent case has been reported from Zimbabwe (22). It is uncertain whether HIV infection played any role in the etiology of paralytic poliomyelitis in these six children. One possible explanation in the Romanian outbreak was that they were exposed to a risk factor (e.g. non-sterile intramuscular injections) which placed them at increased risk of both HIV infection and provocation paralytic poliomyelitis (143,144). Recent outbreaks of poliomyelitis (including one in Hispanola) due to vaccine-derived poliovirus have important implications for current and future vaccination strategies for eradication of polio worldwide and stress the importance of maintaining vaccination coverage, especially among travelers to endemic areas (145).

Hepatitis A

Many persons at risk for HIV infection (i.e. men who have sex with men, injecting and non-injecting substance users, and high risk heterosexuals) are frequently also at risk of acquiring hepatitis A (146–153). For example, seropositivity for hepatitis A virus antibody in Baltimore was found in 32% of 300 homosexual men, 66% of injecting drug users and 14% of 300 blood donors (152). A study of 185 homosexual and 70 heterosexual men seen in an outpatient genitoruinary medicine clinic in the United Kingdom showed that 32.4% and 30.0%, respectively, were seropositive for hepatitis A; 48.1% of the homosexual men were HIV-positive compared with 4.3% of the heterosexual men (150).

A description of nine HIV-infected persons with relatively well-preserved immune systems (CD4 count range of 239–774 cells/μL) who acquired hepatitis A all had spontaneous recovery without progression of their HIV disease (154). Antiretroviral therapy was suspended for the seven patients who were receiving it, however, the utility of stopping antiretroviral therapy is not known (155). Increases in HIV viral load and declines in CD4 counts during acute hepatitis A have been observed in HIV-infected patients who were previously well-controlled but stopped their antiretroviral therapy during hepatitis A illness (156,157). Ida et al. reported an outbreak of hepatitis A in homosexual men in Japan; 51 (38%) of 137 homosexual men were positive for anti-HAV IgG antibodies. Twenty-three patients had typical symptoms of acute hepatitis A and 28 were asymptomatic; of the asymptomatic patients, 11 had evidence of recent seroconversion (158). The difficulties of vaccinating adults in high risk groups was illustrated by a survey of 210 men who have have sex with men (MSM) in Georgia following an outbreak of hepatitis A and a vaccination campaign in this community; only 66% were aware of the recent outbreak and of the 178 MSM with no previous vaccination or history of hepatitis A, only 19% received the vaccine during the campaign (159).

Fulminant hepatitis associated with hepatitis A superinfection in patients with chronic hepatitis C has been reported (160). The increased risk for both infections in many HIV-infected persons, this observation further supports hepatitis A vaccination for those with hepatitis C co-infection.

Hepatitis B

As for hepatitis A, behaviors such as illicit substance use and high risk sexual practices that place individuals at risk for HIV infection also increase their risk for hepatitis B, so co-infection is common (161–166). In addition, HIV-infected persons are at increased risk of becoming chronic HBsAg carriers once exposed. Hadler et al. (45) reported that among exposed HIV-uninfected men, 7% became carriers compared with 21% of 14 exposed HIV-infected men. Bodsworth et al. (167) found a similar increased risk of HBsAg carriage in HIV-infected men. Similar findings were reported by Taylor et al. (168); 20% of HIV-infected men became carriers compared with 6% of those without HIV infection. HIV-infected persons also have higher levels of viremia (169–171). These data indicate that the current epidemiology of HIV will have a major impact on the risk of hepatitis B carriage. In contrast to the early years of the AIDS epidemic, many high-risk persons are exposed to hepatitis B after they are infected with HIV, resulting in higher carriage rates and facilitating transmission of hepatitis B. Among HIV-infected patients, co-infection with hepatitis B or C correlates with reduced survival (172). A recent study of the incidence of acute hepatitis B infection in a large observational cohort of HIV-infected persons in care showed that hepatitis B vaccination and prolonged time on antiretroviral therapy were associated with a decreased incidence of hepatitis B (14).

Varicella Zoster

Since over 90% of adults in the United States have serologic evidence of previous varicella zoster virus exposure, reactivation (herpes zoster) is a frequent manifestation of immune compromise in HIV-infected adults, sometimes with a severe clinical course. A serosurvey of HIV-infected adults found that 95% had antibody to varicella, including patients with < 200 CD4 T-lymphocytes (173). Another serosurvey of 281 HIV-infected pregnant women with no history of chickenpox found that only three women had no varicella antibody. One later developed clinical varicella (174). However, primary varicella infection, documented by seroconversion, was reported in nine HIV-infected adults with no history of varicella (175). One fatality occurred in spite of acyclovir therapy. Although four of the nine patients reported household contact with a child with chickenpox and two were infected by other hospitalized patients, postexposure prophylaxis with varicella immune globulin was not given in any of these cases. HIV-infected persons may be at higher risk for development of recurrent zoster (176,177).

Other Vaccine-Preventable Diseases

There have been no reports of mumps, rubella, respiratory diphtheria, or tetanus in HIV-infected persons. Although often considered childhood illnesses, all these diseases have been reported increasingly in adults in recent years and the more serious complications occur in older persons or their fetuses. During 1985–1992, the age distribution of mumps and rubella cases shifted from the under-10 year old age group in the prevaccination era to adolescents and young adults, a group that is relatively underimmunized (178,179). Outbreaks of mumps and rubella on college campuses and in the workplace have led to recommendations for vaccination of susceptible adolescents on college entry and child-bearing women postpartum (178,179). Recently, an increasing proportion of reported rubella cases have occurred in persons of Hispanic ethnicity; therefore, persons from countries without rubella vaccination programs should be evaluated for susceptibility (180). In 1985–1989, 92% of tetanus and 64% of diphtheria patients were adults who were inadequately immunized (181).

IMMUNOGENICITY OF RECOMMENDED VACCINES IN HIV-INFECTED PERSONS

A number of studies have compared immunogenicity (i.e. the serologic response postvaccination) in HIV-infected persons with that in healthy HIV-seronegative controls (Table 38.2). Difficulties comparing studies include different classifications of HIV disease, differences in antiretroviral treatment and response to treatment, different vaccines used, and different serologic measures of immunity reported. In general, these studies have shown that responses are impaired as HIV-induced immunosuppression progresses and that even in responders, antibody levels achieved may be lower than in healthy persons. Responses to immunization attempted after the onset of HIV infection appear to be lower than responses to antigens encountered prior to HIV infection. Vaccine-induced antibody may also decline over time to a nonprotective level as other immunologic functions deteriorate. Pirofski and Casadevall provide an excellent perspective on immunogenicity and use of licensed vaccines in the immunocompromised host (182). With the advent of HAART, the resulting partial restoration of immune function, and the prolonged lifespans of HIV-infected persons, vaccine immunogenicity must be re-evaluated.

Polysaccharide Vaccines

One of the earliest indications of the B-cell dysfunction characteristic of AIDS was the poor response of AIDS patients to immunization with T-cell-independent antigens, such as pneumococcal polysaccharides. Immunogenicity studies in different groups of HIV-infected people showed that fewer HIV-infected persons respond to vaccinations than seronegative controls (Table 38.2). Pneumococcal vaccine failures in HIV-infected patients with or without AIDS have been reported (83,84,183,184). Response rates are higher in asymptomatic HIV-infected persons and those with higher levels of CD4 counts compared to AIDS patients and those with □500 CD4 cells/μL (39,185), however, immunogenicity may not depend on CD4 cell count (186–188). Kroon et al. observed normal antibody levels post-vaccination in HIV-infected individuals, including those with □100 CD4 lymphocytes (186). Recent HIV seroconverters and HIV-infected persons with CD4 count > 500 cells/μL also appear to have normal responses (64,189). There are differences in immunoglobulin responses by class; HIV-infected patients had nearly normal IgG responses, while IgM and IgA responses were depressed (190,191).

In spite of the poorer response of some HIV-infected persons, there are indications that vaccination may be useful. Klein et al. noted that 87% of all HIV-infected intravenous drug users and persons infected via heterosexual transmission had a rise in antibody to greater than 400 ngAbN/ml to one or more vaccine types (40). Overall, protective antibody levels to 35% of capsular types were achieved in HIV-infected intravenous drug users and to 54% of capsular types in their infected sex partners. At one year follow-up, in another study, there were no significant differences in the proportions of asymptomatic HIV-infected homosexual men and HIV-negative homosexual men who retained antibody after vaccination, although the level of antibody was lower in the HIV-infected men (49).

HIV, human immunode ciency virus; AIDS, acquired immunode ciency syndrome; ARC, AIDS-related complex; PGL, persistent generalized lymphadenopathy; Hib, *Haemophilus inßuenzae* type B polysaccharide (PRP) and conjugate vaccines; IPV, inactivated poliovirus vaccine; HBV-plasma, plasma derived hepatitis B vaccine; HBV-recomb, hepatitis B recombinant vaccine; NA, not available; AZT, zidovudine; HAART, highly active antiretroviral therapy.

[a] De nition of response varied by study and type of serologic test performed. Percent indicates proportion attaining speci ed antibody level or signi cant titer rise. When a range is given, the percentage varied by serotype.

[b] Geometric mean titer (GMT) in HIV-infected persons equal to controls for speci ed number of capsular types.

[c] Mean titer of antibody postvaccination in μg/ml or reciprocal log dilutions. When a range is given, titers varied by serotype.

[d] Ratio of post vaccination to prevaccination titers.

[e] From < 1.0 ug/ml to > 1.0 ug/ml of PRP determined by ELISA.

[f] Percentage of patients who had □4-fold increase in hemagglutination antibody titers over baseline. When range is given, the percentage varied by antigen.

[g] HIV-negative controls with hemophilia.

Other data indicate that AIDS patients who were treated with zidovudine for a mean of 17.7 weeks prior to vaccination had a signiÞcantly increased response compared to untreated AIDS patients (aggregate GMT 770 vs. 369)(192). However, Loeliger et al. did not Þnd any correlation between antiretroviral therapy and response to vaccination (193). Immunologic response to pneumococcal vaccine in the context of HAART-associated immune reconstitution needs further assessment (194).

HIV-infected persons who do not initially respond to pneumococcal vaccine do not appear to beneÞt from re-vaccination (73,195). Among those who do respond, speciÞc anti-pneumococcal antibodies also rapidly wane after vaccination (188). Talesnik et al. found that about half of initial responders maintained an immune response after one year (196). In another study, follow-up of HIV-infected responders at one and two years after immunization showed similar IgG levels compared with healthy controls (195). Kroon et al. found that immune response is impaired in HIV-infected persons with CD4 counts < 200/μL and this results in a low concentration of antibodies, which declines below the level considered to be adequate for protection within three years (197). They suggested that re-vaccination every three years should be considered for HIV-infected persons. This recommendation is more frequent than current guidelines and needs further evaluation (11).

Unlike the experience with conjugated *H. inßuenzae* vaccines, pneumococcal glycoprotein conjugate vaccine did not elicit higher antibody levels than the polysaccharide vaccine (198). However, two recent studies have been conducted to examine the possibility of enhancing and prolonging the immune response to pneumococcal vaccine in HIV-infected individuals by using a conjugate vaccine followed by a polysaccharide vaccine (199,200). Both studies showed higher antibody concentrations after sequential vaccination with conjugate vaccine and polysaccharide vaccine compared with polysaccharide vaccine alone. Feikin et al. concluded that although the beneÞts of adding conjugate vaccine were not dramatic, a dose of conjugate vaccine and a dose of 23-valent polysaccharide vaccine may be optimal (200).

Over 85% of pneumococcal serotypes causing invasive disease in HIV-infected persons are contained in the currently licensed 23-valent vaccine (90,109), however, because of the relatively poor immunogenicity reported in many studies and waning immunity, the efÞcacy of pneumococcal vaccine in preventing invasive pneumococcal in HIV-infected persons remains controversial (80,95,98,114,201). A large prospective clinical efÞcacy trial in HIV-infected persons was recently conducted in Uganda and showed no protective effect; on the contrary, all-cause pneumonia was signiÞcantly more frequent in the vaccine arm (42). A meta-analysis of randomized controlled trials in adult populations (HIV-infected

patients were included in some of these trials, but were not the primary focus) showed pneumococcal vaccinaton to be efÞcacious in low-risk adults but not in those at high-risk (202). A small study of 48 HIV-infected drug users, some of whom were treated with HAART, also showed no protective effect of pneumococcal vaccine against all-cause pneumonia (203). A recent study in Australia questioned the cost-effectiveness of pneumococcal vaccination because of the low incidence of pneumoccocal disease in patients on antiretroviral therapy and the lack of evidence for efÞcacy; of 34 patients with invasive, presumptive, or possible pneumococcal disease, 16 (47%) had received pneumococcal vaccine (95). Chang et al. have suggested that a possible mechanism for pneumococcal vaccine failure in HIV-infected persons is an aberrant response to pneumococcal vaccine by peripheral B cells (204). Support for pneumococcal vaccine efÞcacy in the United States comes from retrospective case-control studies and longitudinal cohort studies. A case-control study of 85 HIV-infected cases of pneumococcal infection in which the comparison group consisted of HIV-infected patients without pneumococcal disease, showed signiÞcant protection for the pneumococcal vaccine in persons with CD4 > 200 cells/μL (43). Guerrero et al. conducted a retrospective case-control study of more than 2,000 HIV-seropositive patients followed in a large outpatient clinic from 1990 though 1998 (205). Cases of pneumonia (other than *Pneumocystis carinii* pneumonia) were matched by CD4 cell counts to controls without pneumonia. Pneumococcal immunization was associated with 70% reduction in risk of pneumonia. Breiman et al. conducted a case-control study of 176 HIV-infected patients with documented invasive pneumococcal disease compared with age- and CD4 count-matched controls and found overall that pneumococcal vaccine effectiveness was 49% (44); effectiveness among whites was signiÞcant at 76%, but not among blacks at 24%. In a large observational cohort study of nearly 40,000 HIV-infected persons with more than 70,000 person-years of observation, Dworkin et al. found vaccine to be protective in persons with CD4 cell count □500 cells/μL at the time of vaccination, but not in those with lower CD4 counts (16). Pneumococcal vaccination has been found to be cost-effective for HIV-infected persons in two analyses (206,207).

The rationale for immunizing HIV-seropositive adults against *Haemophilus inßuenzae* type b (Hib) has been debated due to the lower incidence of Hib infections in adults compared with children (113). Although asymptomatic HIV-infected men immunized with Hib polysaccharide vaccine had lower levels of antibody post-vaccination than HIV-negative controls, levels in both groups were protective (□1.0 ug/ml) (208). A trial of Hib polysaccharide vaccine (PRP) and ribosylribitol phosphate conjugated with diphtheria toxoid (PRP-CRM) Hib vaccine reported that these vaccines were most immunogenic in descending order among persons who were: (1) HIV-negative; (2) HIV-positive but asymptomatic; (3) diagnosed with AIDS-related complex; and (4) AIDS (209). One month after vaccination, 100% of HIV-negative persons had antibody levels of > 1.0 ug/ml, compared with 97.5% of HIV-positive but asymptomatic persons, 95% of patients with AIDS-related complex, and 80% of patients with AIDS. The conjugated Hib vaccine (PRP-CRM) was more immunogenic (e.g. mean titers, percent > 1.0 ug/ml) than the unconjugated Hib vaccine (PRP) among all groups, except in patients with AIDS who responded better to the PRP vaccine (207). Kroon et al. also found impaired response to conjugated Hib in HIV-infected persons with CD4 counts < 100/μL (210). A comparison of three licensed Hib vaccines in HIV seropositive adults most of whom were on triple-drug antiretroviral therapy showed that all three vaccines were immunogenic in these patients; response was poorer with lower CD4 cell counts and lower IgG2 levels at baseline (211). A study of recent HIV seroconverters showed that response to Hib conjugate vaccine was similar to that of HIV-negative controls (189).

Inßuenza Vaccine

The inßuence of stage of HIV disease on the ability to respond to immunization is clearly demonstrated in prospective studies of inßuenza vaccination of HIV-infected patients with a spectrum of clinical manifestations (Table 38.2). Interestingly, at all stages of HIV disease, responses to inßuenza A hemagglutinins H1 and H3 were higher than responses to inßuenza B antigen (48,212). The proportion of symptomatic HIV-infected patients who respond to monovalent inßuenza A and trivalent inßuenza A and B vaccines was much lower than for seronegative controls (48,186,212,213). The number of CD4 cells present at vaccination was related to antibody titers achieved postvaccination (48,65,186,214). Higher viral load has also been found to correlate with poorer response to vaccination, but on multivariate analysis only CD4 count remained predictive (65). AIDS patients receiving zidovudine had similar CD4 counts as AIDS-related complex (ARC) patients and their responses to immunization were intermediate between those of untreated AIDS patients and ARC patients. The proportions of asymptomatic patients and those with persistent generalized lymphadenopathy who acquired protective levels of antibody were equal to controls for all three vaccine antigens (inßuenza H1 and H3 and inßuenza B) in two studies (39,212) and for one or two antigens in the other two reported studies (48,213). A study of HIV-seropositive drug users showed that those with CD4 counts > 500 cells/μL responded to inßuenza vaccine as well as HIV-seronegative drug users; however, those with CD4 counts < 500 cells/μL showed impaired reactivity (215). GŸnthard et al. found that HIV-infected patients on HAART therapy with relatively high CD4 cells counts responded as well as or better than healthy controls to

inßuenza vaccine (68). However, other investigators have found that HIV-infected patients on HAART, especially those with with higher viral loads and lower CD4 counts, responded less well than healthy controls (69,216,217). Thus inßuenza vaccination, if given early in the course of HIV infection, should provide a measure of protection.

In an attempt to improve vaccine responses, investigators (186,212) studied the effect of a booster dose of vaccine given one month after the Þrst dose. In general, the booster dose did not improve responses in HIV-infected persons. The booster dose increased antibody to protective levels ($\geq$ 1 : 64) in only one asymptomatic HIV-infected person and had no effect on levels in ARC patients. Of 30 AIDS patients on zidovudine therapy, the proportion who reached a protective level of antibody increased from 30% to 33% for H1 antibody, from 37% to 47% for H3 antibody, and from 13% to 17% for antibody to inßuenza B after the booster dose. In a more recent study with three-year consecutive follow-up for annual re-vaccination, signiÞcantly higher prevaccination antibody was seen in the second and third year of vaccination in healthy controls, but not in HIV-infected individuals (218). The authors concluded that annual vaccination of HIV-infected persons with a CD4 cell count $>100/\mu L$ seemed worthwhile.

Tasker et al. evaluated the clinical efÞcacy of inßuenza vaccine in a randomized, double-blind, placebo-controlled trial of 102 HIV-infected persons (the majority had CD4 counts >200 cells/μL and were on antiretroviral therapy) during the fall of 1995Ð1996 inßuenza season (59). Ten placebo recipients and no vaccine recipients had laboratory-conÞrmed symptomatic inßuenza; thus, protective efÞcacy was 100% although response to the vaccine was only 12% for A/Texas (H1N1), 29% for A/Johannesburg (H3N2), and 36% for B/Harbin components.

Diphtheria and Tetanus Toxoids

After primary immunization with tetanus toxoid in childhood, almost all HIV-infected adults maintain protective levels of antibody ($\geq$ 0.01 ug/ml) after the onset of HIV infection (219). Similar experiences have been reported from Africa and Haiti, where HIV-infected women were found to have the same levels of tetanus antibody after two doses of vaccine given during pregnancy as HIV-negative women (220,221). All of 78 Danish HIV-infected men, who probably received primary vaccination with diphtheria and tetanus toxoids before they contracted HIV infection, had tetanus antibodies above the protective level (219). However, 24 (31%) of these same men were unprotected (<0.01 ug/mL) against diphtheria compared to 10% of men of similar age in the general population. Thus, despite adequate vaccinations during childhood, HIV-infected adults appear more likely to be susceptible to diphtheria than non-HIV infected adults. Increases in antibody levels after booster doses of diphtheria and/or tetanus toxoid vaccine were lower in asymptomatic HIV-infected persons than in controls, however, almost all HIV-infected persons maintain protective levels of anti-tetanus toxin antibody (41,186,222). Decreased response in HIV-infected men correlated with the lack of proliferative responses of peripheral blood mononuclear cells postvaccination when exposed to tetanus toxoid *in vitro* (222). However, when tetanus toxoid was coupled to agarose beads creating a T-cell-independent antigen, *in vitro* responses did occur. HIV-infected adults with CD4 lymphocyte counts <300 appear to have impaired secondary (booster) antibody responses to diphtheria and tetanus toxoids (186,223). Talesnik et al. found that only 23% of HIV-infected patients had antibody response to tetanus toxoid at two months after a booster dose, which waned to below minimum protective levels by 12 months (196). Valdez et al. evaluated the recall response to tetanus toxoid in 31 HIV-infected patients receiving HAART for at least 48 weeks; 48% had a four-fold increase in antibody concentration and all patients developed protective levels (3). They recommended that clinicians consider re-immunization of HIV-infected patients after initiation of HAART to restore lost responses to recall antigens. Takano et al. found that fully immunized HIV-infected children without protective antibody levels at baseline had good response to tetanus and diphtheria booster after receiving HAART (224). In another study, children receiving HAART responded well to tetanus toxoid but not to diphtheria immunization; response correlated with immune status (225). The effect of intermittent cycles of interleukin-2 (IL-2) on response to immunization was evaluated in HIV-infected patients on HAART (226). In this study, while IL-2 increased the number of circulating CD4 cells, response to tetanus toxoid was not improved.

Measles, Mumps, and Rubella Vaccine

Most data on the response to measles vaccine are from children in developing countries (132,227,228). There are few data for rubella vaccine and none for mumps. In one study in Zaire, response rates after measles vaccination at nine months of age were related to severity of HIV infection. Among HIV-uninfected, asymptomatic HIV-infected, and symptomatic HIV-infected children, 89%, 77%, and 36% responded to vaccine, respectively (132). In a study in the United States, only three (12.5%) of 24 vaccinated HIV-infected children studied retrospectively had antibody to measles virus; however, a larger number of children had antibody when tested by a more sensitive assay (229). In the same study, among children studied prospectively, only two (25%) of eight responded to measles vaccination. In a larger study, among 127 HIV-infected children, only 35% had documented vaccination

with measles-mumps-rubella (MMR) (230). Of the 80 children whose pre-vaccination serology results were available, 56% were measles antibody-negative and 40% were antibody-positive; after re-vaccination 36% remained antibody negative. Arpadi et al. studied 81 perinatally HIV-infected children and found that 83% who were tested within one year of measles vaccination had detectable antibody compared with 52% who were evaluated more than a year after vaccination (231). The proportion of children with detectable measles antibody was also higher among those with no or moderate immunosuppression. Brena et al. found that at two months post-MMR vaccination, 11 of 20 HIV-infected children had adequate antibody to measles while 12 of 13 HIV-seroreverters responded (232).

Most HIV-infected adults will either have received MMR vaccine during childhood or have had natural disease. Several studies have found that most HIV-infected adults have protective levels of measles antibody (233–237). However, lower levels of measles antibody were reported from two studies of prison inmates (238,239), among women (240), and in persons born in the United States in 1957 or later (237). Data suggest that after primary immunization or disease in childhood, HIV-infected adults retain protective measles antibody regardless of progression of HIV disease (237,241). Only one study has evaluated the response of HIV-infected adults to measles and rubella vaccination. In this study, only three of 39 HIV-infected and two of 17 healthy vaccinees were measles seronegative at the time of vaccination. Of those who were measles seronegative, none of the HIV-infected adults and one of the healthy adults seroconverted (238). Four HIV-infected and three healthy vaccinees were rubella seronegative at the time of vaccination: three and two, respectively, responded to vaccination.

Antiretroviral therapy may improve serologic response to measles vaccine. A recent study of 28 HIV-infected children who lacked measles antibody after initial measles vaccination showed that nine (64.3%) of 14 children undergoing HAART responded to an additional MMR vaccination compared with only three (21.4%) of 14 children undergoing non-HAART regimens. The HAART group had lower mean viral load (27,700 copies/mL) compared with the non-HAART group (86,000 copies/mL); there was no difference in CD4 counts between the groups (242).

Hepatitis A Vaccine

The immunogenicity of hepatitis A vaccine in HIV-infected adults has been evaluated in several studies (243–246). In a study of 25 HIV-infected persons with hemophilia, eight HIV-negative hemophilic controls, and 25 HIV-negative healthy adults, all persons in both control groups responded to one dose of vaccine; however, among HIV-infected persons response was delayed (243). Of the 17 HIV-infected persons who completed all three doses of vaccine and follow-up serologies, four (24%) failed to respond. In a hepatitis A vaccine study in 14 HIV-positive homosexual men compared with 20 HIV-negative men, 77% and 100%, respectively, responded after seven months; mean antibody titres were higher in the HIV-negative men (244). In another similar study, 88% of 90 HIV-infected compared to 100% of 44 HIV-negative homosexual men responded to two doses of hepatitis A vaccine; HIV-infected men who responded had significantly higher CD4 counts at baseline than those who did not (245). Wallace et al. conducted a randomized trial of hepatitis A vaccine compared with placebo in 90 hepatitis A IgG seronegative HIV-infected persons (equal numbers having CD4 count >300 cells/μL and <300 cells/μL). In the vaccinated group, 64% had antibody to hepatitis A by week 4 and 96% by week 28 (246). Changes in antiretroviral therapy were discouraged during the trial; there were no differences noted between vaccine and placebo groups in viral loads or CD4 counts. However, in another study, Kemper et al. found that 68% of HIV-infected persons with CD4 count >200 cells/μL responded to hepatitis A vaccine compared to only 9% of those with CD4 count <200 cells/μL (247).

Hepatitis B

Several studies have demonstrated an impaired response to hepatitis B vaccine in HIV-infected adults (Table 38.2). Three studies in HIV-infected homosexual men, using plasma-derived vaccine, found that 50–56% of HIV-infected adults seroconverted compared with over 80% of HIV-uninfected controls (248–250). Similar results have been reported in studies of HIV-infected hemophiliacs (251). Studies of recombinant vaccine have found similarly low immunogenicity in HIV-infected persons (248,252–255). Re-vaccination of HIV-infected persons who do not respond to the three-dose primary series produces poor results. In a small study, one of six HIV-infected persons, who did not respond to the initial vaccine series, seroconverted after a second series compared with 50% of uninfected adults (256). Among those who responded to vaccine, no difference in geometric mean titers between HIV-infected and uninfected vaccinees was reported by Carne et al. (249); however, lower levels were found in other studies (248,252). In addition to low seroconversion rates in HIV-infected persons, accelerated loss of hepatitis B surface antibody in responders has been reported (257). Thirty-six percent of 75 men without HIV infection lost protective levels of antibody within five years of vaccination compared with 63–86% of 21 men who acquired HIV infection before or during the hepatitis B vaccination series. However, good persistence was reported in another study (258). Among HIV-infected persons who responded to vaccine, vaccine may not

protect against infection but may protect against serious illness: among 17 HIV-infected responders who were subsequently infected with hepatitis B virus, none had severe illness or became chronic carriers (45). Rey et al. enhanced overall response rate to hepatitis B vaccine in HIV-infected patients from 55% with the standard three doses, to 90% by giving initial nonresponders three additional doses (52). Veiga et al. showed that humoral response to hepatitis B vaccination diminishes with decreasing CD4 cell count in HIV-infected persons on HAART and suggested that individuals with CD4 count >200 cells/μL would beneÞt most from vaccination (Table 38.2) (259).

Poliovirus Vaccines

In two small studies, all but one of 22 HIV-infected patients had antibody to all three poliovirus types prior to vaccination with inactivated poliovaccine (IPV) (Table 38.2). The patients had all been vaccinated with poliovirus vaccine in childhood or were exposed to wild polioviruses. Following vaccination, asymptomatic HIV-infected men all responded similarly as uninfected men with substantial increases in antibody. However, none of the symptomatic HIV-infected men had a booster response to IPV. In a study comparing the antibody response to a booster dose of IPV among HIV-infected vs. uninfected hemophiliac patients, both groups responded with increased antibody titers to the three poliovirus types; however; HIV-negative patients exhibited higher titers than the HIV-positive group (260).

RECOMMENDATIONS FOR IMMUNIZATION OF HIV-INFECTED ADULTS

Recommendations for immunization of HIV-infected persons have been made and regularly updated by the Advisory Committee on Immunization Practices (ACIP) (6,10) and the U.S. Public Health Service/Infectious Diseases Society of America (USPHS/IDSA) (11). These are summarized in Table 38.3. Recommendations from disease-speciÞc ACIP guidelines are also included.

Pneumococcal and *H. inßuenzae* type B Vaccines

The use of inactivated vaccines poses no risk of serious adverse events and may be beneÞcial for HIV-infected persons. Although the response to immunization may be less than optimal in HIV-infected persons, the USPHS/IDSA recommends that all HIV-infected persons with CD4+ T-lymphocyte count of >200 cells/μL be immunized with a single dose of 23-valent polysaccharide pneumococcal vaccine if they have not received this vaccine during the previous Þve years (11). Immunization should be considered for persons with CD4 count of <200 cells/μL although clinical efÞcacy has not been conÞrmed for this group. Re-vaccination can also be considered for persons with CD4 counts <200 cells μ/L at initial immunization but whose CD4 count has increased to □200 cells/μL on HAART. The duration of the protective effect of pneumococcal vaccine is unknown. Because rapid declines in antibody levels may occur in persons with HIV infection, a single re-vaccination can be considered after Þve years. However, clinical beneÞts of re-vaccination have not been proven (11). Studies to date have shown no beneÞcial effects of re-vaccination in initial non-responders (195). Sequential immunization of HIV-infected adults with pneumococcal polysaccharide vaccine after prior immunization with conjugate pneumococcal vaccine resulted in enhanced antibody response in one study which may have implications for future vaccination policies (190).

Since the incidence of *H. inßuenzae* type B disease is low, *H. inßuenzae* type B vaccine is not generally recommended for adult use in this country (11). If given, the greatest beneÞt from immunization will occur when HIV-infected patients are immunized before the onset of immunocompromise and possibly after immune restoration with HAART. In studies of recent HIV seroconverters (duration of HIV infection <18 months and mean CD4 cells >500), responses to pneumococcal and *H. inßuenzae* type B conjugate vaccine were equal to those of uninfected controls (189). Others have demonstrated that immune response to *H. inßuenzae* type B vaccine is related to CD4 count with a deÞnite impairment in response at CD4 <100 cells/μL. Although the USPHS/IDSA guidelines do not recommend the vaccine, because incidence of *H. inßuenzae* type B disease may be higher among some HIV-infected adults (100,101), the ACIP recommends the vaccine be considered while taking into account the risk of disease (6).

Inßuenza Vaccine

Inßuenza vaccine should be given annually, because the prevalent virus strain and the vaccine composition changes each year (78). In addition, medical personnel and household members who may expose HIV-infected persons should be vaccinated to prevent transmission of inßuenza virus. Because vaccine efÞcacy cannot be assured, if exposure to inßuenza has occurred or is suspected, chemoprophylaxis with one of the following antiviral agents may be considered: amantidine (inßuenza A), rimantidine (inßuenza A), oseltamivir (inßuenza A or B), or zanamivir (inßuenza A or B). Chemoprophylaxis should be considered for HIV-infected patients (especially those with advanced disease) who may be expected to have a poor response to immunization, although the efÞcacy of these agents in preventing inßuenza among severely immunocompromised persons is unknown (78).

TABLE 38.3. *Recommendations for immunization and prophylaxis of HIV-infected adults, United States*

Disease	Vaccine	Type	Prophylaxis	Recommendation for vaccination
Pneumococcal	Pneumococcal	23-valent polysaccharide		Recommended for patients with CD4 □200 cells; offer to patients CD4 with < 200 cells. Vaccinate as close to diagnosis as possible when CD4 counts are highest. Consider re-vaccinating once if > 5 years have elapsed since initial vaccination.
H. inßuenzae type B	*H. inßuenzae* type B (Hib)	Polysaccharide conjugate		Not recommended by USPHS/IDSA; ACIP recommends considering vaccine for patients at high risk of *H inßuenzae* type B disease.
In uenza	Trivalent in uenza	Inactivated viral	Amantadine or rimantadine (for in uenza A only); oseltamavir or zanamivir (for in uenza A or B)	Recommended for all patients each year.
Tetanus	Tetanus-diphtheria (Td)	Toxoid	Tetanus immune globulin	Primary series (usually in childhood) followed by booster every 10 years.
Diphtheria	Td	Toxoid		Primary series (usually in childhood) followed by booster every 10 years.
Poliomyelitis	Inactivated poliovirus vaccine (IPV)	Inactivated viral		Routine vaccination of adults residing in the United States is not necessary. Consider for persons at risk of exposure to polioviruses, e.g. travel to an endemic area.
	Oral poliovirus vaccine (IPV)	Live viral		Contraindicated.
Measles	Measles-mumps-rubella (MMR)	Live viral	Immune globulin (IG)	Consider for adults without severe immunosuppression and born after 1957 if they have no documentation of previous vaccination or are seronegative for measles antibody; contraindicated for those who are severely immunosuppressed.[a]
Mumps	MMR	Live viral		Consider for adults without evidence of immunity, without documentation of vaccination, or born after 1957. Same contraindication as for measles.
Rubella	MMR	Live viral		Offer to women of childbearing age without documented evidence of rubella immunity. Same contraindication as for measles.
Hepatitis A	Hepatitis A	Inactivated viral	IG	Offer to susceptible persons at high risk of expsoure (see Text). Two doses given 6–12 months apart.
Hepatitis B	Hepatitis B	Recombinant, inactivated viral	Hepatitis B immune globulin	Offer to all susceptible persons. Three doses: one month between 1st and 2nd dose; six months between the 2nd and 3rd dose.
Varicella	Varicella	Live viral	Varicella zoster immune globulin (VZIG)	Vaccine is not recommended for adults at this time.

ACIP, Advisory Committee on Immunization Practices; USPHS/IDSA, U.S. Public Health Service and Infectious Diseases Society of America.

[a] CD4 + T-lymphocyte count < 200 cells/μL or CD4 + T-lymphocytes < 14% of total lymphocytes.

During nosocomial outbreaks, chemoprophylaxis should be given to all institutionalized patients regardless of previous inßuenza vaccination. Chemoprophylaxis may also be given during the two-week period after inßuenza vaccination and before the development of antibodies if an inßuenza outbreak has begun in the community. Finally, during periods of inßuenza A activity, chemoprophylaxis may be given to unvaccinated or recently vaccinated institutionalized HIV-infected persons and to those who will be exposed in the community. There are almost no data on the safety of these agents in HIV-infected persons (116,78). No data are available on possible interactions with other drugs used in the management of patients with HIV infection. Patients should be carefully observed for adverse drug reactions, especially when neurologic conditions or renal insufÞciency is present. Dosages should be adjusted in patients with renal insufÞciency or severe hepatic dysfunction (78). During inßuenza outbreaks, unvaccinated hospital and clinic personnel and household care-givers should also receive prophylaxis to prevent transmission of virus to HIV-infected persons.

Diphtheria and Tetanus Toxoids

Diphtheria and tetanus toxoids and inactivated poliovirus vaccines may be used for immunization of unvaccinated or inadequately vaccinated HIV-infected adults or for boosters as recommended for immunocompetent adults (6). A history of immunization with tetanus and diphithera toxoids (which is often not known for adults) may not indicate present immunity and regular booster doses of combined tetanus and diphtheria toxoid should be considered for adolescents and adults, regardless of HIV infection status, particularly in countries experiencing a resurgence in diphtheria. Prophylaxis with tetanus immune globulin (TIG) and a tetanus booster are recommended for HIV-infected adults who sustain a signiÞcant wound exposure (6).

Polio Vaccine

In the United States, only inactivated poliovirus vaccine (IPV) is recommended for routine vaccination of adults and children in order to eliminate the risk of vaccine-associated paralytic poliomyelitis (VAPP) (24). Oral poliovirus vaccine (OPV) may be used for mass vaccination to control polio outbreaks, however, OPV should never be used to immunize immunocompromised persons because they are at substantial risk for VAPP. Children residing in households or having close contact with known HIV-infected adults should receive inactivated polio vaccine (IPV) for primary immunization (6,9,24). If OPV is inadvertently administered to a household contact of an immunodeÞcient person, the OPV recipient should avoid close contact with the immunodeÞcient person for about four to six weeks after vaccination (224). If this is not possible, rigorous handwashing and avoidance of contact with feces and saliva should be instituted.

Routine polio vaccination of adults residing in the United States is not necessary. Most adults have a minimal risk for exposure to polioviruses in this country, and most are immune as a result of vaccination during childhood. Some unvaccinated adults (including those who are HIV-infected) at greater risk of exposure to polioviruses than the general population (e.g. those who travel to polio-endemic areas; members of groups with disease caused by wild polioviruses; laboratory workers; health care workers in close contact with patients who might be excreting wild polioviruses; and unvaccinated adults with children receiving OPV) should be vaccinated with IPV. If they have no documentation of vaccination, they should receive a primary series consisting of two doses of IPV at intervals of four to eight weeks; a third dose should be administered six to 12 months after the second. Adults who have had a primary series of OPV or IPV and who are at increased risk of exposure can receive a single booster dose of IPV (24).

Measles Vaccine, MMR

All adults born in or after 1957 should have evidence of immunity to measles vaccine by documentation of receipt of measles vaccine after the Þrst birthday, laboratory evidence of immunity, or history of physician documented measles disease. Adults born before 1957 can generally be considered to be immune from natural disease (25). The ACIP does not recommend measles vaccination of HIV-infected persons with evidence of severe immunosuppression, deÞned as CD4+ T-lymphocyte <200 cells/μL or $<14\%$ of total lymphocytes for persons ≥ 13 years for the following reasons: a case of progressive measles pneumonitits occurred in a person with AIDS after receipt of MMR; evidence of diminished antibody response among severely immunocompromised HIV-infected persons; morbidty related to measles vaccination in non-HIV-infected persons with severe immunosuppression; and the low incidence of measles in the United States (25). The ACIP continues to recommend measles vaccine for HIV-infected persons without evidence of measles immunity who are not severely immunocompromised. Exposure to measles is not a contraindication to vaccination; MMR administered within 72 hours of exposure may provide some protection and should be to administered in HIV-infected patients who are not severely immunocompromised (25). Because of the reduced immunogenicity of measles vaccine in HIV-infected persons, previously vaccinated persons, as well as those with no history of vaccination or disease, should receive prophylaxis with immune globulin within six days of measles exposure (25). Persons receiving regular (e.g. monthly) intravenous immune globulin for HIV infection or other indications

may not respond to MMR due to presence of high levels of passive antibody (25).

Hepatitis A Vaccine

Hepatitis A vaccination is recommended for susceptible HIV-infected persons at increased risk for hepatitis A including men who have sex with men, injecting and non-injecting drug users, hemophiliacs, travelers to developing countries, travelers to endemic areas, those with chronic liver disease (e.g. due to hepatitis B or C), and others (11,261). Persons recently exposed to hepatitis A virus who have not been previously vaccinated, should be given a single dose of immune globulin intramuscularly as soon as possible, but not more than two weeks after the last exposure (261). If indicated, hepatitis A vaccine may be administered simultaneously with immune globulin at a separate anatomic site (261).

Hepatitis B Vaccine

Indications for the use of hepatitis B vaccine in HIV-infected persons are the same as for uninfected persons (6,11). A routine three-dose schedule (with an interval of one month between the Þrst and second doses and six months between the second and third doses) is recommended for HIV-infected persons who lack evidence of prior immunity (antibody to hepatitis B surface or core antigens (anti-Hbs or anti-Hbc)). A larger than normal vaccine dose, 40 μg which is recommended for some immuno-compromised persons, may be considered but has not been studied in HIV-infected adults. Post vaccination serologic testing is recommended for all HIV-infected persons between one and six months after completion of the vaccination series. Re-vaccination with one or more doses should be considered if the anti-Hbs is below 10 MIU/ml. Postexposure recommendations for HIV-infected persons are the same as those for uninfected persons (6). Hepatitis B immune globulin and initiation of the hepatitis B vaccination series is recommended for all nonimmune HIV-infected persons who have accidental percutaneous or mucous membrane exposure to blood or body ßuids containing hepatitis B surface antigen or who have sexual exposure.

Varicella Zoster Postexposure Prophylaxis

Susceptible HIV-infected patients who have a signiÞcant exposure to varicella should be given prophylaxis with varicella immune globulin (VZIG) within 96 hr of exposure, as recommended for other immunocompromised persons (6,11). HIV-infected adults who are believed to have had varicella on the basis of a carefully obtained history by an experienced interviewer can be considered immune. However, a past history of varicella, a previous positive serologic test for varicella antibody, or recent administration of VZIG does not guarantee immunity (9). Recently, varicella vaccine has been licensed in the United States (262). Varicella vaccine is not currently recommended for HIV-infected adults at this time (262). However, the ACIP does recommend that varicella vaccine should be considered for asymptomatic or mildly symptomatic HIV-infected children (263). Susceptible medical personnel and household members of HIV-infected persons should be immunized to decrease the risk of transmission to HIV-infected contacts.

HIV-Infected Travelers

HIV-infected persons who wish to travel to developing countries pose a special problem. They should be made aware of the risk of travel to areas in which many diseases are endemic and that lack supportive medical care. A recent survey of 89 HIV-infected adults found that, in a period of two years, 45% had traveled to a median of three U.S. destinations for at least a week and 20% traveled to at least one international destination (mean duration 20 days) (264). There are no data concerning adverse reactions, immunogenicity, or efÞcacy of vaccines usually recommended only for travel outside the United States. The live attenuated virus vaccine for prevention of typhoid is contraindicated for HIV-infected persons (6). Live attenuated vaccines for measles and varicella may be administered to some HIV-infected persons as discussed previously. For necessary travel to countries requiring proof of vaccination, a waiver letter should be provided by the travelerÕs physician. For persons who cannot avoid possible exposure to yellow fever, the physician should inform the patient of the risks and beneÞts of immunization and offer the choice of vaccination (265). Vaccinees should be monitored for possible adverse effects. Inactivated typhoid vaccines are available and theoretically may be safe alternatives for symptomatic and asymptomatic HIV-infected persons (266). Persons at risk for exposure to typhoid should be administered an inactivated parenteral typhoid vaccine instead of the live-attenuated oral vaccine (9). Prior to travel, determination of an adequate antibody response to vaccination is desirable. All HIV-infected persons should be advised to avoid exposure to mosquitoes by using barrier methods of protection. Other vaccines containing killed antigens (including diphtheria-tetanus, hepatitis A, hepatitis B, Japanese encephalitis, rabies, plague, and anthrax) do not pose a risk to HIV-infected persons and should be used for the same indications as for uninfected persons (6,265). Because immunity to diphtheria wanes with time since the last dose of diphtheria vaccine, a booster dose of combined tetanus and diphtheria toxoids should be administered to adults wishing to travel to countries currently experiencing a resurgence of diphtheria. This recommendation is particularly important for HIV-infected adults who may have lower antibody

levels against diphtheria than non-HIV infected adults. The available cholera vaccine is not recommended for persons with a routine tourist itinerary, even if travel includes countries reporting cases of cholera (11).

Other vaccine-preventable diseases, including rabies, Japanese encephalitis, meningococcal infection, and plague, are rare in American travelers. Recent reviews of these vaccines and their use in immunocompromised persons have been published (81,182). These vaccines are inactivated and could be considered in the unusual circumstance when exposure cannot be avoided.

Bioterrorism-Related Vaccines

Following terrorist incidents in New York City and Washington, D.C. on September 11, 2001, and intentional release of anthrax in October 2001, the Centers for Disease Control and Prevention has recommended heightened surveillance for illnesses that may be indicative of bioterrorism (267). Although the safety and efficacy of anthrax vaccine in HIV-infected persons has not been evaluated, because it is an inactivated bacterial vaccine, the risks to this population may be expected to be minimal should vaccination be recommended. In contrast, severe complications after vaccinia (smallpox) vaccination in HIV-infected persons have been reported (34,268). Although smallpox vaccination has been discontinued for many years, recommendations for use of smallpox vaccine in the situation of intentional release are being revised (269). Careful consideration must given on how to identify HIV-infected persons and others who are risk for severe complications to this vaccine (269).

CONCLUSION

As the number of HIV-infected persons continues to increase, as more patients are identified earlier in their disease, and as survival is increased, there will be more opportunity for acquisition of vaccine-preventable diseases. Current vaccines are most likely to be effective when HIV-infected persons are immunized before the onset of immune compromise. Past experiences with adult immunizations indicate that provision of recommended vaccines and immuno- and chemoprophylaxis to HIV-infected persons needs to be much more aggressive. Additional techniques to improve responses to immunization are necessary. Research should include modifications of vaccination schedules including higher vaccine doses, booster or multiple dose schedules, vaccination concurrent with anti-HIV therapy, and development of more immunogenic vaccines.

Chapter 39

Progress in the Development and Testing of HIV Vaccines

Marta-Louise Ackers, Bradford N. Bartholow and Timothy D. Mastro

Since the start of the human immunodeÞciency virus (HIV) epidemic in the late 1970s, more than 60 million HIV-1 infections are estimated to have occurred worldwide.(1) In general, behavioral interventions on a national level have had limited success; however, these efforts in Thailand, Uganda, and Senegal have slowed the epidemic substantially (2Ð5). Antiretroviral medications, although capable of controlling HIV viremia and slowing the rate of disease progression, do not eradicate HIV, have substantial adverse effects, are expensive, and are not widely available globally. The development and subsequent widespread administration of a safe, effective, and affordable HIV preventive vaccine is essential to halt continuing spread of the epidemic.

The Þrst U.S. HIV-1 vaccine human clinical trial started in 1988 (6). However, 14 years later, despite more than 80 phase I/II clinical trials of various vaccine constructs conducted worldwide and the involvement of numerous U.S. and international government agencies, nongovernmental organizations, universities, and industry, we still do not have an efÞcacious vaccine. In comparison, two other viral diseases, hepatitis B and hepatitis A, had licensed vaccines available 16 and 22 years respectively, after pathogen identiÞcation (7Ð8).

Marta-Louise Ackers: HIV Vaccine Section, Epidemiology Branch, Division of HIV/AIDS Prevention-Surveillance and Epidemiology, National Center for HIV, STD & TB Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia.

Bradford N. Bartholow: HIV Vaccine Section, Epidemiology Branch, Division of HIV/AIDS Prevention-Surveillance and Epidemiology, National Center for HIV, STD & TB Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia.

Timothy D. Mastro: HIV Vaccine Section, Epidemiology Branch, Division of HIV/AIDS Prevention-Surveillance and Epidemiology, National Center for HIV, STD & TB Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia.

Since the correlates of human protection are still unknown, current scientiÞc opinion advocates development of a preventive HIV-1 vaccine capable of inducing both humoral and cellular immunity. A vaccine should induce broad cross-neutralizing antibodies against primary isolates from differing HIV-1 genetic subtypes and against viruses of both major phenotypes: lymphotropic, syncytium-inducing viruses that use the CXCR4 coreceptor and macrophage-tropic non-syncytium inducing viruses that use the chemokine CCR5 coreceptor. Also, the vaccine should elicit cross-subtype reactive cytotoxic T lymphocyte (CTL) responses, helper CD4 responses, mucosal immunity, and long-term protection. Although development of such a vaccine appears to be a daunting task, this does not imply that these expectations are unrealistic. This chapter describes obstacles hindering the development of a preventive HIV vaccine, progress toward developing and evaluating vaccine candidates, clinical trials, the social and ethical issues involved in conducting HIV vaccine trials, and plans for future efÞcacy trials.

OBSTACLES TO THE DEVELOPMENT OF AN HIV VACCINE

Three obstacles are widely considered to be responsible for hindering the development of an HIV-1 vaccine. These obstacles are: (1) the extensive antigenic variability of HIV; (2) uncertainty regarding which immune responses are correlated with protection; and (3) the lack of an ideal animal model in which to test vaccine constructs.

Antigenic Variability

AIDS is caused by two different lentiviruses, HIV-1 and HIV-2; HIV-1 accounts for most AIDS cases. Phylogenetic analyses of the nucleotide sequences of the envelope (*env*)

and core (*gag*) genes of a large number of HIV-1 isolates have identified at least 11 different genetic clades or subtypes (A, A2, B, C, D, F1, F2, G, H, J and K) (9). These subtypes form the major group of HIV-1, group M, and are of approximately equal genetic distance from one another. In addition, two other groups distantly related to group M have been identified in patients from Cameroon (subtypes O and N), Gabon (O), and Guinea (O) (10,11).

The majority of this genetic variability is due to the high error rates of the HIV-1 reverse transcriptase. Most genetic variation appears to occur in the envelope (*env*) gene. The extent of genetic variability increases over time as HIV-1 spreads within populations. Furthermore, genomic recombination between one or more different subtypes is common, giving rise to various circulating recombinant forms (CRF): e.g. CRF01_AE, CRF02_AG, CRF03_AB, CRF04_cpx (12,13). Currently, the importance of genetic HIV-1 subtypes for vaccine-induced protection from infection or disease is not known. Could a vaccine designed for HIV-1 subtype B protect against a subtype C infection or will subtype specific vaccine formulations be required? Furthermore, if immune protection is dependent on a specific, variable HIV sequence, then HIV vaccine development may require continuous modification as new genetic strains evolve.

Correlates of Protection

In the past, scientists studied persons who became infected with a pathogen and survived in hope of identifying immunologic features among these survivors that protected them from re-occurrence of disease. Vaccines were designed and developed to elicit the immune responses of these survivors. However, for HIV there appear to be no known survivors who clear the virus. Clinical research has focused on natural history studies of HIV-infected persons, including HIV-infected persons in whom HIV-related disease does not develop (long-term non-progressors), persons whom have had multiple exposures to HIV yet remain uninfected, and discordant and concordant mother-infant pairs (14), examining both viral and genetic host factors. However, to date, no single immune correlate has been identified. Rather, the data suggest that immunity from HIV will require activity from multiple immune components. Consequently, vaccine immunogenicity studies strive to elicit a wide range of humoral and cellular immune responses, including both neutralizing antibodies and CTLs, in an attempt to include multiple modes of protection.

Humoral antibody responses have previously been shown to be important in preventing disease. Other viral diseases (e.g. polio, inßuenza, rabies, and hepatitis B) have been prevented through the administration of immunoglobulin containing protective antibodies or vaccines designed to induce a humoral antibody response. Therefore, early HIV-1 vaccine constructs focused on subunit proteins designed to induce neutralizing antibodies and thereby prevent HIV infection. However, other epidemiologic and immunologic studies among long-term non-progressors (15), highly exposed persistently seronegative African and Asian sex workers (16,17), and acutely exposed infants (18) led to the belief that CTL responses are important in controlling virus replication during acute infection. Subsequent vaccine constructs were designed to induce these cell-mediated responses. However, these latter constructs did not induce a humoral response, leading to the development of a prime-boost concept whereby a CTL-inducing construct is administered first, followed by an antibody-inducing subunit protein boost (19).

Animal Models

Pharmaceutical products are commonly tested using animal models before advancing to human clinical trials. Suitable animal models are those that develop human signs of disease after infection with a pathogen known to cause human illness. HIV has posed an additional challenge to investigators in that no non-primate animal model has thus far been identified in which an AIDS-like illness develops from HIV infection. Chimpanzees are the only animal species to have demonstrated susceptibility to HIV-1 infection; however, they are not susceptible to infection with all strains of HIV-1 and rarely exhibit an AIDS-like illness once infected (20–22). Severe restrictions on the supply and research use of chimpanzees further limits the use of this model.

Consequently, most HIV vaccine research among animals has been performed using a common primate species, the Asian rhesus macaque. Macaques can be infected with an HIV-related lentivirus, simian immunodeficiency virus (SIV), and demonstrate signs of an AIDS-like illness leading to death within a few weeks or months (23,24). Consequently, SIV-based vaccine constructs have been developed and administered to macaques, and subsequent challenges are performed with SIV strains. Many of these SIV vaccine/macaque protection experiments have demonstrated impressive results (25–27). However, it is unknown how closely these macaque experiments may approximate HIV vaccine clinical trials in humans.

In the early 1990s, SIV/HIV hybrids (SHIV) that carry and express the HIV-1 *env*, *tat*, and *rev* genes within SIV were developed (28,29). These early SHIV strains replicated well within primates but did not induce disease. However, further studies demonstrated that serially passaged SHIV produced an AIDS-like illness in macaques leading to death within weeks (30–33). Recent SHIV vaccine constructs and protection experiments in macaques have demonstrated the ability to contain pathogenic SHIV infection (34,35). However, as with the SIV-based model, it is unknown how well the SHIV-macaque model predicts the HIV-human situation.

CANDIDATE HIV-1 VACCINE CONSTRUCTS

To date, over 100 different HIV-1 vaccine constructs have been developed and tested in animal models. These constructs have been developed using various approaches or strategies (Table 39.1). The approaches that appeared the most promising (recombinant subunit, live vector, DNA, and live-attenuated) have progressed the furthest. However, only the Þrst three have progressed to human clinical trials.

Recombinant Subunit Vaccines

Early HIV-1 vaccine development focused on the production of recombinant protein subunit vaccines capable of eliciting neutralizing antibodies. These HIV protein subunit vaccines generally were from envelope proteins (e.g. gp120 and gp160) and were expressed or produced through mammalian cells, baculovirus, or insect cells. These vaccine constructs were developed from laboratory T-cell line adapted (TCLA) strains and showed good neutralizing antibody response (against TCLA strains) and protection of chimpanzees against infection with homologous HIV-1 strains (36Ð38). Results from numerous human clinical trials indicated subunit vaccines to be both safe and capable of eliciting a neutralizing antibody response in humans (39,40).

However, advancement to large-scale efÞcacy trials was controversial due to subsequent study results and new scientiÞc discoveries that found the recombinant subunit approach lacking. Later studies indicated that neutralizing antibody activity generated by subunit vaccines was limited to only laboratory-adapted viruses, and that primary or wild-type HIV isolates were not neutralized with sera from subjects with neutralizing antibodies (41). Other studies indicated the importance of the cell-mediated immune response and CD8+ CTL activity (42,43). Although the subunit vaccine constructs stimulated lymphoproliferative responses to HIV-1 antigens and antibody-dependent cytotoxicity, they did not induce CTL responses (39,44). Both cell-mediated immune responses and the neutralization of wild-type isolates were widely considered to be important for vaccine efÞcacy; the inability of subunit vaccines to induce these responses was perceived as a major drawback. In June 1994, a U.S. government panel (the AIDS Research Advisory Committee) decided not to fund a large-scale efÞcacy trial of recombinant (r)gp120 protein subunits that had advanced through early human clinical trials (45), and directed subsequent research towards vaccine constructs that would elicit both neutralizing antibody activity against primary isolates and cell-mediated responses. However, one biotechnology company, VaxGen, Inc., (Brisbane, Ca) decided to proceed and privately sponsored large-scale efÞcacy trials of a rgp120 subunit construct (AIDSVAX) in North America, the Netherlands, and Thailand (46).

Live Vector Vaccines

The perceived importance of cellular immunity and the CTL response encouraged the development of live vector vaccines. In these vaccines, various HIV-1 genes (e.g. *env, gag, pol*) were incorporated into a replicating system through live vector constructs such as adenovirus, *Salmonella*, alphaviruses, canarypox, vaccinia, or attenuated vaccinia vectors (i.e. modiÞed vaccinia Ankara or MVA), resulting in antigen expression. Preliminary studies using canarypox or vaccinia-based constructs appeared promising in that they induced HIV-1-speciÞc CTL responses and indicated that cross-subtype killing did occur (47). However, when administered alone, these constructs elicited poor neutralizing antibody responses. Since 1994, efforts

TABLE 39.1. *Approaches to HIV-1 vaccine development*

Recombinant subunit vaccine: a vaccine produced by genetic engineering, mostly generated from laboratory-adapted HIV-1 strains, simulating a part of the outer surface envelope or other part of HIV
Peptide vaccine: HIV-1 internal proteins or synthetic peptides that contain relevant epitopes of HIV-1 envelope
Live vector vaccine: a live bacteria or virus that is harmless or can be modi ed to be harmless to humans that contains various combinations of HIV-1 genes (*env*, *gag*, *pol*, and *nef*). Current vectors include vaccinia virus, canarypox, adenovirus, *Salmonella*, bacille Calmette-Guerin, poliovirus, and Venezuelan equine encephalitis virus
DNA immunization (naked DNA or nucleic acid vaccine): segments of genome or plasmid that undergo transcription to express proteins
Whole-killed or inactivated vaccine: live HIV that has been inactivated by chemicals, irradiation, temperature, or other means to render it noninfectious but that retains its antigenicity and the ability to stimulate the immune system. Such formulations would theoretically require additional doses of vaccine or “boosters” to provide long-lasting immunity
Live-attenuated vaccine: live HIV that has had its virulence or pathogenicity reduced or removed through the deletion of genes responsible for viral replication or disease, usually accomplished by repeated passage of the wild-type or disease-causing strain through different hosts or cell lines. Live-attenuated vaccines produced for other diseases (e.g. polio) have demonstrated long-lasting immunity. Generally considered to be too great a risk because of the potential to revert to the disease-causing form.

have focused on a combination (prime-boost) regime consisting of the administration of a live vector construct "prime" followed by a subunit protein "boost" to enhance the humoral immune response.

Subsequently, numerous small and medium-sized human clinical trials conducted in the United States and abroad that employed canarypox or vaccinia vector construct primes plus subunit boosts demonstrated these constructs to be safe and immunogenic. However, consistent and durable CTL responses among all vaccinated individuals have been difficult to achieve; only 15–30% of vaccine recipients have had detectable CTL activity at any given time point (19,48–50). In addition, the evaluation of CTL responses has been complicated by the lack of a simple, reproducible assay, although results from studies using a new enzyme-linked immunospot (ELISPOT) assay look promising (51). Despite these difficulties, two large-scale efficacy trials using canarypox constructs with and without subunit protein boosts were originally proposed for initiation in 2002 and 2003 in Thailand and North/Latin America (52,53). The North/Latin American trial, designed to have statistical power to evaluate correlates of protection, was subsequently canceled after data from two phase II trials indicated that this outcome would not be possible; however, the Thai trial, powered to show efficacy, will proceed as scheduled (54).

DNA Vaccines

Advances in technology have promoted the exploration of DNA-based constructs as potential preventive vaccines for malaria and HIV-1. HIV DNA vaccine constructs encode for virus proteins that are expressed by cells of the vaccine recipient and stimulate neutralizing antibodies to circulating free virus, as well as prime cytotoxic T-cells, to recognize HIV and destroy infected cells. DNA vaccines are an attractive option because they are potentially highly immunogenic, relatively inexpensive, and easy to manufacture and administer (55).

Initial HIV DNA vaccine studies demonstrated that sole administration of DNA constructs, referred to as "naked DNA," elicited antigen specific lymphocyte proliferative responses and antigen specific production of interferon gamma and beta-chemokines. However, these responses were not persistent or consistent among individuals (56), and CTL and humoral immune responses were relatively weak. Subsequent animal studies demonstrated that both cell-mediated and humoral immune responses improved with the development of more complex and immunogenic DNA vaccine constructs, including naked DNA with cytokine enhancement (34), combination prime-boost regimens (i.e. naked DNA prime plus recombinant protein boost (57–59) naked DNA prime plus vaccinia boost (58,60) and DNA prime plus MVA boost (35,61,62)) and replicon-based vaccines using various alphaviruses: e.g. Sindbis virus, Semliki Forest virus, and Venezuelan equine encephalitis virus (VEE) (63,64).

Several SHIV DNA animal vaccine/challenge studies in macaques failed to demonstrate sterilizing immunity but did show the ability of these constructs to control infection by maintaining a low viral load (34,35,65). Several small human clinical trials of combination DNA prime-boost construct regimens have recently been initiated or are in the early planning stages to evaluate safety and immunogenicity in humans (65,66).

Live Attenuated Vaccines

Live attenuated vaccines developed against polio, measles, and mumps are examples of efficacious vaccines capable of providing long-lasting immunity. Attempts to develop a live attenuated HIV-1 vaccine have been made despite the inherent risks of such a vaccine being pathogenic or spontaneously reverting to a highly pathogenic form. The most impressive protection from a SIV challenge to date has been established by a live attenuated SIV vaccine administered to macaques (67,68). However, subsequent animal studies indicating that a SIV strain constructed with triple deletions (*nef*, *vpr*, and a negative regulatory element) was pathogenic in neonate and adult macaques (69) has halted further progression of a live attenuated HIV-1 construct to human clinical trials.

CLINICAL TRIALS

After animal studies showed HIV-1 vaccine constructs to be safe and immunogenic, investigators initiated human clinical trials to evaluate the most promising candidates. Human HIV-1 vaccine clinical trials are generally performed in three steps or phases.

Categories of Clinical Trials

In phase I trials, vaccine constructs are administered to approximately 10–40 persons at low risk for HIV infection to assess safety and immunogenicity. These trials may involve the use of placebo, randomization, and blinding of participants. Phase II trials are generally conducted among 50–400 persons at low risk (although can include some at higher risk), and additional safety and immunogenicity data are collected. Placebo, randomization, and blinding are generally used in these trials. Phase I and II trials may sometimes be combined if certain constructs have been satisfactorily tested in prior phase I trials. Phase III (large-scale efficacy) trials are performed after successful phase I and II results. They are conducted among thousands of persons at high risk to assess safety, immunogenicity, and efficacy. These trials involve control groups (possibly a placebo), randomization, and blinding of both investigators and participants (double-blind). Phase III trial results provide data leading to vaccine licensure and the

recommendations for its use among the public. After phase III trials, vaccine bridging studies and/or phase IV trials may be performed to examine different immunization schedules and assess the vaccineÕs protective effects against various HIV strains, within different population groups, and when coadministered with other vaccines or drugs.

Major Organizations Involved in Clinical Trials

From 1986 through 2001, there have been more than 80 HIV-1 phase I and phase II trials conducted worldwide evaluating more than 30 vaccine constructs from a wide variety of vaccine developers and only one phase III trial. The vast majority of HIV-1 vaccine trials have been conducted in the United States and France (Table 38.2) and have consisted largely of subtype B vaccine constructs. Only 15 trials have been conducted in developing countries; African countries have participated in three trials. Numerous governmental agencies, non-governmental organizations, universities, clinical sites, and industry representatives have been involved in the support, coordination, and evaluation of these vaccines. A few of these organizations are described below.

U.S. Federal Agencies

In the United States, HIV vaccine clinical trials are predominantly sponsored either through the National Institutes of Health (NIH) or privately through individual pharmaceutical or biotechnology companies (e.g. Aventis Pasteur, VaxGen, Inc., Merck Research Labs). From 1988 to 2000, NIH sponsored over 50 phase I and II clinical trials through the AIDS Vaccines Evaluation Group (AVEG) or the HIV Network for Prevention Trials (HIVNET). AVEG consisted of a group of six U.S. university-based clinical testing sites formed in order to evaluate HIV-1 vaccine candidates in phase I and II clinical trials. HIVNET, composed of both international and domestic sites, was created to assess the feasibility and design of future efficacy trials in high-risk uninfected individuals, to develop clinical trial-related infrastructure, and to eventually conduct clinical trials to evaluate the safety and efficacy of interventions to prevent sexual, perinatal, and parenteral HIV transmission. HIVNET research areas included: HIV preventive vaccines, topical microbicides, sexually transmitted disease (STD) treatment, prophylaxis to prevent mother-to-infant transmission, hormonal contraception, and behavioral risk-reduction strategies.

In May 2000, AVEG and HIVNET were merged to form the international HIV Vaccine Trials Network (HVTN). HVTN is a comprehensive network of clinical sites located in the United States, sub-Saharan Africa, Asia, Latin America, and the Caribbean that will develop and test preventive HIV vaccines (70). Within this framework, HIVNET protocol 026, a phase II trial of a subtype B-based canarypox construct (ALVAC vCP1452) with a gp120 subunit protein boost (AIDSVAX B), was initiated in Haiti, Trinidad and Tobago, and Brazil (71). This study was the first HIV vaccine clinical trial for both Haiti and Trinidad.

Two other federal agencies, the Department of Defense through the Walter Reed Army Institute of Research (WRAIR) and the Centers for Disease Control and Prevention (CDC) are also active in vaccine development and clinical trials. WRAIR supports basic science research, nonhuman primate studies, and human clinical trials, with a particular focus on non-subtype B candidate vaccines. It has been active in Thailand and East Africa and worked with Thai officials on plans for a possible phase III trial of a subtype B/E-based canarypox construct (ALVAC vCP1521) plus a bivalent rgp120 (AIDSVAX B/E) for late 2002 (72). Planning and implementation of the trial and other WRAIR vaccine activities will be funded through the NIH at the end of 2002. CDC is collaborating with VaxGen, Inc. on the two ongoing AIDSVAX phase III efficacy trials in the United States and in Thailand. In addition, CDC has been collaborating with Emory University scientists and public health officials from the CÔte dÕIvoire, West Africa, to develop and prepare to evaluate a DNA vaccine based on HIV-1 A/G viruses (CRF02_AG) from CÔte dÕIvoire.

France and Thailand

Although several foreign countries have been involved in vaccine clinical trials, of special note are France and Thailand. In France, lÕAgence Nationale de Recherches sur le SIDA (ANRS) was established in 1989 to promote, fund, and coordinate HIV research. The agency contains three research sections: basic science, clinical studies and epidemiology (includes vaccine and other clinical trials), and social and behavioral science. ANRS-sponsored phase I and II vaccine clinical trials have been performed only in France, but ANRS plans to conduct future international vaccine trials through its collaborative clinical research program with the French Secretary of State for Overseas Cooperation in Africa and southeast Asia (73).

Thailand has staged eight preventive HIV-1 vaccine clinical trials since 1994 (Table 39.3) including one of the first two phase III efficacy trials (74). These trials have been coordinated by Thai officials and have been conducted by a variety of Thai institutions in collaboration with international partners and industry. In the face of a rapidly expanding HIV-1 epidemic in the early 1990s, Thailand took several steps to prepare for HIV vaccine trials. With the assistance of the World Health Organization (WHO), Thailand developed a national plan for HIV vaccine development and evaluation. This plan was very helpful in setting the course for subsequent trials. To complement this plan, efforts were made to strengthen

Thailandõ scientiÞc and ethical review process, conduct epidemiologic and behavioral studies of at-risk populations, characterize the molecular epidemiology of HIV-1, and build laboratory and data management capacity. In response to these efforts, three companies (Chiron Corp., VaxGen Inc., and Aventis Pasteur) made candidate vaccines based on the predominant HIV-1 subtype circulating in Thailand, HIV-1 subtype E (CRF01_AE).

International Organizations

WHO, the Joint United Nations Programme on HIV/AIDS (UNAIDS), and the International AIDS Vaccine Initiative (IAVI) support the international research and development of vaccine constructs. In 1991 WHO announced that four countries (Brazil, Rwanda, Thailand, and Uganda) would be developed and supported as HIV-1 vaccine testing sites (75). Subsequently, WHO assisted Brazil, Thailand, and Uganda with the development of National AIDS Vaccine Plans. In addition, WHO/UNAIDS has supported the development of an African AIDS Vaccine Program, sponsored workshops and conferences for developing country researchers, and developed ethics guidelines on the conduct of HIV vaccine trials in developing countries (76). All activities are conducted in collaboration with the private and public sectors of both developed and developing countries. In January 2000, the joint WHO/UNAIDS HIV Vaccine Initiative was established to expand the activities initiated and implemented by WHO/UNAIDS in the preceding years and to increase efforts to promote and facilitate vaccine development and evaluation for developing countries (77).

IAVI was formed in 1996 to promote the development of safe, effective, accessible, preventive HIV vaccines for global use. Its work focuses on four areas: accelerating scientiÞc progress, mobilizing public support through advocacy and education, encouraging industrial involvement in vaccine development, and working to assure global access to a vaccine (78). To accomplish these objectives, IAVI assisted in forming partnerships between the private research sector (vaccine manufacturers) and developing country researchers to speed the progress of promising vaccine candidates into clinical trials. As of 2001, Þve main vaccine development partnerships were being supported by IAVI: the Oxford/Kenya (DNA vaccine with MVA boost) (79, 80), AlphaVax/South Africa (VEE replicon particle vaccine) (79,80), Targeted Genetics/ChildrenÕs Research Institute/South Africa (AAV vector), the Institute for Human Virology/Uganda (Salmonella vector), and Therion Biologics/India (MVA vector) (81,82). The Oxford/Kenya partnership was the Þrst group to begin phase I clinical trials; these trials began in the United Kingdom in August 2000 and in Kenya in March 2001.

Phase III (EfÞcacy) Trials

Phase III trials evaluate the efÞcacy of a pharmaceutical product in humans. These trials require a large number of volunteers to provide sufÞcient statistical power to demonstrate efÞcacy and are conducted as placebo-controlled, double-blinded, randomized studies. Trial size is determined by the incidence of the disease of interest and the trial endpoints. For example, phase III vaccine efÞcacy trials for other infectious diseases such as hepatitis B, Japanese encephalitis, and Haemophilus inßuenzae required 1,000 to 60,000 participants and lasted approximately two years (83Ð85).

Endpoints and Effects of HIV Vaccine EfÞcacy Trials

Preventive HIV vaccine efÞcacy trials are designed to determine if a candidate vaccine is able to achieve speciÞc, desirable, measurable parameters or Òendpoints.Ó HIV vaccines, like most vaccines for infectious agents are designed to prevent infection, disease, or both. Consequently, endpoints in efÞcacy trials would be measures of HIV infection, measures of HIV-related disease, or both. EfÞcacy trials can also measure various serologic and immunologic parameters to identify laboratory correlates of protection from infection or disease, adverse clinical effects to evaluate the safety of a candidate vaccine, and effects on HIV transmission.

Endpoints and Correlates of Protection

When phase III HIV vaccine efÞcacy trials were initially considered in the early 1990s, the main efÞcacy endpoint considered was HIV infection, as deÞned by serologic assays and HIV-speciÞc nucleic acid tests (86). This endpoint or the complete prevention of HIV infection, termed Òsterilizing immunity,Ó is a type of protection thought to be conferred by neutralizing antibodies.

Recent data from phase I and II HIV vaccine trials in humans (87,88) and from trials in macaques (34,35) suggest that the goal of providing sterilizing immunity in humans may be difÞcult to attain. Consequently, there has been increasing interest in assessing the ability of HIV vaccines to induce cellular immune responses that control HIV replication, resulting in a mitigation of HIV-related disease in those vaccine recipients who do become HIV infected (89). HIV viral load as determined by plasma HIV RNA levels, is the most readily measurable indicator of the degree of HIV infection. The plasma viral load Òset point,Ó established by six months after infection, is the best single predictor of progression to AIDS and death (90). Plasma viral load is also closely associated with the rate of CD4 T-lymphocyte decline. Consequently, it is hypothesized that a lowered HIV viral load (compared with the viral load of placebo recipients) resulting from HIV vaccination will be associated with less severe HIV-related disease and delayed progression to AIDS and death. HIV vaccine efÞcacy trials are now being designed to assess HIV RNA levels as an important endpoint and a surrogate marker for severity of HIV infection. However, it remains to be established whether a vaccine-induced reduction in viral load has the same beneÞcial effects as a natural reduction in viral load.

The parameter most commonly used to assess HIV disease progression is the CD4 T-lymphocyte count.

Decline in CD4 cell count is closely associated with the onset of HIV-related opportunistic infections and AIDS and is the main laboratory indicator for the initiation of antiretroviral therapy (90). Therefore, like viral load, the CD4 cell count in vaccine recipients who become infected may be a useful endpoint in efficacy trials. An HIV vaccine that slows the rate of decline in CD4 cells would be hypothesized to slow disease progression and delay AIDS and death. An efficacy trial would compare CD4 counts of placebo recipients and vaccine recipients who became HIV infected during the trial. The endpoint could be the rate of decline of CD4 cell count or the time from infection to a CD4 count of a given level; e.g. 500, 350, or 200 cells/mm^3.

Plans for future HIV vaccine efficacy trials will include evaluations of the HIV RNA level and CD4 counts in infected participants. However, each of these endpoints is dramatically altered by antiretroviral therapy. The design of trials will need to account for the prevailing treatment practices, especially if these practices include treating recently identified HIV seroconverters. The early initiation of antiretroviral therapy would make it impossible to interpret the vaccine's effect on subsequent viral load or CD4 cell count determinations.

Determination of readily measurable correlates of immune protection is an important goal of HIV vaccine efficacy trials. Consequently, selected blood specimens are collected to determine serologic and cellular immune responses, and semen specimens and genital secretions may be collected to assess immunologic and virologic factors associated with HIV transmission. In addition to HIV-specific antibodies, current trials are being designed to measure HIV-specific CTLs by traditional assays and by newer ELISPOT assays.

Trial-related Effects

Scientific models have been developed to examine HIV vaccines, their trial-related effects, and potential transmission effects or outcomes. The most traditional type of HIV vaccine efficacy is related to susceptibility to HIV infection (VEs) and is measured by the endpoint of HIV infection status in the vaccine and placebo recipients. The VEs is equal to 1 minus the attack rate in the vaccine recipients divided by the attack (HIV incidence) rate in the placebo recipients; the equation is: $VEs = 1 - (ARv/ARp)$ (91). The endpoint of HIV infection is relatively easy to determine. It is also possible to measure the vaccine efficacy for disease progression (VEp). The endpoints related to progression could be HIV RNA levels, decline in CD4 cell counts, or time to HIV-related disease or AIDS. However, as discussed above, these endpoints would be modified by antiretroviral therapy and may require a longer period of observation to clearly establish a meaningful endpoint.

Another important effect of an HIV vaccine would be the reduction in the infectiousness of vaccine recipients (91,92). Such an effect could profoundly affect the course of the epidemic in a community (93). The vaccine efficacy for infectiousness (VEi) can be determined by novel partner augmentation trial designs (91,92). In such a trial, the sex partners of the vaccine trial participants are assessed to determine if there is differential transmission from vaccine recipients and placebo recipients to the respective partners. Plasma and genital fluid HIV RNA levels are also assessed as they are associated with sexual transmission to partners (94).

The assessment of vaccine efficacy for susceptibility (VEs), disease progression (VEp), and infectiousness (VEi) would provide a comprehensive profile of the beneficial effects of a preventive HIV vaccine.

Current Phase III Trials

Despite the large number of constructs developed and tested in phase I and II trials, only one product (two formulations), a recombinant subunit protein product, rgp120, (AIDSVAX (VaxGen, Inc., Brisbane, Ca.)) has advanced to phase III trials.

Genentech, Inc., a biotechnology firm located in South San Francisco, California, began research to develop a preventive HIV-1 vaccine in 1984 and subsequently developed a recombinant gp120 protein subunit vaccine shown to protect chimpanzees against HIV infection. In 1995, after NIH decided not to proceed with the funding of gp120 vaccine efficacy trials, a new company named VaxGen, Inc. was formed and maintained a relationship with Genentech, Inc. By 1997, VaxGen, Inc. had produced two bivalent rgp120 vaccines (AIDSVAX B/B and AIDSVAX B/E). Both formulations contained the gp120 sequence of the subtype B, T-cell lymphotropic strain "MNÓ in addition to the gp120 sequences from a macrophage-tropic strain (GNE8 (subtype B) or A244 (subtype E)). Both vaccines were demonstrated to be safe and immunogenic in human volunteers in phase I and II studies (46,95).

In June 1998, a phase III trial evaluating AIDSVAX B/B was initiated in North America and the Netherlands, and in March 1999 a second trial evaluating AIDSVAX B/E was started in Thailand (96,97). The AIDSVAX B/B phase III trial is a randomized double-blinded, placebo controlled (2 : 1 vaccine : placebo ratio) trial conducted in 5,109 HIV-1 uninfected men who have sex with men (MSM) and 309 uninfected women at high risk recruited from 61 clinical sites in the United States, Canada, and the Netherlands. Study participants attend 16 study visits, receive HIV counseling and testing at six-month intervals, and are administered seven intramuscular AIDSVAX B/B immunizations over three years (at months 0, 1, 6, 12, 18, 24, and 30). The AIDSVAX B/E trial is being conducted among 2,545 HIV-1 uninfected injection drug users (IDUs) attending seventeen drug treatment clinics in Bangkok, Thailand and, with the exception of a 1:1

vaccine : placebo ratio, has a study protocol similar to that of the AIDSVAX B/B trial.

An independent data safety and monitoring board (DSMB) composed of American and Thai members oversees both trials and reviews study data every six months to assess safety and trial conduct. Community advisory boards (CABs) are used for the AIDSVAX B/B trial; a Community Relations Club was established in Bangkok. Composed of a variety of community members, a CAB serves as an advocate for the study volunteers and represents the perspectives of the affected communities and people at risk for HIV infection. For the AIDSVAX B/B trial, there is one national VaxGen Study CAB and approximately 25 local CABs. Participants who become infected during the trial are referred for medical care by the trial sites in the AIDSVAX B/B trial or followed up by the Bangkok Metropolitan Administration (BMA) in Thailand. The AIDSVAX B/B trial will be completed in late 2002, while the AIDSVAX B/E trial will be completed in late 2003.

Criteria for Phase III Trials

Identifying or developing the appropriate trial conditions and infrastructure within a country for an HIV-1 vaccine phase III efficacy trial requires substantial time and effort (Table 39.4). Initial steps include developing a national plan for the conduct of HIV-1 vaccine research development and evaluation within a specific country and gaining national political and institutional support for vaccine trials. Once support is established, various locations should be evaluated for their potential to serve as vaccine trial field sites.

Site Identification

An ideal field site has access to a population that meets well-defined epidemiologic and social-behavioral criteria and a research and clinical infrastructure that provides appropriate laboratory and data management facilities and trained personnel. In addition, this site would have the involvement of the community, and a trial staff that is aware and recognizes the social and ethical issues involved so as to ensure the protection of human rights for trial participants. It is rare to identify a field site that meets all these criteria. Most often areas that have a high HIV-1 prevalence and/or seroincidence are identified, and further assessment is required to determine their feasibility as vaccine trial field sites.

Site Preparation

If field assessments are favorable, additional study is essential to characterize the populations and to prepare both participants and communities for a potential vaccine trial. It is not unusual for field site preparation to require two to five years of preliminary epidemiologic study and infrastructure development before a vaccine trial can be initiated. Epidemiologic characterization involves identifying high-risk persons and risk behaviors within that population, determining HIV seroincidence with prevention efforts in place, genetic sequencing of prevalent and incident HIV strains, and assessing the ability to enroll and follow up persons at risk. Infrastructure development includes identifying or developing several review boards to oversee the ethics, science, and participant needs throughout the trial; training clinical research personnel; and developing or improving trial facilities and procedures (e.g. data management, laboratory, medical referrals).

TABLE 39.4. *Preparing for a HIV-1 vaccine phase III trial*

National items
- Plan for HIV-1 vaccine research, development, and evaluation
- Political will and institutional support for HIV-1 vaccine trials

Epidemiologic and social-behavioral features
- Well-characterized population with high HIV-1 incidence rates despite ongoing prevention efforts
- Molecular characterization of the circulating HIV strains in the community
- Recognition of factors in uencing the recruitment, enrollment, and retention of potential participants

Infrastructure requirements
- Scienti c review process
- Ethical review process
- Community advisory board to address participant and community concerns and needs
- Clinical research facility with adequate laboratory and data management support
- Trained clinical research personnel (doctors, behavioral scientists, nurses, lab technicians, etc.)

Social issues
- Protection of human rights through discussion, identi cation and awareness of ethical issues pertaining to trial participation (e.g. con dentiality, stigma, etc.)
- Procedures to assure comprehension of informed consent
- Procedures in place to refer or offer medical care to persons who become HIV infected within the trial

Community Preparation

Both communities and potential vaccine trial participants should be provided with information on the conduct of HIV vaccine trials and participantsÕ rights. Discussions should occur to identify ethical issues and to determine how to address issues related to conÞdentiality and stigma that may arise during the trial. Studies performed in communities and among potential participants to determine trial acceptability and willingness to participate in vaccine trials are commonly referred to as vaccine willingness-to-participate studies, and the epidemiologic and behavioral studies are termed vaccine feasibility studies or vaccine preparedness studies. Willingness-to-participate and vaccine feasibility studies are not mutually exclusive and have been performed simultaneously or concurrently among a variety of communities, researchers, and potential vaccine trial participants (98Ð118).

Participant Selection

Identifying a study population or potential cohort can be challenging. Participants must be from a population that has sufÞcient HIV seroincidence, be interested in participating in an HIV vaccine efÞcacy trial, and be available for enrollment and follow-up. These cohorts may be difÞcult to locate, enroll, and follow up (110,119). Female commercial sex workers and young MSM, selected because of their populationsÕ high HIV seroincidence, proved to be difÞcult populations to enroll or retain in several vaccine feasibility studies (114,120,121). Conversely other studies that successfully enrolled and retained cohorts of high risk persons experienced decreases in HIV seroincidence over time because of early seroconversions in persons at higher risk, selective loss to follow-up, and decreases in risk activity due to changes in risk behavior over time or HIV risk-reduction counseling and prevention measures (99,115,122).

Paths Leading to the Current Phase III Trials

Advancement towards a phase III HIV-1 vaccine efÞcacy trial can be envisioned as two stone columns of an arch (Fig. 39.1). Numerous steps or stones must be placed in order to develop a suitable cohort and to evaluate and prepare a vaccine construct for efÞcacy trials. Once both cohort and vaccine construct are ready, they can be linked together through a phase III efÞcacy trial. A phase III efÞcacy trial cannot take place without completion of both columns.

In the AIDSVAX phase III efÞcacy trials, VaxGen, Inc. constructed the right column by scientiÞcally developing gp120 constructs, successfully conducting animal studies and human phase I and II clinical trials, and satisfactorily meeting the U.S. Food and Drug Administration and Thai approval processes to advance to phase III trials in the United States and Thailand. However, successful initiation and implementation of the trials required the simultaneous construction of the left column of the arch: the collaboration of many people and institutions to address the epidemiologic and behavioral factors, infrastructure requirements, and social issues.

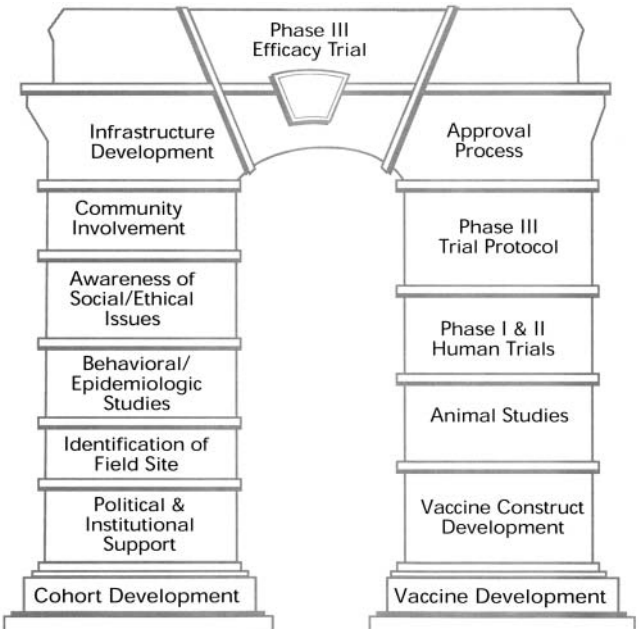

FIG. 39.1. Steps toward a phase III HIV vaccine ef cacy trial.

United States

The United States began AIDS surveillance in 1981, identifying high-risk populations and risk factors for infection. Molecular epidemiologic studies identiÞed the predominant HIV-1 subtypes and strains (123,124); seroincidence and vaccine preparedness studies among cohorts of MSM, IDUs, and other high-risk groups identiÞed factors related to recruitment, enrollment, and retention of potential vaccine participants (99,108,125Ð129). One of the largest studies, the HIVNET Vaccine Preparedness Study (VPS), successfully enrolled and retained 4,892 HIV-negative persons at high risk for HIV in nine U.S. cities between 1995Ð1997 (115).

Participation in AVEG and other industry-sponsored phase I and II clinical trials provided trained clinical research staff at community and academic sites. Procedures to address social and ethical issues, (e.g. conÞdentiality, stigma, and access to HIV-related medical care during HIV vaccine trial participation) had evolved through vaccine preparedness studies and clinical trials (130Ð132). Many AVEG and HIVNET clinical sites had formed local CABs to ensure that the investigators attended to the communityÕs needs and concerns.

Throughout the 1990s, social support and political will for vaccine trials had slowly been gaining momentum. Organizations, such as the American Foundation for AIDS Research (amFAR), the Treatment Action Group (TAG), and the AIDS Vaccine Advocacy Coalition (AVAC) encouraged research and evaluation of HIV vaccine candidates. In May 1997, President Clinton called for the development of a successful vaccine within 10 years, by 2007 (133).

Thailand

Thailand has had well-established national HIV surveillance since 1989. Multiple epidemiologic studies performed early in the epidemic identiÞed and described various at-risk populations; e.g. female commercial sex workers, male army conscripts, STD clinic patients, IDUs, and pregnant women (134Ð137). In 1991, WHO selected Thailand as a potential developing country site for preventive HIV vaccine efÞcacy trials and later supported investigation of Bangkok IDUs as a potential cohort. Subsequent epidemiologic and molecular studies documenting risk factors for infection, a high HIV-1 seroincidence rate, prevalent and incident HIV-1 strains, and the ability to enroll and retain IDUs (109,138Ð141), as well as the presence of the BMA, a public agency that oversees the administration of 17 drug treatment centers in Bangkok, made this location and population an attractive site for efÞcacy trials.

Complementary to the development of this cohort was the presence of a strong medical and public health research infrastructure. There had been high-level national support for HIV vaccine research and evaluation since the early 1990s. The National AIDS Committee created a subcommittee on HIV vaccines and, with WHO and UNAIDS support, a national plan was established for HIV vaccine development and evaluation. In addition, from 1994 to 1998, Þve HIV vaccine phase I and II clinical trials had been conducted in Thailand, far outnumbering that of any other developing country. When a 1995Ð1998 preparatory cohort study of Bangkok IDUs in treatment programs indicated that HIV-1 subtype E accounted for 80% of incident infections (138,140), VaxGen, Inc. formulated AIDSVAX B/E for use in this population. The AIDSVAX B/E phase I/II trial, started in 1998, was a collaborative effort involving the BMA, Mahidol University (Bangkok) and VaxGen, Inc. (142). Data from this successful trial led to a proposal for a phase III efÞcacy trial. The Bangkok AIDS Vaccine Evaluation Group (BVEG) was formed by the BMA, Mahidol University, the HIV/AIDS Collaboration (a joint activity of the Thai Ministry of Public Health and the U.S. CDC), and VaxGen, Inc. to conduct this trial. The trial, initiated in 1999, used existing facilities in Bangkok, and a new data management center was developed at Mahidol University.

ETHICAL, SOCIAL, AND BEHAVIORAL ISSUES ASSOCIATED WITH HIV VACCINE TRIALS

The ethical, social, and behavioral issues associated with the conduct of HIV vaccine trials have received substantial attention given the unique nature of HIV infection and the potential for stigma, discrimination, coercion, or other harms related to trial participation. Scrutiny of a 1987 phase I trial of vaccinia-gp160/LAI in Zaire resulted in allegations of human subjectsÕ regulatory violations, causing the NIH to terminate their collaboration in this trial (143). Since then, continued attention has been given to the ethical, behavioral, and social aspects associated with the conduct of HIV vaccine trials (131,144Ð149). A brief review of the bioethics related to clinical trials provides a conceptual framework for considering informed consent, the potential of experiencing social harms as a result of trial participation, possible vaccine-induced antibody responses, HIV risk behavior change, and access to medical care for trial participants who become infected while participating in HIV vaccine trials.

Bioethics and Research Ethics Involving Human Subjects

ScientiÞcally rigorous research involving human subjects did not become common in the United States and Europe until shortly before World War II; thus, interest in human subjects research emerged relatively late in the twentieth century (150). The Nuremberg trials of the Nazi doctors accused of conducting murderous human experiments in concentration camps was a salient catalyst stimulating interest, concern, and action regarding human subjects research (150,151). As a result of these trials, directives for human experimentation were published as the Nuremberg Code in August of 1947. The Nuremberg Code has subsequently been referred to as the most important document in the ethics of medical research (151).

The General Assembly of the World Medical Association (WMA) perceived the disclosures at Nuremberg to be such a threat to the integrity of biomedical research that they drafted an oath for physicians to not use medical knowledge in a way that is contrary to the laws of humanity, published as the Declaration of Geneva in 1948 (151). In 1964, the WMA distinguished between ethical and unethical clinical research in the Declaration of Helsinki (151). It has been said that Nuremberg was the Þrst code prescribed for medicine externally by a court system and the Declaration of Helsinki, the Þrst code prescribed internally by a professional body in medicine (151).

In the 1970s, the revelation that Tuskegee Syphilis Study researchers withheld effective therapy from infected African-American men in order to study the natural

history of syphilis resulted in a national commission to develop principles and guidelines for the protection of research subjects (152,153). These guidelines were published as the Belmont report in 1978 (154). Although compatible with the WMAÕs Declaration of Helsinki, the Belmont report articulated three principles: *respect for persons* (the recognition of the right of persons to exercise autonomy), *beneficence* (the minimization of risk incurred by research subjects and the maximization of benefits to them and to others), and *justice* (the principle that therapeutic investigations should not unduly involve persons from groups unlikely to benefit from subsequent applications of the research) (154).

Another important ethical construct regarding the conduct of clinical trials is that of *equipoise*, defined as a state of genuine uncertainty regarding the comparative therapeutic merits of each arm in a trial (155). Equipoise is considered to be an essential condition for conducting randomized clinical trials and avows that only when there is no known effective treatment is it ethical to compare a potential new treatment with a placebo (156). Furthermore, should it be discovered that participation in one trial arm confers superior therapeutic merit than another, an ethical obligation to offer that treatment is assumed (155). If it becomes apparent during the course of a trial that one treatment is superior, the trial may need to be terminated and all participants and possibly other persons within the same population may have to be offered the superior treatment (155). This occasionally happens when interim analyses demonstrate efficacy, resulting in trial termination, distribution of product to placebo recipients, and commencement with product licensing.

Informed Consent

The Nuremberg code established the foundation for informed consent, stating the voluntary consent of human subjects in research trials is absolutely essential:

> ÒThis means that the person involved should have legal capacity to give consent; should be so situated as to be able to exercise free power of choice, without the intervention of any element of force, fraud, deceit, duress, overreaching, or other ulterior form of constraint or coercion and should have sufficient knowledge and comprehension of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision. This latter element requires that before the acceptance of an affirmative decision by the experimental subject there should be known to him the nature, duration, and purpose of the experiment; the method and means by which it is to be conducted; all inconveniences and hazards reasonably to be expected and the effects upon his health or person which may possibly come from his participation in the experimentÓ(157).

Federal policy stresses two key elements regarding voluntary consent; the decision to participate in research should be made without undue pressure and should be based on sufficient information to confer informed consent (158). Regardless of whether an HIV vaccine is tested in developing or developed nations, informing potential participants about the risks, benefits, and requirements of trial participation may be extremely challenging. Participants attending a 1997 UNAIDS meeting to address the ethical issues of HIV vaccine trials recognized the challenge of explaining to individuals of radically different cultural backgrounds and vastly different levels of education the meaning of randomization, placebo, partial efficacy, adhering to safer sex practices, potential exclusion of early trial participants from future trials, and the potential of trial-related discrimination (147). In Uganda, for example, researchers preparing for HIV vaccine trials found that there were no linguistic equivalents for terms such as, Òbeing HIV infected,Ó Òhaving AIDS,Ó or ÒplaceboÓ (159). A Brazilian pilot study to identify problematic aspects of informed consent found that understanding of ÒrandomizationÓ and the potential of being excluded from future trials because of participation in current trials were lacking (160).

Problems with obtaining truly informed consent have been widely discussed in the literature of various disciplines including epidemiology (161), psychology (162, 163), clinical and international research (156), and HIV vaccine research (158). Expanded guidelines for the protection of human subjects in biomedical research from the U.S. Department of Health, Education, and Welfare have resulted in consent forms that are longer and more difficult to read (164). In one early HIV vaccine trial, 22 pages of HIV vaccine-related educational materials, judged to be at a reading level exceeding that of a significant percentage of the U.S. population, were used to inform participants of trial-related benefits and risks (158). These issues raise concerns about the ability of potential trial participants to adequately comprehend trial-related information presented to them during the informed consent process.

Comprehension of information presented during the informed consent process has been assessed in some HIV vaccine trials; however, little data have been published. The phase III trial of AIDSVAX B/E in Bangkok, Thailand includes a comprehension assessment and excludes the participation of individuals who score below a minimal threshold. Comprehension of trial-related information at enrollment has been found to be high among IDUs participating in a phase II trial (165). Simplified, restructured, and visual materials have been shown to facilitate recall of key trial-related risks and benefits among low-income women at risk for HIV infection (158).

Because limited data about comprehension are available, it is not known how comprehension might change over time or whether diminishing comprehension might pose a risk of harm to participants or threaten trial integrity. Participants in the two AIDSVAX HIV vaccine efficacy trials receive HIV risk-reduction and trial-related counseling at six-month intervals as reinforcement. Including standardized comprehension monitoring and associated education in future trials may reinforce the understanding

of trial-related concepts, mitigate potential risks among participants, and improve trial compliance.

Coercion

The Nuremberg Code asserts that participants should be free to choose without coercion to participate in research (151). Clinical trials, including HIV vaccine trials, that seek to enroll disenfranchised persons at risk for HIV infection (e.g. IDUs or sex workers of low socioeconomic status) or persons from developing countries with few economic or social support resources may inadvertently coerce individuals to participate by offering incentives that would be difficult to refuse given the personsÕ economic circumstances. Similarly, individuals choosing not to participate in trials must not be denied care that would have otherwise been provided if they did participate in a clinical trial. Potential trial participants could also experience social pressure to join a trial from peers, family, or community members who perceive that participation might provide benefit beyond the individual level (145). Sponsors of trials need to be vigilant about the potential for social coercion and should seek to identify and minimize this potential threat using appropriate formative and action research methods.

Social Harms Related to HIV Vaccine Trial Participation

There have been concerns that vaccine trial participation may result in stigmatization of trial participants by identifying them as high-risk individuals or by subjecting them to discrimination related to vaccine-induced HIV antibody (166–168). In a survey of 247 AVEG trial participants enrolled from 1994 to 1995, 18% reported at least one adverse social incident they perceived to be related to their trial participation; the most common (74%) was that disclosure of trial participation sometimes resulted in a mistaken presumption that participants were infected and possible subsequent avoidance or fear of the participant (131). Few problems related to jobs (1.2%), health or life insurance (1.6%), and immigration or travel (0.8%) were perceived by participants (131). Similarly, a subsequent report from 1,516 AVEG participants enrolled from 1995 to 1998 found that 5% reported social harms related to trial participation, primarily related to negative reactions of friends, family or co-workers; less than 10% of reported harms were reported to be associated with HIV testing (132).

Early data from the AIDSVAX B/B phase III trial indicate that between 4% and 8% of trial participants reported Òdisturbances in personal relationshipsÓ at their six- and 12-month visits. Disturbance typically involved negative comments about trial participation from family and friends or misperceptions that a participant was infected (169). Furthermore, trial-related employment or insurance problems accounted for less than 0.4% of reports (169). Similarly, preliminary data on 1300 IDUs participating in the Thai trial of AIDSVAX B/E, only 0.4% reported problems with personal relationships, and no social harms were associated with vaccine-induced antibody test results (170).

Vaccine-Induced Antibody Responses

The antibodies induced by some HIV vaccines can react with standard serologic assays (e.g. EIA and Western blot), resulting in HIV vaccine-induced seropositivity and may be misinterpreted as true HIV infection (168). These false-positive results could lead to social harms and discrimination regarding employment, insurance, travel, blood donation, and joining groups such as the military or the Peace Corps.

If a recipient of a complex HIV vaccine has positive serologic screening test results, it is necessary to perform confirmatory HIV testing with a Western blot and may also require assays to detect proviral DNA from peripheral blood mononuclear cells or HIV RNA from serum or plasma to determine whether or not there is true HIV infection. However, performing DNA or RNA assays, which are relatively complex and expensive, on a routine basis in large-scale HIV vaccine efficacy trials will add greatly to the cost and complexity of a trial. In addition, these assays are not routinely used for HIV diagnostic testing and are not widely available in resource-poor settings. However, given the potential social harms associated with vaccine-induced antibody responses being interpreted as natural infection, the development of new serologic tests or testing algorithms to distinguish between these two situations will be critical.

HIV-Related Risk Behavior

Concerns about the potential risks of trial participation have included speculation that HIV risk behavior might increase (171). Hypothetically, participation in HIV vaccine trials might bestow optimism regarding protection and a lowered perception of HIV risk among participants. If optimism and decreased perception of risk are prevalent among trial participants, HIV risk behavior could increase and result in subsequent infections.

Despite several reports in the literature that higher risk individuals are more willing than lower risk individuals to participate in HIV efficacy trials and that some individuals may participate in trials seeking protection from HIV infection (96,105,112,126,129,172,173), it is not known how participation in a trial actually influences HIV risk behavior. There has been one report of increased risk behavior among phase I/II HIV vaccine trial participants (171), however, methodologic constraints preclude casual

attribution to vaccine trial participation. For example, comparison groups not receiving vaccine injections were not enrolled, reported HIV risk behavior at baseline was signiÞcantly lower than what would be expected of high-risk participants, and factors other than trial participation could account for the slight increase in HIV risk behavior reported in this study (e.g. increased perception of HIV as a chronic manageable disease).

Traditionally, efÞcacy trials are designed to evaluate endpoints for those who receive an experimental product compared with those who receive a placebo or an existing standard of care, not to evaluate the effect of trial participation on risk behavior. If risk behavior increases over time among efÞcacy trial participants, causal attributions to trial participation are not possible unless a contemporary contrast arm that does not receive an injection of vaccine or placebo is built into the trial design. Without such a contrast group, potential confounders such as biased selection, history, maturation, statistical regression, experimental mortality, etc. (174), rather than vaccine trial participation, could account for observed risk behavior change within the context of a trial. For example, increased risk behavior might be due to the availability of and optimism about emerging treatments. Similarly, decreased risk behavior could be due to the fact that the highest risk individuals are enrolled into efÞcacy trials and a decline in risk behavior over time would be expected due to regression toward the mean (174).

Including perception measures within trials may help identify any association between trial participation, related perceptions, and HIV risk behavior. For example, assessing participant perceptions of randomization or of vaccine efÞcacy provides a conceptual basis for determining whether such perceptions are related to risk behavior change within a trial. In fact, these perceptions have been shown to be related to HIV risk behavior within the context of a trial (175); however, the trial participants at highest risk appear more likely to perceive randomization to vaccine arm and the vaccine itself to be of greater efÞcacy from baseline throughout the trial, so the association of risk behavior and perceptions may say more about these participants at highest risk than about the effect of trial participation on risk behavior. Unless control arms that receive no vaccine injections are included in future trial designs, nonequivalent group comparisons may be the only way to gain an understanding as to the potential for trial participation to increase risk behavior. Despite the potential confounders associated with nonequivalent group comparisons, comparing vaccine cohorts with other cohorts enrolled using similar eligibility criteria could provide convergent validity for this methodologic approach.

From a methodologic perspective, differential HIV risk behavior change between vaccinated and unvaccinated participants could confound the determination of vaccine efÞcacy (176). Behavior change could occur if participants discover through HIV antibody testing outside of the trial the presence or absence of vaccine-induced antibody. For example, if participants with vaccine-induced antibody assume protection and increase their risk behavior relative to those without such antibody, the calculation of efÞcacy will be biased. Furthermore, an increase in risk behavior among those who receive vaccine would expose these participants to an increased risk of infection, especially with a low-efÞcacy vaccine. Currently, participants are counseled to avoid testing outside the context of trials and are provided nonscheduled, on-demand antibody testing to minimize the risk of unblinding from outside testing. Through trial-provided testing and counseling, participants are informed about their antibody status related to actual infection but are not told if they have vaccine-induced antibody.

Beyond efÞcacy trials, there is concern that mass HIV vaccination campaigns might lead to increased risk behavior and HIV incidence, increasing the severity of the epidemic (177). Modeling studies suggest that even with extremely effective HIV vaccines, failure to simultaneously implement efÞcacious HIV risk behavior interventions will make prevention of HIV extremely difÞcult (177). Because of these ethical, empirical, and public health concerns, it is important to evaluate HIV risk behavior in the context of actual HIV vaccine efÞcacy trials so that adverse behavioral manifestations may be identiÞed, understood, and prevented in current and future trials and eventual HIV vaccination programs.

Access to Care

Related to the ethical construct of beneÞcence is whether vaccine trial participants are entitled to medical care as a result of participating in trials; and if so, what level of care should be provided? These questions are complex; the answers, controversial. Many trials have been and will continue to be conducted in resource-poor countries with limited health care infrastructures. In the developing country environment, should care be provided commensurate with the local standards or that provided by the sponsoring country? Thus, if the local standard of care does not include antiretroviral therapy, should these drugs be provided to individuals with positive screening test results or to those who seroconvert while participating in the trial? What if the laboratory, monitoring, and clinical capacity are unavailable for long-term follow-up of infected patients?

These issues have been fervently debated in the literature (145,147,152,178,179). The International Ethical Guidelines for Biomedical Research Involving Human Subjects, published by the Council for International Organizations of Medical Sciences (CIOMS), quotes the Declaration of Helsinki statement: ÒIn any medical study, every patientÑ including the control group, if anyÑ should be assured of the *best proven diagnostic and therapeutic method*Ó(180). Because of the complexity and potential

implications of providing the best proven therapeutic methods in the context of the developing world, an alternative proposal is that the *highest attainable standard* of care be provided in the context of HIV vaccine efficacy trials conducted in the developing world (144).

To address these issues, UNAIDS in September 1997 convened a meeting to identify and review the ethical considerations involved with international HIV vaccine trials (181). A plan was developed to conduct regional workshops in countries previously involved in HIV vaccine research, including Brazil, Thailand, and Uganda. In April and May of 1998, regional workshops were conducted that included biomedical and social scientists, community members, members of nongovernmental organizations, activists, persons living with AIDS, ethicists, lawyers, and government representatives (181). Consensus was not reached with regard to level-of-care issues. Some meeting participants felt that care should be provided commensurate with that offered in sponsoring countries for at least the duration of the trial; whereas, others favored providing treatment for those infected during trial participation, but not as a result of the trial, at a level consistent with that available in the host country (147). Concerns were voiced that promising care might constitute unethical and undue inducements to participate; however, one participant declared that providing the best available care would be tantamount to, ÒleaveÓ a Cadillac or Rolls in our country when no one can afford to drive or even repair themÓ (147,181). A final concern was that if the ethical bar is set below the maximum, it becomes easier to lower ethical standards in the future.

Access to care for trial participants will continue to be debated by ethicists, activists, and scientists. In the future, antiretrovirals may become more available as policy efforts establish global funds to support the purchase and distribution of these medications in the developing world. However, it is unlikely in the near future that such efforts will ameliorate the access-to-care debate regarding HIV efficacy trial participants.

The ethical, social, and behavioral questions associated with HIV vaccine trials will continue to be debated, and definitive answers will be elusive. The world of clinical trials is dynamic with regard to experimental context, product development, and the ethical, social, and behavioral implications of both research design and experimental products. Given the dynamic nature of the clinical trial context and the associated ethical, social, and behavioral questions, it will be important to continue to evaluate their effect on individual trial participants, targeted communities, and the conduct of trials.

FUTURE TRIALS

The AIDSVAX efficacy trials were successfully implemented due to the availability of a safe and immunogenic vaccine construct approved for phase III trials, access to suitable cohorts, and an infrastructure created by previous vaccine feasibility studies and clinical trials. However, the perceived importance of cellular immunity and the new discoveries related to HIV viral structure and pathogenesis have promoted further research, new vaccine construct development, and preparations for additional vaccine efficacy trials.

The next proposed phase III efficacy trial may begin in late 2002 in Thailand (52). This trial will evaluate a live canarypox virus vector construct in combination with AIDSVAX, a vaccine regimen that is anticipated to elicit both cellular and humoral immune responses. It is likely that additional trials will be needed to identify a broadly protective HIV vaccine. Other promising vaccine constructs (*Salmonella* vectors, VEE constructs, DNA constructs, and other envelope and regulatory protein strategies) are still in the very early stages of human clinical trials, implying that the next efficacy trials will be at least three to five years away.

The design of future efficacy trials may differ considerably from the AIDSVAX trials. These trials may require substantially more participants if vaccine constructs evaluated in earlier phase III trials demonstrate partial efficacy and additional study arms are required to compare products. In addition, the study endpoints may include reductions in plasma viral levels and rate of disease progression, necessitating longer trials. Importantly, future trials will evaluate non-subtype B vaccine constructs and will subsequently require new field sites, countries, and populations. Even though many new constructs have not yet advanced through phase I and II trials, trial sites and cohorts are being identified. It is estimated that future HIV vaccine efficacy trials could require 5,000 to 60,000 participants, several countries and trial sites, and participant follow-up for three to 10 years, at a cost of millions of dollars. To prepare for these efficacy trials, current efforts are focused on expanding existing and developing new field sites worldwide. Current stages of cohort preparation in various geographic regions follow.

North America

U.S. and Canadian clinical sites successfully recruited high-risk persons into vaccine feasibility studies and the AIDSVAX trial and could probably recruit additional high-risk persons into future efficacy trials (115,182). However, participation in future trials would require expansion of existing sites and populations. Many of the early vaccine preparatory cohorts established in 1994–1995 consisted primarily of white MSM and IDU; few included women and minorities. A substantial proportion of these ÒolderÓ cohorts may have since seroconverted, reduced their risk behaviors, or volunteered for the AIDSVAX trial, and may now be ineligible for future efficacy trials. Meanwhile, the HIV epidemic has

expanded in North America, and U.S. surveillance and study data indicate high HIV seroprevalence rates among minority MSM and heterosexual women (183–185) in addition to white MSM and IDU populations. Future efficacy trials will need to expand existing field sites and add new sites to include all populations at high risk.

Asia

Thailand, India, China, and Russia (usually considered part of Europe) are all potential participants in future HIV vaccine trials. Russia, India, and China have conducted HIV epidemiologic studies in high-risk populations and are at the preliminary stages of vaccine cohort preparation (186–188). In comparison, Thailand, a current phase III trial site, has performed vaccine feasibility and willingness-to-participate studies among numerous groups.

Latin America

Although four Latin American countries (Cuba, Brazil, Haiti, and Trinidad/Tobago) have conducted or are conducting phase I/II HIV vaccine trials, few have identified potential phase III trial cohorts through vaccine feasibility or willingness-to-participate studies. Three noteworthy exceptions are Brazil, Haiti, and Trinidad/Tobago, participating sites in the 2001 HVTN phase II canarypox/gp120 trial. These sites have been working on vaccine cohort development since the early 1990s. Brazil has concentrated its efforts on three MSM/bisexual male cohorts in Rio de Janeiro, Belo Horizonte, and São Paulo and has produced a wealth of HIV epidemiologic and vaccine feasibility data on those cohorts as well as recent data on heterosexual populations at high risk (100,113,189–193). Similarly, in Haiti, researchers have explored STD clinic patients, individuals referred for HIV testing, discordant couples, and commercial sex workers as potential phase III cohorts (102,194). And in Trinidad/Tobago epidemiologic and willingness-to-participate studies have been performed among STD clinic attendees (195–198). It is anticipated that cohorts from these three countries, as well as new cohorts being developed in Argentina (199) and Peru,(200) will participate in future trials.

Africa

Multiple countries (Kenya, Uganda, Tanzania, Malawi, Rwanda, and South Africa) have explored potential cohorts for phase III trials. Numerous HIV seroincidence, vaccine feasibility and willingness-to-participate studies have been conducted among diverse populations, such as commercial sex workers (105,201,202), truck drivers (105,201,203), rural community residents (204–207), police officers (208), factory workers (209,210), military personnel (211,212), family-planning clinic attendees (213), and postpartum women (214–216). Not unexpectedly, some cohorts had lower than anticipated seroincidence rates (122,217) and retention problems. Other cohorts were disrupted due to political instability (Rwanda, Democratic Republic of Congo). In some settings, the stigma associated with HIV and the limited care available to persons identified as HIV infected were associated with reluctance to be HIV tested and to receive HIV test results (208). This latter set of problems is complex and not easily resolved. It will require the concentrated efforts of both the developing and developed countries to address these concerns and to determine strategies to support existing vaccine preparatory cohorts and to encourage additional countries to pursue cohort preparations.

CONCLUSION

Despite the difficulties involved in developing an HIV vaccine, more than 80 vaccine constructs have proceeded to human clinical trials and two large-scale efficacy trials are almost complete. In addition, other new vaccine candidates appear promising and will be entering clinical trials within the next year. Experienced HIV vaccine trial sites have been developed in several countries and contain necessary epidemiologic, data management, laboratory, and ethical infrastructures. There is an increasing awareness among trial investigators regarding the ethical and social obligations to protect trial participants' rights and provide important human rights protections. Future efforts will be necessary to identify financial mechanisms to ensure global access to an effective HIV vaccine and to determine optimal vaccination strategies to bring the HIV/AIDS pandemic under control.

Chapter 40

The Public Health Response to the HIV Epidemic in the United States

Richard J. Wolitski, Robert S. Janssen, David R. Holtgrave and John L. Peterson

During the past 20 years, remarkable progress has been made in the treatment and prevention of HIV infection and AIDS. Highly active antiretroviral therapy (HAART), coupled with other advances in HIV treatment, has led to signiÞcant and widespread decreases in AIDS-related morbidity and mortality (1). Substantial gains also have been made in public health efforts to stem the spread of HIV. The licensing of HIV-antibody tests in 1985 made it possible to detect asymptomatic HIV infection, ensuring the safety of the blood supply and giving HIV-seropositive persons the opportunity to seek early medical care, access social services, and prevent transmission to others (2). The use of antiretroviral drugs to reduce perinatal transmission is another major success (3,4). From 1992 to 2000, mother-to-child transmission declined 75% from 697 to 162 reported cases (5,6). Community-based organizations and public health agencies have successfully provided essential information about HIV to the American public, implemented effective behavioral interventions, and motivated widespread behavior change among men who have sex with men (MSM), injecting drug users (IDUs), and other populations at increased risk (7Ð9). Considered as a whole, these efforts have reduced HIV incidence from more than 150,000 cases per year in the mid-1980s to approximately 40,000 cases per year in the late 1990s (10).

Despite these successes, the HIV epidemic continues to pose unprecedented challenges to the individuals, organizations, and agencies responsible for monitoring and protecting the health of the American people. Many persons living with HIV do not know that they are infected, and a substantial number of who learn that they are seropositive delay seeking medical care (11,12). Among those who attempt to seek care, the considerable expense of HIV treatments and racial/ethnic disparities in health care have made it particularly difÞcult for some people to access HAART (13,14). Of those who are able to obtain HAART, many have difÞculty adhering to their prescribed regimen and develop drug-resistant virus that can limit treatment effectiveness (15Ð17).Transmission of drug-resistant HIV has increased and can severely limit the treatment options of newly infected persons. Primary infection with drug-resistant HIV increased in San Francisco from 17% in 1996 to 28% in 2001 (18). Changes in the proÞle of the epidemic continue to present new challenges for HIV prevention. African-Americans, Latinos, and women account for an increasing proportion of HIV and AIDS cases in the United States, which signals a pressing need to re-examine prevention efforts for these populations. As people with HIV infection live longer and healthier lives, the prevalence of HIV infection has increased to an estimated 850,000Ð950,000 people in 2000 (19). The greater prevalence of HIV infection increases the probability that uninfected people will come in contact with HIV-seropositive sex partners and has drawn attention to the relative lack of prevention programs for this population (11). Furthermore, there are ominous signs that previous prevention gains among MSM have started to erode. Rates of unprotected sexual intercourse and sexually transmitted diseases (STDs) have risen among MSM,

indicating the potential for a resurgence of HIV infections (20Ð22).

This chapter provides an overview of the public health response to meeting the challenges of HIV and AIDS prevention in the United States (23). The six major elements of this response are shown in Fig. 40.1. Surveillance provides comprehensive monitoring of the epidemic, which guides planning activities and can be used to gauge the combined effects of prevention efforts on HIV/AIDS morbidity and mortality. Research provides in-depth information that is necessary for the development and testing of efÞcacious biomedical and behavioral interventions. Local health departments and community-based organizations are primarily responsible for implementing and delivering prevention services. The evaluation of these services provides feedback about the delivery and real-world effectiveness of HIV prevention programs and facilitates the continued improvement of these efforts. Policy guides and shapes the public health response to HIV at the local, state, and national level by setting standards, encouraging adoption of some prevention strategies, and discouraging the use of others. All of these components are supported by capacity building and technical assistance activities that seek to improve the ability of public health ofÞcials, researchers, prevention programs, evaluators, and policy makers to make informed decisions and do their jobs effectively. The model represents a dynamic process in which each element inßuences, and is inßuenced by, all of the other elements. This representation of the public health response to HIV and AIDS does not adequately recognize the extensive collaboration and involvement of a myriad of prevention partners, advocates, and community members. These partners have provided leadership and expertise that kindled and shaped the public health response to HIV (24). Their inßuence has been profound and has signiÞcantly affected all of the components of the model, which are described in detail in the following sections.

HIV AND AIDS SURVEILLANCE

Surveillance activities are a cornerstone of the public health efforts to stop the spread of HIV. Epidemiological surveillance is deÞned as the Òongoing systematic collection, analysis, and interpretation of health data that are essential to the planning, implementation, and evaluation of public health practiceÓ(25). HIV and AIDS surveillance guides public health efforts by providing essential information about trends in HIV-related disease and deaths and by identifying groups that are at increased risk based on demographic, behavioral, and geographic characteristics. This information is used to guide the development and implementation of prevention programs, suggest future directions for epidemiological and behavioral research, evaluate the combined impact of prevention efforts and clinical care, and to formulate public policy (25,26). Surveillance data also play an important role in the equitable allocation of treatment, social service, and prevention funds, including Þnancial resources provided to states and large metropolitan areas under the Ryan White Comprehensive AIDS Resources Emergency Act and federal prevention funding administered by state and local health departments (26).

A comprehensive system of AIDS surveillance was initiated in the United States shortly after the Þrst cases were identiÞed in 1981. Health departments in all 50 states and United States territories report AIDS cases to the Centers for Disease Control and Prevention (CDC) following a uniform case deÞnition (6). AIDS surveillance data are highly complete (27). and have been the primary basis for assessing changes in AIDS incidence and prevalence and identifying unmet public health needs. For example, surveillance data showed that the availability of HAART led to a dramatic decline in AIDS-related morbidity and mortality in 1996 and 1997 that later stabilized in 1998 and 1999 (1). These declines were not equal across all groups, however, and demonstrated a critical need to improve the timely diagnosis of HIV infection and expand access to life-extending treatments among African-American women, women living in the southern United States, and people infected through heterosexual contact.

The surveillance deÞnition of AIDS has been modiÞed several times in response to advances in etiology, diagnosis, and treatment of advanced HIV disease (6,26). These revisions have improved the sensitivity and speciÞcity of the surveillance deÞnition by increasing the number of AIDS-indicator diseases and incorporating laboratory evidence of severe immunosuppression and HIV infection (6). Without these revisions, early advances in the treatment of AIDS (such as effective prophylaxis for *Pneumocystis carinii pneumonia*) would have diminished the ability of surveillance efforts to monitor accurately advanced HIV-related disease. In recent years, advances in antiretroviral treatment have reduced the ability of AIDS surveillance to characterize the course of the HIV epidemic in the United States. These advances have dramatically increased the time from infection to development of AIDS-deÞning conditions, making it difÞcult to estimate reliably trends in HIV incidence and prevalence from AIDS surveillance data.

The decreased utility of AIDS case reports for estimating trends in HIV infections has led to greater recognition of the need for national HIV surveillance. Prior to June 1997, HIV infection was a reportable disease in only 25 states (28). In 1999, the CDC issued guidelines for a national HIV surveillance system that encouraged all states and territories to conduct case surveillance for HIV (29). These guidelines provided standards for the collection, reporting, and protection of patient information from public and private sources of HIV testing and clinical care. The guidelines encouraged the use of name-based data collection systems at the local level but allowed states to

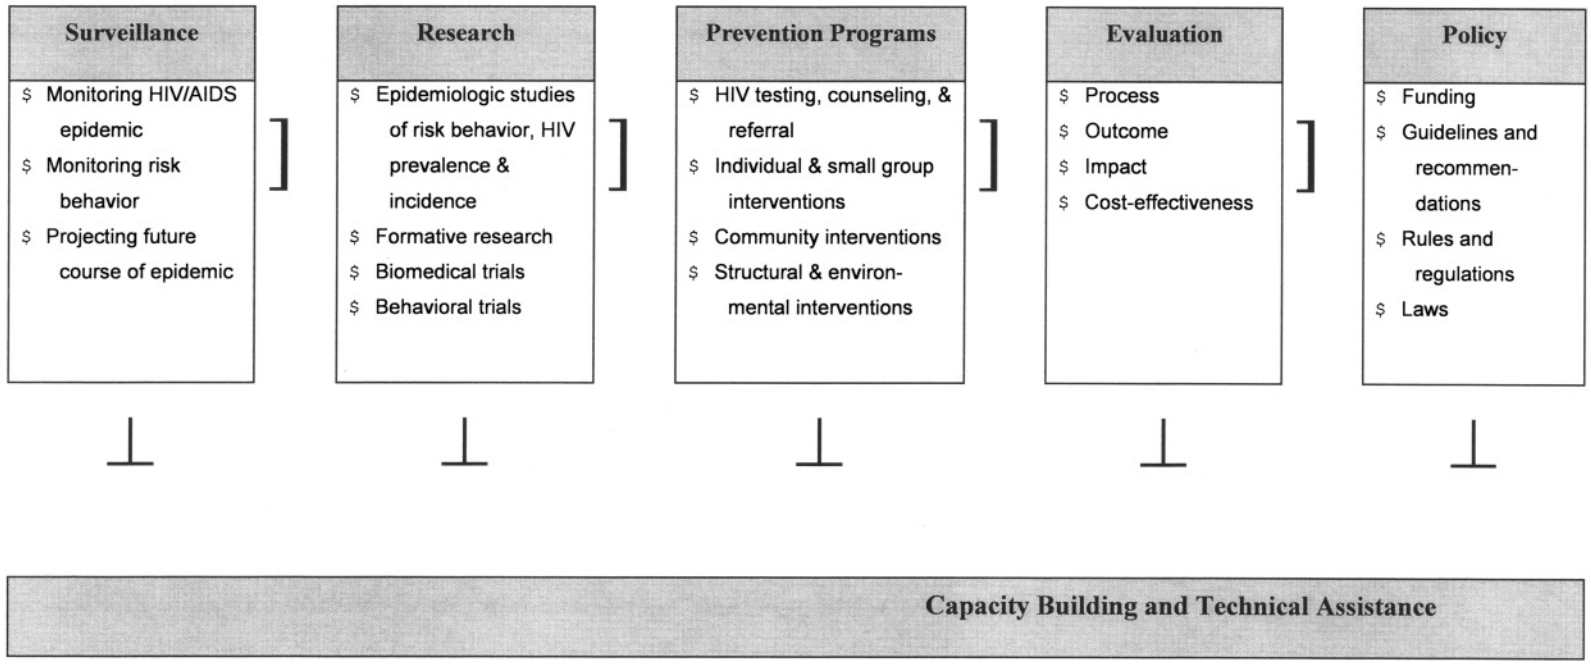

FIG. 40.1. Key elements of the public health response to HIV prevention*
* Although a linear process is ampli ed by the gure, this is not the actual, or the ideal case. All elements are *interrelated* and have the potential to affect all of the other elements of the model. In addition, all elements are in uenced by political, social, and organizational processes that are not re ected in the model.

adopt the use of coded identiÞers to provide additional protection against breeches of patient conÞdentiality or misuse of the data. In addition, the guidelines call for the reporting of rare or previously unrecognized modes of HIV transmission, unusual clinical or virologic manifestations, and other atypical cases of public health importance in order to assess potential changes in the transmission or clinical impact of HIV infection.

As of February 2002, all but three states were conducting HIV case surveillance. Although the reporting of HIV cases provides a better picture of recent trends in the epidemic, they do not provide a complete description of the HIV epidemic in the United States. HIV case surveillance represents a minimum estimate of people living with HIV that is highly dependent upon the availability and utilization of conÞdential HIV testing and treatment. In fact, there has been concern that implementation of HIV surveillance would cause some at-risk persons to avoid HIV testing and further erode the utility of these data (30). Research suggests that name-based reporting has little overall effect on HIV testing rates, but it may deter some persons at elevated risk for HIV infection from being tested (26,29). In order to reduce the impact of reporting on HIV testing rates, CDC has recommended that states provide anonymous testing so that at-risk people have the option of being tested in a setting where they do not have to provide their name or other identifying information (31). In addition, CDC and others have supported the development and adoption of a model law that protects public health information against unauthorized acquisition, use, and disclosure in order to protect the conÞdentiality of people living with HIV infection (32).

The implementation of HIV case surveillance has substantially improved the ability of public health agencies to monitor the epidemic, identify unmet needs, and evaluate the effects of prevention and treatment services. New challenges continue to arise, however, as the epidemic and efforts to limit its impact evolve. These challenges include the need to document the effects of HAART on HIV transmission rates, assess the spread of drug-resistant virus, evaluate the positive and negative effects of HAART therapy, and monitor trends in risk behavior among infected and uninfected persons (33). Addressing these challenges may require additional adaptations to HIV and AIDS case surveillance systems and the integration of other data sources such as sexually transmitted disease (STD) surveillance, HIV seroincidence and behavioral surveillance, and epidemiologic research. STD surveillance provides national information about the incidence and prevalence of STDs that are surrogate markers for unprotected sexual activity and important cofactors for HIV transmission (34). Using the serologic testing algorithm for recent HIV seroconversion (STAHRS), public health agencies can determine whether HIV-seropositive persons have recently acquired HIV and use this information to monitor seroincidence in sentinel sites (e.g. STD clinics, anonymous testing sites) (35Ð37). In addition to data on STD and HIV trends, there is also a need for behavioral surveillance to monitor trends in risk behavior among persons living with HIV infection and those who are at increased risk for HIV infection. To date, however, national behavioral surveillance efforts have been hampered by the lack of population-based studies of persons at increased risk for HIV infection and an over reliance on surveys of the general population that include few at-risk individuals and a limited number of HIV-related questions (38). The broader implementation of these strategies is paramount for establishing a comprehensive system of HIV surveillance that is responsive to changes in the epidemic and better meets the needs of those responsible for planning HIV prevention efforts and reach those at greatest risk for acquiring or transmitting HIV.

EPIDEMIOLOGIC, BEHAVIORAL, AND BIOMEDICAL RESEARCH

Research remains an important element in the public health response to HIV. The continued spread of HIV in the United States indicates a need for additional research on biomedical and behavioral interventions that are more effective and provide at-risk persons with additional prevention options. Given the changing face of the epidemic, there is also much to be learned about behavioral, psychosocial, and environmental factors that facilitate HIV transmission and progression to AIDS in understudied populations. In this section we consider the contributions of four types of research to HIV prevention: (1) epidemiologic studies; (2) formative research; (3) biomedical intervention trials; and (4) behavioral intervention trials.

Epidemiologic studies. Epidemiologic research has provided important information about HIV prevalence and incidence, risk factors for HIV transmission, and barriers to accessing and adhering to care. These studies have documented that rates of HIV infection remain elevated in vulnerable populations and are especially high among those who are African-American or Latino (39Ð42). For example, the Young MenÕs Survey reported that 7% of young MSM (aged 15 to 22 years) were infected with HIV and that prevalence differed signiÞcantly between racial/ethnic groups despite the fact that self-reported risk behaviors were similar across the groups (43). HIV prevalence was 3.3% for white MSM, compared with 6.9% for Latino MSM, and 14.1% for African-American MSM. Epidemiologic studies have also provided important information about HIV risk factors and the ability of condoms and access to sterile needles to reduce HIV transmission. Studies examining the protective effects of condoms have found that consistent condom use is associated with an 80% to 95% reduction in risk in HIV transmission and provide compelling support for condom-based strategies to HIV prevention (44Ð46).

The advent of HAART has directed increased attention to the need to improve access to HIV testing, utilization of medical care, and adherence to care. Despite the availability of free and low-cost anonymous and conÞdential HIV testing, one-quarter of people living with HIV do not know that they are infected (19). Troubling disparities in access and utilization of health care have been reportedÑ a national probability sample of adults receiving HIV care found that some groups, including African-Americans, IDUs, women, and those without insurance, were less likely to have received HAART (13). Descriptive research has also made important contributions to our understanding of adherence to HAART. These studies show that many patients, even those who experience difÞcult life circumstances, can achieve satisfactory levels of adherence and have identiÞed factors associated with poor adherence that are amenable to intervention (15Ð17).

Formative research. The success of prevention programs and clinical trials is often dependent on a thorough understanding of the needs, perspectives, and experiences of community members. Formative research, needs assessments, and other data-based strategies are increasingly being used to guide the development of prevention programs, behavioral intervention trials, and clinical trials. These methods can be used for many purposes including: (1) deÞning and describing target populations; (2) developing sampling and recruitment plans; (3) deÞning program/research objectives; (4) documenting facilitators and barriers to behavior change; (5) assessing the feasibility and acceptability of potential intervention and research strategies; and (6) evaluating potential wording of questions, biologic sample collection techniques, and other aspects of data collection (47,48). These activities draw on research techniques that are commonly used in the social and behavioral sciences such as Þeld observations, case studies, focus groups, qualitative interviews, and quantitative surveys. One approach, the community identiÞcation process, provides a qualitative methodology for rapidly assessing at-risk populations from the perspective of professionals who work with the population, those who interact informally with population members, and members of the target population (49). Formative research has been useful in the planning and implementation of biomedical interventions, including preparation for large-scale HIV vaccine trials. This research has provided valuable information about the concerns of potential participants, their willingness to participate and HIV risk, and the acceptability and feasibility of various data collection methods that will pave the way for Phase III vaccine trials (50Ð52).

Biomedical intervention trials. Randomized clinical trials have provided important information about the efÞcacy of medical and pharmacological strategies to reduce HIV transmission, AIDS incidence, and mortality. These trials, which have been extensively reviewed in this volume and elsewhere, have resulted in medical treatments that reduce viral load, improve immune function, delay progression to AIDS, and increase survival (53). Clinical trials of biomedical interventions have also made signiÞcant contributions to the prevention of HIV transmission. ACTG 076 showed that perinatal transmission could be substantially reduced by providing AZT to HIV-seropositive women during pregnancy and delivery and to their newborns following delivery (3). Subsequent studies have demonstrated that other antiretroviral regimens are also effective (54Ð56).

Research on biomedical interventions to prevent sexual transmission of HIV has been less successful. Efforts to create an effective preventive vaccine have been hampered by an inadequate understanding of the factors that protect against HIV infection, a lack of good animal models, differences between HIV subtypes, and other factors (57Ð59). Although many researchers remain optimistic about their ability to develop an effective preventive vaccine in the next seven to ten years, others believe that it will be much longer before an effective vaccine is available (57,59,60). There have also been considerable setbacks in the development of vaginal and rectal microbicides that can protect against HIV infection. Although a variety of agents that inactivate HIV, inhibit viral entry, or inhibit viral replication have been identiÞed, none has been shown to signiÞcantly reduce rates of HIV infection in a Phase III clinical trial (61,62). Nonoxynol-9, the only product to be tested in large-scale trials, was found to increase vaginal lesions and to increase womenÕs risk of HIV infection or provide no protection compared to a placebo (62,63). Other potential microbicides have been identiÞed and are being tested. As of 2000, 22 products were being evaluated in early trials to evaluate safety and ability to prevent HIV infection *in vivo* (61).

Behavioral intervention trials. Prevention of HIV transmission among at-risk adults and adolescents continues to depend primarily on motivating individuals to change their personal drug-use and sexual practices. Researchers have drawn on epidemiological data, behavioral theory, and formative research to develop interventions for a variety of at-risk populations. Most of these interventions attempt to change the behavior of at-risk individuals by inßuencing self-efÞcacy, perceived norms, attitudes regarding condom or sterile needle use, motivation/intention to adopt risk reduction strategies, or other psychosocial factors articulated in models and theories of human behavior. Typically, intervention activities focus on bringing about changes at the individual or small group level (see Table 40.1). A limited number of interventions have sought to change entire communities (or subgroups within a community) by mobilizing community members, changing social norms, or removing barriers to safer sex or injection practices.

A large number of studies evaluating the effectiveness of behavioral interventions have been published. Although not every intervention has been successful, literature reviews have consistently found evidence indicating that behavioral interventions can motivate reductions in HIV

risk in a wide range of populations including adolescents, MSM, IDUs, and women (64–69). An objective scientific panel convened by the National Institutes of Health in 1997 reached the same conclusion, stating that "behavioral interventions to reduce risk for HIV/AIDS are effective and should be disseminated widely" (70). A comprehensive effort to evaluate the effectiveness of behavioral interventions, the HIV Prevention Research Synthesis

TABLE 40.1. *Typology of HIV prevention interventions*

Level of Intervention	Characteristics	Examples
Individual	• Directly influences knowledge, attitudes, and behavior of people participating in intervention activities • Information delivered in one-on-one setting by professionals, peers, and/or media (e.g. brochures, radio, internet) • Limited number of people reached • Often provides the most flexibility to meet client needs	• HIV counseling and testing • Risk reduction messages given by primary care providers • Prevention case management
Small Group	• Directly influences knowledge, attitudes, and behavior of people participating in intervention activities of newly formed or existing groups of individuals • Activities conducted with couples, small groups, or family members that use professionals, peers, and/or media • Moderate numbers of people reached • Some flexibility to meet needs of individuals	• Interventions for HIV-serodiscordant couples • Single-session and multi-session workshops • Programs that train parents to talk with their children about HIV
Community	• Directly and indirectly influences knowledge, attitudes, and behavior of entire community • Often focus on changing social norms • May have multiple intervention components that use peers or professionals and/or media • Large numbers of people reached • Little flexibility to meet needs of individuals	• Mass media and social marketing campaigns • Peer outreach • Community mobilization
Structural	• Indirectly affect risk behavior by changing structures, laws, or policies that may influence transmission risk or the availability of prevention information or tools • Changing policy/law may be require few resources but implementing structural changes may be expensive • Affects large numbers of people at the city, state, or national level • Not tailored to individual needs	• Needle exchange programs • Reducing cost/increasing availability of condoms • Laws permitting sale of sterile syringes without a prescription • Policies supporting provision of safer sex education and condom availability in schools
Superstructural	• Indirectly affect risk behavior by changing social and economic structures or pervasive societal customs and attitudes that result in unequal advantages to groups, communities, or countries • Can result from governmental effort, social movements, or revolution • Affects large numbers of people at the city, state, or national level • Not tailored to individual needs	• Antipoverty programs • Antidiscrimination programs • Provision of housing to people living with HIV • Licensing of generic versions of antiretroviral drugs
Medical/Technological	• Directly and indirectly affect risk through scientific advances in medical care and other fields that reduce infectivity or provide new/improved prevention technologies • Can affect HIV transmission but rely on other intervention strategies to motivate dissemination and adoption • Can affect large numbers of people but cost and other factors may limit access	• Female condom • Microbicides • Use of antiretrovirals to prevent perinatal transmission • Post-exposure prophylaxis • Preventive vaccine

Adapted from Sweat & Denison (128) and Waldo & Coates (2000) (175).

Project, has reviewed more than 5,000 scientiÞc reports and identiÞed 303 studies that evaluated the effects of behavioral interventions (71,72). Of these, 122 (40%) were conducted in the United States and met standardized criteria for relevance and methodological rigor. Meta-analyses of 61 studies that met these criteria showed signiÞcant reductions in sexual risk among young adults (OR = 0.65, 95% CI = 0.56Ð0.85), MSM (OR = 0.69, 95% CI = 0.56Ð0.86), heterosexual men and women (OR = 0.81, 95% CI = 0.69Ð0.95), and drug users (OR = 0.86, 95% CI = 0.0.76Ð0.98) (66Ð68,71,73). Of the studies reviewed to date, 36 have met additional criteria for effectiveness and have been included in the Compendium of HIV Prevention Interventions with Evidence of Effectiveness (74). The compendium has been widely disseminated to community-based providers and is used as a resource for identifying effective interventions that address local needs.

HIV PREVENTION PROGRAMS IN THE UNITED STATES

The rapid emergence of AIDS and the magnitude of the epidemic led to an unprecedented mobilization of community and public health resources. Responding to a new public health emergency of this size has required overcoming substantial logistical, scientiÞc, social, and political challenges. Addressing these challenges necessitated the development of innovative partnerships that include community members, community-based and national organizations, and local, state, and federal public health ofÞcials. The combined efforts of these groups have resulted in a multitude of HIV prevention programs that seek to increase public awareness, encourage at-risk persons to be tested for HIV infection, and motivate those at increased risk for acquiring or transmitting HIV to reduce their risk. As shown in Table 40.1, these programs can be categorized by whom (or what) intervention efforts are directed toward. Most interventions have focused on individuals or groups of individuals. These interventions include information hotlines, risk reduction counseling, prevention case management, and other strategies that attempt to bring about changes in knowledge, beliefs, motivation, and behavior among people who participate in the intervention. Institutional or community-level interventions focus on larger groups and seek to change risk behavior not only among intervention participants but also among members of an institution or a community who do not participate in the intervention. These programs include peer outreach, social marketing campaigns, and syringe exchange programs that work to change community-wide norms regarding HIV risk reduction or improve access to condoms, sterile syringes, and other risk reduction tools. Changes in public policy and laws act as structural interventions that can make it easier for individuals to adopt reduced risk practices or make it more difÞcult to engage in risky practices. Fundamental changes in the social structure of a community, state, or nation also have the potential to affect risk behavior and HIV transmission. Such programs include those that address economic or social disparities (such as poverty, racism, and homophobia) that are associated with life circumstances that can increase persons risk of being exposed to HIV. Finally, scientiÞc advances in HIV prevention and treatment also act as interventions by reducing infectivity or providing new prevention options that are more effective or easier to use.

Early in the epidemic, public health agencies devoted a great deal of attention to providing basic information about HIV and AIDS to the general public and those at increased risk. Mass mailings, public service announcements, and other large-scale efforts disseminated basic information about HIV, risk behaviors, and risk reduction strategies (75,76). Other programs worked to integrate HIV education into a wide range of community settings including schools, workplaces, churches, beauty parlors, and other locations (75Ð79). These efforts have increased basic knowledge about HIV transmission and prevention (although some myths about casual contagion persist) and helped reduce negative attitudes about people living with AIDS (80Ð82).

Important as these changes are, it was recognized early on that increasing HIV knowledge and awareness would not be sufÞcient to motivate widespread changes in risk behavior. This recognition and the differential risk of HIV infection in well-deÞned subpopulations led to the development of more intensive programs that were designed to meet the needs of those who are at greatest risk. Many different strategies have been developed to encourage people to protect themselves from HIV (see Table 40.1 for examples). Many of these programs are based on interventions that have been shown to be efÞcacious in rigorous research trials. Behavioral interventions do not always originate with researchers. Other HIV interventions have been developed by prevention providers working in health departments and community-based organizations. These interventions have the advantage of being responsive to local needs and the realities of the agencies that implement these programs. Many of these interventions have not been subjected to outcome and impact evaluations due to limited evaluation budgets and methodological challenges, making it difÞcult to identify successful programs and compare their effectiveness. One effort to identify successful programs used an extensive nomination and review process that resulted in the selection of 18 interventions that were considered by prevention providers to be model programs (83). Site visits to these programs revealed important characteristics of the interventions, agencies, and staff that appeared to contribute to their success. The characteristics of effective interventions are summarized in Table 40.2.

For more than 15 years, HIV counseling and testing has been the single most widely available prevention program

TABLE 40.2. *Characteristics of effective HIV prevention programs*

Intervention Characteristics	Staff Characteristics	Agency Characteristics
• Clearly de ned goals, measurable objectives, audience, and intervention activities • Based on behavioral theory, scienti c literature, and needs of community • Culturally competent and client centered • Ongoing monitoring of implementation and client needs • Use evaluation ndings to improve program	• Adequate training and prior experience • High level of commitment • Understand needs of local community • Flexible and able to make changes in response to client needs • Respect clients • Able to listen to, and advocate for, client needs • Do not adopt "top-down" approach • Able to deal with stress	• Support from administrators and managers of agency • Suf cient staff, equipment, space, and other resources • Integration/consistency with agency's mission • Partnership and collaboration with other agencies • Able to retain staff • Credible and respected in community

in the United States. The primary goals of HIV counseling, testing, and referral programs are: (1) to promote knowledge of HIV status and early diagnosis of HIV infection; (2) to provide high-quality prevention counseling; and (3) to provide referrals to medical, preventive, and psychosocial support services (31). The CDC has recommended that people being tested for HIV receive pretest and posttest counseling since testing became available in 1985 (84). Initially, this counseling provided information about the test itself and the meaning of positive and negative results, but by 1987, greater emphasis was placed on encouraging risk behavior change (85–87). Early studies found that counseling and testing led to signiþcant reductions in risk among people who learned that they were HIV-seropositive but motivated little change among those who were HIV-seronegative (88–90). Based on these þndings and expert consultation, the CDC recommended a shift to client-centered counseling that emphasizes increasing clientÕs perception of risk and developing a personalized risk-reduction plan (2,91). This approach has been shown to increase condom use and decrease new STDs among STD clinic patients who received client-centered counseling compared to those who received standard risk reduction messages (92). In 2001, the CDC issued new guidelines in an effort to make HIV testing more accessible, address technological advances in HIV testing, recognize resource and provider constraints, and accommodate the diverse needs and preferences of people seeking testing (31).

Federally funded HIV prevention programs are guided by a comprehensive HIV prevention plan that is developed locally through a community planning process. Community planning involves members of affected communities, prevention providers, and others in the on-going development of prevention plans that reßect local needs and are based on sound science and public health practice (93). Members of community planning groups are responsible for monitoring and anticipating the course of the HIV epidemic in their community, assessing and prioritizing prevention needs, and identifying science-based interventions to meet these needs. This value- and science-based decision making process has led to important shifts in the allocation of prevention funds that more adequately reßect the racial/ethnic characteristics of people living with HIV/AIDS, increased funding for health education and risk reduction programs, and provided more resources to community-based organizations (94,95). Other positive outcomes of community planning include greater recognition of the needs of different geographic, cultural, and risk groups, improved coordination of HIV prevention activities, and an increased attention to evaluation (96).

EVALUATION OF HIV PREVENTION EFFORTS

Limited prevention resources and the painful realization that HIV has become endemic in the United States have placed greater emphasis on accountability and the continued need to improve the effectiveness of prevention efforts. Ongoing evaluation of HIV prevention programs is an essential component of the public health response to HIV. It provides useful information regarding the implementation of intervention activities, the ability of interventions to achieve program objectives, the cumulative impact of prevention efforts, and the economic beneþts and relative costs associated with various intervention strategies. In this section, we review four major types of program evaluation: (1) process monitoring and evaluation; (2) outcome monitoring and evaluation; (3) impact evaluation; and (4) economic evaluation.

Process monitoring and evaluation. Process measures are used to describe and assess the delivery of prevention services. Process monitoring refers to information that is collected in order to document and describe the intervention services that are conducted, the characteristics of persons who receive these services, and the resources that were used (97,98). Process evaluation involves the collection and analysis of information about the implementation of program activities (97,98). Process evaluation provides

feedback on the quality of prevention services that are provided, whether those at greatest risk are being reached, and how these programs are implemented within the realities of community-based providers (99). When combined with outcome data, process measures facilitate the identiÞcation of the program elements that are most strongly associated with behavior change (99). Process data have proven to be extremely useful for monitoring the implementation of HIV prevention efforts at local, state, and national levels. At the national level, for example, process data have indicated that the types of prevention services provided in local communities have changed since community planning was initiated and have identiÞed gaps in prevention services for African Americans, MSM, and IDUs (95).

Outcome monitoring and evaluation. Relatively little is known about the effectiveness of interventions that are developed and/or implemented by community providers (100). A number of these interventions have not been evaluated to determine their effects on risk behavior. Other programs are based on interventions that were rigorously tested in randomized trials. Although it is hoped that these interventions would continue to be effective when conducted by community-based providers, this cannot be assumed with certainty. Reasons to question the real-world effectiveness of these interventions include characteristics of the original intervention research (e.g. training of staff, payment for participation, methods for recruiting participants), characteristics of community-based organizations (e.g. staff turnover, limited resources, Þdelity to intervention protocol), and changes in the needs of at-risk persons that may affect the ability of these interventions to motivate behavior change in community settings. These factors, coupled with substantial diversity across interventions in terms of strategies used, settings, and populations served, necessitate the continued evaluation of intervention effects at the local level.

Outcome monitoring measures the effects of an intervention on those who receive it and allows for an evaluation of the extent to which program participants have experienced measurable changes in knowledge, perceptions, or behavior (97,98). Outcome monitoring does not employ comparison or control groups, and because of this, does not rule out the possibility that factors other than the intervention were responsible for the observed changes. Outcome evaluation is a more rigorous, and employs experimental or quasi-experimental research designs to rule out the inßuence of factors other than the intervention that might be responsible for the observed changes. A small number of outcome evaluations of community-based programs have been reported (100), but these represent only a tiny fraction of active prevention programs. In order to address this gap, the CDC now requires jurisdictions that receive one million dollars or more in federal funding each year to monitor outcomes on at least two programs or conduct outcome evaluation of at least one program (97).

Impact evaluation. Measurement of the long-term and combined effects of multiple HIV prevention efforts is the goal of impact evaluation (97,98). This type of evaluation goes beyond the outcome evaluation of a given intervention among program participants by assessing the broader societal effects of multiple interventions on communities as a whole. The cumulative impact of HIV prevention programs may be affected by a number of factors including the number and type of interventions available in the community, the individual effectiveness of each intervention, the number of people reached, and the duration of intervention activity. The impact of prevention programs may also be affected by external factors that are not associated with these efforts such as changes in social norms, technological advances, and historical events.

The most basic and direct measure of the impact of HIV prevention is HIV incidence in the community or population of interest. Other biological, behavioral, service, and sociopolitical measures also can serve as important indicators. A series of consultations sponsored by the CDC identiÞed 37 core indicators in these categories that have been Þeld tested to assess their utility in Þve jurisdictions (101,102). These pilot projects demonstrated the overall usefulness of the core indicators and documented progress toward reaching prevention goals in some populations (102Ð104). All of the indicators were not available in all sites, however, and there were signiÞcant gaps in the available indicators for MSM, IDUs, high-risk heterosexuals, and childbearing women (102).

Economic evaluation. The goal of economic evaluation is to provide information about the costs of prevention efforts and the resources that are required to achieve a given outcome. Cost analysis involves the assessment of the resources that are needed to conduct a speciÞc program (105). Cost effectiveness analysis links the monetary value of the resources needed to deliver an intervention with outcomes (e.g. the cost per HIV infection averted) (97,105). Cost effectiveness analysis facilitates the comparison of interventions with common outcomes, making it possible for decision makers to choose interventions that are likely to have the greatest impact on risk behavior for a given expenditure of resources. Other types of economic evaluation include cost-beneÞt analysis, in which outcomes are assigned a monetary value (e.g. cost of medical care for each HIV infection averted), and cost utility analysis, which converts intervention outcomes into units that represent changes in the quantity and quality of life (e.g. increases in life expectancy, gains in quality adjusted life years) (105). The advantage of these analyses is that they translate intervention outcomes into standard units (i.e. dollars or quality adjusted life years) that can be readily used to help make decisions about the potential monetary or health beneÞts associated with very different types of programs or services (e.g. interventions to reduce unprotected sex versus programs to improve air quality).

A review of the economic evaluation literature identiÞed 28 studies that examined HIV prevention interventions in

the United States (106). Most of these studies (79%) were cost effectiveness evaluations, and provided evidence that HIV interventions can be cost effective or cost saving. Cost effective interventions have been identified for IDUs, MSM, male African-American adolescents, and at-risk women but some populations and promising intervention strategies have been understudied (106–111). The economic evaluation literature is growing rapidly and many other types of HIV prevention interventions are being subjected to cost effectiveness analyses.

PUBLIC POLICY

The main goals of HIV-related public policy are to reduce HIV/AIDS morbidity and mortality by supporting the adoption and maintenance of practices that reduce the spread of HIV, encouraging early identification of HIV infection, and promoting access and adherence to high-quality medical care. Policy is both a product of the public health response to HIV and an external influence that has shaped this response. Policies issued by public health agencies establish standards and provide recommendations for monitoring and responding to HIV/AIDS, conducting prevention programs, and delivering medical care. Other forms of policy, such as laws, regulations, and funding allocations are often generated outside of public health. They indirectly affect morbidity and mortality by influencing the number and types of prevention programs in communities, the availability of condoms, sterile needles and syringes, and other prevention tools, and the rights of people living with HIV and those who are at risk of infection.

All forms of policy are affected by multiple factors including empirical data, expert and public opinion, and political concerns. Although many have argued that policy should be based solely on published empirical evidence, this not achievable (112,113). The rapid emergence of HIV and AIDS required that policies be developed before sufficient empirical data could be collected. Even when data were available, policy decisions were often influenced by ethical, moral, and political values. These values included beliefs about the appropriate role of government in public health, the importance of HIV compared to that of other health threats, the rights and responsibilities of those who are infected with HIV, and the rights and responsibilities of those who are uninfected. The far reaching effects of public health policy makes it undesirable for decision makers to act unilaterally and necessitates the active participation of diverse stakeholders, consideration of intended and unintended consequences, and trade offs between private rights and public good (112). Unfortunately, however, this process can become polarized. Extreme views on either side of a particular issue can lead to inaction or the formulation of public policy that unnecessarily deprives individuals of basic rights, is inconsistent with empirical data, or fails to achieve the goal of protecting the health of the American public.

Many policies and laws have been developed in an attempt to influence the risk behavior of individuals and direct the public health response to HIV and AIDS. These include laws and policies that protect the confidentiality of people living with HIV, encourage the availability of anonymous HIV testing, mandate HIV testing in some circumstances, restrict the types and content of HIV prevention programs, regulate the purchase, exchange, and possession of needles and syringes, increase access to HIV-related medical care, or govern the sexual practices of people living with HIV (12,114–117). There are many strongly voiced opinions about the positive and negative effects of specific policies, but often empirical data are not available to evaluate the relative merit of divergent perspectives on either side of a given issue.

In some cases, extensive empirical data are available to inform the development of public policy or to evaluate its effects on public health efforts to limit the spread of HIV. For example, a considerable amount of research has demonstrated that limiting the availability of sterile needles and syringes increases HIV risk and that efforts to reduce barriers to obtaining sterile injection equipment decreases the sharing of contaminated needles and syringes among IDUs (37). Higher levels of HIV prevalence and incidence have been observed in communities with laws that restrict the sale of sterile syringes to IDUs compared to communities without these restrictions (118). Successful efforts to repeal laws restricting the sale of sterile needles have improved access to sterile syringes and decreased the sharing of used syringes among IDUs (116,119). The bulk of the research on the effects of syringe exchange programs has demonstrated that these programs are cost effective, reduce needle sharing, and do not lead to increased drug use or initiation of drug injection by non-IDUs (112,120–126). Despite the preponderance of evidence and the recommendations of objective review panels, federal restrictions on the funding of syringe exchange programs remain in place because of questions about the interpretation of the available data and concern that the existence of these programs would condone the use of illicit drugs or lead to other negative consequences (112,125,126). Barriers to the implementation of syringe exchange programs are increasingly being overcome at the local level. From 1994 to 1998, the number of identifiable syringe exchange programs nearly doubled from 68 to 113 (127). In 1998, 110 programs provided more than 19 million syringes to IDUs and almost all provided other prevention services including condoms, bleach for cleaning syringes, voluntary HIV counseling and testing, and referral to drug treatment (127).

Well-informed policies and laws can be powerful interventions that further public health efforts to limit the continued spread of HIV infection (128,129). However, much remains to be learned about the impact of public

policy on HIV risk and the ways in which research and public health practice can inform the development of sound public policy. New policy challenges will emerge as the epidemic, science, and the social and political landscape continue to change over time. Although some battles may be lost, it is essential that researchers and public health officials remain fully engaged in these debates if they hope to win the war against HIV (129).

TECHNICAL ASSISTANCE AND CAPACITY BUILDING

All elements of the public health response to HIV and AIDS are strengthened by a wide range of activities conducted at the local, state, and national levels that provide technical assistance and support capacity building. The goal of capacity building is to enhance and sustain the ability of individuals, organizations, and communities to perform the core public health functions that are essential to HIV prevention (130). These efforts include: (1) technology transfer; (2) technical/capacity building assistance; (3) training; (4) skills building; and (5) information dissemination. Some efforts, such as HIV/AIDS postdoctoral training programs, have the potential to have a broad effect on public health activities by increasing the availability of highly trained and culturally competent professionals. Other efforts directly improve the current ability of individuals and agencies conducting HIV/AIDS surveillance, community planning, behavioral interventions, or program evaluation.

Substantial resources have been dedicated to improving the ability of community-based organizations and health departments to conduct effective HIV prevention programs. Activities supported by these resources have sought to overcome the challenges faced by many of the community-based organizations that were created in response to the HIV epidemic. Many of these agencies are relatively new, have small staffs, experience rapid staff turnover, may not have access to scientific publications, and have limited financial resources (98,131,132). Technical assistance and capacity building to overcome these challenges is provided by CDC, the National Association of State and Territorial AIDS Directors (NASTAD), the National Minority AIDS Council, and other organizations. These activities include:

- The National Technical Assistance Providers Network for Community Planning, which provides technical assistance on management of the community planning process and the development of local HIV prevention plans (133).
- The Capacity Building Assistance Providers program that works to strengthen the efforts of organizations serving racial and ethnic minority populations (98).
- Fact sheets, guidelines, resource manuals, and user-friendly replication packages that provide information on community planning, HIV counseling, testing, and referral, effective behavioral interventions, evaluation, and other topics (134–136).
- A national database of prevention resources and programs, the National Prevention Information Network, that can be accessed by telephone or the internet (137).
- National conferences and televised satellite broadcasts for prevention providers that address emerging issues, disseminate information about effective interventions, and provide opportunities for skill building, networking, and resource sharing (138,139).
- Regional training on behavioral interventions and formative research provided by the STD/HIV Prevention Training Centers (140).
- Local consultation and hands-on assistance provided by behavioral and social scientists who participate in the American Psychological Association's Behavioral and Social Science Volunteers program (141).

ADDITIONAL CHALLENGES AND FUTURE DIRECTIONS

There have been many accomplishments in the fight against HIV and AIDS, and prevention efforts have contributed to substantial declines in HIV- and AIDS-related morbidity and mortality in the United States. Unfortunately, it is clear that HIV will remain a major threat to the health of Americans for many years to come. An effective preventive vaccine remains out of reach, and HIV infection rates continue to be unacceptably high. As we look forward and consider the next steps in the public health response to HIV, we must grapple with difficult questions that continue to have major implications for the planning and delivery of prevention efforts:

- Why do 40,000 people a year continue to contract HIV in the United States despite widespread awareness of HIV and the presence of community-based prevention programs?
- Why does the disproportionate impact of HIV and AIDS on African Americans and Latinos continue to increase?
- Why do one-quarter of people who are infected with HIV not know that they are seropositive?
- How can the effectiveness of public health efforts to prevent HIV transmission be improved, particularly when some communities have been saturated with prevention messages?

Answering these questions and implementing prevention efforts have become increasingly difficult in light of the challenges that public health now faces. The growing number of people living with HIV and the expense of HAART has strained the budgets of drug assistance programs, requiring significant increases in funding and the implementation of strategies to ration access to this life-saving therapy in some communities (14). The

availability of HAART has changed perceptions about the severity and transmissibility of HIV and has caused some people to be more willing to risk infection (142–144). As the number of people living with HIV has increased, so has the probability that uninfected persons will have contact with sex or needle sharing partners who are HIV-seropositive. This growing risk is compounded by the transmission of drug-resistant HIV that may limit the treatment options of people who are newly infected and outbreaks of STDs that facilitate HIV transmission (18,20,145). A comprehensive approach to prevention for people living with HIV infection is needed and should include early diagnosis of HIV infection, linkages to medical care and prevention services, strategies to improve adherence to care, and life-long support for the adoption and maintenance of reduced risk practices (11,146).

Other emerging factors have also presented additional challenges to HIV prevention efforts in communities that had previously demonstrated substantial reductions in HIV risk. The internet has created new opportunities for people to meet sex partners and may facilitate the formation of risky partnerships (147,148). A new generation of MSM that has had little first-hand experience with the effects of HIV is at considerable risk of infection (43,149–151). There is evidence that "safer sex fatigue" that results from years of exposure to prevention messages and long-term efforts to maintain safer sex practices has led to increased risk among older MSM (152). Dissatisfaction with prevention programs in the gay community has contributed to a backlash against prevention and a view that prevention messages for MSM are outdated or overly simplistic (7,20). In particular, the ability of prevention efforts to reach African-American and Latino MSM has been increasingly questioned given that these groups continue to represent a disproportionate and growing percentage of HIV and AIDS cases among MSM (20,153). Addressing the urgent needs of these men will require further examination of the unique cultural experiences of African-American and Latino MSM that may facilitate or hinder prevention efforts and for research leading to the development of effective interventions that are tailored to meet the needs of these populations (154,155).

In some cases, prevention programs do not have the resources or tools they need to limit the further spread of HIV. Spending on prevention efforts represents a small proportion of state and federal governments' expenditures on AIDS. Less than 8% of federal HIV/AIDS funding is spent on prevention (156). Changes in perceptions about the importance of HIV has contributed to a decline in donations to AIDS organizations, which has limited the activities of some prevention programs and jeopardized the existence of others (157). There is an inadequate number of effective interventions for some high-risk populations. There is a surprising lack of rigorously evaluated interventions for MSM; this is particularly true for racial/ethnic minority MSM and young MSM. Although MSM represent more than half of all people living with HIV (158), just six of the 36 effective interventions (17%) in the compendium of effective interventions were developed for MSM (none of which focused specifically on racial/ethnic minority MSM) (74). As the epidemic evolves, the critical need for interventions for racial/ethnic minority youth, at-risk women, people living in rural areas, incarcerated populations, and people living with HIV infection has become increasingly apparent (65,70). There is still much that needs to be learned about the "active ingredients" of behavioral interventions. Most behavioral interventions consist of multiple elements and little is known about which components are critical to their success, the optimal number of intervention sessions, and their duration. Important questions remain unanswered regarding the characteristics of staff and volunteers who make effective interventionists and how community membership, professional training, demographic characteristics, and personal traits of interventionists affect intervention outcomes. Finally, there is a clear need to develop a better understanding of why some intervention participants change their behavior and others do not. This knowledge should lead to the creation of second and third generation intervention strategies that better address the needs of those whose behavior is unaffected by existing interventions.

The HIV epidemic does not exist in isolation. It is intricately intertwined with other health problems that facilitate the spread of HIV and make it more likely that some individuals (and some communities) will be exposed to HIV than others. The interaction between HIV risk and other health issues involves factors that exist within the individual as well as structural and environmental factors in the community. At the individual level, health factors that interact with HIV risk include the effects of substance use, sexual abuse, and other mental health issues (159–162). Structural factors that influence HIV risk at the community level include: (1) differential educational and economic opportunities that contribute to poverty and homelessness; (2) differential access to drug treatment, testing for sexually transmitted infection and HIV, medical care, and antiretroviral therapies; and (3) the effects of racism, sexism, homophobia and HIV-related stigma (128,163,164). In order to move prevention efforts to the next level, public health must better understand and address the influences of these factors that limit the effectiveness of prevention programs and sustain the epidemic within vulnerable populations.

Improving efforts to prevent HIV transmission and AIDS not only requires that we develop a better understanding of factors that contribute to individuals' risk but we also critically examine the performance of the public health system. There are substantial gaps in the delivery of medical care and prevention services that limit the effectiveness of the public health response to HIV. Health care providers are not always aware of current public health guidelines and may fail to provide recommended

treatments or appropriate counseling to their patients (165–167). Racial/ethnic disparities, fear of discrimination, and stigma can affect the health care system and limit the ability and willingness of some people to access appropriate care (164,168,169). Furthermore, the effectiveness of community-based HIV prevention programs may be decreased by barriers to the adoption of rigorously evaluated interventions that significantly reduce HIV risk (132,170). In the years to come, we must devote more effort to addressing these and other problems that diminish the ability of public health agencies and their partners to function effectively.

As public health struggles to deal with disparities in HIV treatment and care in this country, there is a clear consensus that America needs to provide additional leadership and resources to combat HIV and AIDS in developing countries. The burden of HIV-related disease in these countries is overwhelming. Globally, there are 40 million people living with HIV, the vast majority of whom live in sub-Saharan Africa and Southeast Asia (171). In sub-Saharan Africa, HIV prevalence is estimated to be 8.8% among adults, and exceeds 20% in seven southern countries (172). The effects of HIV have been devastating in these countries, causing infant mortality to double and overall life expectancy to decline by 10 or more years (172,173). The magnitude of the global HIV pandemic is sobering and makes the role of structural factors that concentrate the virus within marginalized populations even more apparent (174). Strengthening our response to the global HIV crisis will require a substantial increase in human and financial resources to ameliorate these long-standing disparities. Doing so will require that we look back on the hard-earned lessons of the past 20 years, while at the same time looking ahead to the new and recurring challenges that HIV will continue to present for many years to come.

Chapter 41

The Global Impact of HIV and AIDS

Marjorie Opuni and Stefano Bertozzi

The human immunodeÞciency virus (HIV) and its most severe clinical manifestation, the acquired immunodeÞciency syndrome (AIDS), have produced a devastating pandemic of enormous proportions. As of the end of 2002, the Joint United Nations Programme on HIV/AIDS (UNAIDS) and the World Health Organization (WHO) estimated there were 42 million persons worldwide living with HIV or AIDS (Fig. 41.1) (1). In addition, more than 20 million people have already died making a cumulative of more than 60 million HIV infections since the beginning of the epidemic (2).

The spread of HIV/AIDS has far exceeded expert predictions made earlier in the epidemic (4). And the epidemicÕs demographic, social and economic impacts have been much greater than expected. This is especially true in developing countries where 95% of people living with HIV live (1). It is most particularly true in sub-Saharan Africa the continent with over 70% of people living with HIV.

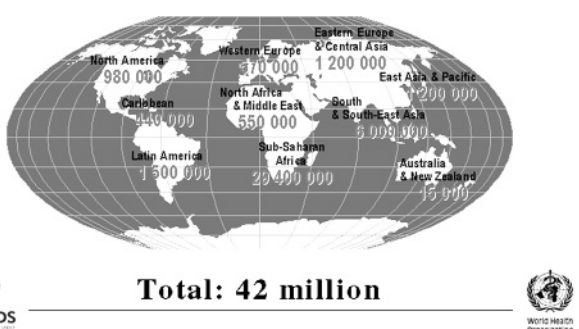

FIG. 41.1. Adults and children estimated to be living with HIV/AIDS as of end 2001.
Source: UNAIDS/WHO, AIDS epidemic update: December 2001. Geneva: UNAIDS, 2001.

Marjorie Opuni, PhD candidate: Bloomberg School of Public Health, John Hopkins University, Baltimore, USA.

Stefano Bertozzi, Director: Division of Health Economics and Policy, National Institute of Public Health, Cuernavaca, Mexico, and the Center for Research and Teaching of Economics (CIDE), Mexico City, Mexico.

Despite the rapid ascertainment of the epidemiology of HIV and AIDS, the discovery of the etiologic agent itself and ways to prevent its spread, and the development of diagnostic tests and antiretroviral therapies, it is clear that HTV will continue to be a global problem well into the 21st century. There were Þve million new HIV infections globally in 2002 and there is every reason to believe that the epidemic will evolve much further (1). The epidemic is spreading rapidly in regions that had previously kept HIV at bay, such as Eastern Europe. And though prevalence in the worldÕs most populated countries in Asia remains low, in many of them, the preconditions exist for increasing spread.

This chapter summarizes the global impact of HIV/AIDS outside of the United States, with a focus on the developing world, including overviews of the epidemiology, demographic impact and socioeconomic impact of the epidemic. The monitoring of these trends is essential to the planning and implementation of a global response to HIV/AIDS. It is also crucial to evaluating the effectiveness of HIV/AIDS prevention, care and impact itigation interventions around the world.

EPIDEMIOLOGIC PATTERNS OF HIV INFECTION AND TRANSMISSION

The pandemic of HIV/AIDS reßects many coexisting sub-epidemics in different regions and populations (6). As described elsewhere in this book (Chapter **00**), HIV-1 is the predominant type of HIV throughout the world while HIV-2 is found primarily among persons from West Africa. Many epidemiologic, sociodemographic, behavioral, and biologic factors contribute to the differential spread of HIV. The character of each sub-epidemic remains largely determined by the extent to which people are exposed to HIV by one or more of the three primary modes of transmission: (1) sexual (vaginal, anal, and oral); (2) parenteral, i.e. by injection (including the sharing of drug-injecting equipment), transfusion, or transplantation

of HIV-infected blood, blood components, tissues, or organs; and (3) maternal-infant, from woman to her fetus or infant.

The vast majority of HIV infections in the world are transmitted sexually, most often through heterosexual intercourse (7). Many factors influence the risk of sexual transmission, including specific sexual practices, presence of other sexually transmitted infections, and stage of HIV infection in the source partner (8).

The transfusion of HIV-infected blood, notably to children with malaria-associated anemia, accounted for up to 10% of new HIV infections earlier in the epidemic (9,10). While screening for HIV in transfused blood is generally available, the window period during which recent infection is not detectable, as well as interruptions in the supply of HIV test kits and laboratory errors continue to contribute to an HIV risk of variable and undetermined importance associated with this medical procedure. The transmission risk posed by clinical injections is difficult to quantify but is thought to account for some infections (11–13), and has been associated with significant outbreaks (14,15).

Mother-infant transmission has become common in areas with high rates of HIV infection among women of childbearing age. In the absence of interventions, approximately one-quarter to one-third of infants born to HIV-I-infected women become infected, regardless of the subtype of HIV-I involved (16–20). In contrast mother-infant transmission of HIV-2 is much less efficient, with closer to 1% of infected mothers transmitting to their infants (21–23). While most transmission occurs during pregnancy or at delivery, breast-feeding has also contributed to overall mother-to-child transmission, at least of HIV-I (24–26).

In a relatively short time, the epidemic has evolved quickly and differently in the various regions of the world. As the epidemic emerges in a given area, there have been common attributes regardless of the predominant modes of transmission. The emerging stage is characterized by limited numbers of detected infections that increase rapidly though silently over a few years in groups at highest risk (e.g. sex workers, patients at sexually transmitted infection clinics, injection drug users), particularly in urban settings, well before the clinical impact of advanced HIV disease is recognized. After rising quickly, HIV infection prevalence in higher-risk groups then begins to level, while spreading more gradually to lower-risk and rural populations.

EPIDEMIOLOGIC PATTERNS OF THE CLINICAL MANIFESTATIONS OF HIV/AIDS

Although the clinical and immunologic manifestations of HIV infection are addressed in other chapters of this book, it is important to realize that the wide spectrum of clinical conditions described in North America does not necessarily reflect the typical clinical picture of HIV disease in other parts of the world (27-29). With the rapid global spread of HIV and AIDS, a plethora of opportunistic pathogens— viruses, bacteria, fungi, protozoa, helminths, and arthropods— that are more frequent or severe in HIV-infected persons have been reported from various areas (30). Some of these organisms are only locally important, while relatively few pathogens cause the majority of morbidity and mortality in HIV-infected persons.

Although the reasons for the different clinical manifestations of HIV-related disease are not completely understood, they are likely to include the differing prevalence of opportunistic organisms in the environment and the behaviors and environmental conditions that expose persons to these pathogens. In addition, the differences in recognized disease patterns reflect varying capabilities to diagnose reliably specific conditions (29). Determining the spectrum of opportunistic infections and conditions in a given region requires well-functioning surveillance systems and diagnostic services; both are often limited in developing countries.

Tuberculosis (TB) is probably the most common and serious opportunistic infection in persons infected with HIV in Africa, Asia and Latin America (29,31–33). In many developing countries, half or more of the adult population have been infected with *Mycobacterium tuberculosis* and are at greatly increased risk for reactivation of tuberculosis when cell-mediated immunity declines following HIV infection (34). Beyond the TB-related morbidity and mortality in the AIDS patients themselves, the increased frequency of clinical tuberculosis due to HIV infection enlarges the reservoir and the risk of TB transmission to the public at large. The HIV epidemic has had a devastating impact on tuberculosis control efforts in many countries and given the magnitude of the burden of tuberculosis infection in the world compounded by the emergence of drug-resistant *M. tuberculosis* strains, tuberculosis will remain a major opportunistic infection globally (31).

Compared to data from industrialized countries, relatively little information is available on HIV disease progression in resource-poor settings, including the chronological order and the stages of immune deficiency at which different opportunistic diseases occur. Apparent differences in disease progression may reflect late initial diagnosis of HIV/AIDS, lack of access to medical care, or death from prevalent opportunistic infections such as tuberculosis that occur relatively early in the course of HIV infection, rather than any appreciable differences in the rate of decline of immunologic function.

EPIDEMIOLOGY BY REGION

Sub-Saharan Africa

Africa has been the region most severely affected by the HIV/AIDS epidemic. At the end of 2002, there were an

estimated 29.4 million people living with HIV/AIDS in sub-Saharan Africa (Fig. 41.1) (1). And the region accounts for three-quarters of the 20 million people that have already died (5). The high prevalence of HIV in many parts of Africa, the wide distribution of HIV-I and HIV-2 subtypes, and the genetic variation within subtypes, suggest that HIV has been on that continent for a relatively long time compared to other regions (6,35,36).

The observed prevalence of HIV infection in Africa varies greatly. Southern Africa has the highest HIV infection rates in the world. The sub-region includes seven countries with adult HIV prevalence rates above 20%: Botswana, Lesotho, Namibia, South Africa, Swaziland, Zambia and Zimbabwe (2). Botswana has the highest prevalence rate with 38.8%, followed by Lesotho, Swaziland and Zimbabwe, which have prevalence rates between 31.0% and 33.7% (2). Prevalence rates in East Africa are slightly less high, although they range from 5–15% with the highest rate found in Kenya (2). In most countries of West and Central Africa prevalence rates remain under 5% in the general population (2). However there are countries in the region where infection rates are higher. In Côte dÕIvoire, Cameroon and the Central African Republic between 9.7 and 12.9% for example, adult HIV prevalence is estimated (2). In Nigeria, a country with a population of almost 110 million, prevalence is estimated to be almost 6% and steadily increasing (2). Burkina Faso and Togo are two other countries in the region with prevalence rates above 5% (3). Extensive demographic changes with shifts from rural to urban areas and numerous population displacements from migrant labor and civil disturbances over the recent decades may have facilitated the spread of HIV in many areas. In the early years of the epidemic, groups at especially high risk for HIV-I infection in Africa included female sex workers, sexually transmitted infection (STI) clinic patients, and men with occupations that involved traveling or being away from family for long time periods such as truck drivers; with urban residents being more at risk than rural populations. Today, the epidemic in most of the region has shifted from those at highest risk to a generalized epidemic with rural populations impacted almost as much as urban populations (4).

Heterosexual HIV transmission is the major mode of spread among adults, with very little transmission recognized from male-to-male sexual exposure or injection drug use. As a result, this transmission pattern in Africa has resulted in male-to-female ratios of HIV-I infection and AIDS cases approaching unity (38). However, age-speciÞc rates of infection and disease vary by sex. For example, among persons with AIDS in Uganda, women outnumber men in the 15 to 24-year age group, whereas men outnumber women in the 30-year and older age group (39). In many African countries, the highest HIV-I seroprevalence rates are among women aged 20–25 years and men aged 25–35 years, reßecting sexual contact between older men and younger women (40). Dominant heterosexual transmission also means that there is a signiÞcant level of mother-to-child transmission. By the end of 2001, an estimated 2.6 million children under 15 were living with HIV/AIDS in sub-Saharan Africa with almost all of them acquiring the virus from their mother (2).

A number of explanations have been proposed for the relative efÞciency of heterosexual transmission and the rapid spread of HIV-1 in sub-Saharan Africa. HIV-1 infection in Africa has been associated with increased numbers of heterosexual partners, a history of prostitution among women, and sexual contact with prostitutes among men (41–43). The role of sexually transmitted infection (STI) in augmenting the transmission of HIV-1 has received considerable attention (44). A number of STIs, especially genital ulcer disease, have been associated with HIV-1 infection in both men and women in various studies (45,46). For men in eastern and southern Africa, lack of circumcision also appears to contribute as a risk factor for HIV infection, either independently or perhaps due to an association between genital ulcer disease and an intact foreskin (47,48). HIV-1 subtypes other than B (relatively little subtype B has been recognized in Africa) have been suggested as contibuting to the heterosexually-transmitted epidemics in Africa (and Asia) based on ecologic patterns of infection, but documentation that the non-B subtypes are actually transmitted more rapidly than subtype B *in vivo* is lacking (49).

Asia and the PaciÞc

By the end of 2002, it was estimated that 1.2 million people were living with HIV/AIDS in East Asia and the PaciÞc while 6 million people were living with HIV/AIDS in South and Southeast Asia (Fig. 41.1) (1). This represents prevalence rates of 0.1% in East Asia and the PaciÞc and 0.6% in South and Southeast Asia (2).

Though these rates remain low, factors such as cross-border opiate traÞc between countries, drug use invloving the sharing of injection equipment and the sex trade pose a substantial risk for further HIV-1 spread in the region.

Studies in China have shown rapid spread of HIV-1 among injecting heroin users in western Yunnan province, a region that shares a border with Myanmar (Burma) (50). Increases in STIs are another important risk factor for HIV in China. In 1999, there were 863,000 reported cases of STI compared to 5,800 reported cases in 1985 (51).

In India, a country with a population larger than all of Africa, the epidemic is very different from state to state. While in some states, there are almost no reports of HIV infection, others such as Tamil Nadu, have reached adult HIV prevalence rates of 2% (37). In southern states epidemics are driven by heterosexual sex while in the northeastern states, there are signiÞcant epidemics among injecting drug users (4).

Commercial sex is also responsible for a high proportion of cases in the most affected countries in Southeast

Asia, with adult prevalence close to 2%: Cambodia and Thailand (1,52). The epidemic in Thailand has been very well documented. Extensive HIV transmission in Thailand began around 1988 with rapid increases in HIV-1 seroprevalence among injecting drug users (IDUs), as evidenced by the prevalence among persons attending drug treatment centers in Bangkok increasing from I% to approximately 40% by the end of 1988 (53). The second wave of the epidemic, which was later shown by molecular epidemiologic studies to be distinct from the Þrst (53Ð56), occurred primarily among female sex workers (53,57). Between June 1989 and June 1990, the median province-speciÞc HIV-I seroprevalence among brothel prostitutes increased from 3.5% to 9.5% with more than 60% among some groups of prostitutes in northern Thailand found to be infected (58,59). Commercial sex was quickly recognized as being the major source of both heterosexual and homosexual HIV transmission. The increased infectiousness that occurs in the primary phase of HIV infection and the large number of clients served by prostitutes, compounded by prevalent sexually transmitted diseases, are likely to have contributed greatly to extensive transmission and the rapidly expanding HIV epidemic (60). The many men who were infected by sexual contact with prostitutes, transmitted HIV in turn to their other female sex partners (61,62) resulting in a subsequent increase in maternal-infant HIV transmission (63,64). Additionally, a substantial number of HIV infections have occurred among men who have sex with men (MSM) (65). Thailand has made considerable progress in the Þght against HIV/AIDS and its HIV prevention campaigns have been well documented. As condom use has increased and visits to female sex workers have decreased, sexual behavior has changed and as a result, HIV prevalence has decreased (52).

In contrast to some of the developing Asian countries mentioned previously, the number of HIV infections appears to be relatively low in industrialized countries in the region. By the end of 2002, an estimated 15,000 adults and children were living with HIV/AIDS in Australia and New Zealand (Fig. 41.1) (1). The pattern in these two countries and other high-income countries in the region such as Japan is similar to that in North America and Western Europe, with homosexual men and injecting drug users predominantly affected.

Latin America and the Caribbean

By the end of 2002, it was estimated that 1.5 million adults and children were living with HIV/AIDS in Latin America and the Caribbean (Fig. 41.1) (1). HIV prevalence rates are especially high in the Caribbean and Central America. Six of the seven countries in the Caribbean have HIV prevalence rates above 1% with the prevalence rate in Haiti estimated at 6.19% at the end of 2001 (2). In Central America, Belize, Guatemala, Guyana, Honduras, Panama and Suriname all had estimated prevalence rates above 1% at the end of 2001 (2).

The geographic distribution of HIV/AIDS in Latin America and the Caribbean is far from homogenous either among or within countries. The great diversity of the countries and populations in the region has led to substantial variations in the patterns and rates of HIV-infection and AIDS.

As in North America, most Latin American and Caribbean countries experienced rapid spread of HIV-1 among homosexual and bisexual men early in the epidemic (66Ð69). High rates of infection among bisexual men and, in some countries (notably Brazil), heterosexual male IDUs have led to an increase in heterosexual transmission of HIV-1 to women (70,71). Transmission of HIV-1 among IDUs has been substantial, at least focally, in many countries in the Americas (72,73). Parenteral transmission of HIV-1 from unscreened blood and the improper use of needles and syringes has also been a problem in some countries (68,73,74).

The proportion of reported AIDS cases resulting from heterosexual transmission has increased dramatically since the early 1980s in most Latin American countries (and heterosexual transmission appears now to be the predominant pattern in a number of countries) (66). Increases in perinatal transmission of HIV-I and pediatric AIDS cases have paralleled the increase in HIV-I infection in women in several countries. The prevalence of infection in antenatal women, although considerably lower than in Africa, nevertheless is appreciable in some areas.

Europe and Central Asia

By the end of 2002, there were an estimated 570,000 people living with HIV/AIDS in Western Europe (Fig. 41.1) (1). As in North America, groups predominantly affected in Western Europe are homosexual and bisexual men and IDUs with very low rates among heterosexuals in the general population (5). Recent information suggests that like in the United States, although risk behavior among homosexuals dropped signiÞcantly during the mid- and late 1980s, there has been a rise in unsafe practices in some communities (4). Among IDUs, the situation varies across countries. Some countries have been successful in containing HIV prevalence in this group at low levels with aggressive prevention efforts and needle-exchange programs (37). In other countries, prevalence rates among IDUs are very high. In Spain, for example, a recent study in Barcelona found a prevalence rate of 51% among injecting drug users (37).

Also like in the United Sates, ethnic minority and poorer populations within Western European countries are at higher risk (4). Several countries, including Belgium, France, the United Kingdom, and Portugal, have had appreciable numbers of HIV infections in persons who came from or were infected in developing countries or

who have had heterosexual sex with a person from a high-prevalence country (4). The HIV strains involved extend well beyond the well-characterized subtype B of Europe and North America and include non-B HIV-I subtypes and HIV-2 (6,75,76).

Until 1995, countries in Eastern Europe and Central Asia had reported few HIV cases, mostly among homosexual men (52). But in the past few years, the rates have changed substantially. Sociodemographic changes due to economic difficulties and ethnic and religious conflicts have led to important increases in high-risk behavior and subsequent HIV spread. By the end of 2002 there were an estimated 1.2 million people living with HIV/AIDS in Eastern Europe and Central Asia (1). Since 1995, HIV has spread quickly among IDUs in the region with prevalence rates in this group ranging from low estimates of 0.2% to a high of 65% in Odessa Ukraine (4). In the Russian Federation, there were more new infections in 2000 than there were for all previous years of the epidemic combined (4).

There are also signs that a sexually transmitted HIV epidemic could evolve quickly in Eastern Europe and Central Asia (52). Rates of sexually transmitted infections, most notably syphilis, have increased significantly. In 1998, WHO found a 50-fold increase in syphilis cases in Russia (77). From these data, they estimated that 1 in 400 Russians were infected with syphilis.

North Africa and the Middle East

Relatively few cases of AIDS have been reported from the countries of the North Africa and the Middle East and surveillance continues to be poor (Fig. 41.1) (1). By the end of 2002, there were an estimated 550,000 people living with HIV/AIDS in the Middle East and North Africa (1).

In areas where data exist, transmission can be attributable to injection drug use, heterosexual contact and contaminated blood transfusion (78). Recent evidence does indicate that new infections are on the rise in this region (42). Studies in one area of Algeria, for example, found prevalence rates around 1% in pregnant women attending antenatal clinics (42). HIV prevalence among STI patients has increased in Sudan, Yemen, and the Syrian Arab Republic (52). And there are signs that HIV-infection rates among tuberculosis patients are increasing. By mid-2001, these rates had reached 8% in the Sudan, 4.8% in Oman, 4.2% in the Islamic Republic of Iran and 2.1% in Pakistan (1).

CHANGING DEMOGRAPHIC PATTERNS DUE TO HIV/AIDS

Mortality

Since the virus eventually causes the death of virtually all infected adults and children, the HIV/AIDS epidemic has caused mortality rates to increase dramatically in highly affected countries especially in sub-Saharan Africa (79). It has changed the age and sex patterns of mortality, increasing the death rates for adults in their most productive ages as well as increasing death rates for children.

Since HIV is primarily spread through sexual transmission, most of the people becoming infected with the virus are adults and youths. HIV survival time in developing countries for incident cases is estimated to be approximately 8–11 years (80). This means that HIV is not only increasing mortality; it is increasing it in age groups that have historically had the lowest mortality rates. It also means that it takes some time before the long-term effects of the epidemic on country mortality rates become evident.

Data from national-level surveys and censuses provide information on mortality levels and trends, though these data do not specify cause of death. Between the late 1980s and mid 1990s, national surveys in Uganda, Zambia and Zimbabwe record huge increases in adult mortality concentrated in early adulthood, at the ages at which one would expect most AIDS deaths to occur (81). In just six years men's death rates in Uganda almost doubled while women's death rates more than doubled. In Zambia, over a six-year period, women's death rates almost doubled while men's death rates more than doubled. Similarly, national data from Zimbabwe show that within a decade, one of the countries in Africa with the lowest mortality rates became one of those with the highest mortality rates. The probability of dying between ages 15 and 60 years in the mid 1980s was less than 20%, while 10 years later it was more than 40%.

Several community studies have also identified HIV/AIDS as a major cause of death providing further insight into these national surveys. In studies in Tanzania and Uganda with adult HIV prevalence rates of 7% and 8% respectively, 47% and 40% of adult deaths were attributable to HIV (82,83). In another Ugandan cohort with an adult HIV prevalence of 16%, 73.5% of adult deaths were attributable to HIV infection (84). Even in a cohort in rural Tanzania with a relatively low HIV prevalence of 4%, HIV increased overall adult mortality by more than 50% (85).

HIV-related deaths among children are harder to measure than among adults (80). In low-income countries, background mortality rates for young children are much higher than for young adults. Also, children who die of AIDS are more likely than adults to die without an HIV-related diagnosis. As mentioned above, it is estimated that in the absence of interventions, approximately one-quarter to one-third of infants born to HIV-I-infected women become infected and this is reduced by close to 50% with antiretroviral therapy (86). Since most infected children will develop AIDS and die within a few years of birth, infant and child mortality will increase in high HIV-prevalence countries as a result of AIDS. The impact of the epidemic on child mortality is likely to be even larger

since the probability of death for HIV-negative children born to HIV-positive mothers may be greater than children born to HIV-negative mothers given the quality of care that they are able to provide (87).

Life expectancy at birth, which is determined by the proportion of the population dying at each age, is particularly sensitive to HIV/AIDS as deaths among young adults and young children result in many years of life lost (79). According to country models compiled by the United States Bureau of the Census, life expectancy in many sub-Saharan African countries has declined drastically because of HIV/AIDS. In two of the most highly affected countries, Botswana and Zimbabwe, it is estimated that life expectancy in 2000 was 39 and 38 years respectively compared to the 70 years estimated in the non-AIDS scenario in both countries (88).

Fertility

There is increasing evidence that HIV/AIDS also has major impacts on fertility in highly affected countries (89). The epidemic impacts fertility in several ways. Biological effects of the epidemic have an impact on women with HIV. In addition, the epidemic may cause behavior changes in the general population.

HIV lowers a woman's fecundity and ability to bear a pregnancy to term (89). Studies in a number of countries in sub-Saharan Africa have shown significant reductions in fertility with estimated reductions in the risk of pregnancy in HIV-infected women ranging from 16% to 26% (90–94).

Throughout sub-Saharan Africa, the lower fertility in HIV-infected women is unlikely to be explained by an increased use of contraception since the use of modern contraceptive methods is low and most women are unaware of their HIV-serostatus (89). Instead, these lower fertility rates are likely to be due in part to lower rates of conception. This is due in part to the fact that there is an association between HIV infection and infection with other STIs. Because serological tests for syphilis are quite easy to undertake, several studies have shown that higher proportions of HIV-positive women have been infected with syphilis at some time in the past (95,96). Other STIs that are less easily detected including gonorrhea and chlamydia independently lead to reduced fertility and it is probable that these are also having an impact on the fertility of HIV-positive women (89). The fecundity of HIV-positive women may also be reduced for several other reasons. Women with HIV are more likely to have amenorrhea or irregular menses than are HIV-negative women; there may be repercussions for women's fertility from the decreased production of spermatozoa in their HIV-infected male partners; and there may be reductions in the frequency of sexual intercourse due to illness (92,97–99). Another factor causing lower fertility rates among women with HIV are the increased rates of pregnancy loss (part of the increased loss may also be explained by the association between HIV infection and infection with other STI) (92,95–97,100). Finally, it should be noted that pregnancies may accelerate disease progression and development of AIDS, causing HIV-positive women who remain fecund to have shorter mean survival times than those who do not (89).

As or more importantly, the epidemic is also likely to cause behavior changes in the general population. The HIV/AIDS epidemic appears to cause important changes in contraceptive use with an increase in the use of condoms and the switching to condom use from other forms of contraception (89). If condoms are used by couples who did not practice contraception previously, this will result in an overall decline in fertility. However, if they replace more effective methods of contraception with condoms, this will cause slight increases in fertility. The epidemic is also having an impact on fertility by increasing women's age of first sex (101–103). Finally, changes in post-partum behavior including reduction in breastfeeding or shortening of abstinence after the birth of a child to discourage a partner from seeking other partners that may be HIV-infected would tend to increase fertility (89).

The Combined Impact of HIV on Mortality and Fertility

The combined impact of the HIV/AIDS epidemic on mortality and fertility is causing the population structure in highly affected countries to change. Graphs of population structure depict populations according to age groups with men on one side of a central axis and women on the other. When both mortality and fertility rates are high, the graph has a wide base and tapers off steadily with increasing age. In most developing countries, therefore, the structure of the population by age and gender usually has the shape of a pyramid, while in developed countries the pyramid becomes more like a column.

As illustrated by the projected population structure of Botswana for 2020 in Fig. 41.2, the HIV/AIDS epidemic is introducing a completely newly shaped population structure in highly affected countries that the UN HIV/AIDS program refers to as the "population chimney" (37). Fewer babies are born since many HIV-infected women die or become infertile before the end of their reproductive years and up to a third of the infants born to HIV-positive mothers acquire HIV/AIDS. This causes the base of the pyramid to be less broad. In addition, the center of the pyramid shrinks radically as the populations of women above their early 20s and men above their early 30s die 10 or 15 years after the age at which they become sexually active. Since only those who have not been infected survive to older ages, the pyramid becomes a chimney.

Orphanhood

DeÞned by UNAIDS and UNICEF as children who lose their mother to AIDS before reaching the age of 15, AIDS orphans are an important consequence of the epidemic in highly affected countries (104). Many of these children also lose their fathers to AIDS. However, because reliable data on the number of paternal orphans are not available in many countries, UNAIDS/UNICEF orphan statistics do not include children who have only lost their fathers. It is estimated that by the end of 2001, globally, a cumulative total of 13 million will have lost their mother or both parents to AIDS and 10.4 million of them will be under the age of 15 (104).

Given the severity of the epidemic in sub-Saharan Africa, the proportion of children orphaned by HIV/AIDS in Africa is much higher than in other regions. Cohort studies in rural populations with levels of HIV prevalence of around 10% estimate that between 7% and 15% of children have lost at least one parent to HIV/AIDS (105). A limited number of community studies have been conducted on the impact of AIDS orphanhood on the health and development of these children (94,106Ð111). These studies from sub-Saharan Africa, show that most children are taken care of by extended family members. As death rates continue to increase, however, the consequences for the health and development of AIDS orphans can be severe as extended family absorption capacities are stretched to their limit (87).

SOCIOECONOMIC IMPACT OF HIV/AIDS

Macroeconomic Impact

Determination of the macroeconomic impact of HIV/AIDS is extremely difÞcult. Most economists agree that in high prevalence countries, the epidemic has had a major impact on national economies but not necessarily a major impact on per capita gross domestic product (GDP). The epidemic stimulates higher demand for health care as well as a reduction in income among those directly affected. This leads to increases in health spending with associated reductions in savings and in nonhealth spending. It also causes cost pressures for companies in terms of higher turnover due to AIDS mortality especially when that mortality includes skilled workers or workers with employer-based health insurance or disability and mortality beneÞts. It may also reduce business markets. Nonetheless, predictions of the net macroeconomic impact of AIDS have varied widely and economists continue to debate this issue. Numerous factors affect economic performance and attributing changes in performance to one particular cause is difÞcult.

During the early years of the epidemic, several economists projected that the macroeconomic impact of HIV/AIDS would be catastrophic leading to a major reduction in the economic output of certain countries (112Ð114). SigniÞcantly less alarmist, later analyses claimed that in high prevalence countries, growth rates of

national income may decrease by two-thirds of a percentage point and annual growth rate of national income per person may decrease by as much as one-third of a percentage point through the year 2010 (115–117). More recent studies using similar methodologies concluded that by 2015, the economies of Swaziland and Botswana will grow 1.1 and 2.5 percentage points less than they would have because of the epidemic (118,119).

On the other hand, cross-country regressions involving 51 countries in 1997, suggested that there was "little support for the widespread claim that the AIDS epidemic will slow the growth rate of income per capita (120)." The authors argued that even though the epidemic was advanced in some countries, after they controlled for other influences on economic growth, they found no evidence that economies in higher HIV prevalence countries grew at significantly slower rates than countries with lower HIV prevalence rates. This view has also been supported by the World Bank which argues that the macroeconomic impact of HIV/AIDS is likely to be small in most countries as declines in population growth due to HIV/AIDS will tend to offset declines in economic growth causing the net impact on gross domestic product (GDP) growth per capita to be small (121).

Two recent modeling exercises in South Africa, one of the hardest-hit countries in the world, further illustrate the uncertainty of macroeconomic analyzes due in large measure to the assumptions underlying the model. At the same time these results do indicate that in highly affected countries like South Africa, even the most optimistic scenarios project negative impact on the macroeconomy. The first conducted by ING Barrings forecasts that over the next 15 years, South Africa's economy is likely to grow 0.3 to 0.4 percentage points less per year than it would have because of HIV/AIDS (122). The second study concluded that between 1997 and 2010, GDP growth rates in the AIDS and non-AIDS scenarios diverge steadily, reaching a maximum differential of 2.6 percentage points in 2008 (123). The result is a GDP level in 2010 that is 17% lower in the AIDS scenario than it would have been without AIDS.

Impact on Health

In all countries, the HIV/AIDS epidemic has meant additional pressure on the health sector, as countries have invested resources in HIV prevention interventions. In highly affected countries, the epidemic has also had an important impact on both the demand and supply of health care services. On the one hand, HIV/AIDS increases the number of people demanding health care services and causes significant increases in national health spending. On the other hand, it reduces the supply of care available at a given quality and price due to illness and death among health care workers.

Two decades into the epidemic, there is increasing consensus on the components of an effective HIV prevention response within countries (124,125). In Thailand and Uganda, where there is evidence that prevention interventions have had an impact on decreasing HIV incidence rates, it is estimated that US$ 78.5 million and US$ 37.5 million was spent on prevention respectively (126). The cost of the "successful" prevention programs in Uganda and Senegal, the latter another comparatively well-funded effort that has been successful in maintaining low prevalence rates, was extrapolated to the rest of sub-Saharan Africa correcting for a number of factors expected to affect the cost of large-scale prevention programs. This exercise suggested that in 1996 the continent would have had to spend approximately US$1 billion in national and donor resources combined (126,127). A more recent exercise performed for the UN General Assembly on AIDS in June, 2001 estimated that by 2005, approximately US$ 4.8 billion will be needed to implement globally a comprehensive package of HIV/AIDS prevention interventions in middle and low-income countries (128).

The health care sector does not bear all of the costs of HIV prevention efforts as some of these interventions are multisectoral or even coordinated by other sectors. Nonetheless, the health sector does bear large proportions of these costs as many interventions, including STI prevention and care, voluntary counseling and testing and prevention of mother-to-child transmission are health sector specific. In countries where per capita health expenditure can be as low as US$ 5.00, HIV prevention interventions alone constitute a significant burden (129). However, as prevalence rises, the impact of prevention efforts on the health sector is quickly overtaken by the increased demand for care by people living with HIV/AIDS and by illness and death among health care workers. And this impact is even worse because it is concentrated in low-income countries.

As described above, the natural history of HIV illness and the pattern of opportunistic illnesses differ across regions. This means that the palliative care, treatment of opportunistic infections and prophylaxis for opportunistic infections required by an HIV-infected person also varies from region to region (130). Regardless, HIV/AIDS treatment costs are high. The World Bank estimated lifetime cost per patient for palliative care and prevention of the more common opportunistic illnesses to range between US$ 300 and US$ 1,000 (1996 dollars) (121). When including care costs for rarer opportunistic illnesses, the figures were estimated to range between US$ 500 and US$ 1,700. And these costs have increased dramatically in the age of highly active antiretroviral therapy (HAART). An estimated US$ 4.4 billion will be needed in middle and low-income countries to provide medical care to those people who have access to health services and to provide support to orphans (128).

Data from studies in Eastern and Southern Africa show that there has been a steady increase in the number of HIV-infected patients in hospitals. In a Tanzanian hospital, the

prevalence of HIV-I infection among hospitalized patients was 32.8% indicating that HIV infection was the major cause of illness leading to admission to the hospital (131). In Zimbabwe, 50% of all in-patients in wards studied were infected-with HIV (132).

Tuberculosis and other clinical conditions become more difficult to diagnose when associated with HIV/AIDS. This and the chronic nature of HIV/AIDS translate into increased cost of care to both the health care service and the users (37). A recent study in Zimbabwe showed that costs per in-patient stay were twice as high for HIV/AIDS patients compared with other patients (132).

Not surprisingly, these increases have led to overcrowding in the medical establishments of high prevalence countries. Total hospital admissions in a rural South African hospital increased by 81% between 1991 and 1998 (133). In Kenyatta National Hospital in Nairobi, Kenya, there was severe overcrowding in 1997, with bed occupancy estimated at 190%Ñ doubled from 1988/1989 (134).

It has been argued that the increased demand for health care services by people with HIV would also lead to the crowding out of non-HIV/AIDS related patients in high prevalence countries (121). Data from several studies have suggested that the epidemic was having a negative impact on the overall quality of care provided (135). However, a longitudinal study in Kenya from 1988/1989 through 1992 to 1997, revealed that the hospital Òdoes not appear to have been overtaken by the chronic care demands of the terminally ill, in particular those with clinical AIDSÓ (134). In 1997, fewer sick patients with advanced HIV/AIDS disease and more HlV-negative patients were admitted. Compared with 1992, HIV seroprevalence among patients stabilized. And though there was overcrowding, fewer patients died compared with 1992.

Just as the epidemic affects the demand for health care, it also has an important effect on the supply of health care in highly affected countries. As in other sectors of the economy, rising rates of HIV infection in health care workers will increase rates of absenteeism, reduce productivity, and lead to higher levels of spending for treatment, death benefits, additional staff recruitment and training of new health personnel (37). In Zambia, deaths among health care workers in one hospital increased 13-fold between 1980 and 1990, largely because of HIV (136). Furthermore, the risk of HIV infection is likely to have a negative impact on the supply of health care workers by dissuading some individuals from these occupations (121). HIV/AIDS is also affecting the supply of health care by increasing the cost of maintaining safety levels for medical procedures (121).

One of the alternatives to hospital care that has been advocated as a solution in highly affected countries is home-based care including both hospital-initiated home care and care provided by nongovernmental organizations (NGO) working on HIV/AIDS (137). Both of these models have important limitations. Most NGO home care initiatives have focused on providing counseling and spiritual support. At the same time, hospital outreach services have not necessarily been less expensive. A study in Zimbabwe estimated that each home visit is equivalent to one to three hospital days (138). In addition, the study found that coverage was low and the care often inefficient with a large proportion of the resources not directly benefiting the patient or family. Gradually, community-rooted home care initiatives are emerging; often organized by people living with HIV/AIDS themselves (137). Ideally, these initiatives are well integrated within a larger continuum of care including health facilities and NGO service providers. Experts believe that community-based initiatives integrated within the larger continuum of care available in a country will reduce the cost of institutional health care and improve the quality of life of people living with HIV/AIDS and their families (137).

Impact on Education

The epidemic can have significant impacts on both the demand and the supply of education in high prevalence countries. On the one hand, it has an impact on the number of children in the school system as well as on the ability of these children to learn. On the other hand, the epidemic also affects the provision of education given the frequency of HIV infections among teachers and other professionals in the education sector.

On the demand side, as discussed above, the demographic effects of the epidemic in high prevalence countries will result in an overall reduction in the absolute number of school-age children. Likewise, changes that occur before and after an AlDS-related death in a household tend to reduce the demand for education. The extended illness that infected parents experience places an increased demand on the time of children for providing care and support (139). The ability of families to pay for school fees and other education costs are also compromised in HIV/AIDS affected households. It may become necessary for children to be withdrawn from school in order to work to subsidize the family income. There is also some indication that the expected returns of investment in childrenÕs education may be reduced where prime-age adult mortality is high (121).

As children are orphaned and are taken in by extended families, considerable financial burden is placed on families who may not be able to afford to keep all children in school. In other cases, as they lose their primary source of financial support with the death of one or both parents, orphans are forced to find work to support themselves and their younger siblings, thereby causing them to drop out of school. A study in Zambia found that in urban areas 32% of orphans were not enrolled in school compared to 25% of non-orphans. In rural areas 68% of orphans were not enrolled compared to 48% of non-orphans (139). In a study in Zimbabwe, 48% of orphans of primary age had

dropped out of school and no orphans of secondary school age was still in school (37).

On the supply side, the most important impact of the epidemic is the increased rates of morbidity and mortality among teachers. In the absence of better data, and given recent experience in Africa with teacher attrition, it can reasonably be assumed that HIV prevalence is as high among teachers as it is in the general population. Teacher attrition due to HIV/AIDS is especially devastating in the highly affected countries in Africa where there are only one or two teachers per school and the loss of a teacher can completely deprive students in that area of access (139). In the Central African Republic, for example, a country that has only a third as many primary school teachers as it needs, almost as many teachers died as retired between 1996 and 1998 with 85% of them being HIV-infected (37).

Even among teachers who are not infected, morale can be highly compromised. Rates of absenteeism are increasing as teachers take time off to attend funerals and mourn lost friends and family members or to moonlight to subsidize family income (139). In addition, with rising AIDS mortality the education sector will also be faced with attrition among planners and administrators at all levels. Even if these personnel are replaced there would be a considerable loss of experience, which can be expected to have an effect on the functioning of the system.

Impact on Agriculture

Data on the impact of HIV/AIDS on the agriculture sector in highly affected countries are limited. Most of the arguments presented on this issue are based on conventional wisdom supported by a few small-scale studies, most of which were conducted by the UNÕs Food and Agriculture Organization (FAO) (140Ð145). Yet agriculture is the most important sector in most developing countries both in terms of production and employment. In some countries, it might provide employment to as much as 80% of the countryÕs population (37). The mere size of this sector therefore implies that in highly affected countries, the epidemic will have a signiÞcant impact.

The Food and Agricultural Organization has estimated that in the 27 most affected countries in Africa, seven million agricultural workers have died from HIV-related causes since 1985, and 16 million more deaths are likely in the next two decades. In the ten most affected African countries (Namibia, Botswana, Zimbabwe, Mozambique, South Africa, Kenya, Malawi, Uganda, Tanzania, Central African Republic, Ivory Coast, Cameroon), labor force decreases ranging from 10Ð26% are anticipated (146).

The epidemicÕs impact on agricultural labor in turn causes cost pressures on agricultural estates and diminishes disposable cash income available for household agricultural production (147,148). A study of six agricultural estates in Kenya found that rates of HIV prevalence were high with one estate having a rate of 25% (147). Illness and death primarily due to HIV/AIDS was the most important reason for employee exits from the estates. All estates experienced substantial cost increases with medical expenses increasing ten-fold between 1989 and 1997 and funeral expenses increasing Þve-fold over the same period. HIV/AIDS also resulted in psychological and economic difÞculties among employees and increased illness and funeral related absenteeism and loss of skilled labor. The authors of this study concluded that the epidemic has led to a decline in quantity and quality of processed products, increased costs of production, and a decline in company proÞtability.

A study of the impact of HIV/AIDS on rural Ugandan families in subsistence agriculture illustrates that these households are particularly vulnerable to the impact of the epidemic (144). Household members had longer working hours to make up for labor shortages and loss of income from ill persons; remote Þelds tended to be left fallow and the total output of the agricultural unit declined to accommodate for labor shortages. Some agricultural yields declined as a result of delays in essential farming operations and lack of resources to purchase agricultural inputs. Labor-intensive crops were abandoned in favor of less demanding ones reducing the variety of crops that may lead to less varied food, with a negative impact on nutrition. This study found that the burden of HIV/AIDS on rural households was born disproportionately by women. Single men generally remarried and most single headed households were headed by women with limited economic opportunities and limited rights to land and property.

Impact on Business

The epidemic impacts the business sector in two different ways. As discussed above in the agriculture impact section, companies face cost pressures given the impact of HIV/AIDS on business productivity and company costs. In addition, it also affects business markets given its impact on the general population in high prevalence countries.

Conventional wisdom suggests that the epidemic affects business productivity and costs through its effects on company employees, although the effect of HIV/AIDS on the workforce is disputed (149). Conventional wisdom also suggests that HIV/AIDS-related mortality reduces the supply of available productive and skilled labor (150). Absenteeism rates increase as a result of employees becoming ill due to HIV and its associated opportunistic infections, the demands of caring for family members who are ill, and the need to attend funerals. Absenteeism rates have risen signiÞcantly in highly affected countries. This disrupts the production cycle, causes under-utilization of equipment and increases the use of temporary staff. In short, high rates of HIV morbidity and mortality lead to

increases in staff turnover, loss of skills and knowledge and declining employee morale.

The most important analysis of African Þrms to date including almost 1,000 companies from 1992Ð1994 concluded that the impact of HIV/AIDS on staff turnover was minimal, although it recognized the situation could change with the evolution of the epidemic (151). This result may be due to the fact that the analysis was conducted relatively early on in the epidemic. It may also reßect that the workforce in many of these Þrms was relatively unskilled with high rates of turnover, even in the absence of AIDS. A number of smaller studies and anecdotal evidence indicate that the epidemic has an important impact on the workforce which in turn lowers productivity of Þrms and increases company costs (150). In Kenya, Zambia and Malawi, it is estimated that HIV/AIDS-related absenteeism accounts for 25% and 54% of company costs (152). In Kenya, a survey of Þve companies found that AIDS was costing companies 3% of their proÞts in the mid-1990s and could cost as much as 8% of proÞts by 2005 (153). In one transport company in Zimbabwe, the total cost to the company arising from HIV/AIDS was assumed to equal 20% of company proÞts (154).

The demand for recruitment and training rises as a result of increased staff turnover and loss of skills (150,154). Company life insurance premiums and pension fund commitments rise as a result of early retirement or death. In Zimbabwe, for example, life insurance premiums quadrupled as a result of HIV/AIDS (155). Finally, considerable costs can be added where businesses provide for the funeral costs of employees.

The impact of the epidemic on the customer base is only now beginning to be studied. But Òwith HIV/AIDS beginning to have a substantial impact on the demographic proÞle of the most-affected countries, markets are changingÓ(149). Young adults are the group that is most affected by HIV/AIDS and are also the major source of demand for goods and services. Those who are ill will redirect spending towards caring costs and since they are less likely to work, they are likely to have less money to spend. Moreover, as mentioned above in the hardest hit countries, governments are likely to redirect spending towards health and away from items favorable to growth including education and infrastructure investment.

Impact on Households

As economists have expanded their HIV/AIDS impact analyses to include studies of the epidemicÕs impact on particular sectors in addition to macroeconomic impact analyses, they have also increasingly focused on the impact of the epidemic on individual households. It is at this level that the epidemic has its most signiÞcant impact. The epidemic usually strikes prime-age adults who are at the peak of their economically productive years incapacitathlg them for signiÞcant periods of time before killing them. These adults are often parents, as well as workers providing for their households. And unlike other illnesses, HIV/AIDS-related illness and death tend to be clustered within selected households with two or more adults affected as one member infects his or her partner(s).

Prime-age adult deaths affect households both directly through medical expenses and funeral costs and indirectly because of the foregone earnings of the deceased (156). The World BankÕs publication entitled *Confronting AIDS* provides a detailed overview of data from studies in Abidjan, CÔte dÕIvoire, Kagera, Tanzania, Rakai Uganda, and Chiang Mai, Thailand on the impact of prime-age adult deaths (121). These studies conÞrm that the impact of any prime-age adult death in a household is signiÞcant and the direct impact of HIV-related deaths is slightly greater because of the higher medical expenditures of people with HIV. Household income usually decreases as the main breadwinner ceases to work for wages and other household members reduce the number of hours they work for wages in order to care for the sick person. These households devote increasing shares of their expenditure on medical and funeral costs, decreasing their consumption of basic necessities including food, energy, accommodation, hygiene and maintenance.

These studies also show that affected households have developed a variety of strategies to cope with the impact of an HIV-related death (121). The composition of households is altered to cushion the shock of the death as dependent children are sent to live with relatives or relatives join the household to assist in household or farming tasks. Savings decrease as households sell available assets such as land, livestock, or durable goods such as bicycles and radios to pay for medical treatment or burial costs. Finally, affected households often Þnd external assistance in the form of cash transfers or loans from extended family members and the local community, as well as nongovermnental organizations, to help pay for medical and burial costs.

Given these coping strategies, it follows that in general the poorer the household, the greater and more persistent the impact of a prime-age adult death from AIDS. Poorer households do not have the assets to cushion the impact of the death and have greater difÞculties accessing credit as they are unable to guarantee repayment. This greater impact on poorer households is illustrated by the 15% drop in food consumption during the year that followed an adult death in Tanzania (121). Though there are no data available on the impact of an adult death on child malnutrition, it is likely that this decrease in total food consumption has had a signiÞcant impact on child malnutrition in these households. In addition, as was discussed above under the impact on the educational sector, one of the responses to a prime-age adult death in poorer households is to remove children from schools as school fees become unaffordable and their labor is required in the household. In short, the epidemic not only

has a greater impact on poorer households, it also facilitates the intergenerational transmission of poverty.

CONCLUSION

As the HIV/AIDS pandemic enters the twenty-Þrst century, the pace of HIV transmission is increasing in sizeable parts of the world. Given the existing numbers of persons with HIV infection, the number of AIDS cases would continue to increase even if there were no further HIV transmission.

In contrast to most industrialized countries where HIV incidence and prevalence have stabilized, for the developing countries of sub-Saharan Africa, Asia and the PaciÞc, Latin America and the Caribbean, Eastern Europe and Central Asia, North Africa and the Middle East, available epidemiologic data predict continued high rates of transmission and increases in HIV seroprevalence. Large parts of Africa have already been devastated by the epidemic and the coming years will bring an increased burden of AIDS-related death. Asia, home to half of the worldÕs population, will be an important region in the AIDS epidemic in this next millennium. India alone has more people than all of Africa and extensive HIV transmission has begun in south and Southeast Asia. In many countries, AIDS has become or will likely become the leading cause of death in adults and one of the leading causes of infant and child mortality.

Data from several countries have shown that it is possible to reduce the spread of HIV with existing technology and interventions. Prevention successes in Senegal, Thailand and Uganda demonstrate the importance of aggressive national intervention programs that include well-deÞned components. The experience of these countries shows that sound programs and political commitment make a difference.

The challenge of HIV and AIDS underscores the importance of well-coordinated research to support strong prevention and treatment efforts. Epidemiological and surveillance data have been essential in tracking the HIV epidemic, directing prevention activities, and guiding research. What continues to be lacking is information on the patterns of risk behavior. Work in this area with increasing emphasis on behavioral research and surveillance will be needed to target prevention interventions better. Second generation surveillance systems that compare biological and behavioral data for maximum explanatory power and adapt to the changing needs of epidemics will be essential to producing quality data that increase and improve the national responses.

Important progress has been made in the area of research on the demographic impact of HIV/AIDS in the last 10 years. Data on the demographic impact of the HIV/AIDS epidemic has highlighted the devastating effects of HIV on mortality and fertility. Likewise, advances have been made in measuring the socio-economic impact of the epidemic. And these data together with epidemiological data have aroused global awareness on the importance of action.

However, there remain signiÞcant gaps in our understanding of the socioeconomic impact of the epidemic. Important areas of uncertainty exist on the macroeconomic impact of the epidemic as well as on the impact of HIV/AIDS on certain speciÞc sectors including agriculture and business. Research efforts in these areas are essential to ensure data-driven policy development and decision-making.

Chapter 42

Nursing Perspectives in Care of Persons with HIV Infection

Richard L. Sowell, Troy Spicer and Arlene J. Lowenstein

Human immunodeÞciency virus (HIV) infection and the resultant acquired immunodeÞciency syndrome (AIDS) Þrst thought, in the U.S., to be a disease of urban homosexual males, is growing at a rapid pace among other populations. HIV infection is increasingly associated with drug use and heterosexual transmission, and is occurring in both urban and rural communities. Women currently represent one of the fastest growing groups being diagnosed with HIV/AIDS with African-American women being disproportionately affected by this disease (1). Providing high-quality care to such a diverse population with HIV infection is a complex and challenging task.

THE NURSING RESPONSIBILITY MODEL

HIV infection is a care-intensive disease across the continuum of the illness and involves patient contact with many health care and social service disciplines. Nurses play a major role in direct clinical care of HIV-infected patients, and have a responsibility to help patients adapt socially, psychologically, and physically to the illness. Figure 42.1 depicts a model of nursing responsibility in HIV/AIDS that provides a comprehensive overview of the nurseÕs role in caring for persons with HIV infection (2).

Nursing involvement actually begins before diagnosis, through the provision of health education about prevention strategies and wellness care in the community. From the original HIV-antibody testing to the end stage of AIDS, it is nurses who handle client assessment and offer direct patient care, which also includes symptom management, counseling support, health education, and bereavement support for families and friends. Care problems are complex and unique to each patient, because each patient exhibits a different constellation of symptoms as the disease progresses. Nursing care follows the patient, in homes and ambulatory care settings, as well as in hospitals and in all types of urban and rural communities.

Nurses must take the responsibility to coordinate interdisciplinary resources, linking the HIV-infected individual to appropriate services, including primary and acute care facilities and social and community support services that may be needed during the course of illness (3,4). Nurses can provide education about the importance of recognizing both families of biologic origin and families of choice, including signiÞcant others and partners, as participants in care and decision-making, if that is the clientÕs choice. Financial, housing, nutrition, and transportation problems frequently grow worse as the disease progresses. Clients must be linked to services that will help them make decisions in these areas, and participate in treatment planning. Nurses must understand and navigate through the legal and ethical issues involved in Þnding the necessary linkages and services for their clients. In many locations, nurses take full responsibility as case managers (5), or work within interdisciplinary case management systems that are based on client need for type of services (6,7).

Nurses are well positioned for involvement in the sort of community advocacy that encourages communities with inadequate services to develop programs and linkages, and the political awareness to develop programs and linkages, along with Þnancial resources to carry out programs (8,9). Nurses also are a prime resource for funneling information to the community at large and to other health care professionals that can reduce fear and discriminatory action toward persons with HIV infection (10Ð13).

Recent advances in treatment using highly active antiretroviral therapy (HAART) have resulted in a

FIG. 42.1. The nursing responsibilities model (© Richard Sewell, with permission).

decrease in the number of deaths from AIDS (1,14). As a result of HAART, HIV infection has become a chronic disease for many individuals. However, the number of new HIV infections is estimated to have remained constant. This situation has resulted in a growing number of persons with HIV infection who require care. Nursing administrators will need to encourage their staffs to develop and implement HIV/AIDS patient care program-planning in the community and in hospitals, in both urban and rural settings (2,9,15). Nursing care standards and quality improvement programs should be developed and monitored for effectiveness. Nursing administrators, as part of the senior management team, must work to ensure the presence of a safe workplace through development and implementation of appropriate employee orientation, work-place safety programs, and supportive human resource policies.

Nurse educators must be well-educated about HIV infection, so that their students can benefit from accurate, up-to-date information and develop a supportive rather than a judgmental attitude toward HIV-infected clients. Students and beginning practitioners will work with diverse populations of persons with HIV infection, diagnosed and undiagnosed, and they must learn to confront their own fears and attitudinal barriers (16). Students will need guidance and emotional support from nurse educators as they learn to elicit, understand, and negotiate their own and their clientsÕ multicultural health beliefs (17). Students need support as they deal with occupational hazards and become aware of the need for self-protection, through the use of universal precautions and personal safe health care practices. HIV-related research is needed to provide the research base for future nursing practice; nurses in academic settings have the responsibility to develop and facilitate research programs and studies that will add to the current knowledge base.

MAJOR CONCEPTS ACROSS THE CONTINUUM OF ILLNESS

When structuring care for persons with HIV infection, there are underlying concepts that providers must consider throughout the illness, regardless of stage. These concepts may be emphasized more strongly at certain points or developed differently during the course of illness, but they shape the assessment and structuring of care.

Holistic nursing practice concepts can provide the framework for care. The focus of holistic practice, according to one group (18), is Òaimed not at ameliorating symptoms but at improving clientÕs ability to live, to be well, to live a high quality of life, and to focus their lives in meaningful and useful directions.Ó They view the essence of nursing practice as helping clients to develop and fully use their sense of self as they cope with changes in their physical, psychological, spiritual, and social worlds. This client-nurse relationship must also be expanded to the patientsÕ families, both families of origin and families of choice.

The chronic disease model of Corbin and Strauss (19) holds that persons with any chronic disease must Òwork hardÓ to manage their illnesses. There are whole sets of decisions to be made and tasks to be carried out by the individual, or parents, in the case of children. These decisions and tasks may be carried out by the client alone, or in conjunction with others. Each person fashions his or her own unique response to the illness and to the health care providerÕs recommendations for treatment. Required tasks for the affected individual and/or their families are: to become informed about the disease and its progression; to meet personal resistance to staying in treatment; to prepare for pain management; and to face the issues of needing to be cared for, coping with body concept changes and body deterioration, and as McKusick (20) suggests, to make friends with the notion of dying.

Relationships with supportive practitioners can allow the patient and family members to incorporate and expand their senses of self, while making the myriad decisions that will be required as they work to manage the illness. Client and family involvement in decision-making must continue through the duration of the illness and is essential to the death-relating tasks and, in the end stage, dissolution of the relationship. Investigators have found that clients with HIV infection who participated in illness management activities improved their quality of life (21). Others have found that bereaved partners of gay men who died from AIDS were better able to work through the loss when they and their partners were involved in those activities (22). Nurses are in a pivotal position to foster client and family participation in decision-making and to assist in gathering information on which to base those decisions.

Besides provision of care, nurses work to prevent further transmission of HIV in the community at large and within health care settings. Prevention of transmission can be fostered through practice of universal precautions and by extending health education and information to clients, their families, and to a wider community.

Many HIV-infected clients have a history of health behavior that places them at risk for poor health. These behaviors may be related to cultural norms within their ethnic backgrounds or chosen life styles. These behaviors and attitudes may be difficult, if not impossible, to change (23). According to one study (24), the more symptoms persons with AIDS reported, the greater the tendency toward unhealthy behaviors.

The Mersey Harm Reduction model (25) was developed to deal with the harmful consequences of the growing substance-abusing population in the Mersey area of Liverpool, England. This model can be applied to other populations with protracted illness. The first principle is that total avoidance of unhealthy behaviors should not be the only objective of services to this population, since that would exclude a substantial proportion of people who are committed to their current life styles. For example, many

clients are well aware that HIV can be transmitted through sexual activity, but they will not or cannot practice abstinence or even protected sexual activity. Nurses and other providers who are committed to changing unhealthy behaviors in their clients will face frustration and burnout when those clients ignore the information and education that they have worked hard to provide.

The second principle of the adapted Harm Reduction Model holds that behavior change should be conceptualized as the Þnal goal in a series of harm-reduction objectives. Rather than anticipating total change in behavior, nurses and health care providers need to recognize that small changes may be easier for clients to adopt. When a series of health-promoting behaviors are developed, the clients may choose to select those behaviors that they feel they can accomplish, while ignoring those they have no intention of changing. For example, clients who are not willing to abstain from sexual activity, may accept information about types of sexual activities that provide sexual gratiÞcation other than direct, unprotected, intercourse.

The third principle is to provide user-friendly services. Nurses should help establish a supportive rather than judgmental milieu; they should avoid overwhelming clients with excessive information and instead should emphasize information and explanations that the clients feel they can handle. If trust can be established, clients will be more likely to maintain contact. Continuing contact provides opportunities to provide reinforcement and support for behavior changes that have been accomplished. In addition, it will enable clients to obtain assistance for further behavior change, and for other problems as they arise.

The harm reduction concept is gaining growing acceptance as a realistic approach in the areas of care delivery, education, and prevention. Initial evidence of effectiveness has been encouraging (26). Harm reduction considers the user's wants along with the provider's wants, so that consensus and realistic goal setting can occur. Harm reduction is future-oriented; it is not concentrated on past practices. Information that can lead to positive behavior changes can be supplied without negative judgments about past practices. Outreach is required; social and health services need to be brought to people on their own turf and on their own terms. User-friendly, rather than judgmental and punishment-based services, make it more likely that less-harmful options will be considered as acceptable in lieu of abstinence or total avoidance of harmful behaviors. Harm reduction considers providers as well as clients and is focused on future-oriented community health rather than on institutional agendas. The harm reduction model provides a useful framework within which nurses can work effectively to integrate the complexity of issues associated with HIV infection. It can be implemented successfully with diverse populations and across the continuum of illness. Nurses can take leadership in interdisciplinary planning to introduce and support these concepts.

NURSING RESPONSIBILITIES IN PREVENTION AND TESTING

The various physical, social, and psychological consequences of HIV infection may result in severe stress for clients and their families (27–31). Many people are aware that their behavior and life-style decisions have put them into a high-risk category for HIV infection. Fear of stigmatization and/or discrimination and real or perceived lack of access to services may keep them from conÞrming their fears of infection. Diagnosis and medical intervention may be delayed until symptoms can no longer be ignored, and when they may be less effective (32).

The seemingly sudden advent of the HIV/AIDS epidemic had a profound impact on both health care professionals and the overall health care system. In the early 1980s, a generation of health care providers were faced with an inßux of patients with an incurable, life-threatening, infectious disease; they were ill prepared to respond. The response of health care workers has mirrored that of society in general. This response has often been characterized by fear of contagion and avoidance of individuals infected with or thought to be at risk for AIDS (10).

Today, more than 20 years into the AIDS epidemic, there has been rapid advancement in knowledge related to the causative agent of AIDS, modes of transmission of HIV and the course of the disease (33,34). Such information should provide a rational basis for the health care professional's response to caring for people with this illness. Yet the contrary attitude prevails. Research examining the attitudes and knowledge of health professionals (including nurses) about HIV infection indicates that fear, misinformation, and prejudice remain pervasive (35–38).

Nurses have been in the forefront of responding to the HIV/AIDS epidemic both in the provision of direct care and in organization of care delivery systems (6,39). Yet many nurses lack knowledge and experience related to the care of patients with HIV infection. This lack of experience has resulted in part from nurses avoiding care of these patients or from working in communities with a low incidence of HIV infection.

The rapid increase of reported cases of AIDS in diverse segments of the population, as well as in all geographic regions, including rural areas, strongly suggests that at some point all nurses will be involved. For nurses having limited experience with this disease, ongoing education is necessary to provide a knowledge base that supports quality nursing practice. However, education does not always change attitudes or behavior (35,40,41). Additionally some clinically based health care providers continue to mistrust the experts and question exactly how much is really known about transmission of HIV in the patient care setting (42).

Fear of HIV infection by health care professionals can still result in refusal to provide care and in unnecessary isolation practices (6,43). The more likely scenario, however, is the exhibiting of behaviors by health care providers that make the HIV-infected person feel stigmatized or devalued. In a focus group study of HIV-infected women (44), it was reported that fear and insensitive behavior by health care providers affected the patientsÕ quality of care, and their willingness to seek health care services. Other studies of low-income and gay populations have shown similar results (45).

Nurse practitioners are providing an increasing amount of care for vulnerable populations and may be in a primary position to provide education and encourage appropriate testing and early intervention for populations at high risk for HIV infection (46). Other nurses, who are involved in community activities, including school and community health education programs, should also be a major resource for information regarding available services. Nurses can provide a non-threatening atmosphere, in which questions can be raised, thus encouraging earlier diagnosis and treatment, and prevention of further transmission of the infection. School health programs provide an ideal opportunity to instruct appropriate, healthful behaviors. Risk-related sexual and drug practices may begin in adolescence, and this group needs to be a prime target for health education and risk reducing programs (32). Studies of school-based AIDS education have been shown to have impact on risk-related behaviors (47). However, adolescents are not all alike, and effective health education and sex education programs must be tailored to their culture and lifestyle. Investigators (48) found that different interventions were needed for sexually active and high-risk teenage populations than were effective with lower-risk groups.

Making the decision to undergo antibody testing requires the courage to face the possibility of HIV infection and the courage to take the chance that the provider will exhibit a professional, supportive attitude and maintain conÞdentiality. Regardless of whether the test results are positive or negative, post-test counseling is essential (32). Figure 42.2 models a comprehensive approach to HIV/AIDS education and prevention. The person who tests negative may still be at risk for HIV infection and needs continuing health education and ongoing counseling and support for behavioral changes, to reduce the likelihood of infection. Also, follow-up testing may be needed if the incubation period has not been long enough to reveal a positive test. Knowledge of the disease may be Òstreet knowledge,Ó learned from friends, Þlled with many untruths, half-truths, and inappropriate emotional overtones. This is an opportune time for nursing intervention, to help correct some of those misconceptions.

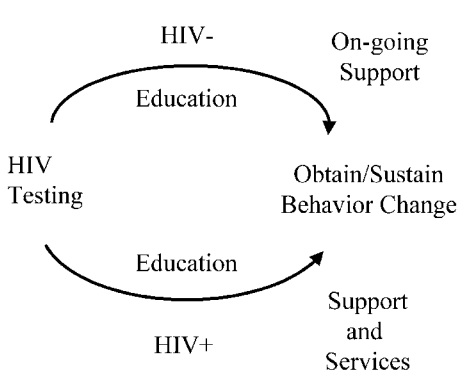

FIG. 42.2. Comprehensive approach to HIV/AIDS education and prevention (© Richard Sewell, with permission).

Persons testing positive have had their worst fears conÞrmed. Counseling support is crucial at this point and must be delivered with sensitivity to the gender and cultural and ethnic background of the client (32,49). Clients need to know what the test results actually mean, and unless Western blotting was done, about the need for conÞrmation to avoid false positives. Persons who test positive will need to learn a whole new vocabulary, as providers talk about T cells and CD4s. They must be linked to services that may be needed over the course of the illness. Even though the person testing positive may be asymptomatic, this is an appropriate time to begin case management activities. A case manager may assist the client to develop a plan of care. Case managers may provide education about the natural history of the disease and information on access to health services, so the early symptoms may be reported and treated appropriately. Case managers must assess the psychosocial, spiritual, and educational needs and prepare for linkages to services that will be needed in the future (6).

EARLY INTERVENTION

Increasingly, testing and counseling are being viewed as early intervention activities. Individuals who are identiÞed will then have the opportunity to implement behavior changes and health promotion activities that can, potentially, delay deterioration of immune status. Early identiÞcation allows a thorough medical and psychosocial assessment to deÞne immediate and long-term needs, that can maximize the length and quality of life (32).

The goal of early intervention is to keep people well as long as possible. The tasks required in early intervention for both client and provider are many. A client seeking early intervention may require treatment for many common illnesses not associated with HIV infection. The health assessment can identify additional infections and health care problems that need treatment. The nursing assessment should incorporate the health assessment into the psychosocial and spiritual context of the individualÕs life in devising a comprehensive client plan of care.

Education and information may be the greatest needs at this point, to permit the client to take part in the shared decision-making that will be necessary. Decisions such as

when or if to start antiretroviral therapy, prophylaxis for opportunistic infections, and the appropriate course of management and treatment, need to be jointly made by a well-informed client and provider. (50) When decisions are made unilaterally by the provider, the client may not Þnd them relevant or acceptable, decreasing chances of adherence to the prescribed treatment or regimen. It is important to acknowledge the use of alternative therapies by many individuals with HIV infection (51). When possible, incorporation of such therapies promotes adherence to the treatment plan, and allows providers to be knowledgeable about all the medications and approaches being used by clients.

To be effective, education needs to be ongoing and interactive. A trusting relationship needs to be developed between client and provider. The provider must acknowledge and respect the clientÕs competence in making decisions about his or her own life. In addition, some clients with HIV infection are better informed about their condition and its treatment than many providers. We have found that when providers were not forthright with information, some clients interpreted this as a lack of knowledge by the provider, diminishing their willingness to adhere to treatment.

The nurse has a critical part to play in explaining a treatment program to the client. Medications currently in use to treat HIV infection and related opportunistic infections can have many unpleasant side effects. Clients must be given explanations about the reasons for taking the medications, and their potential side effects, and information that will allow them to make an informed choice about whether the expected beneÞt outweighs the potential harm due to side effects (52Ð54). Nurses can be particularly helpful in providing information to the client and family, as appropriate, to manage those side effects so that discomfort can be reduced to a tolerable level. Support provided by nurses can be an important factor in assisting patients in adhering to drug treatment regimes that include multiple drugs and require rigorous dosing schedules (55,56).

Certain studies indicate that good nutrition, exercise, and stress management may have positive impacts on the bodyÕs ability to Þght infection and maintain or improve functioning (57Ð59). Nurses can provide information on these and other health promoting behaviors, to both the client and family. Family members may make more concrete contributions to these health promotional behaviors when they are well informed (22). Such information may also beneÞt the family members by enhancing their own general health behaviors.

Whenever possible, a comprehensive plan of care, that includes both medical and psychosocial issues, needs to be developed early. Tables 42.1 and 42.2 list frequent nursing diagnoses and selected interventions across the stages of HIV infection. The plan will differ for each client, and nursing diagnoses and interventions other than the ones illustrated will also be needed.

Decisions such as advanced medical directives, medical power of attorney, and guardianship of children need to be considered before the potential neurologic and emotional complications associated with AIDS places legal decision-making at risk. Many HIV-infected patients are not ready to deal with the prospect of severe illness, disability, or death, when they do not yet feel sick. Because of their role in direct care and education with clients and clientsÕ families, nurses are in a good position to develop a trusting relationship. This relationship will be necessary so that clients can be assisted in confronting these issues in a timely manner, though they may still be in denial or unprepared to consider such sensitive and distressing subjects. However, one of the most important issues to be considered is how to balance the need to plan for future illness with the desire to maintain hope and a focus on living.

Psychological assessment needs to be done to identify levels of depression, anxiety, and suicide risk. Anxiety and depression are two of the most common emotional responses to a diagnosis of HIV infection (27,31). Such emotional responses can be linked to the uncertainty and stigma associated with this illness (60Ð62). For some people, peer support groups can be an effective method to help cope with fear, anxiety, and feelings of isolation. Nurses can provide information and linkages about available resources. IdentiÞcation of problems with drug and alcohol use is also an important part of psychosocial assessment. Many people living in poor social conditions have used drugs and alcohol as a means of coping, and the option of substance abuse treatment needs to be made available. Behavior change related to substance abuse may require long-term solutions and incorporate principles of the harm-reduction model previously discussed.

Because Þnancial, housing, nutrition, and transportation problems frequently grow worse as the disease progresses, these areas must be included in assessment. Problems in these areas may be pre-existing or begin emerging after the diagnosis of HIV infection, especially if clients lose their jobs because their HIV status becomes known. The usual debilitating course of HIV infection mandates that issues of long-term housing, medical care Þnancing, and general Þnancial management be regularly addressed in psychosocial care planning. Practical concerns such as mobility and wheelchair access should be considered. Case management can provide a framework in which medical and psychosocial aspects can be integrated into a comprehensive care plan.

Case management models are found in both inpatient and community settings (6,7,63,64). Models in both settings have the overall objective of coordinating and linking clients to an appropriate level of service based on need. Nurses have the expertise needed to be effective case managers. Nurse care managers can be particularly beneÞcial to clients with early HIV infection, when information and health promotion is a critical need, and in later stages when physical assessment and symptom

management become prime considerations. An interdisciplinary approach is critical and the case management role may be to link to available services and provide a conduit for appropriate information to reach service providers. In instances where services are not available, the nurse case manager, in collaboration with social service providers, can take the initiative to develop services or community networks that support the needed

TABLE 42.1. *Physiologic challenges: Selected nursing interventions*

Nursing Diagnosis	Potential Source/ Cause	Early Interventions	Late Interventions
Impaired gas exchange	Pneumocystis arinii pneumonia (PCP) Anemia Cytomegalovirus (CMV) pneumonia Pulmonary Kaposi's Sarcoma	• Educate populations at risk of bene ts of early intervention and treatment • Encourage and provide early HIV screening to identify at risk persons • Monitor compliance with PCP prophylaxisexaminations • Monitor hemoglobin and hematocrit	• Monitor mental status • Monitor vital signs, blood gasses • Position for comfort, elevate head of bed • Educate regarding treatments and examinations • Implement actions to reduce fear and anxiety • Monitor effects of assisted ventilation
Diarrhea	Cryptosporidium Isospora Mycobacterium avium-intracellulare complex (MAC) Salmonella Giardia	• Educate regarding dietary risks, e.g., raw chicken, eggs, meat • Educate regarding good hygiene and handwashing • Educate regarding refraining from risky oral-anal sex practices	• Monitor for weight loss, malnutrition • Implement measures to ensure adequate hydration • Educate regarding good hygiene and handwashing • Diet counseling • Educate regarding treatments and examinations
Potential for infection due	IV devices Herpes Zoster Psoriasis Herpes simplex virus Immobility Poor nutritional status Diarrhea	• Assess skin for lesions, pressure areas, turgor • Monitor for signs and symptoms of secondary infection • Monitor for disruption of skin integrity • Educate regarding good hygiene	• Ensure good hygiene • Use pressure-relieving devices • Turn and position frequently • Meticulous IV device care • Infection control measures • Work with physicians to eliminate/treat underlying conditions
Pain	Peripheral neuropathy Tumor Reiter's syndrome Herpes zoster Herpes simplex	• Monitor for pain, assess location, duration, type, etc. of pain • Identify contributing and/or risk factors for pain • Monitor and educate regarding drug therapy and reporting symptoms	• Explore alternative techniques to cope with pain, e.g. relaxation, visualization, distraction • Encourage client verbalize pain • Comfort measures such as egg-crate mattresses, positioning and supporting limbs • Administer and monitor the effectiveness of analgesics
Altered Nutrition	Anorexia Nausea/vomiting Malabsorption In ammation/lesions of GI tract Diarrhea	• Educate and monitor regarding measures to promot lean body mass • Educate and assess regarding sound nutritional practices • Early detection and treatment of conditions such as in ammation/ lesions of GI tract and diarrhea	• Assess and monitor nutrition parameters (e.g. weight, serum albumin, food intake) • Treat underlying conditions • Dietary change as appropriate (high calorie—high protein, bland) • Offer dietary supplements • Implement and monitor parenteral nutrition and assess effectiveness and related complications or side effects; begin nursing measures to respond to complications

TABLE 42.2. *Physiologic challenges: Selected nursing interventions*

Nursing Diagnosis	Potential Source/ Cause	Early Interventions	Late Interventions
Knowledge de cits	New diagnosis Impaired or dereased learning disability Lack of awareness of need for education Development of new conditions	• Increase awareness of need for education • Assess level and readiness to learn • Develop an individualized teaching plan • Evaluate and revise education approaches • Referral of client to other services such as peer or professional counseling services • Include family/signi cant others in education process • Provide suf cient, accurate, timely information (e.g. treatment options, informed consent, prevention of transmission, health promotion)	• Refocus education of information from general to speci c with regard to each client's infections and conditions • Provide speci c teaching regarding treatments and procedures • Educate regarding realistic self-care goals; teach speci c delegated nursing tasks such as IV maintenance • Referral to resources/agencies providing supportive care
Social isolation	Stigmatizing disease Fear of contagion by others Alterations of body image Decreased ability to socialize Alterations in life-style due to chronic illness (related to fatigue, medications, and changes in physical appearance, hospitalizations) Avoidance and/or pity by family and friends of clients	• Establish open and therapeutic communication • Referral to peer and professional counseling • Assist client in inventorying sources of social support • Assist client in identifying need and timing for disclosure of HIV status to signi cant others • Referral of family and signi cant others to sources of social support across the potential circumstances of disease progression • Identify HIV sensitive health and social services providers as potential referral sources	• Develop supportive, therapeutic environment in clinical setting • Establish open communication across the continuum, including talking and explaining procedures during nursing care, even with clients with limited ability to respond • Appropriate but not excessive infection control measures • Establish liberal visitation with incorporation of family and signi cant others in the plan • Provision of safe space and opportunity for socialization for clients and signi cant others • Use radio and television as source of stimulation • Appropriate use of touch
Altered body image	Stigma of disease Past experiences with others with disease Urinating Skin lesions Fatigue Decreased mobility Reaction to responses of others	• Assess for early problems of altered body image, e.g. ruminating about imagined alterations, issues of contagion • Assess clients' understanding and acceptance with physical manifestations of disease progression • Provide accurate information and assist client in establishing realistic plans to respond to physical changes in appearance • Assist client in exploring measures to control or disguise manifestations (e.g. skin lesions, eruptions)	• Work with client to maximize functional abilities • Work with client to minimize physical manifestations • Refer to peer and professional counseling • Establish open, accepting communication with client • Establish and support a therapeutic, caring, clinical environment • Assist client and signiticant others in establishing an accepting and supportive home environment • Identify and implement nursing measures to decrease effects of physical problems such as incontinence, nausea, vomiting, fatigue

TABLE 42.2. *Continued*

Nursing Diagnosis	Potential Source/ Cause	Early Interventions	Late Interventions
		• Referral to peer support and counseling • Provide information and education to family and signi cant others related to client's need for acceptance and emotional support in the face of physical manifestations of disease	
Anxiety	Stigmatizing disease Uncertainty Perceived lack of control New diagnoses Fear of rejection/ descrimination related to societal attitudes Fear of pain Fear of dis gurement Fear of death	• Provide accurate information • Open communication • Assist client in articulating source of anxiety • Assist client in developing a plan to address anxieties • Refer to peer and protessional counseling • Spiritual/pastoral support • Informed consent regarding power of attorney, living will, shared decision making	• Facilitate return of control to patient • Facilitate open communication • Provide accurate information regarding treatments and procedures • Spiritual/pastoral support • Implement nursing measures to control pain • Maximize functional abilities • Inclusion of family and signi cant others in plan of care • Obtain informed consent regarding treatments and procedures • Facilitate shared decision making
Altered role performance	Fatigue Physical debilities Pain Emotional Distress/fear Alteration of body image Lack of information	• Assess client's emotional status, physical status, and knowledge level regarding transmission of virus and legal rights • Educate and advocate for client regarding his rights • Identify HIV-sensitive services and make appropriate referrals • Job/career counseling as appropriate reterrals • Family counseling • Referral to community-based case management	• Explore and assist negotiating of role expectations and obligations with client and family • Identify and assist in obtaining entitlements • Referral to community-based case management • Maximize tunctional abilities • Support maintenance of control

services. Where formal case management services have not been established, both hospital and community nurses need to provide health care networks that promote the continuity of services for people with HIV infection, across the continuum of their illness.

ACUTE CARE

Persons with HIV infection can be hospitalized for a wide range of infections and symptoms related to immune suppression. For the individual patient, hospitalization can represent the initial acute disease, or one in a series related to debilitating opportunistic infections. Regardless of the personÕs stage of illness, a primary reason for admission to the hospital is the need for supportive nursing care.

An important objective for the professional nurse providing care to HIV-infected patients is to establish a therapeutic environment. The overall nursing goal is to maximize the quality of life for the patient, while responding to the individualÕs current manifestations of HIV disease. A challenge for nurses is to help to maintain the clientÕs functional ability even when the person is experiencing rapid disease progression.

Hospitalization may exacerbate emotional distress and be viewed by the individual and family members as representing a deterioration of health status. The HIV-infected patient often enters the hospital uncertain of the future, concerned about loss of functional ability and

afraid that this will be the infection that he or she will be unable to overcome. Universally, the health care professional who has the most frequent contact with the patients is the nurse. It is the nurse who is most responsible for establishing open communications that acknowledge the fears and concerns of the patient. There is a valid need for health care workers to take appropriate precautions to prevent transmission of disease within the hospital setting. However, the practice of unnecessary or exaggerated precautions with the HIV-infected patient can limit patient-nurse interactions and increase the patientÕs sense of isolation, abandonment, and anger (65). There is a growing understanding that emotional stress can negatively affect an individualÕs physical status (66,67). For the patient entering the hospital in a state of immune suppression, unnecessary stress encountered within the health care setting may, potentially, compromise further the patientÕs ability to respond to treatment.

While respecting the patientsÕ conÞdentiality, inclusion of family and signiÞcant others in the daily hospital routine can serve to decrease the sense of isolation. As part of the nursing function, nurses need to establish a ßexible schedule with their patients and families that promotes a balance between the patientÕs need to rest and receive treatment and to interact with signiÞcant other individuals who provide ongoing emotional support. It is essential that the nursing plan of care be developed with the patient and that it integrates the medical treatment required into a holistic approach.

Nurses can serve appropriately as coordinators within the interdisciplinary therapeutic inpatient care team. An important nursing responsibility is to ensure that the hygiene, nutrition, emotional, and spiritual needs of a patient are adequately considered in overall delivery of treatment and care. The nursesÕ central role in providing information/education to patients and family members, along with an understanding of treatment options, care procedures, and relevant infection control precautions by the patient and family, can facilitate the holistic treatment of the patient.

Provision of Care

Persons with HIV infection are often admitted to the hospital in acute crisis, or with the potential for their conditions to deteriorate rapidly. This requires that nurses fully utilize their assessment skills in establishing baseline measurements from which future changes in condition can be evaluated. Nursing assessment should focus acutely on respiratory, neurologic, and gastrointestinal status, because opportunistic infections affecting these systems can be life-threatening (68Ð70).

The nurse as the direct care member of the treatment/care team should take responsibility for frequent, ongoing, monitoring of a patient who is potentially unstable or in distress. Changes in the patientÕs condition should be noted as early as possible and the nurse prepared to respond knowledgeably, as well as to communicate the necessary information to the physician and other team members. Once an initial assessment of the patient is complete, the nursing process (assessment, planning, intervention, and evaluation/reassessment) provides a framework for comprehensive nursing care to the patient.

Special Problems

Frequently associated with HIV-related gastrointestinal opportunistic infections (such as those caused by cryptosporidium, cytomegalovirus, or *Mycobacterium avium* complex) are alterations in hygiene and nutritional needs. Diarrhea, due to these and other causes, is a common condition encountered in HIV-infected patients. Episodes of diarrhea can be explosive and last for days or weeks. Profuse diarrhea can affect the individualÕs willingness to eat, affect his or her electrolyte balance, and may be associated with severe abdominal pain. Skin breakdown in the perianal area may result, providing a new avenue of infection. Diarrhea also adds to the psychological burden of the patient, with fear of loss of control and embarrassment. Monitoring response to antidiarrheal therapy, and communications with the physician regarding the treatment plan, are essential.

Debility and weight loss that typically accompany HIV infection over time also carry enormous psychological implications for the patient. The physical and emotional complications of HIV infection are quite complex and often interrelated. Maintaining or assisting the patient who has this challenging illness, with its special problems, will test the nursing skills of even the most experienced nurse.

Alteration of Nutrition Status

In addition to diarrhea, prolonged fevers and poor nutritional intake contribute to generalized wasting in many individuals with HIV infection (71,72). Nutritional assessment for each patient and early intervention by the nurse are crucial in identifying and modifying the risk of this complication. Assessment should include a review of pertinent laboratory values, patient weights, diet recall, and direct observation of nutritional intake (73). Once patients at risk are identiÞed, the nurse must institute early nutritional intervention, such as frequent weights, dietary intake monitoring, offering foods of choice, and teaching dietary strategies. Consultation with a dietitian or nutritionist may help to individualize a dietary program. Appropriate strategies to avoid weight loss include assisting patients in selecting high-calorie, high-protein foods, avoidance of lactose in the intolerant, and offering frequent small meals. Nurses must also be alert to factors that contribute to poor dietary intake such as stomatitis, early Þlling, or a disagreeable taste in the mouth from

medications, and must then take appropriate action to ameliorate these conditions.

Early assessment of those at risk for weight loss and wasting, initiating appropriate interventions, and identiÞcation and communication of factors associated with poor dietary intake to other members of the health care team, offer the patient the hope of avoiding enteral and parenteral interventions. Early nutritional intervention and preservation of normal dietary routines as much as possible are more palatable to patients than the inconvenient, expensive, and potentially harmful invasive interventions such as long-term intravenous lines and parenteral nutrition. Prompt recognition of correctable problems, combined with appropriate nutritional interventions by the nurse, can delay and possibly diminish the impact of intractable wasting.

Alteration of Mental Status

Alteration of mental status, including cognitive, motor, affective, and behavioral changes, is common in patients with HIV infection, especially those with advanced immune deÞciency. An estimated 20Ð30% of persons with very late stage HIV infection will suffer profound cognitive and motor impairment (74,75). The difÞculty experienced in performing a health assessment of any acutely ill patient is often made even more complicated by such severe alterations in mental status in HIV-infected individuals. This difÞculty in assessment can complicate the formulation of an appropriate plan of intervention for the patient. Maintaining meaningful and effective patient-nurse communication is a challenge under such circumstances and can make evaluation of signiÞcant changes in physical and mental condition even more difÞcult.

Mental status alterations can present the nurse with another dilemma. The nurse is often faced with making decisions related to preserving the safety of a mentally compromised patient. Decisions about physical restraint or chemical sedation of a patient are most often made by the nurse. The nurse must weigh the patientÕs need for safety against his or her right of self-determination and need for self-care.

Dual Infection with Tuberculosis

The development of tuberculosis in the HIV-infected individual represents a serious situation with pressing implications for the nurse. First, it may be the nursesÕ responsibility to ensure initiation of respiratory precautions for any patient with HIV infection and suspicious pulmonary symptoms (76). Further, the nurse must be vigilant in maintaining appropriate respiratory precautions by staff and patient families (77). The importance of adherence to proper respiratory precautions goes beyond the nurseÕs responsibility to advocate for the patient and their families. Although HIV is rather difÞcult to transmit from patient to nurse, pulmonary tuberculosis represents a real occupational hazard for the nurse and others in health care. Therefore, the nurse is obligated to ensure that the workplace is made as safe as possible.

In addition to supplies and teaching about isolation, the patient and family must receive from the nurse timely and accurate information about treatments, procedures, and examinations. It is essential that the nurse establish continuity with community agencies, particularly with public health nurses and epidemiologists, for follow-up upon discharge.

Discharge Planning

An ideal example of the importance of discharge planning is tuberculosis follow-up after hospital discharge. Effective discharge planning for a patient with tuberculosis has public health implications because of the requirement for compliance with long-term treatment. As discharge planner, the nurse identiÞes potential needs of the patients as they return to their communities and also identiÞes the resources in the community to meet those needs (78). Communication and feedback between hospital nurses and nurses and other health care providers in the community (hospice, the public health departments, and home health) are critical for continuity of care. Nurses should work to provide discharge planning and encourage that communication. Communication information systems need to be developed to permit hospital nurses to be kept up-to-date on community resources and to allow for those necessary linkages outside of the hospital.

END STAGE

ÒI am not afraid of death; I am afraid of dyingÓ(79) is a major concern for patients as the disease takes its course. The psychological work of coping with the fear of disability is replaced by the specter of going through the process of dying. A major issue for persons in the Þnal stage of the disease is the need to stay in control of their lives and their deaths. There are several important issues to be addressed in this area. Considerations of quantity versus quality of life will require decisions about life support and advance directives, aggressive treatment versus supportive care options, and institutional or home care.

Choices of where dying will take place need to be made. Patients and families have the task of deciding whether dying at home is an option (80). Home care is not easy, given the physical, mental, and Þnancial problems to be faced, but may be an option in those families with the necessary resources. Hospice support may be available, at home or in an institution. Nurses have the responsibility to

ensure that individuals and families understand their available options and support them in their choices.

Fear of pain may be a major component in facing the process of dying; pain management takes on special importance in the end stage (81). Pain is common in people with AIDS (82). Common types of pain include abdominal, neuropathic, esophageal, head, and pain related to Kaposi's sarcoma. Pain may make it impossible to maintain quality of life. Negative attitudes about the need for pain relief have been documented among health care providers for their patients who were chemically dependent, and these attitudes have affected the treatment provided (83). This is especially important because substance abusers are the second most common risk group for HIV infection in the United States. Pain control needs to be highly individualized. The client has the right to deÞne when pain exists and to expect adequate interventions to provide relief when possible.

Issues centering on family relationships often come to a head at this time. Special problems may arise for HIV-infected parents with regard to their ability to maintain relationships with their children. This can be especially difÞcult for women, who have traditionally been the caretakers within families. as parents approach the end stage of their illnesses, the care and well being of children after the parents die must be faced. A growing number of children who are orphaned by parents with AIDS are requiring foster care. Many of these children are also HIV-infected (84,85). In 1991, 1,149 HIV-antibody positive children were already in the foster care system (86). Conßicts may arise in decisions to be made about families of choice and families of origin and how family members will be integrated into the Þnal stage of life. Responsibilities for making Þnal decisions need to be clearly spelled out. Nurses need to support clients' decisions about who is most important to them and who will play integral roles in the Þnal stages of life. Finally, surviving families cannot be forgotten once death has occurred; bereavement counseling may be needed to resolve issues of loss. Some family members or signiÞcant others will face their own deaths from AIDS, and may require support to deal not only with loss but also with their future prospects (87).

NURSING ADMINISTRATION

Nurse managers may be found in hospital or outpatient settings, and are responsible for establishing speciÞc policies that outline clinical standards, and procedures that ensure a high quality of care for patients with HIV infection. Clearly linked to standards of care is the need to establish personnel performance criteria. Consumerism in health care demands that high quality care measures focus on patient care outcomes. This does not suggest that the "end result" outcome for HIV-infected patients will be cure, but rather that incremental process outcomes are achieved. Patient satisfaction with care can be an important outcome for patients with terminal disease (88,89). Nurse managers can support the nursing staff in delivering quality care by establishing consistent organizational policies and procedures that guide staff in making controversial decisions encountered in the care of HIV-infected patients. Issues such as self-determination, use of alternative therapies, or referral to sources that may offer speciÞc medical treatments, can produce controversial patient care situations in which nurse managers need to support the patient's rights, as well as those of the nursing staff.

A nurse's refusal to care for an HIV-infected patient presents an important challenge for the nurse manger. Institution-speciÞc policies are needed to guide supervisory actions in such situations. Often, existing personnel and grievance procedures can be used if disciplinary measures are required (90). The optimal approach to responding to staff fear or concerns associated with the care of persons with HIV infection is establishment of an ongoing in-service program focusing on updated information related to this disease. Education should be reinforced by clearly articulated clinical guidelines that promote a safe working environment for all staff. The low risk of infection with HIV when following the Centers for Disease Control (CDC) guidelines for handling blood and other bodily ßuids (91) make it critical that staff be taught universal precautions and safe needle disposal practices.

Approximately 80% of signiÞcant exposures to HIV among health care workers involve needle sticks (92). Of those health care workers most likely to sustain a needle stick, nurses constitute 60Ð70% of them (93,94). However, even among nurses who have a good understanding of HIV-related issues, implementation of universal precautions is not consistent (95,96).

Universal precautions guidelines need to be mandated as part of institutional policy. Employees unwilling to incorporate these precautions into routine practice need to expect corrective or disciplinary action. It is no longer acceptable to isolate or avoid the admission of persons with HIV infection because nurses or other hospital staff do not take advantage of available safety precautions when caring for patients.

HEALTH CARE WORKERSÑCONCERNS AND EMPLOYEE ASSISTANCE

Persons with HIV infection require a large physical and emotional investment from nurses. Hospitalized patients are often young and exhibit a wide range of disÞguring signs. No direct care provider should be expected to withstand repeated encounters with stress without support. Nurse managers need to work creatively to develop strategies that support their staff. While support efforts need to be individualized to speciÞc agencies, the inclusion of psychologists and pastoral care workers in the interdisciplinary care team may be valuable to patients and staff. Clinical support groups for nurses that care for

patients with HIV infection have been successful in a teaching hospital in New York City (97).

The AIDS epidemic has raised questions about whether the HIV-infected health care worker may safely continue his or her patient care activities. Universal precautions should be adequate to ensure staff and patient safety in most clinical settings. Nurses who develop symptomatic HIV infection often require support and assistance. Nurse managers need to take the lead in establishing clear employment assistance procedures for all HIV-infected health care workers, where they do not already exist. When appropriate procedures are in place, the nurse manager is responsible for helping the employee to implement appropriate procedures.

NURSING EDUCATION

The AIDS epidemic has resulted in a compelling need in nursing education to reach students early in the educational and socialization process (98). Faculty in schools of nursing must develop a comprehensive approach to HIV infection within the curriculum.

Issues associated with HIV infection span the continuum of care and affect the delivery of nursing care at a variety of levels. Educational content in schools of nursing will need to reßect this, if future nurses are to be prepared adequately for the realities of the work environment. HIV/AIDS care issues should not be limited to advanced adult health nursing courses. These issues are also relevant content for those studying parent-child, mental health, community health, and nursing administration, as well as in courses dealing with ethical and professional issues. A necessary Þrst step within educational institutions may be the need to update faculty knowledge in the area of HIV infection. If faculty are not knowledgeable or comfortable in provision of care to HIV-infected persons, students will sense their discomfort. The value of positive faculty role modeling in developing positive attitudes and behaviors toward AIDS care in nursing students cannot be overemphasized.

Without a vaccine or a curative treatment, the need to care for persons with HIV infection can be expected to increase for many years to come. Nurse educators have a unique opportunity and responsibility to take a leadership role in responding meaningfully to the AIDS epidemic. Research studies need to be designed to examine current interventions and to develop and test creative approaches to care. The National Center for Nursing Research has acknowledged the need for nurses to investigate both the physiological and psychosocial aspects of HIV infection (99). Research needs to be based on the clinical realities of caring for HIV-infected persons and to focus on the evaluation of nursing interventions as they relate to client outcomes. Student involvement in research activities can set the stage for further work and interest in the area. The future of nursing lies with the next generation of nurses. It is that future that nurse educators have the chance to inßuence positively to the beneÞt of society, the nursing profession, and especially to those persons and their families who are at risk for HIV infection.

Chapter 43

Ethical Challenges of the Global AIDS Epidemic

Ronald Bayer

In a quite fundamental sense the AIDS epidemic has provided the occasion for the effort to articulate an ethics of public health. Although such an effort drew upon the insights and perspectives of bioethics, it was clear that more was needed. Bioethics had taken root in the United States largely in an effort to redress the balance of power between clinicians and patients and researchers and subjects. Central to that effort was an explicit focus on the rights of the individual. Hence the protection of autonomy became the core commitment of bioethics. Important as was the protection of the individual, it could not serve as the only or even preeminent principal in the context of public health, where the focus was, by deÞnition, on the protection of the community. Nevertheless, as the ethics of public health took shape in the context of the AIDS epidemic, the critical importance of individual rightsÑ claims of privacy, bodily integrity, freedom from unwarranted restraintsÑw as clear. Only in later stages of the epidemic when therapeutic advances made access to care a critical matter did questions of justice take on greater salience. Finally, it was the emerging demand for access to care on the part of the poorest peoples in nations which bore the brunt of the global epidemic that set the stage for vital questions about the moral duties of the world's richest nations to the poorest.

EXCEPTIONALISM AND PUBLIC HEALTH: THE ETHICS OF TESTING, REPORTING AND PARTNER NOTIFICATION

In the early and mid-1980s, at the outset of the American encounter with AIDS, it was necessary to face a set of fundamental questions: Did the history of responses to lethal infectious diseases provide lessons about how best to contain the spread of HIV? Should the policies developed to control sexually transmitted diseases or other communicable conditions be applied to AIDS? If AIDS were not to be so treated, what would justify such differential policies?

To understand the importance of these questions, it is necessary to recall that conventional approaches to public health threats typically provided a warrant, when deemed appropriate, for mandating compulsory examination and screening, breaching the conÞdentiality of the clinical relationship by reporting to public health registries the names of those diagnosed with ÒdangerousÓ diseases, imposing treatment, and in the most extreme cases, conÞning persons through the power of quarantine. To be sure, many aspects of this public health tradition, forged at the outset of the 20th century, had been modulated over the decades, in part because of changes in the patterns of morbidity and mortality.

Nevertheless, it was the specter of the historically coercive aspects of the public health tradition that most concerned proponents of civil liberties and advocates of gay rights and bioethics as they considered the potential direction of public health policy in the presence of AIDS, a disease that so disproportionately affected disfavored groups, gay men, drug users, the poor in minority communities. Although there were some public health traditionalists in the United States who pressed to have AIDS and HIV infection brought under the broad statutory provisions established to control the spread of sexually transmitted and other communicable diseases, they were in the distinct minority. In place of the conventional approach to public health threats, there emerged an alternative viewÑbroadly deÞned as e xceptionalist (1)Ñthat took as its starting point the need to craft policies that were persuasive rather than coercive, that viewed the protection

Ronald Bayer: Program in the History of Public Health and Medicine, Department of Sociomedical Sciences, Mailman School of Public Health, Columbia University.

of the rights of those who were infected as integral rather than as antagonistic to the goals of disease prevention. For those who advanced this new perspective, privacy and conÞdentiality were to be accorded great importance. In all, the goal was to avoid, at all costs, measures and practices that might be counterproductive, that might Òdrive the epidemic undergroundÓ by inspiring fear and distrust rather than fostering engagement between public health ofÞcials and those most at risk. How the exceptionalist perspective with its commitment to non coercive approaches to HIV affected policy is most clearly illustrated in the debates over HIV testing, reporting of HIV by name to public health registries, and partner notiÞcation efforts.

From the moment of its introduction in 1985, the HIV test became the subject of intense debate. Fear that those identiÞed as having HIV might be subject to discrimination and stigma; concern about how the diagnosis of HIV infection, in the absence of effective therapy, could produce unbearable psychological burdens; and a belief that testing had little to do with behavioral change, led AIDS activists generally, and gay leaders speciÞcally, to adopt a posture of hostility and/or skepticism regarding the test. On the other hand, many public health ofÞcials believed that the identiÞcation of infected persons could play a crucial role in fostering behavioral change. Out of their confrontations emerged a broad consensus that, except in a few well-deÞned circumstances, people should be tested only with their informed, voluntary, and speciÞc consent (2).

Much of the early discussion of HIV testing occurred in the context of extreme therapeutic limits. And indeed in the epidemic's early years the primary function of testing was as an adjunct to prevention efforts. As a result of clinical developmentsÑ the belief that treatment with zidovudine could delay the onset of symptomatic AIDS and the recognition of the importance of primary prophylaxis against *Pneumocystis carinii* pneumoniaÑ by 1990, the medical signiÞcance of identifying those with early HIV disease had become clear. Consequently, the clinical and political contextÑ involving a wide range of constituenciesÑ of the debate about testing underwent a fundamental change (3). Gay organizations began to urge homosexual and bisexual men to have their antibody status determined under conÞdential or anonymous conditions. Physicians pressed for AIDS to be incorporated into the medical mainstream and for the HIV-antibody test to be treated like other blood testsÑ i.e. given with the presumed consent of the patient. In the face of such pressure, those committed to the protection of the rights of the infected continued to insist that testing only occur with speciÞc informed consent. Whatever, in fact, occurred in the context of clinical settings, public policy at the federal and state level continued to reßect a commitment to the voluntaristic premise of the exceptionalist perspective and the enduring inßuence of the ethical underpinnings Þrst enunciated in the mid-1980s when medicine was all but impotent.

Nevertheless, pressure to shift the paradigm of testing away from the exacting standard of informed consent continued to mount. It was especially pronounced in the case of pregnant women and newborns (4). Diagnostic progress was to make it possible to determine whether HIV-positive newborns were truly infected soon after birth, and the improved prospects of clinical management were to make such determinations for infected infants appear all the more critical. So it is not surprising that pediatricians became increasingly impatient with the strict regimen of explicit and speciÞc consent that surrounded the testing of newborns for HIV (5)Ñ all the more so because routine and unconsented testing of newborns for inborn errors of metabolism such as phenylketonuria was mandated in virtually every state, and had provoked little by way of ethical objection.

In late spring 1993, New York State, which together with California had pioneered the enactment of stringent informed consent requirements for HIV testing, seriously considered legislation that would have mandated the screening of newborns for HIV infection. When that legislation ultimately passed in 1996 (6), it provoked a cry of outrage from the advocates of women's rights. Ironically, the passage of a mandatory newborn testing statute occurred when interest had already begun to shift to the question of screening pregnant women. That shift occurred as the result of the 1994 Þnding that the administration of zidovudine during pregnancy could reduce the rate of vertical transmission by two thirds (7).

In the aftermath of that Þnding, pressure mounted to ensure that infected women were identiÞed early in pregnancy. Although advocates on behalf of women's interests fought hard to preserve the right of pregnant women to undergo HIV testing only after speciÞc informed consent, the prospect of saving newborns from HIV infection provided the foundation for a vigorous challenge (8). In June 1996 the American Medical AssociationÕs House of Delegates passed a resolution calling for mandatory testing of pregnant women (9).

Even the Institute of Medicine, which early in the epidemic had opposed testing policies that abrogated the privacy rights of pregnant women, was by the end of the 1990s to endorse routine testing on the basis of an informed right of refusal, a much less exacting standard than speciÞc informed consent (10).

In other contexts as well, the retreat from the exacting standard of speciÞc informed consent with pretest counseling has taken the form of efforts to integrate HIV testing into clinical practice where standards of presumed consent prevail. Strikingly, however, when in 1999 the CDC suggested, as one of several options, a relaxation of the standard of speciÞc informed consent for HIV testing in populations other than pregnant women, it provoked sharp opposition. Ultimately, those who favored a change in course were defeated (11).

A course similar to that which occurred with testing characterized the debate surrounding case reporting for HIV infection. Given the profound stigma that surrounded AIDS in the epidemic's Þrst years, and the extent to which individuals with or at risk for HIV feared the social consequences of having their diagnoses made public, it is not surprising that conÞdentiality of AIDS-related information assumed great salience. From the pragmatic perspective of public health ofÞcials it was crucial to preserve conÞdentiality as a way of assuring that those at risk would come forward for testing and counseling (12). Others objected on grounds of principle. Privacy was a value that should not be lightly set aside.

But, however central were the claims of privacy and the duty to protect conÞdentiality, they were not absolutes. Among the conventionally accepted limits to those claims occurred when individuals with infectious diseases were reported by name to conÞdential public health registries. It was thus not surprising that despite concerns about privacy, little opposition existed in the epidemic's Þrst years to making AIDS cases reportable by name (13). AIDS activists appreciated that such reporting was crucial to the understanding of the epidemiology of the new disease. The acceptance of AIDS case reporting requirements was facilitated by the well-established record of state health departments in protecting such records from unwarranted disclosure.

With the inception of HIV testing, however, debate emerged about whether the names of all infected persons, regardless of whether they had received an AIDS diagnosis, should be reported. Activists who accepted AIDS case reporting opposed HIV reporting because of heightened concerns about privacy, conÞdentiality, and discrimination. For them the potential public health beneÞts of reporting were too limited and the burden on those who would be the subject of reporting too great to justify an abrogation of privacy.

While many public health ofÞcials, especially those who came from states with large AIDS case loads, opposed HIV reporting because of its potential effect on the willingness of people to seek testing and counseling, some public health ofÞcials did become strong advocates of such reporting. Their claims sought to underscore the extent to which the public health beneÞts of HIV reporting would be like those that followed from more broadly conceived reporting requirements, such as those that applied to syphilis, tuberculosis, and AIDS itself (14).

As therapeutic advances began to emerge in the late 1980s, and as the logic of distinguishing between HIV and AIDS became increasingly difÞcult to sustain, Þssures began to appear in the relatively broad and solid alliance against named HIV reporting.

At the end of November 1990, the CDC declared its support for HIV reporting, which it asserted could Òenhance the ability of local, state and national agencies to project the level of required resourcesÓ for care and prevention services (15). The House of Delegates of the American Medical Association also endorsed the reporting of names as well (16). In 1991, New Jersey became the Þrst relatively high-prevalence state to require HIV case reporting by name.

In the following years, the CDC continued to press for name-based reporting of HIV cases, supported by a growing number of public health ofÞcials, including the Council of State and Territorial Epidemiologists (17). Central to their argument was the assertion that AIDS case reporting captured an epidemic that was as much as a decade old and that an accurate picture of the incidence and prevalence of HIV infectionÑ especially in light of the impact of treatmentÑ required a surveillance system based on HIV case reporting. Nothing more tellingly underscores the change that had occurred and the extent to which the claims of public health necessity had trumped the arguments of privacy than an editorial jointly authored by a CDC ofÞcial, an AIDS activist and a lawyer-ethicist long involved in AIDS-related work that appeared in the *New England Journal of Medicine* in 1997.

> We are at a deÞning moment of the epidemic of HIV infection and AIDS. With therapy that delays the progression to AIDS, mental illness, and death, HIV infection or AIDS is becoming a complex clinical disease that does not lend itself to monitoring based on end stage illness. Unless we revise our surveillance system, health authorities will not have reliable information about the prevalence of HIV infection. . . . To correct these deÞciencies, we propose that all states require HIV case reporting (18).

At the end of 1999, in the face of lingering opposition from most AIDS activists, the CDC Þnally proposed that all states put in place an HIV reporting system. And while it left open the possibility of reliance on unique identiÞers that met strict performance criteria, it was clear that the use of names was viewed as preferable (19). Remarkably, of those states that adopted HIV case surveillance after the publication of the CDC's recommendations, virtually all adopted coded systems. By 2002 only a handful of states had not adopted some form of HIV reporting.

In the controversy over partner notiÞcation the limits of privacy were also encountered. What emerged as a source of contention in that period was the extent to which the protection of identiÞable third parties who had been or were currently placed at risk for HIV by already infected individuals provided a warrant for public health interventions. This was not a new issue; it had been confronted in the context of psychiatry in the so-called *Tarasoff* doctrineÑ that physicians who knew that their patients were about to inßict serious harm on other identiÞable individuals had a duty to act to warn or protect (20). While opinions differed about the wisdom of such efforts, there was little principled objection to breaching conÞdentiality under such circumstances.

Thus in the mid to late 1980s, when many AIDS activists argued that the principle of conÞdentiality had to be inviolable, and when public health ofÞcials were loath to endorse legislative mandates *requiring* third party notiÞcation, many ethicists suggested that protection of

unsuspecting sexual partners took precedence over privacy.

> When there are strong clinical grounds for believing that a speciÞc contact has not been informed . . . the prudent course for the physician is to inform the contact of the positive serological status of the patient (21).

When, despite the opposition of most civil libertarians and activists, the American Medical Association's House of Delegates embraced the duty to warn in mid-1988, the AssociationÕs president asserted,

> This is a landmark in the history of medical ethics. We are saying for the Þrst time that, because of the danger to the public health and the danger to unknowing partners who may be contaminated with this lethal disease, the physician may be required to violate patient conÞdentiality. The physician has a responsibility to inform the spouse. This is more than an option. This is a professional responsibility (22).

Some states sought to meet the challenge of endangered third parties by enacting statutes that secured a Òprivilege to disclose.Ó Under such laws physicians could, if they chose, breach conÞdentiality to warn unsuspecting individuals but would not be held liable if they failed to do so.

The depth of antagonism to public health interventions in matters of sexual intimacy was further demonstrated by the deep suspicion of contact tracing programsÑ under which public health ofÞcials would notify those who had been placed at risk without divulging the identity of the individual who had imposed the risk. Such efforts were typically voluntary and relied on the willingness of the index patient to provide the name of his or her contacts.

Despite the four decades of experience with contact tracing, efforts to undertake such public health interventions in the context of AIDS met with Þerce resistance in the Þrst years of the epidemic. Opposition by gay leaders and civil liberties groups had a profound impact on the response of public health ofÞcials, especially in states with relatively large numbers of AIDS cases, where contact tracing efforts remained all but moribund (23). In part, the opposition was fueled by the fact that throughout most of the 1980s, no therapy could be offered to asymptomatic infected individuals. Thus, the role of contact tracing in the context of HIV infection differed radically from its role in the context of other STDs. In the latter case, effective treatments could be offered to notiÞed partners. Once cured, such individuals would no longer pose a threat of transmission. In the case of HIV, nothing could be offered other than information about possible exposure.

For public health ofÞcials, who saw in such information an opportunity to target efforts to foster behavioral changes among individuals still engaging in high-risk behaviorÑ behavior that could place both the individual contacted and future partners at riskÑ that was reason enough to undertake the process. For opponents of contact tracing, the very effort to reach out to such individuals represented a profound intrusion on privacy with little or no compensating beneÞt. The task of behavioral change, they asserted, could be achieved more effectively and efÞciently through community-based HIV prevention efforts (24).

Early misapprehensions about the extent to which public health ofÞcials typically relied on overt coercion in the process of contact tracing, and the degree to which conÞdentiality might be compromised, had by the end of the 1980s all but vanished. With such concerns allayed, many gay leaders had come to recognize that partner notiÞcation, in fact, could be a Òuseful toolÓ in efforts to control AIDS (25). The debate began to shift to one centered on relative efÞcacy (26). That dispute was informed by questions that had already surfaced about the utility of contact tracing in the control of syphilis in populations where individuals had large numbers of sexual partners, many of whom were anonymous (27).

In short, by the early 1990s the exceptionalism of the Þrst years of the AIDS epidemic began to fade and a process of normalization had set in.

THE ETHICS OF RESEARCH

As was true of public health practice, the Þrst years of the epidemic forced a rethinking of the ethics of human subjects research. Such a rethinking extended beyond the U.S. as the debate in the late 1990s broadened to questions of research conducted in poor countries under the sponsorship of wealthy nations.

The ethical analysis of research involving human subjects emerged against a backdrop of torture, abuse and scandal. From the Nuremberg Code, which sought to set out the basic moral principles for research in the wake of the post-war trial of Nazi doctors, to the establishment of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, created in the wake of the revelations about the infamous Tuskegee syphilis experiment, the need to protect potential subjects captured the attention of those appalled by the practice of science. In 1978 the National Commission issued the *Belmont Report*, which codiÞed a set of ethical principles that sought to inform and guide the work of researchers (28). Those principles provided the foundations for regulations subsequently enacted by the Department of Health and Human Services and the Food and Drug Administration. At the core of those guidelines was the radical distinction between research designed to produce socially necessary, generalizable knowledge and therapy designed to beneÞt individuals. Against the former, the *Belmont Report* held, individualsÑ especially those who were socially vulnerableÑ needed protection against conscription. AIDS forced a reconsideration of this formulation.

The HIV epidemic provided the circumstances for the emergence of a broad and potent political movement that sought to reshape radically the conditions under which

research was undertaken. The role of the randomized clinical trial, the importance of placebo controls, the centrality of academic research institutions, the dominance of scientists over subjects, the sharp distinction between research and therapy, and the protectionist ethos of the *Belmont Report* were all brought into question. Although scholars concerned with the methodological demands of sound research and ethicists committed to the protection of research subjects played a crucial role in the ensuing discussions, both as defenders of the received wisdom and as critics, the debate was largely driven by the articulate demands of those most threatened by AIDS (29). Most prominent were groups such as the People with AIDS Coalition and ACT-UP, organizations made up primarily of white, gay men. They were joined by community-based physicians who identiÞed closely with the plight of their patients.

What was so stunning, disconcerting to some, and exciting to others was the rhythm of challenge and response. Rather than the careful exchange of academic arguments, there was the mobilization of disruptive and effective political protest. Most remarkable was the core demand. As Carol Levine noted, ÒThe shortage of proven therapeutic alternatives for AIDS and the belief that trials are, in and of themselves, beneÞcial have led to the claim that people have a right *to be* research subjects. This is the exact opposite of the tradition started with NurembergÑ that people have a right *not to be* research subjectsÓ(30). That striking reversal resulted in a rejection of the model of research conducted at remote academic centers, with restrictive (protective) standards of access, and strict adherence to the Ògold standardÓ of the randomized clinical trial.

Blurring the distinction between research and treatmentÑ expressed forcefully through the slogan ÒA Drug Trial Is Health Care TooÓÑthose insistent on radical reform sought to open wide the points of entry to new Òtherapeutic Ó agents both within and outside of clinical trials; they demanded that the paternalistic ethical warrant for the protection of the vulnerable from research be replaced by an ethical regime informed by respect for the autonomous choice of potential subjects who could weigh, for themselves, the potential risks and beneÞts of new treatments for HIV infection. Moreover, the revisionists demanded a basic reconceptualization of the relationship between researchers and subjects. In place of protocols imposed from above, they proposed a more egalitarian and democratic model in which negotiation would replace a scientiÞc authority. Indeed, research Òsubjects Ó were now thought of as Òparticipants.Ó Furthermore, the role of the carefully controlled clinical trial as providing protection against the wide-scale use of drugs whose safety and efÞcacy had not been proven no longer commanded unquestioned respect (31).

The new perspective did not go without challenge, of course. Some were concerned that the proposed regime would make the conduct of research, so crucial to the needs of those with HIV/AIDS, all but impossible (32), others feared that desperate individuals would, in the absence of the now discredited (paternalistic) ethos, be subject to deception (33).

The AIDS-inspired challenge to the ethics of research was not restricted to issues within the United States. Just as the protective regime surrounding research in the United States was a product of a history of abuse, efforts to enunciate ethical standards for the conduct of research in third world nations was shaped by a history of exploitation, a history characterized by investigations on the poor designed to serve the interests of the privileged. Central to those efforts was the belief that the ethical principles Þrst encountered in industrialized nations, had direct bearing on the norms that should govern research in very different settings (34). Such universalism took as a given the need to assume that insights regarding cultural differences not serve as the basis for moral relativism.

Just as individual informed consent was the Þrst principle of the ethics of research in advanced industrial nations, it was at the heart of the codes designed to guide research in the poorest nations. To preclude exploitation, international consensus also existed on the extent to which it was critical that research be responsive to the health needs and priorities of the community in which it is to be carried out (35). What would remain a matter of uncertainty, however, was whether the needs of the poorest and the requirement of responsiveness could justify research that would be unacceptable in the richest nations, whether the principle of universalism could accommodate research in Burundi that would be prohibited in Brooklyn.

That was the issue that would animate a furious international debate occasioned by the 1994 Þnding that AZT administered to infected women in the second and third trimesters and to their infants for six weeks could reduce by two-thirds the rate of vertical transmission (36). Although superÞcially a conßict over a technical matter involving research designÑ the role of placebosÑ the dispute touched on the deepest questions of what ethical conduct meant in a world characterized by great inequalities and profound inequities.

In 1997, an editorial appeared in the *New England Journal of Medicine* denouncing an international trial designed to determine if it were possible to develop an inexpensive clinical intervention that could provide something approaching what had been attained in wealthy nations in reducing the risk of mother-to-child HIV transmission (37). Those trials assumed that even if successful, the more affordable interventions would be less effective than was standard in Europe and America.

Given the burden of pediatric AIDS in Africa and Asia, it was a matter of some urgency that trials begin to determine whether radically cheaper alternatives to the standard regimen could achieve at least some measure of reduced maternal-fetal HIV transmission. In June 1994, a special consultation of the World Health Organization

considered the challenge and called for the launching of studies to achieve that goal. The consultation made clear its conclusion that placebo-controlled trialsÑ trials in which a comparison is made between an inert substance and the potentially active agentÑÒoffer the best option for obtaining rapid and scientiÞcally valid resultsÓ(38).

There was no question that a placebo-controlled trial would have been considered unethical in the United States or any other advanced industrial nation. No trial that denied access to the effective standard, or to an intervention thought to hold the promise of being at least as effective as, if not more effective than, the prevailing standard of care, would have satisÞed the requirements of ethical review. The question posed by the furious controversy that unfolded was whether it was ethical to conduct such a trial in a poor country. *The New England Journal of Medicine* gave its answer unambiguously:

> Only when there is no known effective treatment is it ethical to compare a potential new treatment with a placebo. When effective treatment exists, a placebo may not be used. Instead, subjects in the control group of the study must receive the best known treatment (37).

Given this premise, the *Journal* rejected as irrelevant the fact that health care available in most Third World countries provided nothing like health care available in industrialized countries. Citing the Declaration of HelsinkiÑ the international code of research ethics adapted by the World Medical Association in 1964Ñ for authority, the editorial noted that control groups had to be provided with the best current therapy, not simply that which was available locally. ÒThe shift in wording between Ôbest CÕ and Ôlocal CÕ may be slight, but the implications are profound. Acceptance of this ethical relativism could result in widespread exploitation of vulnerable Third World populations for research programs that could not be carried out in the sponsor countryÓ(37).

Those who rejected the JournalÕs viewpoint made clear that placebo-controlled trials were dictated by the urgency of the situation. Only placebo-controlled trials could provide Òdef Þnitive,Ó Òclear,Ó ÒÞrmÓ answers about which interventions worked, thus allowing governments to make Òsound judgments about the appropriateness and Þnancial feasibility of providing the intervention.Ó The failure to employ a placebo would have made it difÞcult to clearly determine whether the affordable but less effective intervention was better than no intervention at all. In short, they concluded placebos were crucial to policymakers required to make relatively costly decisions under conditions marked by profound poverty and scarce public health resources (39).

Paralleling the debates over maternal-fetal transmission of HIV were those that surfaced over the ethics of AIDS vaccine trials. In this case the focus was on those research participants who might become infected with HIV during a trial. On the one hand there were those who argued that such individuals be provided with optimal careÑ the retroviral therapy available in the developed countries. On the other hand there were those who asserted that care should reßect that which was consistent with what was available in the host nation (40). So divisive was this controversy that UNAIDS could not come to an agreement on the appropriate ethical norm and indeed had to settle for a procedural rather than substantive solution, a solution that focused on how to reach acceptable agreement rather than one that put forth a standard to guide such deliberations (41).

Thus were the issues joined. So critical were stakes involved in the controversies that they ultimately provoked an international effort to consider ethical standards of research in the Third World. The World Medical Association undertook a series of consultations on the revision of the Declaration of Helsinki; the Council for International Organizations of Medical Sciences (CIOMS) did so as well. Finally, within the United States, which funded much of the international research that had been subject to scrutiny, the National Bioethics Advisory Committee took up the issue of studies in poor nations.

While those who saw in any effort to craft ÒßexibleÓ standards that reßected the uniquely pressing context of international poverty and inequality the treacherous embrace of moral relativism, their opponents persisted in arguing that a failure to consider the context of investigation a failure of moral understanding. Principles could be universal; their application could not be rigid (42).

How profoundly difÞcult the issues of research in the context of global poverty were is best demonstrated by conclusions reached by the World Medical Association, the CIOMS and the National Bioethics Advisory Committee. Despite the fact that each body understood the considerable attention that was focused on their efforts, and the importance of forging a common standard, consensus could not be attained. Only the World Medial Association in its revision of the Declaration of Helsinki adopted the position that once an effective therapy was found it became the standard against which all further interventions had to be measured (43). Regardless of the cost of the intervention, placebo controlled trials were no longer tolerable. The CIOMS recommendations, on the other hand, concluded that there might be sound scientiÞc and ethical reasons to reject the Òbest currentÓ method standard, if the failure to use a placebo would make the results inapplicable in the host country where the search for affordable alternatives was essential (44). That too was the position adopted by the U.S. National Bioethics Advisory Committee (45).

In the end then, the AIDS-inspired debate over research ethics did not end in consensus. Rather it opened wide the question of whether ethical principles could serve as a universal standard in a world characterized by gross inequality, whether that very inequality made adherence to universal standards morally imperative.

SECURING ACCESS TO CARE

In the Þrst years of the epidemic there was little that medicine could offer those with HIV disease. Indeed, that was the context, as noted, within which AIDS activists struggled to increase access to experimental trials. As the prospects for clinical intervention improved, Þrst with the use of prophylactic treatment to prevent Pneumocystis pneumonia and other opportunistic infections and then with AZT, the Þrst widely prescribed antiretroviral agent, it was inevitable that the inequities of the U.S. health care system would be encountered.

Some who needed treatment had private insuranceÑ although they not infrequently faced efforts on the part of their insurers to deny them coverage for their HIV-related conditionsÑ those who were poor or who became impoverished because of their disease could qualify for Medicaid, but many remained unprotected (46). To meet their needs, special programs were developed. The federal government, through the Ryan White Care Act, directed signiÞcant sums to localities to provide medical services. Among the initiatives under the act was the AIDS Drug Assistance Program (ADAP), designed to pay for AIDS-related medicines. But the patchwork effort was never adequate and left many without needed protection (47). Like the End Stage Renal Disease Program that assured access to dialysis and transplantation regardless of the ability to pay, those programs left untouched the basic patterns of medical inequality.

When the protease inhibitors emerged in the mid-1990s and combination antiretroviral therapy became the standard of care, the system was strained to the limits. Medication costs alone for those receiving care could range from $10,000 to $15,000 a year (48). One review of dramatically improved therapeutic prospects added the caveat that the new achievements were important Òat least for those socioeconomically privilegedÓ (49). ADAP experienced persistent shortfalls in funding. When that was the case it was necessary to resort to a host of rationing strategies. At one point, nearly half of the ADAP programs limited access to protease inhibitors (50). In 1996, the coordinator of Oregon's program explained that such coverage Òwould blow our budget out of the waterÓ (51). A 1998 report by the National ADAP Monitoring Project found that 15 states maintained waiting lists for entry to ADAP or for access to protease inhibitors. North Carolina, which had no formal waiting list, had simply stopped authorizing new clients for its ADAP. Only two state programs covered the 14 drugs strongly recommended by the Public Health Service for the prevention of opportunistic infections (47).

The remarkable advances in therapeutics have provided a critical element in the argument that the exceptionalism of the epidemic's early years is no longer appropriate. It is therefore a remarkable paradox that the very same achievements have set the stage for challenging the exceptionalist programs that seek to ensureÑ however inadequatelyÑ access to those same treatments. Thus in one analysis it was argued, Ò The absence of (beneÞts like those in the Ryan White Act) for persons with other stigmatizing diseases is troubling. We believe that this discrepancy leaves AIDS exceptionalism vulnerable to the accusation of injusticeÓ (52). The ÒinjusticeÓ was underscored by one AIDS activist who boldly noted, Ò There are certainly other life-threatening diseases out there. Some of them kill a lot more people than AIDS does. So in one sense, it is almost an advantage to be HIV positive. It makes no senseÓ (53). These expressions of disquiet must be understood, at least in part, as a reßection of concern that in a changing political climate, where the American AIDS epidemic may no longer be seen as immediately threatening, unique services for those with HIV would become vulnerable unless they were embedded in a broader system of a just health care system.

On an international plane the prospect of effective antiretroviral treatment would pose challenges vaster by many orders of magnitude. What justiÞcation was there for a system of pricing that made the cost of drugs beyond the reach of the desperate? Could markets ever respond to need where effective demand was nil? Could the monopoly conÞrmed by patent rights be compatible with a response dictated by claims of the dying? Was the treaty on intellectual property rights, incorporated into the World Trade Organization's international regime, a barrier to survival in context of the AIDS epidemic? What moral obligation did the wealthiest nations have to the poorest to provide the resources necessary to purchase the new life-saving agents and build the medical infrastructure necessary for their appropriate administration? Was there any reason to believe that a global community that permitted millions to die each year from treatable and preventable diseases such as tuberculosis and malaria would respond differently in the face of AIDS?

AIDS activists ultimately seized on this issueÑ Life Over ProÞtsÑ and began an international campaign to confront the pharmaceutical industry. What might have seemed an utterly quixotic undertaking would, however, ultimately take on worldwide dimensions linking protesters in the United States, France, and South Africa, institutional proponents of global health such as the World Health Organization, and a sympathetic public. By the end of the 1990s the pharmaceutical industry was placed on the defensive, perceived as protecting narrow self interest when the lives of millions were at stake. Against the claims that high prices were necessary to fuel the engine of research, that patent protections were crucial to spurring investments in drug investigations, those who sought to turn the terms of discourse asserted that urgency demanded that the barriers to drug access tumble. As a leader of the International AIDS Society said in 2001, Ò This is a war, and when you are in a war as we are worldwide with HIV which will claim more lives than any other infectious disease in history, the rules of the game have got to changeÓ (54).

In the face of continuing criticism, drug companies argued that at most the price of drugs was a small part of the problem. The issue, they said, was the fundamental limits of the medical infrastructure of poor nations and the inability of the poorest to pay for even heavily discounted drugs. But such arguments, whatever their merits, carried little weight, as long as prices remained high or as long as the offer to negotiate price reductions entailed protracted processes. In early 2001 *The Lancet* thus wrote, ÒThe time has come for the pharmaceutical industry and the governments who represent them in trade disputes to acknowledge that the world is facing an extraordinary challengeÓ(55).

> Ultimately, under pressure from generic drug manufacturers, prices began to tumble, and pharmaceutical Þrms began to accept the notion of differential or equity pricing (56).

As drug prices began to fall, it became ever more apparent that challenges posed by the international pharmaceutical industry as it resisted pressure by activists, the generic manufacturers and international public opinion, were not without foundation: Even if drugs were to be provided at cost, even if the principle of equity pricing were to guide sales, even if nations pursued the option of compulsory licensing and parallel imports, the cost of providing antiretroviral therapy was simply beyond the reach of the poorest and most HIV-burdened nations. And even if drugs could be paid for, the necessity of a medical infrastructure that could offer and monitor the use of drugs in a way that was attentive to the needs of individual patients and the risks to public health from drug resistance would require huge investments. This was the context within which a remarkable movement to create a massive funding effort to respond to the threat of AIDS would take shape.

In 2001 a Harvard University group issues a call to the global community. In an era of effective antiretroviral therapy access to care was a moral imperative (57). ÒWe believe that on moral, health, social and economic grounds the international community should provide new scientiÞc and Þnancial leadership for a rapid scaling up of AIDS treatment in the poorest and hardest hit countries of the world.ÓThe goal was to treat one million patients in Africa within three years. It was simply untrue that the infrastructural capacity of African health care systems precluded the provision treatment. There were limits. But they could be overcome with appropriate international assistance.

To those who had asserted that efforts to provide treatment would subvert already fragile prevention programsÑ a claim made by many of the humanitarian foundations that had funded such effortsÑ the Harvard group responded directly: ÒTreatment is necessary to optimize prevention efforts. When treatment is not available less incentive exists for an individual to take an HIV test since HIV positive status not only is associated with social stigmatization but is tantamount to a death sentence. Ultimately, treatment of infected individuals may become a major tool in AIDS prevention.Ó

Finally, it was argued that the provision of treatment was necessary to preserve the social fabric of societies affected with high levels of infectionÑÒIf the current lack of treatment continues a demographic shift is predicted . . . such that teenagers will outnumber their elders by 2020. Further, without treatment, millions of adults in the prime of their working lives will die of AIDS and with them skills and knowledge that are necessary for human and economic development.Ó

In assessing the potential costs of such an effort the Harvard group calculated that one million Africans could be treated for $1.1 billion dollars a year. Were the program to expand to three million individualsÑ a goal achievable in Þve yearsÑ the cost would rise to $3.3 billion a year. (In considering the extension of care to non-Africans who could beneÞt from inaccessible treatment, it was estimated that approximately $1.4 billion would be needed in the Þrst year and $4.2 billion by year Þve.) But even so vast an effort would not cover large numbers of people in need of care. To reach those millions could require signiÞcant investments in medical infrastructure that were not calculated. Finally, in addition to the costs of care it was estimated that for prevention efforts for Africa alone $3 billion was needed annually. Thus, in all, the Þrst yearÕs effort in Africa would require $4 billion. To meet this vast commitment it was proposed that an HIV/AIDS Prevention and Treatment Trust Fund be created. The sum involved, while very large, was not beyond the capacity of the wealthiest nationsÑ 0.01% of an aggregate GNP of $23 trillion.

The moral urgency of AIDS treatment was ampliÞed by UN Secretary General KoÞ Annan, who called for a global trust fund that would spend $7Ð10 billion a year over Òan extended periodÓto face the threat to the worldÕs poorest people (58). Most striking was his assertion that the care which had for so long eluded men, women and children in the less developed nations was a matter of right. Speaking to AfricaÕs lenders he said, ÒEven a year ago few people thought that effective treatment could be brought within reach of poor people in developing countries. . . . There has been a worldwide revolt of public opinion. People no longer accept that the sick are dying simply because they are poor. Everyone who is infected should have access to medicine and medical care. Now we know that that is possible, it is surely an ethical imperative.Ó

Strikingly, the idea of a global trust fund not only won the support of editorialists identiÞed with a liberal or social democratic posture, but by powerful institutions as well. Within days of AnnanÕs speech the International Monetary Fund and the governing committee of the World Bank endorsed the fund, in principle (59). The Gates Foundation pledged $100 million to the effort (60). But between dramatic proposals based on moral principles of solidarity with the most vulnerable and willingness to provide the resources necessary to give life to such

principles and commitments, there is a vast distance. When the G8 met in Genoa in July 2001 they committed $1.2 billion to the global fund that Annan had called for. Declaring the gesture ÒlaudableÓthe UN secretary general was quick to add, ÒIt is not enoughÓ(61).

The gulf between conviction and action has become all the more stark as prevailing and pervasive international inequality has taken on moral signiÞcance: What was the unfortunate has become unfair; inequality has become inequity. In that translation the possibility of human agency, of political action to effect change, has opened wide. It is far from certain how that opportunity will be apprehended.

CONCLUSION

This chapter began with an analysis of ethical and policy issues that emerged in the United States as it confronted the AIDS epidemic. These issues were commonly addressed in other economically advanced nations bounded by the liberal tradition, even when the resolution of the controversies that surfaced may have taken divergent forms. The chapter has concluded with a discussion of the profound moral challenge posed by the AIDS epidemic in the poorest nations, focusing on the question of access to care. It is in those nations that the epidemic will take its toll in tens of millions of lives.

No ethical analysis of the challenges posed by AIDS will ever again be sufÞcient if it is restricted to the challenges faced in wealthy developed nations. Indeed, increasingly the analysis will need to be driven by the complexities of an epidemic in the worldÕs poorest nations. Older concerns rooted in a focus on the need to protect the privacy rights of individuals will inevitably be overshadowed by new concerns about equity. It is not that the older ethics will have no relevance. But with life itself in the balance, unless the material requirements of those who need access to care are given preeminence, little else will matter.
